Acronyms and Abbreviations

APTT, activated partial thromboplastin time; AT, antithrombin; CT, computerized tomography; DAMPs, damage-associated molecular patterns; DIC, disseminated intravascular coagulation; ECs, endothelial cells; EPCR, endothelial protein C receptor, FDPs, fibrin(ogen) degradation products; EVs, extracellular vesicles; FV/FVa, factor V/activated factor V; FVII/FVIIa, factor VII/activated factor VII; FVIII/FVIIIa, factor VIII/activated factor VIII; FIX/FIXa, factor IX/activated factor IX; FX/FXa, factor X/activated factor X; FXI/FXIa, factor XI/activated factor XI; FXIII, factor XIII; HMGB1, high-mobility group box-1 protein; IMHA, immune-mediated hemolytic anemia; ISTH, International Society on Thrombosis and Haemostasis; LPS, lipopolysaccharide; NETs, neutrophil extracellular traps; PAI-1, plasminogen activator inhibitor-1; PAR, protease-activated receptor; PS, phosphatidylserine; PT, prothrombin time; SSC, Scientific and Standardization Committee; TAFI, thrombin-activatable fibrinolysis inhibitor; TCT, thrombin clotting time; TF, tissue factor; TFPI, tissue factor pathway inhibitor, tPA, tissue plasminogen activator.

Our understanding of hemostasis has undergone a paradigm shift over the last 10 years, shedding new light into the pathogenesis of disseminated intravascular coagulation (DIC). Hemostasis is now recognized not only as the process that stops hemorrhage after blood vessel injury, but as an integral part of innate immunity. Fibrin and platelet thrombi entrap pathogens and recruit leukocytes, thereby promoting immune clearance. Moreover, platelets have bactericidal capabilities. Together these actions lead to the concept of "immunothrombosis."[18] In this context, DIC can be thought of as a variant of immune dysfunction, where hemostasis is no longer localized to the site of pathogen invasion or vessel wall injury, but rather progresses to a systemic, overexuberant reaction to pathogen-associated or damage-associated molecular patterns (DAMPs). Typical manifestations of DIC include microvascular thrombosis (in arterioles, venules and capillaries), with mixed thrombi consisting of fibrin, platelets, leukocytes, and extruded nuclear DNA, histones, and DNA–histone complexes (nucleosomes) and mitochondrial DNA, with few erythrocytes. Dysregulated and unopposed

TABLE 92.1 Characterization of overt and nonovert DIC.

	Nonovert DIC	Overt DIC
Alternate names and subtypes	Compensated DIC, chronic DIC, subclinical DIC, pre-DIC, asymptomatic DIC	Uncompensated DIC, acute DIC, fulminant DIC, consumptive coagulopathy
Pathophysiology	Procoagulant excess opposed by coagulation inhibitors, partial compensation modulates fibrin deposition	Decompensated hemostasis with fibrin deposition throughout the microvasculature. Platelet and factor depletion may develop. Can be hyperfibrinolytic, hypercoagulable/hypofibrinolytic, or hypocoagulable
Clinical features	Primary inciting disease, subclinical or tissue thrombosis	Primary inciting disease with some or all of the following: Systemic microvascular thrombosis, pulmonary thromboembolism, multiorgan dysfunction syndrome, hemorrhage from single or multiple sites
Screening test abnormalities	No screening test abnormalities and/or progressive fall in platelet count and/or progressive increase in screening clotting times, FDPs and D-dimers	Some or all of the following (generally 3 out of 6): Thrombocytopenia, prolonged screening coagulation tests (APTT, PT, TCT), hypofibrinogenemia, low AT activity, high FDPs or D-dimer
Tests of prethrombotic state	Evidence of thrombin generation (either by-products of thrombin generation or activity): Prothrombin fragment 1+2, thrombin–antithrombin complex, activated protein C–protein C inhibitor complex, fibrinopeptides A & B More rapid kinetics of thrombin or fibrin generation: Endogenous thrombin potential, thromboelastography/elastometry	Not applicable

activation of hemostasis in DIC can also result in cleavage, inactivation, inhibition and consumption of coagulation factors and platelets, manifesting as hemorrhage due to a hypocoagulable state. The shift in the DIC pendulum toward thrombosis or hemorrhage is governed by the inciting disease and whether procoagulant, antifibrinolytic, anticoagulant, or fibrinolytic forces dominate. The complex and intricate balance among these opposing forces changes dynamically and unpredictably within and between affected patients, complicating recognition and treatment of DIC. With the goals of standardizing terminology and improving diagnosis, the Scientific and Standardization Committee (SSC) of the International Society on Thrombosis and Haemostasis (ISTH) defined DIC as "an acquired disorder characterized by excessive thrombin generation with loss of localization and endothelial dysfunction that can result in organ injury." Scoring schemes and guidelines to subclassify DIC into nonovert and overt phases were also described (see Table 92.1).[69] The clinical impact of DIC is exemplified by studies that show DIC, particularly in the overt phase, increases the likelihood of mortality in humans[2,22] and animals.[4,10,17,24,74]

PRIMARY DISEASE CONDITIONS

Disseminated intravascular coagulation has been documented in most domestic animals, except for camelids. It is not a primary disorder, but is always induced by an underlying disease (see Table 92.2). In dogs and cats, cancer and systemic inflammation (e.g., sepsis, pancreatitis, immune-mediated hemolytic anemia [IMHA]) are the most common initiating diseases.[4,20,24,66,74] Endotoxemia (secondary to strangulating, inflammatory or ischemic gastrointestinal disorders) and sepsis are the main causes of DIC in adult horses and neonatal foals, respectively.[3,10,67] Similarly, DIC is most often recognized in ruminants with endotoxemia or septic inflammation (metritis, mastitis).[6,31,32]

PATHOGENESIS

Disseminated intravascular coagulation represents a disease continuum. At first, activation of hemostasis is kept in check by natural inhibitors. If activation is excessive (akin to a dysregulated immune response) such that regulatory mechanisms are overwhelmed or if regulatory mechanisms are inhibited by the primary disease, DIC progresses to a decompensated disorder characterized by systemic microvascular thrombosis and potentially, a consumptive coagulopathy.[71] Although disease- and species-dependent differences influence the initiation and clinical course of DIC, the consistent pathogenic mechanism maintains excessive thrombin generation through dysregulated activation of coagulation.[22,69,71] For ease of understanding, the DIC continuum can be separated into three stages: initiation, amplification, and progression with maintenance of thrombin generation.[71]

Initiation of Thrombin Generation

Since DIC represents normal hemostasis gone awry, the aberrant exposure of tissue factor (TF), the physiologic

TABLE 92.2 Inciting diseases and pathophysiologic mechanisms of DIC in animals.

Disease categories and specific disorders	Potential mechanisms
Infections: Bacterial sepsis (Gram-positive and Gram-negative bacteria, including Leptospira; rickettsia [Rocky Mountain spotted fever]), viruses, protozoa (Babesia), parasites (Angiostrongylus)	Induced TF expression on monocytes (and ECs): Secondary to LPS and proinflammatory cytokines, with shedding of PS- and TF-expressing EVs
	Contact pathway activation (FXII): From bacterial polyphosphates and release of DAMPs (cell-free DNA) from tissue injury and inflammation (NETosis). Histones can activate FXI in a platelet-dependent manner
	Endothelial injury: Exposure of extravascular TF, induction of TF on ECs, release of DAMPs
Neoplasia : Solid tumors, such as hemangiosarcoma, carcinomas (e.g., mammary); hematopoietic neoplasia, such as lymphoma, acute myeloid leukemia	Cancer cell expression of TF: Constitutive or induced by hypoxia, cytokines, or cell death
	Induced TF expression on noncancer cells: Tumor-secreted or proinflammatory cytokines stimulate TF expression on monocytes, fibroblasts, and ECs
	Expression/secretion of procoagulants: Cancer procoagulant (a vitamin-K-dependent cysteine protease), mucin, upregulation of factor V receptor, factor XIII-like activity, platelet activators
	Shedding of TF- and PS-bearing EVs from tumor cells, hematopoietic cells, other cell types
	Tissue injury/inflammation: NETosis, release of DNA/histones, exposure of subendothelial TF
	Chemotherapy-induced changes: Tumor lysis, myelotoxicity causing inflammation, release of DAMPs
Inflammation/necrosis: Trauma, IMHA, pancreatitis, heat stroke, hepatitis, vasculitis, gastric dilatation-volvulus, strangulating obstructions, and inflammatory gastrointestinal disorders	Proinflammatory cytokines and release of DAMPs
	Endothelial injury
	Tissue injury/necrosis/apoptosis: Exposure of TF, shedding of TF- and PS-enriched EVs by apoptotic cells, NETosis
	Release of procoagulant proteases (e.g., trypsin)
Intravascular hemolysis: IMHA, acute transfusion reactions, insect/snake bites.	Endothelial injury
	Erythrocyte procoagulant activity: RBC membrane-associated elastase, PS expression (eryptosis), shedding of PS-enriched EVs
Envenomation	Snake venom proteases: Direct coagulation factor activation and fibrinogen cleavage, phospholipase-induced tissue injury/cell lysis

DAMPs, Damage-associated molecular patterns; ECs, endothelial cells; EVs, extracellular vesicles; LPS, Lipopolysaccharide; PS, phosphatidylserine; TF, tissue factor.

trigger of hemostasis, often initiates DIC (Table 92.2).[22,25] Tissue factor (tissue thromboplastin, factor III) is a transmembrane protein whose expression is normally restricted to interstitial perivascular fibroblasts and smooth muscle cells. Some extravascular TF may be prebound to its ligand, factor VII (FVII), leading to the concept of an "idling" hemostatic system, poised for activation on exposure to plasma.[29]

Under physiologic conditions, exposure of extravascular unbound TF to plasma FVII or exposure of FVII-prebound TF to its plasma substrate, FX, occurs only at focal sites of endothelial injury. In DIC triggered by massive tissue trauma, widespread endothelial injury exposes large amounts of extravascular TF. In conditions such as viral infections, intravascular hemolysis, and vasculitis, generalized endothelial injury exposes extravascular TF and/or induces TF expression on damaged endothelium. Proinflammatory cytokines also contribute to TF expression on endothelial cells (ECs) in these latter disorders (see in the following text and Table 92.2).[23,26,70]

In the absence of endothelial injury, DIC may be initiated by both the extrinsic and "contact" pathways of coagulation (see Table 92.2 and Figure 92.1). With the extrinsic pathway, proinflammatory cytokines induce TF on the surface of intravascular cells, particularly monocytes, and likely ECs. This is thought to be the main mechanism of initiation of DIC in bacterial sepsis and many nonseptic inflammatory states.[22,68,70] Pro-oncogenic mutations may induce high constitutive expression of TF on cancer cells,[76] thereby promoting cancer-associated thrombosis and DIC.

Activation of FXII in the contact pathway of coagulation may also trigger DIC in sepsis, tissue injury, inflammatory states, and cancer. Factor XII can be activated by negatively charged polyphosphates and alarmins or DAMPs, such as cell-free or extracellular DNA.[22,49,51,70] Long-chain polyphosphates are found in acidocalcisomes of bacteria and cancer cells and are particularly potent activators of FXII.[47,51,57] Localized release of short-chain polyphosphates from activated platelets may also contribute to excessive thrombin generation.[49]

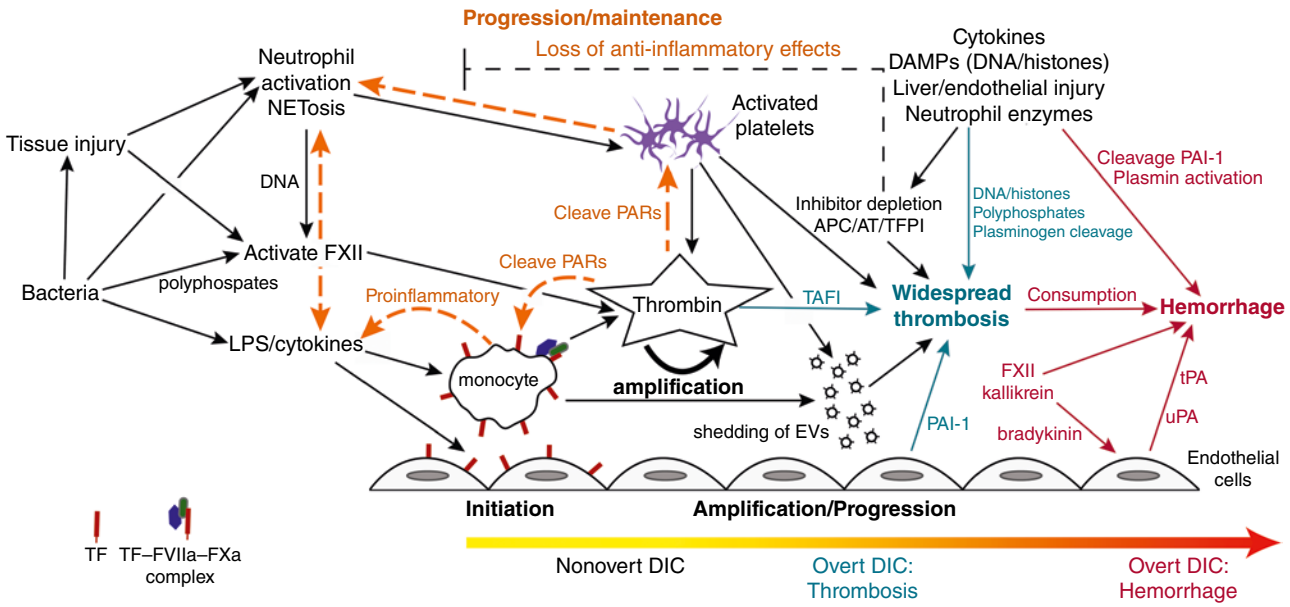

FIGURE 92.1 The DIC continuum. Disseminated intravascular coagulation is typically initiated by lipopolysaccharide (LPS)-induced or proinflammatory-cytokine-induced upregulation of tissue factor (TF) expression on monocytes and likely endothelial cells (ECs) in sepsis due to Gram-negative bacteria. Tissue factor can also be expressed and released by other cells, including platelets and eosinophils, but monocytes are thought to be the main source of TF in bacterial sepsis. In cancer, constitutive expression of TF on cancer cells and induction of TF on monocytes by proinflammatory cytokines are the likely trigger of DIC (not shown). Monocyte- or cancer-surface TF, FVIIa, and FXa form an active complex, which generates thrombin. Bacteria, via release of long-chain polyphosphates, or induction of tissue injury, inflammation, or NETosis, can also initiate DIC through activation of FXII. Bacteria can also activate platelets, promoting release of short-chain polyphosphates and procoagulant activity, via toll-like receptors (particularly TLR4, not shown). Endothelial injury, via release of long strings of von Willebrand factor, can capture and activate circulating platelets in conditions associated with endothelial injury (not shown). Release of damage-associated molecular patterns (DAMPs, e.g., cell-free DNA) from injured tissues (including ECs), inflammatory cells (via NETosis), or cancer can similarly trigger DIC via FXII and potentially other mechanisms (e.g., upregulation of TF via HMGB1). In early, nonovert DIC, inhibitors such as activated protein C (APC), antithrombin (AT), and tissue factor pathway inhibitor (TFPI) control the activated hemostatic system. If inhibitory mechanisms become overwhelmed, then thrombin amplifies its own production, simultaneously inhibiting fibrinolysis via thrombin-activatable fibrinolysis inhibitor (TAFI), resulting in microvascular thrombosis (progression/dissemination). This is now the hypercoagulable or thrombotic phase of overt DIC. Procoagulant extracellular vesicles (EVs) shed from thrombin-activated platelets and other cells, as well as DNA in extracellular traps, provide a negatively charged surface that supports systemic coagulation complex assembly, which is no longer held in check by inhibitors, which are rendered deficient or dysfunctional from DAMPs, liver injury, proinflammatory cytokines, and neutrophil proteases. Systemic thrombin production is also mediated by distant endothelial injury and dysfunction from microvascular thrombi, inflammatory mediators, and histones. Inhibition of fibrinolysis via endothelial release of plasminogen activator inhibitor-1 (PAI-1), bacterial and platelet polyphosphates, DAMPs, and neutrophil protease-mediated cleavage of plasminogen promotes persistence of thrombi. In the maintenance phase, cross talk between activated coagulation factors and platelets, such as through protease-activated receptor (PAR) signaling, potentiates the inflammatory response, including NETosis and release of proinflammatory cytokines from monocytes and other cells. The depletion of anti-inflammatory coagulation inhibitors further facilitates inflammation, thereby maintaining the inflammation–DIC cycle. As coagulation factors are cleaved or consumed (along with platelets), DIC may shift to an overt hemorrhagic or hypocoagulable phase. This phase of DIC may also occur if profibrinolytic forces dominate, such as through PAI-1 cleavage and FXII-, kallikrein-, protease-mediated cleavage of plasminogen to plasmin and release of tissue-type (tPA; stimulated by bradykinin or endothelial injury) or urokinase-type plasminogen activators (uPA).

Cell-free DNA from nuclei or mitochondria and potentially within nucleosomes (complexes of DNA and histones) released from activated neutrophils or damaged cells can also activate FXII, typically in concert with activated platelets.[1,15,22,26,44,62] The expelled DNA entraps bacteria, leading to the term neutrophil extracellular traps (NETs) in a process referred to as NETosis, although other cells (e.g., eosinophils, monocytes) can similarly extrude DNA. The released DNA is found in long strands decorated with histones, nuclear-associated cytokines, such as high-mobility group box-1 protein (HMGB1), and neutrophil enzymes, such as elastase and cathepsin G. NETosis directly links innate immunity to hemostasis as activated coagulation factors and platelets form fibrin strands enclosing the invading pathogen.[1,53] Excess exogenous histones and polyphosphates alone can trigger a DIC-like syndrome in murine models that is inhibited by degradative proteases (e.g., polyphosphatases, DNase) and facilitated by platelets via toll-like receptors.[26,44,49,62] Studies in dogs show that NETs are also procoagulant[34] and high concentrations of cell-free DNA and histones are seen in dogs with IMHA, sepsis, and trauma, suggesting that these DAMPs may have a role in triggering DIC.[35,39–41] As a cautionary note,

TABLE 92.3 Mechanisms of anticoagulant deficiency in DIC.

Mechanism	Primary condition
Decreased hepatic synthesis of AT, protein C, protein S	Hepatic injury (e.g., ischemia, histones), inflammatory cytokines
Decreased activity of TFPI, AT, protein C, protein S	Decreased protein C and TFPI activity due to decreased free protein S (from increased C4-binding protein, a positive acute phase reactant protein which binds protein S) Decreased protein C activation due to downregulation or modulation of thrombomodulin and endothelial protein C receptor by inflammatory cytokines and nuclear material Decreased protein C activation due to cleavage of thrombomodulin and endothelial protein C receptor by neutrophil elastases Decreased AT activity through downregulation of heparin-like glycosaminoglycans on endothelial cells by inflammatory cytokines and histones
Increased consumption of AT, protein C	Rapid clearance of thrombin–antithrombin complexes and activated protein C–protein C inhibitor complexes
Loss of TFPI, AT, protein C, protein S	Vascular leakage (e.g., bradykinin, histones)
Degradation of TFPI, AT, protein C, protein S	Proteases, e.g., neutrophil elastases, bacterial peptides (e.g., omptin Pla), histones (degrade TFPI)

AT, Antithrombin; TFPI, tissue factor pathway inhibitor.

some study results may have been influenced by the presence of procoagulant contaminants in commercial kits used to generate data[65] and the procoagulant activity of DNA and histones is dependent on their interassociation and tertiary structure.[52,53]

Additional DIC triggers include cancer proteases and mucin, or snake venoms that directly activate FX (see Table 92.2).

Initiation of DIC also depends on the ability of naturally occurring inhibitors to regulate and contain the activated hemostatic system. In physiologic hemostasis, the TF–FVIIa–FXa complex is rapidly neutralized by tissue factor pathway inhibitor (TFPI). This inhibitor is primarily expressed on ECs, with its activity enhanced by free protein S and cell-surface heparin and heparin-like glycosaminoglycans.[43,61] In the process of DIC, TFPI is rendered ineffective through a number of mechanisms (see Table 92.3), including the generation of excess TF–FVIIa that overwhelms TFPI's inhibitory capacity.[22]

Amplification of Thrombin Generation

Thrombin is pivotal to DIC progression (see Figure 92.1). In a positive feedback cycle, trace amounts of thrombin, is amplified by intrinsic pathway reactions, generate a massive burst of thrombin.[30,71] The thrombin burst cleaves soluble fibrinogen to form fibrin polymers and activates FXIII to cross-link fibrin. Thrombin simultaneously inhibits fibrin degradation via thrombin-activatable fibrinolysis inhibitor (TAFI). Thrombin generation is further enhanced by activated platelets, which release their intracellular stores of coagulation factors (e.g., factor V and fibrinogen).

The thrombin burst also relies on membrane exposure of phosphatidylserine (PS), a negatively charged phospholipid normally expressed on the inner membrane leaflet of cells. Activated cells exteriorize PS and shed PS-enriched extracellular vesicles (EVs).[30,54,59] Outer membrane or EV-associated PS is the binding site for assembly of coagulation factor complexes, amplifying their activity and protecting them from inhibition.[30] Although they have a short half-life (in order of minutes),[36] EVs expand the surface area for thrombin generation far beyond that of the cells from which they are derived.[64] In physiologic and pathologic hemostasis, activated, procoagulant platelets represent the major source of outer membrane PS; however, other cells, including leukocytes, cancer cells, dying or apoptotic cells, and RBCs, can express PS and shed PS-expressing EVs.[54,59] Activated monocytes, certain cancer cells, and their shed EVs express both PS and TF, thus bringing the initiator and amplifier of thrombin generation in close proximity.[54,59] Neutrophil extracellular traps also may serve as a scaffold for thrombin generation.[1,15,62]

Decreased Inhibition

The generation of thrombin through the coagulation cascade is opposed by the plasma anticoagulants, antithrombin (AT), protein C, and protein S (the cofactor for protein C). Activated protein C (APC) is generated on EC surfaces through the action of thrombin engaged with its receptor, thrombomodulin, in the presence of the endothelial protein C receptor (EPCR). Endothelial surface APC is a potent inhibitor of FVa and FVIIIa, whereas the initiating TF–FVIIa–FX complex is inhibited by TFPI. Nonovert DIC refers to a state of systemically activated hemostasis whose inhibitory mechanisms are stressed, but not overwhelmed (see Table 92.1 and Figure 92.1).[69] With continuing activation of coagulation and ensuing endothelial dysfunction, natural inhibitors may be downregulated or depleted (see Table 92.3), leading to unopposed thrombin generation. Nonovert DIC represents a hypercoagulable condition, characterized by incipient or formed thrombi, particularly if fibrinolysis is inhibited (see Figure 92.1).

Progression/Maintenance of Thrombin Generation

The evolution and progression of DIC from a nonovert to overt phase and persistence of DIC in spite of treatment are believed to result from potentiating interactions between hemostasis and inflammation, and endothelial dysfunction and tissue injury.

Hemostasis-Inflammation Cross Talk

A self-perpetuating cycle develops in DIC, particularly that triggered by inflammatory processes, such as sepsis (see Figure 92.1). Inflammation initiates hemostasis via tissue injury, induced TF expression, and platelet and leukocyte activation with microvesiculation and NETosis. Hemostasis, in turn, fuels inflammation, through the proinflammatory properties of active coagulation factors, including thrombin, FXa, and FVIIa. Activated coagulation factors act as chemotaxins and bind to protease-activated receptors (PARs) on inflammatory cells and ECs, stimulating proinflammatory cytokine secretion and upregulating adhesion molecules, which facilitates continued TF expression, NETosis and platelet activation, and recruitment of inflammatory cells, respectively.[13,68,70] Fibrin and related degradation products can stimulate proinflammatory cytokine release via toll-like receptors.[68,70] Thrombin, FXa, kallikrein, and plasmin can act as C3 and C5 convertases and FXIIa can activate C1q of the classical complement pathway.[37] In turn, classical-pathway-produced and lectin-pathway-produced complement components can activate platelets and ECs, induce TF expression, and act as procoagulant proteases.[37] A C3 convertase inhibitor (compstatin) reduced laboratory findings of DIC in a baboon model of sepsis, revealing the importance of complement in sepsis-associated DIC.[63] Activated platelets can also release proinflammatory cytokines, activate complement, and induce NETosis.[55]

Anticoagulants not only limit hemostasis, but also have anti-inflammatory actions, including degradation or inactivation of inflammatory mediators, such as HMGB1, activated complement components, and histones.[22,70] Activated protein C with its associated cell-surface receptors, thrombomodulin and EPCR, has endothelial cytoprotective functions, inducing signaling cascades that maintain vascular integrity or preserve the glycocalyx.[70] Thus, anticoagulant depletion helps sustain DIC.

Endothelial and Tissue Injury

Healthy ECs secrete potent platelet inhibitors (e.g., prostacyclin, adenosine diphosphate [ADPase]) and express receptors, including PARs, thrombomodulin, and EPCR, which modulate coagulation and inflammation. As a direct consequence of the primary disease or as a sequela to DIC, various factors including proinflammatory cytokines, ischemia, perturbed blood flow (secondary to bradykinin and other vasoactive proteins), histones, neutrophil proteases, activated complement, EVs, and acidosis can result in loss of the normal protective functions of ECs.[8,70] Histones accumulate in specific tissues and induce endothelial and tissue injury, potentially through binding to and causing direct damage to cell membranes.[1,22] Injured or dysfunctional organs can also contribute to DIC perpetuation, via release of DAMPs, TF upregulation, and microvesiculation of necrotic or apoptotic cells.

Fibrinolysis

The balance between antifibrinolytic and profibrinolytic forces may dictate outcome and clinical manifestations of DIC. Multiple factors affect fibrinolysis in DIC, shifting the balance from a profibrinolytic and more hemorrhagic phenotype to an antifibrinolytic or more thrombotic phenotype. In human-sepsis-associated DIC, antifibrinolytic forces dominate, mediated by endothelial injury and inflammatory cytokines (e.g., tumor necrosis factor-alpha) that stimulate plasminogen activator inhibitor-1 (PAI-1) release.[22] Similarly, increased concentrations of PAI-1 that were associated with endotoxemia have been reported in horses with colic,[11] suggesting that impaired fibrinolysis contributes to the typical thrombotic manifestation of DIC in colicky horses. Cell-free DNA, histones, NETs, and short- and long-chain polyphosphates (from bacteria or platelets) promote the formation of strong fibrin clots resistant to fibrinolysis.[1,34,47] Nuclear material also inhibits tissue plasminogen activator (tPA)-mediated conversion of plasminogen to plasmin,[1] whereas polyphosphates act as cofactors for thrombin-mediated activation of TAFI.[56]

Alternatively, stimulation of fibrinolysis can occur in DIC, secondary to increased tPA or urokinase-type plasminogen activator release from ECs, leukocytes, or cancer cells. A profibrinolytic response occurs early in septic humans, but is quickly opposed by the antifibrinolytic actions of PAI-1.[22] In addition, FXIIa and kallikrein promote plasminogen activation and generate the vasoactive reactant bradykinin that is a potent stimulator of tPA release. Histones may also stimulate tPA release. A hyperfibrinolytic bleeding phenotype, most often described in patients with severe trauma, is considered a variant of DIC by some investigators,[72] but may represent a distinct hemorrhagic syndrome.[23] Fibrinolytic pathways vary among species, including higher tPA activity reported for dogs compared with humans.[38] This difference may shift the balance toward a relatively hemorrhagic phenotype in canine DIC.

DIAGNOSIS OF DIC

Every animal with an inciting primary disease should be considered at risk for developing DIC (see Table 92.2). Confirmation of DIC is challenging because animals may be examined at any point of the DIC continuum, clinical signs may be subtle or nonspecific, and individual laboratory tests are variably sensitive and specific for this syndrome. Histopathologic detection of fibrin thrombi in the microvasculature with phosphotungstic acid–hematoxylin staining or immunohistochemical staining is definitive for DIC; however, these methods are variably sensitive.[9,12] Histologic detection of fibrin thrombi has low diagnostic utility not only due to the requirement for tissue samples, but fibrin thrombi lyse rapidly after death.[48] Indeed, there was no correlation between the laboratory diagnosis of DIC and postmortem evidence of fibrin thrombi in one study of 48 horses with gastrointestinal disorders.[9]

Scoring criteria for the diagnosis of overt and nonovert DIC have been developed by the ISTH and British, Italian, and Japanese hemostasis and thrombosis or hematology societies.[69,73] These schemes have allowed for a degree of standardization across studies and, in 2013, the SSC on DIC of the ISTH recommended the use of any grading scheme, albeit different, for diagnosis and treatment of DIC. The SSC on DIC also recommended the use of serial testing (based on moderate quality of evidence).[73] Two studies have evaluated scoring criteria for the diagnosis of overt DIC in dogs and both showed an association between DIC diagnosis and mortality.[24,74] However, variability among studies and inherent species differences demonstrate the need for an evidence-based approach to standardize diagnostic criteria for the diagnosis of DIC and define appropriate criteria for each animal population of interest.

Overt DIC

The term *overt DIC* is applied to patients with clinical manifestations of thrombosis and/or hemorrhage, and is diagnosed by a combination of abnormal screening test results indicating activation of hemostasis, inhibitor depletion, and fibrinolysis.

Clinical Diagnosis of Overt DIC

Documentation of a primary initiating disease is an essential requirement for the diagnosis of DIC in all species (see Table 92.2). In human medicine, DIC may be subclassified into three distinct clinical types—a bleeding type secondary to hyperfibrinolysis (e.g., prostatic cancer, acute promyelocytic leukemia), an organ failure type due to thrombosis from a combination of hypercoagulability and hypofibrinolysis (e.g., bacterial sepsis), and an often lethal, massive bleeding type due to a consumptive hypocoagulability (e.g., obstetrical or surgical complications).[72] In veterinary medicine, organ failure/thrombotic and consumptive bleeding phenotypes are most common. Bleeding typically manifests as epistaxis, petechiae, bruising, prolonged bleeding, or oozing after venipuncture or minor surgical procedures, and spontaneous hematoma formation and body cavity hemorrhage. Antemortem detection of thrombi is relatively difficult, due to unavailability or cost of advanced imaging modalities, such as computerized tomography.[58] Patients with primary inciting diseases should be monitored, therefore, for the adverse effects of thrombosis on organ function, e.g., hypoxia, azotemia, liver injury, or lactic acidosis. In the author's opinion, overt DIC is characterized first and foremost by widespread microvascular thrombosis, which causes hypoxic tissue injury, a major contributor to the high morbidity and mortality of DIC.[5,17] However, the clinical import of systemic thrombosis depends on species, underlying disease, and nature of progression of DIC. For example, hemorrhagic DIC is more common in dogs than in horses or cats; species frequently referred to as having "subclinical" DIC. The reason for these species differences is unclear; however, the naturally high fibrinolytic activity in dogs[38] may be a factor. Since dysregulated fibrinolysis contributes to pathogenesis and clinical manifestations of DIC, further studies of fibrinolysis in animals with DIC are needed. Due to the difficulties with detecting thrombosis and lack of bleeding in many animals with DIC, screening tests to detect overt DIC is recommended in all patients with primary inciting disorders (see Tables 92.1 and 92.2).

Laboratory Criteria of Overt DIC

Diagnosis of overt DIC in animals and people relies upon identifying abnormalities in multiple standard tests of hemostasis, rather than a single laboratory abnormality (see Table 92.1). Traditional criteria for diagnosis of overt DIC in animals include a combination of two or more test abnormalities, specifically thrombocytopenia, prolonged screening coagulation times, such as the prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin clotting time (TCT), hypofibrinogenemia, low AT activity, and high fibrin(ogen) degradation product (FDPs) or D-dimer concentrations.[4,9,17,20,24,66,67] The apparent diagnostic utility of these tests varies depending on species and stage at presentation. In the last 10 years, these criteria have remained unchanged, although additional tests, such as measurement of thrombomodulin for detection of organ injury, are used in people[72] and clot curve analysis has been evaluated in dogs with DIC, liver failure, biliary obstruction or rupture, and anticoagulant rodenticide toxicosis (revealing some differences in clot curve results between these disorders).[60]

Thrombocytopenia (typically mild to moderate) is a consistent finding in dogs with overt DIC (75–100% sensitivity),[5,66] but not in cats[20] or horses (0–64% sensitivity).[17,67] Of the routine coagulation screening tests, the APTT appears to be more sensitive for detecting DIC in animals than the PT or TCT.[17,20,24,66,67] Hypofibrinogenemia is generally an insensitive indicator of DIC because fibrinogen is upregulated secondary to underlying inflammation, which often accompanies the DIC process or the initiating disease.[17,20,24,66,67] Indeed, normal fibrinogen concentrations in a patient with active inflammation suggest ongoing consumption of fibrinogen balanced by increased production. Low AT activity can be a sensitive test for diagnosis of DIC in dogs (77–90%)[5,66] and horses (83–93%),[17,67] but AT activity is not a reliable indicator of DIC in cats.[7] For markers of fibrinolysis, assays for D-dimer have largely replaced those for FDPs. D-dimer is a sensitive test for DIC in dogs (75–100%),[50,66] but is less sensitive in horses (50% in one study[67]), and has not been adequately evaluated in cats. D-dimer concentrations can be prognostic; horses with gastrointestinal disorders and D-dimer concentrations >1000 ng/mL (MiniQuant immunoturbidimetric assay) were 5 times more likely to die than those with lower concentrations.[10] Red blood cell fragments, such as schistocytes and keratocytes, can be seen in dogs (75%[66]) and cats (8%[20]) with DIC, but have not been reported in horses. The combination of RBC fragments and thrombocytopenia in clinically ill dogs with

relevant diseases warrants additional hemostasis testing for overt DIC.

Viscoelastic-based tests for hemostasis, including rotational thromboelastometry (ROTEM™), thromboelastography (TEG®), and an oscillatory probe method (Sonoclot®), have been described in dogs with overt DIC[4,75] and in horses with gastrointestinal disorders or critically ill neonatal foals.[14,19] In canine studies, using TF-activated clot formation (analogous to a PT), hypocoagulable profiles were seen in 22%[75] and 34%[4] of dogs with DIC and were associated with bleeding,[4] lower platelet counts,[4,75] and higher mortality.[4,75] These findings are consistent with the long-held anecdotal opinion that the hemorrhagic phenotype in dogs is associated with fulminant, "end-stage" consumptive DIC. Horses had variable changes, with some having evidence of hypocoagulability (based on maximum clot strength).[14,19] Together, these studies do not provide strong evidence that viscoelastic-based tests are more informative than routine hemostasis testing to diagnose overt DIC in animals.

Nonovert DIC

In contrast to overt DIC, nonovert DIC is clinically inapparent and the diagnosis depends on laboratory tests indicating an activated, but not overwhelmed, hemostatic system (hypercoagulable).[69] Nonovert DIC also applies to the older term of "chronic DIC," which reflects continuous low grade, but compensated, activation of coagulation (see Table 92.1 and Figure 92.1). Routine clotting-time-based tests are insensitive to this phase because they are configured to detect coagulation factor deficiencies, rather than accelerated coagulation. Nonovert DIC is marked by excessive thrombin generation and tests geared toward detection of excessive thrombin are useful. This might include measurement of TAT complexes, D-dimer, and assays that measure the kinetics and rate of thrombin generation, e.g., thrombin potential assays. Unfortunately, with the exception of D-dimer (which is not specific for DIC), these tests are not available for routine clinical diagnosis. Detection of nonovert DIC in animals thus remains an index of suspicion based on 1–2 abnormal hemostasis results in an animal with a predisposing condition. The diagnostic utility of serial testing, which is recommended in humans for detection of nonovert DIC[69] and monitoring of overt DIC,[73] has not been evaluated in animals.

In veterinary medicine, viscoelastic-based methods were initially thought to be a "breakthrough" enabling us to detect hypercoagulability. Although these assays have detected hypercoagulability in up to 45% of dogs with DIC, results strongly correlate with fibrinogen concentration, particularly when hypercoagulability is based on clot strength.[4,75] In addition, these assays are impacted by sample collection (e.g., timing of analysis, agitation) and methodologic (e.g., choice of activator, definition of hypercoagulability) and patient-related (anemia in particular) variables, which influence results and interpretation.[4,16,21,27,33,45,46] At this time, viscoelastic-based testing cannot be recommended for diagnosis of DIC in animals. Similarly, there is insufficient evidence to warrant the use of viscoelastic hemostasis testing for diagnosis of DIC in humans.[42]

Scoring Schemes for DIC

The ISTH SSC on DIC developed practical systems for the diagnosis of overt and nonovert DIC in people in 2001.[69] For overt DIC, the system is applied to patients with an underlying disorder associated with DIC and derives a summary score from four readily available laboratory tests: platelet count (<100 × 10^6/L: score of 1; <50 × 10^6/L: score of 2), PT (>3 but <6 sec: score of 1, >6 sec: score of 2), fibrinogen (<1 g/L: score of 1), and fibrin-related markers (soluble fibrin, FDPs, or D-dimer, moderate increase: score of 2, marked increase: score of 3). A composite score of 5 or more was compatible with overt DIC and a score of <5 was suggestive of nonovert DIC. For nonovert DIC, scores were given for a disease associated with DIC, major criteria or tests that are globally available including platelet count, PT and fibrin-related markers, and minor criteria or tests that are not offered by most laboratories, including but not limited to AT, protein C, and thrombin–antithrombin complexes. The scoring scheme also incorporated points for progressive deterioration (positive) or improvement (negative) in major test results on serial testing every 24 hours. Several studies have shown that the ISTH score for overt DIC is associated with higher 28-day mortality rates, although this is dependent on the initiating disease.[2,22] Other societies have developed different scoring schemes. While prospective validation of the ISTH nonovert DIC score is lacking, the basic recommendation of the ISTH is to use a scoring scheme to diagnose and determine treatment regimens for DIC.[73]

The ISTH overt DIC scheme was used to develop a multiple logistic regression model for diagnosis of DIC combining expert opinion and laboratory data from 63 serially tested dogs from one institution.[74] A final model was based on the continuous variables of fibrinogen, PT, and APTT and the dichotomized variable, D-dimer (cutoff, 0.5 mg/L, NycoCard assay), with a score of >0.401 being considered as a high probability of DIC. This model was then applied to data obtained from 46 dogs at risk for DIC at a second institution. Compared to the "expert panel," the model identified DIC in 83% of dogs, with a specificity of 77%. Using the model, dogs with DIC were 2.8 times more likely to die versus dogs without DIC. This logistic regression model was subsequently applied to data analyzed retrospectively from 804 dogs in which hemostasis testing was performed at a single institution.[24] In the latter study, the investigators evaluated 4 different schemes for diagnosis of overt DIC and compared scheme performance as predictors of overall mortality (21% in this cohort). The investigators found that traditional criteria of DIC diagnosis, namely, three or more abnormalities in standard test results (based on relevant changes above or below the institution-derived reference intervals), was the most sensitive (73%) and specific method (81%) for predicting mortality in this large cohort of dogs. By contrast, the ISTH score was poorly sensitive (7%), whereas the unmodified multiple logistic regression

model was highly sensitive (98%), but not specific (3%). These studies show that traditional criteria for diagnosis of DIC are still relevant and that further work is needed to identify the optimum tests and test cutoffs to include in a DIC scoring scheme. Furthermore, due to species differences in underlying diseases and diagnostic test sensitivity for DIC, it is unlikely that a single scoring system will apply across species. Ultimately, there is still a need to establish consensus guidelines for diagnosing nonovert and overt DIC in animals with the goals of achieving consistency across studies in patient stratification and assessment of various treatment protocols on defined clinical outcomes.

TREATMENT OF DIC

Affected animals should always be treated for their primary disease with the goal of breaking the DIC cycle. Supportive care aimed at alleviating metabolic and hemodynamic sequelae of DIC (shock, hypoperfusion, and acidosis) helps minimize organ damage, inflammation, and continued activation of hemostasis. Effective treatment modalities beyond primary disease-specific and supportive care remain unproven. Treatment recommendations are generally derived from older human literature and should be applied with the knowledge that they may not be suitable for animals, due to species-specific differences in hemostasis and drug pharmacokinetics and efficacy. Randomized, controlled clinical trials, with collaboration between multiple institutions or practices and consensus on testing criteria and a defined outcome (e.g., 28-day mortality), are urgently needed in veterinary medicine to identify safe and cost-effective DIC treatment strategies. In 2013, the ISTH SSC on DIC issued evidence-based guidelines for treatment of DIC including treatment of the primary disease (moderate evidence), replacement of coagulation factors and platelets, anticoagulant therapy, and antifibrinolytic therapy.[73]

Replacement of Coagulation Factors and Platelets

The fear that transfusion "fuels the fire" of DIC is largely unfounded; however, the recommendation from the ISTH, despite a low quality of evidence, is that replacement of platelets and coagulation factors (in the form of fresh frozen plasma or cryoprecipitate, rather than whole blood) be restricted to actively bleeding patients (platelet count < 50×10^6/L, prolonged PT or APTT by 1.5 times, fibrinogen < 1.5 g/L) or those at risk of bleeding (e.g., surgery, platelet counts 10–20 × 10^6/L). Fresh frozen plasma and cryoprecipitate are recommended to treat prolonged clotting times or hypofibrinogenemia at rates of 15–30 mL/kg.[73]

Anticoagulant Therapy

The ISTH SSC on DIC considers a low quality of evidence for the use of heparin (preferentially low-molecular-weight) to treat patients with DIC and thrombosis, with stronger support for the use of low-dose heparin for prophylaxis of venous thromboembolism in ill, nonbleeding patients with DIC.[73] Without prospective clinical trials, heparin therapy should be used with caution in dogs with DIC, although heparin therapy may be applicable for horses or cats, in which thrombotic sequelae appear to dominate over hemorrhage. Some inhibitor concentrates or recombinant proteins, e.g., TM, have shown some efficacy for reducing mortality in human patients with sepsis.[22,28,73] Unfortunately, comparable products are unavailable for animals.

Antifibrinolytics

Antifibrinolytics are reserved for human DIC patients with evidence of excessive fibrinolysis (e.g., patients with acute promyelocytic leukemia or trauma). A role for antifibrinolytics in the treatment of canine DIC has not been established.

Future Treatment Approaches

Recognition of the complex interplay between inflammation and hemostasis, the discovery of the toxic and procoagulant activities of histones and cell-free DNA, respectively, and renewed interest in the contact pathway as an initiator of DIC through polyphosphates and NETs, hold promise for development of new strategies to interrupt the DIC cycle that will be applicable to all species. While still at the investigational stage, targeted therapy aimed at minimizing NETosis, inhibiting polyphosphates, or inactivating FXIIa or FXIa[22] may provide opportunities to improve DIC outcomes in veterinary and human patients.

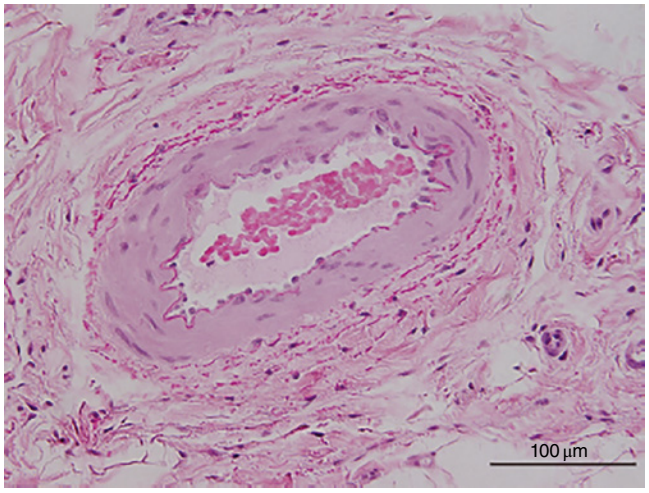

FIGURE 93.1 Cross-section view of a normal muscular arteriole. A single layer of endothelial cells adjacent to the lumen is surrounded by smooth muscle cells and fibroblasts in the media, and an outermost loosely organized layer of adventitial cells. H&E stain; 40×.

Blood vessels contain three concentric layers: intima, media, and adventitia (Figure 93.1). The intima is a single layer of endothelial cells (ECs) that rests on scant subendothelial connective tissue, separated from the media by the internal elastic membrane. The media is composed of smooth muscle cells (SMCs), collagen and elastin fibers, and fibroblasts. The outermost adventitia is a layer of dense fibroelastic connective tissue separated from the media of larger arteries by an external elastic membrane.

Hemodynamic stress evokes a variety of responses from all mural elements.[11,16] Vascular injury induces intimal migration and proliferation of SMCs. Smooth muscle contraction regulates regional blood flow and pressure. ECs have a myriad of functions, including the transfer of molecules across vessel walls and the modulation of blood flow, vascular resistance, hormone metabolism, SMC growth, and inflammatory and immune responses. Moreover, the prothrombotic and antithrombotic properties of ECs play a critical role in regulating hemostasis.

CONGENITAL ANOMALIES AND MALFORMATIONS

Shunts

Persistent Ductus Arteriosus

The ductus arteriosus is the fetal vascular communication between the pulmonary artery and aorta. Hypoplasia or asymmetry of ductal SMCs and aorta-like elastic tissue in the ductus cause failure to contract properly after birth and persistence of a vascular lumen.[2] Persistent ductus arteriosus (PDA) occurs in all species, but is most common in dogs.

Persistent Ductus Venosus

The fetal ductus venosus (DV) allows umbilical and portal venous blood flow to bypass the liver.[34] An abrupt decrease in blood flow and pressure in the umbilical sinus shortly after birth causes retraction and narrowing of the DV orifice, resulting in functional shunt closure. Permanent closure via connective tissue deposition starts within days after birth and is complete by 15–18 days in the dog. Persistent DV may cause hepatic lobular atrophy, reduplication of the hepatic arterioles, and unapparent portal veins in hepatic triads. The associated clinical signs include poor growth and hepatic encephalopathy.

Arteriovenous Fistula

Arteriovenous fistulas (AVFs) are direct arterial–venous communications without intervening capillary beds. AVFs may be congenital or develop from wounds, rupture of arterial aneurysms into adjacent veins, or inflammatory necrosis of vessel walls. AVFs consist of enlarged congested vessels with disorganized arterial walls and thin-walled, dilated venous channels. AVFs typically cause signs of recurrent hemorrhage; however, large AVFs may induce high-output heart failure, and AVF in the central nervous system (CNS) may cause neurologic signs and acute death.[12]

Telangiectasia

Telangiectasias are congenital or acquired exaggerations of preformed vessels. The condition is most common in the liver of cattle, characterized by increased deposition of basement membrane components and fibrosis resulting in hepatocyte atrophy and disruption of sinusoids.[14]

Varicose Veins

Varicosities, most common on the ovary and vulvar lips of horses, are dilated, tortuous veins produced by prolonged increased intraluminal pressure and loss of vessel wall support.

DEGENERATION OF ARTERIES

Atherosclerosis

Atherosclerosis is a chronic inflammatory response initiated by EC injury in the arterial wall, with progression mediated by macrophages, T cells, SMCs, and adjacent extracellular matrix.[37] Atherosclerosis is common in parrots and lesions occasionally develop in the coronary arteries of dogs with hypothyroidism or diabetes mellitus.[9] In early lesions, lipid-laden macrophages, T cells, and small amounts of extracellular lipid accumulate in fatty streaks. Over time, macrophage-derived interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF-α) recruit leukocytes, produce toxic oxygen species, and elaborate growth factors that stimulate medial SMC

migration, division, and deposition of extracellular matrix. Fatty streaks may evolve into atherosclerotic plaques that protrude into the vessel lumen causing ischemic damage. Focal plaque disruption exposes a central necrotic core of lipid, cholesterol clefts, cellular debris, foam cells, fibrin, variably organized thrombi, and other proteins. These substances are highly thrombogenic, resulting in vascular occlusion and embolization. Atrophy of the media underlying atherosclerotic plaques may lead to aneurysmal dilation and arterial rupture.

Vascular Amyloid

Amyloid is a pathologic protein formed from precursors such as serum-amyloid-associated protein, immunoglobulin light chain, and apolipoprotein A. Abnormal folding of precursors leads to oligomer formation and eventual deposition of fibrils as β-pleated sheets. Histologically, amyloid is an amorphous, acellular eosinophilic extracellular deposit. Amyloid shows a characteristic apple green birefringence under polarized light when stained with Congo red. Vascular amyloid deposition in the media of splenic and cardiac vessels is a common incidental finding in aged dogs, occasionally associated with EC necrosis and obliteration of the vascular lumen. Cerebral amyloid angiopathy in cortical and leptomeningeal vessels is common in aged dogs and cats due to the deposition of β-amyloid produced by SMCs. Apolipoprotein-AI-derived amyloid has been described in pulmonary vessels of old dogs, perhaps due to aberrant metabolism or mutant forms of apolipoprotein AI.

Mineralization

Uremic Gastropathy

Uremic gastropathy occurs most often in dogs with renal disease and occasionally in cats and horses. Vascular damage, presumably induced by a poorly characterized toxic peptide, results in gastric mucosal edema, congestion, and hemorrhage.[21] Medial necrosis, mineralization, and thrombosis of arterioles in the middle and deeper portions of the gastric mucosa may accompany EC injury. Despite vasculopathy, gastric necrosis and ulceration rarely develop.

Medial Calcific Sclerosis

Medial calcific sclerosis (Monckeberg's arteriosclerosis) refers to flat plaques in the media of elastic arteries composed of calcium and phosphorus deposits. Osseous metaplasia with hematopoietic tissue in the intertrabecular spaces may develop at these sites.

Metastatic Mineralization

Metastatic mineralization, due to disturbance of calcium and phosphorus metabolism, occurs in vitamin D toxicity, secondary to chronic granulomatous diseases such as Johne's disease, and in herbivores that consume plants such as *Solanum malacoxylon* or *Cestrum diurnum* that contain 1,25-dihydroxycholecalciferol or related compounds.[17]

Arterial Ruptures

Trauma is the most common cause of arterial rupture in all species. Aortic rupture, from the level of the aortic valve to the brachiocephalic trunk, is best documented in horses,[29] but has been reported in camelids and woodchucks. Degenerative changes of the media, including cyst formation, fragmentation and mineralization of elastin fibers, and accumulation of myxomatous ground substance, have been proposed as risk factors for aortic rupture. Rapid death is usually due to hemopericardium; however, dissection into the myocardium may occur. Additional syndromes in horses include uterine artery rupture and mycotic ulceration of the internal carotid or maxillary artery. Experimental copper deficiency in pigs leads to aortic rupture due to deficiency of the copper-containing enzyme lysyl oxidase. Similarly, lathyrism due to β-aminopropionitrile inhibits lysyl oxidase.

Aneurysms

Aneurysms are localized abnormal dilations of a vessel. True aneurysms consist of multiple layers of the vessel wall, while false aneurysms are hematomas (surrounded by fibrous connective tissue) that communicate with the vessel lumen. Abdominal artery aneurysms are common in Holstein cattle in the Northeastern United States.[13]

HYPERTROPHY OF ARTERIES

Chronic Hypoxic Pulmonary Hypertension

High-altitude disease refers to a syndrome of heart failure in cattle and pigs secondary to chronic hypoxic pulmonary hypertension. The pulmonary vasculature of cattle has a distinctive, well-developed media in small arteries and veins. After initial vasoconstriction, chronic hypoxia induces medial hypertrophy of the small pulmonary arteries and functional obstruction. Hypertrophy and dilation of the right ventricle eventually lead to right heart failure with ventral edema (brisket disease).[24] A mechanism of variable transforming-growth-factor-β1-mediated response to hypoxia has been proposed. This growth factor, elaborated by perivascular neutrophils and mononuclear cells of small pulmonary arteries, appears to stimulate differentiation of vascular fibroblasts into myofibroblasts, a crucial step in hypoxia-induced vascular remodeling.[8]

Hypertension

Systemic Hypertension

Systemic hypertension is most often reported in dogs and cats with chronic renal failure, diabetes mellitus,

hyperthyroidism, hyperadrenocorticism, and chronic anemia.[1] Systemic and local hypertension is reported in horses and cattle with laminitis. Chronic renal disease is typically associated with hyperplastic arteriosclerosis, as interlobular and intralobular renal arteries and afferent arterioles thicken due to medial hypertrophy and adventitial fibrosis. Hyaline arteriosclerosis refers to the deposition of a homogeneous, pale pink hyaline material that obscures mural elements. These changes occur frequently in the nodular arterioles of the spleen of dogs and pigs, and in the uterine and ovarian arteries of pregnant and postpartum animals. Similar changes, but of unknown significance, occur in the intramural coronary arteries and small meningeal and cerebral vessels of dogs. Arteriolar hyaline degeneration is seen in the heart of pigs with vitamin E/selenium deficiency (mulberry heart disease)[23] and edema disease.

Pulmonary Hypertension

Pulmonary hypertension can either cause or result from pulmonary artery disease. Cardiac anomalies that lead to left to right shunting, hypoxic pulmonary vasoconstriction, and pulmonary thromboembolism may increase vascular resistance resulting in pulmonary arterial hypertension, whereas left-sided heart failure causes venous pulmonary hypertension and pulmonary edema. A secondary vasculitis, resulting from EC degeneration and fibrinoid necrosis of the media, often accompanies the acute pulmonary hypertension of PDA. Chronic pulmonary hypertension leads to a spectrum of changes including medial hypertrophy, medial hypertrophy with intimal thickening, and medial hypertrophy with intimal thickening and concurrent plexiform lesions (plexogenic pulmonary arteriopathy). Plexiform lesions, indicative of end-stage damage, consist of small vessel networks spanning the lumen of thin-walled, dilated arteries.

Pulmonary Capillary Hemangiomatosis and Pulmonary Veno-Occlusive Disease Pulmonary capillary hemangiomatosis (PCH) and pulmonary veno-occlusive disease (PVOD) are uncommon idiopathic disorders that cause pulmonary hypertension. The hemodynamics of PCH and PVOD are caused by widespread vascular obstruction that originates either in alveolar capillaries (PCH) or pulmonary venules and small veins (PVOD). It is unknown if PCH and PVOD are two separate diseases or are manifestations of a single disease. Foci of PCH commonly occur in the lungs of dogs with PVOD.[35] Pulmonary capillary hemangiomatosis consists of areas of alveolar hypercellularity due to increased number of capillary ECs. By contrast, PVOD is characterized by severe and widespread remodeling of postcapillary venules and small pulmonary veins and occlusion of the vascular lumen by SMCs.

Feline Pulmonary Artery Medial Hypertrophy

Pulmonary artery medial hypertrophy is a striking vascular lesion in cats.[25] The vascular changes, however, do not cause pulmonary hypertension or right ventricular hypertrophy. Medial changes range from mild thickening to marked hypertrophy and hyperplasia, with intimal proliferation and encroachment on the vascular lumen. Fibromuscular hyperplasia commonly develops in the adjacent pulmonary parenchyma and around alveolar ducts. The cat lungworm, *Aelurostrongylus abstrusus*, produces similar lesions, but most cats with medial hypertrophy are parasite-free.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is an idiopathic, noninflammatory, nonatherosclerotic segmental vascular wall thickening and central stenotic disease of arteries (and rarely veins).[30] Subtype classification is based on the layer of affected vessel wall, i.e., media, intima, or adventitia. Several canine studies have demonstrated intramyocardial coronary arterial changes similar to intimal FMD. These lesions are often clinically insignificant, but may develop secondary to pathologic conditions such as subaortic stenosis.[5] In the author's experience, segmental FMD characterized by stenosis, intimal thickening, and proliferation of SMC in coronary and atrial arteries may be associated with myocardial necrosis, fibrosis, and sudden cardiac death in dogs.

VASCULITIS

A wide variety of agents cause infectious vasculitis, including viruses, bacteria, chlamydia, rickettsia, fungi, protozoa, and helminths. These agents may directly injure ECs or act indirectly through the elaboration of toxins. Noninfectious vasculitides include hypersensitivity and drug reactions, toxins, and uremia. Although the etiology of vasculitis is often unknown, humoral and cell-mediated immunity are thought to play important roles.[3] Clinical significance varies depending on the number, size, and type of affected vessels, and the presence of thrombosis, ischemia, and infarction.

Vasculitis is characterized histologically by accumulation of leukocytes within and around vessel walls. Fibrinoid change refers to the deposition of a homogeneous or granular material composed of fibrin, immunoglobulins, complement, and platelets, with collagen and SMC degeneration. Inflammatory cells may consist primarily of neutrophils, lymphocytes, or macrophages. The presence of fragmented neutrophil nuclei is classified as leukocytoclastic vasculitis, whereas its absence is classified as nonleukocytoclastic vasculitis.

Viral Vasculitis

Equine Herpesvirus-1

Neurotropic strains of equine herpesvirus type 1 cause an abrupt onset of neurological signs, often due to spinal cord lesions.[36] Grossly, hemorrhagic foci are scattered throughout the brain and spinal cord. Histologic lesions

include lymphocytic infiltrates in the media and adventitia, and EC degeneration.

Canine Herpesvirus-1

Canine herpesvirus-1 infection has been associated with keratitis, encephalitis, abortion, neonatal mortality, and infertility.[26] Serosanguinous pleural and peritoneal effusions are typically accompanied by petechial and ecchymotic hemorrhages scattered throughout the subserosal tissues. Small necrotic foci are found in many organs; however, inflammation and intranuclear inclusions are rare.

Malignant Catarrhal Fever

Malignant catarrhal fever (MCF) is an acute, fulminant vasculitis of cattle, wild ruminants, and occasionally swine. A T-lymphotropic gamma herpesvirus causes Wildebeest-associated MCF in exotic hoofstock, whereas ovine herpesvirus 2 causes sheep-associated MCF in cattle. Signs of MCF include generalized lymphoproliferation and mucocutaneous and cutaneous ulceration. Characteristic vascular lesions consist of focal or segmental perivascular accumulation of herpesvirus-infected CD8+ T cells in many organs.[28] Fibrinoid necrosis may affect a single vascular layer or may be transmural. Although mortality rates are high, survivors develop striking proliferative concentric fibrointimal plaques.

Equine Viral Arteritis

Equine viral arteritis (EVA) is caused by a non-arthropod-borne enveloped positive stranded RNA virus in the order Nidovirales.[4] Panvasculitis develops in many organs, causing clinical signs of edema, congestion, hemorrhage, or abortion due to myometritis. Mild vascular changes consist of perivascular edema with EC hypertrophy and lymphocytic infiltrates, whereas severe lesions include fibrinoid necrosis with marked perivascular and vascular lymphocytic and occasional histiocytic infiltrates. Virus localizes to vascular EC, SMC, and pericytes, but may be found in a variety of epithelial cell types.

Feline Infectious Peritonitis

Feline infectious peritonitis virus (FIPV) is a single-stranded, positive sense, linear RNA virus composed mainly of nucleocapsid, transmembrane, and spike proteins. FIPV evolves from feline enteric corona virus (FECV) in a multistep mutational process. FECV infection generally causes no signs, or mild enteritis. Transition of FECV to FIPV is accompanied by the acquisition of macrophage tropism due to mutations in the C-terminal domain of the spike protein. FIPV infects macrophages and efficiently disseminates when the virus complexes with antibodies against the spike protein, a process referred to as antibody-dependent enhancement. Virus bound to spike-protein-specific antibodies is taken up by Fc-receptor-mediated endocytosis, with subsequent escape of the viral genome into the cytoplasm.[27,32] Most FIPV-infected cats clear the virus, but fecal shedding may persist for several months. Cats that develop clinical signs are typically less than 2 years of age and mount an ineffective cell-mediated immune response characterized by low CD4+ T-cell counts, decreased levels of IL-12 and interferon-gamma (IFN-γ), and increased TNF-α and IL-1β.[18]

Effusive (wet) and noneffusive (dry) FIP represent extremes of a clinical continuum. Effusive vasculitis often manifests as abdominal effusion, with serosal surfaces covered by fibrin and perivascular necrosis and inflammation. Pleural and pericardial effusions are less common. Noneffusive FIP typically affects eyes, CNS, kidneys, liver, pancreas, and intestines. Microscopically, varying proportions of lymphocytes, macrophages, plasma cells, and neutrophils accumulate in and around venules. Fibrin deposition correlates with vasculitis severity, while vascular degeneration and thrombosis lead to parenchymal necrosis. Noneffusive FIP clinically resembles lymphosarcoma, steatitis, mycotic infection, and toxoplasmosis; however, histopathology provides the definitive diagnosis of FIP.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii*, a Gram negative bacterium transmitted by tick vectors including *Dermacentor variabilis*, *Dermacentor andersoni*, and *Amblyomma americanum*.[33] Rickettsia replicate within ECs of small blood vessels in a wide variety of mammals, but dogs most often develop disease. Clinical signs include myalgia/arthralgia, lymphadenomegaly, dyspnea, conjunctivitis, edema, vomiting, diarrhea, and petechial or hemorrhagic diathesis. Acute meningoencephalitis, often affecting the vestibular system, may be seen as well as inflammation of retinal vessels. Necrotizing vasculitis of small veins, capillaries, and arteries is accompanied by perivascular lymphocytic infiltrates. EC necrosis and inflammation lead to increased vascular permeability, edema, and multifocal hemorrhage and thrombosis.

Verminous Arteritis

Strongylus Vulgaris

Strongylus vulgaris is the most serious of the large and small equine strongyles.[7] Larvae are unable to penetrate the internal elastic lamina and therefore migrate within the vascular intima. After reaching the cranial mesenteric artery, larvae undergo 3–4 months of development before molting and returning to the cecum and colon walls. Tortuous intimal tracks, consisting of fibrin, necrotic cellular debris, and mixed inflammatory cells are eventually covered by ECs and converted into fibroelastic thickenings. Clinical signs develop secondary to occlusive thrombi, often in the cranial mesenteric artery, but also in the aorta, renal arteries, and celiac artery. Affected vessels may develop saccular or

fusiform aneurysms due to weakening of the wall. Cecal and colic artery thromboembolism, pressure on abdominal autonomic plexuses, and release of toxins from dead larvae induce colic.

Heartworm Disease

Heartworm disease caused by *Dirofilaria immitis* is common in dogs, but occurs in other mammals including domestic and wild felids, wild canids, ferrets, sea lions, muskrats, and horses. Mosquitoes of the genera *Aedes*, *Culex*, and *Anopheles* transmit infective third-stage larvae that migrate through connective tissues to veins, ultimately maturing in the heart 3–4 months later. Adult worms reside primarily in the pulmonary arteries and right ventricle, but may extend into the right atrium and vena cava in heavy infestations. Pulmonary veins in the caudal lung lobes often develop fibromuscular intimal proliferation, resulting in pulmonary hypertension and right heart failure. Worm larvae, adults, and an intracellular bacteria *Wolbachia* induce eosinophilic and neutrophilic endoarteritis, and rugose myointimal proliferation. Adulticide therapy may exacerbate thromboembolism, pulmonary hypertension, and induce granulomatous reactions.

Photosensitization Dermatitis

Photosensitization dermatitis occurs in animals that ingest plants containing photodynamic agents or drugs (type I), have an inability to metabolize heme pigments (type II), or have liver disease that impairs excretion of phylloerythrin, a degradation product of chlorophyll (type III). Type III, or hepatogenous photosensitization, is associated with cholestatic liver disease. Gross lesions occur in lightly colored areas of skin exposed to sunlight, with histopathologic findings of fibrinoid vascular degeneration, dermal edema, and epidermal coagulation necrosis.[15]

Immune-Mediated Vasculitis

Among the various immune mechanisms causing vasculitis, antigen–antibody complexes formed in the circulation (type II hypersensitivity) or locally (type III hypersensitivity) are most common. Complexes precipitate in vascular walls and bind to neutrophils via Fc or C3b receptors, thereby triggering inflammation, proinflammatory cytokine and lysosomal enzyme release, and generation of oxygen-derived free radicals. Complement activation leads to neutrophil and monocyte recruitment and increased vascular permeability. Immune complex injury results in vascular wall necrosis and fibrinoid changes. Lesions may resolve as immune complexes are catabolized.

Equine Purpura Hemorrhagica

Equine purpura hemorrhagica occurs in 1–2% of horses after acute infection with *Streptococcus equi*.[22] Deposits of streptococcal M protein complexed with IgA or IgM damage ECs, and induce systemic leukocytoclastic vasculitis. Head and hind leg edema is accompanied by petechia on mucosal and serosal surfaces. Serious sequelae include immune complex glomerulonephritis and infarction of skeletal muscle, skin, gastrointestinal tract, pancreas, and lungs, similar to the human syndrome Henoch–Schönlein purpura.

Canine Juvenile Polyarteritis Syndrome

Canine juvenile polyarteritis syndrome (CJPS) occurs primarily in young Beagles, but has been documented in other breeds.[6,31] Affected dogs have a sudden onset of fever, anorexia, and a hunched stance, with frequent remissions and relapse. Small to medium muscular arteries in the dura mater and leptomeninges of the cervical spinal cord, extramural coronary arteries, and cranial mediastinum develop segmental vasculitis and perivasculitis. Lymphocytes, macrophages, and plasma cells encircle the vessel and often expand into an eccentric nodule, with neutrophils predominating in acute lesions. Fibrinoid change and rupture of the elastic lamina, and fibrin thrombi, hemorrhage, and necrosis of adjacent tissues characterize severe lesions. CJPS has many features of an immune complex syndrome of children, Kawasaki disease, including high serum IgA, low peripheral T cells and high B cells, mononuclear activation, antineutrophil cytoplasmic antibodies, and suppressed mitogenic response. Other causes of canine systemic vasculitis include leishmaniasis and drug toxicities.

Proliferative Arteritis of the Nasal Philtrum of Dogs

Proliferative arteritis of superficial and deep dermal blood vessels restricted to the nasal philtrum is seen infrequently in large breed dogs. SMC proliferation, accompanied by fibrin thrombi, occludes the vascular lumen. The resulting ischemia causes ulceration and potentially fatal hemorrhage.[20]

Paraneoplastic Vasculitis

Paraneoplastic leukocytoclastic vasculitis with variable degrees of necrosis is occasionally seen in association with lymphosarcoma.[19]

Thrombotic Microangiopathy

Thrombotic microangiopathy (TMA) is a clinical syndrome characterized by a variable combination of fever, thrombocytopenia, microangiopathic hemolytic anemia with schistocytes, neurologic deficits, and renal failure.[38] The causes of TMA in people are diverse. External triggers include viruses, bacterial Shiga toxins (hemolytic uremic syndrome), endotoxin, antibodies, and drugs. Thrombotic thrombocytopenic purpura (TTP) is caused by either an inherited or acquired deficiency of the enzyme a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13), which cleaves very large von Willebrand factor multimers and prevents inappropriate platelet aggregation and microvascular thrombosis. Regardless of cause, widespread hyaline thrombi form in the microcirculation

leading to platelet consumption and organ dysfunction. Although disseminated intravascular coagulation (DIC) also causes widespread thrombosis in the microvasculature, DIC is pathophysiologically distinct from TMA. Activation of the coagulation cascade resulting in factor depletion and fibrin degradation is typical of DIC, but uncommon in TMA.

Cutaneous and renal glomerular vasculopathy is a TMA of unknown etiology in dogs, characterized by ulceration of the distal extremities and acute renal injury.[10] Although first recognized in Greyhounds in the Southeastern United States of America, the disease has been recognized in multiple breeds in North America and Europe. Fibrinoid necrosis of glomerular arterioles with less frequent involvement of intralobular and arcuate arteries is accompanied by thrombosis. Fibrinoid necrosis of small dermal blood vessels underlies areas of cutaneous ulceration. Dermatohistologic features include atrophic sebaceous glands and hair follicles surrounded by variable numbers of neutrophils and foamy macrophages that obscure the follicular dermal epithelial interface.

Acronyms and Abbreviations

ACS, acute coronary syndromes; aPTT, activated partial thromboplastin time; AT, antithrombin; ATE, arterial thromboembolism; AXA, anti-Xa activity; BMBT, buccal mucosal bleeding time; COX, cyclooxygenase; CRASH-2, Clinical Randomization of an Antifibrinolytic in Significant Haemorrhage 2; CRI, constant rate infusion; CURATIVE, Consensus on the Rational Use of Antithrombotics in Veterinary Critical Care; DDAVP, desamino-8-D-arginine vasopressin (desmopressin); DIC, disseminated intravascular coagulation; DMSO, dimethyl sulfoxide; EACA, ε-aminocaproic acid; FP, frozen plasma; FFP, fresh frozen plasma; FWB, fresh whole blood; IM, intramuscular; IMHA, immune-mediated hemolytic anemia; IMT, immune-mediated thrombocytopenia; IV, intravenous; LMWH, low-molecular-weight heparin; PAR, protease-activated receptor; PC, platelet concentrate; PCI, percutaneous coronary intervention; PO, per os; PRP, platelet-rich plasma; PT, prothrombin time; PTE, pulmonary thromboembolism; SC, subcutaneous; tPA, tissue plasminogen activator; TXA, tranexamic acid; TXA_2, thromboxane A_2; UFH, unfractionated heparin; VTE, venous thromboembolism; VWD, von Willebrand disease; VWF, von Willebrand factor.

This section provides a management overview of hemorrhagic syndromes, and more in-depth review of antithrombotic agents, i.e., antiplatelet, anticoagulants, and thrombolytic drugs. Although knowledge gaps remain, the American College of Veterinary Emergency and Critical Care recently published consensus guidelines on the rational use of antithrombotics in veterinary medicine.[47]

TREATMENT OF HEMORRHAGIC DISORDERS

Transfusion should be considered for any patient with a documented bleeding disorder with signs of active bleeding or before invasive procedures. Blood component therapy (Table 94.1 and Section VIII) is usually the best means to provide cells or proteins to support hemostasis while minimizing risks of antigen exposure or volume overload. Since transfusion may transiently correct underlying deficiencies, baseline samples (EDTA and citrate blood) for laboratory assays should be collected before transfusion. At minimum, platelet count and coagulation screening tests such as the prothrombin time (PT) and activated partial thromboplastin time (aPTT) should be evaluated, with ancillary testing as needed to diagnose and manage complex disorders (see Chapter 88 and Section VI).[63,18] Global hemostatic tests may help monitor response,[48] but cessation

TABLE 94.1 Blood products for hemorrhagic disorders.

Products	Dosage guidelines	Indications
Platelet-rich plasma[a]	6–10 mL/kg	Thrombocytopenia, platelet dysfunction
DMSO cryopreserved platelets[b]	1 unit/10 kg	Thrombocytopenia, platelet dysfunction
Lyophilized platelets[c]	3×10^6 particles/kg 1 × 8 mL vial/5 kg	Thrombocytopenia, platelet dysfunction
Fresh frozen plasma	6–12 mL/kg	Coagulation factor and VWF deficiencies
Cryoprecipitate[d]	1 unit/10 kg	Fibrinogen, factor VIII, factor XIII, and VWF deficiencies
Cryo-poor plasma	6–12 mL/kg	Deficiencies of factors II, VII, IX, X, and XI
Fresh whole blood	12–20 mL/kg	Replacement of platelets and all factors

[a]Platelet-rich plasma containing at least 200×10^6 platelets/mL.
[b]100 mL unit containing at least 5×10^{10} platelets total, minimum concentration 5×10^8 platelets/mL.
[c]Lyophilized powder, reconstituted with 8 mL water for injection, final concentration 1.5×10^9 particles/mL.
[d]1 unit cryoprecipitate prepared from 200 mL fresh frozen plasma.

of hemorrhage, cardiovascular stabilization, and a stable hematocrit remain the most important clinical endpoints.[28]

Transfusion for Platelet Disorders

Thrombocytopenia is the most common primary hemostatic defect, but acquired and hereditary platelet dysfunction may also cause hemorrhage (see Chapter 86). Management of the underlying disorder is the most important intervention for control of bleeding for thrombocytopenic patients. Severe, life-threatening hemorrhage may require transfusion, although transfused cells are often rapidly removed from circulation, thus precluding normalization of platelet count. Acquired platelet dysfunction typically causes mild to moderate bleeding that resolves after correction of the underlying disorder. By contrast, patients with hereditary platelet dysfunction typically require transfusion for treatment or prophylaxis. In human medicine, platelet counts above 10 000/μL are considered safe in the absence of bleeding, while counts below 100 000/μL associated with severe bleeding or central nervous system hemorrhage prompt intervention.[1]

Options for platelet transfusion include fresh whole blood (FWB), platelet-rich plasma (PRP), platelet concentrates (PC), cryopreserved platelets, and lyophilized platelet products (see Chapter 86).[21] FWB is often used in clinical practice as the source of platelet transfusion. Platelets cryopreserved at –30°C in dimethyl sulfoxide (DMSO) have longer shelf-life than fresh platelets (6 months vs 5 days),[65] but are less effective.[21,50] A second-generation, trehalose-stabilized, lyophilized canine platelet product is commercially available, and under evaluation in clinical trials. Other novel platelet products are also in development.[83]

Transfusion for Coagulopathy and VWD

Plasma product transfusion is the mainstay for management of severe coagulopathy and von Willebrand disease (VWD). The choice of product depends on the underlying disorder (see Chapters 88 and 100). Transfusion of components rather than FWB is preferred to reduce the risk of volume overload and antigen exposure. A shift toward whole blood transfusion for major trauma in people has resulted from landmark trials indicating survival advantage for red blood cells, plasma, and platelets transfused in a 1:1:1 ratio.[58] However, comparable indications and product availability are uncommon in veterinary medicine.

In single-factor defects such as hemophilia A or B, components optimize use of resources. Components for hemophilia A (FVIII deficiency) include fresh frozen plasma (FFP) or cryoprecipitate, whereas hemophilia B (FIX deficiency) is appropriately managed with FFP or cryo-poor plasma (Table 94.1). Simultaneous deficiency of many factors occurs in patients with severe liver disease, vitamin K deficiency, hemorrhagic disseminated intravascular coagulation (DIC), and following massive transfusion. These patients are typically best managed with FFP particularly if the nature of the underlying disorder is uncertain. The various products have distinct dosing guides (Table 94.1).

Drug Therapy

Vitamin K Therapy

Vitamin K deficiency is a common acquired coagulopathy, often arising due to anticoagulant rodenticide toxicity or hepatobiliary disease (see Chapter 89). Patients with severe hemorrhage should be transfused with FWB or components to immediately replace active factors. Pretransfusion samples for coagulation testing should be drawn to identify characteristic coagulopathy (e.g., prolonged PT and aPTT), whereas samples for toxicologic testing may identify specific products.Vitamin K replacement should be given as vitamin K_1 (phytomenadione or phytonadione), rather than vitamin K_3 (menadione). Oral administration is appropriate in the absence of gastrointestinal signs or malabsorptive disorders and may provide better bioavailability than subcutaneous (SC) injection. The SC route is preferred for parenteral

vitamin K_1, because intravenous (IV) administration may cause anaphylaxis, and intramuscular (IM) injection risks hematoma formation. Vitamin K_1 should be given at an initial dose of 5 mg/kg SC using a small-gauge needle, followed by a maintenance dosage of 2.5 mg/kg per os (PO) every 12 hours. New factor synthesis to correct coagulopathy occurs over a lag period of 12–24 hours from initiation of therapy. Prolonged vitamin K_1 therapy (4–6 weeks) may be required for long-acting rodenticide toxicities. A recheck PT to gauge response can be performed 48 hours after cessation of therapy. If the PT is prolonged, vitamin K_1 therapy should be continued for 1–2 weeks, with recheck after 48 hours. Gastrointestinal decontamination within 6 hours of known rodenticide ingestion may prevent the need for vitamin K_1 therapy, provided PT is normal at presentation (to identify prior exposure) and PT remains normal 48 hours later with no signs of hemorrhage.[96]

Desmopressin

Desmopressin (desamino-8-D-arginine vasopressin, DDAVP) is a synthetic analog of arginine vasopressin that produces antidiuresis without vasoactive side-effects. In people, DDAVP effectively induces (via V2 receptors) von Willebrand factor (VWF) release from endothelial stores.[80] Dogs demonstrate relatively low qualitative and quantitative VWF release in response to DDAVP, but the drug shortened in vivo bleeding time and improved surgical hemostasis in dogs with type 1 VWD and platelet dysfunction.[22] In addition to VWF release, DDAVP enhances platelet function via VWF-independent mechanisms including microparticle formation,[61] and enhanced procoagulant expression.[27] Desmopressin is most often used in human medicine to treat mild to moderate VWD, hemophilia A, and platelet dysfunction.[80] In dogs, DDAVP is used as adjunctive treatment of type 1 VWD, and for surgical prophylaxis (administered 30 minutes before surgery). Intravenous DDAVP reversed aspirin-induced buccal mucosal bleeding time (BMBT) prolongation in dogs.[35] Injectable or intranasal DDAVP is administered at 1–4 mcg/kg SC or IV.[69] Onset of action is approximately 30 minutes, duration is usually 2 hours, with diminished effect of repeated doses due to depletion of VWF stores. Response varies among individuals; thus, blood products should be available to control bleeding.

Antifibrinolytic Drugs

The lysine analogs tranexamic acid (TXA) and ε-aminocaproic acid (EACA) (Table 94.2) suppress fibrin degradation by reversibly blocking the lysine-binding sites for fibrin on plasminogen. In people, the potency of TXA is approximately 8–10 times that of EACA.[111] In 2010, the Clinical Randomization of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2) human trauma trial showed reduction in mortality with early administration of TXA as a loading dose of 1 gram over 10 minutes, followed by 1 gram infused over 8 hours.[107] However, TXA administration more than 3 hours after injury appeared to increase the risk of fatal hemorrhage.[101] TXA is also used to reduce surgical blood loss.[94] Although efficacy data are limited, TXA has been used in dogs for clinical bleeding secondary to neoplasia, immune-mediated thrombocytopenia (IMT), trauma, surgery, anticoagulant intoxication, and liver failure.[66] Dogs may be relatively hyperfibrinolytic, suggesting higher dosages may be needed to inhibit fibrinolysis in dogs versus humans.[44] A recent study in healthy dogs demonstrated safety of TXA after a 10 mg/kg IV bolus followed by 10 mg/kg/h constant rate infusion (CRI) over 3 hours. Vomiting associated with initial doses of TXA of 15–20 mg/kg was noted.[67] In another canine study, TXA induced vomiting in a dose-dependent manner and a single IV dose of 50 mg/kg produced a prolonged duration of antifibrinolytic activity.[64] The use of EACA has been described in Greyhounds to prevent delayed postoperative bleeding,[72] and another study of limb amputation or gonadectomy demonstrated significantly decreased incidence of bleeding in EACA-treated greyhounds.[81]

Administration of antifibrinolytic agents to patients with prothrombotic disease is controversial.[52] Antifibrinolytic agents are generally contraindicated for secondary hyperfibrinolysis associated with DIC.[123] Experimental administration of TXA to cats caused adverse effects, including seizures and myocardial injury, thus warranting cautious use in this species.[98,62]

Topical Agents

Topical agents, classified as hemostats, sealants, and adhesives, are used for direct application to control bleeding and close tissue surfaces at sites of surgical or traumatic injury (Table 94.3).[116–118] Hemostats provide a

TABLE 94.2 Drug therapy for hemorrhagic disorders.

Drugs	Dosage guidelines	Indications
Vitamin K_1	2 mg/kg/day PO[a] or SC	Vitamin-K-dependent coagulopathy
Desmopressin	1 μg/kg SC[b]	Type 1 vWD, platelet dysfunction
ε-aminocaproic acid (EACA)	100 mg/kg IV or PO q6h	Perioperative hemorrhage, trauma, spontaneous hemoperitoneum
Tranexamic acid (TXA)	10 mg/kg IV q3–4h Or initial loading dose of 10 mg/kg IV then 30–50 mg/kg PO q3–4h	Perioperative hemorrhage, trauma, spontaneous hemoperitoneum

TABLE 94.3 Topical hemostatic agents.

Category	Products (tradename, source)
Hemostats: mechanical	Porcine gelatin (Gelfoam, Pharmacia; Surgifoam, Ethicon/J&J) Bovine collagen (Avitene, Davol/Bard; Helistat, Integra; Instat, Ethicon/J&J) Oxidized regenerated cellulose (Surgicel, Ethicon/J&J) Polysaccharide spheres (Arista, Medafor; HemoStase, CryoLife; Vitasure; Orthovita)
Hemostats: active	Bovine thrombin (Thrombin-JMI, King/Pfizer) Pooled human thrombin (Evithrom, Ethicon/J&J) Recombinant human (Recothrom, ZymoGenetics/BMS)
Hemostats: flowable	Human thrombin with bovine gelatin (Floseal, Baxter) Porcine gelatin ± thrombin (Surgiflo, Ethicon/J&J)
Hemostats: fibrin sealant	Pooled human plasma (Tisseel, Baxter; Evicel, Ethicon/J&J) Human plasma/bovine collagen/bovine thrombin (Vitagel, Orthovita) Pooled human plasma/equine collagen (Tachosil, Baxter)
Synthetic sealants	Polyethylene glycol (PEG) polymers (Coseal, Baxter) PEG and trilysine amine (DuraSeal, Covidien) PEG and human serum albumin (ProGel, NeoMend) Bovine serum albumin/10% glutaraldehyde (BioGlue, Cryolife) Octyl cyanoacrylate and butyl lactoyl cyanoacrylate (Omnex, Ethicon/J&J)
Adhesives	Octyl cyanoacrylate (Dermabond, Ethicon/J&J; Derma+Flex, Chemence) Octyl cyanoacrylate (LiquiBand Flex, AMS; Octylseal, Medline; SurgiSeal Adhezion) Butyl cyanoacrylate/polyester mesh (Indermil, Covidien; Histoacryl, TissueSeal) Pooled human plasma (Artiss, Baxter)

Source: Modified from Spotnitz and Burks.[118]

mechanical barrier and matrix for fibrin formation and include products derived from porcine gelatin, bovine collagen, cellulose, and polysaccharide spheres. Thrombin combined with hemostats enhances their activity, and thrombin is used with plasma-derived fibrinogen as "fibrin sealants." Synthetic products include cyanoacrylate adhesives for superficial skin closures and polyethylene glycol sealants for durotomy and abdominal procedures. A two-component adhesive consisting of bovine serum albumin and glutaraldehyde is also approved for cardiac and vascular surgery. The potential side-effects of the topical agents include allergic reactions, sensitization to heterologous proteins, embolization, wound infection, and delayed healing.

TREATMENT OF THROMBOTIC DISORDERS

Clinical Thrombotic Disorders

The Consensus on the Rational Use of Antithrombotics in Veterinary Critical Care (CURATIVE) guidelines assist in management of thrombotic disorders by categorizing patients as high-risk or low/moderate-risk,[33] accounting for the underlying disease. Dogs with immune-mediated hemolytic anemia (IMHA) or protein-losing nephropathy, cats with cardiomyopathy, and dogs or cats with more than a single thrombotic risk factor are categorized as high-risk. The low/moderate-risk category comprises dogs or cats with a single or transient risk factor. Formalized human thrombosis risk scores, such as the PADUA index, have not yet been developed for animals.[46]

In diseases associated with venous thromboembolism (VTE), fibrin-rich and platelet-poor thrombi typically form under low-shear conditions.[2] By contrast, arterial thromboembolism (ATE) is characterized by platelet-rich thrombi that form under high shear. This pathophysiologic difference leads to use of anticoagulants for VTE,[134] and antiplatelet agents for ATE.[112] However, platelets support fibrin formation,[54] with potential benefit for antiplatelet drugs in VTE,[17,110] and anticoagulants may be used for human acute coronary syndromes (ACS).[25] Many hypercoagulable states in small animals result in VTE and ATE, providing rationale for combined use of anticoagulants and antiplatelet drugs (Table 94.4).

Antiplatelet Drugs

Aspirin

Aspirin inhibits platelet aggregation by irreversibly acetylating platelet cyclooxygenase (COX), thereby preventing formation of thromboxane A_2 (TXA_2). Aspirin also inhibits endothelial cell COX activity, resulting in decreased prostacyclin synthesis and loss of anti-aggregating and vasodilating properties. Endothelial cell COX inhibition is reversible (via de novo synthesis), therefore aspirin exerts a net antithrombotic effect.

Multiple studies in various canine models demonstrate effective prevention of ATE by aspirin administration more than 2 days before thrombogenic insult. Aspirin therapy is effective in endarterectomy and angioplasty models,[20,42,84] and after therapeutic fibrinolysis in

TABLE 94.4 Antithrombotic Agents.

Drug	Drug class	Drug type	Dose
Aspirin	Oral antiplatelet agent	Cyclooxygenase inhibitor	Dogs: 1–2 mg/kg PO q24h Cats: Not recommended
Clopidogrel	Oral antiplatelet agent	ADP receptor antagonist	Dogs: 1.1–3 mg/kg PO q24h Cats: 18.75 mg PO q24h
UFH	Parenteral anticoagulant	Antithrombin potentiator FIIa, FXa inhibitor	Dogs: IV 100 U/kg bolus, then 20–37.5 U/kg/h CRI SC 150–300 U/kg q6h Cats: SC 250 U/kg q6h
Dalteparin	Parenteral anticoagulant	Antithrombin potentiator FXa inhibitor	Dogs: 100–175 U/kg SC q8h Cats: 75 U/kg SC q6h
Enoxaparin	Parenteral anticoagulant	Antithrombin potentiator FXa inhibitor	Dogs: 0.8 mg/kg SC q6h Cats: 0.75–1 mg/kg SC q6–12h
Fondaparinux	Parenteral anticoagulant	Antithrombin potentiator FXa inhibitor	Dogs: No data Cats: 0.06–0.20 mg/kg SC q12h
Rivaroxaban	Oral anticoagulant	Direct FXa inhibitor	Dogs: 1–2 mg/kg PO q24h Cats: 0.5–1 mg/kg PO q24h
Apixaban	Oral anticoagulant	Direct FXa inhibitor	Dogs: No data Cats: 0.2 mg/kg PO q24h

dogs.[102] Graft-model studies also suggest aspirin is efficacious in dogs.[125,19,9,41] Dosages as low as 0.5 mg/kg/day and as high as 15 mg/kg/day are reportedly safe and effective. Oral aspirin, given for 2–3 days prior to insult, may be effective for ATE prevention in dogs. No evidence base supports a defined dosage; however, the authors suggest 1–2 mg/kg/day.

Experimental studies yield conflicting effects of aspirin on feline platelet function, potentially due to varying dosages, outcome measures, and test methodologies.[100,10,23] In at-risk cats, ATE recurs in 20–28% cases treated with aspirin.[104,115] A randomized controlled trial of aspirin for secondary prevention of feline ATE found a 75% incidence of recurrence within 12 months. This trial demonstrated inferiority of aspirin to clopidogrel for feline ATE thromboprophylaxis;[56] thus, CURATIVE guidelines recommend against aspirin as a sole antithrombotic in cats at risk for ATE.

Clopidogrel

Clopidogrel is a thienopyridine that irreversibly inhibits platelet $P2Y_{12}$ ADP receptors. Clopidogrel must undergo hepatic biotransformation to its active metabolites. Inhibition of $P2Y_{12}$ impairs degranulation and aggregation, thus reducing thrombus stability under flow conditions. In people, clopidogrel's maximal effects develop after 3–5 days of daily administration, while activity disappears by 5–7 days after discontinuation. Clinical trials demonstrate that clopidogrel significantly reduces the risk of stroke, myocardial infarction, and vascular death compared to aspirin. Clopidogrel is used with aspirin as dual antiplatelet therapy for stable angina, ACS, and stroke prevention.[68]

Clopidogrel is an effective antiplatelet agent in canine studies,[136,59,128,127,13,12] particularly against provoked ATE. Dosages and efficacy vary, likely due to differences in model systems and thrombotic stimuli. A dose of 4 mg/kg PO q24h after a 10 mg/kg loading dose provides protection against provoked ATE in dogs.[12] The CURATIVE guidelines recommend clopidogrel 1.1–3 mg/kg PO q24h for ATE prevention in dogs.[47]

Multiple studies in cats suggest clopidogrel is effective for ATE thromboprophylaxis.[55,121,34,53] Dosages of 18.75 mg PO q24h are typically used, and a well-conducted randomized clinical trial of feline ATE demonstrated that clopidogrel is a more effective antithrombotic agent than aspirin.[56]

Other Antiplatelet Agents

Other antiplatelet agents target a wide range of cell-surface receptors.[45] Prasugrel, ticagrelor, and cangrelor target the $P2Y_{12}$ receptor.[130] Prasugrel is a potent, orally administered thienopyridine with more consistent biotransformation than clopidogrel. Ticagrelor is an active, orally administered, reversible $P2Y_{12}$ inverse agonist. Both prasugrel and ticagrelor are used for management of ACS. Cangrelor is a modified ATP derivative with high-affinity, reversible $P2Y_{12}$ inhibition immediately active upon intravenous CRI.[4] Cangrelor has a short half-life and is used for myocardial infarction or emergency percutaneous coronary intervention (PCI).

Abciximab, tirofiban, and eptifibatide are potent, reversible inhibitors of the platelet fibrinogen receptor (GPIIb/IIIa) given by IV infusion for PCI. There are no defined indications and no clinical studies have evaluated these drugs in veterinary practice. Experimental

studies suggest efficacy in dogs,[124,60] and abciximab demonstrated efficacy in a feline model of arterial injury.[16] Eptifibatide was associated with fatal cardiotoxicity in cats.[15]

Vorapaxar is an inhibitor of protease-activated receptors (PARs) that act as tethered ligand receptors for thrombin. Vorapaxar reduces the risk of cardiovascular death, myocardial infarction, and stroke in patients with stable atherosclerosis receiving standard therapy with aspirin and/or clopidogrel. Vorapaxar increases risk of bleeding and is contraindicated in patients with previous cerebrovascular events.[24] Lack of homology between human and animal platelet PARs may limit use of vorapaxar in veterinary medicine.

Anticoagulants

Warfarin

Warfarin (Coumadin), an oral vitamin K antagonist, was the principal anticoagulant in human medicine for decades. Warfarin inhibits vitamin K epoxide reductase, thus, preventing the cyclic conversion of vitamin K necessary for activation of the vitamin-K-dependent clotting factors.[133] Concomitant inhibition of vitamin-K-dependent anticoagulants, protein C and protein S, leads to a temporary prothrombotic tendency. An alternate anticoagulant (e.g., unfractionated heparin, UFH) is typically given for the first 4–5 days of warfarin therapy to prevent thrombosis.

Efficacy of warfarin has been described in dogs,[88,5,132] albeit with variation among studies.[32,71,95] The use of warfarin in cats is less well-defined.[113,114] Warfarin's therapeutic index is narrow, increasing the risk of excessive anticoagulation and life-threatening hemorrhage. Close monitoring is required through measurement of the PT, preferably with reporting of PT^{INR}.[109] The PT^{INR} minimizes the influence of assay variability to standardize anticoagulant intensity. Warfarin's anticoagulant effect is influenced by many factors,[30] including medications, diet, and protein binding.[93,11] The CURATIVE guidelines do not support the routine use of warfarin for dogs and cats.[11] If warfarin is administered, close monitoring to achieve a target PT^{INR} of 2–3 or a prolongation of 1.5–2.0 times the baseline PT is recommended.[109]

Unfractionated Heparin

UFH is a common, inexpensive anticoagulant that acts indirectly by greatly enhancing endogenous antithrombin (AT) activity.[133] UFH is a mixture of variably sized glycosaminoglycan molecules. UFH inhibits multiple serine protease factors, although its anticoagulant action is primarily due to inhibition of FIIa and FXa[133,37] Thrombin inhibition occurs via ternary complex formation between long-chained UFH and AT, and anticoagulant effects also result from loss of thrombin's activation of other procoagulant factors. UFH is administered parenterally (IV or SC);[91,36,106] neither oral nor inhalational administration is effective.[40,79] The CURATIVE guidelines for dogs suggest an initial IV bolus of 100 U/kg followed by a CRI of 480–900 U/kg/day (i.e., 20–37.5 U/kg/h). Alternatively, UFH may be administered at 150–300 U/kg every 6 hours SC in dogs or 250 U/kg every 6 hours in cats.[11]

Efficacy of UFH has been described in dogs,[91,36,106,51,6,40,79] with relatively few reports in cats.[3] Pharmacokinetics of UFH are unpredictable, due in part to heterogeneity of the drug preparation, variable protein and cell binding exacerbated by inflammatory states, and endogenous AT.[51] Individualized monitoring with dose adjustment is therefore advisable.[109] The dose of UFH can be adjusted to attain target factor Xa inhibitory activity (anti-Xa activity, AXA) within a range of 0.35–0.7 U/kg. This dosing target is extrapolated from human guidelines and supported by an experimental canine venous thrombosis model.[91] A clinical study of canine IMHA reported improved survival for individually adjusted UFH (based on AXA), compared to fixed doses.[51] Several point-of-care coagulation tests have been investigated as rapid alternatives to AXA for UFH monitoring.[6,82] Preliminary studies describe aPTT and RapidTEG® (i.e., thromboelastography with a proprietary activator) monitoring,[109] with a suggested target aPTT prolongation between 1.2 and 2.0 times baseline.[6]

Low-Molecular-Weight Heparin

Low-molecular-weight heparins (LMWHs) are produced by UFH depolymerization and consist of relatively short, uniform glycosaminoglycan chains that retain the ability to potentiate AT.[133] Few LMWH molecules have sufficient length to form the ternary complex required for thrombin inhibition, thus most anticoagulant effects result from FXa inhibition.[133,37] In people, LMWHs have predictable pharmacokinetic profiles and rarely require monitoring, except for renal insufficiency or body weight extremes.[57] Unfortunately, canine and feline LMWH pharmacokinetic profiles are less predictable.

Dalteparin and enoxaparin are the most commonly used LMWH in dogs and cats. The CURATIVE guidelines suggest initial dalteparin dosage in dogs of 100–175 units/kg SC,[11] given q.8 hours to attain human-defined target AXA (0.5–1.0 U/mL).[85,14,76] Coagulation screening tests (i.e., PT, aPTT) are not suitable for dalteparin monitoring.[86] Adverse effects associated with dalteparin in dogs are typically minor (e.g., local bruising from SC injections). One canine study reported fewer bleeding complications with dalteparin (100 U/kg SC twice daily) than UFH (100 units/kg IV then 900 units/kg/day).[106] Dalteparin dosing appears more problematic in cats.[86,105] A dose range of 75–150 units/kg SC with frequent dosing to attain AXA targets has been described.[3] The CURATIVE initiative recommends a starting dose of 75 units/kg SC every 6 hours,[11] with insufficient evidence for routine AXA monitoring.[109]

The CURATIVE guidelines recommend a starting canine enoxaparin dose of 0.8 mg/kg SC q.6 hours.[91,75,11] A breed variation in pharmacokinetics may exist, since this dose failed to attain AXA targets in healthy Beagles.[99] Clotting time tests (e.g., PT, aPTT) are insensitive to target enoxaparin concentrations; however, there is insufficient evidence to recommend routine AXA monitoring.[109] Few

reports describe enoxaparin usage in cats.[3,126,87] CURATIVE guidelines recommend a dosage of 0.75–1 mg/kg SC q.6–12 hours, with more frequent dosing to limit interindividual variation in AXA.[11]

Fondaparinux is a synthetic pentasaccharide FXa inhibitor that augments AT's anti-FXa activity, similar to LMWH. No clinical studies have investigated its usage in dogs; however, a feline study reported doses of 0.06 or 0.20 mg/kg SC q.12 hours achieved human therapeutic AXA targets without complications.[43]

Direct Oral Anticoagulants

Direct oral anticoagulants (DOACs) are replacing vitamin K antagonists and parenteral anticoagulants in human medicine due to predictable pharmacokinetic profiles and ease of administration. The DOACs inhibit the activity of single factors, targeting FXa or FIIa through direct competitive inhibition, with no reliance on endogenous AT.[29] Dabigatran is a direct thrombin inhibitor whose use in dogs and cats has not yet been investigated.[133] The DOACs rivaroxaban and apixaban inhibit FXa and prevent its interaction with FVa to form the prothrombinase complex (see Chapter 87).[92]

Rivaroxaban appears well-tolerated in healthy and sick dogs.[90,135,29] A dose of approximately 2 mg/kg twice daily was associated with a sustained anticoagulant effect in healthy dogs;[29] however, this dosage may be cost prohibitive in larger dogs. Consequently, lower doses and once daily dosing appear commonplace in clinical practice.[90,135] The CURATIVE guidelines recommend a dose of 1–2 mg/kg/day PO for rivaroxaban in dogs, but optimal dosing is unknown.[11] The pharmacokinetics and pharmacodynamics of rivaroxaban in healthy cats administered a fixed dose of either 2.5 mg or 5 mg per cat have been described.[38] Dose-dependent increases in rivaroxaban AXA were found, without adverse effects. Based on this data, the CURATIVE guidelines suggest 0.5–1 mg/kg/day in cats.[11] A single study has reported the pharmacokinetics and pharmacodynamics of apixaban in healthy cats. A single daily dose (0.2 mg/kg) effectively inhibited FXa without adverse effect. The bioavailability of rivaroxaban improves in people when taken with food. Although a pilot study failed to identify an effect of feeding on rivaroxaban AXA in healthy dogs,[78] further study is needed to confirm these findings.

The importance of rivaroxaban monitoring in animals is currently ill-defined, since indications for people are limited to emergency surgery or renal insufficiency.[7] The rivaroxaban assay AXA is appropriate for pharmacokinetic studies and long-term therapeutic monitoring; however, point-of-care assays are preferable for rapid dose adjustments. Prothrombin time may be a useful surrogate for rivaroxaban AXA in people and in dogs,[103,77] although variable reagent sensitivity may influence diagnostic utility.[122]

Therapeutic Thrombolysis

Supraphysiologic doses of agents that activate plasminogen to accelerate plasmin generation will induce thrombus dissolution. Agents may be infused systemically or delivered directly at the thrombus site (catheter-directed lysis).[39] Thrombolytic drugs include recombinant tissue plasminogen activator (tPA) products alteplase, reteplase, and tenecteplase. These thrombolytic drugs have distinct pharmacokinetics, activities, and fibrin specificities.[131] The tPA products activate fibrin-bound plasminogen more efficiently than circulating plasminogen. However, all tPA products are associated with risk of hemorrhage due to systemic fibrinolysis.[120] Alteplase has the shortest half-life,[97] followed by reteplase and then tenecteplase. Thrombolysis is generally safest and most effective when performed early, using a fibrin-specific drug with a short half-life such as alteplase.[74] The potential benefits and risks of administration depend on the location, size, and duration of thrombosis and the clinical, cardiovascular, and neurological status of the patient.

Veterinary clinical thrombolysis was first reported for feline ATE,[89,129] where it was associated with high rates of hemorrhage and reperfusion injury. Thrombolysis for feline ATE is not currently recommended,[73] although recent data suggest some potential benefit.[49] Alteplase was used in a dog with ATE,[26] and tPA used in experimentally induced canine pulmonary thromboembolism (PTE) .[119] Alteplase has been used for device-associated thrombosis in canine cardiology and dialysis patients.[31,70] Human studies suggest that low-dose tPA may be effective and safe for PTE.[108] A tPA protocol for PTE involves administration of half maximum dose (0.2–0.5 mg/kg IV), over the first 30–60 minutes followed by reassessment. No additional drug is given to hemodynamically stable patients, with the remaining half-dose administered after suboptimal response. This approach generally reduces dose-related bleeding complications. Reported tPA protocols in small animals include 0.2 mg/kg locally infused,[8] a locally infused CRI of 0.03 mg/kg/h (maximum 1 mg/kg),[31] and systemic administration of 0.2 mg/kg IV bolus, then 0.7 mg/kg IV over 30 minutes, then 0.5 mg/kg IV over 60 minutes (total 1.4 mg/kg).[5] Ultimately, clinical trials are needed to optimize patient selection and dosage regimens.

CHAPTER 95

Avian Hemostasis

KAREN E. RUSSELL and J. JILL HEATLEY

Introduction
Physiology of Avian Hemostasis
  Thrombocytes
  Coagulation Pathways
Diagnostic Testing
  Thrombocyte Counts
  Coagulation Assays
    Activated Clotting Time (ACT)
    Prothrombin Time (PT)
    Activated Partial Thromboplastin Time (APTT)
    Thrombin Time (TT, TCT)
    Fibrinogen
  Thromboelastography (TEG)
Coagulation Disorders
  Vitamin-K-deficiency States
    Dietary-Related Coagulopathies
    Vitamin K Antagonists
    Anticoagulant Rodenticides
  Infectious Disease and Disseminated Intravascular Coagulation (DIC)
  Hepatopathies
  Unknown Mechanisms

Acronyms and Abbreviations

ACT, activated clotting time; ADP, adenosine diphosphate; APTT, activated partial thromboplastin time; CI, confidence interval; DIC, disseminated intravascular coagulation; PT, prothrombin time; TCT, thrombin clotting time.

INTRODUCTION

Hemostasis is essential in the control of bleeding and is the first step in wound healing (see Chapter 87). It is achieved through complex, highly controlled interactions between the vasculature, blood cells, and proteins, all of which carefully balance procoagulant and anticoagulant forces. Hemostasis culminates in clot formation through the action of thrombin, which converts soluble fibrinogen to insoluble fibrin. These enzymatic reactions occur rapidly and almost immediately following vessel injury. Fibrinolysis completes the process of endothelial repair through slow dissolution of the clot. Imbalance of these complex processes may result in hemorrhage or thrombosis.

PHYSIOLOGY OF AVIAN HEMOSTASIS

Many of the enzymatic reactions of coagulation leading to thrombin generation are conserved in avian species; however, there are important differences from mammals (see Figure 95.1). Moreover, thrombocytes, the avian equivalent of mammalian platelets, are unique.

Thrombocytes

Thrombocytes are small, round to oval to slightly spindled, nucleated, bone-marrow-derived cells that represent the second most numerous cell type in avian peripheral blood after erythrocytes. They measure approximately 5 μm in width by 8–10 μm in length.

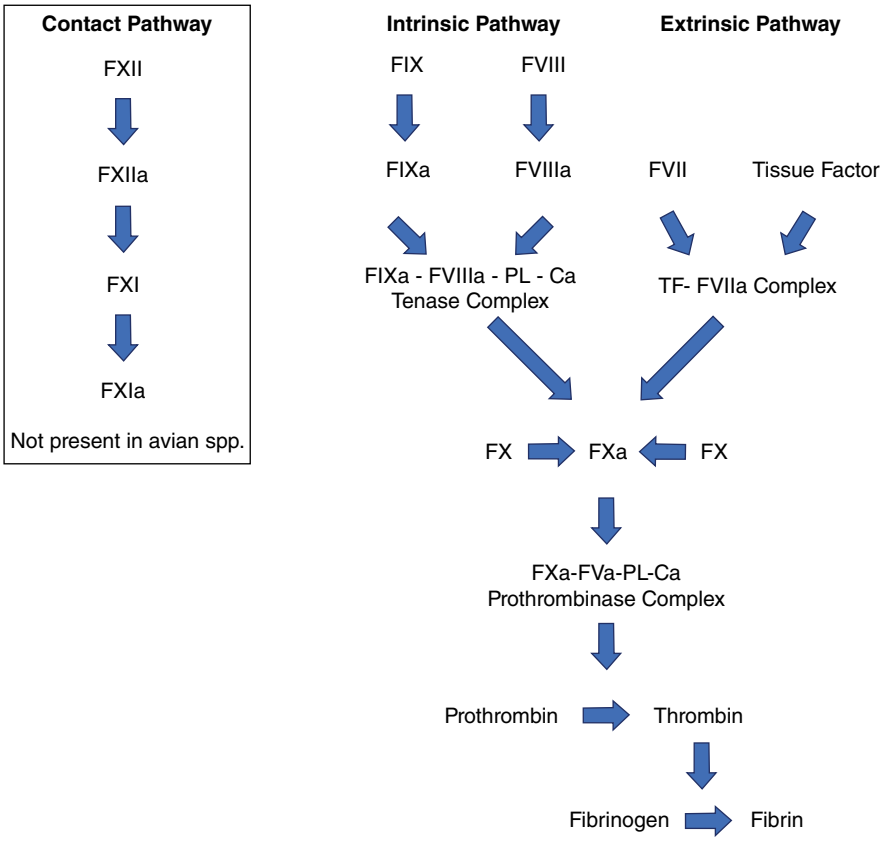

FIGURE 95.1 Diagram of Avian Intrinsic and Extrinsic Coagulation Factor Pathways. (**Source:** Modified from Thompson et al.[72])

A distinct mononuclear cell in marrow is thought to be the progenitor cell for avian thrombocytes. Stages of thrombopoiesis include thromboblasts, immature thrombocytes (early, mid, and late stages), and mature thrombocytes.[7]

Similar to mammalian platelets, the primary function of thrombocytes is hemostasis. Thrombocytes also play an important role in innate immunity because of their phagocytic ability to engulf foreign material.[28] Chicken thrombocytes constitutively express transcripts for several toll-like receptors, and have surface expression of major histocompatibility complex II and costimulatory molecules CD40, CD80, and CD86, suggesting a role in adaptive immunity.[20] Avian thrombocytes contain dense granules, mitochondria, and have microtubules and vacuoles that connect to a canalicular system or open to the surface.[6,20,28,63]

Thrombocytes possess much of the same molecular machinery and, with few exceptions, respond to the same primary agonists that activate mammalian platelets.[63] Thrombocytes are activated by collagen and thrombin, but contain little ADP and do not respond strongly to this platelet agonist.[3,64,66] Thrombocytes can adhere and spread on collagen, albeit less efficiently and more slowly than platelets. Thrombocytes have substantially lower levels of the glycoprotein IIb–IIIa receptor and do not appear to form shear-resistant aggregates.[64] Instead, thrombocytes form a single layer over a larger surface area, and the process takes longer to expand and cover the injured area.[56,64] Comparative genomics reveals that avian hemostasis involves fewer genes compared to mammals.[56] Avian thrombocytes have less than 50% of the sequence for the GPIbα, a glycoprotein that induces shape change in mammalian platelets upon engagement with its ligand, von Willebrand factor.[57] Incomplete GPIbα may therefore reduce thrombocyte aggregate strength and thrombin production, resulting in delayed fibrin clot formation.[56]

Coagulation Pathways

Avian species have many of the coagulation proteins found in mammals. These proteins are primarily synthesized in the liver, and like mammals, birds require vitamin K for post-translational modification of factors II, VII, IX, and X, and proteins C and S.[4,6,10,22,50,72]

While the tissue factor, or "extrinsic" pathway, is conserved in birds, activation of the intrinsic pathway differs from mammals (see Figure 95.1).[72] Birds lack prekallikrein and other contact pathway serine proteases, factors XII and XI, thus coagulation is not initiated by contact with negatively charged surfaces.[14]

Rather, the intrinsic pathway is initiated by activation of factor IX, which is accomplished by the tissue factor–FVIIa complex.[6,50] The tenase complex of FIXa–FVIIIa–calcium–phospholipid then assembles to amplify factor X activation, which in turn drives the reactions of the prothrombinase complex to form a burst of thrombin.

Avian coagulation inhibitory pathways are poorly defined. Tissue factor pathway inhibitor has not been confirmed to exist in avian species.[6,10] However, cDNAs with sequence identity for several anticoagulant factors, including protein C, have been found in chickens, and antithrombin has been cloned in various avian species including the chicken and ostrich.[4,6,10,22,23] Ostrich thrombin and antithrombin appear closely related to the corresponding proteins of other species based on physicochemical and kinetic properties.[23] Antithrombin has been quantitated for the adult chicken.[2]

DIAGNOSTIC TESTING

Common assays used to assess hemostasis in mammals are often problematic in avian species due to nucleated thrombocytes and the lack of optimized or species-specific coagulation reagents.

Thrombocyte Counts

The thrombocyte concentration of most avian species ranges from 20,000 to 30,000 per cubic millimeter of whole blood, representing approximately 10–15 thrombocytes per 1000 erythrocytes.[7] Automated thrombocyte counts are not possible due to the nucleated character of the cell. A hemocytometer method for counting thrombocytes has been described, but is rarely performed.[7] Avian thrombocytes are prone to clumping; large clumps on blood smears make accurate estimated thrombocyte counts challenging. The presence of approximately 2–5 thrombocytes over several erythrocyte monolayers at 1000× magnification is an indication of adequate thrombocyte numbers. Fewer than one to two thrombocytes over several monolayers suggests thrombocytopenia (in the absence of clumping), whereas greater than five thrombocytes over several monolayers suggests thrombocytosis.[7] Functional studies of thrombocyte aggregation have been described, but are rarely performed for diagnostic purposes.[27,48,78]

Coagulation Assays

Numerous studies describe coagulation testing in birds, with reported values for various assays and methods summarized in Table 95.1. The sample required for many coagulation assays is citrate anticoagulated plasma, collected at a ratio of one part 3.2% or 3.8% sodium citrate to nine parts whole blood. Venipuncture should be atraumatic, and the plasma should be free of hemolysis, which may interfere with colorimetric endpoint assays. Whole blood should be centrifuged to separate plasma within 30 minutes or less of collection. Frozen storage of plasma is described; however, freeze–thaw cycles may affect results. To the authors' knowledge, no commercial sources of avian-derived and avian-optimized coagulation reagents are available at this time.

A comprehensive study in Japanese quail described 20 coagulation and fibrinolysis assays.[4] While many assays were primarily applicable for research settings, the more readily available tests in this study, and others, are described in the following text.

Activated Clotting Time (ACT)

The ACT measures the time for clot formation in fresh whole blood in the presence of a contact pathway activator and is designed to evaluate the intrinsic and common pathway factors. Although birds lack key contact factors, the use of tubes containing diatomaceous earth has been described for avian ACT.[79]

Prothrombin Time (PT)

Prothrombin time (one-stage prothrombin time) assesses the tissue factor (extrinsic) and common pathways and is a functional test of factors V, VII, and X, prothrombin, and fibrinogen. The test methodology is based on the addition of a calcium and tissue factor/phospholipid reagent, referred to as thromboplastin, to warmed citrated plasma. The time for clot formation represents the PT. Avian PT varies widely depending on the source of thromboplastin (typically a brain extract). Clotting times are relatively prolonged and may not yield an endpoint using heterologous (mammalian) thromboplastins, thus avian-sourced thromboplastins are preferred.[4,22,71,79] Although the body temperature of most avian species is higher than 37 °C, incubation of the assay at 37 °C versus higher temperatures does not appear to affect results.[70]

Activated Partial Thromboplastin Time (APTT)

The APTT, similar to ACT, evaluates the intrinsic and common pathway factors: factors XII, XI, IX, VIII, X, and V, prothrombin, and fibrinogen. This assay measures the time of clot formation after the addition of calcium to citrated plasma preincubated with a negatively charged contact activator and phospholipid reagent. Because birds lack factors XII and XI, APTT endpoints are variable and often markedly prolonged compared to those of mammals.

Thrombin Time (TT, TCT)

The thrombin clotting time (TCT) measures the time for clot formation following the addition of a calcium and thrombin reagent to citrated plasma. The TCT is

TABLE 95.1 Summary of coagulation test results reported for avian species.

prolonged in cases of fibrinogen deficiency, dysfibrinogenemia, or in the presence of inhibitors such as heparin anticoagulants or fibrin degradation products.

Fibrinogen

The heat precipitation test can be performed on EDTA plasma to get an estimate of fibrinogen concentration. Clauss fibrinogen is a modified TCT that provides functional and quantitative determinations of fibrinogen concentration. In this assay, clotting times are inversely related to fibrinogen content and values are transformed to fibrinogen concentration (mg/dL or gm/L) by comparison with a calibrated fibrinogen standard.

Thromboelastography (TEG)

Thromboelastography is a viscoelastic assay that monitors the kinetics of clot formation in whole blood. The results represent a "global" assessment of platelet function, coagulation, fibrin clot strength, and fibrinolysis. Recent studies describe TEG analyses in different avian species (see Table 95.2).[36,67] A TEG study in Hispaniolan Amazon parrots revealed relatively slow clot formation times and a reduced clot strength compared to dogs or cats.[36] The use of a contact pathway activator (kaolin) and 37 °C reaction times may not represent optimized conditions for birds. Of note, a tissue factor activator yielded values more similar to feline and canine samples.[36,67]

COAGULATION DISORDERS

Vitamin-K-Deficiency States

Vitamin K's cofactor activity is required for carboxylation of glutamate residues on the vitamin-K-dependent factors. Without this modification, phospholipid binding via calcium bridging fails, preventing assembly of active coagulation complexes (see Chapter 87). Vitamin-K-dependent coagulopathies are reported in a variety of avian species due to dietary deficiencies, vitamin K antagonists, and anticoagulant rodenticides.[6,33,44,45,55,79]

Dietary-Related Coagulopathies

Early reports of hemorrhage in chicks fed low-fat diets were ultimately attributed to lack of an antihaemorrhagic factor that was found to be a fat-soluble vitamin designated "K" for German "koagulation." [9,32] Dietary vitamin K deficiencies in most avian species, except for poultry, are now relatively uncommon. In the hatchling chicken, very low levels of plasma vitamin K (approximately 2%) are not uncommon and relate to low levels in the maternal diet, lack of intestinal synthesis, extent of coprophagy, or the presence of sulfur drugs and other feed additives in the maternal diet.

A coagulopathy associated with high dietary vitamin E has been described in pink-backed pelicans (*Pelecanus rufescens*). Three of six affected birds succumbed with necropsy findings of extensive hemorrhage at subcutaneous,

TABLE 95.2 Summary of thromboelastography parameter results for select avian species.

Common name	Scientific name	Time to clot formation, R (min)	Clot formation time, K (min)	α-angle (°)	Maximum clot strength amplitude (mm)	References

Legend: data formats:	[Range]	Mean ± SD (95% CI)	Reference range*
Thromboelastographic parameters:	Parameter	Definition	Units
	R	Time from test start to initial fibrin formation; detected on tracing as first deviation from baseline	minutes (min)
	K	Time from initial fibrin formation to deviation of 20 mm from baseline	minutes (min)
	Alpha	Angle defined on tracing from baseline at R to K	degrees
	MA	Maximum width of tracing	millimeters (mm)

intramuscular, and multiorgan sites. Three survivors had hemorrhage and prolonged clotting times that responded to vitamin K treatment. The mechanism is unknown, but vitamin-K-responsive coagulopathies have been reported in humans and other species after chronic ingestion of high levels of vitamin E.[8,46,50,52] In vitro studies have shown the quinone metabolites of alpha-tocopherol may competitively inhibit vitamin K.[17,47,52,76]

Vitamin K Antagonists

In chickens, sulfonamide antibiotics (sulfaquinoxaline) and p-aminophenylarsonic acid (roxarsone) can act as vitamin K antagonists and have caused increased bleeding tendencies and prolongation of clotting.[21,30,69] These compounds have been used as growth promoters and coccidiostats; the latter compound, an organic arsenic, is no longer available.[19]

Anticoagulant Rodenticides

Anticoagulant rodenticides inhibit vitamin K_1-2,3-epoxide reductase, which in turn impairs vitamin K metabolism. Second-generation rodenticides include brodifacoum, bromadiolone, chlorophacinone, difenacoum, difethialone, and diphacinone. These longer-lasting rodenticides have high lipid solubility and enterohepatic circulation, increased hepatic accumulation, a greater affinity for vitamin K epoxide reductase, and the ability to inhibit the vitamin K epoxide cycle at various steps. This results in a longer acting and increased potency rodenticide that persists in the environment, thereby increasing risk of toxicity to nontarget species. Furthermore, a single high-level exposure can be lethal and multiple, sublethal exposures have the potential to be fatal.

Anticoagulant rodenticides pose a risk to nontarget avian species, most commonly birds of prey (raptors) and scavengers, but other species can be affected. Exposure can occur through ingestion of bait, or if the bird preys upon animals that have ingested bait. The toxicity of various rodenticides is dose-dependent, but differences in species sensitivities also occur. In general, raptors are more sensitive to pesticides and certain rodenticides than other bird species.[53–55]

Infectious Disease and Disseminated Intravascular Coagulation (DIC)

As in mammalian species, DIC triggered by vasculitis or bacterial infections (especially Gram-negative organisms) has been reported in avian species.[6,51] Acute infection with *Escherichia coli* in chickens can cause fibrin deposition in various tissues, thrombocytopenia, and elevations in bleeding times, clotting times, and PT.[6,80] *E. coli* lipopolysaccharide administration shortens TCT and decreases fibrinogen in broiler chickens.[49] Evidence for DIC and thrombocytopenia was found in chickens infected with *Salmonella gallinarum* and *Salmonella pullorum*.[37,80] Birds infected with *Erysipelothrix rhusiopathiae* have prolonged PT and APTT, and fibrin thrombi are found on histological sections of liver, kidney, and lung.[65] *Streptococcus zooepidemicus* is a recognized cause of vascular lesions in layer chickens, and hyperfibrinogenemia, prolonged PT, and TEG parameters of hypercoagulability have been described in chickens experimentally infected with this organism.[62]

Viral diseases may result in coagulopathies due to direct effects of the viral infection, secondary to the development of DIC, or immunosuppression and subsequent bacterial or fungal infections leading to DIC or hepatic injury. Varying signs of hemorrhage (superficial or internal), petechiation or ecchymosis, vasculitis, hepatic necrosis or hepatopathy, and combinations of these findings are often associated with avian viral infections. While hemorrhage provides evidence of hemostatic compromise, the underlying pathophysiology is often unknown.

Studies of chickens infected with highly pathogenic avian influenza A virus have revealed severe hemorrhage in multiple organs and fibrin thrombi in the lung.[43] Experimentally, highly pathogenic strains of influenza caused significantly decreased thrombocyte counts, prolonged PT, and high levels of tissue factor expression compared to control chickens infected with an avirulent strain. These findings support a consumptive coagulopathy as the underlying cause of hemorrhage.[43]

Infectious bursal disease is a highly contagious viral disease in chickens that causes marked hemorrhage, especially in skeletal muscles and the bursa of Fabricius. In addition to hemorrhage, studies comparing experimentally infected birds show thrombocytopenia, prolonged PT and APTT, and prolonged whole blood recalcification times.[82] Histological findings in the bursa are compatible with DIC.[82]

Pathologic findings associated with Eastern encephalitis virus infection in a flock of emus included petechial and ecchymotic hemorrhages in the viscera, liver, and rarely the kidney, hepatic necrosis, necrotizing vasculitis in the spleen and intestinal lamina propria, and hemoabdomen.[75,77]

Subcutaneous and/or multifocal hemorrhages, hepatic necrosis, profuse or prolonged bleeding, and hematuria have been reported in various psittacines and other avian species infected with polyomavirus.[24,34,38,39,57]

Psittacines infected with reovirus have hemorrhage under the skin, in the heart, and focal or disseminated hepatic necrosis.[26,58] Reoviral infections are also associated with hepatitis, immunosuppression, and secondary infections with other viruses and bacterial and fungal agents.

Infection with paramyxovirus-1, the causative agent for Newcastle disease, has been associated with multifocal petechiation and hemorrhages affecting periorbital tissues, thymus, tonsil, or proventriculus.[18,68] Gastrointestinal hemorrhage was also described in lories from which an unclassified paramyxovirus was isolated.[40,59]

Avian herpesviruses are host-specific, widespread, and can cause signs of hemorrhagic tracheitis, intestinal petechiation or ecchymosis, and hepatic necrosis.[25,29,60]

Pathological findings in psittacines infected with herpesvirus (Pacheco's disease) include an enlarged liver with areas of hemorrhage, intestinal hemorrhage, and hemoabdomen.[60]

Clinical findings in psittacines infected with adenovirus include cloacal hemorrhage, hepatitis, or enlarged, friable liver with whitish surface mottling and subcapsular hemorrhage.[29] Adenovirus in poultry or water fowl can be associated with hepatitis, hemorrhage, or hemorrhagic enteritis.[25]

Hepatopathies

Severe hepatic disease, of any etiology, can impair factor synthesis and result in hemorrhage. Aflatoxins and other mycotoxins in moldy feed contaminated with *Aspergillus* or *Fusarium* species are especially a problem in poultry, but other avian species can be at risk.[13,41] Aflatoxins are difuranocoumarin derivatives metabolized primarily in the liver. Aflatoxins have toxic and carcinogenic properties with effects of teratogenesis, immunosuppression, and reduced protein synthesis. High doses cause hepatocellular necrosis with subsequent coagulopathy. Ochratoxin A, another Aspergillus mycotoxin, is nephrotoxic and hepatoxic in poultry and has also been associated with coagulopathies; factors VII and V and fibrinogen are found to be especially sensitive to this mycotoxin.[15] T-2 toxin produced by *Fusarium spp*. primarily affects factor VII, prothrombin, and fibrinogen.[16]

Fatty liver hemorrhagic syndrome (FLHS) is a complex metabolic disorder of laying hens influenced by nutritional, environmental, genetic, and metabolic factors. Necropsy in affected birds reveals excessive abdominal fat and hepatic hemorrhages. Birds with enhanced susceptibility to FHLS have different plasma phospholipid composition that may influence factor activities and increase risk of hemorrhage.[73,81]

Unknown Mechanisms

Conure hemorrhagic syndrome has been recognized in several species of conures, but the etiology remains unknown.[51,61] Erythremic myelosis was initially suspected due to the presence of increased erythroid precursors in the liver; however, some birds appear to recover, making hematopoietic neoplasm unlikely.[61] Hepatopathy associated with poor-quality diet may play a role. Some birds respond to calcium treatment; however, hypocalcemia sufficient to cause coagulopathy is unlikely.[51]

Polysulfated glycosaminoglycans (PSGAGs), used to manage degenerative joint disease, have been implicated as a cause of fatal hemorrhage in birds. A case report of four different avian species and anecdotal reports of seven additional species from the American Association of Zoo Veterinarians LISTSERV describe hemorrhage from intramuscular injections of PSGAGs.[1] Necropsy findings described in the case report included hemorrhage into the left pectoral muscle and from injection sites. PSGAGs are synthetic heparinoids, suggesting that an anticoagulant action may cause bleeding. Transient prolongation of APTT, PT, and ACT in dogs and APTT and PT in cats has been reported following intramuscular injection of PSGAG; however, fatalities have not been attributed to PSGAGs in these species.[11,12] Coagulation studies of PSGAGs in birds are warranted to clarify the cause of hemorrhagic complications.

Acronyms and Abbreviations

CMAH, cytidine monophospho-*N*-acetylneuraminic acid hydroxylase; DLH, domestic longhair; DSH, domestic shorthair; EA, erythrocyte antigen; FUT1, fucosyl-transferase 1; FUT2, fucosyl-transferase 2; NeuAc, N-acetylneuraminic acid; [NeuAc]2GD3, NeuAc-NeuAc-galactose-glucose-ceramide; NeuGc, N-glycolylneuraminic acid; [NeuGc]2GD3, NeuGc-NeuGc-galactose-glucose-ceramide; NI, neonatal isoerythrolysis; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; SNPs, single nucleotide polymorphisms.

Inherited cell surface antigens located on the RBC membrane are referred to as blood group antigens. Their detection is primarily based on polyclonal or monoclonal antibody serology. The antigens can vary in immunogenicity and, therefore, in clinical importance. In veterinary medicine, the clinical significance of blood group antigens is usually in the areas of transfusion reactions and neonatal isoerythrolysis (NI). Blood group antigens are genetic markers and, in the past, were used for parentage testing. Though not yet proven

in veterinary medicine, blood group antigens may play a role in immune-mediated hemolytic anemia and may serve as markers of disease. In this chapter, our current understanding of blood group nomenclature, serology, biochemistry, inheritance, incidence, and transfusion significance in the dog, cat, cattle, horse, sheep, goat, pig, llama, and alpaca is reviewed.

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN THE DOG

Historical Background

Canine blood groups are among the first to be described in a species other than humans and were originally recognized by von Dungern and Hirszfeld in 1910, who defined four different blood groups based on immune isoagglutinins.[110] Animal experiments aimed to advance human medicine through multiple blood transfusions and organ/bone marrow transplantation led to the investigation of further canine blood groups. By a series of systematic experimental blood transfusions between dogs, Swisher and coworkers at the University of Rochester, NY, studied in vivo mechanisms of RBC destruction and characterized the in vivo and in vitro behavior of the alloantibody systems.[107,108]

Nomenclature

The first blood groups identified were named by letters from A to G in the order of their discovery.[107] Two categories of A cells were recognized: a strongly reactive group (A) and a distinct series of less strongly reacting cells designated as A′ that could only be detected by the Coombs antiglobulin test; they were eventually designated A1 and A2, respectively.[24,107] Subsequent studies led to the discovery of several other blood groups including He and Tr.[17,108] Anti-E and anti-G typing sera were lost, so no future comparisons could be made.[12,26,108]

In 1973 and 1976, two international workshops led to the standardization of canine blood group systems, as defined by their isoimmune sera.[119,120] The first workshop designated the terminology canine erythrocyte antigen (CEA) followed by a number to indicate the blood group antigen.[120] To avoid confusion with the carcinoembryonic antigen (CEA) system, the nomenclature was later modified to dog erythrocyte antigen (DEA). The second workshop specified that the number immediately after DEA designated a locus, whereas alleles within a locus would be identified by adding a number after a (.), e.g., DEA 1.1 and DEA 1.2. The previous edition of this chapter includes an extensive review of the dog blood group systems nomenclature, which is useful in understanding past and present literature on the subject.[4]

More recently, DEA 1 antigen analysis by flow cytometry using a monoclonal antibody revealed that the expression of DEA 1 is a continuum of reactions ranging from negative to strongly positive. Thus, all the alleles of the DEA 1 system have a similar epitope recognized by the monoclonal antibody.[1] Consequently, the historical nomenclature DEA 1.1, 1.2, 1.3, and DEA-1.1-negative should be substituted by DEA-1-positive and DEA-1-negative. An updated standardized international nomenclature system is required, which should include novel blood groups such as Dal and Kai 1/Kai 2.[14,35,49,71] Typing sera are commercially available in the United States, however, only for DEA 1, DEA 4, DEA 5, and DEA 7. There is limited accessibility to DEA 3, 5 and Dal reagents and a complete lack of accessibility to DEA 6 and 8 reagents. Other blood group factors and systems have been described,[64,84] but the lack of commercially available typing sera does not diminish their potential clinical significance in transfusion medicine.

Dog Erythrocyte Antigen System

DEA 1 (A System)

Originally designated by the letter A, the DEA 1 system is clinically the most important blood group system in dogs, mostly because of its well-documented immunogenicity, but also due to its overall prevalence, e.g., an almost equivalent proportion of DEA-1-positive and DEA-1-negative individuals.[46,92,119,120] Until recently, the DEA 1 system was named according to its subtypes: DEA 1.1, DEA 1.2, DEA 1.3, and DEA-1-negative. Historical accounts of these subtypes and their properties can be found in the publications of Swisher, Young, Symons, and Bell.[118,122] As stated in the earlier text under the "Nomenclature" section, recent findings by Acierno et al. suggested that this nomenclature should be replaced by DEA-1-positive and DEA-1-negative.[1]

The production and characterization of a murine monoclonal anti-DEA 1.1 antibody (IgM) in 1992 facilitated the clinical accessibility to DEA 1.1 blood typing thereafter.[2] Currently, two murine monoclonal anti-DEA 1.1 antibodies are utilized in clinical typing kits and in research settings.[1,16,69,70,72,92] Attempts to produce specific anti-DEA 1.2 and anti-DEA 1.3 antibodies have been unsuccessful without performing RBC absorption procedures.[107,110]

Analysis of the DEA 1 antigen by immunochromatography and flow cytometry suggested that the variation in the DEA 1 system is quantitative rather than qualitative. All the alleles within the DEA 1 system have a similar epitope that is recognized by a monoclonal antibody to varying degrees based on the surface expression of the DEA 1 antigen. Dogs that had been typed DEA 1.2 would actually be DEA-1-positive dogs with low antigenic expression, rather than having a morphologically different epitope.[1] However, a subsequent study by Polak et al. demonstrated no direct correlation between the historical DEA 1.2 and the strength of DEA 1 reactions.[88] The same group also studied the mode of inheritance in the DEA 1 system and confirmed an autosomal dominant Mendelian mode of inheritance. They determined that there were ≥4 alleles, which demonstrated differing degrees of antigenic expression based on a normalized blood PCV (20%): DEA-1-negative, DEA-1-positive weak (1+), intermediate (2+), and strong (3+ and 4+).[88]

Prevalence Several prevalence studies have been carried out in various countries with an overall prevalence of DEA-1-positive ranging from 33% to 65% in dogs of various breeds.[22,39,46,58,75,88]

Molecular Identity The biochemical and molecular characterization of the DEA 1 system requires further investigation, so that the data in the literature may be clarified. For example, western blotting experiments using the anti-DEA 1.1 monoclonal antibody characterized by Andrews et al. in 1992 identified two membrane proteins of 50 and 200 kDa.[2] Immunoprecipitation techniques using a polyclonal antisera to DEA 1.2 isolated a protein with a molecular mass of 85 kDa; however, this study lacks comparison to DEA-1.1-positive and DEA-1.1-negative dogs.[28] By contrast, using a second monoclonal anti-DEA 1 antibody, Polak et al. were unable to repeat these findings and did not detect the presence of any polypeptide bands in western blot experiments. They suggested that the anti-DEA 1 antibody may be specific for conformational or combinatorial epitopes lost during sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).[88]

Transfusion Reactions From a practical standpoint, the DEA 1 system is the most important blood group system in the dog. Fortunately, naturally occurring anti-DEA 1 antibodies have not been documented and pregnancy has never been reported to cause sensitization in dogs;[15,126,127] however, the immunogenicity of DEA 1 remains well-documented.[46,128] Given this, first time acute hemolytic transfusion reactions do not occur in the dog; however, subsequent incompatible transfusions may result in severe hemolytic transfusion reactions (see Chapter 104).

Conflicting data have also been published regarding the immunogenicity of the historical DEA 1.2 (reported as A2), notably that DEA 1.2 (A2) dogs sensitized with DEA 1.1 (A1) RBCs can produced antibodies which react to DEA 1.1 (A1) RBCs.[107] Similarly, Hale reported in 1995 that the administration of DEA 1.1 RBCs to a sensitized DEA 1.2 dog results in an immediate hemolytic transfusion reaction.[57] Given the recent investigations into the DEA 1 system with monoclonal antibodies, modern transfusion studies are required to clarify the clinical significance of the DEA-1-positive in terms of antigenic strength. For instance, the effect of transfusing weakly DEA-1-positive blood to a DEA-1-negative dog or of transfusing strongly DEA-1-positive blood to a weak DEA-1-positive dog remains unknown.

DEA 3 (B System)

This is currently understood to be a one factor, two phenotypes system with the antigen DEA 3 dominant over a null phenotype. In the general canine population in the United States, the proportion of DEA-3-positive dogs is relatively low with a reported frequency varying from 6–11%.[17,57,58,105–107] Two studies in Japan have shown that some Japanese breeds such as Akita, Shikoku and Shiba Inu have more DEA-3-positive individuals. By contrast, non-Japanese breeds were predominantly DEA-3-negative.[32,33] Of 122 Labrador Retrievers tested in Australia, all were DEA-3-negative.[111] In a study from 2010 in retired racing Greyhounds in Ohio (n = 113 dogs), 25% were DEA-3-positive, which is similar to previous findings in the breed.[57,63] Naturally occurring anti-DEA 3 antibody has been reported in 2–20% of DEA-3-negative dogs.[57,107] The experimental administration of DEA-3-positive RBCs to a previously sensitized dog resulted in sequestration and destruction of the transfused RBCs within 5 days.[107] Given the rate of RBC loss, this degree of delayed post-transfusion reaction is most likely significant only if the recipient's ability to produce RBCs is compromised.[57]

Accessibility to typing sera for DEA 3 remains limited, threatening the ongoing ability to perform DEA 3 blood typing.

DEA 4 (C System)

This is a one factor, two phenotypes system with the antigen DEA 4 dominant over a null phenotype. DEA 4 is a high-frequency antigen with a prevalence of over 97% in the majority of tested populations.[17,34,46,57,58,63,69,107] Naturally occurring antibodies to DEA 4 have not been documented in the few DEA-4-negative individuals identified. Experimental studies have shown that DEA-4-negative dogs can produce antibodies to this antigen when exposed by transfusion, although sensitized dogs do not necessarily show RBC loss or hemolysis when subsequently transfused with DEA-4-positive RBCs.[108] Attempts to induce NI with DEA 4 (reported as C) incompatibility were unsuccessful.[126] However, a clinical report of an acute hemolytic reaction has been documented in a DEA-4-negative Shih Tzu previously sensitized by multiple transfusions.[77] The clinical significance of the DEA 4 is related to its high prevalence within the population, thus placing DEA-4-negative dogs at high risk of transfusion incompatibility when they require multiple blood transfusions. Immunoprecipitation techniques using polyclonal antisera have demonstrated that DEA 4 is a 32–40-kDa-sized protein present in a single band.[28] Blood typing for DEA 4 is performed with polyclonal canine antibodies available in a lyophilized formulation, which generate easily interpretable strong agglutination reactions (Animal Blood Resources International, Stockbridge, MI, USA).

DEA 5 (D System)

This is a one factor, two phenotypes system with the antigen DEA 5 dominant over a null phenotype. The prevalence of DEA 5 is usually less than 25% in the general population, although there are breed and geographic variations.[32,34,57,58,63,105–107,119] Naturally occurring anti-DEA 5 antibody has been reported in up to 10% of DEA-5-negative dogs. However, the titers expressed are generally weak (<1:16).[24] Swisher et al. reported sequestration and RBCs loss in less than 3 days in previously sensitized DEA-5-negative dogs transfused with DEA-5-positive blood.[108] Experimental attempts to induce NI with DEA 5 incompatibility were unsuccessful.[129] An in-house agglutination test card for DEA 5 was recently commercialized

(DMS Laboratories, Flemington, NJ, USA), which will facilitate clinical investigation of blood incompatibilities. The molecular structure of the DEA 5 has not been investigated.

DEA 6 (F System)

This is a one factor, two phenotypes system with the antigen DEA 6 dominant over a null phenotype. DEA 6 was initially suspected to be a high-frequency antigen with a prevalence greater than 98%.[106,107] However, subsequent studies have demonstrated a prevalence between 60% and 74%, suggesting significant breed and geographic variation of DEA 6 expression.[32,105,119] Naturally occurring anti-DEA 6 antibodies have not been documented. Following experimental sensitization of one DEA-6-negative dog, a moderate rate of RBCs destruction without clinical sign was observed.[107] Typing sera for DEA 6 no longer exist and the last prevalence study was published in 1986.[32]

DEA 7 (Tr System)

The DEA 7 system, previously referred to as Tr, was initially defined by a naturally occurring alloantibody and by an identically reacting antiserum produced by isoimmunization.[17] Factor O is an allele in the DEA 7 (Tr) system, resulting in the DEA 7 (Tr) system being a two factors, three phenotypes (Tr, O, and null) system with the order of dominance being Tr > O > null.[27] Unlike the other identified canine blood groups, DEA 7 antigen is not an integral RBC membrane antigen, rather it is believed to be produced elsewhere in the body, secreted into the plasma, and adsorbed onto the RBC surface.[20] The prevalence of DEA 7 varies significantly from one study to another, with reported prevalence of 8–82%, which is believed to be due to geographical and breed variations.[17,58,63,98,119] The existence and clinical significance of natural alloantibodies in DEA-7-negative dogs are controversial, but have been reported in 0–50% of DEA-7-negative dogs.[46,50,98,99] When present, their titers are rather low (rarely above 1:8).[57,97,98] Previously sensitized DEA-7-negative dogs transfused with DEA-7-positive RBCs show sequestration and loss of RBCs within 72 hours, without clinical evidence of hemolysis.[57] In this regard, the clinical importance of DEA 7 in transfusion reactions appears to be similar to that of DEA 3 and DEA 5. Immunoprecipitation experiments using polyclonal antisera to DEA 7 isolated three proteins of molecular mass 53, 58, and 66 kDa.[28]

DEA 8

DEA 8, originally designated as He, was discovered following systematic sensitization of dogs, and the antigen was present in 17–40% of dogs tested in the 1960s–1970s.[106,119] The clinical significance of DEA 8 has never been investigated. Similar to DEA 6, typing sera for DEA 8 no longer exist and the last prevalence study was published in 1976.[119]

Novel Blood Groups and Other Specificities

Japanese Blood Group Systems

As previously mentioned, two typing reagents (referred to as anti-D1 and anti-E) were produced in Japan and later found to be identical to the anti-DEA 3 antibody.[30] However, in contrast with the DEA 3 system, the Japanese D system describes two antigens (D1 and D2, codominant genes) and three phenotypes (D1, D2, and D1D2), based on agglutination testing with two rabbit heteroimmune antisera (anti-D1 and anti-D2). Although the D blood group system has been extensively studied in over 3000 Japanese dogs, the D2 antigen has not yet been identified outside of Japan. The incidence of D1 (i.e., DEA 3) is high in purebred dogs indigenous to Japan such as the Akita, Shiba Inu, Kishu, Shikoku, and in native Japanese Mongrel and mixed breeds, while most Western and European breeds are negative.[30,32,33] Ejima et al. observed severe acute hemolytic transfusion reactions following repeated transfusions of D2 type blood to a D1 type patient, or conversely of D1 type blood into a D2 type dog, indicating the clinical importance of this system in transfusion medicine.[33]

In Japan, a lectin extracted from the seeds of *Clerodendrum trichotomum* has demonstrated the ability to agglutinate RBCs in a small subpopulation of dogs (designated type C) at titers up to 128, while demonstrating no reaction for the majority of dogs (type c), which was later confirmed to be an autosomal dominant trait.[65] This system, designated as "C," has been compared to the DEA system and has been found to be different.[30,65]

Dal Blood Group

In 2007, a blood incompatibility between a previously transfused anemic Dalmatian patient and 55 non-Dalmatian blood donors led to the identification of a newly recognized blood type. The patient was found to be compatible to 4/25 Dalmatians, and the RBC antigen was therefore named Dal.[14] Although Dal was initially thought to be a high-frequency antigen, a survey of 1130 dogs from North America confirmed that it should actually be classified as a blood group system where Dal-positive is dominantly inherited over Dal-negative.[49] Goulet et al. identified several breeds with Dal-negative dogs, in addition to the previously reported Dalmatians (15/128; 11.7%), most notably Doberman Pinschers (183/432; 42.4%), Shih Tzus (12/21; 57.1%), and also sporadically in mixed-breed dogs (3/122; 2.5%), Lhasa Apsos (1/6), and Bichon Frises (1/3).[49]

At this time, no naturally occurring anti-Dal alloantibodies have been detected.[14,35,48] However, the strong immunogenicity of Dal has been documented following the sensitization of three Dal-negative research Beagles (published data on two of these dogs), with the detection of anti-Dal alloantibodies as early as 4 days post-transfusion and evidence of accelerated removal of Dal-positive RBCs using a gel column

technology.[48] In addition to the rapid production of anti-Dal alloantibodies, particularly high maximum agglutination titers were documented (i.e., as high as 2048) after a period of 1–2 months. Anti-Dal alloantibodies, which were confirmed to be IgG, remained detectable for as long as 2 years post-transfusion, thus providing evidence that they are long-lasting.[14,48]

Considering the fact that all non-Doberman Pinschers blood donors tested to date are Dal-positive, Dal-negative dogs are at high risk of transfusion incompatibility if they are to receive multiple blood transfusions. Therefore, Dal blood typing, in addition to standard DEA 1 typing, is recommended in Dalmatians, Doberman Pinschers, and Shih Tzus, especially in previously transfused dogs.[49] The Dal immunization study performed at the University of Montreal allowed for a considerable amount of anti-Dal polyclonal reagents stable through freezing to be banked for further clinical and research use.[48]

Kai 1 and Kai 2 Blood Types

Following the production of monoclonal antibodies by mouse hybridoma technique, two additional canine blood types (Kai 1 and Kai 2; Kai meaning "dog" in Korean) have recently been identified.[71] To date, Kai 1 and Kai 2 antigens have not been shown to coexist in any of the dogs tested (n = 203 dogs from South Korea; 42% Kai-1-positive, 37% Kai-2-positive), but both antigens may be absent (20% Kai-negative).[71] By contrast, the majority of dogs tested in North America (94%; n = 503) were Kai-1-positive, with barely 1% of dogs Kai-2-positive and 5% Kai-negative, with no dogs expressing both RBC antigens.[35] A comparative study confirmed that Kai 1 and Kai 2 are unrelated to DEA 1, 3, 4, and 7 and Dal.[35] No naturally occurring anti-Kai alloantibodies have been documented, but presumed anti-Kai alloantibodies were documented in four dogs 21 days post-transfusion (Kai-1-negative and Kai-2-negative dogs receiving mismatched Kai-positive blood).[71] Although the antigenic nature of Kai 1 and Kai 2 is likely, their clinical relevance is currently unknown.

Several additional specificities have been reported and proposed to represent new blood group systems.[26,30,105,111,119] As multiple blood transfusion recipients become more prevalent, novel blood groups are likely to be identified, as demonstrated by the discovery of the Dal blood type.

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN THE CAT

Historical Background

The current nomenclature of blood groups A and B was first used by Eyquem et al. in 1962.[36] In addition to stating that these antigens are related to the ones previously described by Holmes in 1950, Eyquem also observed that 20% of cats possessed natural isoagglutinins.[36] In 1981, Auer and Bell used two naturally occurring antibodies, anti-A and anti-B, to further characterize the cat blood group system which they designated as AB, and first reported the rare AB phenotype where both antigens are present on the RBC.[7] They were also the first to describe immediate experimental and naturally occurring transfusion reactions in previously unsensitized cats of known incompatible blood type.[9]

Cat AB Blood Group System

The AB blood group system characterized by Auer and Bell is the predominant blood group system in cats.[7] Three phenotypes occur: type A, type B, and type AB. A null phenotype does not occur. The types are defined by naturally occurring alloantibody against the antigen they lack, which can be produced in kittens as young as 6–8 weeks of age.[19] Approximately one-third of type A cats have alloantibodies in their plasma capable of weak macroscopic agglutination of type-B RBC, which are weak anti-B hemagglutinins of the IgM class and weak hemolysins consisting of equal amounts of IgG and IgM. All type B cats have high-titered anti-A hemagglutinins and hemolysins mainly of the IgM class with lesser amounts of IgG.[19,123] The presence of naturally occurring alloantibodies, in particular of strong anti-A alloantibodies, is responsible for transfusion reactions and NI in blood type incompatible cats. Type AB cats do not possess alloantibodies against either A or B antigens.

Genetics

Systematic pedigree analysis of Abyssinian and Birman cat families confirmed that the blood group antigens A and B are inherited as simple autosomal Mendelian traits with A being dominant to B.[12,45] In spite of extensive breeding experiments and pedigree analysis, the mode of inheritance of the AB phenotype remains unclear due to apparently different inheritance patterns in different breeds.[55] The *ab* allele, causing blood type AB, was found to be separately inherited, being (co)dominant to *b* and recessive to the *A* allele.[55,68] Thus, all type B cats are homozygous for the *b* allele (genotype *b/b*), type A cats can be either homozygous (genotype *A/A*) or heterozygous (genotype *A/b* or *A/ab*), and the rare type AB cats can either be homozygous (genotype *ab/ab*) or heterozygous (genotype *ab/b*).

Prevalence of the Antigens

The percentage distribution of types A and B in domestic shorthair (DSH) and domestic longhair (DLH) cats can vary markedly with geographic location worldwide, ranging from 62–100% type A cats and 0–36% type B cats. Type B domestic cats are uncommon in some countries such as the United States and Switzerland; however, in other countries such as Australia, Greece, and Turkey, their prevalence can reach up to 36% of the nonpedigree feline population.[6,7,47,61,73,80] Similarly, the variation per breed is significant. For instance, the incidence

of type B in the United States ranges from 0% up to 60% among different purebred cats, with the highest prevalence found in Exotic and British Shorthair, Cornish Rex, and in Devon Rex.[45,47,56] To this day, type B has not been documented in Siamese cats worldwide.[40,45,94,118] By contrast, Turkish Van and Angora cats are reported to have a prevalence of type B cats of 60% and 46.4%, respectively.[5] Type AB is exceedingly rare and only found in breeds in which type B is detected.[55] In a survey of cats in the United States and Canada, 13 of 9239 cats (0.14%) were type AB.[55] Similarly, only seven of 1895 cats (0.4%) were type AB in a survey conducted in Australia.[7] Type AB has, however, been reported more frequently in certain random bred populations, based on surveys done in Israel (14.5%), Japan (9.7%), Portugal (6.3%), and England (8.5%).[31,78,94,112] Compared to all other cat breeds, Ragdolls are commonly type AB with reported frequency in Italy ranging of 18–24%.[89,96]

Molecular Characterization of the Antigens

The A and B blood types of cats are caused by differences in the neuraminic acid residues present on a ceramide dihexose backbone on the RBC membrane.[3,41] Type A RBCs have mainly N-glycolylneuraminic acid (NeuGc) and a small amount of N-acetylneuraminic acid (NeuAc). More precisely, type A RBCs have NeuGc-NeuGc-galactose-glucose-ceramide ([NeuGc]2GD3) as the major disialoganglioside, which is predominantly detected by feline anti-A antisera.[3] Type A RBCs also have NeuAc-NeuGc-GD3, NeuGc-NeuAc-GD3, and a very minor amount of [NeuAc]2GD3. Homozygous and heterozygous type A cats have some differences in their ganglioside profiles, which can be used to determine the genotype of type A cats.[54]

NeuAc is the determinant of the B antigen. Type B RBCs have [NeuAc]2GD3 as the only form of the disialoganglioside and do not express any detectable NeuGc.[3] Agglutination testing with the lectin from *Triticum vulgaris* (wheat), which binds sialoglycoproteins containing NeuAc, demonstrates selective agglutination of type B RBCs.[21] Type AB cats have both NeuAc and NeuGc present on the RBCs in similar quantities, each at approximately 50% normal expression levels.[54] Therefore, type AB RBCs are agglutinated by both anti-A and anti-B feline antisera, and by the lectin of *T. vulgaris* (see Chapter 107). Using a murine monoclonal anti-A antibody in agglutination testing, ganglioside thin-layer chromatography immunostaining, and flow cytometry, studies have suggested that there is more than one biochemical phenotype present among the AB type cats.[52,53]

Molecular Genetics

Cytidine monophospho-*N*-acetylneuraminic acid hydroxylase (CMAH) is the enzyme that catalyzes the conversion of NeuAc (B antigen) to NeuGc (A antigen).[79] Recent studies have identified several variants in the *CMAH* gene believed to disrupt the enzyme's function, so that it can no longer convert NeuAc to NeuGc.[13,42,43,85,112] The *b* allele was associated with several variants, including single nucleotide polymorphisms (SNPs) upstream of the *CMAH* start codon, a deletion in the 5′-untranslated region of exon 1, and four non-synonymous variants within the open reading frame.[13,112] The discovery of polymorphisms in *CMAH* ascribed to type B led to the development of commercial genotyping tests based on PCR and sequencing blood to identify the *AA*, *Ab*, and *bb* genotypes. However, despite high agreement reported, the assays have the significant limitation (particularly in pretransfusion settings) of not being able to differentiate between type A and type AB cats.[13] In addition, many examples of phenotype–genotype discordances for cats with type B and AB blood have been reported.[42,43,85] More recently, a study in Ragdoll cats identified a novel variant (c.364C>T) in *CMAH* exon 4 highly associated with blood type AB in the breed.[42] In addition, the feline *CMAH* coding regions were further examined in 70 cats, which allowed identification of 13 additional variants.[68] Analysis of three single nucleotide variants along with blood typing of an additional 351 typed cats, for which the phenotype was confirmed by additional typing assays (including backtyping), showed complete phenotype–genotype concordance. The authors concluded that three *CMAH* variants, i.e., c.179G>T (seen in type B in Turkish breed), c.268T>A (seen in type B cats of most breeds), and c.1322delT (seen in type B in some Ragdolls and DSH), are the main reasons for the defective NeuGc synthesis causing blood type B in domestic purebred and nonpedigreed cats.[68] These variants, combined with the variant identified for type AB in Ragdolls (c.364C>T), represent a promising molecular diagnostic scheme to genotype cats for the AB blood group system and differentiate type A, type B, and type AB.[42,68] It is likely that additional genetic variants will be identified in specific breeds and geographical regions.

Transfusion Reactions

The presence of naturally occurring alloantibodies is responsible for transfusion reactions in previously unsensitized cats (see Chapter 104). Of utmost clinical significance is the presence of highly potent anti-A agglutinins and hemolysins in virtually all type B cats, which can result in severe acute hemolytic transfusion reaction, and even death, if type A blood is administered to a type B cat.[8,9,124] Rapid intravascular destruction of the type A RBCs occurs within minutes to hours and is complement- and IgM-mediated. Transfusion of type B blood to type A cats also proved ineffective and is associated with extravascular hemolytic reactions, involving IgG and IgM without marked complement activity, and a half-life of transfused type B RBCs of about 2 days.[8,44]

Neonatal Isoerythrolysis

The strong anti-A naturally occurring alloantibodies present in type B cat can also be responsible for NI in type A or type AB kittens born to a type B queen.[55] The colostrum of type B queens contains high concentrations of anti-A antibodies, and colostral antibodies are

detectable in the serum of newborns as early as 4 hours after birth.[19] Clinical signs in affected kittens can be variable, ranging from unapparent to severe hemolytic anemia with hemoglobinuria, icterus, and death. NI is believed to be a major cause of the "fading kitten syndrome."[45]

The Mik Red Blood Cell Antigen

Based on the presence of a naturally occurring alloantibody in three blood donor cats, the Mik blood group system was described in 2007.[121] Incompatible crossmatch reactions with plasma from a transfusion-naïve blood donor cat (named Mike) resulted in a detailed survey of blood compatibilities within Penn Animal Blood Bank blood donors. Upon further investigation of 65 type A donors, a total of three unrelated cats (Mik-negative) were found incompatible with the same cats (Mik-positive), yet compatible to each other, indicating that they lacked the same RBC antigen (Mik antigen) and had natural anti-Mik alloantibodies. Three type B and one type AB cat also appeared to express the Mik antigen. The clinical relevance of anti-Mik alloantibodies was documented after an acute hemolytic transfusion reaction following inadvertent transfusion of Mik-positive blood to a thereafter confirmed Mik-negative renal transplant recipient upon its first blood transfusion.[121] Unfortunately, anti-Mik antibodies are currently not available, preventing future investigations.

Naturally Occurring Alloantibodies Outside of the AB system

There is some evidence for the presence of other naturally occurring alloantibodies outside the AB blood group system, like anti-Mik, but their clinical importance at the time of a first transfusion has not been defined.[51,74,122] Major crossmatch incompatibilities outside of the AB system in transfusion-naïve cats have been documented in 23 of 154 cases (14.9%) in one study and 10 of 52 (19%) in another. [74,109] However, the crossmatch screening of 112 cats in the United Kingdom failed to detect any non-AB incompatibilities.[112] In a prospective controlled study, 48 client-owned transfusion-naïve anemic cats were randomized to receive either type-compatible and crossmatched-compatible packed RBC transfusions or non-crossmatched blood-type-compatible pRBCs. Their findings did not detect any difference in the increase in PCV after transfusion or in the incidence of transfusion reactions between crossmatched and uncrossmatched groups; however, crossmatched-incompatible cats were not included (i.e., transfused) for obvious ethical reasons.[109]

Other RBC antigens outside of the AB blood group system can also be suspected based on the prevalence of non-AB RBC incompatibilities in previously transfused cats, which has been reported to be approximately 25–27% (see Chapter 99).[60,74,122]

RED BLOOD CELL ANTIGENS AND BLOOD GROUPS IN LIVESTOCK SPECIES

Historical Background

The identification of blood group antigens and analysis of their patterns of genetic inheritance in livestock species were the subject of intense investigation for about 50 years since the late 1940s. In contrast to humans and cats, naturally occurring antibodies are seldom found in the sera of cattle, horse, sheep, goat, pig, llama, and alpacas. Production of isoimmune and heteroimmune antisera by immunization and the use of RBC absorption procedures to isolate monospecific antibodies (blood typing reagents) were critical to uncover the genetic diversity of blood groups in these species. The molecular nature and function of the RBC antigens in farm animals remain largely unknown.

This section describes the blood group systems (or loci) of six livestock species: cow, horse, sheep, goat, pig, and llama (and the related alpaca). Although blood group systems were historically named as a single letter, we use here the more recent nomenclature convention in which the two letters "EA" for erythrocyte antigen precede the traditional system designation. The literature in blood groups of livestock species is extensive and cannot be fully represented in this section. Excellent reviews that offer historical accounts and details of the complex serological intricacies of blood group loci in the major livestock species are published by Stormont,[101] Bell,[12] Di Stasio,[29] Hines,[59] Juneja and Vogeli,[66] and Sandberg & Cothran.[91] The major application of blood type variation in farm animals was in the area of animal identification and parentage verification, because of the high level of individual discrimination that could be achieved and their classic Mendelian modes of inheritance. The advent of DNA genotyping methods and technologies in the late 1990s led to a replacement of methodology for this application in farm animals.[18,116,117] From a clinical perspective, knowledge of blood groups is significant only in horses and mules because of the risk of NI posed by maternal–fetal incompatibility for certain factors.

Methods of Blood Group Detection

Hemolytic and agglutination techniques are used to assay blood group antigens. The choice of procedure is largely determined by RBC characteristics of each species. Blood grouping assays for cattle, sheep, goat, llama, and alpaca are hemolytic tests because the RBCs of these species are not prone to agglutination. Horse and pig blood group antigens are assayed by saline agglutination or by hemolytic tests. Some pig factors require an antiglobulin test (Coombs test) or addition of dextran to facilitate agglutination and improve scoring of reactions.

Blood typing reagents (monospecific antisera) for livestock species are not commercially available. They have been traditionally prepared in laboratories that provided

blood typing services. Comparison tests sponsored by the International Society for Animal Genetics for several decades provided a forum for standardization of blood factor specificities and nomenclature for each species. Blood typing comparison tests are no longer held, and production of blood typing reagents has virtually ceased worldwide.

Hemolytic and Agglutination Tests

Hemolytic tests are typically set up in round-bottom, 96-well microtiter plates. A standard procedure consists of combining, in order, 50 µL of blood typing reagent with 25 µL of a 2–2.5% saline suspension of washed, packed RBCs and 25 µL of undiluted rabbit complement. The plate is then shaken, and reactions are read twice to record degree of hemolysis: once 30–45 minutes after set-up and a second time 2–3 hours later. A concave mirror is used for visual determination of hemolysis, which is graded as 0 (negative, no visible hemolysis, RBCs pelleted at the bottom), 1 (partial hemolysis), 2 (intermediate), 3 (strong, almost complete), and 4 (complete hemolysis, no visible RBCs). A complement control containing saline instead of reagent is run in parallel with the test reactions.

Rabbit serum is the source of complement for hemolytic tests, but because rabbits lack the heterophile Forssman antigen, their sera can have Forssman antibodies in high titers. Cattle and camelids are Forssman-negative and thus hemolytic tests in these species are not affected by Forssman antibodies. For the Forssman-positive horse, sheep, goat, and pig, the rabbit serum needs to be absorbed with RBCs from these species prior to use as complement.[103] Two serial absorptions, carried out at 4 °C, for 15–20 minutes each and a 1:2 volume ratio of washed, packed RBCs to rabbit serum are usually sufficient to remove heterophile antibodies without affecting complement function.

Agglutination tests are set up in the same way as hemolytic tests, but without complement. Reactions proceed at room temperature for 2–3 hours after which time the plates are shaken briefly to resuspend cells and degrees of agglutination are recorded 5–10 minutes later as 0 (no agglutination), 1 (partial clumping), 2 (intermediate clumping), and 3 (total clumping of red cells). A microscope helps distinguish between negative and weak positive reactions.

Antiglobulin tests are used with incomplete antibodies that require the addition of rabbit antiglobulin serum to produce agglutination. This procedure is used to detect some blood group factors in pigs. Addition of dextran to a saline agglutination reaction at a final concentration of 1.5% has been used with some incomplete antibodies in pigs as an alternative to the antiglobulin test.

Blood Group Systems

Cattle

The blood groups of cattle were the first to be studied in detail and provided a model for investigation in other species. The early studies in the 1940s demonstrated the value of isoimmunization and heteroimmunization for development of antibodies for blood group factors and established the procedures for preparation of monospecific antibodies through absorption and for assaying blood groups with hemolytic tests.[37,38]

Cattle blood groups remain the primary example of extreme genetic variation of RBC antigens, as evidenced by more than 70 blood group factors internationally recognized and by the extensive allelic series known in the complex *EAB* and *EAC* systems. An alphabetical nomenclature designated blood group factors (e.g., A, L, S, Z) with numerical subscripts added to describe serologically related subtypes (e.g., A_1, A_2, Y_1, Y_2). The use of symbols ′ and ″ (e.g., A′, B′, A″, G″) indicated second and third rounds of use of alphabet letters, respectively. One of the most important contributions of the early cattle blood group research was the demonstration that multiple factors segregated together in specific combinations (phenogroups) that defined allelic variants.[100,102] Evidence of infrequent recombination within *EAB* and *EAC* systems suggests that these complex systems may involve linked genes,[59] but the genomic basis of cattle blood group systems remains unknown. The *EAJ* system is not an intrinsic component of the RBC membrane and anti-J is the only antibody that occurs naturally. The J factor is a tissue and serum antigen that attaches to RBCs as serum concentrations become sufficiently high. The attached J substance has been shown to be a glycolipid, while the serum form occurs as both glycolipid and glycoprotein.[113] The J factor is serologically related to human A, sheep R, and pig A factors. Cattle blood group loci were mapped to chromosomes by linkage analysis.[67] Hines[59] provides a good review of the status of cattle blood group systems.

Horse

The first 16 blood group factors in the horse were identified through isoimmunization and heteroimmunization followed by agglutination and hemolysis testing.[104] Research worldwide led to the characterization of 34 factors distributed in seven systems as summarized in Table 96.1. By convention, factors within a system are assigned lower case letters and blood group alleles (phenogroups) are designated by the capital letter for the system, followed by lower case letters for the factor or factors detected. Five blood group loci were mapped to chromosomes by linkage analysis.[86]

The horse is the only livestock species for which blood group incompatibilities are clinically relevant. Blood group antibodies that cause transfusion reactions or NI can be found in the sera of horses either "naturally" or as a result of a blood group incompatible pregnancy. The majority of NI cases are explained by blood group incompatibilities between stallion and mare at either *EAA* or *EAQ*.[10] Naturally occurring anti-Aa (in any of its allelic combinations) and anti-Ac are occasionally found in the sera of Aa-negative horses, usually as agglutinins. Anti-Aa in mares may also be present as a hemolysin, particularly if produced by a blood group incompatible pregnancy. Where possible,

hemolytic screening for this antibody (and others) prior to foaling can provide an effective test to identify mares whose foals are at risk for NI. In *EAQ* sensitization, the mare is negative for factor Qa (for most breeds this means negative for Q^{abc}), while the stallion has this blood group. The detectable antibody response for Qa has only been reported as a lysin and would be missed if antibody screening is based solely on agglutination testing. Occasionally, presence of antibody can be detected only very late in pregnancy. Antibodies for blood group factors in *EAC*, *EAD*, *EAK*, *EAP*, and *EAU* pose little risk as they do not occur naturally and have only rarely been implicated in NI cases, possibly as a result of blood-incompatible pregnancies.

Sheep and Goat

Eight blood group systems were described in sheep: *EAA*, *EAB*, *EAC*, *EAD*, *EAM*, *EAR*, *EAF30*, and *EAF41*.[83] The nomenclature of systems and factors followed that of the horse and pig. Although many antigen specificities were identified, only 22 blood group factors were internationally recognized in sheep. Hemolytic tests are the method of choice for sheep blood group factors with exception of the D system whose antigens are detected by agglutination tests. The sheep *EAB*, *EAC*, and *EAR* systems are homologous to cattle *EAB*, *EAC*, and *EAJ*. *EAR* locus R and O antigens, where EAR^R is dominant to EAR^O, are soluble substances found in the serum and saliva that attach to the RBC membrane and whose expression is under the control of the suppressor gene *I*. Sheep with genotype *i*/*i* do not express R or O antigens in RBCs, serum, or saliva. The *EAC* locus is closely linked to the *amino acid transport* gene. This association is of interest because RBCs with defective transport are never Cb-negative. The *EAM* locus is associated with RBC potassium transport such that low-potassium cells are always Mb-positive and high-potassium cells are always Mb-negative. It has been postulated that Mb inhibits active potassium transport into cells.[115] Several sheep blood group systems were mapped by linkage analysis. Di Stasio[29] provides a good review of sheep blood group systems.

In goats, six genetic systems were identified and named *EAA*, *EAB*, *EAC*, *EAE*, *EAF*, and *EAR*.[82] Several goat blood group factors cross-react with sheep blood typing reagents. The *EAA* system has a single specificity A1 homologous to sheep EAAa. In the *EAB* system, among 14 specificities identified, four are homologous to sheep factors Bb, Be, Bd, and Bi. The *EAC* system has a single specificity related to sheep EACa. The *EAE* system contains two factors E6 and E18 and the EAF system is defined by a single specificity F19. The *EAR* system is defined by a single specificity R related to sheep R.

Pig

Development and expansion of pig blood groups resulted in large part from work carried out in Denmark, Germany, Poland, and Russia using alloantibodies that behaved as agglutinins and a few as hemolysins. The 16 genetic systems internationally recognized are summarized in Table 96.2.[66] Some of these systems, e.g., *EAE* and *EAM*, approach the *EAB* and *EAC* systems of cattle in complexity and allelic diversity. Blood group loci were mapped to pig chromosomes by linkage analysis.[90] The nomenclature of pig blood group factors followed that of the horse, except for the *EAA* system.

The *EAA* system is related to cattle *EAJ*, human A, and sheep *EAR* systems. Pig EAA-A and EAA-O factors are soluble substances in the serum and saliva of A-positive and O-positive animals, respectively, that attach to the RBC membrane a few weeks after birth. The genetic inheritance of A and O factors is similar to sheep *EAR* system. EAA^A is dominant to EAA^O and their expression on RBCs is controlled by the suppressor gene, *EAS*.

The EAA^A allele codes for uridine diphosphate *N*-acetylgalactosamine transferase that adds a terminal fucose residue to the H substance.[76] The recessive EAA^O allele corresponds to a large deletion that removes part of intron 7 and exon 8 of the gene and results in a non-functional enzyme product.[81,125] The *EAH* and *EAS* systems correspond to fucosyl-transferase 1 (*FUT1*) and fucosyl-transferase 2 (*FUT2*) that are involved in the production of the H substance and are related to human *H* (*FUT1*) and *secretor* (*FUT2*) genes.[25,76] Antigens of the

EAN system also occur as soluble substances in the serum and milk, but are not secreted into the saliva.

Llama and Alpaca

Little is known about blood group variation in the domestic South American camelids, llama and alpaca. From isoimmune and heteroimmune sera developed for these animals, six blood group factors were identified and given alphabetical designations in order of discovery: A, B, C, D, E, and F.[87] Factors A and B are inherited as codominant alleles and assigned to blood group system *EAA*. Factors C, D, E, and F were assigned to four separate systems, as they appeared to be transmitted independently from each other and from the *EAA* system. Blood groups in llamas and alpacas are detected by hemolytic tests.

Blood Transfusion

Clinically, knowledge of blood groups in cattle, sheep, goat, pig, and llama/alpaca has not affected conventional veterinary practice in transfusion. Large animals are not commonly transfused, and blood group matching is not practical because of the high variability between individuals and limited availability of donors. Blood transfusions in large animals are indicated for certain acute, life-threatening conditions and for plasma transfusion when failure of passive transfer occurs. Single, unmatched whole blood transfusions are generally safe and well-tolerated. A gross crossmatch, with hemolytic and/or agglutination tests according to species, is sufficient when repeated transfusions are required. Matching involves testing of the recipient's serum for antibodies against the RBCs of potential donors (major) and of the donors' sera for antibodies against the recipient's RBCs (minor) (see Chapter 107).

Pigs are often used as an animal model for organ or hematopoietic transplantation. Blood group compatibility is an important component of experimental protocols because of problems associated with immune-mediated tissue rejection or the need to provide transfusion support to patients.[95] In transplant experiments, mismatched transfusions for the *EAA* system result in adverse reactions that include disseminated intravascular coagulation, bleeding, and progressive hypotension[62,93] rather than typical hemolytic reactions seen in humans. Development of an efficient PCR-based DNA assay[23] allows accurate determination of EAA genotype for selection and matching of pigs for allotransplantation, and selection of EAA-O pigs in xenotransplantation experiments.

Horses merit special consideration because mares given a whole blood transfusion can be sensitized to blood group factors that may subsequently lead to NI problems for foals (see section in the following text). Selection of suitable donors that are negative for highly antigenic factors such as EAAa, and without antibodies in the serum, is recommended although currently not practical because very few laboratories can perform the serological test for blood group specificities. In the United States, horse blood typing service for veterinarians is

available through the Clinical Laboratory Services of the School of Veterinary Medicine, University of California, Davis, California. Mares that received a blood transfusion should always be screened for potential risk of NI prior to foaling.

A plasma transfusion in horses may fulfill the clinical requirements to restore fluid loss and replace necessary proteins when the RBC component is not compromised. Potential donors can be selected in a hematology laboratory by screening their sera against a RBC panel from 10 to 20 horses to identify those without antibodies against RBCs. Plasma can be collected and stored frozen to administer as needed.

Neonatal Isoerythrolysis in Horses

NI, or jaundice foal syndrome, is an acute hemolytic disease of newborn foals caused by immunologically mediated RBC destruction resulting from maternal–fetal blood group incompatibility. Affected foals are born healthy, but within 2–5 days develop signs of jaundice, lethargy, elevated pulse and respiration rates, and clinical evidence of anemia. NI foals are usually from the second or later pregnancies of a mare, but, on rare occasions, first foals can be affected. The antibodies that sensitize the RBCs of the foal are passively acquired from the dam's colostrum. Recovery may be spontaneous, or the disease may progress to severe anemia and death.

The most common antibodies involved in NI are anti-Aa and anti-Qa, although others are infrequently found. Not all mares negative for EAAa or EAQa factors become sensitized, although they may have produced Aa-positive or Qa-positive foals. One source of sensitization is whole blood transfusion, but this accounts for only a small number of cases. Mares negative for both Aa and Ca factors may be protected from sensitization to Aa by naturally produced anti-Ca antibodies.[11] At present, no simple hypothesis explains why blood group sensitization occurs in only a few percent of mares at risk.

A serum sample taken about 1–3 weeks before a pregnant mare is due to foal can be screened for evidence of blood group incompatibility. If test results are positive for hemolytic activity, it is strongly advised to withhold the foal from its dam's colostrum for 36–48 hours before putting it back to its dam's milk. An alternative colostrum and milk source must be provided to the foal during that period. Appropriate management for a severely anemic NI foal may be a RBC transfusion to alleviate the anemia and prevent death (see chapter 37).

Neonatal Isoerythrolysis in Mule Foals

Mule breeders are keenly aware that mares bred to jacks (male donkeys) can become sensitized to blood group factors of asses.[114] Monitoring of a pregnant mare's serum for antibodies against the RBCs of the jack to which she is bred is a prudent precaution to identify mule neonates at risk for NI.

CHAPTER 97

Granulocyte and Platelet Antigens

JENNIFER S. THOMAS

Granulocyte Antigens
- Laboratory Techniques to Identify Neutrophil Antigens and Antigen–Antibody Interactions
- Clinical Disorders Associated with Neutrophil Antigens

Platelet Antigens
- Laboratory Techniques to Identify Platelet Antigens and Antigen–Antibody Interactions
- Clinical Disorders Associated with Platelet Antigens

Acronyms and Abbreviations

CD, cluster differentiation; CTL2, choline transporter-like protein 2; EDTA, ethylenediaminetetraacetic acid; GP, glycoprotein; HLA, human leukocyte antigen; HNA, human neutrophil antigen; HPA, human platelet antigen; IMN, immune-mediated neutropenia; IMT, immune-mediated thrombocytopenia; LFA-1, leukocyte function antigen-1; PCR, polymerase chain reaction; TRALI, transfusion-related acute lung injury.

Cell surface antigens on granulocytes and platelets play a role in recognition of self. Antigens vary in their ability to stimulate an immune response and, therefore, in their association with immunologic disorders. Exposure to an antigen during pregnancy, after transfusion or following transplantation, causes immune response if given to individuals that lack the antigen.[58] Immune-mediated destruction of platelets and neutrophils is implicated in a variety of disorders.[58] Much of published research has focused on the role of platelet and granulocyte antigens in immunologic disorders; however, antigen identification is also used as a marker of disease and antigens may play a role in a variety of disorders including infections, neoplasia, and cardiovascular disease.[63] In veterinary medicine, platelet or granulocyte antigens are identified to characterize myeloproliferative disorders, and expression of certain antigens is used to determine cellular activation or function.[64]

Immune responses targeting granulocyte or platelet antigens have been implicated in the pathogenesis of primary (autoimmune or idiopathic) and secondary immune-mediated neutropenia (IMN) or immune-mediated thrombocytopenia (IMT), neonatal alloimmune neutropenia or thrombocytopenia, and transfusion reactions.[10,39,40,47] Binding of antibodies to cell antigens may cause dysfunction of the target cells.[8,27] Immunologic disorders resembling those listed in the earlier text have been identified in veterinary species; however, the pathogenesis of these conditions is better characterized in people because transfusion therapy and neonatal cytopenias are more common.[47] Most of the information provided in this chapter is based upon current understanding of the role of platelet and granulocyte antigens in people. Whenever possible, comparisons between humans and veterinary species are presented.

Platelet or granulocyte antigens can be specific to one cell type, shared by other blood cells, or widely distributed on systemic cells. Antigens are generally classified based upon their biochemical nature into glycolipids, glycoproteins (GPs), or proteins.[40] The roles of some of these antigens in normal cellular function are known. The molecular structures of many antigens have been characterized in people, allowing development of molecular techniques to detect alterations in the nucleic acid structure of the genes encoding the antigens.

Antigens with variable structures that are present in some, but not all, individuals in a species are termed alloantigens. Alloantigens are the products of polymorphic genes. Most granulocyte and platelet alloantigens

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

have been linked to single-nucleotide polymorphisms that cause a change in a single amino acid on a protein structure on the cell membrane.[58] The prevalence of the different alloantigens in people varies significantly between ethnic groups.[8,40] It is likely that similar differences exist in the expression of alloantigens among different breeds and species of animals.[47]

Alloantibodies are antibodies directed against alloantigens. Alloantibodies form when an individual receives a blood product that contains an alloantigen not present on self-cells or when there is incompatibility between fetal and maternal blood cells. Isoantibodies are antibodies that target a nonpolymorphic antigen found on the cells of the vast majority of normal individuals in a species. Isoantibodies usually form when an individual who has an inherited deficiency of an antigen is transfused with blood products from a normal individual.[47]

Antibodies that target self-antigens are termed autoantibodies. The production of autoantibodies may be idiopathic or may be secondary to an underlying disorder.[10,53,66] Autoantibody production sometimes follows drug administration. In some cases, the drug or its metabolite must be present for antibody binding to occur. In other cases, the drug induces an antibody that persists after drug administration ceases.[3]

GRANULOCYTE ANTIGENS

Granulocytes include neutrophils, eosinophils, and basophils. Neutrophils are present in highest concentrations in the blood and are most commonly implicated in immunologic disorders.[47] In people, immunologic disorders are associated with antigens in the human leukocyte antigen (HLA) system or the human neutrophil antigen (HNA) system.[17,55,58]

HLA antigens are widespread in distribution and found on many different cell types. HNA antigens are predominantly expressed on neutrophils (Table 97.1), but some are found on other cell types.[17] Because neutrophil antigens exhibit polymorphism, there are a variety of alloantigens. Currently 11 antigens have been characterized and are divided into five systems (HNA-1–HNA-5).[17,58] HNA-1 antigens are found on FcγRIIIb (cluster differentiation (CD)16b), a low-affinity receptor for the Fc portion of immunoglobulins. The HNA-1 system contains four identified alloantigens (HNA-1a, HNA-1b, HNA-1c, and HNA-1d).[17,58] The HNA-2 antigen is found on a 56–64-kDa GP (CD177) that is involved in adhesion to endothelial cells and neutrophil transmigration through the endothelium into the extravascular space.[17] The HNA-3 antigens are found on the choline transporter-like protein 2 (CTL2), a 68–72-kDa transmembrane protein. The HNA-3 system contains two alloantigens, HNA-3a and HNA-3b.[17,58] The HNA-4 antigens are located on the CD11b/α_M-subunit of the CD11b/CD18 complex (Mac-1, CR3), a β_2-integrin that plays a role in adhesion to endothelial cells, transmigration, phagocytosis, and cell-mediated toxicity.[17] Two alloantigens (HNA-4a and HNA-4b) have been identified.[17,58] The HNA-5 antigen system contains two antigens, HLA-5a and HLA-5b. It is found on the α_L-subunit (CD11a) of the CD11a/CD18 complex (leukocyte function antigen-1 [LFA-1]), a β_2-integrin involved in adhesion to endothelial cells.[8,17,55,58]

Some of the GPs in the HNA systems have been identified on neutrophils of domestic mammals using monoclonal antibodies. The relationship between the antigens recognized by these antibodies and the antigens associated with immunologic disorders is not currently known.[47] Antibodies to CD11a and CD11b bind to bovine neutrophils.[22,52] Antibodies to CD11a recognize antigens on neutrophils from dogs, horses, sheep, goats, and rabbits.[6,29,31,46,57] Antibodies to CD11b bind to neutrophils from cats, dogs, sheep, goats, and pigs.[6,46] Anti-CD16 antibodies bind to canine neutrophils.[31,57]

TABLE 97.1 Human neutrophil antigens and associated disorders.

Antigen location	CD designation	Antigen system	Clinical conditions in people associated with antibody–antigen interactions
FcγRIIIb	CD16b	HNA-1	Neonatal alloimmune neutropenia, primary immune-mediated neutropenia, TRALI*, drug-induced neutropenia
56-64-kDa GP	CD177	HNA-2	Primary immune-mediated neutropenia, drug-dependent neutropenia, TRALI
Choline transporter-like protein 2	Undefined	HNA-3	Neonatal alloimmune neutropenia, TRALI, febrile transfusion reaction
MAC-1; CR3	CD11b	HNA-4	Neonatal alloimmune neutropenia, primary immune-mediated neutropenia
LFA-1	CD11a	HNA-5	Unknown

*TRALI = transfusion-related acute lung injury.

Laboratory Techniques to Identify Neutrophil Antigens and Antigen–Antibody Interactions

Identification of neutrophil antigens or antineutrophil antibodies has traditionally relied on agglutination or immunofluorescence assays.[54,55] Monoclonal-antibody capture assays have been developed to detect antibodies to specific human neutrophil antigens.[54] Genotyping assays using PCR techniques are replacing agglutination or immunofluorescence assays in people for immunophenotyping neutrophils,[55] and several commercial kits are available for HNA-1, HNA-3, HNA-4, and HNA-5 antigens.[58] Similar assays are not readily available for veterinary species.

Flow cytometry is used to phenotype neutrophils in people and animals,[46,52,54,55,64] but is limited by availability of monoclonal antibodies that specifically target antigens of interest. Flow cytometry has been used to identify antineutrophil antibodies in animals, but specific target antigens have not been identified and the diagnostic usefulness has been questioned.[61,64]

Clinical Disorders Associated with Neutrophil Antigens

In people, clinical conditions associated with alloantibody interactions include neonatal immune neutropenia, transfusion-related acute lung injury (TRALI), alloimmune neutropenia after bone marrow transplantation, refractoriness to granulocyte transfusions, and febrile transfusion reactions.[8,10,17,55] Febrile transfusion reactions occur when the recipient has alloantibodies directed against antigens present on the donor leukocytes. TRALI occurs when alloantibodies to HLA antigens or neutrophil specific antigens cause neutrophils to become entrapped in the pulmonary vasculature.[55] Binding of alloantibodies to neutrophil antigens causes functional defects such as impaired adhesion and altered respiratory burst.[8,45]

Disorders associated with alloantibody production are not commonly recognized in veterinary species. Neonatal neutropenia rarely occurs in pigs and foals when the dam was previously exposed to paternal antigens on the fetal neutrophils and produces alloantibodies that are passed to the fetus in utero or to the neonate following ingestion of colostrum.[12,33] Febrile reactions in dogs following transfusion of platelet concentrates have been associated with leukocyte contamination.[1]

In people, autoantibody production is implicated in the pathogenesis of primary IMN, secondary IMN, drug-dependent neutropenia, and autoimmune neutropenia after bone marrow transplantation.[2,8,17] The cause of the autoantibody production is unknown in primary IMN. Studies in people have implicated antibodies targeting FcγRIIIb in many patients.[2,10] Secondary IMN is often multifactorial and is associated with systemic immune-mediated disorders (e.g., systemic lupus erythematosus), immunologic disorders, infectious diseases, malignant neoplasia, transplantation, and drug therapy.[2,10] The antigenic target in secondary IMN is often unknown, but antibodies targeting FcγRIIIb antigens have often been identified.[2] Antibodies bind to antigens on neutrophils and lead to premature neutrophil removal by macrophages. In some cases, autoantibodies target antigens on hematopoietic precursor cells in the bone marrow resulting in myeloid hypoplasia. Patients may also have defective neutrophil phagocytosis as well as concurrent thrombocytopenia or hemolytic anemia. Diagnosis often relies on identification of anti-neutrophil antibodies using agglutination, antigen-specific ELISA, immunofluorescence, or flow cytometric assays.[2,10,23,61]

IMN is infrequently reported in veterinary species.[7,14] Antibodies generally target antigens on circulating neutrophils, but bone-marrow-directed immune response causing white cell aplasia has been reported.[62] IMN is suspected when an animal has unexplained neutropenia that is responsive to immunosuppressive drugs. Identification of antineutrophil antibodies is supportive, but diagnostic assays required to detect these antibodies have limited availability and diagnosis is often made by exclusion.[14] Antineutrophil antibodies have been identified in dogs with IMN, but specific target antigens have not been identified.[59,61] Drug-associated neutropenia due to immune responses is infrequently reported. Antineutrophil antibodies have been identified in neutropenic dogs receiving cephalosporin.[4]

Antibodies to neutrophil isoantigens have been identified in human neonates born to mothers who had neutrophils deficient in FcγRIIIb.[19] Although not reported, a similar disorder is possible in dogs or cattle with leukocyte adhesion deficiency syndrome, a deficiency of membrane CD11/CD18 complex.[47]

PLATELET ANTIGENS

In people, platelet membrane surface antigens that play a role in immunologic disorders include those in the HLA system, ABO blood type antigens, and the human platelet antigen (HPA) systems (see Table 97.2).[11,20] HPA antigens are found predominantly on platelets, though some are expressed on other blood cells.[40] There are currently 35 identified HPA antigens[63] that are located on six platelet membrane GPs: $GP\alpha_{IIb}$ (IIb, CD41), $GP\beta_3$ (IIIa, CD61), GPIa (α2, CD49b), $GPIb_{\alpha}$ (CD42b), $GPIb_{\beta}$ (CD42c), and CD109.[11,20,39,40,63] The majority of HPA antigens are found on $GP\alpha_{IIb}$ or $GP\beta_3$.[11,20] Twelve of the antigens are located in six biallelic systems (HPA-1, HPA-2, HPA-3, HPA-4, HPA-5, HPA-15). Most result from a single-amino-acid substitution resulting from a single-nucleotide change. The frequency of the different alloantigens varies in different ethnic populations.[39,40] A total of 28 systems have been identified.[20]

$GP\alpha_{IIb}\beta_3$ is an integrin that is critical for platelet aggregation. Following activation, $GP\alpha_{IIb}\beta_3$ undergoes a conformation change that allows binding to adhesive proteins such as fibrinogen. Glanzmann's thrombasthenia, an inherited or acquired functional or physical deficiency of $GP\alpha_{IIb}\beta_3$, causes a bleeding disorder in people, dogs, and horses.[21] GPIa forms a complex with GPIIa(β_1) to act as a collagen receptor to participate in adhesion

TABLE 97.2 Human platelet antigens and associated disorders.

Antigen location site	CD designation	Human antigen systems	Clinical conditions associated in people with antibody–antigen interactions
$GP\beta_3$ (IIIa)	CD61	HPA-1, HPA-4, HPA-6, HPA-7, HPA-8, HPA-10, HPA-11, HPA-14, HPA-16, HPA-17, HPA-19, HPA-21, HPA-23, HPA-26	Neonatal alloimmune thrombocytopenia; post-transfusion purpura; primary IMT*
$GPIb_\alpha$	CD42b	HPA-2	Primary IMT
$GP\alpha_{IIb}$ (IIb)	CD41	HPA-3, HPA-9, HPA-20, HPA-22, HPA-24, HPA-27, HPA-28	Neonatal alloimmune thrombocytopenia; post-transfusion purpura; primary IMT
GPIa	CD49b	HPA-5, HPA-13, HPA-18, HPA-25	Neonatal alloimmune thrombocytopenia; post-transfusion purpura; primary IMT
$GPIb_\beta$	CD42c	HPA-12	Primary IMT
CD109	CD109	HPA-15	Neonatal alloimmune thrombocytopenia; post-transfusion purpura; refractoriness to transfusion

* IMT = immune-mediated thrombocytopenia.
Sources: Curtis and McFarland[11]; Hayashi and Hirayama.[20]

and signaling for activation of $GP\alpha_{IIb}\beta_3$.[20] $GPIb_\alpha$ and $GPIb_\beta$ covalently bind and associate with GPIX and GPV to form a complex that plays an important role in platelet adhesion to the vessel wall. A functional or physical deficiency of GPIb/GPIX/GPV, termed Bernard-Soulier syndrome, is found in people and is associated with thrombocytopenia, giant platelets, and functional defects.[20] The role of CD109 is not clear. It is detected on activated platelets and may be involved in cell binding to substrates and intercellular communication.[20]

Major platelet GPs appear to be conserved between the species, suggesting systems similar to those in people are likely in domestic mammals. Canine $GPIb_\alpha$ was cloned and is 82% identical with the human sequence in the carboxyl terminus.[24] The nucleotide sequence of canine $GP\beta_3$ is 92% homologous with the human sequence.[34] The amino acid sequence of canine $GP\alpha_{IIb}$ has 83% identity with the human peptide.[9] Monoclonal antibodies are used to identify platelet antigens in a number of species. The association between antigens recognized by the monoclonal antibodies and disease is not known. Monoclonal antibodies to CD41 ($GP\alpha_{IIb}$), CD42a (GPIX), and CD61 ($GP\beta_3$) bind to canine and equine platelets.[35,46] Monoclonal antibodies to CD41/CD61 ($GP\alpha_{IIb}\beta_3$) bind to bovine, porcine, and equine platelets.[35,41,49] Monoclonal antibodies to CD61a and CD62P (P-selectin) bind to bovine platelets.[52] Monoclonal antibodies to GPIb react with feline platelets.[56]

The number of different alloantigens associated with the major platelet antigens and their role in immunologic disorders in veterinary species is unknown.[5,9,34,37] In dogs, sequencing of the genes that encode $GP\beta_3$, $GP\alpha_{IIb}$, and $GPIb_\beta$ identified four single-nucleotide polymorphisms that resulted in amino acid substitutions in the gene encoding GPIIb and the identification of five protein isoforms. No association between breed and the development of thrombocytopenia was identified.[9] In a limited number of horses, sequencing of the genes that encode $GP\beta_3$, $GP\alpha_{IIb}$, GPIa, and $GPIb_\alpha$ identified several nucleotide polymorphisms that resulted in amino acid substitutions.[5]

Laboratory Techniques to Identify Platelet Antigens and Antigen–Antibody Interactions

Platelets are commonly typed in people for purposes of platelet transfusion and as part of a diagnostic workup for suspected immune platelet disorders. Genotyping using a variety of molecular techniques has become standard practice in human medicine to identify platelet antigens and high throughput assays are available.[11,16,58] Advantages include independence from availability of antibodies for typing, capacity to test for large numbers of antigens, and ability to extract DNA from leukocytes or from cell-free material plasma for fetal testing. Serologic phenotyping is still offered, but is more labor-intensive and limited by the availability of reliable antibodies.[16,39,58] Flow cytometry is used in human and veterinary medicine for serologic phenotyping.[16,64]

No single test has proven sufficient to detect antiplatelet antibodies in people.[51] A range of techniques including immunofluorescence, flow cytometry, ELISAs, and immunoradiometric methods have been used to detect antiplatelet antibodies, but testing in veterinary species is not commonly performed.[25,27,30,47,48]

Clinical Disorders Associated with Platelet Antigens

Clinical disorders related to platelet alloantigens are usually associated with the ability of antigens to induce an immune response; however, polymorphisms in the platelet receptors that occur with the different alloantigens may also alter function.[39] Studies suggest that some HPA alloantigens are associated with increased platelet

reactivity and increased risk for coronary heart disease and stroke, metastasis of certain neoplasms, and response to some infections.[63]

The binding of autoantibodies and alloantibodies to platelet membrane GPs often causes platelet destruction and thrombocytopenia. These antibodies may also cause platelet inhibition and increased risk for bleeding or platelet activation and increased risk for thrombotic disorders. Functional defects may be present independent of any associated thrombocytopenia.[13] One study suggested that platelets from dogs with IMT have impaired platelet function due to circulating antibodies.[28] Platelet aggregation was inhibited in mule foals with neonatal alloimmune thrombocytopenia, possibly due to alloantibody competition with collagen-binding sites.[43]

In people, disorders associated with alloantibody production include fetal/neonatal alloimmune thrombocytopenia, post-transfusion purpura, and refractoriness to platelet transfusions.[20,40,44] Neonatal alloimmune thrombocytopenia occurs when a mother produces alloantibodies against a paternal alloantigen expressed on fetal platelets. The majority of cases are associated with an alloantibody against fetal $GP\beta_3$ (HPA-1a). Alloantibodies against fetal GPIa (HPA-5a), CD109 (HPA-15b), or $GP\alpha_{IIb}$ (HPA-3a) are less commonly implicated.[44] Neonatal alloimmune thrombocytopenia has been described in pigs, horses, and mules.[18,42,43] The specific target alloantigen was not identified.

Post-transfusion purpura is a rare condition that occurs 5–12 days after an individual receives a blood transfusion. It is most common in HPA-1a-negative women who have been sensitized by prior transfusion or pregnancy. Other platelet-specific antigens or HLA antigens have been less frequently implicated. The immune response causes the destruction of the individual's own platelets as well as the transfused platelets.[40] Post-transfusion purpura has been described in dogs and pigs; however, an association with a specific alloantigen has not been identified.[32,60]

Platelet refractoriness occurs in people who receive multiple platelet transfusions. These individuals produce alloantibodies that result in shortened survival of transfused platelets. Anti-HLA antibodies are most commonly implicated; however, anti-HPA antibodies are found in a minority of individuals.[40] Platelet refractoriness has been experimentally reproduced in dogs.[50]

IMT occurs when antibodies bind to platelet antigens and cause premature destruction of platelets by the mononuclear phagocytic system or lysis in a complement-dependent manner.[26,66] Studies also implicate direct T-cell-mediated cytotoxicity and impaired megakaryopoiesis and thrombopoiesis in the pathogenesis of thrombocytopenia.[53] In people, target antigens are most commonly located on $GP\alpha_{IIb}\beta_3$.[66] Other targets include specific regions on GPIb/GPIX, GPIV, and $GP\alpha_2\beta_1$.[26] Antibodies to multiple antigens are found in many patients.[53]

Cryptic epitopes, particularly involving $GP\alpha_{IIb}\beta_3$, have been implicated in both initiation and perpetuation of thrombocytopenia in patients with IMT.[66] These epitopes are normally hidden, but may become exposed and initiate an immune reaction following an insult such as an infection. Exposure of cryptic antigens is also involved in EDTA-dependent thrombocytopenia in people. EDTA binds calcium, causing a conformational change in $GP\alpha_{IIb}\beta_3$ and exposing normally hidden epitopes which bind to circulating antibodies. EDTA-dependent pseudothrombocytopenia has been rarely reported in dogs, horses, and pigs. The underlying mechanism in these veterinary species has yet to be determined.[65]

IMT is commonly diagnosed in dogs and sporadically identified in other veterinary species (see Chapter 80).[15,48] In primary IMT, the immune response is directed against autoantigens and an underlying disease is not identified. In secondary IMT, the immune response is associated with an underlying disorder (e.g., systemic immune-mediated disease, infection, neoplasia). The antibodies can be directed against either autoantigens, foreign antigens absorbed to platelet membranes, or altered platelet antigens. Platelet-surface-associated antibodies (PSAIg) have been demonstrated in dogs, cats, and horses with IMT.[15,25,27,30,38,48] In most cases, the target antigens are not identified. $GP\alpha_{IIb}\beta_3$ and GPIb were identified as target antigens in some dogs with a clinical diagnosis of primary IMT.[30]

Isoantibodies have been detected in people with an inherited deficiency of platelet membrane antigens. People with a deficiency of $GP\alpha_{IIb}\beta_3$ produce isoantibodies following transfusion of platelets from normal individuals.[36] The isoantibodies appear to target epitopes on β_3 or intact $\alpha_{IIb}\beta_3$, leading to inhibited function and rapid removal of transfused platelets. Although not reported, similar responses could occur in animals with inherited membrane GP deficiencies.[47]

ACD, acid-citrate-dextrose; APS, anticoagulant–preservative solution; AS, additive solution; CPDA-1, citrate-phosphate-dextrose-adenine-1; DPG, 2,3-diphosphoglycerate; EBV, estimated blood volume; FeLV, feline leukemia virus; FFP, fresh frozen plasma; FP, frozen plasma; FWB, fresh whole blood; Hgb, hemoglobin; MAP, mean arterial pressure; PAGGGM, phosphate-adenine-glucose-guanosine-gluconate-mannitol; PCV, packed cell volume; pRBCs, packed red blood cells; PC, platelet concentrate; PRP, platelet-rich plasma; RBC, red blood cell; RT, room temperature; SAGM, saline-adenine-glucose-mannitol; WB, whole blood; WBC, white blood cell.

BLOOD BANKING—INTRODUCTION

The advent of large-scale veterinary blood banks has made the practice of high-quality transfusion medicine possible by increasing availability of blood components. Strict adherence to blood collection, processing, and storage guidelines is essential to providing safe and effective transfusions. This chapter details the currently accepted blend of human protocol and veterinary modifications where necessary for the collection, processing, and storage of canine and feline blood components.

DONOR CONSIDERATIONS

Canine

Veterinary blood banks currently use resident dogs, client-owned dogs, or a combination of the two to meet supply demands. Because human blood packs are used for collection, a donation has historically been one unit of blood (450 ± 45 mL), which was the human standard. In some countries, including the USA, some 450 mL packs are no longer available, necessitating the use of packs provided for a collection of 500 ± 50 mL.

Based on an estimated blood volume (EBV) of 85 mL/kg body weight[42] and a recommended collection volume of 15–22% EBV,[1,18] the maximum donation volume is approximately 19 mL/kg. In a study evaluating changes in systolic blood pressure in 19 Greyhounds (27–41 kg) after donating 450 mL blood, the mean systolic pressure dropped from 145 to 134 mmHg, not a clinically relevant decrease.[18] Recommended minimal donor body weight varies among veterinary blood banks from 24 to 27 kg, with dogs of this size able to donate a 450–500 mL unit as often as every 3–4 weeks on a short-term basis.[1,66] Donor blood-type considerations are discussed in Chapters 96, 97, 99–101, and 104.

For the safety of both donor and recipient, the health of a dog is evaluated prior to enrollment as a donor and then annually through a complete medical history, physical examination, and laboratory evaluation including a hemogram, serum biochemistry profile, and infectious disease screening. In addition, a brief history, physical examination, and measurement of PCV or hemoglobin (Hgb) concentration are performed prior to each donation; donor PCV or Hgb concentration should be at least 40% or 13 g/dL, respectively. Donors should be current on vaccinations and maintained on regionally appropriate parasite prophylaxis. Most other drugs are unacceptable for use during the donation period because of unknown effects on blood quality and potential for adverse reactions in the recipient.

Minimal and optimal screening for infectious diseases are detailed in the American College of Veterinary Internal Medicine Consensus Statement[86] and elsewhere.[21] Briefly and considering endemic diseases, blood donor candidates should be negative for infectious diseases including *Anaplasma spp*., *Babesia canis* and *Babesia gibsoni*, *Bartonella henselae* and *Bartonella vinsonii*, *Ehrlichia canis*, and *Mycoplasma haemocanis*. Screening for other *Babesia* and *Bartonella spp*.; *Brucella canis*; other *Ehrlichia spp*.; *Hepatozoon spp*.; *Leishmania donovani*; *Mycoplasma haematoparvum*; *Neorickettsia risticii*; *Rickettsia felis*; and *Trypanosoma cruzi* should be considered depending on region. Exclusion from a blood donor program does not imply that the animal should be treated for the disease. Iron supplementation in canine blood donors is not a common practice,[1,41] although frequent blood donation (e.g., 13% EBV every 2 months, or more frequently) and long-term donation can result in iron deficiency.[27,29,95] Donation intervals should be considered in light of these findings.

Prior transfusion is an exclusion criterion for dogs to become blood donors. Following a transfusion, dogs may develop antibodies against foreign RBC antigens, resulting in an increased risk of incompatibility reactions to their plasma. Previous pregnancy had long been considered an exclusion criterion in the event that a dog negative for a specific RBC antigen became sensitized by her pups positive for that antigen. This risk is minimal considering zonal placentation of dogs, and there is little evidence to support this exclusion.[7]

Feline

Because cats have typically been sedated/anesthetized for blood collection, most blood banks have relied on resident or fostered cats. The EBV of cats varies with the reference, ranging from 40 to 60 mL/kg in the anesthetized cat,[33] to as high as 67 mL/kg.[80] Donation volume should be calculated based on lean body weight; recommendations for maximum donation range from 11 to 15 mL/kg, and standard volumes collected (including anticoagulant) range from 45 to 70 mL.[1,34,38,39] Because of sedation and blood volume collected, hypotension during donation is a major consideration, especially given the emerging concept that cumulative episodes of subclinical acute kidney injury contribute to chronic kidney disease.[19] Further details regarding sedation and hypotension are provided in the following text in the "Preparation and Collection of Whole Blood" section. Supplemental iron can be given, but is not a common practice.[1,41] Assuming a similar mean concentration of 0.5 mg iron/mL blood in cats as in humans, a 60 mL donation represents a loss of 30 mg of iron. This may be replaced with 150 mg oral ferrous sulfate, typically divided into several doses in between donations and adjusted based on predonation PCV.

Initial and predonation health assessment and health maintenance are similar to canine donors.[63] Because cats may have subclinical heart disease, thorough cardiac auscultation should be performed prior to each donation and periodic screening by echocardiography and pro-brain natriuretic peptide should be considered. Donor PCV or Hgb concentration should be at least 30% or 10 g/dL, respectively. Feline donors should be kept indoors and be given parasite prophylaxis to minimize the risk of infectious disease transmission and maintain optimal health. Similar to dogs, minimal and optimal infectious disease screening recommendations are outlined in published guidelines.[50,63,86] Briefly, cats should be negative for *Anaplasma phagocytophilum*, *Bartonella spp*., feline leukemia virus (FeLV), feline immunodeficiency virus, and hemotropic *Mycoplasma spp*. Due to the possibility of regressive FeLV infection being transmitted via blood transfusion,[59] updated guidelines recommend FeLV provirus PCR testing in addition to, or in lieu of, antigen testing.[50,59,63,86] Screening for *Cytauxzoon felis* and rickettsial diseases may be considered based on exposure risk. As with dogs, exclusion from a blood donor program does not imply that the cat should be treated for the disease. In addition, one must consider the potential ramifications of false positive results for feline retroviral infections, especially unwarranted euthanasia.

BLOOD COLLECTION PRINCIPLES

Blood is usually collected as whole blood (WB) and then separated into components by centrifugation. Alternatively, single components may be collected by apheresis (see Chapter 101). For optimal quality, WB should be collected into commercially available, sterile, airtight systems that allow for subsequent processing and storage of components without exposure to the environment. These systems, known as closed systems, prevent exposure of blood components to air except when the component unit is entered with an

administration set for transfusion. Conversely, an open system has one or more additional sites of entry and possible bacterial contamination, such as occurs when preparing for blood collection into syringes or bags into which anticoagulant is added after manufacture. Components prepared from blood collected into an open system are not intended for storage. If an open collection system is used, the American Association of Blood Banks and European Directorate for the Quality of Medicines advise that RBC components (stored at 1–6 °C) should be used within 24 hours and platelet components (stored at 20–24 °C) should be used within 4 hours.[26,30] The shelf-life of plasma from an open system is unaffected if it is frozen within 8 hours.[26,30] In veterinary medicine, current standard canine and feline donations use closed and open systems, respectively, but the feline components are stored similarly to the canine ones. Detailed illustrated methods of blood collection and processing have been previously described and will be summarized here.[1,2,43,49,72,92]

BLOOD COLLECTION SUPPLIES

Canine

Commercial 450–500 mL collection bags manufactured for human blood banking are used for canine donations. These contain an anticoagulant–preservative solution (APS) and a sterile collection line with a 16-gauge thin-walled needle attached to the bag. The bags are available in a variety of configurations consisting of a primary collection bag with attached satellite bags (0–4). These satellite bags, some of which may contain RBC nutrient additive solutions (AS), are used for the separation of components as discussed later. After centrifugation and removal of plasma from the main collection bag, the nutrient AS is added to the packed red blood cells (pRBCs). Various AS are composed of saline, adenine, and dextrose ± mannitol ± citrate–citric acid, and are intended to extend the shelf-life of stored pRBCs (see Storage – "Red Blood Cell Components" section and Chapter 99).

Collection bags are available in a variety of other sizes (150 mL, 250 mL, and 350 mL) and contain the appropriate amount of APS and AS. Another option for collection of <450–500 mL WB is to transfer the unwanted portion of the APS from the primary bag of a 450–500 mL pack into an empty satellite bag, which is later discarded. This allows collection of proportionately smaller units in a closed system without excessive concentration of anticoagulant; the desired ratio of APS to blood is 1.4:10.[30]

Feline

The closed collection systems used in dogs have been used in cats, although some find the large needle unwieldy.[1] A closed collection system using a 21-gauge needle and citrate-phosphate-dextrose-adenine-1 (CPDA-1) designed specifically for feline blood donation has recently become commercially available (TEC 724 Kit, Futurlab Srl, Limena, Padova, Italy).[22] A feline closed collection system has also been prepared by sterilely docking a collection needle to a 75 mL pediatric transfer pack (Pedi-Pak, Genesis BPS, Hackensack, NJ) containing APS using a commercial sterile tubing welder (Terumo BCT or Genesis BPS).[81] However, most blood collection systems currently in use for cats are open using a 19- or 21-gauge butterfly needle attached to a syringe or collection bag. These systems include: (1) collection into syringes for prompt transfusion of WB; (2) commercial 100 mL bags and collection tubing with attached butterfly needle for gravity collection; (3) attached three-way stopcock, 60 mL syringe, and butterfly needle for syringe collection and subsequent transfer to bag (Animal Blood Resources International, Stockbridge, MI); and (4) collection into syringes (preferably 35 or 60 mL) and then careful injection (to avoid hemolysis) into a transfer pack, either 75 mL (Pedi-Pak) or 150 mL (Fenwal). If an open system for cats is used, care must be taken to maintain sterility where possible, especially if the blood or blood components are to be stored.[22] Periodic culture of stored bags is recommended. The APS used most often are CPDA-1 at an APS:blood ratio of 1:7 (e.g., 7.5 mL CPDA-1 + 52.5 mL blood = final volume 60 mL) or acid-citrate-dextrose (ACD)-A at an APS:blood ratio of 1:6.4–6.5 (e.g., 7 mL ACD-A + 45 mL blood = final volume 52 mL; 8 mL ACD-A + 52 mL blood = final volume 60 mL). As with dogs, pRBCs may be prepared and an AS added.

PREPARATION AND COLLECTION OF WHOLE BLOOD

Canine

A full unit contains 450–500 mL of WB, but 10% variation (405–495 mL, 450–550 mL, respectively) is acceptable considering the volume of anticoagulant in the collection bag. The volume of collected blood is estimated by weight. The specific gravity of whole blood at 37 °C is 1.053, so in an ideal 450 mL unit the blood weighs 474 g and the acceptable range is 426–521 g, while in an ideal 500 mL unit the blood weighs 527 with a range of 474–579 g.[30,85] The minimum acceptable underdraw into a 450 mL or 500 mL bag for blood to be used to prepare pRBCs is 300 mL (316 g) or 333 mL (351 g), respectively, in which case the plasma is discarded as it contains excessive anticoagulant. Weight during collection may be determined by placing the bag on a scale or by using a blood collection mixer scale which automatically stops the collection at the desired weight (many brands are available).

Fasting prior to donation is not necessary. Postprandial lipemia is not problematic in most blood components and indeed is beneficial for preparing platelet-rich components.[5,70] The main exception is when pRBCs are resuspended in plasma rather than an AS, where lipemia in the plasma will cause hemolysis.[5] Most donors habituate to the procedure and do not require sedation. If sedation is required, butorphanol, 0.2–0.4 mg/kg IM, is

recommended. The jugular vein is the only recommended site for routine blood donation. The authors' choice of position for the donor is lateral recumbency on a table, but sternal recumbency or sitting on a table or floor may be better in some circumstances. The venipuncture site is clipped and surgically prepared.

Blood may be drawn into collection bags aided only by gravity and donor blood pressure, in which case the bag should be continuously and gently rocked by an assistant during collection, which typically takes 5–15 minutes (mean 6 minutes in one study[16]). Alternatively, light suction may be used, shortening collection time to 3–10 minutes (mean 4 minutes[16]). The blood collection bag is hung from a hook inside a clear cylinder with a flat lid (Animal Blood Resources International) such that the blood will be forced to pass through the APS. The collection line with attached needle is brought through a notch between the cylinder and lid, and a tube clamp is placed on the line near the needle. A vacuum source is connected via tubing to an inlet in the chamber. The cylinder is placed on a scale, the scale is tared to zero, and the suction is adjusted to −127 to −178 mmHg (−5 to −7 inches Hg).[43] With one hand, the phlebotomist puts gentle pressure on the jugular vein below the prepared skin site, and the needle held in the other hand is inserted through the prepared site into the donor's jugular vein in either direction. When the tubing clamp is removed, blood flows into the collection line to the bag as the scale measures the grams of blood collected. When the desired amount has been obtained, pressure is released from the jugular below the venipuncture site, the line is clamped, and the needle is removed from the vein as pressure is applied over the site.

During blood collection, the well-being of the donor should be continuously monitored. Mucous membrane color, pulse rate and strength, respiratory rate, and donor attitude are easily evaluated by the phlebotomist and assistant. Mild tachycardia is common. Monitoring of blood pressure and other parameters may be considered.[16,52,54] Any indication of donor compromise is cause for discontinuation of the collection.

Once the needle is removed from the donor, the blood in the tubing is stripped into the bag using a tube stripper, and the bag is gently rocked to ensuring adequate mixing. The bag is then manually compressed to refill the tubing, which is sealed (using hand sealer clips or a thermal sealer) at several points to provide small segments containing WB for quality and compatibility testing.

Feline

As noted in the earlier text, sedation/anesthesia is frequently used to enable blood collection from cats. Oral sedation with gabapentin and/or trazodone prior to transport of fostered donors to the clinic is frequently used at the authors' institution to decrease anxiety associated with transport and facilitate initial handling and further sedation. Reported drug protocols for collection include: ketamine and midazolam (ketamine 5–10 mg/kg + midazolam 0.2 mg/kg IM, or ketamine 2 mg/kg + midazolam 0.1 mg/kg IV), with or without butorphanol (0.2 mg/kg); tiletamine and zolazepam (2.5 mg/kg of each, IM); dexmedetomidine plus butorphanol (dexmedetomidine 10 μg/kg + butorphanol 0.2 mg/kg, IM); alfaxalone plus butorphanol (alfaxalone 2 mg/kg + butorphanol 0.2 mg/kg, IM); or sevoflurane by facemask.[1,2,4,22,24,32,38,39,45,49,51,71,79,84] Optimal sedation/anesthesia protocols will vary between institutions and individual donors. One study comparing alfaxalone plus butorphanol versus dexmedetomidine plus butorphanol revealed similar sedation, ease of blood collection, and recovery scores between the two protocols.[71] A recent study described only minor movement or anxiety-related concerns when using unsedated client-owned cats.[24] However, it is notable that 3 cats in the unsedated group experienced cardiovascular or respiratory distress, while none of the sedated cats exhibited these events.[24] Vascular access ports have also been evaluated for donation to avoid anesthesia.[4,57]

The cat is positioned in lateral (preferred by authors due to steadiness) or sternal recumbency, and the jugular venipuncture site surgically prepared. If a syringe or vacuum chamber is used, only gentle suction (−76 mmHg [−3 inches Hg]) is applied to avoid collapsing the vein or causing hemolysis. Blood collection is typically completed within 3–5 minutes. Careful monitoring, including blood pressure assessment, of the cat is essential because hypotension may be encountered despite all precautions. Studies have reported transient hypotension after collection of 50–55 mL blood in cats sedated with varying protocols. Cats did not show clinical signs related to hypotension in these studies.[4,39,45] Intravenous fluid therapy to treat hypotension was necessary in 84% of blood donors anesthetized with sevoflurane and 42% anesthetized with a combination of ketamine, butorphanol, and midazolam in one study; there was no significant difference in blood pressure between the groups.[45] In that same study, postprocedure hyperthermia and a longer return to normal behavior were noted in donors given ketamine, butorphanol, and midazolam.[45] Signs of hypotension or possibly vasovagal reactions were seen in another study of donation of unsedated cats.[24] Collection via vascular access ports also resulted in suspected vasovagal reactions in two lightly sedated cats from one study,[4] while in another study, 10 mL/kg blood collection from vascular access reports from awake cats did not result in clinical signs of hypotension.[57] A recent study showed that while donor cats sedated with alfaxalone plus butorphanol had a significantly decreased blood pressure following blood collection, no cats experienced hypotension.[32] In contrast to the abovementioned study, one study reported mild increases in oscillometric tail blood pressure readings in donor cats sedated with tiletamine and zolazepam, presumed due to, in part, the increase in sympathetic tone caused by these agents.[79] In the authors' experience, cats donating less than 11 mL/kg are less likely to have hypotension-related problems. Some blood banks routinely give donors intravenous and/or subcutaneous

saline at a total dose of one to three times the volume of blood drawn, while others only treat the donors if hypotension or signs of hypotension occur.

LEUKOREDUCTION

Leukoreduction (LR), or leukodepletion, is the process of removing residual WBC from transfusion components aimed at reducing transfusion-induced inflammatory responses.[10,11,13,55] Leukoreduction is usually performed prior to storage by passing blood through a leukoreduction filter at room temperature (RT), aided by gravity. Blood is typically refrigerated for approximately 4 hours prior to filtration to enhance leukoreduction,[10,11] but this may not be required with some newer filters and manufacturers should be consulted in this regard. Filters retain WBC using either selective pore sizes or adsorption membranes. Most filters also exclude platelets; a platelet-sparing filter is available.[75] The process removes >99.9% of WBC from the blood.[11] Subsequently, blood can be stored as whole blood or separated into components.

Prestorage leukoreduction has been shown to be effective in markedly reducing WBC counts in canine blood, and RBC viability is preserved following filtration.[11,55] In addition to removing WBC, leukoreduction is effective in attenuating the accumulation of bioactive substances in canine packed red cells.[17,31,35,58,74,94]

Leukoreduction has been shown to decrease some transfusion reactions in people, such as febrile nonhemolytic transfusion reactions and complications related to alloimmunization, and improve outcome in some patient subpopulations.[10] In veterinary medicine, leukoreduction has mainly been investigated in healthy dogs. Healthy dogs showed an inflammatory response following transfusion of autologous non-LR pRBCs, while LR pRBCs did not induce this same effect in one study.[55] However, leukoreduction did not mitigate post-transfusion inflammation in another study.[13] A prospective, blinded study of 23 clinically ill dogs receiving pRBC transfusions showed that most markers of inflammation were similar after transfusion of LR versus non-LR pRBCs and no changes in outcome were observed between the groups.[10] Clinical benefits of leukoreduction in veterinary medicine are currently unknown. Drawbacks of leukoreduction include increased processing time for blood components, cost of the filters, and loss of a small volume of blood component in the filter.

IRRADIATION, ULTRAVIOLET TREATMENT, AND PATHOGEN INACTIVATION OF BLOOD COMPONENTS

Irradiation, ultraviolet illumination, and photochemical treatment of blood components may be used to decrease alloimmunization, graft-versus-host disease, and pathogen contamination. These treatments of canine blood have been reported in research trials, but are not used clinically at this time.[60,67,94]

SEPARATION OF WHOLE BLOOD INTO COMPONENTS

A flowchart for the separation of fresh whole blood (FWB, less than 8 hours old) by centrifugation is presented in Figure 98.1. Separation requires a large-capacity, floor-model, swing-bucket, temperature-controlled centrifuge. If a centrifuge is not available, some components may be prepared by gravity separation.[1,48]

Canine Packed Red Blood Cells and Plasma

Standard separation of canine FWB into pRBCs and fresh plasma is begun by centrifugation of the blood bags at 5000 × *g* for 5 minutes at 4 °C. The centrifugation time includes acceleration time, but not deceleration time. To transfer the plasma to a satellite bag, the primary bag is placed in a plasma extractor, and the seal in the tubing of the primary bag is broken. The plasma extractor is slowly engaged and allowed to gently squeeze the primary bag, which expresses the plasma into the satellite bag. Plasma may be transferred entirely to one satellite bag or divided between two or three bags. Expression of plasma is stopped by clamping the tube. If the pRBCs are to be stored in CPDA-1 without an AS, the pRBCs must have a PCV ≤ 80%. This requires leaving ≥50 mL of plasma with the pRBCs, which may be accomplished by stopping the expression of plasma when the buffy coat/plasma interface is about 2 cm from the top of the bag. Once the plasma has been removed to one or more satellite bags, the AS is added to the pRBCs. The seal in the tubing to the AS bag is broken, and the solution is transferred into the primary bag by gravity and gently mixed. If desired, half of the pRBCs can then be transferred to an additional empty satellite bag if available to prepare half-units. The tubing attached to each component bag is then sealed.

Each bag of component is weighed, and the weight of the component calculated by subtracting the weight of the bag. Volumes of plasma and pRBCs at RT are then estimated by dividing by 1.026 and 1.056, respectively[85] (these values are for humans, and specific gravity varies with temperature, PCV, and protein concentration, but effects on volume estimates are clinically negligible). Each component bag is labeled as to component, blood type, donor, volume, and dates of collection and expiration.

Canine Platelet-Rich Plasma and Platelet Concentrate

Fresh whole blood can also be separated into platelet-rich plasma (PRP) and pRBCs. The FWB may be allowed to rest for 1 hour after collection to minimize platelet activation, and the bag should be gently massaged

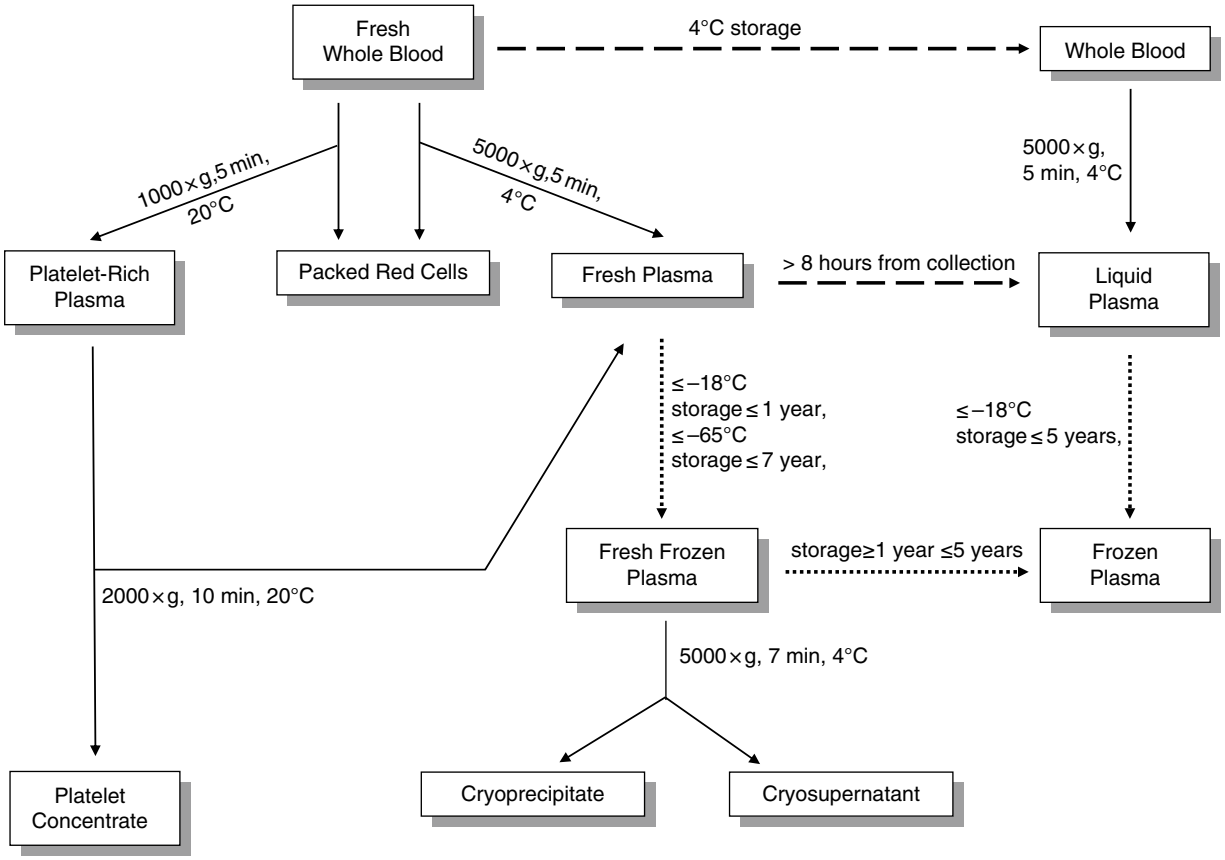

FIGURE 98.1 Flowchart for separation of canine fresh whole blood into components. Further preparation of the various plasma components is discussed in Chapter 100. (**Source:** Abrams-Ogg[1])

before centrifugation to resuspend platelets.[44] Centrifuge temperature should be set at 20–24 °C. Centrifugation to make PRP uses lighter gravitational forces than for standard separation of pRBCs and plasma, and isolates the platelets in the plasma above the buffy coat. When the PRP is expressed into the satellite bag, expression should be stopped when the RBC–plasma interface is 1 cm from the top of the bag to minimize leukocyte and RBC content of PRP while not sacrificing platelet yield.[14] One unit of FWB (450 ± 45 mL; 500 ± 50 mL) yields one unit of PRP.

Percent platelet yield (platelet count in PRP/platelet count in FWB × 100) and PRP platelet count vary with the donor, donor platelet count, blood volume being centrifuged, technician, centrifuge, and centrifugation protocol. In a study comparing protocols to make PRP from small volumes of canine blood, protocols with shorter centrifugation times and higher gravitational forces had better yields than protocols with longer times and lower forces.[15] Most current blood bank protocols use about 1000–1600 × *g* for 4–6 minutes or 2000 × *g* to 2500 × *g* for 2.5–3 minutes.[3,37,70] The brake on the centrifuge should be turned to a low setting or turned off. In the protocol used by the authors (1000 × *g* for 4 minutes), average yield from 450 mL FWB is about 80% (range 35–97%), resulting in a mean of 6×10^{10} platelets/unit (range 3×10^{10} to 10×10^{10} platelets/unit).[3] Donors with high normal platelet counts are preferred.[70] A second centrifugation of the FWB can be used to increase yield with Greyhounds which have low normal platelet counts (W. J. Dodds, personal communication).

Platelet concentrate (PC) may be prepared by centrifugation (2000 × *g* for 10 minutes) of PRP to pellet the platelets. The platelet-poor plasma (PPP) is expressed, leaving 35–70 mL of plasma and the platelet pellet behind in the satellite bag. The resulting PC is left undisturbed for 60–90 minutes to promote disaggregation. Gentle manual kneading and agitation are then used to disperse macroscopic leukocyte–platelet aggregates and resuspend the platelets. Adding prostaglandin E1 to the PRP prior to centrifugation reduces this aggregation and facilitates resuspension without reducing platelet function.[73] The PPP may be used as fresh plasma or fresh frozen plasma (FFP). One unit of PRP yields one unit of PC. Units of PC can be pooled via transfer tubing. The pooled units are centrifuged at 570 × *g* for 15 minutes and PPP is expressed, leaving behind 8–10 mL per unit pooled. Once pooled, the concentrate needs to rest for at least 15 minutes at room temperature (60 minutes preferred), prior to resuspension (K. J. Wardrop, personal communication).

The buffy coat method is an alternate method for producing PC and is used more than the PRP method for humans.[37,64] In a canine study, WB was centrifuged at 3000 × *g* for 11 minutes to push platelets into the buffy coat.[37] All but 30 mL of the PPP was transferred to a

satellite bag, and the remaining plasma, buffy coat, and 20 mL of the upper portion of RBCs transferred to another satellite bag and centrifuged at 1000 × *g* for 5 minutes to separate the platelets from WBCs. Platelet yield was similar to the PRP method, but the buffy coat method resulted in more WBC and RBC contamination. In human blood banks, buffy-coat-derived PC are typically pooled and leukoreduced prior to storage.

Feline Blood Components

Feline FWB is placed in one bag, and the tubing between this bag and an empty satellite bag is obstructed by folding and securing with a rubber band or a hand sealer clamp. Due to the relatively small volume of blood being separated, the collection/satellite bags may be bound (via rubber band or tape) to a 500 mL bag of saline to prevent the bags from collapsing during centrifugation. The blood bags are centrifuged at 3000 × *g* for 10 minutes at 4 °C, and separation is continued as for dogs. The pRBCs may be stored without addition of AS (in which case 10 mL 0.9% sodium chloride is added just prior to administration to the patient), or 10 mL AS may be added to pRBCs prior to storage.

Feline PRP is infrequently prepared due to a limited clinical need, as well as technical challenges; FWB is more likely to be administered to thrombocytopenic or thrombocytopathic cats with severe bleeding. However, preparation of feline PRP has been described, with the transfused platelets exhibiting in vivo efficacy.[15,20]

STORAGE

Red Blood Cell Components

Units of WB and pRBCs are stored at 1–6 °C with lower in the range preferred especially with longer storage times.[6] A refrigerator with an alarm to indicate unsafe temperatures is ideal. Alternatives include a regularly checked thermometer placed in a container of fluid the volume of a small unit, or use of HemoTemp II blood bag thermometer labels (Biosynergy, Elk Village, IL).

Red blood cell viability and function decrease during storage as a result of physical, morphologic, metabolic, and immunologic changes collectively known as the storage lesion, with potential to negatively impact the transfusion recipient.[61] Major cellular changes during storage include depletion of ATP and 2,3-diphosphoglycerate (DPG) and alteration of nitric oxide activity.[61,87,89,91] These changes can impact RBC oxygen delivery, although the significance of 2,3-DPG depletion is questionable, as it is restored following transfusion and does not play a primary role in feline hemoglobin–oxygen modification.[61]

The RBC morphological changes observed early in storage can be reversible following transfusion. Over time, however, changes become irreversible and RBC membranes begin to shed microparticles. Decreased RBC deformability leads to diminished circulation within smaller vessels and RBC adhesion to endothelium, impairing oxygen delivery.[34,61] The accumulating microparticles express negatively charged proteins such as phosphatidylserine and have procoagulant and pro-inflammatory properties.[35,53,76] Progressive hemolysis during storage releases free hemoglobin, heme, and iron into the supernatant.[9,28]

Extracellular changes include accumulation of ammonia, sodium, chloride, and lactate, while pH and glucose concentrations decline; potassium changes are variable over time and between species.[22,23,34,47,90] Some proinflammatory eicosanoids and cytokines have been documented to accumulate in stored blood components.[8,17,23,58,69,94]

The storage lesion impacts RBC shelf-life, which is defined as the number of days after collection, assuming proper closed system collection and storage, at which 75% RBC viability is maintained.[26,30] Viability is measured as 24-hour post-transfusion survival of radiolabeled or biotinylated RBCs.[88] Red cell AS provide substrates for RBC metabolism and help delay onset of storage lesion.[9,47,87,89]

Canine WB in CPDA-1 is by convention stored for up to 35 days, supported by one viability study.[12] Canine pRBCs, based on viability studies, have a maximum storage time of 20 days in CPDA-1,[68] whereas canine pRBCs stored in AS-1 (Adsol) and AS-3 (Nutricel) may be stored for 35 days.[87,89] Similarly, in a study using in vitro tests, including percent hemolysis, of an AS consisting of saline-adenine-glucose-mannitol (SAGM), 35-day storage was acceptable.[28] Maximum storage of pRBCs in AS-5 (Optisol) is also 35 days by convention. As noted in the earlier text, leukoreduction can diminish the accumulation of pro-inflammatory cytokines and other substances, and is thought to reduce development of some storage lesions.[17,25,69,94] One study reported that viability was maintained at 35 days in leukoreduced pRBCs stored in Adsol,[11] and another study suggested a maximum storage of 42 days with SAGM based on in vitro tests.[25] However, using percent hemolysis and other in vitro tests, similar rates of storage lesion development were observed with the AS phosphate-adenine-glucose-guanosine-gluconate-mannitol (PAGGGM), SAGM, Adsol, and Optisol, and a maximum storage of 21 days was suggested.[47]

Feline WB in CPDA-1 is by convention also stored up to 35 days, which is supported by one viability study, and several studies using in vitro; tests including osmotic fragility and degree of hemolysis.[12,22,51,77,78] Feline pRBCs in an AS are also by convention stored for up to 35 days. However, a study of feline pRBCs stored in SAGM recommended a maximum storage of 28 days based on in vitro hemolysis.[9] Other studies of feline pRBC documented similar changes in pRBCs stored in Optisol for 25 days and Nutricel for up to 35 days.[4,34] Clinical implications of the storage lesion and shelf-life are discussed in Chapter 99.

Cryopreservation is approved for longer-term storage of human pRBCs and is feasible for canine and feline pRBCs.[65] Another option to prolong shelf-life is the use of blood substitutes including polymerized hemoglobin, perfluorocarbons, and hemoglobin–albumin clusters under various stages of development.[93]

Plasma and Platelet Components

All plasma components should be stored at −18 °C or lower in a cardboard plasma box which protects the bag from breakage (see Chapter 100). A freezer with an alarm to indicate unsafe temperatures is ideal. If a regular household freezer is used, exposure of the FFP to repeated freeze/thaw cycles will result in loss of the more labile plasma coagulation factors.

Platelet-rich plasma and PCs are usually stored at room temperature in plastic bags under continuous gentle agitation (see Chapter 101).[83] The composition of the plastic bag, high surface area:volume ratio, and agitation facilitate gas exchange and sustain aerobic metabolism, and thereby platelet viability. Platelet additive solutions may potentially be used to prolong storage time.[36]

QUALITY CONTROL

Properly collected blood is anticipated to have a low level of bacterial contamination.[56] Nonetheless, transfusion-associated sepsis is always a risk, and units of WB and pRBCs should be visually inspected during storage and prior to administration. The presence of murky, purple, brown, or red supernatant RBC mass that appears purple and has visible clots or differences in color between the unit and the tubing segments gives reason to suspect bacterial contamination.[38,46,86] Pretransfusion hemolysis is also always a risk.[62] Visual inspection to identify in vitro hemolysis is not an accurate method in determining the precise level of hemolysis, and free hemoglobin measurement can be considered to ensure that red cell units have <1% hemolysis.[28,40]

Plasma components should be inspected when issued for transfusion and discarded if cracks or leaks are noted. Inadvertent thawing during storage may reduce levels of factor VIII and von Willebrand factor, and allow for bacterial proliferation. In the absence of a freezer alarm or chart recorder, the following techniques may be used to detect inadvertent thawing and refreezing of a unit after its original freezing: (1) Store the plasma box initially lying flat in the freezer. After complete freezing, shift the box to sit on one end. Air bubbles present in the bag will move from the front edge to the upper edge of the bag if thawing occurs, and the unit will also be thicker on the lower edge. (2) Place a rubber band around the unit before freezing, so that it makes an indentation in the bag. After complete freezing, cut the rubber band. If thawing occurs, the indentation left by the rubber band will be less obvious or vanish.

CHAPTER 99

Red Blood Cell Transfusion in the Dog and Cat

MARY BETH CALLAN

Indications
- Transfusion Threshold
- Whole Blood Versus Packed RBCs
- Fresh Versus Stored RBCs

Pretransfusion Compatibility Testing
Xenotransfusion in Cats
Administration
- Warming of Blood
- Blood Filters and Infusion Devices
- Route, Volume, and Rate of Transfusion
- Massive Transfusion

Patient Monitoring

Acronyms and Abbreviations

AABB, American Association of Blood Banks; ADCAS, anemic dog clinical assessment score; FDA, Food and Drug Administration; FFP, fresh frozen plasma; FWB, fresh whole blood; Hct, hematocrit; Hgb, hemoglobin; [Hgb], hemoglobin concentration; NTBI, non-transferrin-bound iron; pRBCs, packed red blood cells; SWB, stored whole blood; WB, whole blood.

The term RBC *transfusion* includes administration of packed red blood cells (pRBCs), fresh whole blood (FWB), or stored whole blood (SWB). With the establishment of more commercial animal blood banks, the administration of pRBCs rather than whole blood (WB) has become more commonplace for treatment of anemia in both dogs and cats. Blood component therapy addresses a patient's specific transfusion needs while maximizing the use of a blood unit and decreasing potential adverse events associated with WB transfusion.

INDICATIONS

Red blood cell transfusions are indicated in the treatment of anemia caused by hemorrhage, hemolysis, or ineffective erythropoiesis. Because oxygen is poorly soluble in plasma, nearly all oxygen contained in blood is carried by hemoglobin (Hgb). Therefore, RBC transfusions increase the oxygen-carrying capacity of the anemic patient and thereby treat or prevent inadequate delivery of oxygen to tissues, with consequent tissue hypoxia. Hemorrhage (acute or chronic) was the major cause of anemia in 64–68% of dogs receiving RBC transfusions,[12,23] while ineffective erythropoiesis was the most common indication (47–75%) for RBC transfusions in cats.[24,34,40]

Transfusion Threshold

The decision to administer a RBC transfusion is usually based on a measurement of the patient's PCV, hematocrit (Hct), or Hgb concentration ([Hgb]) and, more importantly, on clinical evaluation of the patient. A "transfusion trigger" or threshold PCV, below which a RBC transfusion is administered, has not been clearly defined in human or veterinary medicine. A landmark multicenter, randomized, controlled clinical trial, the Transfusion Requirements in Critical Care (TRICC), found 30-day mortality was similar with "restrictive" and "liberal" RBC transfusion strategies in which critically ill human patients received blood when the [Hgb] fell below 7 g/dL to maintain the [Hgb] at 7–9 g/dL (restrictive group) or to maintain the [Hgb] at 10–12 g/dL (liberal group).[13] However, the mortality rate during hospitalization was significantly lower in the restrictive group, suggesting that a restrictive strategy of RBC transfusion is at least as effective as and possibly superior to a liberal transfusion strategy in critically ill patients.[13] Based on evaluation of results of 31 randomized clinical trials evaluating

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

restrictive and liberal RBC transfusion thresholds, the American Association of Blood Banks (AABB) made the following recommendations in 2016: (1) a restrictive threshold of 7 g/dL is recommended for hospitalized adults who are hemodynamically stable, including critically ill patients; and (2) a restrictive threshold of 8 g/dL is recommended for patients undergoing orthopedic surgery or cardiac surgery or those with pre-existing cardiac disease.[3]

While there are no clinical trials evaluating RBC transfusion thresholds in anemic dogs and cats, it is clear that measurement of Hct, [Hgb], or PCV alone is an inadequate determinant of the threshold for RBC transfusion because many additional factors (e.g., cardiac output and oxygen consumption) are involved in adequacy of tissue oxygenation. In a prospective study of 24 client-owned euvolemic anemic dogs receiving pRBC transfusions, an "anemic dog clinical assessment score" (ADCAS) based on five clinical variables (mucosa color, heart rate, pulse quality, respiratory rate, and mentation/exercise tolerance; clinically normal dog, score = 0, severely affected dog, maximum score = 12) was developed to provide an objective means to include clinical examination findings in the transfusion decision-making process.[19] There was a significant decrease (improvement) in all ADCAS variables after receiving pRBCs, with a total score ≤3/12 post-transfusion (compared to ≥5/12 pretransfusion) in all dogs that were deemed to not need additional pRBCs.[19] Although the ADCAS has not been validated for reproducibility and reliability, results suggest that the higher the score, the more likely a RBC transfusion would be clinically beneficial.[19]

Whole Blood Versus Packed RBCs

The majority of canine and feline blood collected at commercial blood banks and veterinary teaching hospitals is processed into pRBCs and fresh frozen plasma (FFP) (see Chapter 98). Administration of pRBCs is appropriate in the management of anemia resulting from any cause, but WB transfusion may be considered in certain situations. Fresh whole blood contains functional platelets, coagulation factors, and plasma proteins in addition to RBCs. Potential indications for FWB include anemia and a combined hemostatic disorder; anemia and thrombocytopenia or thrombopathia resulting in uncontrolled or life-threatening bleeding; and possibly massive transfusion. Stored whole blood contains plasma proteins and RBCs, but not functional platelets or coagulation factors. A possible indication for SWB is anemia and hypoproteinemia (e.g., chronic gastrointestinal bleeding), although administration of pRBCs and, if there is a clinical need to increase the patient's oncotic pressure, a synthetic colloid, plasma, or lyophilized canine albumin (Animal Blood Resources International, Stockbridge, MI) would be appropriate. In anemic patients with underlying cardiac disease, pRBCs would be preferable to WB in an effort to avoid circulatory overload.

Fresh Versus Stored RBCs

Although storage of blood components allows for a readily available supply of RBCs for transfusion, it has been well documented that during storage RBCs undergo a number of physical and chemical changes, collectively referred to as the "RBC storage lesion," which reduce RBC function and viability after transfusion (see Chapter 98). By the United States Food and Drug Administration (FDA) criteria, human pRBCs have a maximum refrigerated shelf-life of 42 days. Results of retrospective and observational studies in humans have suggested that transfusions of "older" pRBCs are associated with increased morbidity and mortality.[10,35] However, five randomized controlled trials comparing transfusion of "fresher" (generally stored for 10 days or less) and "standard-issue" pRBCs (storage duration ranging from 2 to 5 weeks) did not find any clinically significant outcome differences.[6,8,14,20,33] It is important to note, however, that none of the randomized controlled trials evaluated pRBCs in their last week of storage. A parallel-group, randomized trial comparing the effects of transfusing healthy volunteers with 1 autologous pRBC unit after 1, 2, 3, 4, 5, or 6 weeks of refrigerated storage found increased extravascular hemolysis, serum ferritin, and serum non-transferrin-bound iron (NTBI) in volunteers transfused pRBCs stored for 6 weeks compared with transfusion after 1–5 weeks of storage.[29] Furthermore, a higher prevalence of infection has been reported in human patients that received pRBCs stored 35 days or more compared to 21 days or less.[10] Due to concern about the potential for increased morbidity and mortality associated with transfusion of pRBCs stored 35–42 days in critically ill patients, there has been a recommendation to reduce the FDA's maximal allowable storage period to 35 days, as has already been done by the National Institutes of Health.[29]

Similar to the situation in humans, the maximal duration of RBC storage for animals that could adversely affect patient outcomes is uncertain. In using the FDA requirement for human pRBC storage of a minimum of 75% post-transfusion recovery (i.e., at least 75% of transfused RBCs should be in the circulation 24 hours later) at the end of the storage period, studies of canine pRBCs stored in additive solutions (Adsol or Nutricel) suggest that 35-day storage is acceptable, while 42-day storage is too long.[37,38]

As is evident from RBC transfusions in humans, acceptable post-transfusion recovery does not equate with clinical safety or effectiveness. In a prospective crossover study of 20 healthy research dogs randomized to two autologous pRBC transfusion events, one after 7 days (fresh) and one after 28 days (old) of storage or vice versa, a proinflammatory cytokine response, exemplified by monocyte chemoattractant protein-1, was observed after only old pRBC transfusions and was accompanied by increased neutrophil counts and decreased platelet counts compared to the fresh pRBC and saline control groups.[2] In another study of autologous RBC transfusions administered to 10 healthy dogs after either 3 or 35 days of storage, only the older pRBC transfusions resulted in evidence of intravascular hemolysis with concomitant marked increases in circulating free iron and cell-free Hgb.[41] In an experimental canine model with the extreme conditions of *Staphylococcus*

aureus-induced pneumonia with sepsis and exchange transfusions with 42-day-stored (vs 7-day-stored) allogeneic pRBCs, administration of older pRBCs increased circulating cell-free Hgb and NTBI, as well as mortality.[32] However, in the absence of established infection, exchange transfusion with neither 7-day-stored nor 42-day-stored pRBCs resulted in mortality.[36]

Retrospective studies evaluating the effect of duration of pRBC storage on morbidity and mortality in dogs after transfusion have not identified a clear association between older pRBC transfusions and increased mortality.[12,23] In a study of 3095 dogs that received 5412 PRBC units with a median storage duration of 23 days (range, 0–40 days), longer duration of pRBC storage was associated with development of new or progressive coagulation failure and thromboembolic disease.[12] In a study of 210 dogs that received 321 pRBC units with a median storage duration of 28 days (range, 0–46 days), age of stored pRBCs was associated with increased risk of transfusion-associated hemolysis.[23]

There is not a consensus of opinion among veterinary blood banks regarding an appropriate maximal storage time for canine (or feline) pRBCs. However, in light of the poor post-transfusion recovery of canine pRBCs stored for 42 days, a maximal allowable storage time of 42 days appears too long. Furthermore, the laboratory evidence of post-transfusion intravascular hemolysis and inflammation documented in healthy dogs receiving autologous pRBCs stored for 35 days and 28 days, respectively, raises the question of whether even 28–35-day storage is too long for canine pRBCs.[2,41] The maximal allowable storage time for canine pRBCs will likely remain a controversial point until there are carefully designed clinical trials in appropriate patient populations.

PRETRANSFUSION COMPATIBILITY TESTING

Blood typing and crossmatching (see Chapters 96 and 107) are essential to providing RBC transfusions that are safe and efficacious. However, the need for a blood crossmatch prior to a *first* blood transfusion in both dogs and cats is controversial. Although naturally occurring RBC alloantibodies have been identified in dogs (see Chapter 96), they are generally not considered of clinical significance, since neither acute nor delayed hemolytic transfusion reactions have been documented in transfusion-naïve dogs receiving RBC transfusions. In a retrospective study of 149 transfusion-naïve dogs, 25 dogs (17%) were found to be incompatible to at least one donor on a tube major crossmatch, and the mean change in Hct was higher in dogs that received crossmatch-compatible RBCs (12.5 ± 8.6%) compared to those for whom a crossmatch was not performed (9 ± 4.3%), though acute adverse reactions were not observed in either group.[26] By contrast, in a prospective study of 80 transfusion-naïve dogs, no RBC incompatibilities were noted on pretransfusion testing performed using both a gel column crossmatch and an immunochromatographic strip crossmatch kit (both antiglobulin-enhanced).[11] Based on the conflicting data available and questionable clinical significance, performing a blood crossmatch prior to a dog's *first* transfusion could be considered optional.

As for dogs, there is not a uniform opinion on the need for a pretransfusion crossmatch for a transfusion-naïve cat receiving AB-matched RBCs. A retrospective study investigating the influence of crossmatch on post-transfusion PCV found that administration of type-specific, crossmatch-compatible pRBCs resulted in a significantly greater mean increase in the post-transfusion PCV when compared to administration of typed, non-crossmatched pRBCs, though pretransfusion crossmatches were performed mostly for previously transfused cats.[40] In a subsequent prospective study comparing change in PCV and incidence of adverse events post-transfusion in transfusion-naïve cats with and without a crossmatch performed, major crossmatch incompatibilities were noted in seven of 24 cats (29%).[34] There was no difference in change in PCV or adverse events when comparing cats that received type- and crossmatch-compatible pRBCs and cats that received non-crossmatched, type-compatible pRBCs, leading to the conclusion that a major crossmatch does not improve efficacy of or decrease adverse events associated with administration of AB type-matched RBCs to transfusion-naïve cats.[34] In a retrospective study of 300 cats receiving RBC transfusions, a pretransfusion crossmatch was performed for 154 transfusion-naïve cats, with 23 cats (14.9%) having major crossmatch incompatibilities.[24] Administration of crossmatch-compatible RBCs was not associated with a greater increase in PCV compared to type-specific, non-crossmatched RBCs.[24] Although the clinical relevance of major crossmatch incompatibilities detected in transfusion-naïve cats is unknown, previous documentation of anti-*Mik* RBC alloantibodies causing acute hemolytic transfusion reactions in transfusion-naïve cats suggests erring on the side of caution.[39]

XENOTRANSFUSION IN CATS

Xenotransfusion, the transfusion of blood from another species, can be viewed as a potentially life-saving option when species-compatible blood is not available and the patient is in imminent danger of dying without additional oxygen-carrying support. Five studies from the 1960s reported on the experimental administration of canine blood to 61 cats, with no evidence of severe adverse events after the first transfusion but anaphylaxis, frequently fatal, upon repeat transfusion with canine blood after 4–6 days.[1] A recent case report described two cats that received canine blood on an emergency basis, both of which stabilized after the transfusion and survived to hospital discharge.[7] Intravascular hemolysis was noted 1 day post-transfusion, and canine RBCs were no longer detectable 4 days after the xenotransfusion.[7] A pretransfusion plasma sample available from one cat did not show an agglutination reaction with canine RBCs;

however, strong (3+ to 4+) agglutination reactions were noted using post-transfusion plasma samples from both cats and random canine RBCs.[7] Despite the apparent transient improvement in the clinical condition of cats that have received canine RBCs, such xenotransfusions should only be considered in a dire situation when compatible feline RBCs are not immediately available.

ADMINISTRATION

Careful attention to administration is essential to prevent damage of the blood product and harm to the patient. Most canine and feline pRBCs purchased from commercial veterinary blood banks are stored with an additive solution, such as Adsol, and can be administered directly, while pRBC products without an additive solution should be diluted with physiologic saline (e.g., 100 mL of saline to 250 mL canine pRBCs) to decrease the viscosity of the donor blood. Concurrent administration of any drugs or fluids other than physiologic saline through the same catheter should be avoided.

Warming of Blood

In the routine administration of RBC products to normovolemic anemic patients, refrigerated blood components do not require warming prior to transfusion. A study comparing the temperature changes in chilled canine pRBCs in an administration line after passing through a dry heat fluid/blood warming device *versus* no warming device at rates ranging from 10 to 500 mL/hour found that, without the heating device, the pRBCs reached an ambient temperature (20–21 °C) at all fluid rates tested within 1 minute.[4] With the warming device (set at 46 °C), canine pRBCs achieved a maximal outlet temperature of 35.8 °C at a flow rate of 100 mL/hour; RBC integrity was not evaluated.[4] In studies evaluating the effect of warming on hemolysis of human pRBCs, there was no difference between warming devices calibrated to 37.5 °C and 41.5 °C,[28] and warming devices with temperatures up to 46 °C did not appear to increase hemolysis.[27] It is uncertain whether this upper temperature limit would be applicable to the warming of canine and feline pRBCs. Indications for the use of blood warmers in human medicine include rapid infusion of blood components (e.g., in trauma or surgery settings) and transfusions to neonates in order to prevent exacerbation or development of hypothermia, the consequences of which may include cardiac arrhythmias and coagulopathies.[9]

Blood Filters and Infusion Devices

Red blood cell transfusions must be administered through a filter designed to remove clots and particles potentially harmful to the patient. Standard blood infusion sets have in-line filters with a pore size ranging from 170 µm to 260 µm that trap large cells, cellular debris, and coagulated proteins. A neonatal syringe (30–60 mL) set with a 150 µm filter (Charter Medical, Winston-Salem, NC) is useful for administration of whole blood or PRBCs, as well as plasma products, to small dogs and cats. A pediatric microaggregate blood filter with an 18 µm pore size and a priming space of 0.7 mL (Hemo-Nate syringe filter, Utah Medical Products, Midvale, Utah) can be used to administer small volumes of blood (<50 mL WB or <20 mL pRBCs); however, administering larger volumes could result in hemolysis due to a progressive decrease in pore size as more blood is filtered. With both the neonatal syringe set and the Hemo-Nate syringe filter, the blood is filtered as it is removed from the blood storage bag, the filter is discarded, and the syringe with extension tubing is then placed on a syringe pump for administration.[9]

In most instances, the blood flow rate through an administration set by gravity alone is adequate to meet a patient's needs. Some electromechanical infusion devices that deliver crystalloid solutions at a controlled rate have been approved by the manufacturer for administration of blood to human patients. In a study comparing three different techniques (volumetric peristaltic pump, syringe pump with a postsyringe 18 µm filter, and gravity flow with a standard in-line 170–260 µm filter) for administration of autologous whole blood (washed RBCs labeled with biotin and reconstituted with plasma) to healthy dogs, there was a significant difference in the number of dogs with detectable labeled RBCs 1 day post-transfusion depending on the technique: biotin-labeled RBCs administered via gravity were detected in all eight dogs, but in only four of eight dogs and one of seven dogs when administered via a volumetric and syringe pump, respectively.[25] After 24 hours, there was no significant difference in the circulating half-life of RBCs administered via volumetric pump compared to gravity flow.[25] It is important to recognize that the syringe pump method of delivery was not evaluated without a postsyringe 18 µm filter, so results might be different for prefiltered whole blood or pRBCs placed on a syringe pump, as recommended by the manufacturer of the Hemo-Nate filter and as done for human neonatal transfusions.[9] In a similar study performed in healthy cats, fresh autologous whole blood was administered via gravity and a pump delivery system using a 20 mL syringe and an 18 µm filter, with no difference in short- or long-term RBC survival noted between groups during a 6-week period.[15] The reason for the striking contrast in results for syringe pump delivery system in the canine and feline studies is unclear. If similar to the situation with blood from humans, there are many factors besides pump mechanics that can influence infusion-pump-mediated hemolysis, including flow rate (low flow rates increase hemolysis secondary to increased RBC exposure to mechanical shear force) and viscosity of the blood (higher hematocrit in pRBC units without additive solution has been associated with increased

hemolysis).[17] If considering the use of an infusion pump designed for crystalloid solutions to administer RBCs, the manufacturer should be consulted first, and ideally the system should be tested to confirm the pump will not damage canine and feline blood components before their use.

Route, Volume, and Rate of Transfusion

The intravenous route of administration is recommended for all RBC transfusions; however, intraosseous administration is an excellent alternative if venous access cannot be obtained. Central veins allow for the use of large-bore catheters and thereby more rapid transfusion in the case of hemorrhagic shock. However, peripheral veins may be preferred in animals with an increased bleeding tendency.

The volume of blood to be administered depends on the degree of anemia, the patient's clinical status, and the size of the animal. Similar to the transfusion threshold, a "target PCV," or the desired PCV post-transfusion, has not been clearly defined and is likely to vary depending on the patient's overall condition. It is typically not necessary to transfuse RBCs with the aim of restoring a normal PCV. In a retrospective study evaluating 4 formulae to predict post-transfusion PCV in 31 anemic dogs administered pRBCs, the most accurate formula was (donor PCV × pRBC volume infused in mL)/(90 mL × body weight in kg).[31] In a similar retrospective study evaluating five formulae in anemic cats administered WB, the best performing formula for predicting the increase in PCV was (WB volume infused in mL)/(2 × body weight in kg), but no single formula was highly accurate.[30] As an alternative to calculating the volume of donor blood required to reach a target PCV, one may administer an average volume of 10–15 mL/kg of pRBCs or 20 mL/kg of WB to a normovolemic dog and, if deemed necessary based on clinical evaluation of the patient post-transfusion, follow with additional blood. For practical purposes, most anemic cats will initially receive one unit of WB (typically 40–50 mL) or one unit of pRBCs (typically 20–25 mL).

The rate of blood administration depends on the patient's overall condition. In normovolemic anemic patients, the maximum rate of transfusion is 10–20 mL/kg/hour to avoid circulatory overload; hypovolemic anemic patients may tolerate replacement of their blood volume as quickly as the blood can be infused. In animals with advanced cardiac disease, the infusion rate should not exceed 2–4 mL/kg/hour; pRBCs are preferable to WB in such cases where the transfusion volume tolerated by the patient may be a limiting factor in providing sufficient oxygen-carrying support. In all cases, including those in which the donor and recipient have been blood typed and/or crossmatched, the initial rate of transfusion should be slow while observing for any immediate adverse reactions. In general, a blood transfusion should be complete within 4 hours to ensure administration of functional blood components and to prevent growth of bacteria in the event of contamination.[9]

Massive Transfusion

Massive transfusion represents a special situation with regard to volume and rate of blood transfusion, as well as blood components administered. In veterinary medicine, the following definitions of massive transfusion have been used: transfusion of a volume of whole blood or blood components that is greater than the patient's estimated blood volume within a 24-hour period, replacement of half the patient's estimated blood volume in 3 hours, or the replacement of 150% of the patient's blood volume irrespective of time.[18,21,22] Massive transfusion protocols have been established in human medicine to treat intravascular volume deficits, preserve oxygen-carrying capacity, and prevent dilutional coagulopathy, with blood products administered in a balanced ratio that is closely approximated to reconstituted whole blood. In a randomized clinical trial of patients with severe trauma transfused plasma, platelets, and pRBCs in ratios of 1:1:1 or 1:1:2, there was no difference in 24-hour and 30-day mortality, though exsanguination was significantly decreased in the 1:1:1 group.[16] In the case of massive transfusion during cardiac surgery, administration of plasma to pRBCs in a ratio ≥1:1 was associated with lower mortality and less organ dysfunction than with lower ratios.[5]

Guidelines for massive transfusion in dogs and cats have not been established. In a retrospective study of dogs receiving massive transfusion for a variety of causes, including intra-abdominal neoplasia and trauma, the mean volumes of pRBCs and FFP administered were 66.5 mL/kg and 22.2 mL/kg, respectively, resulting in a mean plasma to RBC ratio of 1:3, with four of 15 (27%) dogs surviving to discharge.[18] Massive transfusions (with unspecified plasma to pRBC ratios) have been reported for dogs following trauma, with seven of 10 dogs (70%) surviving.[22] In a study of 83 dogs with hemoperitoneum (90% of which were associated with splenic hemorrhage, most commonly due to neoplasia) and undergoing surgery, four dogs met the criteria for massive transfusion, with only one dog (25%) surviving.[21]

PATIENT MONITORING

Early recognition of transfusion reactions (see Chapter 104) requires careful evaluation of patient's attitude, vital signs, and perfusion (i.e., capillary refill time and pulse quality) before, during, and after a RBC transfusion. Measurement of PCV and total protein pretransfusion and post-transfusion (at a minimum, immediately and at 24 hours) and evaluation of the plasma and urine for the presence of Hgb are recommended. Any unexpected change in attitude, vital signs, or laboratory parameters

may be indicative of an adverse reaction, in which case the RBC transfusion should be stopped immediately, the intravenous line left open with physiologic saline, and other supportive care provided as necessary.

Acronyms and Abbreviations

CPD, citrate-phosphate-dextrose; DIC, disseminated intravascular coagulation; FFP, fresh frozen plasma; FP, frozen plasma; IMHA, immune-mediated hemolytic anemia; ITP, immune-mediated thrombocytopenia; IVIG, intravenous immunoglobulin; RBC, red blood cell; rhFVIIa, recombinant human factor VIIa; TRALI, transfusion-related acute lung injury; TRIM, transfusion-related immunomodulation; VWD, von Willebrand disease; VWF, von Willebrand factor.

PLASMA CONSTITUENTS

Plasma contains a myriad of proteins that maintain homeostasis within the body and respond to environmental challenges. The major therapeutic constituents of plasma include hemostatic proteins, albumin, and immunoglobulins. The term "plasma component" is reserved for products prepared by differential centrifugation using blood banking techniques, while "plasma derivative" refers to products prepared by fractionation in manufacturing facilities.[1,3,8] The advent of commercial, referral, and academic veterinary blood banks facilitates routine transfusion of animal plasma components in clinical veterinary practice. By contrast, sources of plasma constituents are relatively limited. Currently available commercial constituents include canine albumin (Animal Blood Resources International) and equine immunoglobulin preparations (Sera, Incorporated).

Hemostatic Proteins

Plasma contains all the procoagulant factors required for fibrin clot formation, adhesive proteins, potent anticoagulants, and fibrinolysins. The transformation of soluble plasma fibrinogen to insoluble, polymerized fibrin occurs through the action of serine protease coagulation factors (factors II, VII, IX, X, XI, and XII), cofactors (factors V and VIII), and a transglutaminase (factor XIII). Platelet adhesion under conditions of high shear requires the large multimeric glycoprotein, von Willebrand factor (VWF). The major anticoagulant proteins in plasma are antithrombin, protein C, and protein

S. Plasma also contains the fibrinolytic enzyme plasminogen and its primary regulatory proteins, antiplasmin and plasminogen activator inhibitor-1. Fibrinogen is the highest concentration hemostatic protein, circulating in plasma at approximately 300 mg/dL. The plasma half-lives of hemostatic proteins vary widely (Table 100.1), thereby influencing appropriate transfusion intervals for different disease syndromes.[13,15]

Albumin and Immunoglobulins

Albumin is the major oncotic protein in plasma and a carrier protein for lipophilic compounds. The immunoglobulin fraction of plasma consists of IgG (up to 85%), IgA, and IgM. The plasma albumin concentration of most species ranges from approximately 2 g/dL to 4 g/dL, with immunoglobulins generally present at equivalent or slightly lower concentration. Derivative concentrates, rather than plasma components, are used in human medicine to supply therapeutic levels of albumin and globulins.[4,7]

PLASMA COMPONENTS

Centrifugation of whole blood sediments the cellular elements from the supernatant plasma. Separation within 8 hours of blood collection optimizes retention of the quantitative and functional properties of all plasma proteins.[1,3] The supernatant plasma can be transfused immediately as fresh plasma, but it is usually frozen and stored as fresh frozen plasma (FFP) for subsequent transfusion, or further processed to yield cryoprecipitate and cryosupernatant (Figure 100.1). The general procedures for preparation of animal components in the United States follow human blood banking guidelines, e.g., collection of whole blood in citrate-phosphate-dextrose (CPD) anticoagulants, initial quick-freeze of separated plasma, and storage temperatures at or below −18 °C.[3,14]

Fresh Frozen Plasma

Fresh frozen plasma refers to plasma separated from whole blood within 8 hours of collection and quick-frozen within 1 hour of separation. It contains essentially all the hemostatic proteins, albumin, and globulin as the plasma from which it was prepared. The term *FP24* is used in human blood banking for plasma separated and frozen within 24 hours from collection. Compared to FFP, this product has diminished activity of labile factors, but is approved as a source of coagulation factors for patients with moderate, combined factor deficiencies.[1,15] Similarly, canine plasma processed up to 24 hours from collection demonstrated retention of factor activity.[20] Additional studies of canine, equine, and feline FFP demonstrated stability of factor content under a variety of storage conditions.[10,21,23,24]

Frozen Plasma

Frozen plasma (FP) refers to FFP units stored longer than 1 year or thawed FFP units stored under refrigeration for more than 24 hours before transfusion. Hemostatic proteins retain variable activity in FP, and the product does not supply replacement levels of the most labile coagulation factors, factors V and VIII. FP is a source of albumin and globulins.

Cryoprecipitate

Cryoprecipitate is prepared by slowly thawing FFP at temperatures between 1 and 6 °C, followed by centrifugation to sediment the large, cold-insoluble proteins.[1,15] The resultant cryoprecipitate fraction is then refrozen within 1 hour of separation for storage times of up to 1 year. Cryoprecipitate contains fibrinogen, the VWF–factor VIII complex, factor XIII, and fibronectin. "Units" of cryoprecipitate may be defined based on the volume of starting FFP, or fibrinogen or factor content. The process of cryoprecipitation yields approximately 50% factor activity, in one-tenth volume, of the starting FFP. The factor content in cryoprecipitate is also related to that of donor plasma.[6] Volume reduction is the major advantage of cryoprecipitate transfusion; therapeutic levels of factors are attained within minutes over the course of a single bolus infusion. Cryoprecipitates are most often used for dogs as sources of VWF and factor VIII.

Cryosupernatant

Cryosupernatant is the plasma component remaining from production of cryoprecipitate.[1,15] This product is deficient in fibrinogen, VWF–factor VIII, and other cold-insoluble proteins, but retains proteins such as albumin and most hemostatic proteins and immunoglobulins.[5]

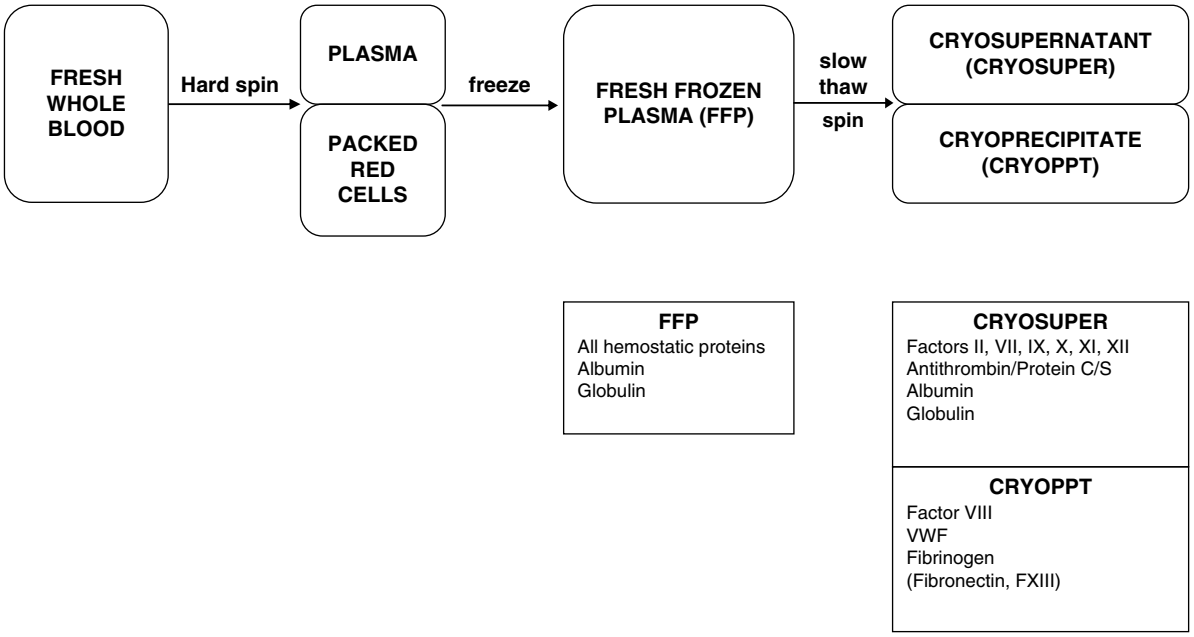

FIGURE 100.1 Flow chart of plasma component processing and composition.

Cryosupernatants are often used as a source of the vitamin-K-dependent coagulation factors (factors II, VII, IX, and X) and are stable for this purpose for at least 1 year of storage.

PLASMA DERIVATIVES AND RECOMBINANT PROTEINS

Human apheresis plasma provides most of the source material for commercial manufacture of pharmaceutical protein derivatives.[8] Human albumin, immunoglobulin, and factor concentrates (factor VIII and VWF) are among the most commonly used derivatives in medical practice. The first production methods developed in the 1940s and 1950s (Cohn's fractionation) separated constituent proteins based on differential solubility under conditions of varying temperature, pH, and ethanol concentration. Subsequent advances include the use of chromatography and immunopurification processing techniques. The final protein concentrates are supplied as solutions or lyophilized powders with long (2–3 year) shelf-lives at room temperature. The manufacturing process of human protein concentrates incorporates donor and plasma screening and highly effective pathogen inactivation procedures.

In addition to high-purity factor VIII and IX concentrates, recombinant human factor VIII and IX products are approved to prevent and control hemorrhage in hemophilic patients. Although recombinant factors carry no risk of blood-borne disease transmission, they do not prevent development of inhibitory alloantibodies, a severe complication of replacement therapy. Recombinant human factor VIIa (rhFVIIa) was developed as a bypassing agent to treat hemophiliacs and other patients with acquired coagulation inhibitors.[12] At supraphysiologic levels, rhFVIIa generates thrombin by directly activating factor X on the surface of procoagulant platelets.

INDICATIONS FOR PLASMA THERAPY

Plasma components are the mainstay for treatment of hemorrhagic disorders caused by hemostatic protein deficiencies. Plasma components are also transfused to animals with the goal of providing albumin and immunoglobulins due to a lack of allogeneic derivative protein concentrates.[13] The indication and therapeutic target for each transfusion should be clearly established in order to select the most specific replacement product (Table 100.2). This approach maximizes the use of scarce plasma resources and helps minimize recipient exposure to foreign antigens.

Hemorrhagic Disorders

Hereditary Bleeding Disorders

Plasma components are indicated to control active hemorrhage and for preoperative prophylaxis for animals with hereditary coagulation factor deficiencies and von Willebrand disease (VWD) (see Chapters 83 and 90). In many cases, appropriate component therapy will eliminate the need for RBC transfusion with its inherent risks of sensitization and adverse reaction to RBC antigens.

Von Willebrand disease, among the most common hereditary bleeding disorders of dogs, horses, and people, is often managed with plasma component therapy. Patients with severe forms of VWD invariably require replacement therapy to safely undergo invasive

TABLE 100.2 Plasma components and plasma derivatives.

Product	Dosage guidelines	Indications
Fresh frozen plasma	6–12 mL/kg q8–12 h	Inherited and acquired coagulation factor deficiencies, von Willebrand disease, hypoproteinemia, hypoglobulinemia
Cryoprecipitate[a]	1 unit/10 kg q4–12 h	Hemophilia A, von Willebrand disease, hypofibrinogenemia
Cryosupernatant	6–12 mL/kg q8–12 h	Hemophilia B, hereditary deficiencies of factors II, VII, X, XI, vitamin K deficiency, hypoproteinemia, hypoglobulinemia
Frozen plasma	12–20 mL/kg q12–24 h	Hypoproteinemia, hypoglobulinemia
Human albumin solution[b]	0.5–1.0 g/kg	Hypoproteinemia
Human intravenous immunoglobulin[b]	0.5–1.0 g/kg	Refractory immune-mediated disorders
Recombinant human FVIIa[b]	35–120 μg/kg	Factor bypassing agent, surgical hemostasis

[a]One unit cryoprecipitate prepared from 200 mL fresh frozen plasma.
[b]Administration of human protein products may induce severe adverse reactions in animals.

procedures and are subject to spontaneous mucosal bleeds that may persist without transfusion. Transfusion requirements are generally related to residual VWF protein levels; however, each patient's risk of hemorrhage should include consideration of prior history of abnormal bleeding, presence of concurrent disorders, and the nature and site of surgery or trauma. The highest potency VWF plasma component is cryoprecipitate; however, FFP can be transfused as a source of VWF if cryoprecipitate is unavailable.

Hemophilia occurs in many different breeds and species. Hemophilia A (factor VIII deficiency) is much more common than hemophilia B (factor IX deficiency). Both are X-linked recessive traits, and, therefore, signs of a bleeding disorder are seen predominantly in males. Heritable coagulopathies caused by deficiencies of fibrinogen and factors II, VII, IX, X, and XI are less common than hemophilia, but have been identified in animals. Transfusion requirements vary among hereditary factor deficiencies. Clinical expression of a bleeding tendency depends on the physiologic role of the deficient factor and the severity of factor deficiency. For example, hemophilia A and B often manifest as clinically severe coagulopathies, whereas most patients with factor VII deficiency have no signs of a bleeding tendency (see Chapter 90). Hemophilia A and fibrinogen deficiency or dysfunction (dysfibrinogenemia) respond to cryoprecipitate or FFP, if cryoprecipitate is unavailable. All other hereditary factor deficiencies can be treated with FFP or cryosupernatant.

Acquired Factor Deficiencies

Acquired coagulopathies are caused by simultaneous deficiencies of many factors rather than specific deficiency of a single factor (see Chapters 89, 92, and 94). Acquired coagulopathies are more common than hereditary disorders and often develop in patients with vitamin K deficiency, liver disease, disseminated intravascular coagulation (DIC), and massive blood loss treated with large-volume fluid replacement.

Transfusion is required for vitamin-K-dependent coagulopathies if fulminant hemorrhage develops in critical sites, e.g., respiratory tract or central nervous system, since vitamin K replacement therapy corrects coagulopathy only after a period of 12–24 hours. Cryosupernatant is the most cost-effective plasma component to supply the vitamin-K-dependent factors (factors II, VII, IX, X),[5] but FFP is an acceptable alternative (Table 100.2).

While FFP provides all coagulation factors and fibrinogen, it also contains plasminogen, anticoagulant proteins, protease inhibitors, and albumin. Volume overload, however, can limit the efficacy of FFP for ongoing replacement of these proteins.[1,2,13,15] The combined use of FFP with platelet and packed RBC transfusion is considered effective for short-term replacement of hemostatic proteins in patients with massive blood loss.[1,15] New, freeze-dried FFP products have also shown clinical benefit in early human trauma studies.[17] A clinical benefit of FFP or cryoprecipitate has not been shown across treatment trials of DIC in humans.[2,15] Therefore, use of component therapy is generally restricted to DIC patients with signs of hemorrhage caused by severe fibrinogen and factor depletion.

Nonhemorrhagic Disorders

Hypoproteinemia

Hypoproteinemia develops in numerous disease conditions including vasculitis, protein-losing disorders, hepatic failure, and peritonitis. In medical practice, albumin concentrates are used to restore the oncotic properties and carrier functions of albumin, and veterinary studies have described the use of human albumin in sick dogs and cats.[7,18,19] Antigenic differences among species, however, render human albumin immunogenic, and severe adverse reactions were described in a study of healthy dogs receiving pharmaceutical human albumin solutions.[9] Off-label use of human albumin solutions for veterinary patients should be carefully considered and proceed only after obtaining owners' informed consent. The plasma components FFP and cryosupernatant are potential sources for albumin replacement therapy. However, high-volume transfusions (20–25 mL/kg) of these components are predicted for calculated increments of 0.5 g/dL plasma albumin in recipients.

Immune Disorders

Human intravenous immunoglobulin (IVIG) concentrates were initially developed for treating immunodeficiencies; however, these products are now used to modulate the immune response for diverse human disease syndromes including immune cytopenias, myasthenia, rheumatic disease, and immune-mediated dermatopathies.[4] The clinical use of human IVIG in animals includes management of refractory immune-mediated disorders, including immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (ITP), pemphigus foliaceus, and cutaneous drug eruptions.[16] The immunoglobulin content of plasma components does not supply supraphysiologic levels of immunoglobulins for immunosuppression; however, FFP (and cryosupernatants) can serve as sources of immunoglobulin replacement therapy for neonates with failure of passive transfer, and potentially to augment response to infectious agents.

GUIDELINES FOR PLASMA ADMINISTRATION

Sources of Plasma Products

The options for obtaining veterinary blood products now include regional and national veterinary blood banks, and local academic centers and specialty clinics. Guidelines for screening canine and feline donors have been recently updated;[22] however, nationwide standards do not exist for unit definition, potency, or processing techniques to prepare plasma components. Information on quality assurance, quality control, and specific dosage and handling recommendations must be obtained from each supplier.

Plasma Product Administration

Plasma Components

Plasma components are prepared in sterile plastic bags and then stored and shipped frozen in individual boxes.[1,13] Plasma bags are brittle and must be handled carefully to prevent breakage. All products should be stored at −20 °C or lower and then warmed to 37 °C in a water bath or incubator just before transfusion. Unopened bags can be refrozen without significant loss of factor activity when kept at 37 °C for up to 1 hour,[24] but any product remaining in opened bags should be discarded if not transfused within 3–4 hours.

Intravenous transfusion of plasma components is the preferred route of administration; however, intraosseous transfusion may be indicated in emergency situations when attempts at vascular access have failed. Catheter sites for transfusion should be aseptically prepared and the catheters reserved for plasma component administration (or flushed with sterile saline before and after plasma transfusion). Plasma components should be infused through blood filters and should not be mixed with other fluids, drugs, or additives to prevent contamination, precipitation, or clot formation.[1]

In the author's experience, routine pretreatment with corticosteroids or antihistamines is not required before plasma component transfusion. Plasma products should be infused at a slow initial rate of 0.1 mL/kg/minute for 15–20 minutes and the recipient closely monitored for signs of transfusion reaction. Maintenance of this rate is advisable for patients at risk for volume overload (e.g., puppies, small dogs, cats, cardiac patients). Transfusion rates of 0.2–0.3 mL/kg/minute (to total transfusion time of 1.5–2 hours) are generally well tolerated for more rapid factor replacement and for larger dogs. Low-volume cryoprecipitate can be transfused as a slow intravenous bolus over a period of 10–20 minutes.

The dose and frequency of transfusion vary for different products and different disease conditions (Table 100.2). In general, FFP, FP, and cryosupernatant are transfused at 10–12 mL/kg, with an interval of 6–8 hours between doses to prevent volume overload. Cryoprecipitates are supplied in arbitrary "units" defined by each blood bank and should be transfused, therefore, according to the suppliers' recommended dosages. The best strategy for rapidly restoring hemostasis in patients with severe factor deficiencies is to initiate high-dose and short-interval component transfusion. The high end of dosage range is also appropriate for preoperative prophylaxis. The dose can be decreased and transfusion interval increased after hemostasis is restored. While coagulation assays and point-of-care monitors aid in assessing patient response (Figure 100.2), clinical assessment and confirmation of rising or stable hematocrit are important parameters to guide subsequent transfusion.[3] Patients with severe factor deficiencies usually require more than a single preoperative transfusion to undergo surgery or to control hemorrhage severe enough to cause blood loss anemia. A second (postoperative) transfusion should be given routinely, with access to additional components as needed. Transfusion over a maximum period of 2–3 days is usually sufficient to support hemostasis and postoperative wound healing in patients with even the most severe factor deficiencies.

Plasma Derivatives and Recombinant Proteins

Administration of human albumin, immunoglobulin, and rhFVIIa has been reported in dogs; however, treatment trials adequately powered to judge clinical efficacy have not yet been performed. In retrospective reviews,[18,19] the use of human albumin was described in canine and feline patients, with disparity among studies in the number of observed clinical complications. Moreover, a study of albumin infusion to healthy dogs described immune-mediated reactions to the heterologous protein.[9] Human IVIG has been used in the dosage range of approximately 0.5–1.5 g/kg for refractory IMHA and ITP in dogs.[16] Cytopenias generally resolved in more than two-thirds of the dogs treated with a single IVIG dose. The hemostatic effects of rhFVIIa have been demonstrated in research dogs

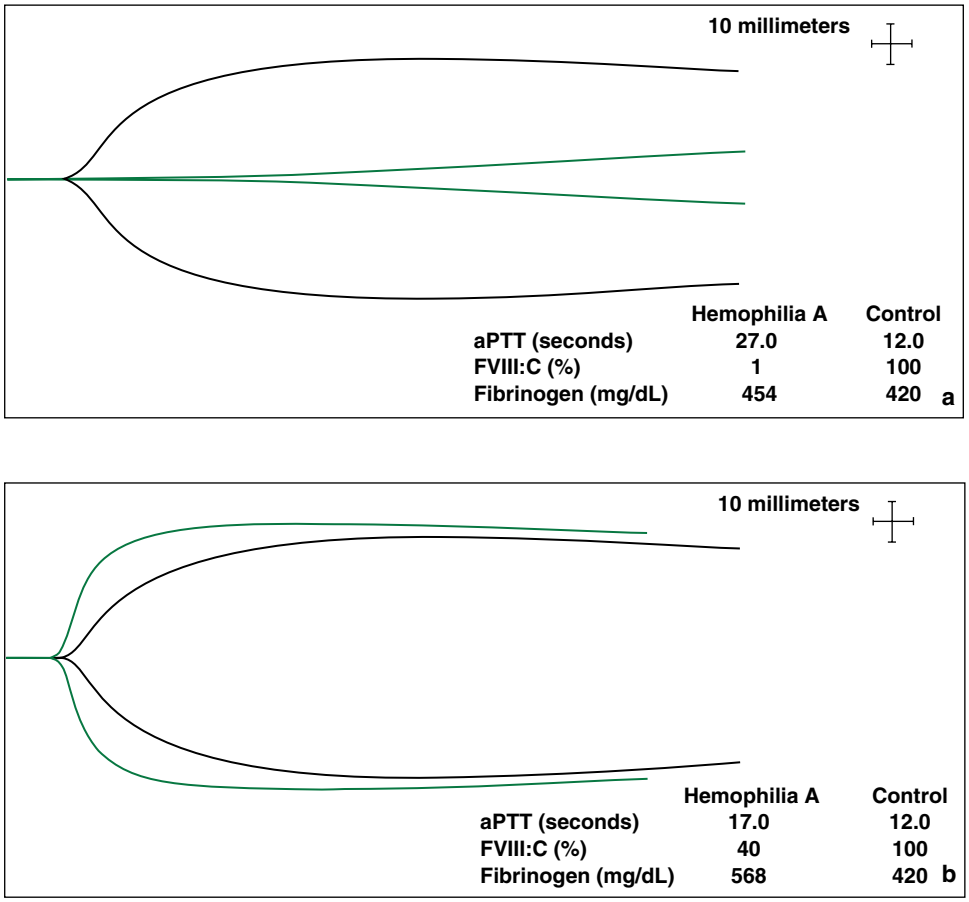

FIGURE 100.2 Response to cryoprecipitate in a dog with severe hemophilia A. Cryoprecipitate was transfused to a hemophiliac dog preoperatively and postoperatively for cutaneous mass excision. Citrate-anticoagulated blood samples were collected before transfusion and 45 minutes after postoperative transfusion to monitor activated partial thromboplastin time (aPTT), factor VIII coagulant activity (FVIII:C), fibrinogen, and thromboelastography (TEG) using recalcified blood and no trigger reagent. In each panel, the hemophiliac dog's TEG tracing (green line) is superimposed over a normal dog tracing (black line). Inset tables display aPTT, FVIII:C, and fibrinogen values. (a) Pretreatment TEG depicts minimal fibrin formation in the absence of factor VIII; (b) Post-treatment TEG depicts a marked increase in the rate and tensile strength of the fibrin clot formed in the presence of hemostatic levels of factor VIII.

with hereditary factor deficiencies (hemophilia A, hemophilia B, and factor VII deficiency), at dosages ranging from 5 to 30 μg/kg.[12,25] Pending additional veterinary studies, any potential benefit of human plasma-derived or recombinant concentrates, must be weighed against their high cost and cross-species immunogenicity.

ADVERSE REACTIONS TO PLASMA PRODUCTS

All plasma recipients should be observed during transfusion, with minimum monitoring of temperature, pulse, and respiration before and after transfusion. Based on the indication for plasma therapy, the appropriate samples to monitor coagulation status, hematocrit, or protein concentration should be collected before and after transfusion to gauge recipient response. Plasma product administration should be stopped immediately, and the product saved for analysis if the recipient displays any signs of discomfort or change in clinical status (see Chapter 104).

Immune-Mediated Reactions

Plasma components and concentrates are acellular but contain potentially immunogenic proteins and other compounds (e.g., anticoagulants) capable of eliciting immune reactions. Acute allergic reactions characterized by urticaria, erythema, and facial edema are among the most common reactions and may occur during a first transfusion, or in patients previously transfused many times. Signs typically manifest within the first 30–60 minutes of infusion. The antigens or factors responsible for these reactions have not been defined, but most patients respond quickly if the transfusion is discontinued and they are given antihistamines and/or short-acting steroids. Cats have clinically significant, naturally occurring alloantibodies to foreign RBC antigens. Therefore, cats should be transfused only with type-matched plasma products. A minor crossmatch (recipient RBCs plus donor plasma component) can be performed in any species to

detect hemolysins and agglutinins before transfusion (see Chapter 107). The off-label use of pharmaceutical agents containing human proteins or any cross-species plasma transfusion carries an inherent risk of potentially fatal acute and/or delayed immune reactions.

The acronyms TRALI (transfusion-related acute lung injury) and TRIM (transfusion-related immunomodulation) refer to deleterious antibody and/or cytokine-mediated plasma component reactions.[11] TRALI is primarily attributed to alloantibodies in donor plasma-activating recipient granulocytes, which results in severe pulmonary edema. Biolipids and soluble CD40 ligand shed from platelets and lymphocytes may also contribute to neutrophil activation. TRIM is an immunosuppressive syndrome caused by donor leukocytes or leukocyte-derived intermediaries inducing an increased susceptibility to cancer recurrence or bacterial infection in recipients.

Nonimmune Reactions

Nonimmune reactions to plasma products are caused by improper collection, storage, or administration procedures, or by disease transmission from infected donors.[1,11] Volume overload is a common nonimmune reaction caused by too rapid rate or too high volume transfusion. Clinical signs of this reaction include emesis, vocalization, and dyspnea. Signs of respiratory distress may also develop secondary to transfusion of unfiltered plasma products containing fibrin clot fragments or precipitates formed by plasma contact with calcium- or glucose-containing solutions. Although RBC and platelet products are more frequently implicated in disease transmission, appropriate donor screening and careful attention to aseptic procedures for catheter placement are important to minimize risk of infection.[22] Blood banking recommendations to minimize plasma component contamination include avoidance of transfusion times longer than 4 hours and prohibiting introduction of any drugs or solutions into the plasma product.

The demand for animal plasma components and derivatives is likely to intensify as veterinarians provide increasingly complex medical and surgical services. The challenge remains for clinicians and researchers to develop mechanisms for evaluating the risks and benefits of plasma transfusion and protocols for optimizing plasma usage and clinical outcomes.

AABB, American Association of Blood Banks; ABRI, Animal Blood Resources International; DMSO, dimethyl sulfoxide; EDQM, European Directorate for the Quality of Medicines; FWB, fresh whole blood; G-CSF, granulocyte colony-stimulating factor; GC, granulocyte concentrate; PC, platelet concentrate; PPR, percent platelet recovery; PRP, platelet-rich plasma; RT, room temperature; WB, whole blood.

PLATELET TRANSFUSION

Platelet transfusion is indicated for the control of bleeding due to thrombocytopenia or thrombopathia. It may be *therapeutic*, given to stop active bleeding, or *prophylactic*, given to prevent spontaneous or excessive bleeding. In humans, platelet transfusions were initially given primarily to patients with leukemia and other neoplasms receiving intensive cytotoxic treatments, which promoted prophylactic transfusion against spontaneous bleeding. More recently, therapeutic platelet transfusion has been employed with increasing frequency in trauma and other non-neoplastic disorders.[29] Platelet transfusion has not been as widely used in veterinary medicine, in part because of short shelf-life of traditional components and short post-transfusion platelet circulation time. Early reports concerned experimental bone marrow transplantation, but, with improved blood banking, the use of more aggressive anticancer therapy, and the increased willingness to treat complex hematologic disorders, there is increasing use of platelet-rich blood and components, including fresh whole blood (FWB), platelet-rich plasma (PRP), and platelet concentrate (PC).[2,8,14,30,35] The latter may be prepared by centrifugation of FWB (see Chapter 98) or by plateletpheresis, the selective removal of platelets from the donor's blood with return of RBCs and plasma to the donor.[9]

ASSESSMENT OF PLATELETS FOR TRANSFUSION

During platelet collection and storage, deleterious physical and metabolic changes known as the *storage lesion* occur, which are greater than that expected with senescence alone. The storage lesion affects both platelet quantity and quality. Methods for the collection and storage of platelets to improve quantity and quality are being continuously evaluated, with results compared on the basis of in vitro and in vivo tests of PRP and PC. The pH of the component is an important aspect of the storage lesion, and standards for human PCs produced by centrifugation specify a pH > 6.2 (American

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

Association of Blood Banks [AABB]) or >6.4 (European Directorate for the Quality of Medicines [EDQM]) in all units at the end of the allowable storage period.[17,20]

The number of transfused platelets is important for hemostatic effect. Platelet *quantity* in the component is typically determined using standard methods of platelet counting for hemograms, but hematology analyzers are not specifically calibrated for this purpose and results will vary with the method (see Chapter 137). Platelet *yield* from centrifugation is calculated by dividing the number of platelets in the final component by the number of platelets in the initial blood or component. Platelet *survival during storage* is calculated by dividing the number of platelets remaining at the end of the storage period by the number present at the beginning. Standards specify that human PCs produced by centrifugation have $\geq 5.5 \times 10^{10}$ (AABB) or $\geq 6 \times 10^{10}$ (EDQM) platelets per unit.[17,20] Plateletpheresis should result in $\geq 3 \times 10^{11}$ (AABB) or $\geq 2 \times 10^{11}$ (EDQM) platelets in ≥90% of units.[17,20]

Platelet *quality* in the blood component refers to both post-transfusion hemostatic effect (in vivo function) and circulation time (in vivo viability). Platelet viability is most important for prophylactic transfusion. Platelet viability is determined by radiolabeling or biotinylating platelets and measuring a decrease in labeled platelets over time[5, 43-49] In the clinical setting, platelet viability is determined by measuring the incremental increase in platelet counts following transfusion. One-hour and 24-hour platelet increments are standard measurements; 10-minute increments have also been used.[15,37]

For assessing platelet function, many of the in vitro tests discussed in Chapter 79 have been used in a somewhat unsuccessful effort to predict post-transfusion function and viability.[1,4,50] The poor predictive value occurs at least in part because the metabolic changes in stored platelets may be reversible after transfusion.[41] The most useful tests, in addition to pH, are lactate concentration, response to hypotonic stress, flow cytometry of activation markers, and evaluation of platelet morphology.[1,10,50] The latter includes shape change in response to agonists, morphology scoring using light or electron microscopy, and evaluation of swirling in the blood bag with the unaided eye. Of these, only swirling is practical as a routine test in most clinics; the others are used primarily in a research capacity. Given the limited data on clinical platelet transfusion in dogs and cats, the following in vitro tests are recommended for routine use: (1) measurement of platelet count in FWB, PRP and PC (2) assessment of swirling in PRP and PC; and (3) measurement of pH and lactate in PRP and PC after storage.

The best proof of platelet function is control of bleeding in experimental or naturally occurring thrombocytopenia or thrombopathia.[27] Improved hemostasis may be documented by subjective observation of the bleeding patient and comparison of pretransfusion and post-transfusion bleeding times or other point-of-care tests of platelet function (see Chapters 79 and 88). In addition to the quality of the PRP or PC, improved hemostasis is dependent on recipient factors affecting platelet function and viability.

WHOLE BLOOD-DERIVED AND APHERESIS PLATELETS

Preparation of PRP and PC from FWB is described in Chapter 98. Leukoreduction during collection with a platelet-sparing filter reduces the storage lesion in human and canine (author unpublished observations) PCs.[38] All PCs should be labeled with donor blood type, as these components invariably contain RBCs.

The main benefit of apheresis PC over whole blood-derived PC or PRP is a greater total platelet yield per donor. Plateletpheresis has been performed successfully in dogs (10–28 kg body weight) using both automated continuous and discontinuous flow centrifugation.[8,9] Blood is typically collected through a 14–16-gauge jugular venous catheter, and platelet-poor blood is returned via a peripheral venous catheter. Platelet concentrate volume and platelet yield from plateletpheresis have ranged from 120 to 322 mL and 1.26×10^{11} to 4.5×10^{11} platelets/PC, respectively.[8,9] Collection time is approximately 1–2 hours, depending on desired platelet yield.[8,9] Platelet recovery (viability 1–2 hours post-transfusion) is approximately 80%, and transfused apheresis platelets have a mean half-life of 3.5–3.8 days and life span of 7–9 days.[8,9]

The main adverse effects of plateletpheresis on the canine donor are thrombocytopenia and hypocalcemia. Thrombocytopenia is usually mild, with most counts remaining above 100,000/μL and returning to baseline by 4–6 days. Ionized calcium levels drop during plateletpheresis because of citrate toxicosis during reinfusion of platelet-poor plasma and RBCs to the donor. Clinical signs of hypocalcemia were noted in three of 14 dogs in one study and were generally mild, but occurred despite intravenous calcium supplementation.[8,9] No long-term side effects have been noted.

STORAGE OF PLATELET-RICH BLOOD AND COMPONENTS

Veterinary clinics with blood-component-producing capabilities usually prepare PRP and PC on an as-needed basis, but PRP and PC may be stored for 5–7 days at room temperature (RT, 20–24 °C) with continuous or intermittent agitation; FWB is standardly stored up to 8 hours at RT, although an overnight holding period is feasible.[53] Due to the increased risk for bacterial proliferation at RT storage, especially in leukoreduced units, there has been re-evaluation of refrigerated storage of platelets as well as studies of pathogen inactivation. Cryopreservation and lyophilization are also long-term storage options for platelets that reduce bacterial proliferation.

Chilled Platelets

Prior to 1969, human platelets were refrigerated at 4 °C, similarly to RBCs.[34] Evidence of reduced viability after 8–24 hours of chilling then prompted the current standard of preparation and storage at RT.[3,7,8,18,47,50] However,

during the first 24 hours of refrigeration, platelets actually had normal-to-increased in vitro aggregation responses and demonstrated immediate in vivo hemostatic efficacy in humans with thrombocytopenia and thrombocytopathia.[7,18,51] Nonetheless, after 24 hours of refrigeration, in vitro aggregation, in vivo viability, and hemostatic efficacy rapidly diminished.[7,18,51] Various mechanisms contributing to reduced in vivo viability have now been elucidated, and there is a resurgence in the use of chilled platelets for therapeutic transfusion and investigations into techniques to improve quality.[23,40,54] There are no reports on the function or viability of chilled canine PRP or PC, and, given the effects of chilling on survival of both murine and human platelets, refrigerated storage of canine platelet-rich PRP and PC is not recommended. However, in vitro aggregation was normal in FWB during the first 6 hours of refrigeration, and remained at approximately 50–75% of baseline over 3 weeks; so, if FWB has been refrigerated immediately after collection, it is reasonable to assume that platelet function in the blood would be acceptable if transfused the same day.[36]

Pathogen Inactivation

Pathogen inactivation uses photochemical and/or ultraviolet illumination to damage pathogen nucleic acids.[54] This is effective against many pathogens, but also reduces platelet quality.[54] Pathogen inactivation is being used increasingly in human blood banks for RT storage, but in dogs has only been used experimentally.[49]

Cryopreserved Platelets

Cryopreservation is approved for human PC and has been used to store canine PC for up to 2 years.[4,5,8,24,54] Platelets are cryopreserved using a cryoprotectant solution in approved plastic bags at a freezing rate of 1–3 °C per minute. In general, cryopreserved human platelets have reduced function and viability compared to RT platelets. For dogs, platelets cryopreserved in 6% dimethyl sulfoxide (DMSO) also have impaired in vitro function based on marked reduction of aggregation, although cryopreserved platelets can be activated in vitro as demonstrated by P-selectin expression.[4,5,8,24] Compared to fresh PC, cryopreserved canine platelets also have had reduced in vivo recovery (approximately 50%) and survival (half-life, approximately 2 days), but had hemostatic efficacy in irradiated dogs.[5,8] These results may reflect the poor predictive value of the in vitro tests and/or the clinical benefit of transient platelet support. Canine platelets cryopreserved in polyethylene glycol–DMSO were also effective in controlling bleeding in Basset Hounds and Otterhounds with thrombopathia (W. J. Dodds, personal communication).[39] Commercial availability of cryopreserved canine PCs (Animal Blood Resources International, ABRI) provides a source of platelets for transfusion for clinics that do not own blood component centrifuges. In one retrospective study, thrombocytopenic dogs transfused with this component tolerated the transfusion well and platelet count significantly increased 24 hours following transfusion. Clinical bleeding scores were not significantly improved following transfusion compared to a control group, but the control group was comprised of dogs that did not receive a platelet transfusion and therefore disease severity could have differed between groups.[35]

Lyophilized Platelets and Platelet Substitutes

Lyophilization has also been used for long-term storage of human and canine platelets. The latter are commercially available as StablePlate RX™ (BodeVet, Rockville, MD). A randomized trial of this component in thrombocytopenic dogs compared outcomes after transfusion of fresh PC versus lyophilized PC.[14] There was no difference in bleeding scores of dogs treated with the different components.[14] Both groups had similar rates of acute transfusion reactions, which were mild.[14] Efficacy of the different platelet components could not be compared in the study due to a low number of dogs.[14]

Several synthetic platelet substitutes are under development as are methods for deriving platelets from cultured progenitor cells.[19]

TRANSFUSION OF PLATELETS

Platelet transfusion is most useful in the management of bleeding in patients with thrombocytopenia due to decreased platelet production, where transfused platelet life span is normal. It is clinically most rewarding when prompt marrow recovery is anticipated, e.g., following anticancer chemotherapy. Platelet transfusion may also be beneficial in dilutional thrombocytopenia associated with massive transfusion. Platelet transfusion is less beneficial in disseminated intravascular coagulation, but may be given if the patient is bleeding. Platelet transfusion is least beneficial in immune-mediated thrombocytopenia because transfused platelets may be rapidly destroyed; however, platelet transfusion has been useful in some cases and should be considered when there is critical bleeding.[8,11,14,35] Platelet transfusion is beneficial in most cases of bleeding due to thrombopathia.

Platelet transfusion triggers and doses have been reviewed.[2,15,25,28,29] Prophylactic transfusion, although controversial, is a common practice in human medicine, with transfusion triggers against spontaneous bleeding of 10,000/μL in the absence of other risk factors for bleeding, and 20,000/μL with other risk factors, and periprocedural triggers of 50,000–100,000/μL. Prophylactic transfusions increase the use of platelet components. Most transfusions given to dogs and cats are therapeutic. The latter approach requires close patient monitoring and readily available FWB, PRP or PC.

Platelet dose is also controversial.[2,15,25,28,29] A strategy of higher-dose, less-frequent transfusions may be used, versus one of lower-dose, more-frequent transfusions. Platelet survival is increased at higher platelet counts, supporting the first strategy, which is particularly applicable if transfusions are given prophylactically against

spontaneous bleeding on an outpatient basis. However, this may increase the total number of units used. Economics and resources often dictate a minimal transfusion dose in animals, which are usually hospitalized and transfused therapeutically, promoting the latter strategy. It is often not necessary to raise the platelet count by large increments—critical spontaneous bleeding can usually be prevented by transfusions to keep the platelet count above 10,000–15,000/μL.[2]

As with RBC and plasma components (see Chapters 99 and 100), platelet transfusions should be given using standard blood administration sets with 170 μm filters. Transfusion sets should be free of latex, which can bind platelets. Most infusion pumps may be used without damaging platelets, but the manufacturer should be consulted.

The success of a platelet transfusion is judged by control of bleeding and by comparing expected and measured platelet increments.[2,15,27] If the transfusion was beneficial, active bleeding will be reduced. If bleeding is well-controlled, existing petechiae and ecchymoses will fade over 12 hours. The expected 1-hour post-transfusion platelet count is calculated as:

Expected 1-hour platelet count = platelet count pre-transfusion + expected 1-hour platelet increment, where expected 1-hour platelet increment = unit platelet count × unit volume × percent platelet recovery (PPR)/estimated blood volume.

The PPR corrects for a fixed loss of transfused platelets due to splenic sequestration and other factors, and may be based on post-transfusion counts (increments) of labeled or unlabeled platelets in normal subjects or on platelet increments in clinical patients in previous studies.[15,25,28,47] If the measured platelet count is much below the expected count, there is accelerated destruction, consumption, increased sequestration, or the quality of the transfused blood or component was suboptimal. If there is minimal platelet production, but no accelerated platelet loss or sequestration, the recipient's platelet count should drop by approximately 33% each day following transfusion.[3] When interpreting the success of a platelet transfusion, it should be noted that platelet counts at low values are imprecise and hematology analyzer calibrations have not been optimized to count platelets altered by various storage methods.

Fresh Whole Blood

Often FWB is the only platelet-rich blood or component available to veterinary clinics. It also has maximum hemostatic properties. In a human trial, 1 unit FWB was equivalent to 10 FWB-derived PCs after open heart surgery, at least partially because the most functional platelets remain in the RBC fraction after centrifugation.[32,33] However, as is consistent with the observation that marked bleeding is required to lower platelet counts, large-volume transfusions are required to substantially raise them. As a rule of thumb, a FWB transfusion of 10 mL/kg will raise the recipient's platelet count by a maximum of 10,000/μL and will stop critical bleeding if there is no ongoing platelet loss.[2,3] The transfusion is given over 1 hour unless a slower rate is indicated.

Platelet-Rich Plasma and Platelet Concentrate

The recommended initial dose for FWB-derived PRP or PC is 1 unit per 10 kg, although resources may dictate a smaller dose. If the units contain on average 6×10^{10} platelets, platelet dose is 6×10^{9} platelets/kg, and the 1-hour platelet increment should be approximately 35,000/μL based on 51% PPR.[3,48] Using an approximately 50% fixed platelet loss may be extreme given that other studies suggest approximately 20% loss.[5,8] However, in the authors' experience, platelet increments are even lower than that predicted with approximately 50% loss, perhaps reflecting decreased platelet survival in the presence of thrombocytopenia.[25,27] Assuming canine apheresis PC contains on average 2.4×10^{11} in 200 mL, a minimum initial dose would be 1 apheresis PC/40 kg. Apheresis PCs are clearly superior for high-dose platelet support and transfusion to large dogs. Cryopreserved apheresis PCs (ABRI) are available as half-units of a minimum of 0.5×10^{11} platelets (typically $0.6–0.8 \times 10^{11}$ platelets) in 100 mL (600,000–800,000 platelets/mL), with a recommended dose of 1 PC/10 kg and an expected 1–2 hour increment of 20,000/μL, i.e., about 50% of that expected with FWB-derived PC.[24] Fresh or cryopreserved PCs are transfused over 1 hour and PRP at 10 mL/kg/hour, unless a slower rate is indicated.

For lyophilized platelet transfusion, StablePlate RX™ is provided as a 1.5×10^{10} particles/50 mL vial, which when reconstituted contains 1.5×10^{9} particles/mL. The recommended dose is 3×10^{9} particles/kg (one vial/5 kg), administered by slow bolus intravenous infusion. This dose is approximately 50% of the FWB-derived and cryopreserved PC dose, and, using the abovementioned formula, predicted 1-hour platelet increment would be at most approximately 15,000/μL.

Platelet-Poor Blood Components

If FWB, PRP, or PC are not available, fresh frozen plasma (10 mL/kg) or cryoprecipitate (1 unit/10 kg) could be considered for therapeutic transfusion. These components contain hemostatically functional platelet microparticles, and have been beneficial in treating thrombocytopenic bleeding.[22] Benefit may also be via augmentation of other aspects of hemostasis. Stored WB or packed RBCs may also reduce thrombocytopenic bleeding in anemic patients, as bleeding time is longer at lower hematocrits.[52] This is likely a benefit in dogs with immune-mediated thrombocytopenia. In addition, platelets retain some function in stored WB.[36]

PLATELET TRANSFUSION REACTIONS

Transfusion reactions are discussed in Chapter 104. Febrile reactions are the most common reaction to PC; frequency is reduced by prestorage leukoreduction.[38] Alloimmunization to platelet antigens occurs readily in immunocompetent dogs receiving multiple transfusions, resulting in platelet transfusion refractoriness, a failure to achieve an expected increment in platelet count in response to a platelet transfusion.[42–49] Two currently

accepted methods for minimizing the development of platelet alloimmunization include leukoreduction and ultraviolet irradiation.[43-45,49] The combination of centrifuge- and filter-leukoreduction was shown to be superior to either procedure alone for prevention of platelet alloimmunization in dogs.[50] Dogs being treated with cyclosporine are less likely to develop alloimmunization.[45]

Transfusion-associated sepsis is a particular concern with RT-stored PRP or PC. The rate of contamination in human PC without pathogen reduction is one in 2000–5000 units.[31] The rate for canine PC is not known, and measurement of this rate is affected by the comparatively low number of units produced. Visual inspection of a contaminated unit may reveal gaseous distention of the bag and loss of swirling, but contaminated units may have a normal appearance. Veterinary blood banks should closely monitor RT-stored platelet components microbiologically.

GRANULOCYTE TRANSFUSION

Granulocyte concentrate (GC) transfusion produces a transient increase in neutrophil numbers to a critical level that may permit survival in otherwise fatal sepsis.[21] While promoted in the 1970s and early 1980s in human medicine, usage of GC then declined because of expense, febrile reactions, controversial benefit, and newer antibiotics. The availability of granulocyte colony-stimulating factor (G-CSF) paradoxically led to a resurgence of GC transfusion.[13] Granulocyte concentrate is usually prepared by continuous-flow centrifugation leukapheresis, with pre-administration of G-CSF (with or without corticosteroids) to the donor to increase neutrophil yield. Donors should be blood-type-compatible, and irradiation of GC (25–50 Gy) is recommended to minimize transfusion-associated graft-versus-host disease.[20]

Therapeutic GC transfusions in dogs have been used primarily in experimental models of myelosuppression and neonatal sepsis.[12,16] They have been rarely used in clinical veterinary medicine. In addition to leukapheresis, centrifugation of FWB, with or without colloid-facilitated sedimentation, may be used to isolate canine and feline buffy coats; sedimentation alone may also be used in the cat.[6,42] Granulocytes are stored at RT without agitation for 24 hours.[20] The initial dose is 1×10^9 granulocytes/kg in a volume of 15 mL/kg once to twice daily.

Granulocytes may also be used diagnostically. Infusion of radiolabeled autologous granulocytes and scintigraphy may be used to detect inflammation in animals with nonspecific clinical signs.[26]

- Administration and Adverse Reactions

Acronyms and Abbreviations

CPDA-1, citrate-phosphate-dextrose with adenine; FFP, fresh frozen plasma; FPT, failure of transfer of passive immunity; HBOC, hemoglobin-based oxygen carrier; NI, neonatal isoerythrolysis; pRBC, packed red blood cell; TP, total protein; USDA, United States Department of Agriculture; WB, whole blood.

Blood product transfusion is an integral part of equine practice, both in referral institutions and in ambulatory practice. Blood products may be administered for conditions ranging from life-threatening acute hemorrhage to failure of transfer of passive immunity (FPT). The available equine blood products and indications for transfusion will be discussed in this chapter. Practical considerations for donor selection and collection and administration of blood will also be provided. A brief discussion of whole blood (WB) and blood product transfusion in ruminants and camelids is presented at the end of the chapter.

INDICATIONS FOR BLOOD PRODUCT TRANSFUSIONS

Whole Blood

Whole blood transfusions are most often indicated for horses that have suffered acute blood loss from trauma, surgery, or other conditions such as splenic rupture or uterine artery hemorrhage. In cases of blood loss, the transfusion serves to restore blood volume as well as oxygen-carrying capacity. While there are no set variables that serve as "transfusion triggers," a combination of physical examination and clinicopathologic parameters can be used to guide the decision to transfuse. It is important to remember that the PCV may initially remain normal in cases of acute hemorrhage due to splenic contraction. Some fluid redistribution occurs almost immediately after blood loss, but it may take hours to days for complete restoration of blood volume, further complicating the assessment of the patient with acute blood loss. Serial monitoring of PCV and total protein (TP) as the horse is rehydrated with intravenous fluids will give an indication of the extent of blood loss. Suspicion of large-volume blood loss, combined with tachycardia, tachypnea, pale mucous membranes, lethargy, and decreasing TP, may lead to the decision to transfuse.[18] Blood transfusion is likely needed during an acute bleeding episode when the PCV drops below 20%, although in acute severe cases, transfusion may be needed before there is a significant drop in PCV.

Estimation of blood loss at surgery can be used to guide the decision to transfuse, with greater than 30% blood loss generally requiring transfusion.[13] Anesthetized horses may have very stable heart rate

and PCV despite massive blood loss; pale mucous membranes with prolonged capillary refill time, decreasing TP, hypotension, and hypoxemia are better indicators of blood loss.[47]

Oxygenation status can help to determine the need for blood transfusion in cases of both acute hemorrhage and chronic anemia. A rise in blood lactate concentration despite volume replacement with crystalloid or colloid fluids may indicate continued tissue hypoxia and a need for blood transfusion.[15,23] The oxygen extraction ratio is also a useful measure:

$$ER_{O_2} \approx \frac{S_{aO_2} - S_{vO_2}}{S_{aO_2}}, \quad (102.1)$$

where ERo_2 is the oxygen extraction ratio, S_ao_2 the arterial oxygen saturation, and S_vo_2 the mixed venous oxygen saturation. A ratio greater than 40–50% in the context of blood loss may indicate a need for blood transfusion.[24]

Transfusion should be considered a temporary measure to restore oxygen-carrying capacity, relying on the horse's erythropoietic response, control of hemorrhage, or resolution of underlying disease to provide long-term resolution.

Packed Red Blood Cells

Packed RBCs (pRBCs) are indicated for normovolemic anemia, such as neonatal isoerythrolysis (NI), erythropoietic failure, and chronic blood loss. In cases of chronic or hemolytic anemia, markers of tissue oxygenation, such as lactate and oxygen extraction, are still useful. PCV is a better "transfusion trigger" for chronic anemia compared to acute hemorrhage, with transfusions suggested for horses with evidence of tissue hypoxia and a PCV less than 10–12%. Transfusions may be given at a higher PCV for horses with concurrent conditions (e.g., respiratory disease, anesthesia, sepsis) or risk of further blood loss. When pRBCs are not available, WB may be used for the same indications, although attention should be paid to the total volume given so that volume overload is avoided.

Plasma

Plasma transfusion is indicated for the treatment of clotting factor deficiency, hypoalbuminemia, decreased colloid oncotic pressure, and FPT. Fresh and fresh frozen plasma (FFP) contain immunoglobulins, coagulation factors (fibrinogen and factors II, VII, IX, X, XI, and XII), and cofactors (factors V and VIII), as well as the anticoagulant proteins antithrombin, protein C, and protein S. Plasma has also been used for treatment of disseminated intravascular coagulation in horses.[45]

Colloid support is generally recommended in patients with a total protein less than 4 g/dL or serum albumin concentration less than 2 g/dL. Other indications for colloid support are colloid oncotic pressure less than 14 mmHg, clinical signs such as ventral edema, and conditions which increase microvascular permeability, such as sepsis. When plasma is not necessary for clotting factor replacement, a synthetic colloid such as hydroxyethyl starch (hetastarch) is preferred for volume expansion and more effective oncotic support. In healthy horses, hetastarch and plasma infusion increased colloid oncotic pressure similarly, with an increase of approximately 2 mmHg after a 10 mL/kg IV infusion.[29]

Failure of transfer of passive immunity in neonatal foals more than 12 hours of age is best treated by plasma transfusion, as colostrum absorption is greatly diminished after 12 hours.[19] An IgG concentration less than 200 mg/dL is considered complete FPT, and IgG between 400 and 800 mg/dL is considered partial FPT. Although plasma transfusion is not always needed for foals with partial FPT, it is recommended for foals that have preexisting infection or exposure to pathogens. Commercially available fresh frozen hyperimmune plasma is most commonly used for treatment of neonatal foals (Table 102.1). Equine FFP is a USDA-licensed product, and most products have a minimum guarantee for IgG concentration and a 2–3-year shelf-life when frozen. Although commercially available hyperimmune plasma has very high IgG concentrations (1500–2500 mg/dL), plasma from local donor horses may provide better protection against specific local pathogens.

There are multiple hyperimmune plasma products with bacterial- or viral-specific antibodies. There is some evidence for the efficacy of *Escherichia coli* (J5) and *Salmonella typhimurium* hyperimmune plasma for the treatment of equine endotoxemia; however, there are also reports which dispute the efficacy of such products.[10,33,38,39] *Rhodococcus equi* hyperimmune plasma has been shown to decrease the severity of pneumonia in foals experimentally infected with *R. equi*, although it did not reduce the incidence of naturally acquired *R. equi* pneumonia.[6,14,35] Other plasma products available for specific disease treatment include plasma from donors vaccinated against *Clostridium botulinum*, Rotavirus, and West Nile virus antibody.

Hemoglobin-Based Oxygen Carriers

A hemoglobin-based oxygen carrier (HBOC) solution, Oxyglobin, has been used in ponies with experimentally induced normovolemic anemia.[3] This product improved

hemodynamic and oxygen transport parameters; however, one pony did have an anaphylactic reaction. The use of an HBOC solution was also reported for treatment of a pony mare with chronic hemorrhage and a history of acute transfusion reactions.[27] Oxyglobin is no longer on the market, but there are newer generations of HBOCs in development.

BLOOD DONOR SELECTION

The ideal equine blood donor is a healthy, young gelding weighing at least 500 kg. Donor horses should be up-to-date on vaccinations, including rhinopneumonitis, tetanus, eastern and western encephalitis, rabies, and West Nile virus. Donors should be tested annually for equine infectious anemia. Because RBC antigens Aa and Qa are the most immunogenic, the ideal donor should lack the Aa and Qa alloantigens. There are breed-specific blood factor frequencies, so a donor of the same breed as the recipient may be preferable, especially when blood typing is not available. Horses that have received blood or plasma transfusions and mares that have had foals are not suitable as donors, as they have a higher risk of carrying RBC alloantibodies. Donkeys have a RBC antigen known as "donkey factor," which is not present in horses; therefore, donkeys or mules should not be used as donors for horses, as the transfused horses can develop anti-donkey factor antibodies.[28]

When a surgical procedure is planned in advance and there is a high risk of blood loss, preoperative autologous donation should be considered, as the horse would be its own ideal blood donor.[31] The half-life of fresh allogeneic transfused RBCs is approximately 34 days for crossmatch-compatible blood and less than 5 days for crossmatch-incompatible blood, and approximately 50 days for autologous transfused RBCs.[32,41] Intraoperative or posthemorrhage cell salvage is also an option for autotransfusion, and its use has been reported in a horse with postcastration hemorrhage.[42] Red blood cell recovery can be performed with specialized cell salvage equipment which washes and filters collected blood, but cell salvage can also be performed with simple anticoagulation and filtration.[20,43]

BLOOD TYPING AND CROSSMATCHING

In an emergency situation, an immediate blood transfusion may be given for the first time with a very minor risk of serious transfusion reaction. Horses can develop alloantibodies within 1 week of transfusion, so blood typing and crossmatching are recommended before a second transfusion is performed.[48] However, a second blood transfusion may be performed safely within 2–3 days of the first transfusion without a blood crossmatch.

Blood typing and alloantibody screening can be used to help find the most appropriate donor horse for the patient requiring transfusion (see Chapters 96 and 107). Unfortunately, since blood typing is time-consuming and laboratories performing blood typing are very limited, this is not often a practical method of donor selection (Table 102.2). Blood typing and antibody screening prior to initial transfusion are more important for horses for which subsequent blood transfusions are anticipated and for broodmares which may produce foals with NI if sensitized to other blood group factors.[48] A rapid agglutination method (Alvedia, Limonest, France) is available for detection of equine RBC antigen Ca, which may be more practical for limited pretransfusion testing.

A blood crossmatch is recommended prior to a transfusion, especially for any horse which may have previously been exposed to RBC antigens (see Chapters 96 and 107). Although preexisting alloantibodies are uncommon in horses, RBC survival time is decreased and febrile reactions are more common when crossmatch-incompatible blood is transfused.[41] Hemagglutination crossmatching is widely available and rapidly performed; however, it will not predict all transfusion reactions, namely, the hemolytic reactions. Rabbit complement can be added to the reaction mixture to detect hemolytic reactions.[2] The gel column crossmatch technique has been shown to have excellent accuracy for agglutination reactions, but not for hemolytic reactions.[21]

COLLECTION TECHNIQUES

Blood is collected from the jugular vein of the donor horse, either via direct needle cannulation or catheterization. When a large volume of blood is needed, a 10- or 12-gauge catheter is recommended, although a 14-gauge catheter is also sufficient. Blood flow may be improved by placing the catheter opposite the venous blood flow (catheter directed toward the head). A healthy horse can donate approximately 20% of its total blood volume every 30 days.[26] When 15% or greater blood volume is collected, volume replacement with approximately 10–20 mL/kg intravenous crystalloid fluids is recommended. The donor horse's heart rate, respiratory rate, and attitude should be monitored during the blood collection. Vital parameters should normalize within 1 hour of collection.

Plastic bags and vacuum-collection glass bottles are available for blood collection in sizes ranging from 450 mL to 4 L (Baxter Fenwal, Deerfield, IL; MWI Veterinary Supply, Meridian, ID; Animal Blood Resources International, Dixon, CA). The glass bottles are preferred by many due to the speed of collection; however, the glass inactivates platelets and causes some damage to RBCs.[30,36]

When blood is collected for immediate transfusion, anticoagulation with 3.2% sodium citrate is adequate. However, when blood is stored for later transfusion, optimal pH and support of RBC metabolism are necessary to sustain RBC viability (see Chapter 98). A post-transfusion viability study demonstrated a viability of 73% at 24 hours post-autologous transfusion, for blood stored for 28 days in citrate-phosphate-dextrose with adenine (CPDA-1).[32] Recommended storage conditions for equine blood are similar to those for canine and human blood (see Chapter 98).

Equine blood can be processed to provide plasma and pRBC components, as with other species. Due to the rapid sedimentation of equine RBCs, the RBC component can be administered without specialized processing; however, the pRBCs will still contain plasma components unless centrifugation and repeated washing are performed. Washing of RBCs is the preferred technique when a transfusion is given to an NI foal using the mare as a donor. When RBC washing or other processing is planned, blood should be collected into bags rather than bottles due to ease of centrifugation and sterile transfer.

Plasma processing can be performed by gravity sedimentation, centrifugation using a double-bag system, or plasmapheresis. Plasmapheresis is the preferred technique for commercial plasma production, as it is more rapid than WB collection and processing, and results in plasma with minimal RBCs and leukocytes.[11] Plasmapheresis of between 4 and 11 L can be performed every 30 days on donor horses.[25] Immunoglobulins are well-maintained for at least 1 year in FFP; however, coagulation factor activity may decrease after 2–4 months of storage.[17]

Plateletpheresis has been described in horses using commercially available apheresis equipment. Platelet concentrations in horses were lower using this technique compared to the concentrations reported in other species, possibly due to the human-specific calibration of the equipment.[40] Equine platelet concentrate can also be produced through processing of whole blood with multiple centrifugations. This technique was reported to produce platelet concentrate that meets the standards of the American Association of Blood Banks.[4]

ADMINISTRATION AND ADVERSE REACTIONS

The volume of blood to be transfused depends on estimated blood loss, estimated total blood volume, and donor PCV:

$$\begin{aligned}&\text{Blood transfusion volume (mL)}\\&= \text{Body weight (kg)}\\&\quad \times \text{Blood volume (mL/kg)}\\&\quad \times \left[\frac{(\text{Desired PCV} - \text{Actual PCV})}{\text{Donor PCV}}\right]\end{aligned} \qquad (102.2)$$

In cases of acute blood loss, PCV is often not useful for estimates of volume to be transfused, since it does not accurately reflect blood loss. Instead, estimates of blood loss and evaluation of clinical parameters are used to determine the volume of blood needed. Between 25% and 50% of the total blood lost should be replaced by transfusion, since much of the circulating volume will be replaced by fluid shifts. It is important to remember that up to 75% of RBCs lost into a body cavity (e.g., hemoperitoneum) are autotransfused back into circulation within 24–72 hours.[34] Therefore, lower percentages of blood volume replacement may be needed in cases of intracavitary hemorrhage. Blood and plasma products should be delivered with an in-line filter to remove small clots and fibrin.

Volumes of plasma for treatment of hypoproteinemia can be estimated by TP or albumin concentrations, although the use of plasma to normalize severe hypoproteinemia can be prohibitively expensive in the adult horse:

$$\begin{aligned}&\text{Plasma transfusion volume (mL)}\\&= \text{Body weight (kg)} \times 45\text{(mL/kg)}\\&\quad \times \left[\frac{(\text{Desired TP} - \text{Actual TP})}{\text{Donor TP}}\right]\end{aligned} \qquad (102.3)$$

Volumes of plasma given for treatment of hypoproteinemia or coagulopathy are often determined by clinical and clinicopathological response. The volume of plasma needed in a foal with FPT can be determined if the IgG concentrations of the foal and the plasma are known. A dose of 20 mL/kg of plasma (IgG approximately 1200 mg/dL) will generally raise the foal's IgG concentration by 200–300 mg/dL, and hyperimmune plasma (IgG > 2500 mg/dL) should increase the IgG by approximately 400 mg/dL. A larger volume of plasma may be needed to achieve a similar rise in IgG in clinically ill foals.[46]

In order to monitor for transfusion reactions, blood should be delivered at a rate of approximately 0.3 mL/kg over the first 10–20 minutes, while monitoring heart rate, body temperature, and respiratory rate. Horses should also be monitored for signs of muscle fasciculation, piloerection, and urticaria. Adverse reactions reported in horses receiving blood transfusions include urticaria, hemolysis, and acute anaphylactic reactions. The rate of adverse reaction to WB transfusion has been reported as 16%, with one of 44 horses (2%) having a fatal anaphylactic reaction.[18] The rate of transfusion reactions to commercial equine plasma was reported as 0% in adult horses and 8.7% in foals, with no fatal reactions.[16] If no signs of reaction are seen, the rate of administration can be increased to 5 mL/kg/hour for normovolemic horses and up to 20–40 mL/kg/hour for hypovolemic horses. If signs of anaphylaxis are present, epinephrine (0.01–0.02 mg/kg IV) should be administered immediately. More mild transfusion reactions, such as urticaria, fever, and tachypnea, may be treated with an anti-inflammatory (e.g., flunixin meglumine 1.1 mg/kg IV) or an antihistamine (e.g., tripelennamine or diphenhydramine 1.1 mg/kg IM).

Similar to the risks in other veterinary species, bacterial contamination of blood, transmission of blood-borne disease from donor to recipient, and hypocalcemia associated with citrate toxicity are all potential concerns related to transfusion in the equine patient (see Chapter 104). An additional concern in horses is the possible sensitization of a broodmare to blood group antigens, leading to the risk of NI in subsequent foals.[47] Although plasma transfusions are not commonly associated with serious adverse reactions, serum hepatitis has been reported in association with transfusions of commercial plasma.[1]

RUMINANTS AND CAMELIDS

Indications for Transfusion

The indications for WB and plasma transfusion in ruminants and camelids are similar to those for horses. Gastrointestinal parasites, especially *Haemonchus contortus*, and ectoparasites (e.g., *Haematopinus spp*. and *Linognathus spp*.) are causes of chronic blood loss anemia, and iron-deficiency anemia can affect neonatal calves.[37] The blood parasites *Anaplasma* and *Babesia* are both associated with the development of chronic anemia, although by different mechanisms. Infections in llamas and alpacas due to *Mycoplasma haemollama* result in a chronic anemia due to extravascular hemolysis, frequently leading to a PCV of less than 10%. In the case of acute hemorrhage or ongoing blood loss (e.g., abomasal ulcers), transfusion should be considered when the PCV falls below 20%. Ruminants with chronic blood loss may not require blood transfusion until the PCV is below 12%.

Failure of transfer of passive immunity is a common indication for plasma transfusion in neonatal calves and crias. While a TP less than 5 g/dL is suggestive of FPT in neonates, radial immunodiffusion can be performed to quantitatively determine IgG concentration.[5,44] Commercial FFP is available for ruminant and camelid transfusion (Animal Blood Resources International, Stockbridge, MI; Triple J Farms, Bellingham, WA), although fresh plasma or even WB can be effective for treatment of FPT. Hyperimmune serum products are available for subcutaneous and intramuscular dosing in ruminants, including products with antibodies against *E. coli*, *Pasteurella*, *Arcanobacterium pyogenes*, *S. typhimurium*, and *Mannheimia haemolytica* (Colorado Serum Company, Denver, CO). The use of Oxyglobin has been reported in a sheep with anemia due to gastrointestinal parasites and in two alpacas with hemolytic anemia, although Oxyglobin is not currently available.[8,12]

Donor Selection

The initial blood transfusion should generally be safe, regardless of the donor; however, a J-negative donor (cattle) is ideal (see Chapter 96).[9] Crossmatching in ruminants must include complement to test for hemolytic reactions, as these are more clinically important than agglutination reactions. Initial transfusions are generally safe to administer without a blood crossmatch. However, if more than 48–72 hours have elapsed since the initial blood transfusion, crossmatching is recommended. Blood donors should be free of disease, including bovine leukosis virus, anaplasmosis, and bovine viral diarrhea virus. If a donor animal is selected from the herd, it is especially important to check PCV and TP prior to blood collection, since the donor animal may also be affected by the same endoparasites or ectoparasites.

Collection Technique

Up to 20–25% of total blood volume can be removed from the donor animal, usually via needle cannulation or jugular catheterization. Total blood volume can be estimated at 80 mL/kg in cattle, and this estimate is also reasonable for goats and sheep, while blood volume of alpacas should be estimated at 100 mL/kg.[22] As with equine transfusions, blood can be collected into bottles or bags with citrate anticoagulant. Blood stored in CPDA-1 may retain adequate viability for 2–3 weeks.[7] Since bovine blood does not readily separate, a centrifuge is needed to process WB into plasma and pRBC components.

Administration and Adverse Reactions

Blood should initially be delivered slowly in order to monitor for transfusion reactions. Complement-mediated hemolysis is the primary transfusion reaction which occurs with ruminant blood type incompatibility. Volume overload should be avoided, and total volumes delivered should especially be considered in neonates and small ruminants.

Acronyms and Abbreviations

ACD, acid-citrate-dextrose; BV, blood volume; BW, body weight; CPD, citrate-phosphate-dextrose; CPDA-1, citrate-phosphate-dextrose-adenine; CRI, constant rate infusion; Hct, hematocrit; Hgb, hemoglobin; HBOC, hemoglobin-based oxygen carrier; IMHA, immune-mediated hemolytic anemia; IO, intraosseous; IV, intravenous; RCS, red cell survival; RHD, rabbit hemorrhagic disease; WB, whole blood.

Blood transfusions can be a lifesaving tool for all exotic species. While basic transfusion medicine concepts can be directly extrapolated from domestic species and applied to exotic species, there is a growing body of peer-reviewed literature and research about blood transfusions in exotic species.

ANEMIA IN EXOTIC SPECIES

Anemia can occur in all species to the point where transfusions may become necessary. Causes of anemia in exotic species are similar to domestic animals, and can include blood loss, hemolysis, and decreased production. Sequestration in the spleen may also lead to a low hematocrit (HCT) or PCV; e.g., in ferrets associated with isoflurane anesthesia.[28,29] Lymph (or cerebrospinal fluid) contamination occurs frequently during reptile venipuncture and accuracy of the PCV should be questioned and confirmed before making the diagnosis of anemia in reptiles.

INDICATIONS FOR TRANSFUSION

A transfusion should be considered in patients with a low PCV (less than 20% in birds and mammals and 10% in reptiles) or in patients experiencing hypovolemic shock from acute blood loss. However, the clinical presentation, chronicity of the anemia, underlying cause, risk of continued loss, and especially the ability of the patient to tolerate the stress of handling are very important considerations to take into account when deciding on this plan of action. Classification and identification of the underlying cause for anemia, as well as associated clinical signs, should be critically evaluated before electing blood product administration, especially in chronically sick animals. In those patients, treatment of the

underlying disease and supportive care may be superior to the risks and stress associated with a blood transfusion.[8]

CROSSMATCHING

Crossmatching is recommended for first transfusions in all exotic species except for ferrets, who have no identifiable blood groups. Crossmatching should be performed prior to all subsequent transfusions.

See Chapter 107 for more details on crossmatching, and Table 103.1 for more information on donor selection. A full crossmatch (major and minor) may not be feasible when managing most exotic species, as they are often much smaller than domestic species. A modification for small exotics to minimize the total blood volume needed (0.3–1 mL) includes the use of plasma instead of serum for full crossmatching. Plasma samples are used commonly in exotics, as it maximizes the volume available for analysis compared to serum.[26] EDTA is the ideal anticoagulant for this testing and has been used successfully for detection of incompatibilities via crossmatching by the authors. However, heparin is also routinely used, especially in avian and some reptile species. An optimized protocol for crossmatching of sea turtle blood using this anticoagulant has been published recently.[13] There are variations in reactions to different anticoagulants among exotic species. Heparin is commonly used for many avian species, as EDTA has been noted to cause hemolysis or reactions in a number of species, including crowned cranes (*Balearica sp*.), jays, brushturkey, crows (*Corvus corone*), and magpies (*Pica pica*).[26] In reptiles, it has been found that EDTA can cause hemolysis in Hermann's tortoises (*Testudo hermanni*)[35] and other chelonian species. Heparin, however, has been noted to cause hemolysis in some snakes (ball pythons (*Python regius*)).[46]

If a full crossmatch is not possible, a simplified crossmatch, using a drop of whole blood with two drops of plasma on a slide and looking for agglutination, can be tried before blood administration.[24] It should be noted that this technique cannot predict hemolysis and that weaker antibody reactions are likely to be missed.

BLOOD COLLECTION AND STORAGE

As a rule, sedation or anesthesia is recommended for blood collection techniques in all exotic species (except for tail collection in reptiles) in order to minimize stress from handling as well as the possibility of excessive blood loss or complications from hematomas, vascular laceration, or hemopericardium.[23,48] Blood collection sites can vary with the species. See Section IX "Species-Specific Hematology" for further information on blood collection sites.

A safe volume to collect from healthy animals is 10% of their blood volume. Blood volume in birds is variable (between 4.8% body weight (BW) in ring-necked

TABLE 103.1 Donor selection criteria for exotic species.

Species	Ideal donor	Donor screening
Avian	Healthy animal of appropriate weight Same species or genus preferred Housed singly or in closed aviary	Yearly physical examination, CBC, and biochemical profiles Screened for polyoma, psittacine beak and feather disease, and chlamydiosis Major or simplified crossmatch
Ferret	Male, less than 3 years of age	Yearly examination, CBC, and biochemical profiles Annual heartworm testing (antibody and antigen) and heartworm prevention in endemic areas Vaccinated yearly for canine distemper and rabies Major or simplified crossmatch after first transfusion
Rabbit	Female, less than 3 years of age Related animals may reduce disease transmission	Yearly examination, CBC, and biochemical profile Negative testing for *Encephalitozoon cuniculi* Screened (and/or vaccinated) for viral hemorrhagic disease (rabbit hemorrhagic disease (RHD)) and myxomatosis (in endemic countries) Major or simplified crossmatch
Rodents	Male guinea pigs less than 3 years of age Female chinchillas less than 5 years of age Male rats less than 1 year of age	Yearly examination, CBC, and biochemical profile in larger species Major or simplified crossmatch
Hedgehogs and other mammalian species	Largest available individual of the same species with an age that is less than half the expected life span of the species	Yearly examination, CBC, and biochemical profile if species size allows Major or simplified crossmatch
Reptiles	Young, healthy animal of appropriate weight Same species or genus preferred Same collection, singly housed animal or no animal added to collection for at least 3 months	Yearly examination, CBC, and biochemical profile, PCV and total solids in small species Screen for hemoparasites, viral testing Major or simplified crossmatch

TABLE 103.2 Anticoagulants for blood transfusions/known storage times. If blood will be stored, it needs to be cooled appropriately and warmed to 25–30 °C before administration.

Anticoagulant	Proportion of anticoagulant to blood	Avian	Mammal	Reptile	Comments
ACD	1:9	X	X	X	American alligators (packed RBCs), at least 35 days at 4 °C[14]
CPD	1:9	X	X	X	
CPDA-1	1:9	X	X	X	Preferred for stored whole blood in domestic species Rabbits, 28–35 days at 4–6 °C[6] Ferrets, 7 days at 4 °C[41] Rats, maximum 24 hours at 4 °C[7] American alligators (packed RBCs), at least 35 days at 4 °C[14]
Sodium heparin (1000 IU/mL)	Avian: 1:40 (0.25 mL per 10 mL blood) Reptile: 1:20–1:10 (5–10 IU per 1 mL/blood)	X		X	Preferred for short-term storage in sea turtles (24 hours at 4–8 °C)[40] Heparin may cause hemolysis in some snakes[46]
Sodium citrate (3.2%)	1:9	X			Citrate binds calcium in blood (use caution in hypocalcemic animals or very small animals)

pheasants (*Phasianus colchicus*) and 20% BW in domestic pigeons (*Columba livia domestica*); average bird blood volume is considered to be 10% of BW. The acceptable safe volume to draw from a healthy bird is 1% BW.[26] In small mammals, there is some variation in blood volume among species: rats/mice (5.5–7% BW),[36] guinea pigs (7.5% BW),[32] rabbits (5–7% BW),[32] ferrets (5–6% BW).[49] In reptiles, blood volume is 5–8% BW.[55] The maximum volume to draw from a healthy reptile is 1% BW.[34] Table 103.2 includes anticoagulants that may be used for blood collection, and known storage times. However, fresh blood (administered within 4 hours after collection) remains the primary and preferred transfusion type in all exotics. There are currently no long-term storage options for avian samples.[17]

BLOOD ADMINISTRATION—GENERAL CONSIDERATIONS

Blood transfusions should be administered in a similar technique to dogs/cats using an intravenous (IV) or intraosseous (IO) catheter via constant rate infusion (CRI). In most cases, the transfusion volume is 10–20% of the recipient's BW. In small species, multiple donors may be needed to achieve an appropriate volume. Warm blood should be administered via pediatric syringe pump and a standard 18 micron blood filter in most species.[22,37,38]

In mammals and birds, it is advisable to start the transfusion slowly (0.25 mL/kg/hour) for 15 minutes and monitor attitude heart rate, respiratory rate/effort, temperature, and appearance of skin for erythema or swelling at 5-minute intervals during that time.[6] The rate can be increased to 10–20 mL/kg/hour if there are no signs of a reaction, and monitoring should be continued at regular intervals until the transfusion is complete. Due to anatomical and physiological differences in reptiles, specific considerations should be taken into account and can be found later in this chapter in the reptile section.

Faster delivery should be considered in cases of acute blood loss. The transfusion may be administered as a bolus using a butterfly catheter, but should be given over at least 5 minutes to prevent circulatory overload.[3,38]

AVIAN SPECIES

For hematology information in different avian species groups, please see Chapters 123–127.

General Considerations

Birds are resistant to the effects of acute blood loss and rapidly regenerate blood cells (the half-life of avian RBCs is short (28–48 days, mean 39.7 ± 3.3 days) compared with other species groups).[44] A comparison of response to acute blood loss in pigeons to IV crystalloids alone, homologous transfusions, and heterologous transfusions demonstrated the best response in the IV crystalloid group.[5] The LD50 of acute blood loss was noted to be 60% of blood volume in mallard ducks (*Anas platyrhynchos*).[25] In this study, regeneration of cells started within 24 hours. In Japanese quail (*Coturnix coturnix japonica*) that underwent a 30% decrease in blood volume, blood volume returned to normal within 1 hour without replacement of volume with crystalloids, and most hematologic values returned to normal within 72 hours.[16,45] Chickens (*Gallus gallus domesticus*) that had acute hemorrhagic shock induced with 50% reduction in blood volume had a notable rise in PCV and hemoglobin (Hgb) within 3 days, and a return to normal values within 7 days, regardless of the presence or absence of fluid resuscitation.[57] If a patient is clinically stable, and

there has been less than 25% of blood volume lost (and the source of hemorrhage is arrested), it may not be necessary to perform a transfusion and the patient is likely to recover with supportive care and time.

Birds that are weak and showing profound clinical signs from anemia would benefit from a whole blood transfusion. However, these birds are more at risk of death from the stress-related effects of handling needed for performing a transfusion, requiring clear communication with clients.

Donor Selection/Blood Groups/Compatibility

There are 28 blood group antigens identified in chickens, with more than 10 alleles for most antigens.[12] Blood groups in psittacines have not been identified,[20] but serologic incompatibility between species of parrots has been noted using crossmatching, existing both prior to initial transfusion and after a heterologous transfusion has occurred.[9,10] A study evaluating crossmatches between 14 different avian species showed crossmatch reactions of varying degrees in 66% of heterologous transfusions.[51] However, heterologous transfusions between birds found to have mild incompatibility via crossmatching did not result in any identifiable negative clinical effects.[9,10]

Autologous transfusions resulted in red cell survival (RCS) of 35 days in red-tailed hawks (*Buteo jamaicensis*), and almost 27 days in pigeons. RCS from homologous transfusions ranges from 6–11 days; RCS from heterologous transfusions ranges from 12 hours–3 days (with the longer time frame for transfusions within the same genus, and the shorter time frame for transfusions between more distantly related species (i.e., pigeon to raptor)), noting that the RCS decreases with subsequent transfusions from the same donor.[9,43]

Ideally, one should aim for donors of the same species. If not available, donors from the same genus are preferred to more distantly related species.[9,10] In an emergency, using blood from a donor from a different class (i.e., chickens to psittacine) can be considered as long as any crossmatch incompatibility is mild. The transfused RBCs will have a very short half-life, but the transfusion may be beneficial as a colloid. See Table 103.1 for more information on donor selection.

Transfusion Reactions

Information from crossmatching can aid in donor selection in birds who have already had multiple transfusions. There are no reports of a bird clinically reacting to a single transfusion, regardless of relation to donor. However, there have been reports of deaths in birds after multiple heterologous transfusions, with histological evidence of a hemolytic reaction.[3]

Incompatibilities may be noted on crossmatch prior to transfusion, or may develop after the first or subsequent transfusions. Despite mild incompatibilities, one heterologous transfusion between conures (different *Aratinga sp.*) and two subsequent heterologous transfusions in cockatiels still did not result in identifiable clinical reactions.[9,10] However, when some species (African greys (*Psittacus erithacus*) and umbrella cockatoos (*Cacatua alba*)) were crossmatched with cockatiels, the incompatibility (agglutination) was noted to be so severe that transfusions were not performed.[9] It is also important to keep in mind that most studies are being performed in healthy animals with limited volumes. Birds with severe clinical signs that require a transfusion may not tolerate crossmatch-incompatible heterologous transfusions.[9,18]

SMALL MAMMALS

General Considerations

For hematology information in different small mammal species groups, please see Chapters 114–118. Transfusion medicine in small mammals most directly correlates with domestic species, and principles/guidelines for fresh blood transfusions in dogs/cats should be followed (see Chapter 99 for details on RBC transfusions in dogs/cats).

Donor Selection/Blood Groups/Compatibility

See Table 103.1 for recommendations for donor selection. There are no blood groups in ferrets, and repeated transfusions from the multiple donors have not led to development of anti-RBC antibodies.[20,42] There is no known information about blood groups in rabbits and other small mammals. Crossmatching should be performed for all transfusions except for a ferret's initial transfusion (crossmatching for subsequent ferret transfusions is advised).

Transfusion Reactions

Acute transfusion reactions have not been reported in small mammal species, but following the same protocols for administration in dogs/cats (slow rate to start and regular monitoring) will allow detection of adverse reactions, should they occur.

REPTILES

General Considerations

Limited research has been done to assess the applicability of blood transfusion medicine in reptiles, but the principles and techniques established in other species should apply. However, species-specific modifications due to hematological variations should be considered (see Chapters 132–134). Blood product administration has been reported with various outcomes in different reptilian species including lizards,[31] chelonians,[15,33,54,56] snakes,[31,54] and crocodilians.[19]

Anemia is caused by similar mechanisms as in other species, but anemia of chronic disease appears to be most common. The physiological PCV of most reptiles ranges between 20 and 40%.[50] Therefore, a PCV < 20% may indicate anemia.

Donor Selection/Blood Groups/Compatibility

Blood donor criteria are presented in Table 103.1. During the last decade, an increasing amount of viruses has been identified in reptiles, especially snakes.[21,30,52,53] The possible transmission of viral diseases via blood should be critically assessed and discussed with the pet owner. Due to the high number of various reptilian species kept in private and zoological collection, an ideal donor from the same species and the same household is often not available. A heterologous blood transfusion may need to be considered and has been performed successfully.[31,54,56] Similar to findings in avian species, preliminary research data support the hypothesis that reptilian post-transfusion RCS can be much shorter after a heterologous blood transfusion in comparison to a homologous blood transfusion (Stöhr, personal communication).[10] Therefore, a donor from the same or a closely related species is preferred.

Blood typing is not established in reptiles, but genomic studies indicate that a blood group system exists in reptiles.[2] Animals that receive repeated blood transfusions may be more likely to experience adverse reactions including hemolysis. However, incompatibilities in crossmatching between individuals from the same as well as between different species have been described in sea turtles,[13] and have also been observed by the authors in other reptiles that didn't have a previous history of blood transfusion. Crossmatching is recommended to assess blood compatibility, but has not been largely studied in reptiles and may be challenging due to limited volume of blood available from small donors and recipients. See section on cross-matching for a more detailed explanation.

Blood Administration in Reptiles

Evidence-based research focusing on blood administration in reptiles is lacking. Based on extrapolation from other species, anecdotal case reports, one study, personal opinions, and the authors' experience, we recommend the following protocol:[8,15,31,37,47]

1. Rehydration of the recipient with crystalloid fluids and increasing animal's temperature to their preferred optimal temperature zone.
2. Sedation (if indicated and safe for the individual).
3. Gain venous access via placement of IV or IO catheter with an aseptic technique. A butterfly catheter can also be used for temporary venous access. A surgical cutdown procedure may be indicated for IV catheter placement in hypovolemic or small animals.
4. Administration of warm blood via pediatric syringe pump, extension set, and a blood filter after negative crossmatch. The use of blood filters has historically not been recommended in reptiles due to concerns of destruction of the large reptilian RBC during the procedure.[27] However, 18 µm filters did not appear to cause hemolysis in red blood cells from American alligators (*Alligator mississippiensis*),[37] have been used by the authors in other reptile species without adverse effect, and its benefit appears to overweight the risk. Caution may be indicated in species with known large RBCs like chelonians or tuataras (*Sphenodon punctatus*).[11] Initial transfusion rate should not exceed 5 mL/kg/hour and can be increased to 10–20 mL/kg/hour if no adverse reaction is seen after 30 minutes; a bolus may be given over 3–5 minutes to reptiles in shock. The total blood volume given should not be more than 20 mL/kg, but 40 mL/kg of blood have been given to a bearded dragon (*Pogona vitticeps*) within a few minutes without adverse reaction.[31]

Transfusion Reactions

No acute transfusion reactions have been documented in reptiles. However, there was suggestion of a potential immune reaction in a diamond python (*Morelia spilota spilota*) after multiple heterologous blood transfusions.[31] Monitoring for the development of acute and delayed transfusion reactions is recommended similar to other animal species.[4] Parameters such as body temperature and blood pressure cannot be applied in reptiles, but monitoring for tachycardia, tachypnea, restlessness, and edema may be useful. Assessing blood for hemolysis may be indicated if a hemolytic reaction is suspected.

OTHER SPECIES/TRANSFUSION ALTERNATIVES

Transfusion protocols are similar between species. Approaching transfusions in unique species should be similar to methodologies listed in the earlier text, noting variability in blood volume, RBC size, and response to anticoagulants.

Hemoglobin-based oxygen carrier (HBOC) products such as Oxyglobin® have been used in many species and are a good substitute for RBCs and are beneficial as colloid support. Unfortunately, this product is no longer available. If it becomes available in the future, the reader is directed to refer to existing literature on its use.[1,24,39,56]

CHAPTER 104

Transfusion Reactions

NICOLE M. WEINSTEIN

Immune Complications
- Hemolytic Transfusion Reactions
  - Acute Hemolytic Transfusion Reactions
  - Delayed Hemolytic Transfusion Reactions
  - Xenotransfusion
- Nonhemolytic Transfusion Reactions
  - Febrile and Allergic Reactions
  - Uncommon Immune Reactions

Nonimmune Complications
- Infectious Disease Transmission
  - Transfusion-Associated Sepsis
  - Uncommon Nonimmune Complications

Prevention and Recognition of Transfusion Reactions
Evaluation of a Patient with a Suspected Transfusion Reaction

Acronyms and Abbreviations

AHTR, acute hemolytic transfusion reaction; DEA, dog erythrocyte antigen; DHTR, delayed hemolytic transfusion reaction; FFP, fresh frozen plasma; FNHTR, febrile nonhemolytic transfusion reaction; HPA, human platelet antigen; HTR, hemolytic transfusion reaction; PCV, packed cell volume; pRBCs, packed red blood cells; PTP, post-transfusion purpura; RBC, red blood cell; TA-GVHD, transfusion-associated graft-versus-host disease; TRALI, transfusion-related acute lung injury; VetALI, veterinary acute lung injury; WB, whole blood.

Blood is a complex biologic product which, like any tissue transplant, can result in as much harm as benefit to the recipient. The term transfusion reaction denotes any adverse event associated with transfusion of blood or a blood component. The reaction may occur during or within hours to weeks after administration of a blood product. Understanding how to lessen the risks of a transfusion reaction and recognizing the potential clinical and clinicopathologic signs of an adverse reaction should one occur are key to good transfusion medicine practice.

Transfusion reactions are most often characterized by their immunologic and nonimmunologic mechanisms. There have been several reviews in the veterinary literature on blood transfusions in cats, dogs, and horses, with the incidence and type of transfusion reactions varying between institutions and species, but ranging from 3–13%.[10,13,14,28,33-35,37] The present chapter deals primarily with reactions in dogs and cats. Additional information on reactions in dogs and cats can be found in consensus statements on reaction definitions, prevention, and diagnosis and treatment.[16,17,48] Further information on transfusion reactions in large animals is given in Chapters 37, 96, and 102. Reports of adverse reactions underscore the need for further education on their prevention and identification.

IMMUNE COMPLICATIONS

Hemolytic Transfusion Reactions

Hemolytic transfusion reactions (HTRs) jeopardize the health of an already compromised patient. An immune-mediated HTR is the result of naturally occurring or induced antibodies present in the recipient plasma, which can destroy donor RBCs immediately upon transfusion or within hours to weeks following transfusion (see Chapter 96). These reactions are classified as a type 2 hypersensitivity and are mediated by antibodies

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

directed against antigens present on the surface of RBCs.[1] After reacting with the RBC surface antigen, IgG or IgM antibodies activate the complement system, culminating in the formation of a membrane attack complex which disrupts the lipid bilayer of the RBC membrane, causing intravascular hemolysis.[1] Also, antibody or complement fragments, primarily C3b or C4b, can adhere to the RBC surface (opsonization), enhancing RBC susceptibility to phagocytosis by leukocytes expressing receptors for these proteins.[1] Intravascular and/or extravascular hemolysis can result, depending on whether the leukocytes recognize the opsonized RBCs while in circulation or within the reticuloendothelial system. The severity of a HTR is influenced by the concentration of recipient alloantibody, the immunoglobulin type, whether the antibody is warm- or cold-reacting, the amount of blood transfused, and the condition of the recipient.

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions (AHTRs) present within 24 hours of an RBC transfusion.[15,54] Preformed antibodies in the recipient react with transfused donor RBCs. The recipient has previously formed an alloantibody against an antigen present on the donor's RBCs, which is not present on the recipient's RBCs. Cats are similar to humans, as both have naturally occurring alloantibodies which can result in a potentially fatal AHTR. Anti-A alloantibodies in type B cats are strong hemagglutinins and hemolysins, and are present in a high concentration[11,40] (see Chapter 96). Transfusion of type A blood to a type B cat can be fatal if not immediately recognized, with subsequent discontinuation of the transfusion and institution of supportive care.[14,22,23] Within seconds to a few minutes of receiving as little as 1 mL of type A blood, a type B cat may exhibit restlessness, vocalization, vomition, urination, salivation, and recumbency.[22,23] Bradycardia, cardiac arrhythmias, decreased pulse strength, pale mucous membranes, and prolonged capillary refill time are also expected in the initial phase.[23] If the reaction is recognized and the transfusion stopped, hemoglobinemia and hemoglobinuria will follow, as these reactions are IgM- and complement-mediated with obvious intravascular hemolysis.[22,23] Acute kidney injury and failure, which are seen in humans with blood type ABO transfusion reactions, have not been documented in type B cats receiving type A blood under experimental conditions.

As type B blood is not commonly stored and type B cats comprise a small percentage of cats (outside of a few breeds), inadvertent transfusion of type B blood to a type A cat is unlikely. Inaccurate blood typing results, however, could result in a type A or AB cat being mislabeled as type B with subsequent transfusion of type B blood.[47] Although type A cats generally have lower concentration of weak anti-B antibodies which are of both IgM and IgG classes, transfusion of type B blood can still cause both clinical and clinicopathologic features of a transfusion reaction including discomfort, listlessness, tachycardia, and tachypnea, as well as mild hemoglobinemia, hemoglobinuria, and bilirubinuria.[11,23,40]

A blood type AB cat could receive either type A or B packed red blood cells (pRBCs), but plasma or whole blood (WB) from a blood type A or B cat could increase the risk of a HTR reaction due to the presence of anti-B and anti-A alloantibodies, respectively. Given the generally weaker nature of anti-B alloantibodies, plasma or WB from a type A cat would be preferred. Type AB WB or plasma would be ideal, but unrealistic in most settings given the low frequency at which type AB cats are found.

The risk of hemolytic transfusion reactions in cats can be greatly minimized by AB blood typing both the donor and recipient. Crossmatching is also advised even in transfusion-naïve cats who are otherwise AB-compatible with the intended donor. A crossmatch test (see Chapter 107) can identify preformed alloantibodies against a blood group antigen, thus preventing an AHTR. Blood types and naturally occurring alloantibodies outside of the AB blood group system can result in incompatible crossmatches, even in transfusion-naïve cats (see Chapter 96).[27,29,32,44,59,66,67] *Mik*, a non-AB blood group in cats, can result in HTRs as well as incompatible crossmatch results.[67] A cat negative for the *Mik*-RBC antigen can experience an AHTR, similar to those described in type A cats receiving type B blood, after transfusion with *Mik*-positive RBCs.[67] Given evidence of alloantibody production in as soon as 2 days post RBC transfusion, earlier crossmatch surveillance prior to additional RBC transfusions in cats is advised.[32] An incompatible crossmatch test in the face of AB blood-type compatibility supports alloantibody formation and should not be ignored.

Some dogs may have naturally occurring RBC alloantibodies (see Chapter 96), though the clinical significance is less clear.[26,55,56] Generally, HTRs require prior sensitization through a previous blood transfusion. Sensitization is unlikely to develop secondary to pregnancy in dogs.[5] A dog erythrocyte antigen (DEA)-1-negative dog who has been sensitized by transfusion of DEA-1-positive blood will develop anti-DEA 1 antibodies. A second transfusion with DEA-1-positive blood will cause an AHTR. Such a reaction has been documented clinically: a DEA-1-negative recipient had been sensitized to the DEA 1 antigen through a previous transfusion, and upon inadvertently receiving DEA-1-positive blood 3 years later exhibited a 2°C rise in temperature within 1 hour of transfusion and developed hemoglobinemia and hemoglobinuria.[24] Following an AHTR plasma will be red-tinged due to hemoglobinemia (Figure 104.1); this is most often identified when a post-transfusion packed cell volume (PCV) is measured. An AHTR is not exclusive to the DEA 1 antigen; alloantibody production and HTRs have been documented for other RBC antigens in dogs, including known DEA, as well as RBC antigens without DEA designation.[4,12,45] When a compatible donor is not easily identified on a blood crossmatch, testing both siblings of the patient or potentially dogs of the same breed has been shown to be successful in identifying a compatible donor.[4,12]

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions (DHTRs) are defined as those occurring more than 24 hours

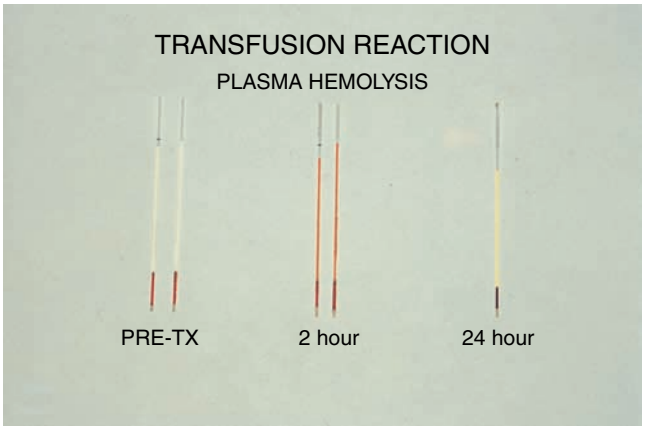

FIGURE 104.1 Serial packed cell volumes (PCVs) from a dog experiencing an acute hemolytic transfusion reaction. Note the transfusion of plasma from clear to hemolyzed to icteric over 24 hours. As a consequence of the transfusion reaction, the PCV fell following the transfusion. (**Source:** Courtesy of *Schalm's Veterinary Hematology*)

following a transfusion, but the time of onset can vary up to 48 hours post-transfusion depending on the reference.[15] DHTRs are often the result of an anamnestic response to a RBC antigen that the recipient lacks, with the previously produced reactive alloantibody weak or present in very low concentrations. Pretransfusion crossmatch testing may not identify the potential incompatibility if the test is insufficiently sensitive. Alternatively, DHTRs may be a result of primary alloimmunization to a RBC antigen, with hemolysis occurring weeks later after sufficient time for alloantibody production.[15]

A DHTR should be suspected if there is a more rapid decline than expected in PCV in the weeks following a blood transfusion, based on the patient's underlying disease. Additional clinicopathologic signs to support a diagnosis of DHTR include hyperbilirubinemia, bilirubinuria, or hemoglobinuria: fever can develop but often goes unnoticed. Confirmation of a DHTR requires documentation of development of antibodies by the recipient against the donor(s) RBCs.

Preventing HTRs requires knowledge of blood groups present within a species, presence of naturally occurring antibodies, prior transfusion history, and blood crossmatch testing. Regardless of the designation of acute versus delayed, the majority of HTRs can be prevented through proper blood typing and crossmatch testing.

Xenotransfusion

Xenotransfusion or the practice of transfusing blood of one species to another species is primarily described in a clinical setting with anemic cats receiving dog blood.[8,19,49] Although not universally accepted or recommended, xenotransfusion was utilized in these cases due to the lack of a suitable feline donor and the severity of the patient's disease necessitating RBC support (see Chapter 99). Xenotransfusion should not be considered a viable therapy for cats in need of ongoing RBC support as subsequent transfusions with canine blood will result in anaphylaxis and possible death.[8,19]

Nonhemolytic Transfusion Reactions

Febrile and Allergic Reactions

Febrile and allergic reactions are two of the most common types of transfusion reactions reported in veterinary medicine, comprising 60–90% of reported reactions.[10,29,34,35] Febrile nonhemolytic transfusion reactions (FNHTRs) are defined in human medicine as a rise in temperature of either 1.8°F and greater or 1°C or greater during or within 4 hours post-transfusion without an obvious other cause for the rise in temperature.[10,39,54] Additional clinical signs can include vomiting and tremors: the vomiting will often resolve without treatment, but a decreased transfusion rate may help to alleviate this symptom.[13,54]

Febrile nonhemolytic transfusion reactions are frequently attributed to recipient alloantibodies which react with histocompatibility leukocyte antigens or other antigens present on donor lymphocytes, granulocytes, or platelets.[6,54] Cytokines released from leukocytes and platelets within stored blood are also implicated as causes for FNHTRs and some allergic-type reactions.[39] Prestorage leukocyte reduction, as a means of minimizing cytokine production and release, has had variable demonstrated success in minimizing the most common of transfusion reactions in dogs.[7,9] In a recent study, the likelihood of FNHTRs did not decrease following transfusion of leukoreduced units to dogs.[7] The total number of transfused dogs and the total rate of reactions were low, when compared to the reported incidences of febrile and allergic reactions in the literature.[7] Although leukoreduction remains a still-examined subject in human transfusion medicine, prestorage leukoreduction has been repeatedly shown to decrease FNHTRs in people.[36,53] Additional investigations in veterinary transfusion medicine are likely needed to fully determine the potential benefit of prestorage leukoreduction on reaction rates and severities and weigh this against the added expense leukoreduction filters contribute. Admittedly, even in leukoreduced WB or pRBCs, platelet antigens would remain a potential source of reactivity, and this may be the source of the febrile reactions not otherwise controlled by leukoreduction. Age of stored RBC products does not obviously increase the risk of a febrile reaction in dogs, but transfusion-related hemolysis is more likely in transfused patients receiving older blood.[43] Given the known storage lesions RBCs can develop, both immunologic and nonimmunologic factors may be at work. Recommendations for management of FNHTRs include stopping the transfusion but maintaining the intravenous line open with saline while excluding an AHTR or transfusion-related sepsis due to bacterial contamination of the unit (Figure 104.2).

Allergic reactions are more often associated with transfusion of plasma products and are triggered by

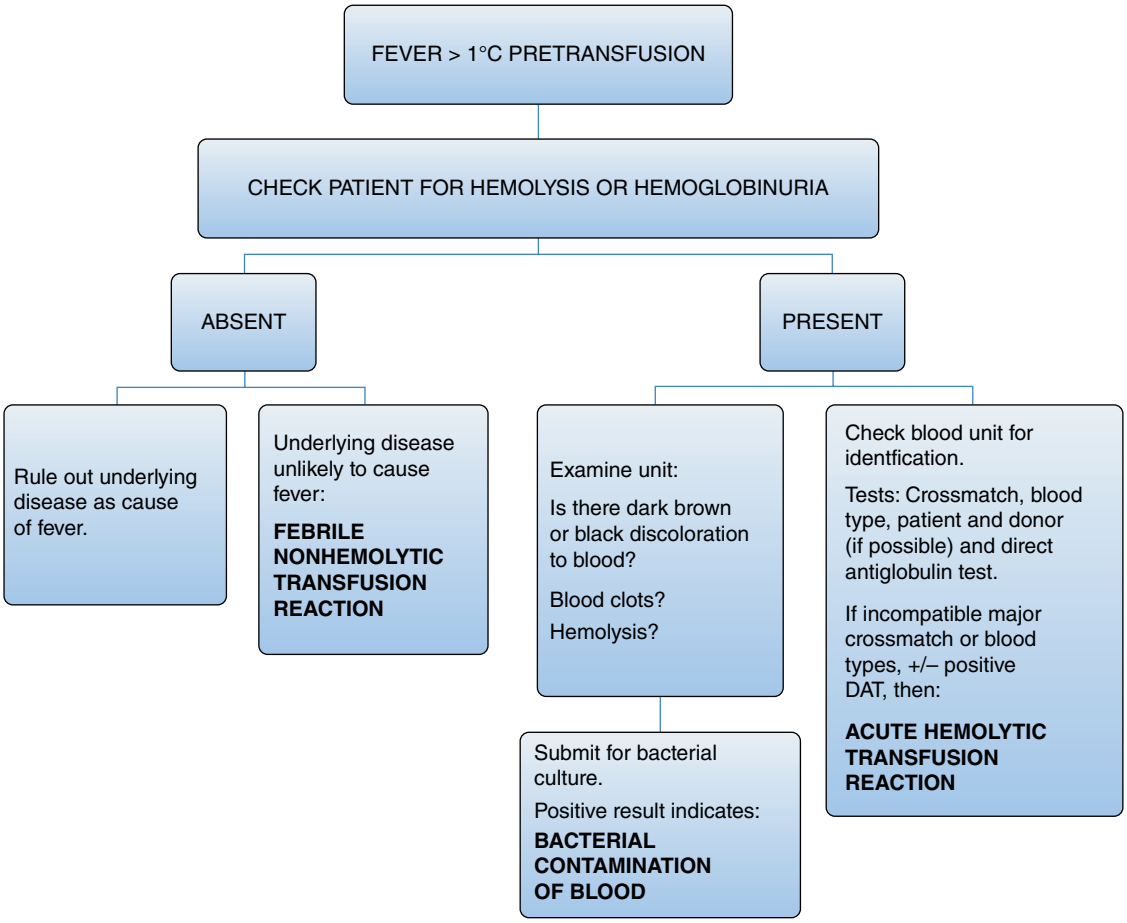

FIGURE 104.2 Algorithm for evaluation of a patient with a febrile transfusion reaction.

exposure to a substance, likely a protein, present in donor plasma to which the recipient has been sensitized.[54] Signs of an allergic reaction typically start within the first 15 minutes of a plasma transfusion, but can occur during or within a few hours of administration. Clinical signs include mild to sometimes dramatic urticaria, pruritis, and erythema (Figure 104.3). Additional signs can include vomiting, nausea, diarrhea, and/or abdominal pain.[15] Treatment of an allergic reaction to a plasma product includes stopping or, at least, decreasing the rate of transfusion, as well as administering an antihistamine such as diphenhydramine (1–2 mg/kg IM). Although administration of diphenhydramine to humans prior to leukoreduced platelet transfusions has not shown to decrease the frequency of allergic-type urticarial reactions, recent veterinary literature supported pretreatment with antihistamines decreasing the incidence of acute allergic reactions in dogs receiving blood transfusions.[10,36,63]

FIGURE 104.3 An urticarial reaction in a dog receiving plasma to treat rodenticide intoxication. Treatment with antihistamines and steroids induced resolution in 24 hours. (**Source:** Courtesy of *Schalm's Veterinary Hematology*)

Uncommon Immune Reactions

Post-transfusion purpura (PTP) is a relatively uncommon transfusion reaction in humans and has been described once in veterinary medicine.[54,65] Thrombocytopenia develops 1–2 weeks post-transfusion due to recipient-produced antiplatelet antibodies. These antibodies are most often directed against a platelet-specific antigen (e.g., in humans, human platelet antigen (HPA)-1a)

which the recipient lacks; platelets targeted for destruction are typically those of the donor, but targeting of recipient/patient platelets has also been documented.[54] PTP must be differentiated from worsening underlying disease or development of a concurrent disorder.

Anaphylaxis secondary to IgA deficiency has been reported in a single dog.[2] Anaphylaxis results from patient anti-IgA antibodies reacting to IgA antibodies in the donor plasma.[2] Clinical signs vary from facial swelling, urticaria, and erythematous skin to respiratory distress, vomiting, diarrhea, and shock.[1] An IgA-deficient patient who previously demonstrated a severe anaphylactic reaction would require future transfusions that are free of IgA.

Transfusion-related acute lung injury (TRALI) is characterized by dyspnea, hypoxia, pulmonary edema, and fluffy, bilateral infiltrates on thoracic radiographs which develop during or within 6 hours of a transfusion, most often secondary to a plasma and/or platelet transfusion. TRALI is well-documented in humans with an incidence approaching 25%.[52,61] It has recently been described as likely occurring in 2 dogs in a prospective observational study of nearly 55 transfused dogs, with the terminology veterinary acute lung injury (VetALI) used in place of TRALI.[60] Although there were several limitations to the study that the authors highlight, the study emphasizes that awareness of the syndrome, the shared features with other commonly seen complications in critically ill patients, and the related risk factors are paramount to correct identification, evaluation of prognosis, and treatment.[60] TRALI or VetALI clinically mimics acute respiratory distress syndrome, circulatory overload, other respiratory diseases, cardiac failure, and potential fever.[61] Transfusion-related acute lung injury may result from several mechanisms, including both antibody-mediated pathways and nonimmune causes, with neutrophil activation and subsequent leakage from capillaries (pulmonary microvasculature leakage) being the common final pathway; underlying inflammatory conditions can increase risk.[52,61] Treatment typically involves oxygen therapy and ventilation, when needed.[54]

Transfusion-associated graft-versus-host disease (TA-GVHD) has yet to be reported in veterinary medicine. It results from the proliferation of viable donor T lymphocytes, which go unrecognized as foreign by the recipient's immune system; these donor T lymphocytes recognize and subsequently attack the recipient (or host).[15] In humans, certain cellular immunodeficiencies predispose the transfusion recipient to this reaction; also, recipients of blood transfusions from close relatives place the recipient at greater risk for TA-GVHD.[15] Since leukoreduction is insufficient in preventing TA-GVHD, component irradiation is recommended in patient populations at increased risk of developing TA-GVHD (e.g., hematopoietic progenitor cell transplant recipients).[15] Clinical signs of TA-GVHD in man reportedly manifest within 2–50 days of transfusion and include a rash, diarrhea, liver dysfunction, and pancytopenia. Mortality is greater than 90%.[15]

NONIMMUNE COMPLICATIONS

Infectious Disease Transmission

Transmission of infectious agents to a blood transfusion recipient, though a relatively infrequent complication in both human and veterinary transfusion medicine, is not a true transfusion reaction, but is obviously an avoidable and potentially devastating complication of transfusion. Infectious diseases documented to have been transmitted via transfusion in veterinary medicine include babesiosis, leishmaniasis, bartonellosis, and diseases caused by hemic *Mycoplasma sp*. as well as viral diseases.[3,18,21,41,42,50,57,62] Although WB and pRBCs carry a greater risk of infectious disease transmission, plasma is not without risk; administration of commercially prepared plasma to horses resulted in inadvertent transmission of herpesvirus.[3] A recently updated consensus statement from the American College of Veterinary Internal Medicine includes guidelines for recommended testing for both canine and feline blood donors based on the literature and known blood-borne agents (see Chapter 98).[64] Documentation of a transfusion-acquired infection requires testing of pretransfusion recipient blood, in addition to testing the donor; unfortunately, pretransfusion recipient samples are not always available. Proper transfusion records will allow for easy identification of the suspected infected donor, removal of any remaining blood units from that donor, and appropriate treatment of the donor.

Transfusion-Associated Sepsis

Bacterial contamination of a blood unit can result in transfusion-associated sepsis. Clinical signs associated with transfusion of a contaminated blood unit include fever, vomiting, diarrhea, hypotension, and hemolysis.[15] Contamination can occur at the time of collection from inadequate preparation of the venipuncture site or contamination of materials used in collection. Once contamination of a unit occurs, bacterial numbers tend to increase with storage time, even when the unit is refrigerated, although this ultimately depends on the bacteria type(s). Storage at room temperature, which is necessary to preserve the post-transfusion survival of platelets in fresh WB and platelet-rich preparations, can also lead to bacterial proliferation in contaminated units. It has been documented that units of human pRBCs stored for longer than 21 days are more likely to contain proliferating bacteria.[25] Monitoring of refrigerated whole canine blood units at various timepoints for 42 days revealed infrequent positive culture results. On a quantitative (q)PCR assay, low amounts of bacterial DNA from at least one timepoint were identified in 53% of the units.[46] It was concluded that the risk of contamination of WB was low, and the common bacteria implicated by qPCR were unlikely to play a role in transfusion-associated sepsis.[46] Ultimately, the occurrence and severity of a reaction will depend on the bacterial species, the number of bacteria present, the blood product and related storage conditions, and the clinical condition of the recipient/patient.[30]

Reports of bacterial contamination of blood products and transfusion-associated sepsis are infrequent in veterinary medicine.[2,31,46] Contamination of feline blood units with *Serratia marcescens* was attributed to contaminated supplies used in donor collection. Vomiting was the most common clinical sign seen in cats receiving contaminated units, and four recipients died.[31] This report illustrates the importance of bacterial culture of materials other than the unit and demonstrates the steps necessary to identify the source of contamination. Contaminated WB or pRBC units are typically discolored (dark brown, purple, or black), and clots and air bubbles may also be present.[31,54] The discoloration associated with bacterial contamination indicates deoxygenation, hemolysis, and the formation of methemoglobin. Blood units with such an abnormal appearance should not be used, and an investigation to confirm bacterial contamination and identify the source of contamination should be pursued. Lastly, administration of a blood component unit should ideally take no longer than 4 hours to reduce the potential for bacterial proliferation. Once a unit is opened, even if refrigerated, it should be used within 24 hours. If bacterial contamination is suspected after the transfusion has been started, the transfusion should be stopped immediately and the unit submitted for a Gram stain and bacterial culture. Blood culture of the recipient may also be warranted.

Circulatory Overload Patients with chronic anemia and a compensatory expanded plasma volume or patients with compromised pulmonary and/or cardiac function may be at risk for circulatory overload.[54] Expected clinical signs include respiratory distress and, in some cases, congestive heart failure; signs may be seen during or soon after transfusion. Management of fluid overload with diuretics is advised. Slowing the transfusion rate and using pRBCs rather than WB in anemic patients can help to decrease the risk of circulatory overload.

Uncommon Nonimmune Complications

Citrate Toxicity Citrate is the anticoagulant used in most standard blood collection systems. Plasma and WB have the greatest concentrations of citrate when compared to pRBCs. Patients most at risk for citrate toxicity include those receiving large volumes of blood products, such as in cases of massive transfusion (see Chapter 99) and, potentially, patients with severe liver disease, since citrate is metabolized by the liver. Ionized hypocalcemia and hypomagnesemia result from chelation of these cations by citrate, and associated clinical signs include muscle tremors, vomiting, cardiac arrhythmias, ear twitching, hypotension and/or tetanic seizures.[2,34] Intravenous calcium can be administered to treat clinically significant transfusion-related hypocalcemia.

Nonimmune Hemolysis Unrelated to Bacterial Contamination Hemolysis unrelated to a blood group incompatibility or bacterial contamination may occur in vitro due to improper storage or handling of blood units, aged units, use of a hot water bath, inadvertent freezing, use of pumps not approved for administration of blood products, and concurrent administration of incompatible fluids, such as 5% dextrose or hypertonic saline through a shared intravenous line.[20,38,43,51,54,58]

PREVENTION AND RECOGNITION OF TRANSFUSION REACTIONS

Prior to blood product administration, baseline values of temperature, heart rate, and respiratory rate should be determined and pretransfusion PCV should be recorded (see Chapters 99–103). Pretransfusion WB and serum samples should be collected from the recipient, if not already submitted for other routine testing. These samples can be invaluable in cases of HTRs and in documentation of infectious disease transmission. Transfusion of any blood product is ideally started at a slower rate for the first 15 minutes while monitoring for signs of any adverse reactions. Clearly, in cases of severe, ongoing blood loss, rapid administration from the start may be necessary. Transfusion monitoring should be performed every 15 minutes for the first hour, with serial measurement of temperature, heart, and respiratory rates. If there is any concern about an AHTR, evaluation of plasma and/or urine for the presence of hemoglobin is indicated. Lack of an expected increase in PCV post-transfusion may also be suggestive of an AHTR.

EVALUATION OF A PATIENT WITH A SUSPECTED TRANSFUSION REACTION

Investigation of hemolytic and febrile reactions should include inspection of the patient's plasma for evidence of hemolysis or icterus; evaluation of the blood product unit administered (including unit labels) and of the administration set; blood culture ± cytology of the transfused product; comparison of patient bilirubin both pretransfusion and post-transfusion; retesting of patient and donor blood type, especially for reactions involving RBC-containing units; and post-transfusion crossmatch testing of recipient–donor compatibility. If a crossmatch test was performed pretransfusion, it should be repeated in the case of a HTR; if one was not performed, a crossmatch test should be done using both pretransfusion and post-transfusion plasma/serum, if available. In general, if a transfusion reaction is suspected, the transfusion should be stopped, but the intravenous line kept open with saline until the patient and blood product can be further evaluated.

Adequately screening potential blood donors, transfusing patients only when clinically indicated, selecting the most appropriate blood component, properly administering blood products, and carefully monitoring transfusion recipients will greatly diminish the risk of a transfusion reaction.

Acronyms and Abbreviations

BM, bone marrow; DLA, dog leukocyte antigen; GVHD, graft-versus-host disease; GVT, graft-versus-tumor; HCT, hematopoietic cell transplantation; HDC, high-dose cytoxan; HLA, human leukocyte antigen; HPC, hematopoietic progenitor cell; IDO, indoleamine-dehydrogenase; IL, interleukin; iPSC, induced pluripotent stem cell; MHC, major histocompatibility complex; MSC, mesenchymal stem cell; PBMC, peripheral blood mononuclear cells; PGE2, prostaglandin E2; OA, osteoarthritis; rhG-CSF, recombinant human granulocyte colony-stimulating factor; TBI, total body irradiation; TBV, total blood volume; TGF-β, transforming growth factor-beta; VEGF, vascular endothelial growth factor.

HEMATOPOIETIC STEM CELL THERAPY

The hematopoietic system is an exquisitely controlled hierarchical tissue with self-renewing, multipotent stem cells residing mainly in the bone marrow that produces all the mature hematopoietic cells that circulate in the peripheral blood. Based on observations of survivors of the atomic bomb explosions toward the end of World War II, it became clear that bone marrow was the most radiosensitive tissue in the body and that marrow transplantation had the potential to rescue radiation victims from death due to complete marrow aplasia. Early unsuccessful attempts at transplantation led to the use of suitable animal preclinical models, to help elucidate the fundamental rules of marrow transplantation biology.

This chapter will briefly summarize important aspects of the preclinical murine/canine models of hematopoietic cell transplantation (HCT) and review the canine HCT literature as it relates to veterinary medicine. The chapter will also contain information on mesenchymal stem cells (MSC) derived from either bone marrow or adipose tissues, and used in either an autologous or allogeneic setting.

Preclinical Studies: Murine Models

Early research using inbred mice proved that the protection of lethally irradiated mice could be achieved by shielding either the spleen or one femur with lead during the radiation[43] or also by infusion of syngeneic spleen or bone marrow after irradiation.[9] For these

"autologous" transplants (progenitor cells harvested from the patient), both "humoral" and "cellular" theories were advanced.[5,43] In 1956, three independent groups confirmed the cellular theory by showing repopulation through donor cells by following various blood genetic markers.[32,61,89] Subsequent studies in mice began to address important issues of marrow transplantation biology, including graft rejection, graft-versus-host disease (GVHD), and the importance of the major histocompatibility complex (MHC). Unfortunately, by 1970, a report covering 200 patients treated with HCT for hematologic malignancies, in which all recipients died of graft failure, GVHD, or disease relapse,[10] made it clear that a more suitable preclinical animal model of HCT needed to be identified.

Preclinical Studies: Canine Models

Dogs were deemed especially useful for understanding marrow transplantation biology for many reasons. They are the only mammalian species that share the following human qualities: they are random bred, have a large body size, have a long life span, exhibit wide genetic diversity, and represent a well-mixed gene pool.[63] In addition, dogs have short gestation times and large litter sizes which allowed studies of donor–recipient combinations that were matched or mismatched for dog leukocyte antigen (DLA or dog MHC antigens), which faithfully mimics human leukocyte antigen (HLA) donor–recipient pairs. Finally, the value of the canine model was heightened by early observations that dogs develop a variety of spontaneous malignant diseases, including hematologic malignancies, that had well-recognized counterparts in humans.

For these reasons, dogs have provided an enormous wealth of information relating to bone marrow biology and HCT that has been directly translated over the past six decades to the clinical setting for a wide variety of human disease. Data from dog studies of total body irradiation (TBI), irradiation and chemical myeloablation, engraftment and GVHD, progenitor cell dose requirements, and graft-versus-tumor effects, to name a few, have been essential to solve the clinical problems seen in human HCT, especially relating to "allogeneic" grafts (progenitor cells harvested from a donor).

Based on the use of random-bred dogs, mainly at the Fred Hutchinson Cancer Research Center (Seattle, WA) by a group led by Dr. Donnall E. Thomas, HCT quickly advanced from an investigational therapy in the early 1960s to a viable treatment for people that produced amazing clinical results in the 1970s.[82,85] In 1990, Dr. Thomas was awarded the Nobel Prize in Medicine for his pioneering work in marrow transplantation. An excellent overview of this work was published in 2007.[52]

Hematopoietic Progenitor Cells

Based on the early successful murine HCT experiments proving that "cellular" components were responsible for engraftment post myeloablation, it was clear that specific cells residing in the bone marrow were able to lead to complete hematologic reconstitution. However, although autologous HCTs in syngeneic mice led to successful engraftment, allogeneic HCTs between unrelated strains of mice were not successful, with most animals succumbing to overt GVHD and graft rejection. These same results were seen in early canine allogeneic HCT experiments and in humans transplanted with unconventional donors. In an effort to reduce the morbidity and mortality associated with allogeneic HCT, clinical investigators expanded their search for more refined sources of hematopoietic progenitor cells (HPC). During this time, the definition of a true HPC evolved: an inexhaustible, self-renewing cell that can give rise to the multilineage clonal expansion of all peripheral blood lineages.[86]

With the development of in vitro clonogenic assays of primitive progenitor activity, such as colony-forming units-spleen (CFU-S),[7] Dexter cultures for observing myeloerythroid differentiation,[25] Whitlock–Witte cultures for observing B-cell lineage differentiation,[96] and the thymus colony-forming cell (CFU-T) assay for testing T-lineage potential,[27] in conjunction with the development of fluorescence-activated cell sorting (FACS),[88] identification of populations of putative murine HPC became possible.

In mice, primitive HPC were found in a subpopulation of bone marrow cells expressing low levels of Thy1.1.[58] This population was further refined to include Thy1.1/Sca-1$^+$ cells, with further refinement to Thy1.1/Sca-1$^+$/Lin1^{-lo} cells. The smallest population of bone marrow cells in mice that can reconstitute lethally irradiated recipients, which represents approximately 0.05% of all bone marrow cells, includes Thy1.1/Sca-1$^+$/Lin1^{-lo}/c-kit$^+$ cells.[70]

The discovery of the surface glycophosphoprotein CD34 was the result of a strategy to develop antibodies that do not recognize mature blood or lymphoid cells, but do recognize small subsets of human and primate marrow cells.[16] CD34+ cells constitute approximately 1.5% bone marrow mononuclear cells in both species and early primate HCT experiments proved that CD34+ cells, but not CD34− cells, could reconstitute hematopoiesis in an autologous setting after myeloablative therapy.[8] CD34+ cells are phenotypically and functionally heterogeneous; therefore, other surface markers, including CD38, Thy-1, and Lin1^{-lo}, can isolate smaller, more primitive subsets of human/primate HPC. However, CD34+ cells remain the "cells of choice" for human HCT, since they are reasonably plentiful, easy to isolate, have a long history of being able to reconstitute the immune system, and can be easily cultured ex vivo. Subsequent research identified enough CD34+ cells in umbilical cord blood[48] to consider its use as a source for HCT and, importantly, identified small numbers of CD34+ cells in peripheral blood.[6,99]

Canine CD34 was cloned in 1996 and mouse anticanine CD34 monoclonal antibodies quickly became available.[56] Early studies in dogs using these antibodies essentially recapitulated human/primate findings. Canine CD34+ cells comprised 1–3% of total bone marrow cells, were 25–50-fold enriched for

granulocyte–macrophage colony-forming units when compared to unfractionated bone marrow cells, and were able to repopulate the bone marrow leading to complete hematologic recovery after myeloablative therapy.[57]

Hematopoietic Progenitor Cell Collection

The source of HPC in early human transplant studies was whole bone marrow collected via multiple bone marrow aspirations that entailed either general or spinal anesthesia, a brief hospital stay, and significant postprocedure discomfort. Whole bone marrow was also initially used in murine, primate, and canine studies. However, bone marrow harvests in people many times did not collect enough cells for HCT and repeating the procedure impacted quality of life and increased anxiety scores. Two important developments led to our ability to harvest enough CD34+ cells from the peripheral blood, instead of bone marrow, to consider HCT: (1) the cloning and large-scale production of recombinant hematopoietic cytokines, and (2) the development of sophisticated apheresis machines/systems to harvest specific populations of cells from the peripheral blood.

Dogs were instrumental in showing that both autologous[13] and allogeneic[73] HCT could be successfully performed using peripheral blood mononuclear cells (PBMCs), although approximately tenfold more PBMCs than marrow cells were necessary to ensure stable engraftment.[2] To induce expansion/peripheralization of bone marrow CD34+ cells, a variety of recombinant mobilizing agents, including canine granulocyte colony-stimulation factor (rcG-CSF),[18,67] canine stem cell factor (rcSCF),[18,67] and canine granulocyte–macrophage colony-stimulating factor (rcGM-CSF),[59] were cloned and introduced in the 1990s. More recently, the CXCR4 antagonist, AMD3100 (Mozobil, Genzyme), was shown to be an effective mobilizing agent in both humans and dogs.[12] To date, human and canine patients undergo mobilization or "G-priming" using recombinant human granulocyte colony-stimulating factor (rhG-CSF) (Neupogen, Amgen: rcG-CSF is not commercially available) or a combination of rhG-CSF and Mozobil in preparation for leukapheresis in both autologous and allogeneic settings.

The large-scale use of PBMC grafts in people could not occur until the development of techniques to collect large numbers of PBMCs and preclinical validation of PBMC grafting protocols. Although leukaphereses were reported in dogs as early as 1967,[73] a variety of harvesting techniques, including artery–jugular shunts and intermittent centrifugation techniques, finally led to the development of continuous flow techniques.[50] Many studies subsequently showed both autologous and allogeneic PBMC grafts reconstituted normal hematopoiesis in dogs after myeloablative therapy. With the introduction of recombinant hematopoietic cytokines and the commercial availability of anti-CD34 monoclonal antibodies, it became possible to isolate large numbers of CD34+ cells from the peripheral blood of dogs as the technology of apheresis advanced. In addition, with the development of highly automated microprocessor-controlled blood cell separators, the desired PBMC component could be retained with the remainder of cells returned to the circulation.[55] Today, most apheresis systems, such as the Optia (Terumo BCT, USA) and Amicus (Fresenius Kabi, USA), can isolate enough PBMCs to ensure postmyeloablation engraftment. In people, a single PBMC procedure yielded 3.7 times more CD34+ cells than a standard bone marrow harvest.[68] In addition, PBMC is generally preferred by human donors over traditional bone marrow (BM)donation.[4] Now >90% of all human autologous HCT protocols for the treatment of hematological malignancies include the use of mobilized PBMC grafts as a source of CD34+ progenitor cells because of higher cell yields, faster engraftment, decreased procedural risks, and shorter hospitalization compared to whole bone marrow grafts. In addition, the generation of canine apheresis data has made it clear that peripheral blood grafts can be harvested from both normal dogs and client-owned dogs with hematological malignancies in a clinical setting.[45,51,65,79]

DLA Typing

As stated previously, early allogeneic HCTs in people failed, with leukemia patients dying from either allograft rejection or recurrent disease. Early canine allogeneic HCT studies also failed, with most dogs dying for the same reasons. Based on these results, it was concluded that our understanding of the histocompatibility barriers between donors and recipients needed to be dramatically expanded. Dogs were the first random-bred species where the impact of donor–recipient matching on HCT outcome was demonstrated.

Beginning an intense period of experimental allogeneic HCT research, a serological canine histocompatibility typing system (DLA or dog leukocyte antigen) was described in 1968,[29] which showed that compatibility between littermate donors and recipients was essential in reducing the risks of both graft rejection and GVHD. Long-term engraftment using both related and unrelated recipients could also be achieved when matching was performed either serologically or with mixed leukocyte culture nonreactivity assays. Antigenic canine histocompatible polymorphisms, later named DLA, were later divided into class I and class II regions, whose identification could be ascertained using microsatellite polymorphisms within class I and II regions that were inherited according to Mendelian segregation (see Chapter 7).[90] With the publication and further characterization of the canine genome,[41] this research has moved rapidly forward, with DLA now a well-defined complex.

The use of the canine model of DLA-matched donor–recipient pairs and post-HCT immunosuppression directly led to physician's confidence when treating humans with aplastic anemia and hematologic malignancies with allogeneic HCTs.

Pre-HCT Conditioning

The lack of pre-HCT conditioning in early human HCTs was postulated to be the leading cause of patient death.

In an autologous setting, conditioning is used for tumor cytoreduction or, ideally, elimination, since an early study proved that TBI itself did not completely eliminate leukemia in human patients.[84] The other beneficial effect of conditioning is thought to be the creation of "space" in the bone marrow via cellular death, so donor HPCs can occupy favorable niches that enhance their ability to repopulate the bone marrow. However, since some animal studies have shown successful engraftment after autologous HCT without conditioning,[71] the question of the absolute necessity for pre-HCT conditioning in an autologous setting remains open. Regardless, early studies showed that dogs given high-dose cyclophosphamide (Cytoxan),[28] in place of lethal TBI, could be rescued from lethal immunosuppression using either autologous or DLA-matched allogeneic grafts, leading to successful engraftment and mixed donor–recipient chimerism. High-dose Cytoxan conditioning regimes were then quickly translated to human patients with aplastic anemia undergoing allogeneic HCTs. Other types of chemotherapy, including dimethyl myleran (DMM), or combinations of DMM and antithymocyte serum (ATS) or DMM, ATS, and procarbazine, were also found to be efficacious.

TBI conditioning regimes have also been extensively studied in dogs to help understand engraftment, toxicity, and the treatment of hematologic malignancies. All dogs treated with 4Gy TBI who did not receive an autologous marrow infusion died from complications of marrow failure, while those that did lived.[83] In addition, it was quickly found that both the total dose and the dose rate that TBI was administered were important parameters for acute toxicity. Finally, it was determined that the overall TBI dose tolerated by healthy dogs given autologous HCTs could be increased from 10 to 14 Gy by reducing the dose rate from 10 to 5 cGy/minute.[46] In general, acute toxicity was related to the TBI dose rate, while chronic toxicity was related to the total TBI dose.[23]

Dogs were also instrumental in determining if TBI-related toxicities in people could be decreased using fractionated TBI treatment schemes. When using total TBI doses of 12–21 Gy given in multiple fractions of 1.5–2 Gy separated by 3–6 hours (also with variable dose rates from 2 to 20 cGy/minute), acute toxicities were lower than seen in nonfractionated treatment schemes at the highest dose rate of 20 cGy/minute.[20]

Pre-HCT conditioning eliminates most, but not all, precursors and mature cells of the recipient immune system. In the allogeneic HCT setting, the immune system in the recipient is reconstituted by the graft and originates from the donor. Therefore, the primary clinical concerns in allogeneic HCTs are not only to prevent graft rejection by recipient cells that survive the conditioning regime, but also to prevent donor cells from causing severe immune-mediated injury, GVHD, in the recipient, while allowing immunologic reconstitution for control of pathogens. Therefore, pre-HCT conditioning in this setting is used to possibly "make space" as described previously, and also to allow the development of some non-life-threatening level of GVHD, since the resultant graft-versus-tumor (GVT) phenomenon is more effective than chemical or irradiation conditioning regimes at tumor cell killing.[94] The cause of acute and/or chronic GVHD, sensitization of donor T cells for disparate major and minor histocompatibility antigens of the recipients, was first described in dogs.[72] Initial studies showed that engraftment of DLA-identical marrow was consistently achieved with a single dose of 4.5 Gy TBI delivered at a dose rate of 70 cGy/minute or a single dose of 9 cGy delivered at a dose rate of 7 cGy/minute.[75] When administering DLA-nonidentical grafts, only higher TBI doses of 15–18 Gy, given in fractionated dosing schemes to prevent acute toxicities, led to sustained engraftment.[21] Importantly, during these studies it was found that DLA-incompatible donor buffy coat cells or lymphocytes could lead to sustained engraftment,[22] which suggested that peripheral blood mononuclear cell grafts may be an alternative to bone marrow grafts.

Further studies using DLA-identical allogeneic grafts in conjunction with 8 Gy TBI in dogs with lymphoma and leukemia proved the graft-versus-lymphoma effect by demonstrating prolonged disease-free survivals ($p < 0.005$) when compared to autologous grafts using the same conditioning regimes.[94]

This large body of canine pre-HCT conditioning research has translated into the routine use of high-dose cyclophosphamide/TBI and other chemotherapy-only protocols for treatment in people.

Graft-versus-Host Disease Prevention

The canine preclinical model of GVHD has produced extremely valuable strategies for GVHD prevention and treatment in people. In humans and dogs, GVHD prevention was initially difficult, in spite of the use of MHC-matched donor–recipient pairs. As mentioned previously, GVHD was first recognized in dogs and the cause, donor-activated T cells attacking host tissues, including gut, liver, skin, and the hematopoietic system, was elucidated. In unrelated DLA-nonidentical dogs, acute and rapidly fatal GVHD occurred within 2 weeks of HCT.[74] This could be delayed, with a prolongation of survival, using a variety of postgrafting immunosuppressive drugs, including methotrexate, cyclosporine, azathioprine, succinylacetone, tacrolimus, or a combination of these.[55] Based on these studies, post-HCT immunosuppressive regimes were successfully translated to human GVHD prophylaxis and to treat acute GVHD once it was established. It was also proven in dogs that postgrafting immunosuppression could be discontinued approximately 3–6 months after HCT. In this allogeneic model, the therapeutic benefit of GVT prompted the exploration of less-aggressive (thus, less-toxic) nonmyeloablative HCT protocols, such as 2 Gy TBI combined with post-HCT immunosuppression with mycophenolate mofetil and cyclosporine.[76] This "minitransplant" protocol was successfully translated to people who were not eligible for conventional myeloablative HCT.

Overall, based almost entirely on this very large body of canine preclinical research, human HCT has become routine in physician-based medicine. However, the awareness of HCT among veterinarians and the

potential beneficial impact of HCT in veterinary medicine, while growing, have been slower to expand.

HCT to Treat Nonhematologic Diseases in Veterinary Medicine

In a research setting, a positive response to HCT has been noted when treating a wide variety of inherited canine and feline monogenetic, recessive genetic diseases including X-linked severe combined immunodeficiency (X-linked SCID),[31,40] mucopolysaccharidoses I, VI, VII (MPS),[11,35,66] α-mannosidosis,[91] α-fucosidosis,[81] pyruvate kinase deficiency,[101] canine leukocyte adhesion deficiency (CLAD),[69] and cyclic neutropenia (Gray Collie syndrome),[100] although this is not a complete list. As such, these spontaneous diseases have provided extremely valuable genetic disease HCT models whose findings can been translated to the treatment of similar human diseases. Importantly, these models provide a necessary intermediate to optimize gene correction protocols (i.e., gene therapy) and assess the safety and efficacy of treatment before initiating human protocols.

HCT to Treat Canine Hematologic Malignancies–Autologous HCT

Attempts to cure client-owned dogs with leukemia and lymphoma, who were referred by local veterinarians, with both autologous and allogeneic HCT were pioneered by Thomas's group in Seattle. As early as 1979, it became clear that dogs with lymphoma who received a combination of chemotherapy-induced remissions and TBI could be long-term survivors after autologous HCT.[93] In this study, 4/17 dogs (23.5%) survived 1–2 years post HCT with no further therapy. Soon thereafter in 1986, 3/12 (25%) dogs with lymphoma became long-term disease-free survivors (334, 631, and 727 days) after chemotherapy-induced remission and TBI when given autologous peripheral blood mononuclear cells grafts collected before TBI.[1] Although these very early results were encouraging, further proof that client-owned dogs with hematologic malignancies could be successfully treated in a clinical setting with HCT was slow to develop.

Currently, autologous (and allogeneic) HCT is offered by four facilities (three private practices and one university hospital) in the United States to treat dogs with hematologic malignancies. The reader is referred to published studies for protocols and results of these HCT treatments.[30,92,98]

HCT to Treat Hematologic Malignancies–Allogeneic HCT

In 2006, a dog with T-cell lymphoma underwent an allogeneic HCT at a private veterinary clinic using a DLA-matched PBMC graft harvested using a COBE Spectra apheresis system.[53] A second case report,[77] in 2015, describes an allogeneic HCT used to treat a dog with a rare acute large granular lymphocytic leukemia of splenic origin.[87] Although a partial retraction relating to the diagnosis was submitted by the authors, the conclusion that allogeneic HCT may be a feasible treatment in dogs remained unchanged.[78]

To date, allogeneic HCTs have been performed by the aforementioned facilities to treat 24 dogs with hematologic and nonhematologic malignancies (Suter, personal communication). And as apheresis systems become more available to veterinarians and the literature supporting the benefits of autologous and allogeneic HCT over conventional chemotherapy expands, a greater number of dogs will be cured of what were once considered incurable hematologic malignancies.

MESENCHYMAL STEM CELL THERAPY

Mesenchymal stem cells as they are currently defined are multipotent stromal cells that can differentiate primarily into osteoblasts, chondrocytes, and adipocytes. In this section, we will confine our discussion to mesenchymal stem/stromal cells derived from either bone marrow or adipose tissues, and used in either an autologous or allogeneic setting. Nearly all stem cell studies currently described in veterinary medicine involve the use of allogeneic or autologous MSC. A number of recent reviews have been published describing the use of MSC to treat companion animals and horses.[17,24,33,38,42,54,97] True tissue-culture-derived MSC have a number of important properties, particularly immune modulatory properties, which make them attractive for treatment of conditions associated with pathologic inflammation, including immune-mediated diseases, osteoarthritis (OA), and bacterial infections.[14,44]

The other major categories of "stem cell therapy" in veterinary medicine, which will not be discussed further here, include stromal vascular fraction cells, which actually consist of a poorly defined mix of cells and debris isolated from enzymatic digestion of adipose tissues, as well as minimally manipulated bone marrow aspirate samples, and platelet-enriched cell products obtained from blood.

Biology of Mesenchymal Stem Cells

Mesenchymal stem cells derived from bone marrow or adipose or other stromal tissues should more appropriately be termed mesenchymal stromal cells, since the true stem cell properties of MSC are relatively limited.[33,38] These cells can be readily cultured as adherent, proliferating cells from bone marrow or enzyme-digested adipose tissues collected from young or old animals. Their proliferative capacity is relatively limited and after typically 10 or fewer passages MSC proliferation greatly slows and the cells become terminally differentiated as stromal cells. Thus, MSC are considered multipotent but not pluripotent, and can generally only generate new osteoblasts, adipocytes, and chondrocytes in vitro, though there are reports of generation of other cell types under very specialized cell culture conditions. Following in vivo injection, MSC rarely generate any new tissues, and typically persist for only several weeks at sites of injection before undergoing either apoptosis or immune destruction.

So why is MSC treatment being considered for so many different disease states? The common denominator appears to involve a reduction in inflammation achieved with this treatment.[26,36,47,49] Numerous studies have established that MSC are inherently immunomodulatory, via a variety of mechanisms. In culture, MSC spontaneously secrete immune modulatory factors, which vary from species to species. In mice, the major immune suppressive factors include reactive nitrogen intermediates, transforming growth factor-beta (TGF-β) and interleukin (IL)-10, galectin, and prostaglandin E2 (PGE2), while in humans the major factors include indoleamine-dehydrogenase (IDO), TGF-β, soluble IL-1R, vascular endothelial growth factor (VEGF), and PGE2.[49] Studies in dogs have identified TGF-b, PGE, and adenosine as major immune suppressive factors, while studies in cats also identify PGE and TGF-b as immune suppressive factors.[3,14,95] While MSC spontaneously secrete immune modulatory factors in vitro, their immune modulatory function can be further modulated and enhanced in vivo, particularly by inflammatory cytokines such as IFN-g and TNF-a, in a process referred to as MSC "licensing."[47] Thus, MSC respond to their inflammatory environment by modulating the local immune responses.

Use of MSC for Treatment of Orthopedic Conditions

The majority of studies using MSC in companion animals and horses have been for treatment of orthopedic disease, typically OA in dogs and tendon and cartilage injuries in horses.[19,33,34,37,39] In the case of tendon injuries, MSC are purported to stimulate healing by differentiating into tenocytes, though direct evidence for this is lacking in equine studies. For treatment of cartilage injuries, the primary goal is replacement of missing or dysfunctional chondrocytes with MSC-derived chondrocytes. Again, with the possible exception of rodent studies and a few studies in goat and rabbit models, evidence for direct cartilage replacement is scant. Beneficial effects in dogs with OA likewise are unlikely to result from replacement of damaged or missing cartilage. Instead, the primary effects of MSC injection for orthopedic injuries appear to be stimulation of endogenous healing processes (e.g., recruitment of host endogenous stem cells, stimulation of angiogenesis), along with suppression of local inflammatory processes, which can be quite profound. Thus, cellular therapy with MSC is best considered as a biological approach to alter the local injury environment to improve healing and reduce inflammation.

Immune Modulation with MSC

Perhaps the most pronounced activity of MSC in vivo is to reduce or modulate inflammatory processes, which is why MSC cellular therapy has increasingly been viewed as a new means of modulating intractable inflammatory diseases. For example, in animal models and in clinical trials in humans, autologous or allogeneic MSC have been evaluated following systemic administration for treatment of severe and unrelenting inflammatory diseases including graft-versus-host disease, inflammatory bowel disease, multiple sclerosis, rheumatoid arthritis, and scleroderma.[26,47]

In veterinary medicine, use of MSC has been evaluated for treatment of asthma and gingivostomatitis in cats, inflammatory bowel disease in dogs and cats, and anal fistulas in dogs.[3,39,42,62,64] Other studies have investigated the use of MSC to treat spinal cord injury, chronic keratitis sicca, and other degenerative or inflammatory conditions.[38,97,17] All of these diseases would be expected to respond to a treatment that suppresses inflammation and stimulates healing processes, regardless of whether there was any true replacement of lost cells or tissues. Dramatic responses have been observed in animals with chronic immune-mediated diseases that have failed to respond to months of conventional immune suppressive therapy (Dow, S., unpublished data).

Anti-Infective Therapy with MSC

An additional and until recently unappreciated property of MSC is their antimicrobial activity. For example, in vitro studies have shown that MSC from multiple different species, including dogs and horses, can exert direct bactericidal activity, mediated by secreted antimicrobial peptides.[44] Moreover, in vivo MSC have been shown to interact with the host innate immune cells to increase antibacterial activity, including stimulation of neutrophil phagocytosis and neutrophil extracellular trap (NET) formation, as well as enhancement of monocyte recruitment.[44,80] A number of studies in acute infection models have demonstrated the ability of MSC to help eradicate infection.[60]

More importantly, MSC can be used effectively to manage chronic bacterial infections, including infections associated with biofilm formation and with drug-resistant bacteria.[44] In these studies, MSC administered IV accumulate at the site of infection, where they significantly reduce the bacterial burden and stimulate wound healing. In a clinical trial in dogs with a variety of different chronic, drug-resistant bacterial infections, infusion of activated MSC several times was an effective means to resolve previously refractory infections.[44] Importantly, the treatments were done using allogeneic MSC, which were administered safely for multiple IV treatments without eliciting immune rejection reactions. This new application of cellular therapy offers considerable promise as an adjunctive therapy to prolonged antibiotic administration for management of chronic infections.

Cellular therapy using MSC is increasingly viewed as an effective tool for managing certain diseases that are difficult to manage with conventional therapy. Future developments may include the use of single sources for cell production and expansion in vitro (e.g., induced pluripotent stem cell (iPSC)-derived MSC), as well as more standardized methods of cell expansion and preparation for injection or infusion.[15]

Acronyms and Abbreviations

AIDS, acquired immune deficiency syndrome; BMT, bone marrow transplantation; CKD, chronic kidney disease; CRF, chronic renal failure; FDA, Food and Drug Administration; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HGFs, hematopoietic growth factors; IL, interleukin; M-CSF, macrophage colony-stimulating factor; PBPC, peripheral blood progenitor cell; rhEPO, recombinant human erythropoietin; SC, subcutaneously; SCF, stem cell factor; TBI, total body irradiation; TNF, tumor necrosis factor; TPO, thrombopoietin.

The hematopoietic system is an exquisitely controlled hierarchical tissue, with multipotent stem cells residing mainly in the bone marrow eventually becoming nonreplicative mature hematopoietic cells that circulate in the peripheral blood. The endogenous elaboration of hematopoietic growth factors (HGFs), stimulatory glycoproteins that affect the growth and differentiation of bone-marrow-derived cells from these stem cells, drives this process. Some of these HGFs exert their effects on multiple cell lineages, while others are cell-lineage-specific. The availability of these HGFs has become invaluable in human medicine, with marked clinical advancements in the setting of bone marrow transplantation (BMT) and chemotherapy-induced myelosuppression, as well as a variety of other disorders.

Several canine and feline HGFs have been cloned, although none are commercially available for clinical applications. The use of recombinant human HGFs is relatively commonplace in veterinary medicine, but still considered strictly an extra label application. The following brief review will discuss the most clinically relevant HGFs commonly used in veterinary medicine.

ERYTHROPOIETIN (EPO)

Background

EPO, a RBC lineage-specific hormone, is produced mainly by juxtatubular interstitial cells of the renal cortex, with a small amount being produced by the liver. EPO cooperates with various other HGFs (interleukin-3 [IL-3], stem cell factor [SCF], thrombopoietin [TPO]) in the development of colony-forming unit-erythroid cells in the bone marrow from a common myeloid precursor. EPO promotes erythroid progenitor cell survival through apoptosis evasion via upregulation of the antiapoptotic protein Bcl-xL[19] and by reducing the level of

cell-cycle inhibitors. The end result is increased production of proerythroblasts and release of more RBCs into the circulation. It is now recognized that hypoxia, the most potent stimulus of EPO production, increases the activity of the primary EPO transcription factor, hypoxia-inducible factor-1α (HIF-1α).[45]

In 1989, EPO became the first HGF to become commercially available for clinical use in the United States. Recombinant human erythropoietin (rhEPO, epoetin alfa) (Epogen®, Amgen, Thousand Oaks, CA; Procrit®, Ortho Biotech, Bridgewater, NJ) is approved for the treatment of anemia associated with chronic renal failure (CRF), with zidovudine (Retrovir) therapy in patients infected with human immunodeficiency virus, and with chemotherapy for nonmyeloid malignancies, as well as for anemia in patients scheduled for elective, noncardiac, nonvascular surgery. In 2001, darbepoetin alfa (Aranesp®, Amgen), a hyperglycosylated molecule based on the protein backbone structure of human EPO, was approved by the Food and Drug Administration (FDA) to allow a new option for treatment of anemia of CRF. The increased level of glycosylation allows a longer duration (up to three times longer than EPO) of the drug in the circulation.[13] Subsequently, darbepoetin alfa was approved for the treatment of chemotherapy-induced anemia in patients with nonmyeloid malignancies.

Use in Veterinary Medicine

Similar to the human experience, EPO most likely plays an important role in the pathogenesis of anemia in companion animals. The suppressed rate of RBC formation caused by lack of renal production of EPO is a major problem in the treatment of patients with CRF.[36,41]

Fortuitously, the structure of EPO is well-conserved across species lines. When given to dogs and cats with CRF, rhEPO causes a dose-dependent increase in the hematocrit (Hct) and corrects anemia.[8] A transient, moderate reticulocytosis is initially seen and the bone marrow myeloid:erythroid ratio decreases, illustrating the increased erythropoietic response. Depending on the dose given and the initial Hct, correction of the Hct to low normal takes from 2 to 8 weeks. When RBC production is noted, it usually results in a 1% increase per day in the dog's or cat's Hct.[8]

Dosing schedules for EPO have not been standardized for veterinary patients. Both intravenous and subcutaneous routes of administration of rhEPO appear effective, although plasma concentrations persist longer after subcutaneous administration, which allows lower total doses to be given. Starting doses of 50–150 U/kg given subcutaneously three times per week are currently recommended for dogs (100 U/kg in cats) with weekly monitoring continued until a target Hct is achieved (30–40% in dogs and 25–30% in cats).[3,18,30,55] Thereafter, the dosing interval should be decreased to twice weekly. To maintain RBC counts and Hcts in the target range, most animals require 50–100 U/kg one to two times weekly, although the dosage required varies significantly among treated individuals. Therefore, periodic monitoring of the Hct is required for proper adjustment of the dose or dosing interval or both. Pharmacological activity in dogs has also been demonstrated using a mucoadhesive tablet containing 100 U/kg rhEPO.[56] Supplementation with oral ferrous sulfate (100–300 mg/day for dogs and 50–100 mg/day for cats) is highly recommended for all patients treated with rhEPO due to the high demand for iron associated with stimulated erythropoiesis, even if the pretreatment transferrin saturation is normal.[24]

Reported adverse reactions to EPO include transient cutaneous or mucocutaneous reactions with or without fever (rare and self-limiting upon cessation of rhEPO), hypertension, seizures, polycythemia, vomiting, discomfort at the site of injection, and, most significant clinically, the development of neutralizing antibodies and RBC aplasia. Approximately 20–30% of rhEPO-treated animals develop neutralizing antibodies against the foreign protein, leading to RBC aplasia.[8,18] Although anti-rhEPO antibody titers may decline after discontinuation of treatment and pretreatment levels of erythropoiesis can be attained, the severe anemia seen before treatment remains, since these levels are not sufficient to maintain adequate RBC numbers. Due to the possible long-term prevalence of anti-rhEPO antibodies in treated dogs and cats, administration of rhEPO is generally not recommended until the anemia of CRF is negatively impacting the animal's quality of life.

The clinical safety and efficacy of recombinant canine EPO (rcEPO) were investigated in dogs with CRF and rhEPO-induced RBC aplasia.[42,44] rcEPO stimulated RBC production in dogs with nonregenerative anemia secondary to CRF without causing the profound erythroid hypoplasia that can occur in rhEPO-treated dogs, although rcEPO was not as effective in restoring RBC production in dogs that had previously developed rhEPO-induced RBC aplasia. More recently, darbepoetin alfa, given weekly at a median starting dose of 0.5 μg/kg subcutaneously (SC), was shown to be an effective treatment for anemia secondary to chronic kidney disease (CKD) in dogs, although adverse events, including high blood pressure, seizures, vomiting, diarrhea, and pure red cell aplasia, were noted.[15]

Recombinant feline EPO (rfEPO) has also been produced in Chinese hamster ovary cells.[1,43] The biological activity of rfEPO was broadly equivalent to rhEPO with the median Hct and absolute reticulocyte count in cats with CRF treated with rfEPO increasing significantly during the first 3 weeks of treatment. Unfortunately, development of RBC aplasia during treatment with rfEPO was also seen, most likely due to the development of antibodies against a Chinese hamster ovary antigen that cross-reacts with feline EPO. Similar to dogs, darbepoetin alfa appears to have activity in approximately 50% of cats that receive a dosage of 1 μg/kg/week or higher.[6] Importantly, a common side-effect of epoetin administration in cats, pure red cell aplasia, appears to be less common with darbepoetin.

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF)

Background

G-CSF, also called colony-stimulating factor 3 (CSF 3), is a 19.6-kDa glycoprotein that exists in two forms, 174 and 177 amino acid long molecules. The 174 amino form is the most abundant and the most active. G-CSF is produced by bone marrow stromal cells, monocytes/macrophages, and endothelial cells. Granulocyte colony-stimulating factor binds to primarily granulocyte progenitor cells in the bone marrow, which stimulates the proliferation and maturation of neutrophil precursors. At higher doses, G-CSF can act in a multilineage fashion, stimulating the differentiation of several other hematopoietic progenitors. Granulocyte colony-stimulating factor also promotes neutrophil migration across the vascular endothelium and primes neutrophils for cell killing. FDA-approved, commercially available human G-CSFs include: lenograstim (Granocyte, Chugai Pharma, USA), filgrastim (Neupogen®, Amgen), and PEGylated filgrastim (Neulasta®, Amgen).

Human G-CSF was cloned in 1986 and approved by the FDA in 1991 to protect cancer chemotherapy patients. In humans, G-CSF administration causes a dose-dependent rise in neutrophils, as well as a moderate increase in monocytes. G-CSF is now routinely given to human patients undergoing chemotherapy to help prevent episodes of severe neutropenia; G-CSF may also be beneficial in the treatment of established afebrile or febrile neutropenia by reducing the length, and thus expense, of hospitalization stays.[7]

Granulocyte colony-stimulating factor has also been used in humans for the treatment of cyclic neutropenia, an inherited disease characterized by recurrent episodes of neutropenia occurring every 20–24 days. Following rhG-CSF administration the mean neutrophil counts increase, and the severity of neutropenia associated with the cycles decreases. Granulocyte colony-stimulating factor does not completely eliminate the neutrophil cycling or the clinical signs associated with disease, suggesting a defect in receptor signaling, rather than a paucity of G-CSF production.

Another important setting in human medicine where G-CSF is routinely used is in association with BMT. The administration of G-CSF after high-dose chemotherapy and autologous BMT improves the rate of peripheral blood neutrophil recovery, reducing the morbidity and mortality associated with febrile neutropenic episodes. Granulocyte colony-stimulating factor also mobilizes hematopoietic CD34+ progenitors for collection prior to myeloablative therapy. After treatment with G-CSF for 5 days, high concentrations of CD34+ progenitor cells are found in the peripheral blood, which can be collected by leukapheresis and administered to a patient after high-dose chemotherapy or total body irradiation (TBI) in place of marrow. "G-priming" of donors is now standard practice in human transplant protocols. Other uses of G-CSF include treating patients with myelodysplasia and acquired immune deficiency syndrome (AIDS)-associated bone marrow aplasia.

Use in Veterinary Medicine

Canine G-CSF (rcG-CSF) has been cloned[57] and produced synthetically for research purposes, but is not commercially available. rcG-CSF transiently increases neutrophil and macrophage numbers in dogs and cats. At a dose of 5 μg/kg/day, mean neutrophil counts in healthy dogs increased to 26,330/μL with 24 hours of the first injection of rcG-CSF and reached a maximum of 72,125/μL by day 19.[38] A similar effect on neutrophil counts was noted in cats following administration of rcG-CSF at a dose of 5 μg/kg/day.[39]

Mirroring the human experience, rcG-CSF is able to reduce the duration and severity of chemotherapy-induced myelosuppression.[40,58] In both studies, the administration of serial daily doses of rcG-CSF beginning 1–5 days after chemotherapy infusion accelerated neutrophil recovery and also decreased the severity of neutropenia. Both studies suggest that rcG-CSF can increase the feasibility of using high-dose chemotherapy in dogs by mitigating the toxic effects of these drugs on bone marrow hematopoietic precursors.

Cyclic hematopoiesis has also been identified in Gray Collie dogs.[59] Dogs with this disease respond similarly to humans given rhG-CSF, although the development of neutralizing antibodies and subsequent prolonged neutropenia with chronic rhG-CSF usage occurs.[26] This problem was negated by giving rcG-CSF at a dose of 1–2.5 μg/kg SC every 12 hours.[33]

The use of G-CSF in the setting of TBI and BMT has also been reported in the veterinary literature. Granulocyte colony-stimulating factor leads to complete bone marrow reconstitution within 21 days after lethal TBI[49,50] and can also mobilize bone marrow CD34+ progenitor cells to the peripheral blood for peripheral blood stem cell transplantation.[11] Granulocyte colony-stimulating factor can also "prime" dogs before marrow harvesting in the setting of malignant lymphoma. rcG-CSF increased donor peripheral blood mononuclear cell numbers (containing CD34+ progenitor cells) for harvesting via leukapheresis with subsequent allogeneic BMT to an unrelated dog with stage V(b) T-cell multicentric lymphoma who received 8 Gy TBI.[29] The transplanted dog maintained a complete remission for at least 58 weeks after BMT. rcG-CSF has also been used to successfully "prime" dogs before bone marrow harvesting via bone marrow aspiration.[16] The reader is referred to a comprehensive review of the use of hematopoietic cytokines, including G-CSF, in the BMT setting,[28] as well as an original study describing the use of leukapheresis, both with and without rcG-CSF "priming," to harvest peripheral blood progenitor cells (PBPCs) from dogs.[27]

GRANULOCYTE–MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)

Background

GM-CSF, also called colony-stimulating factor 2 (CSF 2), was first cloned in 1985. It is a variably glycosylated

(10–30 kDa) monomeric glycoprotein produced by fibroblasts, endothelial cells, monocytes, and T lymphocytes that has a variety of biological activities. These include prolonging the survival of hematopoietic progenitors and mature neutrophils, eosinophils, and macrophages, stimulating the proliferation of progenitor cells, and enhancing the functional capacity of the mature cells.

The FDA-approved pharmaceutical analogs of naturally occurring rhGM-CSF (sargramostim) are Leukine® (Partner Therapeutics, USA) and Prokine (Amgen). Both are approved for use in human patients more than 55 years of age with acute myelogenous leukemia following induction chemotherapy. Leukine is also approved for use in a number of hematopoietic stem cell transplant settings, including BMT failure or engraftment delay, myeloid reconstitution after autologous and allogeneic BMT, and mobilization and following transplantation of autologous PBPCs. The reported side-effects of rhGM-CSF in human patients include bone pain, fever, and flu-like symptoms.

Use in Veterinary Medicine

Recombinant canine GM-CSF (rcGM-CSF) has been cloned,[35] although it is not commercially available for clinical use. rcGM-CSF given to normal dogs caused a significant increase in circulating neutrophils and monocytes, whereas the effect on circulating eosinophils was more variable.[36] rhGM-CSF is active in dogs[32], inducing neutrophilia and eosinophilia, although it produced variable results in dogs with chemotherapy-induced myelosuppression.[50] This is most likely because rcGM-CSF is only 70% homologous with the human protein; therefore, higher doses of rhGM-CSF may be necessary to achieve the same effect as rcGM-CSF. rhGM-CSF also prevents recurrent neutropenia in Gray Collie dogs with cyclic hematopoiesis, although most dogs developed antibodies to the protein within 2–3 weeks of treatment and hematopoietic cycling persisted.[20]

Importantly, GM-CSF also has the ability to activate monocytes and macrophages, increasing their ability to recognize and destroy malignant cells.[17] DNA plasmid vectors containing the coding sequence for GM-CSF can deliver GM-CSF directly to tumors, which theoretically allows the local recruitment and activation of macrophages. rhGM-CSF cDNA was cloned into a xenogeneic expression vector and injected intramuscularly biweekly for a total of four vaccinations into three dogs diagnosed with oral malignant melanoma. In this same study, nine dogs were injected with both rhGM-CSF and human Tyrosinase.[2] The authors reported a median survival time of 148 days for dogs receiving rhGM-CSF alone and >402 days for dogs receiving both rhGM-CSF and human Tyrosinase. Another antimalignancy strategy is to remove the primary tumor or metastatic lesion, culture the tumor cells in vitro, and transfect them with a eukaryotic vector encoding GM-CSF or use GM-CSF-transfected cell lines established from primary tumors.[13,21] There are currently a wide variety of human clinical trials examining the safety and efficacy of both viral and nonviral vectors encoding GM-CSF for the treatment of many types of solid and hematopoietic malignancies.

THROMBOPOIETIN (TPO)

Background

TPO, a 35-kDa glycoprotein produced primarily in the liver by parenchymal cells and sinusoidal endothelial cells and in the kidney by proximal convoluted tubule cells, is an important regulator of thrombopoiesis via its role as a late-acting megakaryocyte maturation factor. It also stimulates CD34+ hematopoietic progenitor cells to undergo proliferation and differentiation into megakaryocytic colonies and synergizes with SCF and IL-3 to stimulate hematopoietic progenitor cell division and differentiation. The receptor for TPO is encoded by the proto-oncogene c-mpl. Eltrombopag (Promacta®, Novartis, USA or Revolade, GlaxoSmithKline, EU) is a small molecule agonist of the c-mpl (TPOR) receptor. Eltrombopag is FDA-approved to treat idiopathic thrombocytopenic purpura and cirrhosis due to hepatitis C in people. Neumega® (oprelvekin, Wyeth, USA) is a man-made, synthetic 19-kDa version of human IL-11 with FDA approval for use to prevent severe thrombocytopenia and reduce the need for platelet transfusions following myelosuppressive chemotherapy. Nplate® (romiplostim, a thrombopoietin analog, Amgen) is a commercially available peptibody protein with FDA approval for the treatment of thrombocytopenia in adults with chronic immune thrombocytopenia purpura.

In the setting of BMT, TPO can stimulate enhanced platelet recovery and improve the recovery of other hematopoietic lineages after BMT and act synergistically with G-CSF to accelerate neutrophil recovery in mice after radiation or chemotherapy. The reader is referred to two review articles for a more thorough discussion of TPO and the development of TPO mimetics.[54,5]

Use in Veterinary Medicine

Nplate (romiplostim) administration to five dogs with refractory immune thrombocytopenia (ITP, three primary and two secondary) increased platelet counts in all five dogs.[23] Four of these dogs attained remissions with no relapses occurring over a 3–10-month follow-up period. Feline, but not canine, TPO has been cloned.[31] However, there are no reports in the veterinary literature describing the clinical use of rfTPO, Neumega, or eltrombopag in companion animals.

INTERLEUKIN-3

Background

Interleukin-3 is a T-cell-derived, pluripotent 25-kDa glycoprotein that is required for the survival and proliferation of CD34+ hematopoietic progenitor cells. Interleukin-3

promotes the survival and expansion of these cells and also, to a lesser extent, produces the same effects on committed progenitors of the granulocyte–macrophage, erythroid, eosinophil, basophil, megakaryocyte, and mast cell lineages.[10] IL-3 also enhances myeloid cell functions. Clinically, IL-3 leads to multilineage expansion of myeloid cells, including platelets, neutrophils, and monocytes, when used alone or in combination with rhGM-CSF. Therefore, IL-3 may be useful to treat chemotherapy-induced myelosuppression, although signs of toxicity, including fever, fatigue, and headaches are common. The reader is referred to these review articles describing the role of IL-3 in hematopoietic cell development.[8,34]

Use in Veterinary Medicine

Canine IL-3, which was cloned in 2001,[22] has approximately 37% amino acid homology to the human protein. This may explain the lack of efficacy of the human protein (rhIL-3) in increasing neutrophil or macrophage numbers when administered to dogs. rhIL-3 failed to correct recurrent neutropenia in Gray Collie dogs with cyclic hematopoiesis, although it did stimulate eosinophilia.[20]

STEM CELL FACTOR

Background

SCF (also known as kit ligand [KL], or steel factor) is a 30-kDa glycoprotein produced by fibroblasts, endothelial cells, and bone marrow stromal cells, which exists as a transmembrane protein and a soluble protein. These different forms are the result of alternative splicing of the RNA transcript. The SCF receptor is encoded by the proto-oncogene c-kit that is expressed on hematopoietic progenitor cells, mast cells, and melanocytes.

Stem cell factor acts synergistically with many other HGFs to promote the production of lymphoid, myeloid, and erythroid lineages from hematopoietic progenitor cells.[53] Therefore, SCF has potential benefit in a number of clinical settings involving either hematopoietic precursor damage or defects and in the setting of BMT. Administration of rhSCF to humans results in significantly increased hematopoietic progenitor cells in the bone marrow and blood. SCF can enhance the proliferation of bone marrow cells derived from patients with aplastic anemia when used with other HGFs. Other uses include the administration of SCF after BMT or chemotherapy to enhance hematopoietic recovery.

Use in Veterinary Medicine

Canine SCF was cloned in 1992 and shares approximately 85% amino acid homology to the human protein.[47] Feline SCF, which has a high degree of homology at both the nucleic acid and protein levels to other species, has also been cloned.[12] The vast majority of veterinary literature describes the use of rcSCF in the settings of hematopoietic recovery after BMT and canine mast cell disease.[51,52] rcSCF supports the survival of hematopoietic progenitors in long-term marrow culture[37] and acts synergistically with rcG-CSF to decrease the time to hematopoietic recovery in dogs after TBI.[46] rcSCF, either alone or in combination with rcG-CSF, also significantly increases the level of PBPCs and stem cells.[11,48] rcSCF logically enhances IgE-mediated histamine and tumor necrosis factor (TNF)-alpha release in canine mast cells, since mature mast cells express c-kit.[4,25] rcCSF, alone or in combination with rcG-CSF, has also been used to treat Gray Collies with cyclic neutropenia.[9]

CONCLUSIONS

Hematopoietic growth factors have significant potential in the treatment of veterinary patients in a wide variety of settings. The greatest benefit associated with the use of HGFs is for those patients with profound blood cell dyscrasias secondary to chemotherapy administration or BMT. Mirroring the human experience, the use of HGFs in conjunction with the administration of chemotherapies that are toxic to the bone marrow may provide an arena to allow the safe exploration of increased anticancer dose intensity which could result in increased survival times while improving quality of life. In addition, as more reports of canine BMT are published, HGFs will most likely become an important part of these protocols in an effort to increase our ability to harvest hematopoietic progenitor CD34+ cells and aid in post-BMT hematologic recovery. Unfortunately, until recombinant canine and/or feline HGFs become affordable and commercially available products, a veterinarian's only option is to use recombinant human proteins which are quite often expensive, ineffective, and have the potential to lead to the development of debilitating neutralizing antibodies with chronic use.

Blood typing and crossmatching are techniques used in the selection of blood components before transfusion. When blood typing is performed, antisera or other reagents are used to identify specific RBC antigens. In crossmatching, antibodies are detected by reacting donor sera and donor RBCs with recipient sera and recipient RBCs. The primary purpose of this pretransfusion testing is to ensure that the transfused RBCs have optimal survival when transfused and do not cause harm to the recipient.

Pretransfusion testing in humans generally involves a type and screen procedure. This consists of an initial typing for ABO and Rh(D) antigens and detection of patient antibody by mixing patient serum with commercially available reagent RBCs that contain known antigens. An indirect antiglobulin test (IAT) is used during this antibody screen. When no clinically significant antibodies are detected, an immediate spin crossmatch, in which serum is mixed with saline-suspended RBCs and centrifuged immediately, can be performed to ensure ABO compatibility. If clinically significant antibodies are found, RBCs that lack the corresponding antigens are used, and an IAT crossmatch is performed. The IAT is best for detecting IgG antibodies. Use of a low-ionic strength saline solution in the IAT further enhances its sensitivity. Techniques for antibody detection using tubes (hemagglutination), red cell adherence solid-phase systems, and column agglutination (gels) have been compared.[5]

Blood typing and crossmatching can also be used before transfusion in most domestic animals. Transfusions performed with untyped or uncrossmatched blood can sensitize recipients to future transfusions or can result in reactions that range from enhanced removal of the transfused RBCs to death of the patient. Pretransfusion testing in veterinary clinical practice is frequently less complex than that performed in the human field, largely because of a lack of appropriate reagents.

BLOOD TYPING

Laboratory Testing and Submission

Blood typing of some animal species can be performed in commercial veterinary laboratories. A partial listing of these laboratories is provided (regional veterinary

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

diagnostic or clinical pathology laboratories may also offer these services and can be contacted):

1. Animal Blood Resources International (dogs, cats) (www.ABRINT.net).
2. University of California (Davis) Hematology Laboratory (horses) (www.vetmed.ucdavis.edu/vmth/lab_services/clinical_labs/Featured_tests/equine_blood_typing.cfm).

To perform blood typing, laboratories usually require the submission of either EDTA or acid-citrate-dextrose (ACD) whole blood. Serum also may be required for antibody testing.

Blood Typing in the Dog

Canine RBC antigens have been previously identified by use of polyclonal antibodies generated through canine alloimmunization. Dog erythrocyte antigen (DEA) 1, an antigen capable of producing acute hemolytic reactions in sensitized animals, can be identified with a monoclonal antibody.[1] DEA typing for dogs varies, depending on the laboratory used, with some laboratories only typing for DEA 1, and others typing for DEA 1, 4, 5, and 7. Other RBC antigens may be present; however, lack of available antisera prohibits or prevents their identification. This is true for both well-known antigens and newly discovered antigens. For example, DEA 6 and 8 are common antigens (DEA 6 is present in 99% of dogs; DEA 8 may be present in 40% of dogs) previously identified in dogs.[4,21] Lack of available antisera prevents their identification by most typing laboratories. The Dal antigen is a more recently discovered RBC antigen of dogs, with Dal-negative dogs found in Dalmatians (11.7%), Doberman Pinschers (42.4%), and Shih Tzus (57.1%).[2,9] Testing is available through the Section of Medical Genetics at the University of Pennsylvania School of Veterinary Medicine (PennGen, http://www.vet.upenn.edu/research/academic-departments/clinical-sciences-advanced-medicine/research-labs-centers/penngen), or at the University of Montreal Small Animal Blood Bank at chuv.umontreal.ca/banque-de-sang/. The newest documented blood types are Kai 1 and Kai 2, whose clinical relevance remains to be elucidated.[6]

Blood Typing in the Cat

The best characterized blood-group system in cats is the AB system. This system consists of three blood types, A, B, and AB. Type A is the most frequent blood type, occurring in more than 95% of domestic short-hair and long-hair cats in the United States. Type-B blood occurs in less than 5% of domestic short-hair and long-hair cats; however, the frequency of types A and B in cats varies with the breed of cat and the geographic location.[7,8] For example, as many as 45% of Exotic and British Shorthair cats and Cornish and Devon Rex cats have the B blood type. Type-AB cats are rare. Most laboratories type for both the A and B antigens in cats.

All type-B cats older than 3 months of age have high titers of anti-A antibodies. These antibodies act as strong hemolysins and hemagglutinins.[3] Type-B cats transfused with type-A RBCs have a significant hemolytic transfusion reaction, and type-A or type-AB kittens born to type-B queens are at risk of developing neonatal isoerythrolysis (NI). Cats that have type-A blood have weak anti-B alloantibodies that produce a delayed transfusion reaction characterized by premature removal of transfused cells. Type-AB cats have no anti-A or anti-B alloantibodies in their plasma.

The newest non-AB blood-group RBC antigen to be described is the Mik red cell antigen.[24] The absence of this antigen was found to be associated with naturally occurring anti-Mik alloantibodies, capable of eliciting a hemolytic transfusion reaction.

Clinical Blood-Typing Methods in the Dog and Cat

Typing of dogs and cats has been simplified for clinical use by production of commercial typing kits. Either typing cards, typing gels, or an immunochromatographic test can be used.

Typing cards (DMS Laboratories, Inc./RapidVet-H, www.rapidvet.com) contain monoclonal antibody that has been lyophilized onto the card wells. A small amount of diluent and patient EDTA whole blood is added, and the card is rocked for approximately 2 minutes. Agglutination indicates a positive response (Figure 107.1). For the dog, cards are available that type for DEA 1. Positive control wells and wells to detect autoagglutination are included with the canine DEA 1 typing cards to aid in reading the reactions. Cats that have types A, B, or AB can be identified using the feline blood-typing cards. The advantage of these tests lies in their speed and simplicity.

Typing gels are being redeveloped for the typing of DEA 1 in dogs (Alvedia Veterinary Diagnostic Company, https://www.alvedia.com) and A, B, and AB in cats (Alvedia, RapidVet-H). Gel tubes contain a monoclonal antibody (for typing determination) in a gel matrix. Antigen–antibody reactions cause agglutinates to form that then become trapped within the gel. Free RBCs pass though the gel and form a button at the bottom of the tube upon centrifugation.

In the immunochromatographic technique, RBCs mixed with a buffer are allowed to migrate on a membrane that contains monoclonal antibodies against either DEA 1 (Alvedia) or against feline types A and B (Alvedia, RapidVet). In a positive reaction, RBCs will agglutinate with the antibodies and form a visible line on the membrane (Figure 107.2). A study comparing this technique with the typing card and the standard tube agglutination typing technique in cats showed good concordance of typing results.[18]

Blood Typing in Large Animals

Blood typing for large animals is complex and best performed by a commercial veterinary laboratory. In the horse, over 30 different erythrocyte antigens from seven

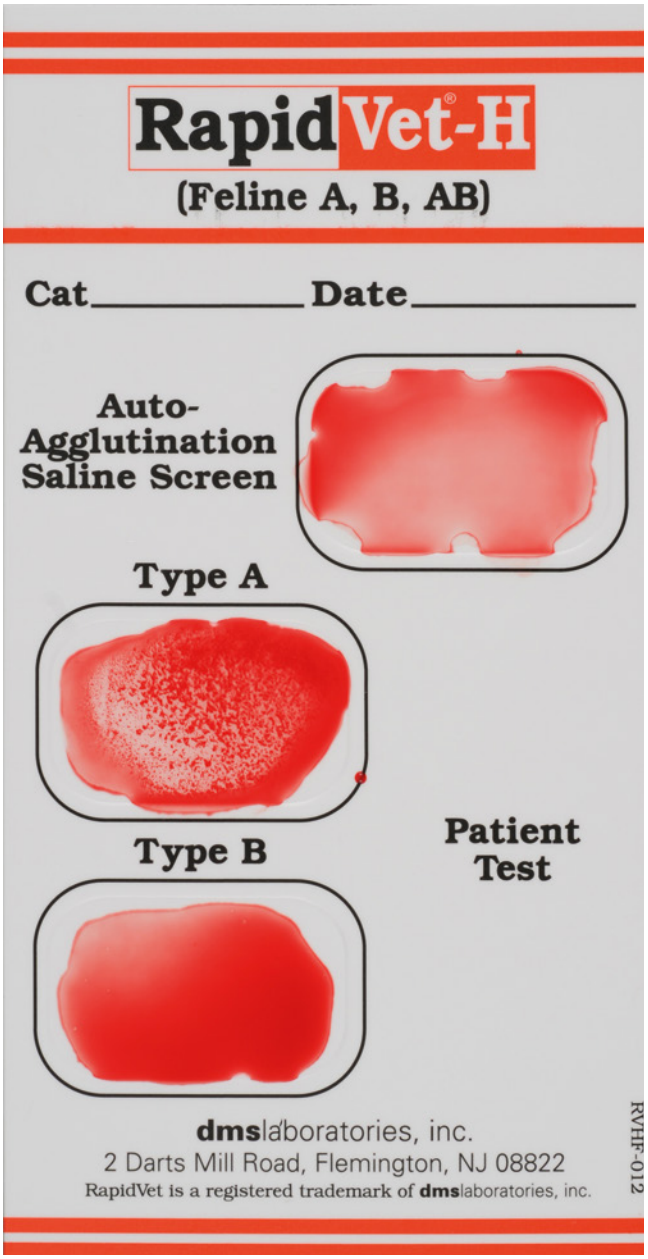

FIGURE 107.1 An example of a feline blood-typing card. The feline patient blood shows agglutination in the type A well and is type-A-positive. (Courtesy of dmslaboratories, inc.)

FIGURE 107.2 An example of a canine DEA 1 immunochromatographic blood-typing test. The presence of a red line by the "DEA 1" arrow indicates a positive reaction. The red line by the "C" arrow is a control line that indicates the test has been run successfully. (Courtesy of Alvedia Veterinary Diagnostic Company, France.)

internationally recognized blood groups have been recognized.[16] This means that identification of a blood donor with identical alloantigen and antibody profiles is difficult, if not impossible. Alloantigens Aa and Qa are the most immunogenic of the equine RBC antigens and are responsible for the majority of equine NI cases.[12] Mares that lack Aa and Qa are at risk of producing antibody to them upon exposure. Mares known to be at risk, either because of blood type or because of previous foaling of an affected foal, can have sera tested for antibody before foaling. In mules, a unique donkey RBC antigen known as the donkey factor has been associated with NI.[22]

Recently, an in-clinic test for the equine Ca antigen (Alvedia Quick Test BT Ca) was evaluated.[13] The test is performed using an immunochromatographic technique with an equine anti-Ca monoclonal antibody. In-clinic typing for detection of Ca and Aa antigens has also been described, using antisera from horses previously identified as having anti-Ca and anti-Aa antibodies.[16]

CROSSMATCHING

Indications and Limitations

Blood typing permits the identification of RBC antigens in a patient. It does not allow the detection of antibodies between a patient and a potential blood donor. In a clinical situation, this is generally determined by crossmatching. Even in animals that have been blood-typed, crossmatching should be performed to detect antibodies against RBCs.

Crossmatching does have its limitations. A compatible crossmatch does not necessarily indicate that the donor and recipient have the same blood type, merely that antibodies against RBCs cannot be detected. Also, the crossmatch technique may lack the appropriate sensitivity to detect some antibodies; thus, it is possible to have a compatible crossmatch and still have increased removal of the transfused cells. A standard crossmatch does not detect platelet or granulocyte antibodies. It cannot predict some types of transfusion reactions, such as urticarial reactions. Nevertheless, crossmatching can be a useful technique and should be performed before transfusion. Incompatibilities in transfusion-naïve dogs have been documented;[15] therefore, crossmatching should be considered before all transfusions. At minimum, crossmatching should be performed before those transfusions where the recipient has a history of previous blood exposure. Crossmatching should always be performed before feline transfusions, regardless of the previous transfusion history, because of the presence of naturally occurring antibody in the cat and the serious consequences of transfusing type-A blood into a blood type-B cat.

Crossmatching in Large Animals

Crossmatching in large animals generally requires both a saline-agglutinating technique and a technique that can detect hemolysis. Agglutination tests can be

performed by most veterinary practices; however, the hemolytic tests require the addition of exogenous complement, usually provided by rabbit or guinea pig serum.[20] This serum is diluted or adsorbed first with RBCs of the species to be tested, to remove the natural heterolysins and heteroagglutinins present in the rabbit or guinea pig serum. Consequently, detection of hemolytic antibodies is usually confined to the veterinary laboratory. In a study evaluating a standard tube crossmatch and a gel column crossmatch in horses, both the tube and gel procedures had excellent accuracy for agglutination, but the gel procedure had marginal accuracy for hemolysis.[13]

One crossmatching technique used in the identification of mare antibody in cases of suspected NI is the jaundiced foal agglutination test.[12] In this test, colostrum from the mare is reacted with RBCs from the foal. The colostrum can also be tested with potential donor blood. Serial dilutions (1:2–1:128) with saline of colostrum are made, and one drop of EDTA foal blood is added to 1 mL of the dilution. Blood is also added to a saline control tube that lacks colostrum. The tubes are centrifuged and judged for agglutination. Positive reactions at dilutions of 1:16 or greater are considered significant in horses.

Standard Tube Crossmatching Procedure

The tube crossmatching procedure described in Table 107.1 is a saline-agglutination crossmatch performed by veterinary laboratories. Some laboratories also use an IAT in this procedure, adding species-specific Coombs reagent after the initial RBC or sera reactions have been interpreted. Antisera-treated RBCs are washed in saline, the Coombs reagent is added in an amount and dilution determined by the manufacturer, and the mixture is incubated. The mixture is then centrifuged and the sample is checked for agglutination. A saline replacement technique is useful to detect rouleaux in species such as horses and cats, in which rouleaux formation is common and can be erroneously identified as agglutination in the crossmatch procedure. Steps in the saline replacement technique[3] are as follows:

1. Recentrifuge the serum or the RBC mixture when rouleaux formation is suspected.
2. Remove the serum.
3. Replace the serum with an equal volume of saline (two drops) and gently mix.
4. Centrifuge the saline or the RBC mixture at 1000 × *g* for 15 seconds.
5. Resuspend the saline or the RBC mixture and observe for agglutination.

Rouleaux disperse when suspended in saline, whereas true agglutination remains. Grading of reactions or antibody titration can also be performed.[14]

Gel column crossmatching methods, requiring gel column cards, low-ionic-strength saline, special centrifuges, and special incubators, have also been described.[2,24]

TABLE 107.1 Crossmatching procedure.

1. Obtain an anticoagulated (EDTA) and non-anticoagulated specimen of blood from both patient and donor. The EDTA tube will serve as the source of RBC (antigen), and the non-anticoagulated tube will serve as the source of serum (antibody). Plasma can be used, but it should be noted that EDTA can interfere with detection of some complement-dependent hemolytic antibodies.
2. Centrifuge and separate plasma or serum from RBC.
3. Wash RBC by adding saline or phosphate-buffered saline (PBS) to a small amount of packed RBC, mixing and centrifuging at 1000 × *g* for 1 minute. Decant the saline and repeat three times, filling the tubes with saline, mixing, centrifuging, and decanting.
4. After last wash, decant supernatant and resuspend cells with saline to give a 4% suspension of RBCs; 0.1 mL blood in 2.4 mL saline gives a 4% suspension.
5. Make the following mixtures by adding the indicated amount of the well-mixed RBC suspension and serum or plasma to 10–12 × 75 mm tubes:
   Major crossmatch: two drops patient sera/plasma, one drop donor 4% RBC.
   Minor crossmatch: two drops donor sera/plasma, one drop patient 4% RBC.
   Controls: two drops patient sera/plasma, one drop patient 4% RBC; a donor control of two drops donor sera/plasma with one drop donor 4% RBC can also be prepared.
6. Incubate tubes 15 minutes at 37 °C.

Note: To detect hemolysis in large animal species, add two drops of complement to the RBC/serum tubes and incubate at 37 °C for 90 minutes.

7. Centrifuge for 15 seconds (3400 rpm/1000 × *g*).
8. Read tubes:
   Macroscopic: Examine tubes first for hemolysis. Then rotate tubes gently and observe cells coming off the red cell "button" in the bottom of the tube. Rotation of the control tubes prior to or simultaneously with rotation of the other tubes allows for optimum comparison of reactions. In a compatible reaction, i.e., where there is no antigen–antibody reaction, the cells should float off freely, with no clumping/hemagglutination (compare to the control tubes). Rouleaux formation can be falsely interpreted as a reaction. If rouleaux formation is suspected, a saline replacement technique can be used.[17] Proceed to the microscopic examination in those tubes with weak or no obvious reactions.
   Microscopic: After tubes have been viewed macroscopically, place a drop of the cells/sera mixture on a slide, apply a coverslip, and examine microscopically. The RBC should normally appear as individual cells, with no clumping or rouleaux formation.

Commercial Crossmatching Kits

Crossmatching kits are available. The RapidVet®-H major and minor companion animal crossmatch test (DMS Laboratories, Flemington, NJ, http://www.rapidvet.com) uses gel tubes to detect incompatible crossmatches.[23] The Alvedia company (www.alvediavet.com) provides both gel tests and an immunochromatographic,

FIGURE 107.3 An example of a canine antiglobulin-enhanced immunochromatographic crossmatch test. The presence of the red line by the "XM" arrow indicates a positive (incompatible) reaction. The red line by the "C" arrow is a control line that indicates the test has been run successfully. (Courtesy of Alvedia Veterinary Diagnostic Company, France.)

antiglobulin-enhanced crossmatch test (Figure 107.3) to detect incompatible crossmatches in dogs, cats, and horses.[11] Care must be taken to follow the manufacturer's centrifugation recommendation when using the gels, as this can impact dispersion of cells through the gel. Kits from both companies can be stored at room temperature for at least a year. They can be ordered directly from the companies or from commercial veterinary laboratories. Microscopic or weak incompatible results or hemolysis seen in the standard tube crossmatching technique are unlikely to be picked up using the gel- or strip-based technique.[10] In addition, a recent study indicated that the tube and gel crossmatching techniques, but not an immunochromatography strip technique, were useful methods for the identification of DEA 7 incompatibilities caused by anti-DEA 7 antibodies.[19]

Blood typing and crossmatching are valuable techniques that must be considered before transfusion in all species. Although some testing should be performed in specialized veterinary laboratories, other tests, such as saline-agglutinating crossmatching and DEA 1 and feline AB blood typing, can be performed in most clinical veterinary practices and provide information that aids in the safe selection of blood components.

ERYTHROCYTES

The canine erythrocyte is a biconcave disc, approximately 7 μm in diameter when measured microscopically on a blood smear and a MCV of 60–71 fL.[3] The biconcave shape is more pronounced in the dog than in other domestic animals, giving their RBCs a clearly visible central pallor when viewed in the monolayer of well-made blood films (Figure 108.1a). This prominent central pallor, which normally encompasses approximately the central one-third to one-half of the cell's diameter, makes spherocyte recognition possible in this species. Central pallor may be lost at the smear edges or in very thin smears, where sheer forces distort normal morphology (Figure 108.1b).

Canine erythrocytes normally display mild anisocytosis and poikilocytosis. Echinocyte formation may be an artifact related to smear preparation (i.e., crenation), but has also been reported in certain disease states. Clear, refractile areas (water artifacts) within RBCs may be seen if the blood smear is not adequately dried before staining. Stain precipitate may sometimes adhere to erythrocytes and must not be confused with parasites (Figure 108.1c).

When blood smears are stained with Romanowsky stains, such as Wright's stain, polychromatophilic (blue-staining) cells may be seen occasionally. In health, these comprise less than 1% of the cells (Figure 108.1d) and are recognized as reticulocytes when blood is stained with supravital stains, such as new methylene blue (Figure 108.1e). Rare nRBCs and Howell–Jolly bodies can be seen in blood smears from normal adult dogs with increased numbers found in normal neonates. Hgb crystals are square to rectangular structures which, depending on staining technique, are similar, slightly lighter, or darker than Hgb in mature RBC and often deform the RBC that contains them (Figure 108.1f). Low numbers (1–10 per slide) of Hgb crystals have been reported in blood smears of clinically normal dogs and dogs less than 3 months of age.[36] They have not been associated with abnormal Hgb molecules (see Chapter 24).

Reticulocytes are released from the canine marrow in a cyclic manner with a periodicity of approximately 14 days.[38] Aggregate reticulocytes, containing one or more large, distinct clumps of blue-staining material, are most common (Figure 108.1e). In dogs, polychromasia noted on Romanowsky-stained smears correlates well with reticulocytosis, although automated reticulocyte counts are a more accurate reflection of the number of early RBCs in circulation especially when polychromasia is not prominent[9] (see Chapters 23 and 137). Reticulocyte RI vary between laboratories based on the methodology and reference population used. Reticulocyte counts should be interpreted using the RI provided by the laboratory, made in accordance with

American Society of Veterinary Clinical Pathologists (ASVCP) reference interval guidelines. Neonatal animals have significantly higher reticulocyte counts, a manifestation of increased erythropoiesis needed for replacement in a rapidly expanding vascular volume. Reticulocyte counts of up to 10% can be seen in apparently healthy dogs during the first 2 months of life.[15,50] This number decreases to adult levels by approximately 5–6 months of age. Greyhounds have significantly increased reticulocyte counts immediately after racing; however, reticulocyte counts return to baseline 1–2 hours post-race.[27] Recently, an increased prevalence of reticulocytosis in the absence of anemia has been recognized in dogs. Reticulocytosis was defined as >2.5% reticulocytes or >110,000 reticulocytes/μL and was associated with several underlying diseases, joint supplements, and nonsteroidal anti-inflammatory medications; however, some dogs were apparently healthy and unmedicated.[16,42]

All three measurements of RBC mass, Hgb, Hct, and RBC count, are interrelated and, in the absence of marked alterations of RBC size and Hgb concentration, tend to parallel each other. Hct, the percentage of blood volume comprising erythrocytes, can be determined either by centrifugation PCV or calculated based on the MCV and RBC count. Most automated hematology analyzers calculate Hct, although manual PCV is commonly determined in practice. PCV should be used as a gold standard when artifactual, calculated Hct values are suspected (see Chapter 137).

The RBC mass of neonatal animals varies significantly from that of adults and changes as dogs age. At birth, Hgb, Hct, and the RBC count are near adult values, but decline rapidly over the first 2 months of life. Hct values reach a nadir in the high 20s to low 30s (%), which is clinically significant and should not be diagnosed as anemia.[46,50] After this, values start to increase, reaching adult levels by 6 months to 1 year of age.[24] Anemia of the elderly (defined as the general population >65 years of age) is well described in human medicine and a recent study showed that this may also occur in the canine population.[21] In one study, senior (8–11.9 years) and geriatric (>12 years) dogs had lower Hct than adult dogs (1–8 years), as well as lower MCV and serum iron (not total body stores) suggesting that as dogs age they develop some degree of iron-restricted erythropoiesis and inflammation.[44] Decreased erythroid mass in geriatric dogs is supported by another study that developed RIs from a large population of apparently healthy senior and geriatric dogs; however, subclinical disease was possible in this population.[2]

Some authors have found a sex effect with males having a slightly higher Hgb concentration than females; however, it is not clinically significant as all values are well within RIs for adult dogs. Pregnant females have significant changes during gestation. In one study, the Hct of pregnant dogs fell from a mean baseline of 53% to 32% at term.[6] Dogs in diestrus may have a 7–8% decrease in Hgb, Hct, and RBC counts compared to dogs in other phases of the estrus cycle, suggesting a possible component of hemodilution which may be related to the elevated progesterone concentrations present in both diestrus and during pregnancy.[57]

Numerous studies have shown that greyhound dogs have increased erythroid mass, with Hct up to 65% reported in clinically healthy animals.[49,58] These higher RBC indices become evident by 9–10 months of age.[49] Erythroid indices in greyhounds may increase further immediately after racing (PCV up to 68%), but return to baseline within 30 minutes post-race.[47] Dachshunds have also been reported to have higher RBC indices than the general dog population with mean PCVs of 52% (46–58%).[53] Akita dogs, with the high potassium RBC phenotype, have slightly lower Hgb, Hct, and RBC counts than their low potassium RBC phenotype counterparts.[10] A slightly higher RI for dogues de Bordeaux erythroid values as compared to the general dog population has been reported. Breed-specific RIs are warranted for these values.[33]

These RBC indices characterize the size and Hgb content of the RBC population and vary in some breeds. In the dog, fetal RBCs are larger than those of adults. The MCV of umbilical cord blood is 100–110 fL and in newborn pups is 95–100 fL. Rapid replacement of fetal erythrocytes after birth brings this value to adult levels by 2–3 months.[39,50] Some lines of toy and miniature poodles have an inherited macrocytosis with abnormal erythropoiesis.[7] These animals have RBC counts that are below standard canine RIs, but due to the large size of the RBCs (84.5–106.7 fL) and increased Hgb content, their Hct and Hgb are comparable to other breeds. Affected poodles may also have circulating nRBCs and a case of an apparently healthy poodle with a concurrent reticulocytosis was reported.[5,7] Greyhound dogs have also been reported to have a higher MCV and MCHC than other breeds.[58]

Japanese Akita and Shiba Inu breeds have microcytic RBCs (55–65 fL).[13,22] A subset of Akitas that display the high-potassium RBC phenotype have been shown to have increased MCV and lower MCHC than their low-potassium RBC phenotype counterparts, which are often microcytic and normochromic.[10] A study determining RIs for Bernese mountain dogs revealed a slightly higher MCHC compared to the reference canine population; however, this slight change is not likely of clinical significance.[41]

The RDW represents the size variability of individual erythrocytes analyzed. Numerically, it represents the coefficient of variation of RBC volumes and can be graphically represented on a histogram. Increases in RDW indicate increased anisocytosis and may be more sensitive than the MCV in detecting early changes in erythrocyte size.[40]

LEUKOCYTES

Normal leukocyte morphology from several different canid species are shown in Figure 108.2. Neutrophils are the most abundant leukocyte in the peripheral blood of normal dogs (Figure 108.3). The mature neutrophil has an elongated nucleus which contains several distinct lobes separated by constricted areas, which may appear as narrowing of the nuclear material or form thin nuclear filaments. The nucleus stains dark purple and has a clumped chromatin pattern consisting of many areas of densely staining heterochromatin. Cytoplasm is typically clear and may be slightly basophilic upon Diff-Quik stain (Mercedes Medical, 12210 Rangeland Pkwy, Lakewood Ranch, FL 34211). Neutrophil granules in the dog are typically indiscernible, but may be faintly eosinophilic. Low numbers of immature, or band-shaped, neutrophils may be present in normal animals and are defined by elongated nuclei with parallel sides that lack distinct lobation and discrete constrictions. The nuclear chromatin of a band cell is often less condensed and lighter staining than that of a mature cell. Cytoplasm is similar to that of mature neutrophils (see Chapter 42).

Lymphocytes in the peripheral blood vary in size, with small lymphocytes being most abundant (Figure 108.3). Small lymphocytes have densely staining nuclei that are approximately the same size as an RBC which range from round to oval to cleaved. Nuclear chromatin is densely clumped. Small lymphocytes have a scant amount of cytoplasm, which is pale blue and may form a thin rim or crescent. Intermediate-sized lymphocytes have nuclei that are approximately twice the size of an RBC and have more abundant, light blue cytoplasm.

Reactive lymphocytes can be seen in blood smears from dogs responding to physiologic (e.g., exposure or vaccination) or pathologic antigenic stimulation. Reactive lymphocytes may be larger and have increased amounts of basophilic cytoplasm (Figure 108.3). Rarely, reactive B lymphocytes may appear plasmacytoid, with an eccentric nucleus and a perinuclear clear (Golgi) area. Large lymphocytes in peripheral blood may approach the size of neutrophils. Occasionally, lymphocytes will contain several small pink-purple cytoplasmic granules and are referred to as large granular lymphocytes (Figure 108.3). These granules may be confined to a small cluster near one side of the nucleus.

Monocytes are larger than neutrophils. Monocyte nuclei are extremely variable and may be round, multilobated, band-shaped, or S-shaped (Figure 108.3). Those that are band-shaped are generally wider and may have rounded, knob-shaped ends that differentiate them from band neutrophils. The nuclear chromatin is less condensed than that of a mature neutrophil. Their cytoplasm is moderate to abundant and gray-blue to deeply basophilic. Canine monocytes may have variable numbers of clear, distinct-walled cytoplasmic vacuoles. Occasionally, faint, dust-like azurophilic granules can be seen evenly spread throughout the blue cytoplasm (see Chapters 48 and 49).

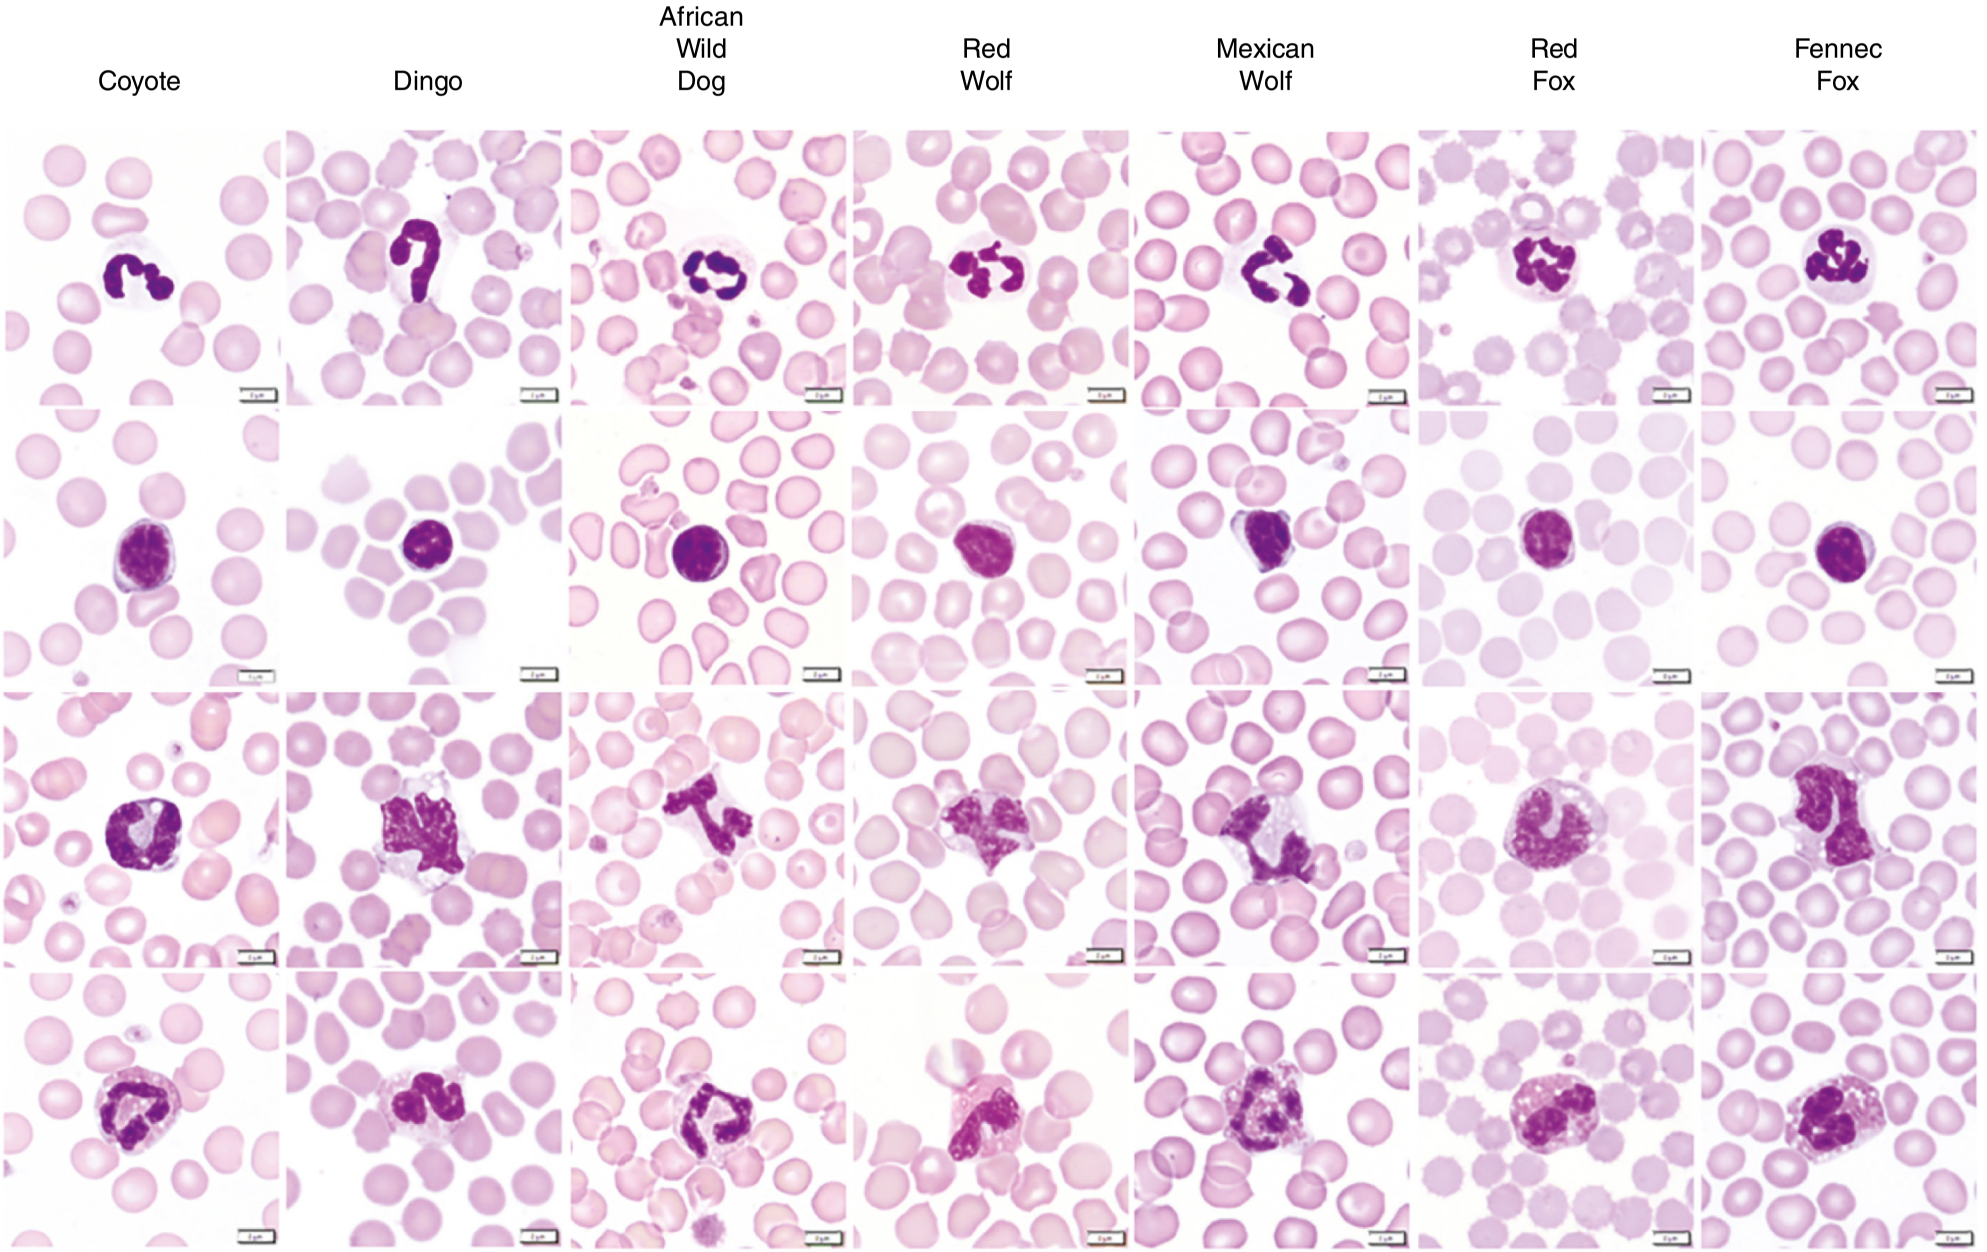

FIGURE 108.2 Leukocytes from seven species of nondomestic canids: coyote (*Canis latrans*), dingo (*Canis lupus dingo*), African wild dog (*Lycaon pictus*), red wolf (*Canis rufus*), Mexican wolf (*Canis lupus baileyi*), red fox (*Vulpes vulpes*), fennec fox (*Vulpes zerda*). Neutrophil, lymphocyte, monocyte, and eosinophil morphology (organized by row) is similar to that of domestic dogs. (Wrights and Diff Quik stains were used. Photo credit: Jennifer D'Agostino, Oklahoma City Zoo and Kari Velguth, Idexx Laboratories.)

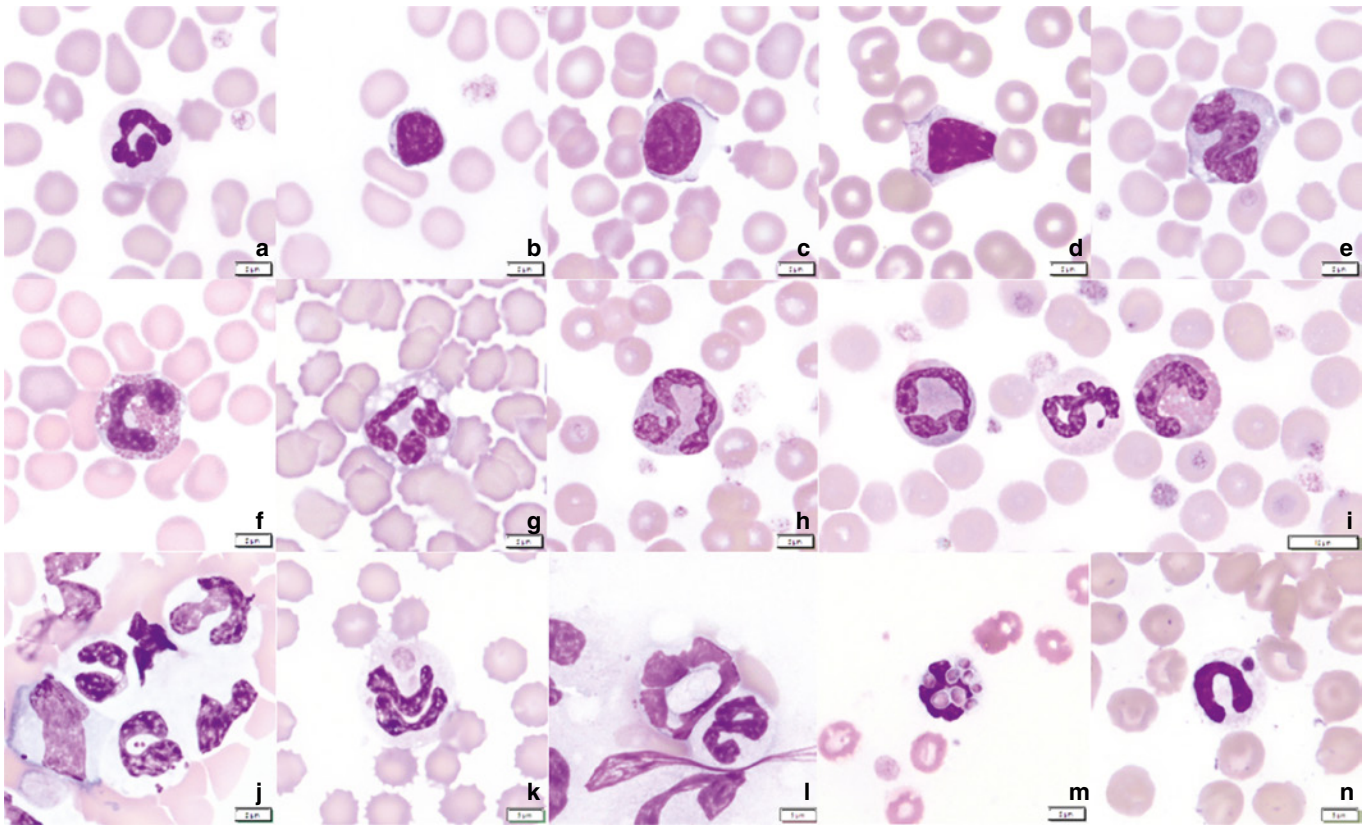

FIGURE 108.3 Canine leukocytes and infectious agents. Wright–Giemsa stain. (a) A mature segmented neutrophil with a segmented nucleus and mature chromatin; (b) A small lymphocyte with mature condensed chromatin and a scant rim of cytoplasm; (c) A reactive lymphocyte with an increased volume of cytoplasm; (d) A large granular lymphocyte with an increased volume of cytoplasm containing magenta-staining granules; (e) A monocyte with a S-shaped nucleus and basophilic cytoplasm containing several small vacuoles; (f) An eosinophil with round eosinophilic and clear cytoplasmic granules; (g) A gray eosinophil from a Greyhound dog with basophilic to gray cytoplasm and many clear vacuoles; (h) A single basophil with a segmented nucleus and pale purple-staining cytoplasmic granules; (i) All three canine granulocytes are seen side by side. From left to right: basophil, neutrophil, eosinophil; (j) Intracellular cocci are seen in a neutrophil from a dog with septicemia; (k) Three light magenta-staining amorphous canine distemper viral inclusions are seen within a neutrophil; (l) A single Hepatozoon gamont is seen as a poorly staining ovoid structure within a neutrophil; (m) Several *Histoplasma capsulatum* yeast organisms are phagocytized in neutrophilic cytoplasm; (n) A single Ehrlichia morulae within a neutrophil's cytoplasm.

Eosinophils can usually be found in low numbers on blood smears from healthy dogs. Eosinophils are slightly larger than neutrophils with the characteristic feature of prominent, round, eosinophilic granules. Eosinophil nuclei are less lobated than those of neutrophils, usually having only two or three lobes (Figure 108.3). In dogs, the number and size of the cytoplasmic granules are variable. Occasionally, an eosinophil may contain only one or two large granules, which could be mistaken for an inclusion body or parasite. Cytoplasm between the granules is lightly basophilic and may contain a few clear, nonstaining granules. Eosinophils of some adult greyhounds, Italian greyhounds, and whippets are unique in that they contain numerous clear granules and often lack distinct eosinophilic granules (Figure 108.3).[19] These "gray eosinophils" are fully functional with no ultrastructural or cytochemical differences when compared with normal eosinophils[28] (see Chapter 46).

Basophils are rare in blood smears from normal dogs and are not pictured in Figure 108.2. Basophils are larger than neutrophils and have a more elongated, convoluted nucleus. Cytoplasm is blue-gray to slightly purple. Compared to other species, canine basophils contain only scattered, small, purple to pink-purple cytoplasmic granules which may be difficult to discern on certain stains (Figure 108.3) (see Chapter 47).

Partitioning Factors

Physiologic leukopenia has been reported in healthy adult North American Belgian Tervuren dogs.[23] No difference in WBC values was found between Belgian Tervuren dogs and other dogs in a more recent study.[20] Study differences in North American Belgian Tervuren and Belgian Tervuren dogs were thought to reflect genetic or environmental factors.[20] Greyhounds, in addition to their varied RBC characteristics, have been

documented to have lower total WBC and neutrophil counts than the general dog population and breed-specific RIs should be used to interpret these values.[58] Bernese mountain dogs have been reported to have a higher upper reference limit for absolute eosinophil counts than the general dog population.[41]

There may be some mild age-associated change in WBC values. Fluctuations in total WBC and neutrophil counts have been noted in beagles during the first 2 months of life; however, with a few exceptions, values generally remained within the RI.[46] In one study, newborn animals (0–3 days) had band neutrophil counts that were slightly outside the adult RI, indicating a left shift. Occasional metamyelocytes were seen during this period without other evidence of disease. Band neutrophils decreased to within RIs by 7–10 days of life.[50] Lymphocyte counts are significantly higher in young dogs while they are establishing their immune system. Dogs <6 months of age typically have lymphocyte counts of at least 2000/μL, with some as high as 10,000/μL.[50]

After maturity, there are minor changes reported in hematologic values. Some studies have found no significant trends in WBC counts in dogs from 1.5 to 14 years of age.[14,35] More recently, senior and geriatric dogs were reported to have lower lymphocyte concentrations than adult dogs; however, absolute lymphocyte counts remained within the RI.[44] Senior and geriatric beagles and Labrador retrievers have a lower RI for absolute neutrophil counts, though geriatric beagles have a higher upper reference limit than the general dog population in one study due to unknown factors.[2]

Reported diurnal and seasonal variations in WBC counts are relatively minor and do not exceed the standard RIs.[34,54] In some geographic areas, dogs may have higher eosinophil counts in certain seasons due to environmental allergens and parasite load.

During pregnancy, total WBC counts may increase to levels that are slightly above RIs (approximately 19,000/μL) near parturition. White blood cell counts decrease during lactation and may not return to baseline values until the pups are weaned.[1] Dogs in diestrus had eosinophil counts 45% higher than dogs in other stages of the estrus cycle (absolute eosinophil count 0.3 vs. 0.2 × 10^3/μL).[57]

Obesity influences total WBC counts with overweight and obese dogs (body condition score ≥7) having a higher total WBC concentration due to higher neutrophil counts than normal control dogs; however, these counts remained within the RI.[45]

PLATELETS

Canine platelets are small, oval to round, anuclear structures on blood smears that are typically one-fourth to one-half the size of an RBC, though some platelets are larger than a RBC (Figure 108.1g,h). They have clear to light-gray cytoplasm and numerous small pink to purple granules. The granules may be dispersed throughout the platelet or aggregated into a central cluster. Occasionally, platelets become partially activated and have a spider-like appearance with cytoplasmic pseudopodia (Figure 108.1i). Activated platelets may form small clumps or a large, agglutinated mass. Platelet clumps are often found at the feathered edge of a smear (Figure 108.1j).

Reference intervals will vary between laboratories and analyzers. A RI determined utilizing the Sysmex XT-2000iV (Sysmex America, Inc., Lincolnshire, IL, USA) was reported to be 108,000–562,000 platelets/μL.[3] Lower platelet counts have been noted in healthy greyhounds (117,000–309,000/μL.[58]

Asymptomatic, inherited thrombocytopenia with enlarged platelets (macrothrombocytopenia) is common in cavalier King Charles spaniels and has also been documented in Norfolk and cairn terriers as well as Akita dogs.[18,26,43] In cavalier King Charles spaniels, Norfolk terriers, and cairn terriers, the condition is associated with a mutation in the β1-tubulin gene, although the exact mutation is different in cavaliers versus the terrier breeds.[11,18] The median platelet count from 105 cavalier King Charles spaniels was 92 × 10^3/μL (25–394 × 10^3/μL) with 56% of the spaniels having platelet counts <100 × 10^3/μL.[43] Affected Akita dogs present with macrothrombocytopenia and often display elongated platelets.[26] The cause of the macrothrombocytopenia in Akita dogs has yet to be elucidated. The few cases to date do not have a mutated β1-tubulin gene.[26] Analyzers that assess plateletcrit rather than impedance-based or optical-based particle counting have shown the total platelet mass in affected animals to be normal and provide clinically useful information when interpreting overall platelet density in these patients.[30,56]

Reference intervals established for dogues de Bordeaux reveal a higher mean platelet volume (MCV), but lower overall platelet counts when compared to the general dog population.[33]

REFERENCE INTERVALS

Table 108.1 provides published RIs for hematologic values of adult, male and female dogs generated in accordance with ASVCP guidelines. Reference intervals are designed to include values found in 95% of normal animals and will vary according to analyzer, population, and the definition of normal using partitioning factors. Many published RIs for canine hematologic values are derived from research animals and represent a single breed raised under controlled, confinement conditions. Such intervals may be narrower than would be applicable to a general patient population in which breed, age, and environmental variables are present. Alternatively, RIs that are derived from shelter dogs or clinically healthy animals brought to a veterinary clinic may be inappropriately wide because of subclinical disease, nutritional status, and physiologic or environmental influences (e.g., short-term alterations in WBC numbers due to an epinephrine- or corticosteroid-induced response in dogs that are not conditioned to blood collection) (see Chapter 140).

TABLE 108.1 Hematologic reference intervals for normal, adult, male and female dogs.

	Units	Reference intervals[a] for laboratory beagles (Advia 2120)	Reference intervals[b] from a blood donor database (Sysmex XT-2000iV)
RBC count	$\times 10^{12}$/L	6–8.3	5.9–8.4
Hgb	g/dL	14.4–19.4	14.2–20
Hematocrit	%	39–54	43–60
MCV	fL	62–71	65–79
MCH	pg	21.5–25.1	22.0–25.9
MCHC	g/dL	33–37	30.8–35.5
RDW	%	11.3–14.5	12.9–18.3
Reticulocytes	$\times 10^{9}$/L	Not reported	20–151
Leukocytes	$\times 10^{9}$/L	6–14.3	5.9–14.5
Neutrophils	$\times 10^{9}$/L	3.4–9.5	3.1–9.4
Lymphocytes	$\times 10^{9}$/L	1.5–4	1.5–4.7
Monocytes	$\times 10^{9}$/L	0.2–0.9	0.1–0.7
Eosinophils	$\times 10^{9}$/L	0.1–1.1	0.2–1.4
Basophils	$\times 10^{9}$/L	0.01–0.08	Not reported
Platelet count	$\times 10^{9}$/L	220–480	102–282
MPV	fL	Not reported	9.8–14
Plateletcrit[c]	%	0.13–0.40[c]	0.14–0.38

BONE MARROW

Bone marrow collection and canine hematopoietic cell morphology have been reviewed[25] (see Chapters 3 and 141).

Nucleated erythroid precursors recognizable in marrow aspirates include rubriblasts, prorubricytes, rubricytes, and metarubricytes. As cells mature, they become smaller, undergo nuclear condensation, and the color of the cytoplasm changes from deeply basophilic to red-orange (Figure 108.4a,b). Rubriblasts, normally present in low numbers, are large with a high N:C ratio. The nucleus is round with fine chromatin and one or more visible nucleoli (Figure 108.4a,b). The moderate amount of cytoplasm is deeply basophilic and is found in a concentric ring around the nucleus. Prorubricytes are slightly smaller with a lower N:C ratio. Prorubricyte nuclei lack visible nucleoli and have coarser chromatin that rubriblasts. The cytoplasm remains intensely basophilic. Rubricytes, while still potentially capable of mitotic activity, are significantly smaller with a lower N:C ratio. The nucleus has coarse chromatin and nucleoli are not visible (Figure 108.4b). Rubricyte cytoplasm matures from deeply basophilic (basophilic rubricyte) to polychromatophilic (polychromatophilic rubricyte) to orange (orthochromatic rubricyte), representing progressive production of Hgb. Metarubricytes are the smallest nucleated erythroid precursors, are characterized by a pyknotic nucleus that lacks a discernible chromatin pattern, and cannot replicate (Figure 108.4b). Progressive maturation results in polychromatophilic erythrocytes (reticulocytes), non-nucleated cells found in low numbers in the peripheral blood.

The granulocytic series exhibits a similar progression of relatively low numbers of early precursors to more numerous maturing cells (see Chapter 41). The recognizable stages of granulocytic maturation in the marrow are myeloblasts, promyelocytes (progranulocytes), myelocytes, metamyelocytes, band cells, and mature granulocytes. Myeloblasts are large cells with a high N:C ratio, fine chromatin, and one or more visible nucleoli. Compared to rubriblasts, the myeloblast exhibits more nuclear pleomorphism and has a lighter-staining blue cytoplasm. Promyelocytes are slightly larger than myeloblasts, but have a lower N:C ratio due to cytoplasmic enlargement. Nuclear chromatin is somewhat coarser and nucleoli may or may not be present. Numerous fine, azurophilic, cytoplasmic granules (primary granules) identify the promyelocyte's granulocytic origin (Figure 108.4c). Myelocytes are smaller than promyelocytes and are characterized by loss of visible primary granules. Round to oval nuclei have dense chromatin and no visible nucleoli. The cytoplasm becomes progressively lighter blue to clear and secondary granules may be present, identifying the cells as neutrophils, eosinophils, or basophils (Figure 108.4e,f). Secondary granules in neutrophilic cells are clear and indistinct. Metamyelocytes are characterized by the nuclear indentation resulting in a kidney bean or reniform shape. Cytoplasm is clear, with prominent secondary granules identifying the granulocytic precursor. The band cell has a rod- or sausage-shaped nucleus with parallel sides and no indentations or constrictions. The final stage is the mature granulocyte, characterized by nuclear constrictions giving rise to the classic polylobated appearance. Cytoplasm remains clear in neutrophilic precursors and has well-formed granules in the eosinophilic and basophilic cells.

Promegakaryocytes and megakaryocytes are typically identified on low magnification, as most are substantially larger than the other hematopoietic precursors. Megakaryoblasts are present in low numbers and have a high N:C ratio, single nucleus, and deeply basophilic cytoplasm. It is difficult to reliably differentiate them from progenitors of other cell lines. Promegakaryocytes are more easily identified. Endomitotic reduplication results in a large cell with two to four nuclei. These may appear to be separate, but are connected by nuclear strands. Promegakaryocytes have more abundant, deeply basophilic cytoplasm than the megakaryoblast. Further maturation with progressive reduplication of the nucleus gives rise to variably sized megakaryocytes that have a polylobated nuclear mass. As megakaryocytes mature, the cytoplasm becomes more abundant and changes from deeply basophilic to eosinophilic and granular, having an appearance similar to platelets in peripheral blood (Figure 108.4f) (see Chapter 75).

The monocytic series comprises a small percentage of cells in normal marrow. Mature monocytes/macrophages

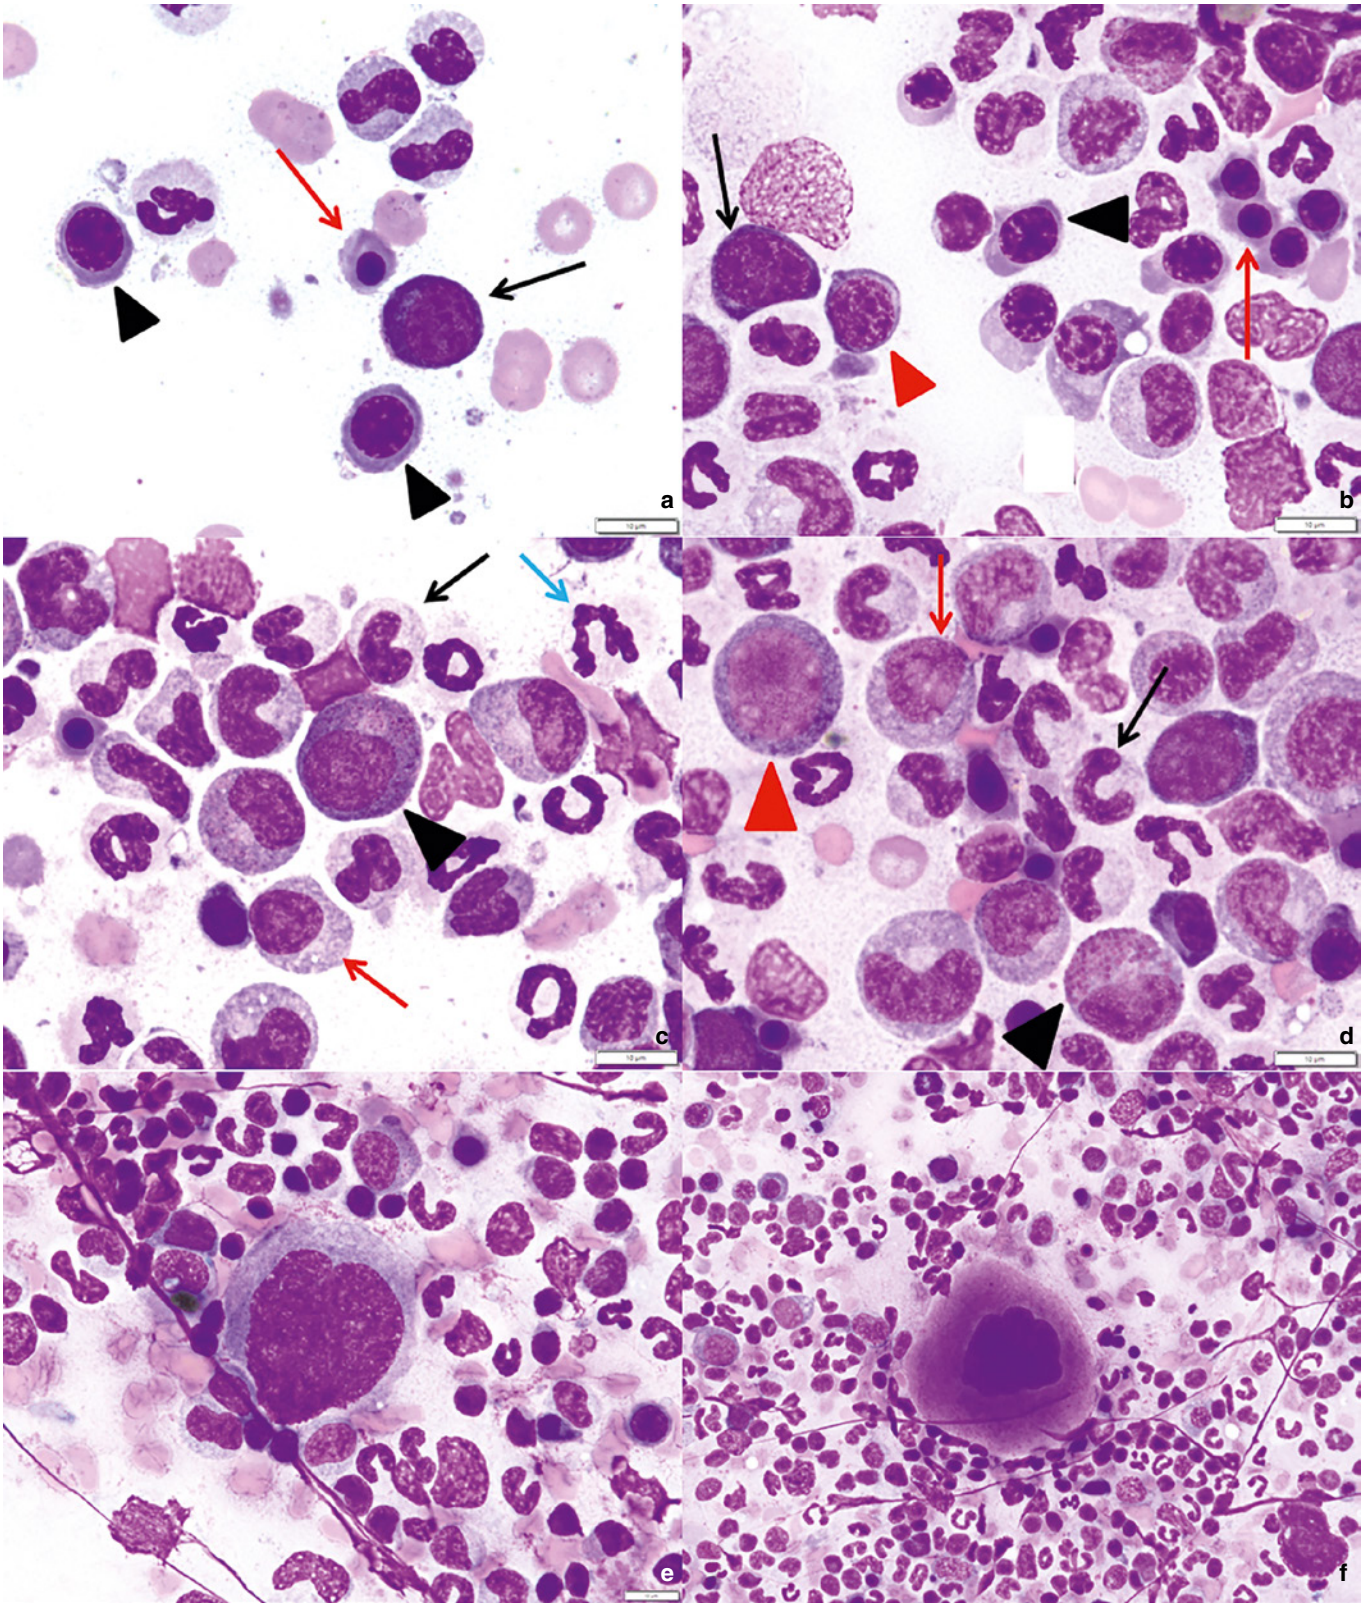

FIGURE 108.4 Morphology of canine bone marrow. Wright–Giemsa stain. (a) Several erythroid precursors including a rubriblast with a round nucleus, nucleoli, and deeply basophilic cytoplasm (black arrow), two rubricytes which are smaller with more condensed chromatin (black arrowheads), and one metarubricyte that is even smaller with a pyknotic nucleus and maturing, lightly polychromatophilic cytoplasm (red arrow); (b) Several RBC precursors including a rubriblast (black arrow), a prorubricyte which is smaller and has no nucleoli (red arrowhead), rubricytes (black arrowhead), and metarubricytes (red arrow); (c) Several myeloid precursors including a progranulocyte with magenta-staining primary granules (black arrowhead), a myelocyte which is smaller with a round nucleus (red arrow), a metamyelocyte with a slightly pinched nucleus (black arrow), and several segmented neutrophils (blue arrow); (d) Several myeloid precursors including a myeloblast with nucleoli and basophilic cytoplasm (red arrowhead), myelocytes (red arrow), an eosinophilic myelocyte with eosinophilic secondary granules (black arrowhead), and a band neutrophil (black arrow); (e) A large immature megakaryocyte with blue cytoplasm and a high N:C ratio; (f) A mature megakaryocyte with abundant purple, granular cytoplasm.

TABLE 108.2 Differential cell counts from bone marrow aspirates from 57 normal dogs.

Cell type		Mean ± SD (%)
Myeloid series		
	Myeloblasts and Promyelocytes	2.3 ± 1.28
	Myelocytes	2.1 ± 0.96
	Metamyelocytes	7.1 ± 3.16
	Neutrophils (bands and segmented)	32.5 ± 8.71
	Eosinophils (bands and segmented)	2 ± 1.32
Total myeloid series		45.3 ± 9.91
Erythroid series		
	Rubriblasts	0.7 ± 0.84
	Prorubricytes	2.1 ± 1.28
	Rubricytes	19.9 ± 5.87
	Metarubricytes	22.3 ± 8
Total erythroid series		46 ± 10.41
Myleoid:Erythroid ratio		1 ± 0.49
Other cells		
	Lymphocytes	6.3 ± 4.08
	Plasma cells	0.6 ± 1.13
	Macrophages/ Monocytes	0.7 ± 1.36

Source: Based on Turinelli et al.[55]

resemble those in peripheral blood. Monoblasts and promonocytes are difficult to clearly differentiate from granulocytic precursors. Their nuclear shape is more irregular and they lack the primary granules seen in promyelocytes (see Chapter 48).Mature lymphocytes may be present in moderate numbers and low numbers of plasma cells can be seen admixed among the hematopoietic precursors. Occasionally osteoclasts, osteoblasts, and stromal cells can be seen.

The relative proportion of hematopoietic cells found in bone marrow samples from normal dogs is given in Table 108.2.[55] The M:E ratio is reported as being between 0.7:1 and 2.5:1 (see Chapter 141). Mild variation in the M:E ratio may be found in samples from different anatomic locations.[12] Samples obtained from the iliac crest had a slightly higher M:E ratio than humeral samples collected in the same dog.[17] Repeated sampling of bone marrow at weekly intervals from the same anatomic location seemed to have little effect on differential cell counts.[37] However, repeated sampling within the same day may result in artifactually hypocellular samples. Neonatal dogs have a significantly increased lymphocyte percentage in bone marrow samples compared to adults.[15] Mean lymphocyte percentages peaked at 54% by 21 days of age, decreasing to 17% by 56 days of age in this older study. Bone marrow samples from normal adult dogs generally have less than 10% lymphocytes.

HEMATOLOGIC DISEASE

Changes in the Erythron

Anemia can be classified as regenerative or nonregenerative based on evaluation of polychromasia on a blood film or reticulocyte enumeration (see Chapter 25). Nonregenerative anemias are generally caused by decreased bone marrow erythropoiesis. Differential diagnoses for persistent nonregenerative anemia include inflammation, chronic disease, chronic renal disease, iron deficiency, or inherent bone marrow disease including immune-mediated disease, infectious disease, neoplasia, myelotoxicity, or myelophthisis (see Chapters 27, 33–35, 38–40, and 65–67).

Regenerative anemias in the dog are caused by either hemorrhage or hemolysis. These mechanisms lead to bone marrow stimulation and increased erythropoiesis, releasing immature erythroid stages into circulation which can be detected as polychromasia and reticulocytosis. Nucleated RBCs may also be released and quantified. Hemolytic anemia may be induced by a variety of etiologies including immune-mediated destruction (primary or secondary immune-mediated hemolytic anemia), erythrocytic parasites, oxidative damage, hereditary enzyme defects, metabolic derangements (e.g., hypoosmolality and hypophosphatemia), and diseases leading to intravascular RBC trauma (e.g., heartworm disease) (see Chapters 29, 30, and 32–35).

Changes in the Leukon

Three major leukogram patterns exist in the canine; physiologic, stress, and inflammatory (see Section IV). A physiologic leukogram is mediated by epinephrine (released during strenuous exercise, fear, or marked excitement) and induces leukocytosis, mild mature neutrophilia, and lymphocytosis. Epinephrine causes demargination of neutrophils, shifting them from the marginal to the circulating pool, resulting in neutrophilia. Lymphocytosis is due to a blockade preventing lymphocytes from entering lymph nodes and mobilization of lymphocytes from the thoracic duct. Monocyte and eosinophil counts may increase slightly. This response is more common in puppies than in adult dogs. When it does occur, the effects are immediate and transient with values returning to baseline within 30 minutes.[29,32]

A stress leukogram is caused by endogenous or exogenous corticosteroids, released during physiologic stress/illness, pain response, hyperadrenocorticism, or administered as therapy. Leukocytosis, mature neutrophilia, lymphopenia, monocytosis, and eosinopenia are induced in the dog. This effect is seen within 4–8 hours and resolution may occur 24 hours to several days after the event, depending on the duration of corticosteroid exposure. Corticosteroids cause demargination of

circulating neutrophils, release of storage pool neutrophils from the bone marrow, and decreased emigration of neutrophils to tissues leading to neutrophilia. Lymphopenia is due to redistribution of circulating lymphocytes and long-term steroid use can lead to lympholysis. Monocytosis is due to mobilization of marginated monocytes. Eosinopenia results from eosinophil sequestration in tissues and decreased release from the bone marrow.[29,32]

Inflammatory leukograms are caused by increased proinflammatory cytokine production due to stimuli, such as infectious or immune-mediated disease, tissue trauma/necrosis, or neoplasia (see Chapters 17–18). The time at which the blood is examined in relation to the onset of the inflammatory stimulus will affect interpretation. With peracute, overwhelming inflammation, as is seen with endotoxemia or sepsis, neutropenia will develop within 1–3 hours due to neutrophil margination, shortened neutrophil half-life, and increased neutrophil emigration to tissues. Acute inflammation (6–8 hours later) is characterized by neutrophilia with or without a left shift due to release of storage pool neutrophils (segmented and band neutrophils) from the bone marrow. Toxic changes may be present. A concurrent stress response is common causing lymphopenia and monocytosis in the dog. Chronic inflammation (days to weeks later) is characterized by a neutrophilia, often without a left shift, as the granulopoiesis has increased and there are adequate mature neutrophils produced and released to compensate utilization and sequestration. Within the bone marrow, there should be expansion of the proliferative, mature, and storage pools in chronic inflammation[29,32] (see Chapters 45 and 49–51).

With certain inflammatory conditions, there can be a severe neutrophilia (>50,000 WBC/μL), termed a leukemoid response, as this degree of neutrophilia mimics chronic granulocytic leukemias. The neutrophilia can be mature, but often there is an orderly left shift that may extend to myelocytes or promyelocytes. Toxic change may be present. Etiologies include localized pyogenic infections (pyometra, peritonitis, internal abscess), immune-mediated disease (immune-mediated hemolytic anemia), *Hepatozoon canis* infection, leukocyte adhesion deficiency, pancreatitis, bile peritonitis, and paraneoplastic reactions (renal tubular carcinoma, metastatic fibrosarcoma, metastatic pulmonary carcinoma, and rectal adenomatous polyp).[31,8,52,51,59]

Mechanisms of neutrophilia include neutrophil pool redistribution (e.g., physiologic or stress leukograms) or increased production (e.g., inflammation). Inflammation is one of the most frequent causes of neutrophilia. Other causes include physiologic or stress responses, hemolysis, hemorrhage, immune-mediated disease, and leukocyte adhesion deficiency. Mechanisms of neutropenia include redistribution from the circulating to marginating pool (e.g., endotoxemia, anaphylaxis), increased utilization or destruction in peripheral tissues (e.g., acute, severe inflammation often due to pyogenic infections, or immune-mediated destruction), or decreased production by the bone marrow. Decreased bone marrow production of neutrophils may be due to irradiation and chemotherapeutics, estrogen toxicity (endogenous or exogenous), parvoviral infection, idiosyncratic drug reactions, chronic ehrlichiosis, myelophthisis (myelonecrosis, myelofibrosis, osteopetrosis, neoplasia), and cyclic hematopoiesis of gray collies[29] (see Chapters 15–18 and 44).

Hypersegmented neutrophils have nuclei with more than five nuclear lobes. Hypersegmentation is often an aging change associated with prolonged neutrophil transit in the peripheral blood due to endogenous or exogenous corticosteroids. Hypersegmentation may also be caused by inherited (e.g., Poodles with congenital macrocytosis) and neoplastic (e.g., myelodysplastic syndrome and granulocytic leukemia) etiologies (see Chapters 65, 67, and 68).

Neutrophil hyposegmentation is often due to inflammatory left shift. Pelger–Huët anomaly, caused by a defect in the lamin B receptor gene, is a benign condition characterized by granulocyte hyposegmentation where neutrophils, eosinophils, and basophils have a band to peanut-shaped nucleus. Eosinophils can be used to identify the anomaly, if banded neutrophils due inflammation are present in the sample. The neutrophils have mature condensed chromatin and normal function. It has been identified in several breeds of dogs[29] (see Chapters 44 and 146).

Toxic changes in canine neutrophil cytoplasm include basophilia, Döhle bodies, vacuolation, toxic granulation, and gigantism. These are associated with proinflammatory cytokines, exposure to infectious agents, and maturational defects secondary to increased granulopoiesis.

Mild lymphocytosis may occur as part of the physiologic, adrenaline-induced leukogram or elicited by antigen during vaccinal response. Differential diagnoses include persistent antigenic stimulation in chronic inflammatory and infectious disease, especially viral and autoimmune disease, as well as lymphoid neoplasia. If the neoplastic population is composed of small mature lymphocytes (chronic lymphocytic leukemia or small cell lymphoma), further diagnostics, including flow cytometry or PCR for antigen receptor rearrangement (PARR), may be required to distinguish neoplastic from non-neoplastic lymphocytosis (see Chapters 56 and 65).

Lymphopenia is most commonly caused by glucocorticoids. Differential diagnoses include viral infections such as canine distemper and parvovirus, which lead to lymphocyte depletion and destruction, loss of lymph-rich fluid (protein-losing enteropathy, granulomatous enteritis, lymphangiectasia, chylothorax), and, rarely, congenital deficiencies of lymphocytes can occur (see Chapters 18, 55, and 146).

Monocytosis is most often either steroid-induced and/or induced by proinflammatory cytokines. Monocytopenia is not of clinical significance, as canine monocyte RIs approach zero (see Chapters 48 and 49).

The most common cause of eosinophilia in dogs is parasitism with a more pronounced response occurring with migrating endoparasites and heartworm. Differential diagnoses for eosinophilia include hypersensitivity,

fungal/algal disease, paraneoplastic disease (T-cell carcinoma, mast cell tumor), or primary neoplasia (eosinophilic leukemia, hypereosinophilic disease). Eosinopenia is not typically of clinical significance as clinically normal dogs can have eosinophil counts of 0/μL. However, when eosinophils approach zero, Addison's disease should be considered if clinical signs are supportive (see Chapter 46).

Basophilia is caused by similar mechanisms as eosinophilia including endoparasitism/ectoparasitism, hypersensitivity, paraneoplastic responses, and primary neoplasia, and the two are often found concurrently. Basophilic leukemia is rare, but has been reported. Basopenia is not of clinical significance as many clinically normal dogs have basophil counts of 0/μL (see Chapter 47).

Infectious Agents

Bacteria can occasionally be seen in neutrophil or monocyte cytoplasm indicating septicemia/bacteremia, typically resulting in degenerative changes (Figure 108.3j). Canine distemper virus is characterized by variably sized, amorphous, homogenous, magenta to basophilic cytoplasmic inclusions in both RBCs and WBCs (Figure 108.3k). These may be most easily visualized using Diff-Quik stain. *Hepatozoon canis* and *H. americanum* gametocytes are poorly staining to lightly basophilic and ovoid to rectangular in shape (Figure 108.3l). They can be present within neutrophils and monocytes, however, especially with *H. americanum*, the parasitemia can be low and organisms are often not identified. *Histoplasma capsulatum* can be identified within neutrophils and monocytes as a small, round to oval yeast with an eccentrically located crescent-shaped nucleus and a thin nonstaining capsule (Figure 108.3m). *Leishmania sp*. amastigotes present within neutrophils are small oval organisms with an oval nucleus and a rod-shaped, red kinetoplast (not pictured). Ehrlichia morulae can be present within neutrophil and monocyte cytoplasm. Species are morphologically indistinguishable requiring PCR for species identification (Figure 108.3n).

Acronyms and Abbreviations

ALL, acute lymphoid leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; CTAD, citrate theophylline adenosine dipyridamole; DAT, direct antiglobulin test; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; IMHA, immune-mediated hemolytic anemia; MDS, myelodysplastic syndrome; MPV, mean platelet volume; PARR, PCR for antigen receptor rearrangements; SD, standard deviation; URL, upper reference limit; 2,3-DPG, 2,3-diphosphoglycerate.

ERYTHRON

Normal Structure, Morphology, and Function

Feline RBCs are anucleate, biconcave, and discoid, similar to those from other domestic mammals. Compared to dogs, domestic cat (*Felis catus domesticus*) erythrocytes have a shorter circulating life span (66–72 days)[6], are smaller (5.5–6.5 μm diameter),[19,27] have less central pallor, more commonly display rouleaux,[27] and have different surface antigens (see Chapters 96 and 99).

Feline Hgb contains eight reactive sulfhydryl groups, while most other species have two to four.[13,12,43] Sulfhydryl groups are readily oxidized, making feline Hgb particularly susceptible to oxidant damage manifesting as Heinz body formation. As a result, low numbers of Heinz bodies (<5% of erythrocytes) can be seen in some healthy cats.[13,12,27] The nonsinusoidal feline spleen is inefficient at removing Heinz-body-laden RBCs from circulation, so anemia may not develop in all cases of RBC oxidation.[12,13]

Cats are unique in that two types of reticulocytes can be identified on blood smears stained with a supravital stain such as new methylene blue: aggregate reticulocytes and punctate reticulocytes. Aggregate reticulocytes form shortly after extrusion of the nucleus. They have large aggregates of precipitated rRNA when stained with new methylene blue and appear polychromatophilic (blue-purple) when stained with a Romanowsky stain (Figure 109.1). Amounts of rRNA diminish as an aggregate reticulocyte matures until it becomes a punctate reticulocyte with only a few small dots of precipitated rRNA on new methylene blue staining and no detectable polychromasia on Romanowsky staining.[27] Maturation of punctate reticulocytes to mature erythrocytes occurs more slowly in cats than in most other species. Because they persist longer in circulation, punctate reticulocytes do not reflect a current increase in erythropoiesis in the marrow. Therefore, only aggregate reticulocytes should be included in the reticulocyte count that is used to determine the current degree of regeneration in cats.[27]

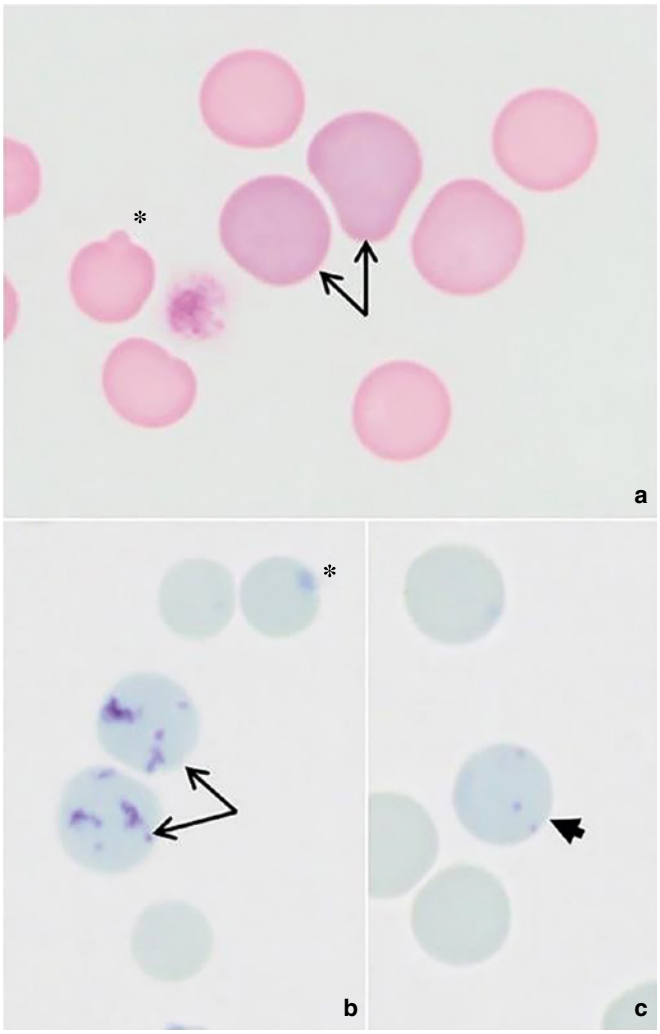

FIGURE 109.1 Reticulocytes and Heinz bodies from a cat with oxidant hemolytic anemia. (a) Polychromatophilic RBCs (arrows) and a pale pink Heinz body (*), Wright stain, 100× objective; (b) and (c) Aggregate reticulocytes with numerous large aggregates of dark blue precipitated rRNA (arrows), punctate reticulocyte with only a few very small dots of blue precipitated rRNA (arrow head), and an aqua blue Heinz body (*), new methylene blue stain, 100× objective.

Distinction of aggregate and punctate reticulocytes in cats is only relevant if reticulocytes are enumerated manually by evaluation of a blood smear stained with new methylene blue. The reticulocyte counts produced by automated hematology analyzers typically only include aggregate reticulocytes[27] (see Chapter 23).

Comparative Physiology

Mammalian Hgb oxygen affinity can be affected by multiple factors including the organic phosphate 2,3-diphosphoglycerate (2,3-DPG). In most mammals, the lower oxygen environment in non-lung tissue promotes reversible binding of 2,3-DPG to β-globin chains. This binding causes a conformational change that decreases oxygen affinity of Hgb, promoting oxygen delivery to tissues.[7] Cat RBCs, however, have low concentrations of 2,3-DPG, and β-chain structural differences cause their Hgb to have diminished responsiveness to 2,3-DPG. Instead, feline Hgb has intrinsically lower oxygen affinity than Hgb from other mammals, allowing adequate oxygen delivery to tissues without the requirement of 2,3-DPG.[7] It has not been established if this has any adaptive significance for cats (see Chapter 21).

LEUKON

The morphology and structure of feline leukocytes are similar to that of other domestic mammals. A compilation of segmented neutrophils, lymphocytes, monocytes, and eosinophils from domestic cats and from seven nondomestic felid species is provided (Figure 109.2). The microscopic appearance and cell size of neutrophils, lymphocytes, and monocytes are similar between domestic and nondomestic cats. Of note, healthy cats may sometimes have Döhle bodies within a few neutrophils or have neutrophil cytoplasm that is faintly blue rather than clear or light pink (Figure 109.2).[28] Therefore, the microscopist should take care in using these findings to define toxic change in cats.

Eosinophil morphology is similar between domestic cats and some nondomestic felids; however, the granules are larger and/or rounder in other species such as the lion, tiger, and leopard. Compared to other domestic species, feline basophil granules are often more elongated and lighter purple (Figure 109.3b,c). In some cases, the margins of the basophil granules can be somewhat indistinct, and the cells may resemble monocytes. On close inspection, though, the granules of the basophils are evident.

PLATELETS

As in other mammals, feline platelets are small anucleate granular cytoplasmic fragments of megakaryocytes. However, cat platelets are commonly larger and more variably sized than those from other domestic species (Figure 109.4). Platelets from dogs are typically 2–4 μm in diameter, with ≤5% of platelets larger than 4 μm. In contrast, cat platelets can be up to 6 μm or larger, with 10–25% of platelets being larger than 4 μm.[5] The β1-tubulin gene in Felidae has two sequence differences which may impact platelet microtubule assembly and contribute to larger and more variably sized feline platelets[5] (see Chapters 76 and 77).

There are important analytical and preanalytical considerations for automated platelet counts in cats. Because there is often overlap in size between feline erythrocytes and platelets, platelets counts obtained using impedance methodology may be inaccurate.[48,28] Additionally, platelet clumping is a frequent preanalytical problem in EDTA-anticoagulated blood samples from cats, and can lead to falsely decreased automated platelet counts.[28,48]

One study concluded that feline blood samples with marked platelet clumping (more than 10 large platelet

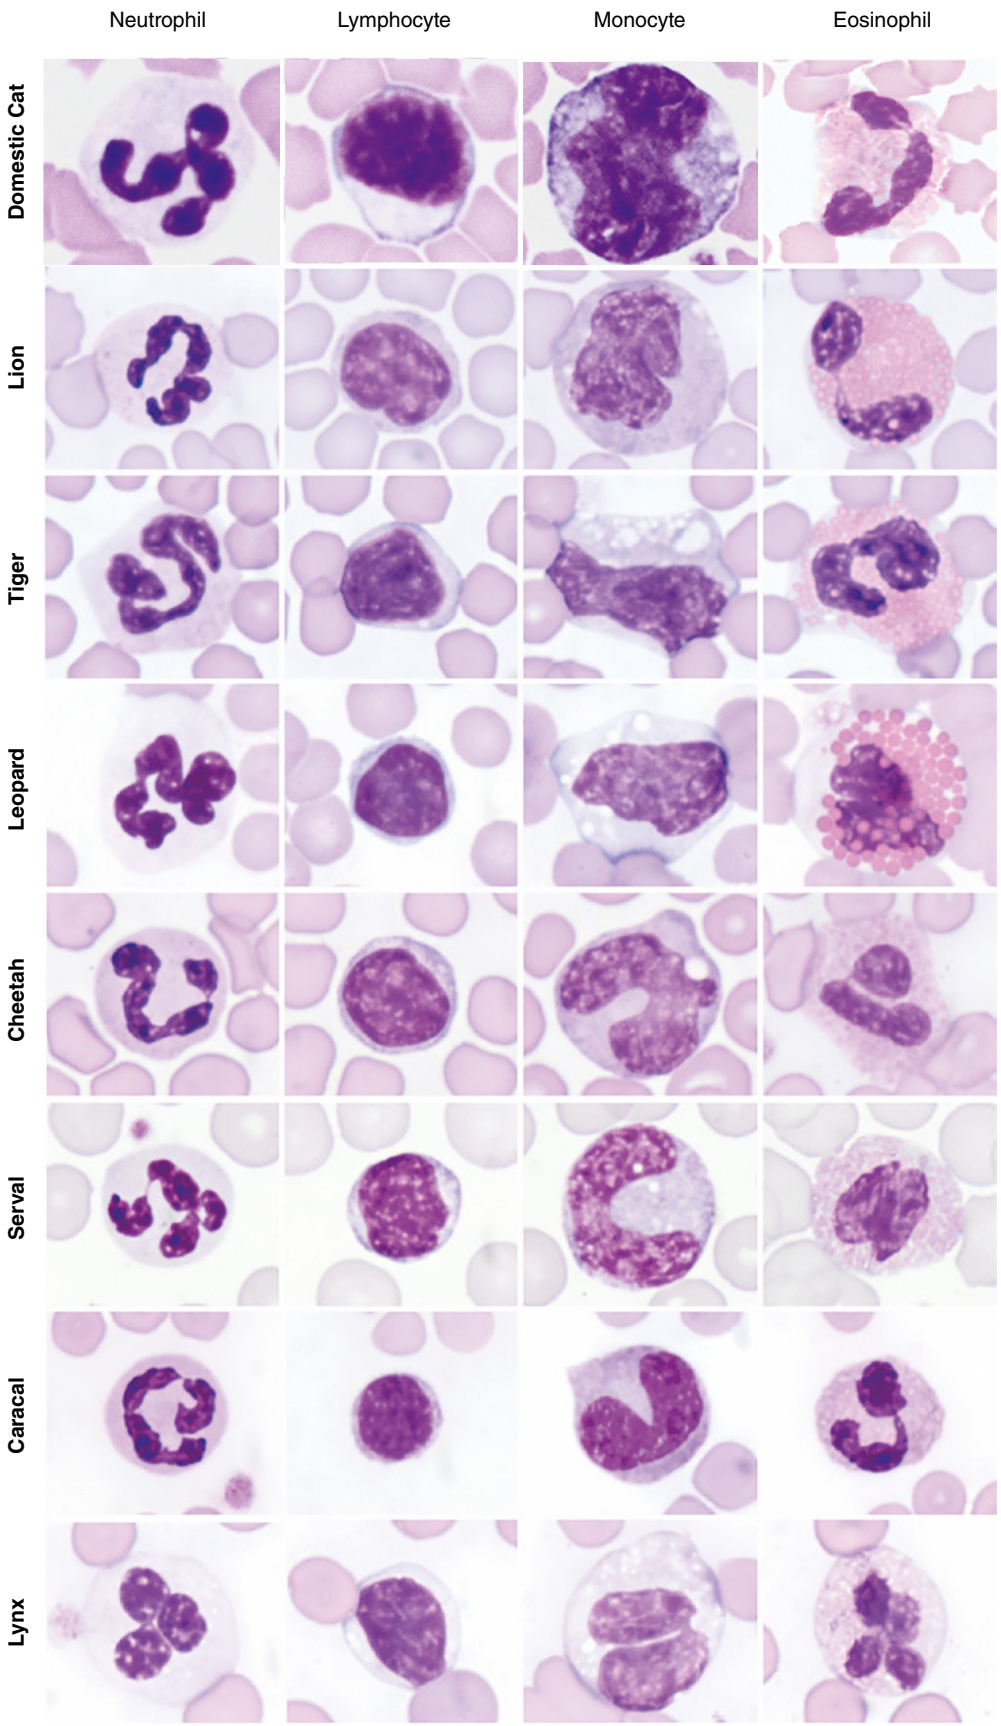

FIGURE 109.2 Leukocytes from selected feline species—the domestic cat (*Felis catus domesticus*) and from seven species of nondomestic felids: lion (*Panthera leo*), tiger (*Panthera tigris*), leopard (*Panthera pardis*), cheetah (*Acinonyx jubatus*), serval (*Leptailurus serval*), caracal (Caracal caracal), and lynx (*Lynx canadensis*). The leukocyte morphology for neutrophils, lymphocytes, and monocytes is similar between domestic and nondomestic cats. Eosinophil granules in some nondomestic felids in the Panthera genus, including lions, tigers, and leopards, are larger and/or more round than those from domestic cats. Wright stain, 100× objective.

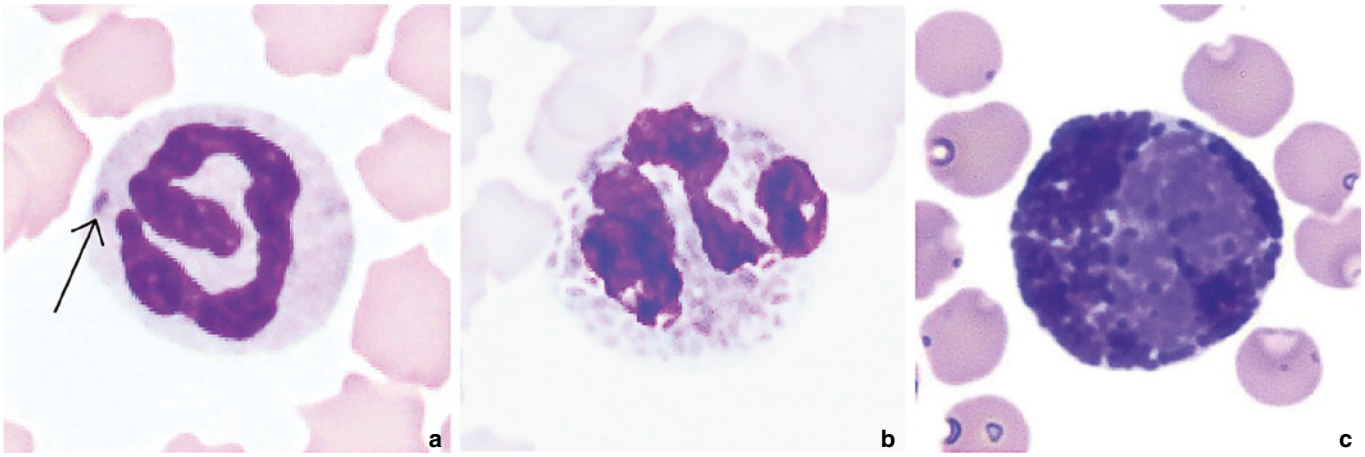

FIGURE 109.3 Neutrophil and basophil from domestic cat. (a) A segmented neutrophil from a healthy cat, which has a Döhle body (arrow) and faintly blue cytoplasm. Neutrophils from some healthy cats may have cytoplasmic features that mimic toxic change; (b) A basophil from a cat, with numerous lavender cytoplasmic granules; (c) A basophil from a horse, which by comparison has much darker purple cytoplasmic granules compared to the cat basophil. Wright stain, 100× objective.

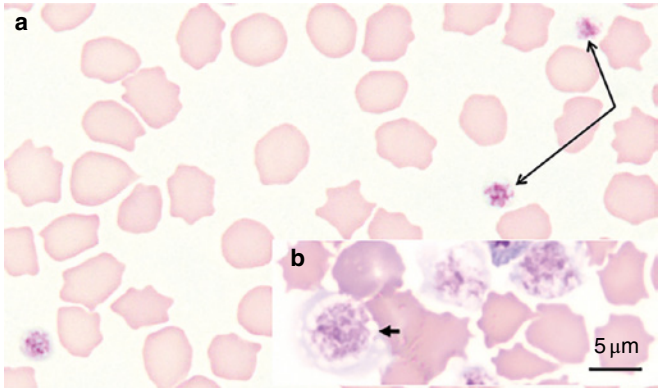

FIGURE 109.4 Feline platelets. (a) Smaller platelets, two of which are indicated by arrows; (b) Large platelets, one indicated by the arrowhead. Cats can commonly have large platelets, with 10–25% of platelets being larger than 4 µm in diameter.

aggregates at the feathered edge of the blood smear) are most likely to have artifactually decreased automated platelet counts.[48] In such cases, it is advisable not to report the automated platelet count, but rather include a comment on the CBC report that "platelets are clumped but appear adequate." If only small aggregates or if only a few large aggregates are noted at the feathered edge, then the error on the automated platelet count may not be significant.[48] The laboratory in such instances may choose to report the automated platelet count, but add a comment that "the automated platelet count may be falsely decreased due to clumping, but is a reasonable estimated minimum."

BLOOD AND BONE MARROW COLLECTION

Blood for hematologic evaluation from cats is commonly collected from a jugular, cephalic, or saphenous vein into a collection tube containing EDTA anticoagulant. Literature documenting differences in results due to differences in venous sites has been found in other species, but could not be found for felids. Collection tube additives such as prostaglandin E1, iloprost, or citrate theophylline adenosine dipyridamole (CTAD) may inhibit platelet aggregation and at least modestly reduce platelet clumping in feline blood samples, but at this time their use is largely restricted to research settings.[21,39,48]

The technique for marrow aspirate collection is similar in cats and dogs, and typical sites include the greater tubercle of the proximal humerus, iliac crest, or trochanteric fossa of the femur[8] (see Chapter 141).

REFERENCE INTERVALS

Hematology reference intervals (RIs) for adult cats using three modern hematology analyzers are provided in Table 109.1. Of note, the RI for reticulocytes was significantly lower on the ProCyte Dx than on the Sysmex XT-2000iV, even though these results were obtained using the same sample group.[21] Since these two analyzers use similar technology, the authors posit that the disparities may be due to differences in manufacturer calibration or software version. The reticulocyte RI established using the ADVIA 120 at the University of Georgia was also lower than that reported for the Sysmex XT-2000iV, but it is unclear if this is due to differences in analytic method or in the reference sample group. Older published studies of hematology results in healthy kittens were reviewed and found to have low sample sizes or use outdated methods.[1,16] These are not reported in this chapter.

BONE MARROW

Expected results from feline bone marrow aspirates are provided in Table 109.2. These values are adapted from multiple sources and should be used as guidelines only. Integrated interpretation of marrow findings should incorporate CBC results and clinical information from the patient.

TABLE 109.1 Hematology reference intervals for adult cats using whole blood collected into EDTA.

Reference	University of Georgia, CVM	Granat (2014)[21]	Granat (2014)[21]
Hematology analyzer	ADVIA 120	Sysmex XT-2000iV	ProCyte Dx
Sample size	120	81	81
Age range (years)	1–14	0.5–9.6	0.5–9.6
Statistical method	Nonparametric	Nonparametric	Nonparametric
Hematocrit (%)	33.6–49	29–51	30–54
RBC count (× 10^6/μL)	7.7–10.9	6.6–10.8 (O) 6.7–11.2 (I)	6.7–11.2
Hgb (g/dL)	11.3–16.2	9.9–16.6	9.4–16.1

RDW (%)	13.7–18.4	19.7–29.3	20.2–30.2
RDW (fL)	NR	24.9–40.6	NR
WBC count (× 10^3/μL)	4.8–15.3	4–15.2	4–15.2
Leukocyte differential method	Manual	Automated	Automated
Neutrophil (× 10^3/μL)	1.9–10	1.7–8.8	1.7–8.8
Lymphocyte (× 10^3/μL)	0.8–6.4	1.2–10.2	1.2–10.2
Monocyte (× 10^3/μL)	0–0.6	0.1–0.6	0.1–0.6
Eosinophil (× 10^3/μL)	0–1.5	0.1–1.2	0.1–1.2
Basophil (× 10^3/μL)	0–0.1	NR	NR
Platelet count (× 10^3/μL)	206–465	87–610 (O) 33–516 (I)	87–610
MPV (fL)	8.9–23.3	NR	NR
Reticulocyte count (× 10^3/μL)	6–52.9	19.1–107.1	3.8–48.6
MCVr (fL)	50.5–72.4	NR	NR
CHr (pg)	13.3–19.5	NR	NR

CHr, reticulocyte hemoglobin content; I, impedance measurement; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MCVr, mean cell volume of reticulocytes; MPV, mean platelet volume; NR, not reported; O, optical measurement; RDW, red cell distribution width.

TABLE 109.2 Proposed guidelines for bone marrow cytology in healthy cats, adapted from multiple references.[19,31,26,52]

Particle cellularity (nucleated cells:fat)	25–75%
Myeloid:erythroid ratio	1.2–2.2
Lymphocyte (%)	<10 (<20 possible)
Plasma cell (%)	<2
Macrophage (%)	<1
Stainable iron deposits	Absent

Sources: Gilmore et al.[19]; Jain[31]; Harvey[26]; Haddad et al.[23]

Marrow samples from healthy cats can have a higher percentage of lymphocytes compared to dog marrow. Small lymphocytes comprise <10% of marrow nucleated cells in most cats, but occasional healthy cats may have up to 20% lymphocytes. Histologically, the lymphocytes may sometimes have follicular or nodular arrangements, particularly in cats with non-neoplastic causes of marrow lymphocytosis such as immune-mediated and infectious diseases.[23,52] Also in contrast to dogs, marrow from cats normally lacks microscopically detectable iron deposits. Marrow iron stores are typically only visible in cats with hemolytic anemia, anemia of inflammatory disease, dyserythropoiesis, or after blood transfusions.[10,23,26,45]

INTERPRETATION OF THE ERYTHRON IN DISEASE

The mechanisms for anemia in cats are the same as in other species: decreased production, hemorrhage, or hemolysis. Anemia is categorized as regenerative or nonregenerative based on the absolute reticulocyte count (Table 109.3). The causative mechanism for regenerative anemia is hemorrhage or hemolysis.

Feline Hgb structure makes RBCs particularly susceptible to oxidant injury, leading to Heinz bodies (Figure 109.3) and possibly methemoglobinemia and/or eccentrocytes. Eccentrocytes and erythrocytes with Heinz bodies have reduced deformability, which

TABLE 109.3 Classifying the regenerative response in anemic cats using absolute reticulocyte counts.

Regeneration	Reticulocyte count (× $10^3/\mu L$)
Nonregenerative	Within or below RI
Weakly to moderately regenerative[a]	URL to 190 × $10^3/\mu L$
Strongly regenerative[a]	≥ 200 × $10^3/\mu L$

Source: [a]Adapted from Korman et al.[33]
RI = reference interval; URL = upper reference limit.

contribute to a shortened RBC life span of 20–60%[13] (see Chapter 32). In some cats, ghost cells can be identified that appear as the outline of a RBC membrane with a visible attached Heinz body.[13] Hgb oxidation may occur in cats exposed to various oxidizing compounds in drugs or food, including acetaminophen, onions, propylene glycol, topical benzocaine, phenazopyridine, phenylhydrazine, methionine, and propofol.[2,13,15,27,29,30,50] Not all oxidants cause overt acute hemolytic anemia in cats, but they may shorten RBC survival time and exacerbate anemia caused by concurrent disease.

Heinz bodies are commonly also identified in cats with certain diseases that promote oxidation, and may be termed endogenous Heinz bodies. Diseases that are associated with erythrocyte oxidation and endogenous Heinz bodies in cats include diabetes mellitus (particularly when there is ketoacidosis), lymphoma, hyperthyroidism, and inflammatory disease.[11,12,53] Cats with endogenous Heinz bodies due to disease typically have low-normal to decreased erythron mass. The average PCV in cats with endogenous Heinz bodies was 28% and 30% in two studies.[11,12]

Immune-mediated anemia occurs in cats, although less frequently than in dogs, and may be idiopathic or secondary to infectious or inflammatory diseases (e.g., feline leukemia virus (FeLV), hemotropic mycoplasma, pancreatitis, cholangitis), neoplasia (e.g., lymphoma, leukemia), or drugs (e.g., propylthiouracil, methimazole)[4,45] (see Chapter 36). There is a wide age range for affected cats, but the majority are young (<3–4 years old).[4,45] As opposed to dogs, where immune-mediated anemia is reported more often in females, sex predilection has not been well-established in cats. Initial reports suggested that the diagnosis is more common in male cats, but a larger retrospective study found no sex predilection.[4,45] In recent studies, the majority of affected cats are negative for FeLV and feline immunodeficiency virus (FIV).[4,45] Some cats may have concurrent neutropenia and/or thrombocytopenia, but it is unclear if these cytopenias are also caused by immune-mediated cell destruction.[4,45]

Spherocytes cannot be identified reliably on feline blood smears, since cat erythrocytes are smaller with less distinct central pallor than dog erythrocytes, making the diagnosis of immune-mediated hemolytic anemia (IMHA) more difficult.[27,45] Diagnosis in cats may be based on detection of RBC agglutination, ghost cells in the absence of Heinz bodies, and/or a positive direct antiglobulin test (DAT) test (direct Coombs test).[27,45]

Precursor-targeted immune-mediated anemia (PIMA) is also recognized in cats and is characterized by anemia that is persistently nonregenerative for at least 5 days and phagocytosis of erythroid precursors in marrow.[4,45] Cases of PIMA in which the immune response targets early erythroid precursors, causing an essential absence of marrow erythroid precursors, are sometimes termed pure red cell aplasia. Coombs testing is negative for the majority of cats with PIMA. However, similar to canine PIMA, some cats may be positive, suggesting the immune target in those cases is also present on mature RBCs[4] (see Chapter 38).

The response to immunosuppressive therapy in cats with IMHA or PIMA is variable, but remission can be achieved. The time to remission may be longer for PIMA than IMHA (up to 42 days in one publication).[45,4] Relapses can occur, sometimes while the cat is still receiving immunosuppressive therapy.[4]

INTERPRETATION OF THE LEUKON IN DISEASE RESPONSE

Catecholamine-induced leukogram changes, termed physiologic leukocytosis, are more common in cats than many other domestic species. Characteristic features are a lymphocytosis and/or mature neutrophilia. The lymphocytosis is caused by altered lymphocyte distribution between blood, lymphatics, and lymphoid tissue, and the neutrophilia is induced by shifting from the neutrophil marginating pool to circulating pool.

The magnitude of the lymphocytosis and neutrophilia is usually mild to moderate, with the lymphocyte count commonly less than 20 × $10^3/\mu L$. However, the degree of lymphocytosis can be higher in cats than in other species with physiologic leukocytosis, rarely exceeding 30 × $10^3/\mu L$.[34] The alterations in leukocyte counts are transient, lasting only about 20–30 minutes after catecholamine release.

Increases in endogenous glucocorticoids or administration of exogenous glucocorticoids can lead to neutrophilia and/or lymphopenia, but monocytosis is infrequent in cats.[34] The lymphopenia is due to altered distribution of lymphocytes between blood and lymphoid tissue or, at high doses, lymphocyte cell death. The neutrophilia is due to increased release from the marrow maturation and storage pool and shifting in the blood from the marginated to circulating neutrophil pool. A neutrophilic left shift is not typically present unless the marrow maturation and storage pool is depleted[34] (see Chapter 43).

Inflammation in cats can cause similar leukogram changes as noted in other species, including a neutrophilic left shift and/or toxic change (see Chapter 45). Interpretation of toxic change in cats is unique in that Döhle bodies are common in cat neutrophils, and may be seen in some apparently healthy cats.[28] Thus, by themselves, Döhle bodies may not indicate toxic change.

Additionally, cytoplasmic granulation is a rare feature of neutrophil toxicity in cats and must be distinguished from the neutrophil granulation anomaly seen in cats breeds such as Birmans.[28]

A mild lymphocytosis can occur uncommonly in cats with certain infectious and inflammatory diseases, including FIV, FeLV, and IMHA.[3,20] In general, however, antigenic stimulation is more likely to result in the detection of reactive lymphocytes on blood smear review than lymphocytosis.

Hypereosinophilia (blood eosinophil count of $>2 \times 10^3/\mu L$) can be seen in a variety of disorders including parasitism and hypersensitivity responses.[35] Concurrent basophilia may or may not be present. In cats, hypereosinophilia is commonly caused by flea allergies, feline asthma, and eosinophilic granuloma complex. Other causes include paraneoplastic disease (e.g., mast cell neoplasia, lymphoma, and rarely carcinoma) and gastrointestinal disease (e.g., feline gastrointestinal eosinophilic sclerosing fibroplasia).[35,36,41] Rare cases of hypereosinophilic syndrome and chronic eosinophilic leukemia are reported in cats[35] (see Chapter 46).

Neoplasia

Circulating neoplastic cells may be identified in cats with leukemia or lymphoma. Chronic lymphocytic leukemia must be distinguished from non-neoplastic causes of lymphocytosis such as epinephrine responses. It is typically a disease of middle-aged to older cats, and the most common immunophenotype reported is CD4+/CD8−/CD3+/CD5+ T cells[9] (see Chapters 65 and 72).

A variety of acute myeloid leukemia (AML) and acute lymphoid leukemia (ALL) subtypes occur in cats and may or may not be associated with retroviral infection.[17,37,47] In contrast to dogs, erythroleukemia (AML M6) is a common subtype of feline AML, and typically is preceded by myelodysplastic syndrome (MDS) with detectable dyserythropoiesis in blood.[17,37] Immunophenotyping may be performed by flow cytometry or immunohistochemistry, and cytochemical staining of blasts may also be helpful in some cases (see Chapter 61). Immunophenotyping of acute leukemia by PCR for antigen receptor rearrangements (PARR) is not advisable, since the false negative rate is reported to be fairly high.[47] Also clonal B or T cell rearrangements have been identified by PARR in humans and dogs with AML,[44] so it is possible this may occur in cats as well (see Chapter 62).

Circulating neoplastic cells can be detected in some cats with lymphoma. This may be particularly common in cats with small intestinal granular lymphocyte lymphoma, where circulating granular lymphocyte numbers occasionally are greater than $200 \times 10^3/\mu L$.[40] These granular lymphocytes may be small and morphologically mature; however, in some cases the cells are large (15–35 μm diameter) and/or have atypically large and coarse (1–2 μm diameter) cytoplasmic granules (Figure 109.5)[40] (see Chapter 65).

MDS is a clonal disorder of hematopoietic stem cells that is associated with peripheral cytopenias, normocellular or hypercellular marrow, intramedullary apoptosis

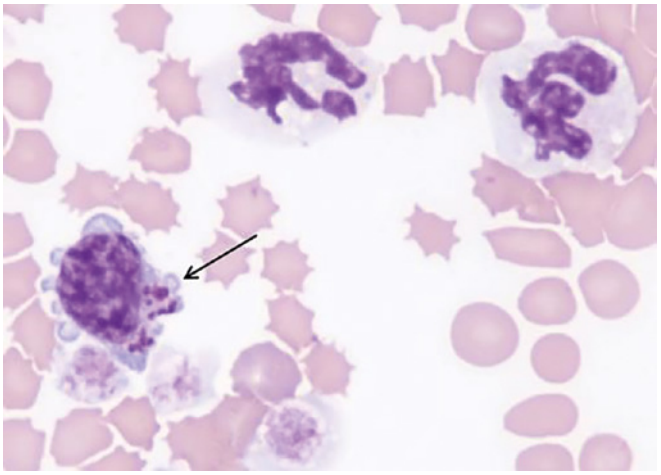

FIGURE 109.5 Circulating neoplastic granular lymphocyte (arrow) from a cat with intestinal lymphoma. In this case, the neoplastic cells were small and morphologically mature, but had atypical large coarse cytoplasmic granules. Wright stain, 100× objective.

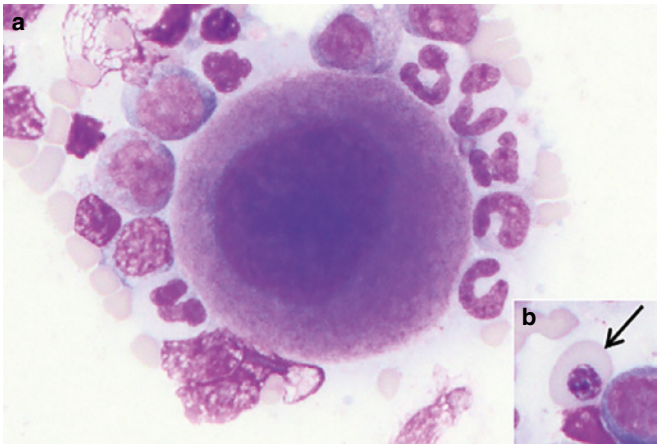

FIGURE 109.6 Bone marrow from a cat with myelodysplastic syndrome (MDS). (a) A dysplastic megakaryocyte with nuclear to cytoplasmic asynchrony evidenced as a hypolobulated (immature) nucleus with abundant pink granular (mature) cytoplasm; (b) A megaloblastic erythroid precursor (arrow), which is macrocytic with mottled, uncondensed chromatin and hemoglobinized cytoplasm. Wright stain, 40× objective.

of hematopoietic precursors, and dysmyelopoiesis (Figure 109.6).[22,32,37,51] Dysplasia may be morphologically evident in one or more hematopoietic lineages. Within megakaryocytes, features of dysplasia may include nuclear to cytoplasmic asynchrony (immature nonlobulated nucleus with mature pink granular cytoplasm, or mature polylobulated nucleus with immature scant dark blue cytoplasm), dwarf megakaryocytes (very small megakaryocytes that are not promegakaryocytes), and/or satellite micronuclei.[22,37,51] Dyserythropoiesis can manifest as nuclear to cytoplasmic asynchrony (immature uncondensed chromatin with mature hemoglobinized cytoplasm), megaloblastic cells (macrocytic cells with nuclear to cytoplasmic asynchrony), multinucleation, fragmented or blebbing nuclei, and other abnormal

nuclear shapes.[22,37,51] Possible dysplastic features in granulocytes include nuclear hyposegmentation or hypersegmentation, increased cell size, abnormal granulation, and bizarre nuclear shapes such as ringed nuclei[22,37,51] (see Chapter 67).

Myelodysplastic syndromes are reported more frequently in cats than dogs, and cats with MDS may subsequently develop AML.[37,51] The prognosis is generally poor. Most, but not all, cats with MDS are infected with FeLV.[22,32,51] MDS must be distinguished from nonclonal dysmyelopoiesis, which can occur secondary to a variety of disorders such as immune-mediated anemia, immune-mediated thrombocytopenia, lymphoma, or drug administration.[22]

Mast cells are identified rarely in feline blood or buffy coat smears.[18,38,42] In dogs, mastocytemia can occur due to a variety of non-neoplastic conditions as well as mast cell neoplasia. By contrast, mastocytemia in cats is almost always indicative of mast cell neoplasia.[38,42] One publication reported two cats with lymphoid neoplasia and one cat with multiorgan hemangiosarcoma that each had one to two mast cells identified per blood smear, so mastocytemia is not completely exclusive to mast cell neoplasia in cats[38] (see Chapter 47).

Inherited Changes in Leukocyte Morphology

Inherited Pelger–Huët anomaly occurs in many species and is rarely reported in cats. Neutrophils from affected cats have hyposegmented nuclei that may appear band-shaped, kidney-shaped, oval, or round. This is distinguished from an inflammatory left shift by detection of mature condensed nuclear chromatin.[28] Detection of nuclear hyposegmentation in both neutrophils and eosinophils can also support a diagnosis of Pelger–Huët. Acquired Pelger–Huët, also known as pseudo-Pelger–Huët, can occur in cats with infectious disease such as FeLV, with myeloid neoplasia, or during chemotherapy[28] (see Chapter 42).

Mucopolysaccharidoses VI and VII are associated with blue to purple cytoplasmic granulation in leukocytes, particularly neutrophils.[28] These granules must be differentiated from toxic granulation and from neutrophil granulation anomaly. Cats with mucopolysaccharidosis VII, GM1 gangliosidosis, GM2 gangliosidosis, α-mannosidosis, and Niemann–Pick can have distinct clear cytoplasmic vacuoles in lymphocytes.[28] Healthy cats of certain breeds, particularly Birmans, but also some Siamese and Himalayan cats, may have neutrophils with red cytoplasmic granules. These are not associated with any clinical disease, but must be morphologically distinguished from lysosomal storage disorders or toxic granulation[28] (see Chapter 44).

Chédiak–Higashi syndrome is a rare inherited disorder caused by a defect in formation of lysosomes and related organelles, causing abnormal granulation in multiple cell types. It has been reported in Persian cats and is associated with large granules in neutrophils and immune dysfunction. Affected cats can also have bleeding tendencies due to platelet granule defects[28,14] (see Chapter 44).

HEMOPARASITES

Three species of hemotropic mycoplasmas have been detected in cats: *Mycoplasma haemofelis* (formerly *Haemobartonella felis*), *Candidatus Mycoplasma haemominutum*, and *Candidatus Mycoplasma turicensis*.[27,46] These epicellular erythrocyte parasites have not yet been cultured, but may be detected by microscopic blood smear examination and/or PCR.[46]

M. haemofelis are small coccoid to ring-shaped organisms measuring about 0.6 μm and may form short chains of three to six organisms (Figure 109.7a). It is reported to be the least prevalent but most pathogenic of the three species and can cause hemolytic anemia which may be severe and life-threatening.[27,46] The number of organisms in blood can fluctuate dramatically within just a few hours, and visual detection of organisms has a low diagnostic sensitivity.[46] Additionally, care must be taken not to misidentify stain precipitate or Howell–Jolly bodies as mycoplasma.

M. haemominutum is about half the size of *M. haemofelis*, so is rarely detected during blood smear examination.[46] *M. turicensis* has only been identified by PCR, and to date there are no reports identifying the organisms microscopically on blood smears.[27,46] *M. haemominutum* and *M. turicensis* are commonly detected by PCR from nonanemic cats, so the pathogenicity of these organisms is questionable. Based on experimental inoculations, they may at least cause a transient mildly decreased HCT during acute infection in some cats or may exacerbate anemia caused by other diseases such as retroviral infections.[46]

Confirmatory PCR testing for feline hemotropic mycoplasmas is widely available and detects the bacterial 16S rRNA gene. Real-time PCR assays have an advantage over conventional PCR in that they may be able to provide information about parasite load. However, it is important to note that a positive PCR result does not define mycoplasma as the etiology of anemia in a patient, particularly for *M. haemominutum* and *M. turicensis*, since nonanemic cats can fairly commonly have positive PCR results.[46]

Cytauxzoon felis is an apicomplexan protozoal parasite of wild and domestic felids, and is endemic in the southern and southeastern United States.[49] Sporadic cases of cytauxzoonosis have also been reported in South America (particularly Brazil) and Europe.[49] The merozoites, termed piroplasms, can be identified on a blood smear within erythrocytes as small (1–2 μm) ring-shaped organisms with a peripheralized blue to purple nucleus (Figure 109.7b).[27,49] Macrophages containing *C. felis* schizonts can be found on cytology or histopathology of various organs or rarely on blood smears (Figure 109.7c).[27,49]

Bobcats are the most common natural host for *C. felis* and generally have subclinical or mild disease. In contrast, the infection was historically thought to be almost universally fatal in domestic cats, causing severe acute hemolytic anemia and organ failure.[49] However, these assumptions are now questioned because of increasing reports of nonfatal infections in domestic cats, as well as occasional fatal or severe cases in nondomestic felids.[49]

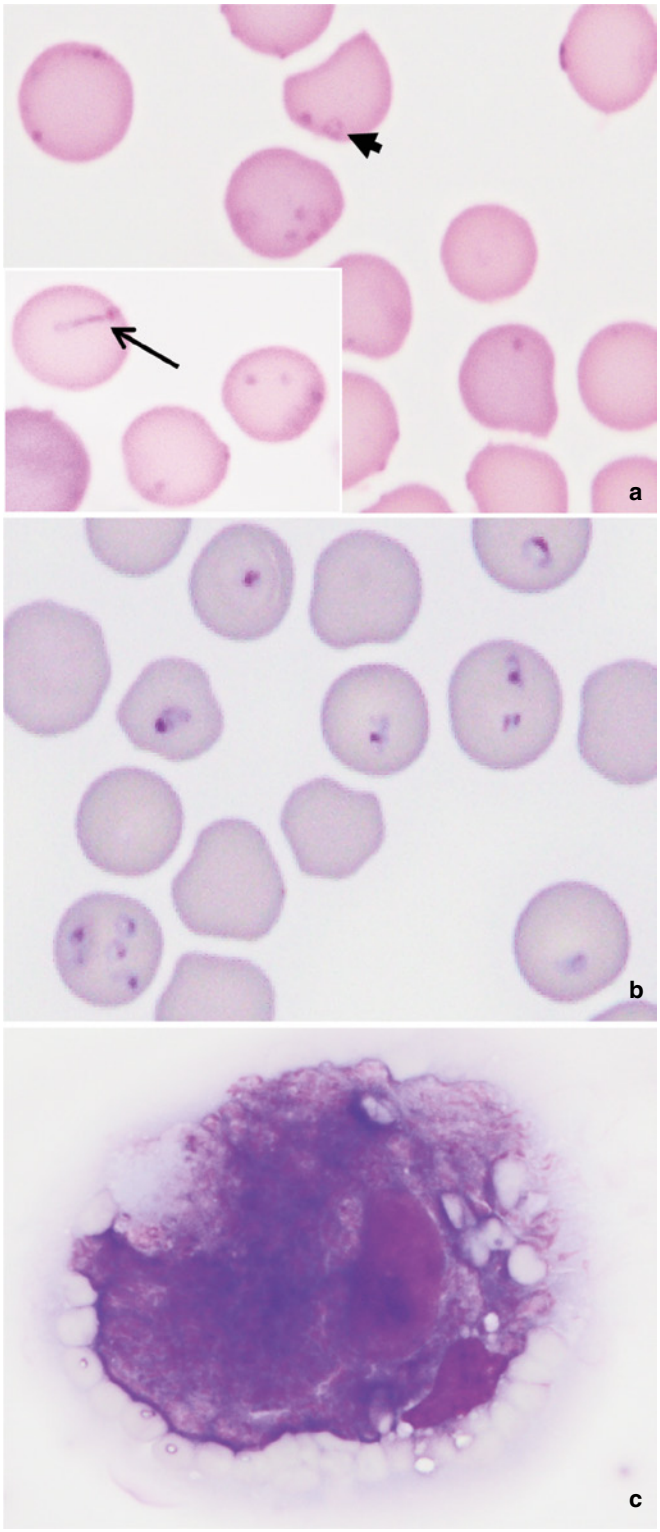

FIGURE 109.7 Feline hemoparasites. (a) Numerous *Mycoplasma haemofelis*, most of which are coccoid. A ring-shaped organism (arrowhead) and short chain of organisms (arrow) are also present; (b) Numerous *Cytauxzoon felis* merozoites, which appear as small ring-shaped organisms that are slightly larger than *M. haemofelis* and have a small peripheralized purple nucleus. Wright stain, 100× objective; (c) Schizont-laden macrophage at the feathered edge of the same blood smear as (b), Wright stain, 50× objective.

These findings suggest that there may be different strains of *C. felis* with variable virulence.[49]

Both small and large Babesia species have been reported in cats. Some species, particularly *Babesia felis*, can lead to severe hemolytic anemia.[27,25] The intraerythrocytic piroplasms in cases of small form Babesia can be morphologically indistinguishable from *C. felis*.[25,49] However, the geographic distribution of feline babesiosis is different, with most cases documented in South Africa.[25,27] Sporadic cases have been reported in domestic and wild felids in other regions.[25]

RETROVIRUS-ASSOCIATED HEMATOLOGIC ABNORMALITIES

Infection with FeLV or FIV can be associated with a variety of hematologic abnormalities in cats[20,24] (see Chapters 53 and 60). Numerous bone marrow disorders can be identified in FeLV-infected cats, including myelodysplasia, leukemia, lymphoma, myelofibrosis, and pure red cell aplasia.[20] These result from incorporation of FeLV provirus into bone marrow hematopoietic and stromal cells, which can alter gene expression, cell maturation, and marrow microenvironment.[24] Cats infected with FIV also have an increased likelihood of developing lymphoma or leukemia, but this is likely an indirect effect of immunosuppression rather than due to intercalation of FIV proviral DNA into host cells.[24]

In a study of cats naturally infected with FeLV or FIV, those with FeLV were more likely than retrovirus-negative cats to have abnormalities identified on CBC, including anemia, thrombocytopenia, neutropenia, and/or lymphocytosis.[20] Mechanisms for these hematologic abnormalities are multifactorial, including decreased marrow production and immune-mediated destruction. Cats with FIV had fewer CBC abnormalities compared to the cats with FeLV, but did have a higher incidence of neutropenia than control cats.[20] Infection with FIV is also associated with decreased numbers of CD4+ T cells in peripheral blood, which likely occurs through multiple mechanisms including decreased production and virus-induced apoptosis.[24]

Abbreviations and Acronyms

ACTH, adrenocorticotropic hormone; ASVCP, American Society for Veterinary Clinical Pathology; CV_A, analytical coefficient of variation; CV_I, intra-individual coefficient of variation; IRI, individualized reference interval; MPC, mean platelet component; MPV, mean platelet volume; PCDW, platelet component distribution width; RCV, reference change value; SAA, serum amyloid A.

INTRODUCTION

Equine hematologic results can be influenced by preanalytical, analytical, and postanalytical factors.

Preanalytical Factors

The equine spleen is a significant blood storage organ, estimated to store between 6 and 12 L of blood at rest, with the potential to release a large volume of blood with stimulation and catecholamine release, such as excitement or exercise.[24,31,34] The time required for hematologic results to return to resting values depends on the degree of the stimulation, and can vary from 40 minutes to several hours.[16] In contrast, tranquilizers or anesthetics can decrease circulating RBCs because of splenic sequestration.[3]

Venipuncture within 30 seconds of entering the stall in a calmly resting animal is suggested, since longer intervals before collection are more likely to be affected by splenic stimulation.[3,31,34] While this may not always be achievable, standardizing the venipuncture technique is recommended, keeping each horse as calm as possible and collection as rapid as possible. The prandial state should be considered, since the PCV has been reported to increase by 8–15% (e.g., a PCV of 40% may increase to 43–46%) within 1 hour of feeding hay and remain elevated for up to 2 hours.[3,18]

The duration between sample collection and analysis and the temperature at which the specimen is maintained prior to analysis may impact results. For ambulatory equine clinicians, there may be a delay in analysis because the clinician may be some distance from the clinic where specimens are analyzed or prepared for delivery to a commercial laboratory. It was found that delayed analysis (24–48 hours) resulted in minimal change in the WBC, RBC, Hgb, and Hct using the ADVIA 120 hematology analyzer.[7] However, increased numbers of normocytic, hypochromic RBCs, increased numbers of macrocytic, hypochromic RBCs, misclassification of granulocytes as mononuclear cells using the basophil reagent method, and pseudothrombocytosis due to misclassification of ghost RBCs as platelets occurred (later corrected by amended software). Many of the

artifactual changes were identified by morphology flags, with cytogram changes that allowed recognition of artifactual changes which were less pronounced in samples stored at 24 °C (room temperature) than those at 4 °C (refrigerated).[7] Other authors recommend refrigeration if there is a delay in analysis.[3] Other analyzers may have different performance due to specimen aging and storage.

Age, training/exercise, sex, nutritional status, and presence of endemic parasites have all been found to influence equine hematology results.[3,14,30] While minor changes due to these factors may not appear to be significant based on general horse RI, they may be significant when considering individual animal reference intervals.

Analytical Factors

Manual versus automated methods and the instrument's make, model, and edition of veterinary software may produce different results. Automated determination of differential leukocyte counts has been reported for several hematology instruments using species-specific programs,[14] but confirmation of WBC differential cell counts by peripheral blood smear examination is recommended.[13,38] Morphologic evaluation is also helpful in identification of band cells and other immature cells, the presence of toxic changes, blood parasites, or other morphologic abnormalities.

Postanalytical Factors

Important postanalytical factors include whether the RIs are appropriately partitioned for the class of horse (hot-blooded, warm-blooded, or cold-blooded), breed, sex, age, and reproductive status.[14,36] Whether population-based RI or individualized reference intervals (IRI) (also called subject-based RI) based on biologic variation are used also should be considered.

Indications for Evaluation of Hematology in the Horse

Hematologic evaluation in the horse has traditionally been used to monitor young animals in training; with the hope of detecting changes indicative of emerging disease or positive or negative effects of training. The premise that the most benefit comes from "emphasizing the negative" findings[3] rather than positive findings has merit in the opinions of the authors. Hematologic evaluation is recommended as part of a minimum database, including biochemistry and urinalysis, in horses with nonspecific clinical signs, such as weight loss, failure to thrive in young growing animals, or failure to perform at expected levels. It has been suggested that the relationship of laboratory results to performance potential in healthy horses may be better assessed with blood collection immediately following a standardized submaximal exercise test, which produces a heart rate of >100 beats per minute, 30 seconds following the completion of the workout,[3] with RI established for sex, breed, and training stage. However, this has not been adopted as a standard approach in the authors' experience.[31]

In overtrained trotters with poor racing performance, red cell hypervolemia is associated with a decline in racing performance, despite high Hgb concentrations. Overtrained horses also have significantly lower basal plasma cortisol values and the response to adrenocorticotropic hormone (ACTH) administration may be attenuated, although evidence for this is variable.[3] ACTH response is improved following rest and removal of one to two gallons of blood.[3]

THE ERYTHRON

The life span of equine RBCs in circulation is approximately 140–150 days.[37] RBCs are primarily released from bone marrow as mature cells, have a mean diameter of 5–6 µm, and a MCV of 40–52fL.[14,19] Central pallor is not present. Equine blood contains few circulating reticulocytes compared with other species, even with mild to moderate anemia. This is likely due to the equine spleen's large RBC storage and buffering capacity.[1] Polychromasia is rarely observed in Romanowsky-stained blood smears. Young animals and healthy warm-blood breeds may have slightly higher reticulocyte numbers than other horses.

Rouleaux formation is a characteristic finding in healthy horses, due to weak surface charges on RBC membranes.[5] In most cases, the characteristic stack-of-coins appearance is sufficient to differentiate it from antibody-mediated agglutination, which has a three-dimensional grape-like cluster appearance. Saline dilution (up to 1:10) will disperse rouleaux, but not autoagglutinated RBCs.[14] Agglutination can cause erroneous MCV values and RBC concentrations determined by impedance because the aggregates interfere with electronic or optical evaluation of RBCs. Pretreating agglutinated blood from heparin-treated horses with trypsin can reverse heparin-induced agglutination and improve the accuracy of cell counts and indices.[14]

Howell–Jolly bodies (nuclear remnants in RBCs) may be seen occasionally in the peripheral blood from healthy horses, in regenerative anemias, or with splenic dysfunction,[14] but are not a consistent finding (Figure 110.1a).

THE LEUKON

Equine neutrophils contain sharply delineated nuclear lobation and coarsely clumped chromatin (Figure 110.1c). Their cytoplasm is clear to pale gray, depending on the stain used. Band neutrophils are less frequently seen in horses compared to dogs or cats, since horses do not exhibit marked left shifts in inflammatory states. Because of this, many hematologic profiles for horses have traditionally included fibrinogen, or more recently, serum amyloid A (SAA); increased acute phase protein concentrations are the most sensitive method to detect systemic inflammation[4] (see Chapter 144).

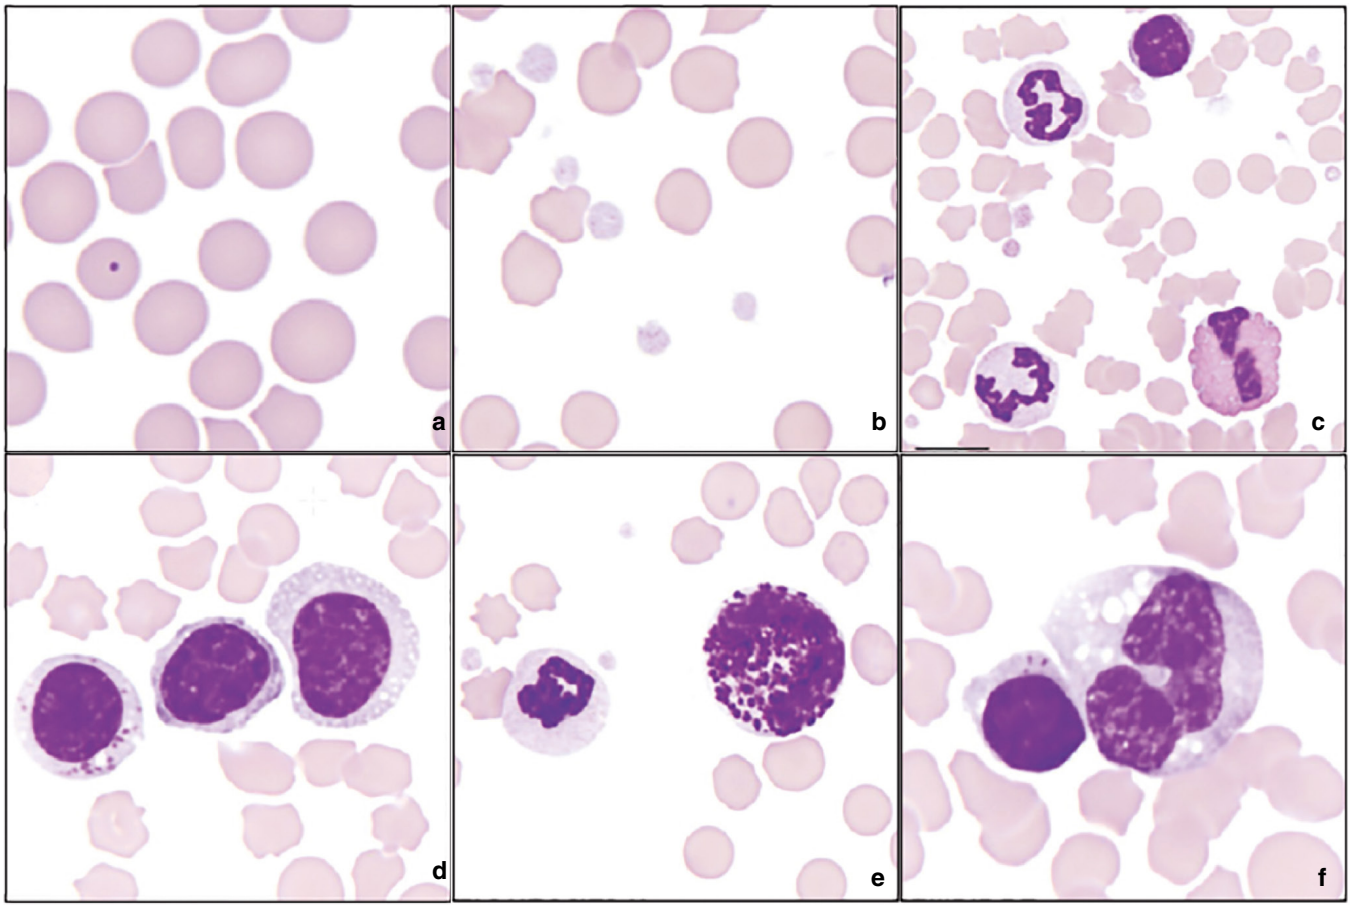

FIGURE 110.1 (a-f) Peripheral blood film from a horse. Modified Wright's stain: (a) Discocytes that lack a central pallor and an erythrocyte that contains a Howell-Jolly body. (b) Six light-staining platelets. (c) Two segmented neutrophils, one small lymphocyte, one eosinophil, erythrocytes and platelets. (d) Three lymphocytes and erythrocytes; small lymphocyte that contains cytoplasmic granules (left), small lymphocyte with scant cytoplasm (center), small lymphocytes with slightly more cytoplasm (right), (e) Segmented neutrophil, basophil, erythrocytes and platelets. (f) Small lymphocyte (with azurophilic granules), monocyte and erythrocytes.

Hypersegmented neutrophils, defined as having >5 nuclear lobes separated by filaments, are rarely seen in health. Prolonged blood storage may lead to the artifactual development of hypersegmented neutrophils. Idiopathic hypersegmentation has been found in quarter horses that lacked evidence of clinical disease.[14] Hyposegmented neutrophils have been reported in apparently healthy Arabian horses that were diagnosed with Pelger–Huët anomaly[14] (see Chapter 146).

Lymphocytes in the peripheral blood of normal adult horses are comprised of 38–66% T cells, 17–38% B cells, and small numbers of null cells.[14] Lymphocytes are smaller than granulocytes with dark-staining round to oval nuclei, coarse chromatin, and scant light blue cytoplasm (Figure 110.1c,d,f). In Wright-stained blood smears, small pink to magenta, irregularly shaped cytoplasmic granules may be present in small numbers of lymphocytes. Occasionally, larger lymphocytes that have smooth chromatin and moderately abundant pale blue cytoplasm are seen.[14] Reactive lymphocytes are rarely seen in smears from healthy, adult horses.[14] They are slightly larger than small lymphocytes, often have scalloped nuclear margins, and moderately aggregated chromatin, with infrequently discernible nucleolar rings, and scant to moderate amounts of intensely basophilic cytoplasm; sometimes, a palely stained Golgi zone will be apparent[14] (see Chapter 50).

The nucleus of the equine monocyte is large, variable in shape (i.e., oval, bilobed, horseshoe-shaped, trilobed, or irregular) and has lacy chromatin. The cytoplasm is gray-blue and may have small azurophilic granules and a few clear vacuoles (Figure 110.1f). Prolonged storage of blood resulted in an artifactual increase in the number of mononuclear cells detected by the ADVIA 120 hematology analyzer[7] (see Chapter 49).

Eosinophils have pale blue cytoplasm and contain large, pink-orange, specific granules that are usually tightly packed within the cytoplasm, and which may obscure the nucleus (Figure 110.1c). The lobulated nucleus seldom shows fine filamentation and often appears to be bilobed. Eosinophil degranulation is reflected by vacuolation and is rare in healthy animals (see Chapter 46).

Equine basophils have clear to light blue cytoplasm and contain variable numbers of purple granules (few to many) that vary in size and shape (Figure 110.1e). Basophil nuclei tend to have fewer lobes than those in mature neutrophils[14] (see Chapter 47).

THE THROMBON

Equine platelet concentrations are some of the lowest reported for mammals.[14] Finding 6–10 platelets/oil-immersion field (100× objective) in a peripheral blood film is consistent with an adequate platelet count, sufficient to prevent spontaneous hemorrhage. Equine mean platelet volume (MPV) has been reported to be 4.3–5.6 fL and mean platelet mass to be 0.47–0.96 × 10^6/fL.[14] Additionally, mean platelet component (MPC) concentration (26.2 ± 3.5 g/dL) and platelet component distribution width (PCDW) (7.9 ± 1.2 g/dL) have been reported,[14] but are not routinely included on most hematology profiles. MPC was found to decrease with disease processes that caused platelet activation. Plateletcrit has been suggested to be a better indicator of platelet mass than platelet count.[30]

Platelets are round, oval, or elongate, usually are 2.5–3.5 µm in diameter, and have light blue cytoplasm containing fine azurophilic granules. Pseudopodia may be noted projecting from activated platelets. Equine platelets are pale when stained with most Romanowsky stains and can be easily overlooked in blood smears (Figure 110.1b). However, platelets stain more heavily with Diff-Quik® stain. Giant platelets (greater than the diameter of an RBC) are associated with increased thrombopoiesis. Platelet clumping due to artifactual platelet activation and aggregation during blood collection can lead to erroneously low platelet counts. Prolonged sample storage can result in pseudothrombocytosis due to misclassification of ghost RBCs as platelets using the ADVIA 120.[7] EDTA-dependent pseudothrombocytopenia has been reported in a thoroughbred gelding.[15] Blood smear examination should be performed to assess platelet clumping and confirm diagnosis of thrombocytopenia.

REFERENCE INTERVALS

RIs are presented in Tables 110.1–110.3 and illustrate reference intervals obtained for various categories of horses based on age, breed, and use (racing, breeding), using different statistical approaches. RIs depend on the reference individuals, the instruments and methods, and the statistical methods applied. Environmental, nutritional, management, and exercise factors in horses should be considered. Partitioning of RI for an instrument/method by sex, age, and facility/management should be conducted.[3] Minor differences reported for age, breed, sex, and levels of training may be significant when evaluating individual animals. Table 110.1 presents partitioned reference intervals from healthy, adult horses in southern England using data from a single large veterinary practice. Health was determined by physical examination, history, and separated according to the animal's age and use. All samples were collected for routine health-monitoring purposes, at owner's or manager's request. The reference intervals have undergone RI transference validation by accumulation of results from healthy horses over an extended period and have shown to be satisfactory in continued use.

TABLE 110.1 Equine hematology reference intervals partitioned for age, breed, and training status generated or verified in accordance with ASVCP guidelines.

Other Equids

Donkeys (*Equus asinus*) are a separate equine species from the horses and ponies are kept commonly as companion animals or used as working animals across the world. Growing numbers of donkeys are also being kept in some parts of the world because of the increasing popularity of donkey milk. The RBCs, leukocytes, and platelets of donkeys appear similar to those of the horse on light microscopy and, as with horses, reticulocytes are rarely present in the peripheral blood. However, the physiology of donkeys is significantly different from horses and there is poor transferability of hematologic RI between horses and donkeys.[6] Donkeys have a higher MCV than horses, and lower RBC count and PCV have been recorded in some studies.[5] Reference intervals for donkeys are available in the literature, but they were not created using American Society for Veterinary Clinical Pathology (ASVCP) guidelines and it is notable that there may be poor transferability of RI between groups of donkeys, possibly due to variation in breed, geographical region, climate, season, age, gender,

reproductive status, nutrition, work load, parasite burden, and methods.

There is little literature regarding hematology from hybrid equids (mules and hinnies). In one study, the hybrids had hematologic results that were closer to those of horses than donkeys.[24] As with donkeys, specifically developed population-based RIs are likely to provide the most useful diagnostic information.

Individualized Reference Intervals Based on Biologic Variation

There has been recent resurgence in interest in the concept of biologic variation and within-subject biologic variation used to determine reference intervals for individual animals.[39] A recent study of privately owned horses in Australia determined the reference change value (RCV), the amount that a measurand must change in order to be of statistical significance with a stated probability (usually 95%). A RCV for Hgb of 17.65% was determined, which is reassuringly close to the 20% found historically.[3] Persson previously determined Hgb concentration on 7 consecutive days in a small number of horses and found that results varied by as much as 2.4 g/dL (42 g/L) or nearly 20% from the mean value for a given individual.[33]

Optimal use of RCV is obtained when the analytical coefficient of variation (CV_A), for the laboratory in which the specimen is analyzed is used in conjunction with the within-subject variation (CV_I) which can be obtained from the literature) or the veterinary biologic variation website (www.vetbiologicalvaration.org) (Table 110.2). The critical number of specimens is used to establish an individual reference interval (IRI = homeostatic set point ± RCV). The degree of dispersion desired may differ for various measurands. It may be preferable to determine the homeostatic set point very precisely if a small change is likely to be clinically significant, while other parameters where larger changes are more likely to occur without clinical significance may not require as precise an estimation. The authors suggest that the dispersion associated with the homeostatic set point should be < CV_I to ensure that the dispersion (range of uncertainty associated with the homeostatic set point estimate) does not add further unacceptable uncertainty to the interpretation. Equine individualized reference intervals calculation can be found in Table 110.3.

BONE MARROW

Indications for bone marrow aspirate and core biopsy in the horse include persistent anemia, leukopenia, thrombocytopenia, or diagnosis of suspected hematopoietic and lymphopoietic neoplasia. CBC and peripheral blood smear, bone marrow aspirate, and bone marrow core biopsy should be collected at the same time or at least within a few days of each other. If finances are limiting, the bone marrow core biopsy can be held, pending the results of the other evaluations, and examined if it may contribute to a diagnosis.

Bone marrow can be collected from the sternum (preferred site), ilium, and ribs in both adult and young horses, as well as from the tuber coxae in young horses. Care must be taken when collecting samples from the sternum or ribs to avoid inadvertent puncture of the thoracic cavity (see Chapter 141). Equine bone marrow cellularity can be routinely assessed on satisfactory bone marrow aspirates or bone marrow core biopsy specimens (Table 110.4). Bone marrow particles in the mature adult horse are typically composed of equal proportions of fat and hematopoietic cells, but young growing horses may have up to 70% hematopoietic cells. Older horses can have up to 70% fat.[14] One to several megakaryocytes are seen per 10× objective field in health; greater than 10–20 per 10× objective field are considered increased, and only finding a few after examination of multiple particles suggests decreased numbers.[31] Maturation of the erythroid series should be orderly and complete, with approximately 5% of the erythroid series consisting of rubriblasts and prorubricytes and 95% consisting of rubricytes and metarubricytes.[20] Maturation of the granulocytic series should be orderly and complete, with approximately 85% of the granulocytes being metamyelocytes, bands, or segmented cells and 15% being myeloblasts and progranulocytes. The M:E ratio varies from 0.9 to 3.8 (Rose Raskin, personal communication). This large range of the M:E ratio limits its usefulness in determining if increased erythropoiesis is present. Other cells present in healthy horses are small lymphocytes (2–9%), plasma cells (<2%), monocytes/macrophages (<1%), mitotic figures (<4%), and rare osteoclasts or osteoblasts.[20]

Stainable bone marrow iron is readily apparent in healthy horses and the amount increases with age.[20] Finding more than 5% reticulocytes in the bone marrow (demonstrated by new methylene blue staining) supports a regenerative response, with up to 60% reticulocytes in intense regenerative responses. Hemodilution can result in a falsely low bone marrow reticulocyte count.

HEMATOLOGIC DISEASE

Anemia

History, physical examination, and other testing should be considered in generating differential diagnoses for equine anemia. Increased reticulocyte counts may be observed in severe anemias, particularly hemolytic anemias; but have not been found to be of prognostic significance to date. Response to anemia in the horse is most often assessed by serial Hct evaluation.[28] Reticulocyte counts that are >5% in marrow aspirates in anemic horses are consistent with accelerated erythropoiesis.[37] Serial monitoring of the peripheral blood and/or bone marrow aspirates is most commonly used to assess whether a bone marrow response to anemia is present.[14] Increased MCV of up to 10–15 fL above the individual's baseline level supports increased erythropoiesis in routine hematologic evaluations.[16] Increased RDW also provides support for increased

erythropoiesis.[11,19] The RDW is wider in healthy horses (14–25%) than in other species.[19] RBC creatinine concentrations have been reported to be higher in immature equine RBCs[40] and correlate well with the reticulocyte counts in bone marrow aspirates,[21] but this assay is not available commercially.

The response to hemolysis is generally greater than following hemorrhage, although the regenerative capability of horses is considered to be relatively poor compared with other species.[5] Recovery from very severe hemolytic or hemorrhagic anemia may take from 1 to 3 months.[22,23,36]

Peracute blood loss may result in splenic contraction, releasing stored RBCs into circulation and masking blood loss for at least several hours following hemorrhage. A decrease in total protein is an initial indicator of hemorrhage and occurs at 4–6 hours posthemorrhage. Decreased Hct occurs at 12–24 hours posthemorrhage. Continued decline with fluid fluxes may continue for up to 72 hours following a single episode of marked blood loss.[22] Chronic blood loss results in slowly developing anemia when blood loss exceeds the bone marrow's erythropoietic capacity. Internal hemorrhage may result in anemia, if severe, prolonged, or repeated.

Investigation of chronic blood loss resulting in anemia is highly dependent on a good physical examination, as well as laboratory tests, to determine if repeated trauma, parasitic disease (including ticks, lice, internal parasites), or ulcers (internal or external) may be contributing or underlying causes. Common causes of gastrointestinal hemorrhage include internal parasitism, gastric and/or duodenal ulcers, nonsteroidal anti-inflammatory toxicity, gastric squamous cell carcinoma, and swallowed blood from pulmonary bleeding. Causes of respiratory hemorrhage should not be underestimated and include guttural pouch mycosis, ethmoid hematoma, fungal rhinitis, nasal amyloidosis, severe pneumonia, pulmonary abscess with erosion of blood

vessels, pulmonary neoplasia, and exercise-induced pulmonary hemorrhage. Important causes of urogenital blood loss in the horse include urinary cystitis/urolithiasis, pyelonephritis, and vascular anomaly or rupture (especially postfoaling). Hemorrhage due to coagulopathy can result in hemorrhage at a variety of sites, depending on the underlying cause, e.g., trauma and environmental or individual factors. Considerations should include parasitic disease, gastrointestinal bleeding (ulceration, neoplasia), recent/prior surgery, thrombocytopenia, neoplasia, arterial rupture, moldy sweet clover toxicity, and hemophilia A, or other inherited coagulopathies[28] (see Chapter 146).

Hemolytic Anemia in the Horse

Hemolytic anemia in the horse may or may not be accompanied by icterus/hyperbilirubinemia. Total serum or plasma protein will likely be within normal limits (or increased compared to anemia from blood loss in which decreased total protein concentration is more common). There may be accompanying leukocytosis with neutrophilia, with or without a regenerative left shift.

Hemolytic anemia that is not associated with an immune response may occur due to RBC enzyme deficiency, chronic disseminated intravascular coagulation, and with any microangiopathic process including thrombosis or fibrinoid degeneration of small vessels. Intravascular hemolysis may occur in some horses with terminal hepatic or renal failure.[41]

Immune-mediated hemolytic anemia (IMHA) may be associated with macroscopic or microscopic autoagglutination. Microscopic autoagglutination may be recognized when macroscopic autoagglutination is not detected. Autoagglutination supports an immune-mediated mechanism for anemia. True autoagglutination must be differentiated from rouleaux, the stack-of-coins appearance which is an expected finding in equine blood. A saline agglutination test (1:10) is helpful in making this distinction. Immune-mediated anemia in the absence of autoagglutination is confirmed by a Coombs test. If autoagglutination is present macroscopically, a Coombs test is unnecessary. False negative Coombs tests may occur immediately after hemolytic crises, if corticosteroids have been administered, or if the test is not conducted with appropriate dilutions and controls. A negative Coombs test does not rule out the possibility of IMHA (see Chapter 143).

Neonatal isoerythrolysis (NI) caused by blood group incompatibility between the dam and foal is particularly important in the horse. Maternal antibodies against foal RBC are absorbed from colostrum and result in foal RBC destruction. Diagnosis may be presumptive in neonates with lethargy, anemia, and icterus during the first 4 days of life. Confirmation is accomplished with a hemolytic crossmatch test or jaundiced foal agglutination test. The condition is best prevented by early blood typing and prevention of colostrum ingestion by foals at risk for this condition (see Chapter 37).

Equine infectious anemia (EIA) is an important cause of hemolytic anemias and is a reportable disease in many countries, requiring euthanasia of confirmed cases, since there is no cure for this infectious disease. Thrombocytopenia is often the first indicator of infection and is a consistent finding. Leukopenia, lymphocytosis, monocytosis, and hypergammaglobulinemia are often present. There may be time periods in chronic carriers and affected individuals during which all hematologic variables are within normal limits.

Immune-mediated anemias also may be secondary to infections, especially *Clostridium perfringens*, injection site abscess or purpura hemorrhagica, drug administration (especially penicillin), as a paraneoplastic condition (especially lymphoma), or miscellaneous conditions (such as protein-losing enteropathy). Idiopathic immune-mediated hemolytic anemia is diagnosed after exclusion of other possible causes (see Chapter 37).

Oxidant-Induced Hemolytic Anemia

Oxidized Hgb results in the formation of Heinz bodies, eccentrocytes, and/or methemoglobinemia (see Chapters 23 and 32). Heinz bodies are aggregates of oxidized Hgb and are visible in peripheral blood smears as small, pale membrane projections or within RBCs. Heinz bodies appear as blue-green granules located near or protruding from the RBC membrane when stained with new methylene blue. Distinctive eccentrocytes may be present. Damaged hemoglobin is located to one side of the RBC with a thin erythrocyte membrane at the opposite side of the eccentrocyte. Icterus and hemoglobinuria are common sequelae in anemia due to oxidative damage.

Differential diagnoses of Heinz body anemia in the horse include phenothiazine, onion, red maple leaf, and petroleum toxicity. Phenothiazine toxicity is now uncommon due to reduced use as an equine anthelmintic, but may be seen as it is present in some ruminant supplements and salt blocks. There may be some individuals that are more sensitive than others to development of toxicity. Onion toxicity is caused by oxidation of a disulfide by wild or domestic onions. Horses usually have a distinctive onion odor present on their breath, urine, and feces. Red maple leaf toxicity results from the ingestion of dried red maple leaves (not fresh or viable leaves) which contain gallic acid and likely other toxins capable of inducing methemoglobin formation and hemolysis in equine erythrocytes.[7] These compounds are not unique to *Acer rubrum*, suggesting that ingestion of leaves from other maple species (e.g., *Acer saccharum* and *Acer saccharinum*) may result in clinical signs similar to red maple leaf toxicity.

Only the most common etiologies of nonregenerative anemia in this horse will be discussed here (see Section III). Anemia of chronic disease is the most common form of equine anemia encountered by the authors. It is usually a mild anemia (Hct >20%). Bone marrow iron is normal to increased, possibly due to inflammation. A special case of anemia of chronic disease is that associated with renal disease with a potentially defective marrow response to erythropoietin, since decreased erythropoietin levels have not been

demonstrated consistently in horses with renal-associated nonregenerative anemia.[8] There may be reduced RBC life span. Neoplasia may induce anemia of chronic disease due to shifts in cytokine production caused by the malignant cell population (see Chapter 39).

Myelophthisic diseases replace or destroy the normal bone marrow environment. Because these diseases do not selectively target RBCs, pancytopenia is often present. Neoplastic and inflammatory infiltration may cause equine myelophthisic disease (see Chapter 17). Myeloid neoplasia is the most commonly reported cause. Peripheral leukemia may or may not be present. When myeloid neoplasia involves the bone marrow but atypical cells are not visible in peripheral blood, this is termed aleukemic leukemia[27] (see Section V).

Iron deficiency is usually a problem of foals rather than adult horses and associated with chronic blood loss. An initial normocytic, normochromic anemia with decreased marrow iron progresses to microcytic, hypochromic anemia. Smaller, Hgb-deficient RBCs are the result of increased divisions of RBCs in an attempt to produce a critical intracellular concentration of Hgb. Serum ferritin assay is a better measure than total iron body stores to diagnose iron deficiency. Serum ferritin <45 ng/mL is suggestive of iron deficiency in horses. However, the assay is species-specific, not widely available, and may be falsely increased by concurrent inflammation, though less so than serum iron. Iron deficiency may be confirmed by bone marrow evaluation finding decreased iron stores and a predominance of rubricytes and metarubricytes with ragged cellular boundaries. Diagnosis of an underlying condition is also supportive with an improvement in the anemia upon treatment and resolution when iron supplements are administered (see Chapter 27).

Aplastic or hypoplastic anemia occurs when bone marrow stem cells fail to differentiate due to toxic, intrinsic, or immune-mediated damage and there is disruption of the bone marrow environment necessary for normal cellular production. This is an uncommon finding in horses, and is usually idiopathic, although rare cases have been reported with phenylbutazone administration. Other causes such as drugs, toxins, ionizing radiation, and immune-mediated destruction at the marrow level have been suggested. Diagnosis is based on finding peripheral anemia and/or pancytopenia with severe bone marrow hypoplasia/aplasia and replacement of marrow by fat. Because it may be difficult to judge if bone marrow aspirates of low cellularity are truly representative, bone marrow core biopsies from at least two sites are recommended for this diagnosis.

Blood Parasites

The most common blood parasites causing anemia in the horse are *Babesia caballi* and *Theileria equi* (formerly *Babesia equi*). These intraerythrocytic protozoan parasites are transmitted by ticks and may be visible in peripheral blood smears during febrile periods; but may be absent at the time of hemolytic crisis. Infection may result in death or chronic disease. Approximately 10% of apparently healthy standardbred horses in racing and training showed microscopic evidence of *B. caballi* and *T. equi* organisms in southern Italy.[31] This is similar to another Italian study which found 35% of Murgese horses were infested but did not show clinical or hematologic abnormalities compared to a group of healthy, noninfected horses.[35] Both studies hypothesized possible genetic resistance to clinical disease.[31,35] Following recovery from clinical babesiosis, horses may become carriers for an indeterminate period. Stress may induce clinical disease in carriers.

Other Blood Parasites

Setaria equina microfilaria have been reported in peripheral blood smears from an adult horse, but did not result in hematological abnormalities.[42] *Anaplasma phagocytophilum* morulae may be seen in granulocytes during the acute phase of disease and the chronic phase is often associated with thrombocytopenia.[30] Equine hemotropic mycoplasmas may be detected microscopically, but microscopic evaluation does not correlate well with findings of PCR testing. A positive correlation was found between PCR status and anemia in young horses (<1 year old), but no correlation between PCR status and anemia was found in horses >1 year old.[10]

Changes in the Leukon

Changes in the equine leukogram rarely constitute a primary diagnosis, but may provide clues as to underlying processes. Interpretation of leukocytosis depends on the degree and types of cells involved. Leukocytosis of up to $20 \times 10^3/\mu L$ is common and considered mild to moderate, while elevations of up to $30 \times 10^3/\mu L$ are considered marked. Elevations $>30 \times 10^3/\mu L$ are relatively uncommon and considered extreme. Leukocytosis with mature neutrophilia is the most common finding in the horse and is often associated with inflammation and/or stress.

The classic stress leukogram typically has slight to moderate leukocytosis (WBC usually $\leq 20 \times 10^9/L$) with neutrophilia and eosinopenia. Monocytosis may or may not be present. Band cells or less-mature leukocytes are not part of the stress leukogram and indicate release of immature cells from the bone marrow. Occasionally, a marked leukocytosis is seen with stress alone, but deserves additional consideration and investigation to rule out other inflammatory causes before attributed to stress alone. Endurance exercise can be associated with the development of a pronounced leukocytosis and neutrophilia, which frequently persist for up to 24 hours.[3] These changes are likely due to prolonged stress and corticosteroid release from the adrenal glands. More extreme stress leukograms are associated with more severely fatigued individual horses. Exhausted endurance horses have similar WBC counts to less-tired endurance horses, but showed a pronounced left shift. One study reported the mean

differential to include 8% band cells, and two horses with 22% band cells.[3] Bayly proposed that the N:L ratio may be used to assess the severity of stress experienced by a horse, with a value >10 compatible with approaching exhaustion.[3]

Band cells typically indicate an acute inflammatory response. In a regenerative left shift, mature neutrophils outnumber an increased population of band cells, which is usually a reflection of acute inflammation. In a degenerative left shift, increased numbers of band cells and other immature myeloid cells outnumber mature neutrophils. This indicates a severe inflammatory condition. In a leukemoid response, there may be difficulty in distinguishing severe inflammation from myeloid leukemia in which atypical immature myeloid cells appear in the peripheral circulation.[27]

Lymphocytosis be caused by epinephrine release when excited or scared, antigenic stimulation, or lymphoid neoplasia (lymphoid leukemia or stage 5 lymphoma).[29] Monocytosis is uncommon as a sole abnormality of the leukogram and may occur in conditions in which necrosis or chronic inflammation is present.[29]

Eosinophilia and/or basophilia are also uncommon as sole abnormalities of the leukogram. Considerations should include endoparasitic or ectoparasitic disease, hypersensitivity, dermatologic conditions, reaction to foreign material or antigenic stimulation, fungal disease, irritation of tissues rich in mast cells (such as skin, lung, gastrointestinal tract, or female genital tract), mastocytosis/mast cell neoplasia, myeloproliferative disease, or leukemia of these cell lines.[2,29] The absence of eosinophilia does not rule out these conditions.

Leukopenia may involve any or all of the cell lines. Mild decreases below reference interval in otherwise healthy horses are due to age or other partitioning factors and of little or no clinical significance.[29] These may represent horses with low homeostatic set points and associated physiological variation, compared to the population used for determination of reference intervals. Primary considerations for leukopenia include conditions resulting in WBC immigration to an inflammatory site (consumption) or decreased bone marrow production. Salmonellosis is a classic equine condition in which marked WBC migration into the intestine and increased fecal WBC found in profuse diarrhea result in leukopenia. There may or may not be a degenerative left shift. Combined immunodeficiency syndrome in Arabian foals and common variable immunodeficiency syndrome may cause lymphopenia.[9,12] Myelophthisic diseases typically result in leukopenia in conjunction with anemia and/or thrombocytopenia.

Neoplasia

Myeloid neoplasia may present with leukocytosis, leukopenia, or WBC that is within normal limits. Abnormal myeloid cells are present in the peripheral blood in most cases. Myeloid neoplasia involves neutrophils, monocytes, and/or eosinophils or has features of both myeloid and monocytoid (myelomonocytic) leukemia. No age predilection is apparent. Reports range from 10 months to 9 years old.[27] Reported clinical signs include weight loss, edema, anemia, mucosal petechiae, fever, peripheral lymphadenopathy hemorrhagic diathesis, and oral ulceration. Diagnosis is confirmed by bone marrow aspirate and/or biopsy of multiple organs.[27] There may be infiltration of many organs, including lymph nodes, spleen, and liver. Usually cellular morphology allows differentiation of malignant myeloid or monocytic cells from malignant lymphoid cells, but cytochemical typing or flow cytometry may be needed to determine the cell lineage involved[27] (see Chapters 64–67).

Acute lymphocytic leukemia results in peripheral lymphocytosis with atypical and immature cells. The most common clinical abnormalities in the horse are chronic weight loss, ventral edema, and regional lymphadenopathy. Chronic lymphocytic leukemia may result in large numbers of small lymphocytes in peripheral blood. These cells appear mature and well-differentiated.

Atypical lymphoid cells in peripheral blood are estimated to occur in 30–50% of horses with lymphoma, but are usually present in small numbers. Leukogram alterations are highly variable, but peripheral lymphocytosis with large numbers of circulating neoplastic lymphocytes is unusual and usually associated with bone marrow infiltration. There may be concurrent paraneoplastic immune-mediated hemolytic anemia, coagulopathy, thrombocytopenia, and/or paraneoplastic hypercalcemia. Common forms of lymphoma in the horse are generalized, intestinal, mediastinal, and cutaneous. Age of onset is usually 5–10 years, although lymphoma can be seen at birth or into old age. Histologic and/or cytologic evaluation of affected fluids or organs is used in diagnosis[26] (see Chapter 65).

Multiple myeloma, a tumor of plasma cells, is rare in horses and manifests in neoplastic proliferation of plasma cells in bone marrow, spleen, and lymph nodes. Hematologic changes are often nonspecific and may include pancytopenia. Focal osteolysis, a common finding in the dog, may or may not be present in horses. Diagnosis is made when there is plasmacytosis in bone marrow or soft tissue with invasion of surrounding tissue and monoclonal gammopathy (see Chapter 70).

ACKNOWLEDGMENT

The authors wish to thank Emma Croser for providing the reference intervals used for horses at Charles Sturt University, Wagga Wagga, Australia.

ERYTHRON

The mature erythrocyte (RBC) of the adult bovine is biconcave, has a width of 5–6 μm, minimal central pallor, and a relatively long life span of 130–160 days.[64] Morphology and life span are similar in bison and water buffalo.[2,13] On a blood smear, anisocytosis is mild to moderate in most ruminants. Red blood cell shape is relatively uniform in adult animals, but poikilocytosis is common in blood smears from apparently healthy calves. This may be a reflection of a unique hemoglobin (Hgb) molecule, its association with the RBC membrane, or inadequate iron stores.[53] Water buffalo tend to have more rouleaux than cattle; but rouleaux formation of bovine RBCs is unusual unless inflammatory proteins are increased.[33] Polychromatophils are generally absent from the blood of healthy adult bovids.

The average Hct of domestic cattle is approximately 0.26 L/L (0.17–0.39 L/L). In water buffalo, the average PCV is approximately 42% (30–56%), more similar to bison than domestic cattle. The average PCV in bison is approximately 47% (24–61%). Compared with reported values for domestic cattle, the following variables tend to be higher in water buffalo and bison: RBC counts, PCV, and Hgb concentration. The average Hgb in bison is about 168 g/L (range, 82–230 g/L)[2,46,61,71] (Tables 111.1 and 111.2).

The bovine erythrocyte membrane, and that of other ruminants, has unique phospholipid composition in the external hemilayer. Instead of a predominance of phosphatidylcholine (PC), sphingomyelin (SM) is present in higher concentration.[18] This is thought to be due to the presence of anti-PC antibodies, formed due to evolutionary pressure of coexisting rumenal ciliates whose membranes contain a similar analog.[22] This variation may decrease rouleaux formation in this species.[63]

Ruminant Hgb is of particular interest because of the large amount of polymorphism that occurs between species, breeds, and even within the individual as it develops from embryo to adult.[33] This polymorphism is greatest in the β-chain. As in many other species, ruminants have two Hgb types. The embryonal type (HgbE) maintains a dam to in utero O_2 gradient, and the adult type (HgbA) for the ex utero environment. Transition from HgbE to HgbA begins in utero and may not be complete until months after birth. Like humans, domestic ruminants have a third type of hemoglobin, fetal hemoglobin (HgbF), which replaces HgbE in utero. As gestation progresses to the perinatal period, bovine HgbF is gradually replaced by HgbA. As prenatal erythrocytes live out their life span, HgbF-containing cells are replaced by HgbA-containing RBCs.

Bovine Hgb is a rich source of antimicrobial peptides.[50] A peptide isolated by Daoud et al. has antibacterial

activity against several organisms including *Escherichia coli* and *Salmonella enteritidis*.[16] Another group isolated four distinct peptides with similar activity, three of which corresponded to the bovine α-chain and one to the β-chain.[51]

Bovine Hgb has also been used extensively as an oxygen-carrying substitute in humans and in small animals.[12,23]

The metabolism of domestic animals' RBCs was reviewed by Harvey.[30] Glucose consumption by bovine

RBCs is approximately 0.6 μmol/hour/mL cells. Most cattle have moderate to high Na^+ and low K^+ erythrocytes. Some cattle with specific autosomal recessive phenotypes have high intraerythrocytic K^+ associated with certain blood groups.[30]

The ferrous iron of oxyhemoglobin (OxHgb) is constantly being oxidized to the ferric iron of methemoglobin (MetHgb) by intracellular metabolic products.[17] Erythrocytes normally contain a low concentration of MetHgb that is cyclically reduced back to OxHgb by the intraerythrocytic antioxidant enzyme, NADH methemoglobin reductase. When the quantity of MetHgb reaches a certain point, polymerization occurs, and the precipitated Heinz body becomes associated with the cell membrane. Accumulation of excessive Heinz bodies may result in both intravascular and extravascular hemolysis.

Erythrocytic 2,3-diphosphoglycerate (2,3-DPG) accumulation modifies the Hgb of some species, but not in cattle.[25] Ruminant fetuses and neonates have greater amounts of erythrocytic 2,3-DPG than adults. However, unlike many other species, 2,3-DPG is not bound as well to ruminant HgbF and HgbA.[25] Bovine HgbF has sufficient inherent oxygen affinity to maintain fetal Po_2.

The copper and zinc metalloenzyme superoxide dismutase was originally identified in cattle.[44] Although its value as an in vivo antioxidant is not entirely known, activity of this enzyme is increased in neonatal calves, presumably due to increased oxidative stress associated with parturition.[18] Another RBC metalloenzyme of clinical diagnostic significance is selenium-containing glutathione peroxidase (GPx). There is a direct correlation between selenium deficiency and enzyme activity. Although erythrocytic GPx deficiency is directly related to white muscle disease, it is inconsistently accompanied by methemoglobinemia. Hemolytic anemia does not frequently occur with selenium deficiency in ruminants. Heinz bodies in selenium-deficient Florida cattle were resolved by selenium treatment.[43]

Differences in hemoglobin types and RBC metabolism of cattle do not appear to make bovid RBCs more susceptible to oxidation. Cattle have intermediate activity of the RBC pentose phosphate pathway's limiting enzyme, glucose phosphate dehydrogenase.[30] When plants containing large amounts of nitrates or fertilizer nitrates are consumed, rumenal microflora reduce nitrate to nitrite, which when absorbed oxidizes OxHgb to MetHgb without Heinz body formation. Sulfoxide-containing kale and other *Brassica sp*. are converted by rumen microflora to an oxidant that, when absorbed, produces Heinz body hemolytic anemia. Methemoglobin with or without Heinz body formation and hemoglobinuria is associated with consumption of onions and ryegrass and may also occur with copper deficiency, toxicosis, and hypophosphatemia.[15,52]

LEUKON

The traditional leukogram is predominantly used to assess leukocyte (WBC) concentrations.[59] Specific cell subset profiles, blood and organ distribution, and cytokines are the current subjects of clinical research and development and may one day supplement or replace the conventional leukogram.[57] Acute phase protein assessment, specifically haptoglobin in bovids, is also frequently used, as it is the most sensitive indicator of systemic inflammation[47] (see Chapter 144).

Cattle have less granulocytic bone marrow reserve than many other species, which is reflected by a myeloid to erythroid (M:E) ratio of about 0.5–1:1.[10] This smaller granulocytic reserve is suspected to be part of the reason why neutropenia develops during the early granulopoietic response to suppurative inflammatory disorders in cattle. Once granulopoiesis is accelerated, a regenerative left shift and neutrophilia develop.

Bovine neutrophils have three types of cytoplasmic granules. The third type of neutrophil granule is larger than the primary and secondary granules and occupies twice the cytoplasmic space as in sheep and other domestic species, giving the bovine neutrophil its characteristic pink cytoplasm (Figure 111.1a).[10] The bovine's large neutrophil granules have more antimicrobial activity than the cytoplasmic granules of most nonruminant species.[8] Cytochemical and immunocytochemical staining reveals a range of enzymes and substrates in ruminant neutrophils.[3,30] Lysozyme, an enzyme common to many species, is not found in the neutrophils of cattle. Immunocytochemical cell membrane antigens add to the specificity of neutrophil characterization[57] and proteomic studies assist in further characterizing the neutrophils' molecular profile.[42]

Neutrophils of water buffalo vary morphologically from those in cattle. They have a mean size of 13.2 ± 0.7 μm and are multilobed or may have decreased lobation in samples from apparently healthy animals. Multilobed neutrophils have an irregular nuclear outline with two to four lobes and a dense chromatin pattern.[33] Monolobed nuclei may have one to two indentations, with decreased amounts of condensed chromatin compared to multilobed neutrophils. The cytoplasm is pale with fine indistinct, sometimes brown granules.[13,33] Band neutrophils are rarely found in healthy water buffalo, but have a smooth nuclear outline with no nuclear constrictions.[33] The neutrophils of bison appear morphologically similar to those in cattle (Figure 111.1f).[2]

Bovine lymphocytes are 8–15 μm in diameter and three sizes are described. Small lymphocytes have a round, centrally located nucleus up to two times the size of a RBC with a densely staining chromatin pattern in a small volume of clear to gray-blue cytoplasm (Figure 111.1b). The paucity of cytoplasm and chromatin density suggest that the small lymphocyte may be metabolically dormant or less active than the other two forms of lymphocytes. Medium lymphocytes have larger, round to indented nuclei in which the same amount of chromatin is spread over a greater area, revealing lighter-staining parachromatin adjoining areas of condensed chromatin. The cytoplasmic volume is also greater and encircles the central to eccentrically placed nucleus. Large lymphocytes have an even larger, lighter-staining nucleus and more cytoplasm than the medium-sized lymphocyte. Large lymphocytes have a round, indented,

or deeply cleaved centrally placed nucleus and are frequently confused with monocytes. Like monocytes, the cytoplasm of large lymphocytes stains blue to gray and sometimes contains small clear vacuoles. Variable shapes, sizes, and numbers of magenta cytoplasmic granules are frequently seen in a focal arrangement and may serve to identify the large bovine lymphocyte. Agranular large lymphocytes and monocytes are ultrastructurally inseparable, and cytochemical and immunocytochemical staining are needed to separate these two cell types. Chromatin centers, nucleolar rings, and nucleoli are seen with low frequency in Wright-stained normal bovine lymphocytes and should not be mistaken for evidence of neoplasia. Lymphocytes in water buffalo and bison are similar in appearance to those in cattle (Figure 111.1g).[2,13]

The bovine monocyte is a round to convoluted-shaped cell 13–19 μm in diameter. It has a large indented, bilobed to ameboid nucleus containing a diffuse chromatin pattern in a blue-gray cytoplasm containing fine, small, indistinct, magenta to pink granules. Vacuoles are frequent and more irregular in shape than those seen in some large lymphocytes (Figure 111.1c). Monocytes in water buffalo and bison are similar in appearance to those in cattle (Figure 111.1h).[2]

The ruminant eosinophil has a band to bilobed nucleus, which is surrounded by numerous, small, round, intensely stained, red cytoplasmic granules in basophilic cytoplasm (Figure 111.1d). Eosinophils may be increased with hypersensitivity disorders and tissue parasitism such as that caused by *Sarcocystis* and *Hypoderma* warbles.[54] Eosinophils in water buffalo and bison are similar in appearance to those in cattle (Figure 111.1i).[2]

The bovine basophil is a rare cell about the same size as the eosinophil, with electron-dense, numerous, small, intensely blue-staining granules that sometimes mask the nucleus (Figure 111.1e). Basophils occur at such low concentrations that they are not reliably quantified by the 100 differential cell method. Basophils in water buffalo and bison are similar in appearance to those in cattle (Figure 111.1j).[2,13]

PLATELETS AND COAGULATION

Bovine platelets in Wright-stained peripheral blood are distributed singly or in aggregates, are generally round but can vary in size and shape, and often contain numerous prominent azurophilic granules (Figure 111.1a,c). Cytoplasmic projections are rare. Platelets are small but numerous with a normal circulating survival time of 5–10 days. Enlarged platelet forms and pseudopodia are associated with activation and accelerated production in the bone marrow. Ultrastructure of bovine platelets reveals extensive invaginations of the surface membrane.[45] At the Animal Health Laboratory at the University of Guelph, reference values for platelets (160–650 × 10^9/L) were created in accordance with American Society of Veterinary Clinical Pathologists (ASVCP) guidelines with 28 proven healthy adult cattle. Platelets in water buffalo and bison are similar in appearance to those in cattle (Figure 111.1f).[2,13]

Blood clotting times for bovids are rarely reported in the literature. At the Animal Health Laboratory at the University of Guelph, reference values were created from 28 clinically healthy adult animals of various breeds resulting in the following: prothrombin time (PT) 18.4–23.1 seconds, partial thromboplastin time (PTT) 22.8–35.8 seconds, fibrinogen concentration 2.08–3.45 g/L.[1] Clotting times for water buffalo and bison have not been reported.

Wright's stain; magnification 1000×.

REFERENCE INTERVALS

Bovine neutrophil counts have increased over the last 50 years, and now the N:L ratio can be equal to or >1 in some healthy cattle. It was previously suggested that a N:L ratio >1 could be used to indicate inflammation, but this is no longer recommended, particularly in the absence of the animal's bovine leukemia virus (BLV) status. Lymphocyte and eosinophil counts have also decreased in this time period.[19,66] Increased diligence to exclude BLV-positive animals from reference value cohorts may be resulting in overall lower lymphocyte counts.[66]

Partitioning Factors

There are many factors that influence hematologic values in cattle that should be considered when interpreting results against reference intervals. Examples include age, breed, sex, production status, geographical location, and diet.[55] Domesticated bovids may have little or no direct physical contact with humans; therefore, when sampling occurs, the animals must be physically restrained and become excited. Reports of reference intervals seldom include consideration of such variables as physiologic state, history, form of restraint, ambient temperature, hydration status, BLV status, or parasite burdens. As in most species, the ruminant neonate has fewer lymphocytes than granulocytes. In a matter of weeks, the lymphocyte concentration increases to values similar to neutrophils, or higher. During adulthood, a slow progressive decline in lymphocyte concentration occurs. These age-related fluctuations in lymphocyte concentration exemplify the need for age-related reference intervals.

During gestation and at birth, Hgb types change and the erythroid compartment increases. At birth, about 60–90% of the neonatal calf's Hgb is HgbF and up to 9% of RBCs are reticulocytes. Fetal calf RBCs are less fragile and larger than adult bovine RBCs. In late gestation, bovine fetal RBCs have a mean corpuscular volume (MCV) of approximately 54 fL, but by birth it decreases to about 46 fL. From birth to about 8–12 weeks of age, the MCV continues to decrease to approximately 37 fL as HgbF-containing RBCs are replaced by cells containing HgbA. Compared to adults, the RBC count and MCV are lower in calves, and then gradually increase up to 15–19 months of age. Erythropoiesis takes about 5–6 days.[14] Veal calves raised solely on a diet of milk or milk replacer have lower RBC values than conventionally raised calves due to milk's low iron content.[4]

Recent studies have generated hematologic reference intervals for water buffalo, which are relatively similar to those for cattle and bison.[32,56,67] Bison calves have significantly higher RBC counts than do adult bison, which is also the case with calves of domestic cattle.[27] Average oxygen-carrying capacity was 17 mL/100 mL from calf blood and 22.2 mL/100 mL blood from adult blood; Hgb concentration averaged 13.6 g/dL in calves and 17.1 g/dL in adults.[27] Other age-related variations in bison CBC results include: RBC, monocyte, Hct, and neutrophil numbers which are negatively correlated, while lymphocyte numbers are positively correlated with increasing age.[2]

Bison raised and/or maintained under ranch conditions comparable to beef cattle operations have similar hematologic values as free-ranging bison living on range lands or in national parks.[61] However, an increased PCV is seen in free-ranging wild bison impounded for 24 hours before blood collection.[28] The authors suggested this may have been due to dehydration and/or excitement. Seasonal variation in PCV, mean corpuscular hemoglobin concentration (MCHC), MCV, and Hgb values may be a factor in establishing reference intervals.[21]

BLOOD AND BONE MARROW COLLECTION

Venipuncture sites for cattle include the jugular and coccygeal (tail) veins. Blood collection can usually be accomplished in an unsedated animal restrained with a halter or in a squeeze chute. A short period of acclimation is recommended to minimize the effects that epinephrine and/or cortisol may have on the hemogram. Blood is collected into tubes containing EDTA anticoagulant followed by two to three tube inversions to ensure proper mixing. Samples should be analyzed within 2–3 hours at room temperature or 12–24 hour if refrigerated (4 °C).[59]

The preferred sites for bone marrow collection in cattle are the sternum and the dorsal ends of the ribs. A unique feature of bovine bone marrow is the lower M:E ratio of 0.5–1.5 compared with other species. Harvey reports a ratio as low as 0.31.[29] The lower bovine bone marrow M:E ratio corresponds with the low–moderate neutrophil concentration in peripheral blood in some cattle and the rapid rate at which neutrophils are depleted during acute inflammation (see Chapters 112 and 141).

HEMATOLOGIC RESPONSE TO DISEASE

Anemia

Anemia can be due to blood loss, hemolytic disease, or decreased bone marrow erythropoiesis. Regenerative anemia occurs due to hemorrhage or hemolysis. Causes of blood loss in bovids include trauma, blood-sucking parasites, gastrointestinal ulcers, coagulopathy, and hemorrhagic enteritides (such as with bovine viral diarrhea virus (BVDV)). Immediately after blood loss, RBC variables remain unchanged until sufficient volume loss occurs to elicit fluid shifts into the intravascular space. Reticulocytosis may be observed as soon as 2–3 days, but the peak response may not occur until the following weeks. Regeneration is at most moderate compared with small animals. When severe regenerative anemia occurs, accelerated erythropoiesis is evidenced by moderate reticulocytosis, which results in macrocytosis, polychromasia, and basophilic stippling of RBCs, indicating accelerated erythropoiesis. Basophilic stippling is common during accelerated erythropoiesis in ruminants and should be interpreted as evidence of a

regenerative response. Healthy cattle typically have no polychromatophils in circulation, but they are released during a regenerative response. If hemorrhage becomes chronic and is of sufficient volume, the regenerative response can decrease as iron stores become depleted, and RBCs released from the bone marrow are microcytic and hypochromic. Veal calves fed all-milk diets will develop iron deficiency anemia.[41]

Hemolysis in bovids occurs with toxins, drugs, heavy-metal imbalances, osmolality abnormalities, immune-mediated, and parasitic and bacterial infectious agents. Some common hemolytic toxins include plants such as *Brassica sp.*, *Allium sp.*, and red maple (*Acer rubrum*). Deficiency of or excess copper may result in hemolytic anemia. Phosphorus deficiency in cattle has been linked to postparturient hemoglobinuria in early lactating cows, although not all animals with hypophosphatemia develop hemolysis, so other factors may contribute to this disease.[24] Water intoxication leading to hyponatremia and hypoosmolality with resultant hemolysis can occur in calves, but perhaps not in adult cattle.[20,35] Coombs-test-positive immune-mediated hemolysis in cattle has been described and is most often secondary to underlying infectious diseases or drug administration.[49]

Nonregenerative anemia most commonly occurs secondary to chronic inflammation when cytokines signal iron sequestration in macrophages, making it less available for full, robust erythropoiesis. The anemia of inflammation is usually mild to moderate, and normocytic and normochromic.[65] A similar mechanism likely occurs with neoplasia. Other causes of nonregenerative anemia include chronic kidney disease, endocrine diseases, and nutrient imbalances such as vitamin B12 or folic acid deficiency (usually macrocytic and normochromic) and iron deficiency (usually microcytic and hypochromic). Macrocytic normochromic nonregenerative anemia has also been described with congenital dyserythropoiesis in polled Hereford calves[64] (see Chapters 37, 29, and 146).

Leukocyte Responses

Physiologic

Transient physiological neutrophilia and lymphocytosis can occur during periods of excitement or fear due to the effects of epinephrine, particularly in younger animals. Mildly increased lymphocyte concentration may occur after vaccination. Endogenous or exogenously administered corticosteroids cause demargination of neutrophils and enhance release from the bone marrow producing neutrophilia, lymphopenia, and possibly monocytosis that is part of the stress leukogram. Leukocyte responses due to corticosteroid injection have been evaluated in buffalo calves. A single injection of corticosteroid, either prednisolone or dexamethasone, resulted in a leukocytosis with neutrophilia and no left shift, lasting from 2 to 24 hours. Prednisolone administration also caused an initial monocytosis 2–8 hours postadministration and an eosinopenia and basopenia by 6 hours postadministration. Interestingly, lymphopenia was not evident after prednisolone administration. Inconsistent changes were noted in lymphocyte, monocyte, eosinophil, and basophil numbers after dexamethasone administration. The lack of lymphopenia with steroid administration is dissimilar to many other species.[34]

Inflammatory Response

In neonatal calves, the inflammatory leukocyte response comprises neutrophilia and a left shift, similar to small animals. Thereafter, as neutrophil concentration declines somewhat,[9] the typical response to severe acute inflammation in cattle is neutropenia with a left shift, similar to horses. Mature cattle have a smaller granulocytic bone marrow reserve, so it may take 3–5 days for rebound from initial neutropenia. Serial leukograms can help determine if the bone marrow is responding adequately, in conjunction with clinical condition. Persistent neutropenia, particularly if accompanied by a degenerative left shift, warrants a more guarded prognosis. Toxic changes in neutrophils are frequently present with acute inflammatory conditions in cattle.

Chronic inflammatory stimulus results in neutrophilia, once granulocytic hyperplasia occurs in the bone marrow. Neutrophilia in cattle rarely exceeds $30 \times 10^9/L$ even with long-standing lesions and closed-cavity processes, such as an abscess or peritonitis. An exception to this occurs with bovine leukocyte adhesion deficiency, where concentration may approach $100 \times 10^9/L$[36] (see Chapters 43 and 44).

Neutropenia can also occur with viral diseases such as BVDV,[69] infection with rickettsial organisms (*Anaplasma phagocytophilum*),[62] toxins, drug reaction, and bone marrow disorders. If persistent neutropenia is accompanied by nonregenerative anemia and thrombocytopenia, bracken fern toxicity should be considered in the differential diagnosis list.[58]

Lymphocytosis that persists on repeat evaluation should prompt suspicion for BLV infection. Animals with persistent lymphocytosis due to BLV infection usually have no clinical signs. Rarely, a BLV-infected animal may develop lymphoma or lymphocytic leukemia. Because of the high prevalence of subclinical BLV infection in some regions, data from apparently healthy cattle may have been incorporated into reference values, thereby falsely increasing expected lymphocyte concentration.[66] Lymphoproliferative diseases are rare in bovids, but are another possible cause of lymphocytosis. Since bovine lymphocyte morphology is so variable, even in healthy cattle, presence of immature cells alone should not be used as the sole determining factor when diagnosing lymphocytic leukemia. Lymphopenia may occur with viral and bacterial disease as well as in the stress response. Congenital immunodeficiency may result in lower lymphocyte concentration.[7]

Monocytosis will occur with chronic inflammatory conditions. Corticosteroid therapy will also induce this change, but may be less common in cattle. Monocytopenia has limited clinical relevance.

Eosinophil counts are low in newborn calves and increase as the animal matures. Eosinophilia typically

occurs with hypersensitivity (especially type 1) and with ectoparasitism and endoparasitism. Blood eosinophilia was observed in a heifer with nasal granuloma caused by *Nocardia sp*.[60] Rarely, eosinophilia might be associated with neoplasia. Eosinopenia has minimal interpretive relevance.

Basophils are rare in cattle, but may be increased in conjunction with eosinophilia. Basophilia has been observed with allergies and parasitic disease. Similar to eosinopenia, basopenia has minimal interpretive relevance.

Hematologic changes are observed in response to endotoxin injection and are dose-dependent. Low-dose endotoxin injection (10 µg) resulted in mild leukopenia, mild lymphopenia, and moderate neutrophilia 6 hours postadministration. A trend toward a more significant leukopenia, neutropenia, and lymphopenia was noted with higher doses of endotoxin. A rebound neutrophilia was not observed after endotoxin administration, although neutrophil numbers returned to normal by 6 hours for endotoxin doses <50 µg and within 24 hours for doses of 100 µg endotoxin.[34]

Hemoparasites

Bovine hemoparasites may cause variable hematologic abnormalities dependent on the specific agent, pathogenic mechanisms, host specificity, and overall health status of the animal. Protozoal organisms include *Babesia sp*.,[11] *Theileria sp*.,[48] and various trypanosomes,[6] and bacteria include *Anaplasma marginale*.[5] Hematologic abnormalities in bison have been reported for infection with *Theileria annulata*, *Trypanosoma theileria* and *evansi*, *Mycobacterium bovis*, and *A. marginale*.[26,38,40,46] Water buffalo can be infected with many of the same organisms as tick vectors are similar.[30,39] Hemoparasitic infestation of WBCs and platelets does not occur frequently or has not been described well in bovids.

Babesiosis results in direct infection of RBCs by the parasite, and subsequent intravascular hemolysis when division is complete. Hyperbilirubinemia and hemoglobinuria are usually present. Reticulocytosis is usually evident. Disease is most often caused by *Babesia bovis* or *Babesia bigemina*.[11]

Theileria are closely related to *Babesia*, but differ by first developing in WBCs before infecting RBCs. Hemolytic anemia ranges from mild to severe depending on the specific organism and host factors. *Theileria parva* and *T. annulata* are two of the more common agents infecting cattle.[48]

Disease-causing trypanosomes include *Trypanosoma congolense*, *Trypanosoma vivax*, and *Trypanosoma brucei*. Anemia is usually present, and organisms may be observed in a blood smear during active infection. Nonpathogenic trypanosomes can occur in cattle in many parts of the world, such as *T. theileri*.

Infection with the intraerythrocytic rickettsial bacterium *A. marginale* typically causes an extravascular hemolytic anemia in affected cattle.[5] Hemoglobinemia and hemoglobinuria are usually absent. Organisms can be observed on a blood smear during the acute phase of infection, but not during the carrier state.

Acronyms and Abbreviations

2,3-DPG, 2,3-diphosphoglycerate; A1AGP, alpha-1-acid glycoprotein; APP, acute phase protein; Auto fib, automated fibrinogen concentration; EPO, erythropoietin; Fib %, percentage fibrinogen measured by the heat precipitation method; Fib sub, subtracted fibrinogen measured by the heat precipitation method; GMT, gelatinous marrow transformation; Hp, haptoglobin; HbA, hemoglobin A; HbAB, hemoglobin AB; HbAD, hemoglobin AD; HbB, hemoglobin B; HbC, hemoglobin C; HbD, hemoglobin D; HK, high potassium; LK, low potassium; SAA, serum amyloid A.

In 2020, worldwide populations of sheep (Ovis aries) and goats (Capra hircus) were estimated at 1.4 and 1.2 billion, respectively, and are economically important livestock species in many countries, including in the Middle East, Asia, and Africa. Furthermore, sheep are extensively used in biomedical research as models for human disease. Despite the widespread use of sheep and goats in research, some variation exists for normal hematologic reference intervals due to differences in methods of restraint, blood collection, laboratory methodologies, and physiologic factors such as age, reproductive status, and breed.

Blood collection is accomplished with the animal restrained in a standing position or tipped onto the hind quarters. Blood for hematologic analysis is obtained from the jugular vein. Animals should be at rest and handled gently to minimize stress.[10]

ERYTHRON

Goat RBCs are the smallest of the domestic species with an average diameter of 3.2–3.4 µm and an average mean corpuscular volume (MCV) of 19.5 fL. Sheep RBCs are slightly larger with an average diameter of 4.4–4.5 µm and an average MCV of 34 fL (Tables 112.1 and 112.2). Because of their small size, sheep and goat RBCs may not be correctly classified by impedance-based analyzers. Anisocytosis and poikilocytosis are prominent common features observed in normal blood films of juvenile and adult goats; RBCs can be round to flat (with a very shallow central depression) to oval or pear-shaped to spindled/fusiform in shape. Spindled/fusiform RBCs are particularly prominent in the Angora goat breed and in some breeds of British sheep (Figure 112.1). This is an innocuous change due to hemoglobin polymerization.

The majority of sheep RBCs appear as round biconcave discs with a shallow central depression and typically show slight anisocytosis. Small wart-like protuberances on the surface of sheep RBCs have also been observed. Since the degree of biconcavity in sheep and goat RBCs is less than in other domestic species, their ability to deform as they circulate is less.[22–24,30,43] Polychromasia and reticulocytes are not normally present in the circulation of adult goats and sheep. Their presence therefore indicates some degree of regeneration.

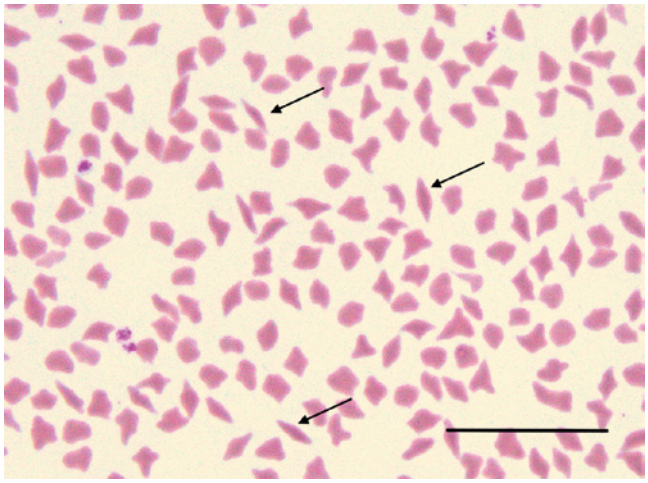

FIGURE 112.1 Blood film from an Angora goat. Poikilocytosis is a normal feature observed in many kids and adult goats. In the Angora goat, fusiform-shaped RBCs (black arrows) are a normal finding and, in this image, can be seen in low numbers admixed with other RBCs. The fusiform morphology results from hemoglobin polymerization (Wright–Giemsa, scale bar 20 μm).

Molecular Structure

The phospholipid classes found within the membrane of sheep and goat RBCs are different to nonruminant species. Membranes in sheep and goat RBCs lack phosphatidylcholine and have relatively higher amounts of phosphatidylinositol. This feature is thought to be dietary-related, reflecting the high level of inositol compounds present in the leaves of plants and grains.[34]

Two types of hemoglobin (Hgb) are present in normal adult sheep, HbA and HbB, which give rise to three phenotypes, HbA, HbAB, and HbB. In goats, three adult hemoglobins have been identified, HbA, HbB, and HbD. Polymorphisms occur with adult goat hemoglobin with four phenotypes HbA, HbB, HbAB, and HbAD being most common. Another hemoglobin type, HbC, demonstrates decreased oxygen affinity and is not readily seen in normal adult sheep, but is present in low concentrations in adult goats, accounting for approximately 5–10% of adult hemoglobin. HbC replaces fetal hemoglobin (HbF) and this remains the predominant hemoglobin in lambs and goat kids up to 4–5 months of age. In severely anemic animals or in animals living at high altitudes, the erythroid line can switch to synthesize HbC.[4,43] General RBC physiology and metabolism are described in Chapters 20 and 21.

Blood Types

Seven blood types are currently recognized in sheep, including A, B, C, D, M, R, and X. The C type is homologous to the C type in cattle and blood types B, C, and M are complex and highly polymorphic.[38–40] The M system is involved in RBC potassium polymorphism resulting in RBCs with high potassium (HK-type cells) or low potassium (LK-type cells) concentrations. In HK-type RBCs, increased (Na^+–K^+) ATPase activity results in increased potassium transport.[12,41] In lambs under 7 weeks of age, RBC potassium levels are higher than

adult levels, irrespective of their potassium genotype, and adult RBC potassium levels are achieved following the full development of M antigens.[47] The X type resembles the F type in cattle and the R type is similar to the soluble J type observed in cattle.[41]

Using sheep reagents, five blood types are recognized in goats, including A, B, C, M, and J, although other reports have described up to thirteen types. Regardless of the study, the B type has been found to be complex, highly polymorphic, and is comparable to that of sheep. The J type is similar to cattle and comprises a soluble antigen.[33,35,37,48]

LEUKON

Changes in the leukon are often evaluated for evidence of inflammation. Both total WBC count and differential cell count should be undertaken, as changes in individual cell types can occur without leukocytosis or leukopenia. Visual examination of leukocyte morphologic changes, such as toxic change, will assist in determining inflammatory conditions and septic etiologies.

Ovine and caprine neutrophils are similar and will be described together. Mature segmented neutrophils are approximately 10–15 μm in diameter and contain a large multilobulated nucleus (Figure 112.2a,g). Segmented neutrophils are similar to other ruminant and nonruminant species; although a third granule population, tertiary granules, is present. Unlike cattle whose tertiary granules are numerous and prominent, tertiary granules in sheep and goat neutrophils only occupy a small amount of cytoplasm; giving the cytoplasm a pale eosinophilic and finely granular texture when stained with Wright- or Giemsa-based stains.[9] In goat neutrophils, granules are electron-dense and markedly pleomorphic when viewed under transmission electron microscopy. The majority appear round to rod-shaped to dumbbell-shaped with fewer granules appearing large and ovoid to rod-shaped.[3] Granule enzymes in sheep and goat neutrophils are similar to other species; however, they lack lysozyme, as do bovine neutrophils.[46]

Ovine and caprine lymphocytes are typically small to intermediate in size (6–9 μm) and are easily distinguished from monocytes on Wright- or Giemsa-stained blood films (Figure 112.2b,h). Cells have scant pale blue to moderately blue cytoplasm and high to moderate N:C ratio. Some lymphocytes may also have low numbers of small azurophilic granules typical of natural killer cells (Figure 112.2n). Lymphocyte nuclei are round to oval with a clumped chromatin pattern. When antigenic stimulation is present in an individual, circulating reactive lymphocytes may be observed (Figure 112.2o).

As in most nonruminant and ruminant species, the monocyte is the largest of the circulating leukocytes

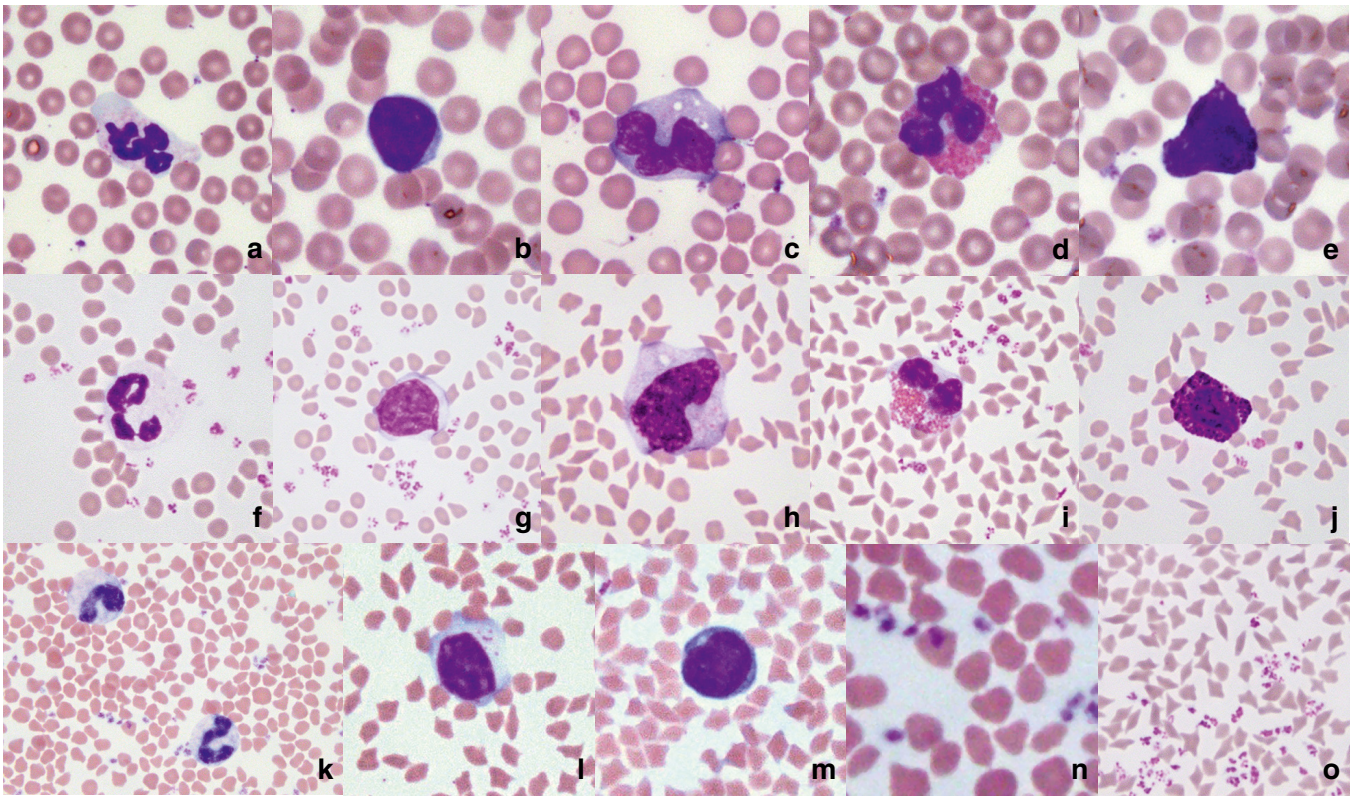

FIGURE 112.2 Comparative leukocytes and platelets. Ovine leukocytes and platelets: (a) Segmented neutrophil; (b) Lymphocyte; (c) Monocyte; (d) Eosinophil; (e) Basophil; (f) Segmented neutrophil. Caprine leukocytes and platelets: (g) Lymphocyte; (h) Monocyte; (i) Eosinophil; (j) Basophil; (k) A toxic band neutrophil demonstrating cytoplasmic vacuolation and basophilia; (l) Granular lymphocyte. Additional caprine leukocytes: (m) Lymphocyte exhibiting features of reactivity including dark blue cytoplasm with a small pale juxtanuclear Golgi area. Wright–Giemsa. (n) Ovine platelets. (o) Caprine platelets.

(13–19 μm). When in circulation, monocytes are round to oval in shape and have pale blue gray cytoplasm which may contain small vacuoles and small azurophilic granules (Figure 112.2c,i).

Eosinophils are slightly larger than neutrophils and basophils (10–15 μm) and have a bilobed or band nucleus which may be partially obscured by granules. Eosinophil granules in sheep and goat are numerous, round, refractile, and stain intensely red (Figure 112.2d,j).

Circulating basophils are infrequently observed in blood films from healthy sheep and goats. Basophils are typically round, measure approximately 8–10 μm, and have a less segmented nucleus than neutrophils. The cytoplasm is generally pale blue and contain numerous basophilic granules which typically obscure the nucleus (Figure 112.2e,k).

PLATELETS

Ovine and caprine platelets are small compared to other domestic species, with mean diameters of 2.6 and 2.2 μm, respectively, and, in the goat, a mean volume of 4.2 fL.[22] In both species, platelet numbers and platelet mass are high when compared to other domestic species.[30] In Wright-stained blood films, ovine and caprine platelets are distributed individually and in aggregates (Figure 112.2f,l). Surface features of ovine and caprine platelets are similar to other domestic species. Scanning electron microscopic studies reveal a discoid shape with a smooth surface and occasional small surface depressions.[22] Pseudopod formations are uncommon. Caprine platelets contain an open canalicular system with dense glycogen particles and small dense bodies which are sometimes surrounded by a clear vacuole. A circumferential microtubule system is also present. Both ovine and caprine platelets readily aggregate with ADP and thrombin, but not with epinephrine, and sheep platelets are unable to adhere to fibrinogen[30] (see Chapters 76, 77, and 79).

PLASMA PROTEINS

Ovine and caprine plasma is colorless independent of diet. Discolored plasma may be indicative of an underlying pathologic disorder including intravascular or in vitro hemolysis (red) and intra and extravascular hemolysis or hepatic disease (yellow).

The major acute phase proteins (APPs) in the sheep and goat are haptoglobin (Hp) and serum amyloid A (SAA). Concentrations increase rapidly following the onset of infectious and noninfectious inflammatory conditions, often peaking within 24–48 hours. In goats, Hp response can decrease in pregnancy secondary to systemic immunosuppression. Therefore, Hp concentrations in goats with unknown pregnancy status should be cautiously interpreted. Similar to other ruminant and nonruminant species, albumin is a negative APP, decreasing in concentration following an inflammatory stimulus.[15,16,21]

Fibrinogen is commonly measured as an indicator of inflammatory disease in ruminants; however, this is only a moderate APP in the goat and a minor APP in the sheep. Furthermore, the hydration status of the animal may affect plasma concentrations. Hypofibrinogenemia may be observed with liver disease and consumptive coagulopathies. A heritable afibrinogenemia has been reported in Saanen goat kids.[8]

BONE MARROW

In the commercial setting, bone marrow collection from sheep and goats for diagnostic purposes occurs infrequently. Bone marrow may be analyzed using one or a few individuals when herd health is of concern, such as cytopenia induced by infections, nutritional disorders, toxicosis, and other less common etiologies such as neoplasia. Under these circumstances, sacrificial euthanasia is often performed. Domestic pet and companion sheep and goats may have diagnostic bone marrow examinations performed for similar indications as those in nonruminant species.

Prior to sample collection in the live animal, sheep and goats should be heavily sedated or placed under general anesthesia and the surgical site aseptically prepared. Hematopoietic tissue is fragile and lyses easily. Therefore, postmortem bone marrow specimens should be collected shortly after euthanasia to minimize any morphologic changes. Bone marrow aspirates and core biopsies are most easily obtained from the iliac crest, although other sites, including the ribs, femur, and sternebrae, may also be used. In goats, however, the latter site is least favored due to the potential for chronic abscesses in this region[10,43] (see Chapter 141).

Bone marrow cell differential values in sheep and goats and cytochemistry of bone marrow cells in sheep have been reported (Tables 112.3 and 112.4). As in other ruminant species, the M:E ratio in sheep and goats is lower than that of nonruminant species and the marrow stores of mature neutrophils are also lower. In sheep and goats, the M:E ratio is currently reported to range from 0.8 to 1.7 and 0.5 to 0.8, respectively.[1,9,43]

REFERENCE INTERVALS

There are several reference interval manuscripts for domestic and wild sheep and goats that are not created in accordance with the ASVCP guidelines and may not have outliers removed.[6] These should be used with caution as misdiagnosis may result.

Partitioning Factors

Red blood cell parameters in sheep and goats may vary widely and are influenced by several physiologic and environmental factors such as collection, storage, age, species, breed, gender, nutrition, seasonal variation, heat stress, and reproductive status.[2,18,20,42]

TABLE 112.3 Cytochemical reactions of bone marrow cells in clinically normal sheep.

Cell type	May–Grunwald–Giemsa stain Mean (%) ± SD	Peroxidase reaction	Sudan black B reaction	Periodic acid-Schiff reaction
Myeloid series				
Myeloblasts	0.96 ± 0.15	–	–	–

Artifactually increased PCV can occur with prolonged storage.[20] At birth, the PCV is high, but this soon diminishes following ingestion of colostrum.[10] Juvenile lambs and kids generally have lower RBC numbers, increased MCV, and decreased mean cell hemoglobin concentration (MCHC) values.[9,13,26] Seasonal variations in RBC parameters have been reported; however, results are highly variable and likely associated with differences in geographic location, breed, and study design.[13,31,42]

There is limited information regarding maternal anemia during gestation in sheep and goats. Anesthetized pregnant sheep have demonstrated low RBC values, including a low PCV and Hgb concentration; however, this has not been found in pregnant sheep kept in a farm environment.[31]

At birth, the total WBC count in sheep and goats is slightly less than or similar to that observed in adults and numbers remain steady for the first 14 days. During this postnatal period, neutrophils are the predominant leukocyte and in kids they account for approximately 60% of the WBC population. By approximately 3–4 months of age, lymphocytes become the predominant leukocyte resulting in neutrophil:lymphocyte (N:L) ratios of 0.5 in lambs and 0.6 in kids. In adult sheep, the N:L ratio is approximately 0.5 and in adult goats it is approximately 1:1[2,9,13,17] (Tables 112.1 and 112.2).

TABLE 112.4 Proportions of bone marrow cells in the goat. This is presented as a rough guide to what may be found in the healthy goat.

Cell type	% cells
Myeloblasts	0.8
Promyelocytes	2.7
Myelocytes	8.3
Bands	8.9
Segmented neutrophils	10.0
Eosinophils	1.8
Monocytes	>0.1
Lymphocytes	7.5
Nucleated RBCs	56.3
Myeloid:erythroid ratio	0.6

HEMATOLOGIC DISEASE

Physiologic

Neutrophilia and lymphopenia may be secondary to corticosteroid administration and are commonly seen as a response to stress associated with restraint for venipuncture or concomitant disease.

Anemia

Anemia is the most common and significant hematologic abnormality of sheep and goats and has many causes. Regenerative anemia occurs secondary to hemorrhage or RBC destruction due to predation, other trauma, internal parasitic disease (anaplasmosis, babesiosis, theileriosis, trypanosomiasis; *Mycoplasma sp*., coccidiosis; *Haemonchus sp*., schistosomiasis, etc.), bacterial endotoxemia (*Clostridium perfringens* type A; leptospirosis), ingestion of toxic plants (*Brassica sp*.; bracken fern), copper toxicosis, phosphorus deficiency, and external parasitic disease (ticks, lice). Neonatal isoerythrolysis is not known to naturally occur in sheep or goats; however, neonatal anemia and death have occurred in lambs and goat kids administered bovine colostrum. Hemolytic disease has been experimentally induced in the goat.[32,45,50]

Polychromasia, macrocytosis, reticulocytosis, metarubricytosis, and basophilic stippling in RBCs usually appear within a day or two of an anemic event. The reticulocyte response to anemia in the sheep and goat is mild to moderate and most obvious when severe anemia is present. The reticulocyte response is usually maximal by days six to eight.[9,10,26] In the acute to subacutely anemic animal, indicators of accelerated erythropoiesis can be observed in bone marrow aspirates, including hypercellularity, decreased M:E ratio, left shifting of the erythroid series, an increase in macrophage activity, and in some conditions (i.e., hemolytic anemias) increased iron turnover.[1,9,44]

Anemias associated with decreased bone marrow production can occur with chronic disease (e.g., *Mycobacterium paratuberculosis*), malnutrition/starvation and nutritional deficiencies (iron, copper, cobalt), and toxicoses (e.g., fluorosis, bracken fern).[10,11,44] Chronic systemic illness in sheep and goats of any age can result in a reduction in bone marrow cellularity with resulting cytopenias. In cases where these conditions lead to malnutrition and emaciation, gelatinous marrow transformation, also known as serous atrophy, is evidenced by focal loss of hematopoietic cells and fat cell atrophy with concomitant deposition of extracellular gelatinous substances (e.g., mucopolysaccharides).[5,44,49]

Erythrocytosis is commonly observed in the dehydrated animal or rarely in those affected by conditions causing hypoxemia, such as chronic pulmonary disease or right-to-left cardio vascular shunting, and animals grazing at high altitudes. Erythrocytosis due to neoplasia has been reported in a sheep with cholangiocellular carcinoma.[7,10]

Stomatocytic and echinocytic changes following administration of chlorpromazine and lysolecithin, respectively, have been reported in the goat.[25] Fusiform RBCs, however, appear to be less affected.

Changes in the Leukon

Mature neutrophilia and a reversal in the N:L ratio often occur with mild to moderate inflammatory stimuli. As the granulopoietic response continues, circulating immature neutrophils may be observed, which may or may not be accompanied by toxic changes (Figure 112.2m). Because of the small granulocyte reserve in the bone marrow, neutropenia is often observed with severe acute inflammatory conditions such as septicemia (often associated with Gram-negative bacteria), peritonitis, pericarditis, pneumonia, polyarthritis, endotoxemia, coccidiosis, and others.[10,24] *Anaplasma phagocytophilum* and *Anaplasma ovis* infection may also cause neutropenia without a left shift.[10,44]

Pathologic lymphocytosis is infrequent, but can occur secondary to various chronic infectious and noninfectious inflammatory disorders. While lymphoma has been described in both sheep and goats, an associated leukemia has not been reported.[27,28] Lymphocytic leukemia has, however, been induced in sheep inoculated with bovine leukemia virus.[14]

Eosinophilia is observed in various hypersensitivity-mediated and other inflammatory conditions including parasitic, bacterial, fungal, and protozoal infections. When present, basophilia often accompanies eosinophilia, particularly in response to the release of chemical inflammatory mediators such as histamine and heparin.[9,10,26]

Acronyms and Abbreviations

APP, acute phase protein.

Blood collection in pigs can be difficult for unpracticed individuals. Pigs are quite excitable and need to be restrained or sedated for animal and human safety. Additionally, the major blood vessels cannot be visualized because they lie below a fair amount of fat and muscle, which makes site identification reliant upon anatomic landmarks. However, adequate blood volume can be obtained from a number of sites.

The jugular vein is the preferred site, as it allows for large volumes of blood to be quickly collected from any aged animals with minimal restraint. The cephalic vein on the foreleg can be used in pigs of any age for up to 5 mL of blood. The lateral auricular vein, or ear vein, can be used for collection of <5 mL of blood. This vein is large and visible, but collapses easily unless a butterfly catheter is used. Access to the anterior vena cava can be technically difficult and may require a cut down, but large volumes of blood may be obtained from this vessel. The coccygeal or tail vein can be problematic, since it is not easily visible, especially in young or small pigs, and lymph dilution is possible. The cranial abdominal vein (external mammary or milk vein) can be used to rapidly obtain 5–20 mL of blood in older animals.[27,58,63]

EDTA anticoagulant and a Romanowsky-type stain are preferred for optimal hematologic evaluation. Because the porcine RBC is relatively fragile, excess turbulence or improper sample handling often results in hemolysis. Routine hemogram values, except the differential cell count, are stable at 20 °C or 4 °C for 36 hours,[34] whereas the WBC differential count becomes less reliable within 12 hours after collection.[15]

ERYTHROCYTES

Porcine RBCs range in diameter from 4–8 μm with an average of 6.0 μm. Spiny crenation and rouleaux formation are common in health (Figure 113.1). Central pallor is not visible in every cell. Anisocytosis is seen in adults, but is more prominent in younger pigs. Blood from young pigs contains many large polychromatic cells, nucleated RBCs, and Howell–Jolly bodies.

The pig erythrocyte is highly susceptible to hemolysis by hypotonic saline and is more fragile than that of other species. Porcine RBCs display a bimodal pattern, with adult and fetal populations being more resistant to lysis than RBCs from weaned pigs. Osmotic resistance is temperature-, pH-, and time-dependent.[36,37] The sedimentation rate is faster than that of other domestic animals.[64]

(**Source:** Volu-Sol, Salt Lake City, UT.)

LEUKOCYTES

Porcine WBC are generally similar in morphology to other domestic mammals. The mature neutrophil is 12–15 µm in diameter. It has an irregular nuclear membrane and moderately coarse chromatin with well-defined lobes (Figure 113.1a). The cytoplasm stains a pale pink or blue and may contain a few pink to purple granules. Band neutrophils have a U-shaped nucleus, but are otherwise similar to the mature form. Low numbers of band cells may be present in the healthy animal.

Lymphocytes are the dominant cell type in peripheral pig blood (Figure 113.1b). Small lymphocytes are 7–10 µm in diameter and have a round to oval nucleus with condensed chromatin and a small rim of pale blue cytoplasm. Large lymphocytes are 11–15 µm in diameter. The chromatin pattern is more diffuse and does not stain as intensely as the small lymphocyte. The cytoplasm is slightly more abundant and stains pale blue. Large lymphocytes may contain azurophilic granules as in other mammalian species.

Monocytes are 14–18 µm in diameter and have a convoluted, bean-, or horseshoe-shaped nucleus. The nucleus has lacy chromatin, often with areas that are more condensed or clumped (Figure 113.1c). The abundant blue-gray cytoplasm may contain vacuoles. Some monocytes may be difficult to distinguish from a large lymphocyte or immature, toxic neutrophil.

Eosinophils are similar in size to neutrophils, but the round to oval cytoplasmic granules stain a pale orange to pink color and tend to fill the cytoplasm (Figure 113.1d). Eosinophil nuclei are poorly segmented and may appear immature. The basophil nucleus stains lavender to dark purple and has a smooth chromatin pattern (Figure 113.1e). The basophilic cytoplasmic granules are coccoid to dumbbell-shaped and stain similarly to or more intensely than the nucleus, which they may obscure.

PLATELETS AND COAGULATION

Porcine platelets are variable in shape and size (Figure 113.1f). They are generally small, 1–3 µm in diameter, with a mean volume of 6.9–8.9 fL.[13] Pliszczak-Król reported a slightly higher range of 8.4–9.75 fL. They are anucleate and have deeply staining purple cytoplasmic granules. Clumps are frequent. The plateletcrit in pigs has been reported as 0.009–0.395%.[51]

Coagulation of pig blood not collected into anticoagulant is rapid. Coagulation tests and platelet function analyses in pigs are seldom used in clinical situations. Kostering reported a prothrombin time of 14.7 seconds for adult Hanover domestic pigs. Pliszczak-Król reported similar findings of 12.2–16.3 seconds for pigs at 24 weeks of age. Thrombin time ranges between 16.7 and 24.5 seconds.[27,35] Activated partial thromboplastin time has a biphasic course, being relatively short before week 5 of age (17.8–19.9 seconds) and then becoming much longer (28.7–52.5 seconds). Coagulation profiles are utilized in research settings.[53,62] Flow cytometry has been used for measurement of platelet activation and assessment of clot quality[30] (see Chapter 118).

BONE MARROW

Similar to blood collection, bone marrow is more frequently collected under research conditions. The iliac crest (tuber coxae) is a common site for collection.[6] However, cortical thickness of this site in swine is much greater than that of other species. Except in neonatal swine, collection of marrow cells from the sternum is possible. The proximal tibia is also accessible, this area has less cortical thickness and is free of muscle.[58] Myeloid to erythroid ratios of 1.2–2.2:1 have been reported[58] (see Chapter 141).

REFERENCE INTERVALS

Many reference intervals for porcine blood have been published, but are not in compliance with American Society of Veterinary Clinical Pathlogy guidelines.[13,23,27] Although these are comparable, the ranges for most elements of porcine blood are quite wide. Variability occurs with age, breed, growth rate, diet, age, stage of gestation or lactation, feeding method, management practices, or season. Interpretation of porcine hematology data requires consideration of these partitioning factors; however, most sex differences are not biologically important.

Partitioning Factors

Many RBC changes take place after birth.[11,35] Within a few days of age, RBC number and hemoglobin (Hgb) concentration drop 30–38% after expansion of plasma volume. Cell size increases soon after birth, decreases to its smallest volume at 2–6 months of age, and then increases again to adult size. In suckling pigs, reticulocyte counts of 3–8% and nucleated red cell counts of 5% are common. These decrease as the pig matures. Changes in hematologic parameters of piglets farrowed and kept on concrete for 10 days and then transferred outside to soil are presented (Table 113.1).

Polychromasia, Howell–Jolly bodies, crenation, rouleaux, and poikilocytes are often seen in the blood of normal young pigs. Red cell count and Hgb concentration increase to reach adult levels at about 5 months of age.

Leukocyte numbers increase over the first 12 hours of birth. Rolinec reported a mean of 5.26×10^3 WBC/μL at birth; this increased to an average of 10.82×10^3 WBC/μL at 12 hours but with a very wide interval ($6.36–17.74 \times 10^3$ WBC/μL). Colostral leukocytes appear in the blood between 5 and 7 hours after colostrum intake.[7] At birth, neutrophils predominate with fewer lymphocytes. By 12 hours, due to colostrum intake, the ratio reverses and most of the cells are lymphocytes. The absolute number of lymphocytes has a large interval at 12 hours ($2.39–17.47 \times 10^3$ μL), and is affected by many factors such as age at weaning, disease, nutrition, stress, social status, and housing. Some apparently healthy, individual animals may not have a neutrophil:lymphocyte reversal until a week of age. Total WBC count wains shortly after birth, then increases at about the fifth week of life.

Platelet numbers are variable and fluctuate markedly in the first few hours and weeks of life, but stay within the reported reference interval of $211–887 \times 10^9$/L.[23,51] After 24 weeks of age, platelet number becomes more stabilized at about $400–450 \times 10^9$/L.[45] The mean platelet volume tends to increase insignificantly over the first 12 hours of life, but stabilizes quickly after that.[51]

The rapid growth rate of young pigs places a large demand on iron requirements that cannot be met by milk alone. Unless supplemental iron is provided, piglets develop a severe microcytic, normocytic to hypochromic anemia. Early contact with soil or intramuscular injection of iron dextran is recommended. Spontaneous recovery occurs about the fifth week of life when the pigs start to derive nutrients from other sources. The effect of low iron on WBC counts is variable;[56] however, iron deficient piglets have less developed immunocompetence.[57]

Pregnancy, Parturition, and Lactation

Hematologic changes occur with pregnancy, parturition, and lactation. Approximately 2 weeks before parturition, RBC values decrease and stay low until the end of lactation. Reticulocytes may be seen during this period. Total WBC number decreases during gestation, and anemia during pregnancy has been documented. Neutrophilia, left shift, and lymphopenia often occur at parturition, likely due to endogenous corticosteroids. Within 24 hours of farrowing, the neutrophil:lymphocyte ratio reverses.

HEMATOLOGIC DISEASE

Physiologic Change

Sampling stress is one of the largest sources of hematologic variation.[9] Pigs are easily stressed through handling and restraint, and the stress response develops within 2 minutes, rapidly affecting the leukogram. The total WBC and neutrophil count can increase by two to threefold. There are also reported elevations in Hgb

TABLE 113.1 Influence of age and husbandry on the hematology of young Duroc-Jersey pigs. Mean and minimum/maximum range for a single litter of five males and four females. Pigs kept on concrete until 10 days of age and then placed on soil.[a] No outliers were removed and this does not represent a reference interval.

concentration and hematocrit (Hct). Long-term stress including transport,[4] disease,[12,32,34] infection, or living conditions[14] can affect hematological values.

Pathologic Change

Anemia

Anemia is a common problem in pigs. Acute and chronic blood loss can lead to hemorrhagic anemia. Active bleeding and injury are possible as group-housed pigs commonly fight to establish social dominance. Gastric ulcers are common in pigs and have been associated with several etiologies such as finely ground feed, stress caused by management failures, and disruptions in feed intake as a result of other diseases. Proliferative hemorrhagic enteropathy caused by infection with *Lawsonia intracellularis* and hemorrhagic bowel syndrome can cause blood to accumulate in the intestinal tract. Internal and external parasites (nematodes and lice), swine dysentery, rectal prolapses, gastric or intestinal torsions, and warfarin poisoning are other potential causes of blood loss.

Nutritional deficiency of iron is a well-known cause of anemia in young pigs, which have limited iron stores, grow quickly, and are usually raised indoors with no access to iron-rich soil. Iron deficiency anemia has been largely alleviated by the ubiquitous management practice of administering supplemental iron to neonatal piglets; however, iron supplementation should not be assumed, especially in small and unconventional herds. Copper deficiency may also cause defective erythropoiesis, as it is needed for the incorporation of iron into the hemoglobin molecule.

Several infectious diseases can also cause anemia directly or secondarily through inflammatory cytokines. In general, recovery from the primary disease leads to resolution of the anemia. Porcine reproductive and

respiratory syndrome virus which infects all age swine, can induce anemia through acute bone marrow failure. Hemolytic anemia and microangiopathic hemolysis can be seen with African swine fever and chronic classical swine fever. Schistocytes are common in blood smears from these animals.

Inflammation

Leukocytosis is a common response in pigs, similar to other animals as a reaction to stress or infection. Similar to parvovirus infections in other species, porcine parvovirus causes a transient leukopenia, usually within 10 days of infection. However, infections with porcine parvovirus are often subclinical except in developing fetuses where the outcome of infection is dependent upon gestational age.

The acute phase protein (APP) response to infections, inflammation, and trauma has been recognized in pigs for over two decades with initial recognition that c-reactive protein, haptoglobin, and α_1-acid glycoprotein were biomarkers of the porcine acute phase response.[10,31] An additional porcine-specific APP named major acute phase protein (pigMAP) also has potential as a biomarker and is analogous to kallikrein-sensitive PK-120, otherwise known as inter-alpha-trypsin inhibitor H4 in human plasma.[1,17] The role of the APP in assessment of health and welfare of pigs, including their use as experimental models of human disease, has been reviewed.[3,40,59]

The porcine APP responds to a variety of infections with a selection of diseases being examined for their role in stimulating c-reactive protein, haptoglobin, α1-acid glycoprotein, pigMAP, and serum amyloid A (SAA) including bacterial (*Actinobacillus pleuropneumoniae*, *Streptococcus suis*, *Mycoplasma hyosynoviae*), parasitic (*Toxoplasma gondii*), and viral (porcine respiratory and reproductive syndrome virus) infection.[24] Increased haptoglobin concentration has been documented in porcine respiratory coronavirus infection, which is a possible model for covid-19 infection of humans.[61] APP responses to single and concurrent infections[46-48] can identify an activated innate immune reaction to infection and, though increases are variable between pathogens, the response reflects active stages of disease with falling concentrations demonstrating recovery or response to treatment.

The use of porcine APP to detect and monitor the health and welfare of pigs in production has also been the subject of extensive research[38,43]with studies examining the change in APP concentration in wasting disease,[49] pleuritis, and cranioventral pulmonary consolidation.[52] Haptoglobin concentrations at slaughter can provide valuable diagnostic information regarding rearing conditions and respiratory disease.[2] Further study of haptoglobin and SAA at slaughter has demonstrated the value of monitoring APP as an aid to meat inspection.[5,39] Haptoglobin has been shown to be a biomarker for stress in pigs, both as a result of transport[22,44] and food deprivation.[41]

Porcine APP concentration has been assessed in alternate biological fluids to determine the presence of an acute phase response without the need for blood sampling, which can be difficult and traumatic for the animal. Haptoglobin and SAA have been examined in porcine saliva,[18,19,21] while the estimation of APP in meat juice[20,25,42] at slaughter has been suggested to assist in meat inspection and the elimination of carcasses from unhealthy animals from the food chain.

Hemoparasites

There are two recognized hemotropic hemoplasmas that infect swine, *Mycoplasma suis* and *Mycoplasma parvum*. A novel hemoplasma has recently been reported in China.[16] *M. suis* is distributed worldwide and where pigs are managed intensively; it causes only sporadic disease across all ages.[26,50] In affected piglets, it presents as life-threatening hemolytic anemia, icterus, fever, anorexia, general ill-thrift, and acute death. In sows, acute *M. suis* infections may cause sudden death due to hypoglycemic coma, while milder acute forms of disease cause decreased fertility.[55] *M. suis* rarely causes spectacular death losses. It is often associated with stress, outbreaks are more likely in the summer along with other concurrent infectious diseases, parasitism, or management problems. *M. suis* is an obligate, 0.8–1.0 µm parasite that attaches to the surface membrane of RBCs and endothelial cells. It is predominantly coccoid-shaped, but may appear rod- or ring-shaped and may be found in chains, solitary, or clustered. Parasitemia is transient, making evaluation of blood smears poorly sensitive and likely underdiagnoses infection.[55] More recently, *M. suis* is diagnosed using PCR or serologic examination of relevant animal groups (whole cell ELISA or recombinant ELISAs).[26] Using quantitative PCR methods, *M. suis* prevalence of 14% and 10% was determined for weaned piglets,[50] 14% for presuckling piglets, and 31% for sows at farrowing.[54] Transmission of *M. suis* occurs with transfer of infected blood during iatrogenic or zootechnical procedures or wounds associated with infighting.[5] Vertical transmission has been recently demonstrated.[54]

M. parvum is similar to *M. suis*, but is a smaller (0.2–0.5 µm), coccoid- to rod-shaped organism, which is observed individually or in short chains. Despite heavy parasitism, *M. parvum* causes few clinical signs.[33]

There are two forms of Babesia that can infect swine. *Babesia trautmanni* is a large Babesia found in the RBCs of infected pigs. The merozoites (which are usually paired) measure 2.5–4 × 1.5–2 µm and are oval or pyriform in shape. Single forms, probably trophozoites, are ameboid or round. The host cell usually contains between one and four parasites. *Babesia perroncitoi* is smaller than *B. trautmanni*, the majority of parasites being pleomorphic, annular, and measuring 0.7–2.0 µm in diameter. *B. trautmanni* may cause severe disease in pigs from Europe, Africa, and China. *B. perroncitoi* is of similar pathogenicity, but has a limited distribution in the areas mentioned in the earlier text. The vectors of these Babesia have not been clarified, although *Rhipicephalus sp*. have been shown to transmit *B. trautmanni*.[60]

Species: Mouse (*Mus musculus*); Rat (*Rattus* sp.); Gerbil (Genera: *Ammodillus*, *Brachiones*, *Desmodilliscus*, *Desmodillus*, *Dipodillus*, *Gerbilliscus*, *Gerbillurus*, *Gerbillus*, *Meriones*, *Microdillus*, *Pachyuromys*, *Psammomys*, *Rhombomys*, *Sekeetamys*, *Tatera*, *Taterillus*); Hamster (Genera: *Mesocricetus*, *Phodopus*, *Cricetus*, *Cricetulus*, *Allocricetulus*, *Cansumys*, *Tscherskia*); Chinchilla (*Chinchilla* sp.).

INTRODUCTION

There are over 2250 known species of mammals classified within the phylogenetic order Rodentia. Individual rodent species have adapted to several vastly different environments, eat varied diets, and have species-specific behavioral traits. This chapter reviews hematologic findings in a small handful of rodent species that are commonly seen in veterinary practice. There are at least 14 species of gerbils and four subgenera. Most studies evaluating hematology in gerbils have been done using *Meriones unguiculatus*. Over 20 species of hamsters are recognized. Hematology indices for Chinese (*Cricetulus griseus*) and Syrian/golden (*Mesocricetus auratus*) hamsters are most commonly reported. There are two species of chinchilla, short-tailed chinchillas (*Chinchilla chinchilla*) and long-tailed chinchillas (*Chinchilla lanigera*). Note that, even among the small sampling of rodents discussed in this chapter, there are significant species differences in hematologic parameters. This must be taken into account when interpreting hematologic data for diagnostic purposes. Reference intervals used for diagnostic purposes should be generated or verified in accordance with the American Society for Veterinary Clinical Pathology (ASVCP) reference interval guidelines.

ERYTHRON

Rodent RBCs are anucleate; biconcave discs approximately 5–7 μm in diameter and 2 μm wide, though additional variation across different-sized species occurs. RBCs of mice, rats, gerbils, and hamsters circulate for 41–52, 42–69, approximately 30 days, and 50–70 days, respectively.[6,8,9,10,43] To the author's knowledge, chinchilla RBC life span has not been reported.

Reticulocytes comprise up to 20% of peripheral RBCs in healthy young rodents, but decrease to 2–5% in adults.[41] Polychromasia and basophilic stippling, indicative of reticulocytes, are common findings in Romanowsky-stained peripheral blood smears of healthy gerbils up to 20 weeks of age.[3,41] Low numbers of Howell–Jolly bodies and nucleated RBCs also may be observed in blood smears from normal rodents. In rats, reticulocyte life span in the peripheral blood is 1–1.5 days.[10]

LEUKON

Approximately 70–80% of peripheral blood leukocytes (WBC) in most rodents are lymphocytes. Neutrophils (or heterophils in hamsters) typically comprise approximately 20–30% of the relative differential cell count in healthy rodents. Monocytes, eosinophils, and basophils are present in very low percentages in healthy rodents. Band neutrophils, earlier neutrophil precursors, and mast cells are not typically observed in the peripheral blood of healthy rodents. A diurnal variation in leukocyte concentration has been reported in rodents;[41] however, the time of blood collection is rarely indicated in published reference intervals or noted on sample submissions. Possible seasonal variations also should be considered; e.g., WBC concentration and lymphocyte concentrations are higher in chinchillas in late winter.[22] The appearance of WBCs in rodents is similar to that of other mammals (Figure 114.1).

Rodents have numerous small, fewer intermediate-sized, and rare large lymphocytes in circulation. In Romanowsky-stained blood smears, lymphocytes have scant, lightly basophilic cytoplasm and a round nucleus with dense to clumped chromatin. The nuclear diameter of small lymphocytes ranges from approximately 6–8 µm. The life span of a small lymphocyte in rat peripheral blood is 60–100 days.[10] Intermediate-sized lymphocytes have a 10–12 µm nuclear diameter. Low numbers of intermediate-sized lymphocytes that contain magenta cytoplasmic granules can be observed in rodent blood smears. Intermediate-sized lymphocytes with more deeply basophilic cytoplasm are occasionally observed and are often considered reactive lymphocytes. Large lymphocytes can have nuclei up to 15 µm in diameter.

The predominant granulocyte in mice, rats, chinchillas, and gerbils are neutrophils. Neutrophils are approximately 10–12 µm in diameter and have abundant clear cytoplasm with small nonstaining to lightly eosinophilic cytoplasmic granules. Murine neutrophils do not contain alkaline phosphatase activity.[14] The nucleus of rodent neutrophils is often segmented, although hyposegmented forms and ring-shaped nuclei can be observed. Mature neutrophil nuclei have clumped chromatin. Neutrophils circulate for approximately 6 hours in rats.[10] In hamsters, the predominant granulocytes are heterophils. Heterophils are similar in size and appearance to neutrophils, but contain small, thin, rod-shaped, eosinophilic to variably staining, cytoplasmic granules. Toxic neutrophils/heterophils can circulate if inflammation is occurring. Toxic neutrophils and heterophils can have more basophilic cytoplasm or may contain increased numbers of eosinophilic cytoplasmic granules.

Monocytes are larger than neutrophils (approximately 15 µm in diameter) and have abundant light blue-gray cytoplasm. Clear cytoplasmic vacuoles may be seen in normal animals. The nucleus tends to be ovoid to horseshoe-shaped with finely stippled chromatin. In rats, monocytes remain in the peripheral blood for approximately 18 hours.[10]

Eosinophils are approximately the same size as monocytes (15 µm). They have pale, basophilic cytoplasm filled with eosinophilic granules and a segmented or bilobed nucleus with clumped chromatin. In mice, granules often clump together making the borders of the granules difficult to discern. Eosinophil granules are rounded in mice and rats. They are ovoid, short, thick, and brightly eosinophilic in hamsters. Rat eosinophils circulate for 18–23 hours.[10]

Basophils are similar in size to monocytes and eosinophils. They have pale, basophilic cytoplasm filled with dark purple granules and a segmented or bilobed nucleus with clumped chromatin.

PLATELETS AND COAGULATION

Much of the platelet and hemostasis research provided in Sections VI and VII of this text was performed using rodents. Rodent platelets are 1–4 µm diameter, anucleate, rounded to ovoid fragments of clear to lightly granulated cytoplasm. Platelet granules can stain basophilic to purple with Romanowsky stains. Platelet life span in mouse peripheral blood is approximately 4–5 days.[30] Whereas in rats, platelet life span is 3.7–8 days.[10] Platelet volume in CD1 mice ranged from 4.5–11.6 fL and in rats from 5.7–10.1 fL.[36] Storage of murine blood at 4 °C for 24 hours can increase mean platelet volume (MPV), likely due to swelling.

Clotting times (2–10 minutes), prothrombin times (7–15 seconds), and partial thromboplastin times (55–110 seconds) for mice are published;[17] however, critical factors such as site of blood collection, age, strain, and sex were not indicated. Similar clotting times and prothrombin times are seen in hamsters[41] and rats,[28] but partial thromboplastic times appear to be shorter. Due to tissue trauma, prothrombin time and partial thromboplastic time may be increased when blood is collected from the retro-orbital sinus. The bleeding time in mice is reported to be 50–60 seconds.[35] Bleeding time may be twice as long in other hamsters[12] and rats, but this should be replicated and confirmed.[28]

REFERENCE INTERVALS

Hematologic reference intervals vary greatly between members of the rodent family and are affected by differences between individual animals, sample collection and handling techniques, hematology analyzers, and any concurrent treatments the animal is receiving. Published reference intervals rarely include details about how samples were handled, instrumentation used, or even number of animals sampled and should be used with extreme caution when interpreting data. Few reference intervals for rodent species have been generated or verified using ASVCP guidelines, including current data available online from research companies supplying rodent species for experiments. Diagnostic interpretation of rodent

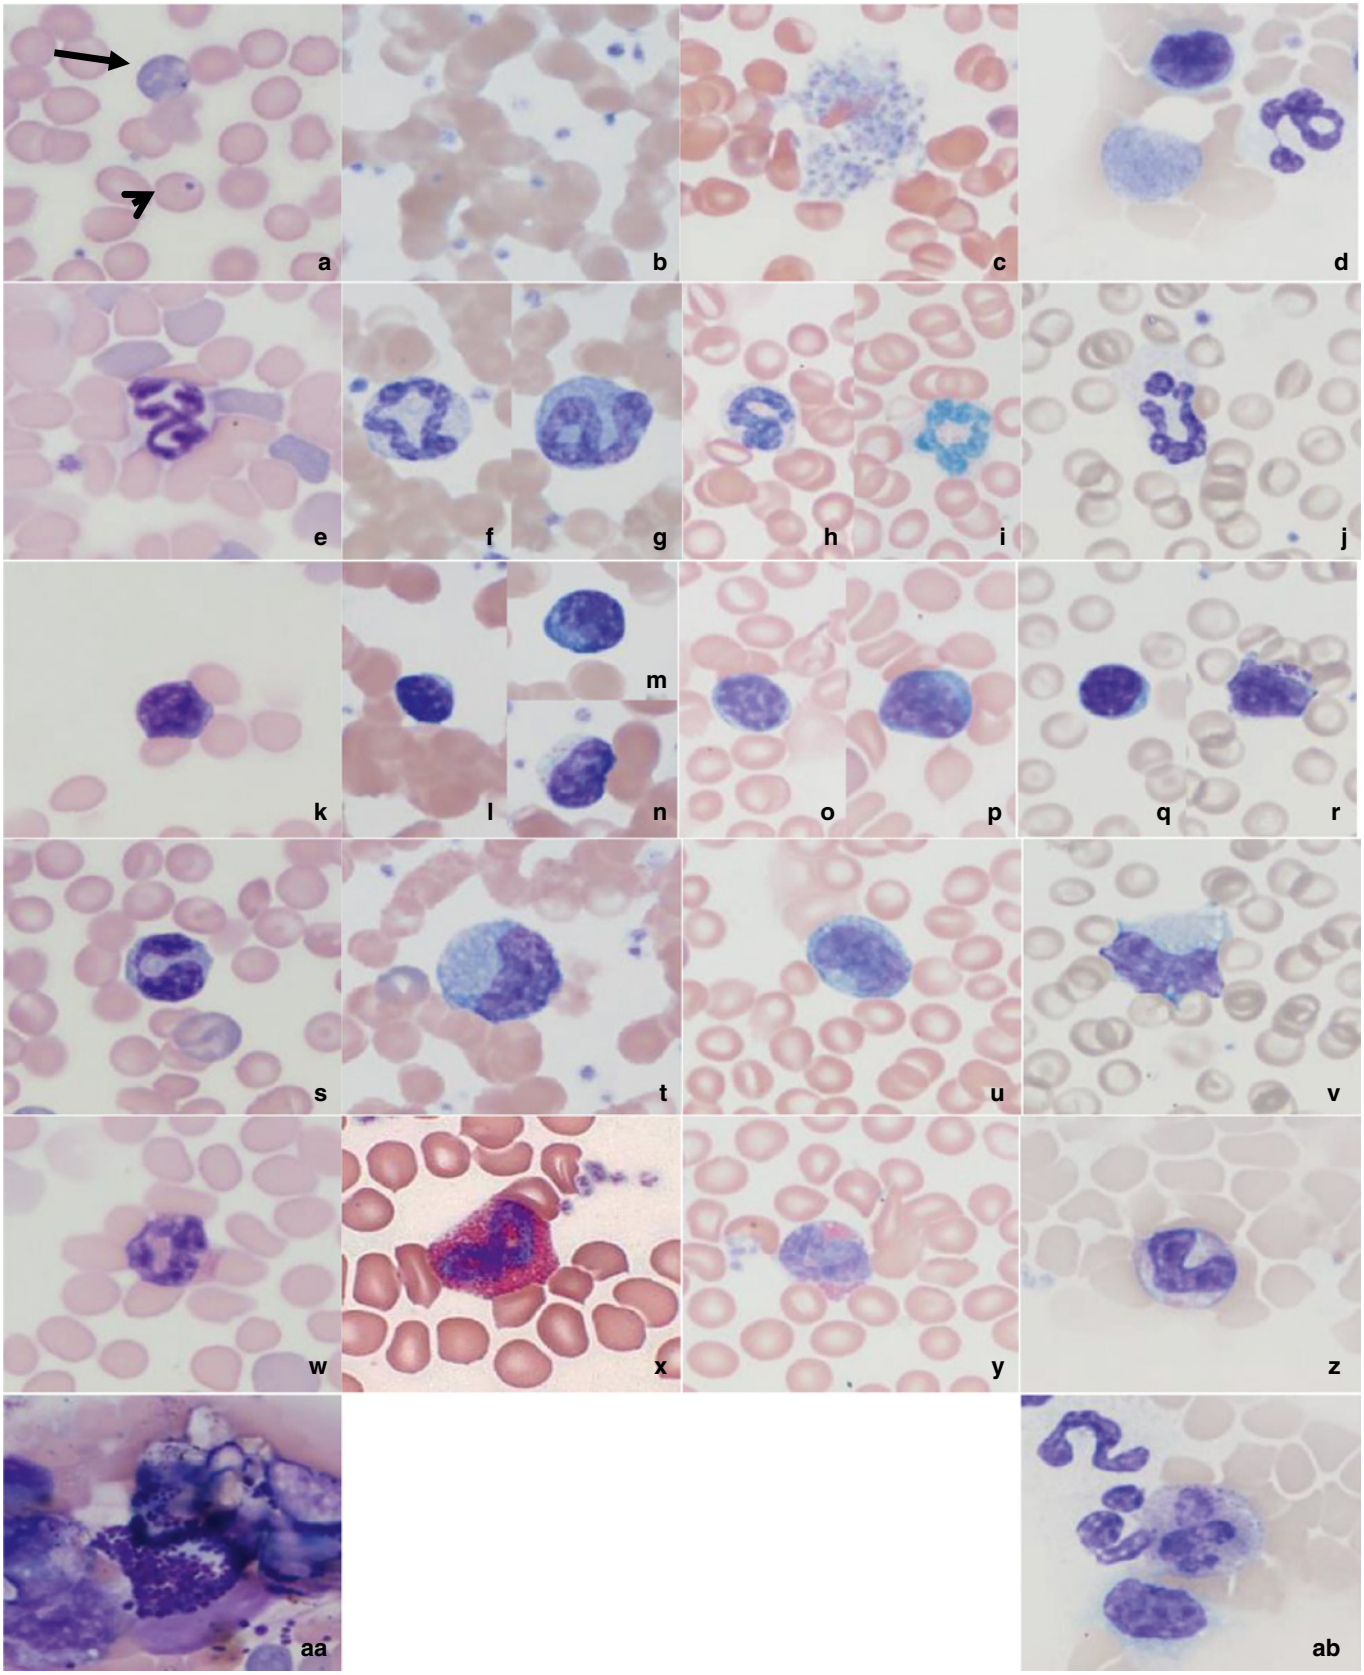

FIGURE 114.1 Representative leukocytes from a mouse (*Mus musculus*), rat (*Rattus* sp.), hamster (unknown genera), and chinchilla (*Chinchilla* sp.) (a) Mouse RBCs and platelets with a Howell–Jolly body (nuclear remnant, open arrowhead) and a polychromatophil (arrow); (b) rat RBCs and platelets; (c) hamster RBCs and a platelet clump; (d) chinchilla RBCs and an atypical giant platelet (approximately 15 μm in diameter, to the left of the neutrophil and below the lymphocyte); (e) mouse segmented neutrophil; (f) rat segmented neutrophil; (g) rat toxic neutrophil with cytoplasmic basophilia; (h) hamster segmented neutrophil; (i) hamster toxic neutrophil with prominent eosinophilic cytoplasmic granules; (j) chinchilla segmented neutrophil; (k) mouse lymphocyte; (l) rat lymphocyte; (m) rat reactive lymphocyte; (n) rat granular lymphocyte; (o) hamster lymphocyte; (p) hamster reactive lymphocyte; (q) chinchilla lymphocyte; (r) chinchilla granular lymphocyte; (s) mouse monocyte; (t) rat monocyte; (u) hamster monocyte; (v) chinchilla monocyte; (w) mouse eosinophil; (x) rat eosinophil; (y) hamster eosinophil; (z) chinchilla eosinophil; (aa) mouse basophil; (ab) chinchilla basophil.

hematology is hindered by the lack of appropriate reference intervals to date.

Some published platelet reference intervals are quite broad (100,000–1,000,000 platelets/μL of blood in mice) and should likely not be used.[17] For rats and gerbils, most publications report 400,000–800,000 platelets/μL. Hamsters are reported to have lower platelet concentration reference intervals than other rodents (200,000–500,000 platelets/μL) and platelet concentration is decreased during pseudohibernation.[32]

Partitioning Factors

It is very important to use reference intervals appropriate for the age, sex, and strain of mice (*Mus musculus*) and in rats (*Rattus* sp.). Charles River (criver.com) provides some strain-specific hematology data ranges for mice and rats that should be interpreted with caution. Compliance with ASVCP guidelines should be assessed prior to use of any reference intervals.

Variations in several rodent RBC indices occur with age. RBC concentrations tend to be lower in young animals and reach adult values by 3 months of age in mice and 4 months in rats.[28] In C57BL/6 mice, age-related changes in Hgb and RBC concentrations reflect the reticulocytosis observed in young mice of all strains: Hgb and RBC concentrations increase while mean cell volume (MCV) decreases between days 0 and 35 of life.[42] The RBC concentration of newborn Mongolian gerbils is approximately half that of adults and Hgb concentration is high; these values adjust to adult reference intervals by 8 weeks of age.[39] As expected, MCV of newborn gerbils also is high and gradually decreases until 12 weeks of age, likely due to decreasing reticulocytosis. The observation that Hgb concentration increases in mice but decreases in gerbils as they age may be due to differences in the amino acid structure of the Hgb molecules in the different species.[23]

There are published sex-specific hematologic values for different species of rodents.[41] Four-week-old, male, Sprague–Dawley rats have higher Hgb concentration, Hct, RBC concentration, RDW, MCV, and MCH, and lower MCHC than age-matched females.[20] However, both MCH and MCHC are lower in male Wistar rats as compared to females.[26] Male Mongolian gerbils have higher MCV, Hct, and Hgb concentration than females.[39]

In some species of rodents, RBC indices differ in pregnant females as compared to males or nonpregnant females. In Wistar Hannover rats pregnant for 18–19 days, Hct, RBC concentration, and Hgb concentration were decreased, while MCH, MCHC, and reticulocyte concentrations were increased, as compared to nonmated, age-matched, female rats.[27] In pregnant chinchillas, Hct and MCV increased gradually between 0 and 112 days of gestation.[19]

RBC indices in rodents also are affected by seasonal changes. During pseudohibernation of adult hamsters in the winter, RBC life span, RBC concentration, and Hgb concentration are increased.[8,35] RBC concentration, Hgb, Hct, MCV, MCH, and MCHC are all higher in chinchillas during late winter.[22] It is possible that dehydration due to pseudohibernation could be contributing to some of these differences.

Leukocyte reference intervals also vary with age, sex, and reproductive cycle, among other partitioning factors. The percentages of neutrophils and monocytes decrease, and lymphocytes increase as C57BL/6 mice age from 0–35 days.[42] The lymphocyte to neutrophil ratio (L:N) decreases in adult rats as they age.[41] As compared to female rats, male rats have a higher WBC, neutrophil, lymphocyte, and monocyte concentration, but a lower eosinophil concentration.[20] Pregnant Wistar Hannover rats were shown to have higher WBC, neutrophil, lymphocyte, and monocyte concentrations when compared to age-matched, nonmated rats.[27] Gerbils tend to have high WBC concentrations at birth, then a relative leukopenia at 4 weeks of age, and then adult values by 8 weeks of age.[39] Relative numbers of neutrophils/heterophils increase during inflammation in all rodent species and following pseudohibernation in hamsters.[35] Increases in WBC, neutrophil, and lymphocyte concentrations are observed during the first 2 months of pregnancy in chinchillas, but then decrease back to nonpregnant female values.[1,19]

As with other hematologic indices, several factors should be considered when evaluating platelet reference intervals. Platelet concentration increases between 0 and 35 days of age in C57BL/6 mice.[42] Female Sprague–Dawley rats have a higher plateletcrit and platelet concentration than their male counterparts.[20] Pregnant female Wistar Hannover rats have a higher platelet concentration than nonmated females.[27]

BLOOD COLLECTION

Blood collection from rodents can be difficult due to the small size of the animals. The recommended blood volume to collect is 1% of the patient's body weight 0.01 mL blood/g body weight and, whenever possible, blood should not be collected more than once every 2 weeks from small rodents. This means that diagnostic tests must be carefully selected to best utilize blood collected from mice, gerbils, and hamsters. Typically, mice reach puberty between 28 and 49 days of age, adult males weigh 20–40 g, and females weigh 18–35 g.[17] The reported adult murine blood volume is 6.3–8 mL/100 g body weight.[13] Gerbils tend to be slightly larger than mice with adult males reaching 65–100 g and adult females weighing 55–85 g.[4] Body weight of Djungarian hamsters (*Phodopus sungorus*) ranges from 18–25 g, Chinese hamsters (*C. griseus*) 39–46 g, Syrian/golden hamsters (*M. auratus*) 110–140 g, and European hamsters (*Cricetus cricetus*) 300–400 g.[16] Blood collection from rats and chinchillas is slightly easier than most mice, gerbils, and hamsters due to the larger size of these rodents. Rats reach puberty at 40–60 days, adult males weigh 300–500 g, and females weigh 250–300 g.[2] Rat blood volume is 5–7.1 mL/100 g body weight.[28] Chinchilla body weight is 400–500 g for males and 400–600 g for females.[16]

Differential cell counts should be determined using fresh whole blood, as WBCs can degrade during storage. In mice and rats, monocyte concentration was significantly decreased after storage of EDTA-blood for 24 hours at 4 °C.[1] Dipotassium ethylenediaminetetraacetic acid (K_2EDTA) is the preferred anticoagulant for most hematologic indices. Due to the small blood sample volume that can be collected from rodents, the needle and syringe used to collect blood can be coated with 7.5% K_2EDTA before sampling to avoid dilution of blood with the excessive anticoagulant volume provided in larger blood collection tubes. Citrated plasma is needed for most coagulation tests. Note that hemolysis, which often occurs during traumatic blood collection, will alter coagulation factors and tends to increase MCH and MCHC; and decrease platelet concentration, RBC concentration, and PCV.

There are numerous rodent blood collection sites that have been described (Table 114.1). Many techniques that lance vessels release tissue factors that affect platelet and coagulation indices. In most rodents, the lateral tail vein is the preferred site for blood collection. The tail can be warmed to 104 °C to dilate vessels. The lateral tail vein is either lanced or blood is collected directly with a needle. If the vein is lanced, the first drop of blood should be discarded, and then subsequent drops can be collected using a microhematocrit tube. Do not squeeze the tail to extrude blood, as this will release tissue factors and alter coagulation measurands.

Sample storage may induce similar changes in hematologic values found in other mammalian species. Blood from rats stored at 4 °C for 24 hours had increased MCV, and decreased MCHC and corpuscular hemoglobin concentration mean. The same was found for murine blood, although RDW also was increased.[1]

BONE MARROW COLLECTION AND EVALUATION

Bone marrow evaluation is beneficial in patients with refractory cytopenias or suspicion of leukemia. However, bone marrow collection is a terminal procedure in the mouse, gerbil, and hamster (see Chapter 141).

Megakaryocytes can be present in high numbers in healthy rodents. In rats, megakaryocytes may have nuclear fragments and variable nuclear to cytoplasmic (N:C) ratios.[7] Erythroid and granulocyte maturation in rodents are cytologically similar to other mammals; however, in neutrophils and eosinophils, ring-shaped nuclei are commonly observed. In apparently healthy gerbils, ring-shaped nuclei can comprise a third of the granulocytes in the bone marrow.[40] Lymphocytes comprise 7–21% of nucleated cells in rodent bone marrow.[7] Plasma cells and histiocytic cells are seen in low percentages. Mast cells, osteoblasts, osteoclasts, and endothelial cells may be observed rarely. No differences in bone marrow differentials were observed when male and female chinchillas were compared.[38]

Myeloid to erythroid ratios (M:E) overlap in most rodent species. The reported M:E ratio in mice is wide and ranges from 0.8–2.4.[31] Rats have a M:E approximately equal to one normally.[21] In gerbils, M:E ranges from 0.6–3.6.[40] Chinchillas are reported to have a M:E approximately equal to 0.5.[38] Hamsters reportedly have a very high M:E (8–10),[12] but the authors believe this count may be artificially increased by inclusion of lymphocyte precursors in the myeloid count.

Hematopoiesis occurs in both the bone marrow and spleen of rodents. Two to four phases of hematopoiesis are described in embryonic and fetal rodents. In mice, two phases are described with primitive hematopoiesis occurring in the yolk sac (embryonic day 7) and definitive hematopoiesis in the liver (embryonic day 10).[24] Mice are born after embryonic day 21. In gerbils, the four-phase description includes: (1) a vitelline phase (embryonic day 12), (2) a hepatic phase with thymic development (embryonic days 14–19), (3) a splenic phase (embryonic days 16–23), and (4) a medullary phase with development of secondary lymphoid tissues (embryonic days 22–24).[37] Gerbils are born after embryonic day 24.[37]

HEMATOLOGIC DISEASE

Physiologic

A common physiologic hematologic change of note is leukopenia associated with endogenous or exogenous glucocorticoids in some rodents.[41] Stress (glucocorticoids) causes lymphopenia and neutrophilia in many rodents, with a marked decrease in circulating lymphocytes, potentially resulting in an overall leukopenia. Alternately, excitement associated with blood collection in rats can alter total WBC concentrations, causing an immediate leukocytosis and increased circulating lymphocytes.

Pathologic

Hematologic diseases in rodents are diagnosed infrequently in general practice. This is likely because a hemogram is rarely performed in small rodent species. In pet rodents, the pre-anesthetic workup often includes evaluation of Hct, but may not include WBC evaluation.

Changes in the hemogram in response to disease conditions are similar to other species; e.g., anemia in laboratory rats fed an iron-deficient diet.[25] In gerbils with *Helicobacter pylori*-induced iron deficiency anemia, findings included decreased MCV and Hgb concentration, along with leukocytosis and thrombocytosis resulting from a systemic inflammatory response.[5] The mouse is commonly used as a model for anemia of inflammation; multiple bacterial infections reliably produce this condition. Exposure to cell wall components of Gram-positive bacteria produces the same in experimental rats.[33] Spontaneous renal disease in pet rodents may result in nonregenerative anemia, and a

CBC should be part of the diagnostic workup for suspected cases.[15] Other reported causes of anemia in rodents include flea infestation, intestinal bleeding, blood loss, immune-mediated hemolysis, renal disease, myelodysplastic disease, and genetic disorders. CBC values in mice, rats, hamsters, and gerbils with intestinal parasites are usually within normal ranges, but the PCV may be elevated if the animal is dehydrated from diarrhea.

Relative numbers of neutrophils/heterophils increase during inflammation in all rodent species.[35] When neutrophils are released from the bone marrow in response to peripheral inflammation, band neutrophils and earlier neutrophil precursors can be observed. Toxins and bone marrow damage can induce changes in neutrophil cytoplasm so that Döhle bodies, cytoplasmic basophilia, and/or cytoplasmic vacuolation are seen. As in other mammals, increased platelet concentrations have been associated with inflammation in rodents. In rodents with pneumonia, the total WBC concentration is not usually elevated, but neutrophilia/heterophilia and lymphocytopenia often are observed. However, neutropenia can be observed if septicemia occurs. The CBC in rats with a chronic respiratory tract infection (e.g., murine respiratory mycoplasmosis) may be normal or consistent with chronic inflammation with neutrophilia and monocytosis.

Eosinophilia is observed in rodents with ectoparasites. Additionally, lice and mites may predispose the animal to a secondary bacterial infection that may induce leukocytosis, monocytosis, eosinophilia, and basophilia.

Hematopoietic neoplasms are recognized in rodents. In aged Fischer 344 rats, large granular lymphocytic leukemia with leukocytosis and hemolytic

anemia can develop spontaneously. Hamster polyomavirus causes a multicentric lymphoma in hamsters that affects a wide range of organs and tissues. During advanced stages of this disease, the CBC is characterized by anemia and leukocytosis with circulating neoplastic cells.[29]

HEMOPARASITES

In healthy rodents, most hemoparasites appear to be nonpathogenic. *Mycoplasma haemomuris* can be observed on mice and rats' RBCs.[34] This organism is endemic in free-ranging rats (*Rattus norvegicus*) in Brazil.[11] Trypanosome trypomastigotes can be observed in peripheral blood samples from *R. norvegicus*. Recently, zoonotic trypanosomes, *Trypanosoma lewisi* and *Trypanosoma cruzi*, have been detected in fleas of rats living in close association with humans in Venezuela, which may put endemic populations at risk for re-emergence of trypanosomiasis.[18]

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathology; ADV, Aleutian disease virus; ADP, adenosine diphosphate; EMH, extramedullary hematopoiesis; CHS, Chédiak–Higashi syndrome; FHS, ferret hemorrhagic syndrome; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time.

The domestic ferret (*Mustela putorius furo*), mink (*Mustela vison*), and otters (subfamily *Lutrinae*) are members of the mammalian order Carnivora and the Mustelidae family. Mustelid hematology literature comprises predominantly research and publications related to ferret hematology, given their increasing popularity as pets as well as their utility as animal models of human disease. Hematologic parameters of both captive-bred and wild-caught mink are generally similar to those reported in common ferrets. The main otter species for which hematologic data are available are wild-caught sea otters, Eurasian otters, and river otters. Otters are uniquely adapted to a marine environment, and, consequently, certain species have hematologic profiles that are more similar to those of unrelated aquatic mammals than terrestrial mustelids.[40]

BLOOD COLLECTION AND SAMPLE HANDLING

The most common locations for venipuncture in ferrets when obtaining larger volumes of blood (1–3 mL) are the jugular vein and the cranial vena cava.[10] Other commonly described and easily accessible phlebotomy sites include the lateral saphenous vein and cephalic vein that yield smaller blood volumes still adequate for a CBC or PCV.[33] Uncommon venipuncture sites that have been described include retro-orbital bleeding and cardiac puncture, which can be highly traumatic and should only be performed with heavy sedation, anesthesia, or during euthanasia.[14] The total blood volume in ferrets is approximately 5–7% of the body weight, or approximately 75 mL/kg.[14,35] Healthy adult female ferrets weighing 750 g have an approximate blood volume of 40 mL, while adult male ferrets weighing up to 1 kg have 60 mL.[14]

Blood can be collected from otters using jugular venipuncture or the proximal aspect of the femoral vein.[38,40] Published total blood volumes in sea otters range from 91 mL/kg to 173.5 ± 9.85 mL/kg of body mass.[8]

There are no recent published studies on blood volumes in mink. Blood collection sites and procedures in mink are the same as in the domestic ferret. Blood is commonly obtained from jugular venipuncture with cranial vena cava or cardiac puncture (during necropsy) rarely utilized.[32,39]

ERYTHRON

Erythrocytes in ferrets are anuclear biconcave disks with central pallor, similar to other mammalian species, with an average diameter of 5.9 µm in males and 6.3 µm in females (range for both sexes, 4.6–7.7 µm).[26,37] Howell–Jolly bodies are observed in approximately 5% of male and female ferrets.[37] The hematocrit (Hct), total RBC count, hemoglobin (Hgb) concentration, and reticulocyte percentage are generally higher in ferrets than in dogs and cats, and the Hct and Hgb are higher than in rats.[26,37] Siperstein reported a shorter RBC life span with increased polychromasia when compared to dogs and cats.[33] Albino ferret mean relative reticulocyte counts are 4% (1–12%) in males and 5.3% (2–14%) in females.[37] The sedimentation rate of RBCs is negligible in ferrets, so longer centrifugation times (20% longer) are required.[14,37]

Mink RBCs are described as biconcave disks with varying degrees of central pallor.[13] Large singular Heinz bodies are observed in <1% of 1000 RBCs.[39] Aggregate reticulocytes range from 0–4%, consistent with the degree of polychromasia observed.[13,39] Nucleated RBCs are rarely recognized in normal mink, but can be a normal finding in postnatal mink pups.[13,21]

River otter RBCs are similar in appearance to those described for other terrestrial mammalian species.[38] Nucleated RBCs are rarely observed in river otters.[38] While some information from Tocidlowski et al. is included in this chapter, no reference intervals are presented, as it is apparent that the reference population includes outlier values which were not eliminated.[38] Sea otters have hematologic parameters more similar to pinnipeds and cetaceans than to mustelids, due to adaptation to a marine environment.[40] This includes reportedly higher Hct and Hgb values together with lower RBC counts.[40]

LEUKON

The morphology of mustelid neutrophils, lymphocytes, monocytes, eosinophils, and basophils are comparable to those of other mammals. Normal ferrets can have lower WBC counts than other mammalian species.[16] Neutrophils and lymphocytes are the most numerous cell types in mustelid species, with neutrophils outnumbering lymphocytes.[13,33,38] However, Hein and colleagues observed lymphocyte predominant leukograms in ferrets.[16] Ferret neutrophil–lymphocyte ratios range from 0.7:1 to 1.7:1.[26] Neutrophil to lymphocyte ratios are approximately equal to unity in mink, although in some animals lymphocytes predominate, and in other animals neutrophils are the dominant cell type.[13,39]

Ferret neutrophils (Figure 115.1a) have a mean diameter of 11.2 µm (10.0–13.1 µm) in males and 9.6 µm (9.2–10.0 µm) in females.[37] They have lobulated nuclei, small occasionally polychromatic cytoplasmic granules, and infrequent vacuoles, though the granules may be less prominent than in dog or cat neutrophils.[33,37] Left-shifting to band neutrophils is uncommon in healthy ferrets.[20]

The mean diameter of small lymphocytes in ferrets is 7.7 µm (6.2–9.2 µm) in males and 8.7 µm (7.7–10.0 µm) in females[37] (Figure 115.1b). Large lymphocytes are similar in size to neutrophils, with mean diameter of 11.1 µm (9.2–13.1 µm) in males and 11.9 µm (9.2–10.0 µm) in females.[37] However, this gender difference is likely not clinically significant. River otters have reactive lymphocytes with increased size, basophilia, and less-clumped chromatin, similar to those of other species.[38]

Ferret monocytes measure 12–18 µm in diameter.[37] The nuclei are round, lobulated, or indented, similar to other species. The cytoplasm is pale basophilic and may contain frequent vacuoles[37] (Figure 115.1c).

Eosinophils have a mean diameter of approximately 12.7 µm in male and female ferrets.[37] Ferret eosinophils have a one- or two-lobed nucleus and many small cytoplasmic granules which are rounder compared to neutrophils[33,37] (Figure 115.1d). Mature eosinophil granules in mink are different from mammals in that they lack a crystalline component based on ultrastructural analysis.[9] Sea otter eosinophils typically have far less pink granulation than ferrets with just a dusting of eosinophilic granules (Figure 115.1j).

Basophils have a segmented nucleus in ferrets, similar to that seen in dogs, and a mean diameter of 13.5 µm in males and 13.8 µm in females[37] (Figure 115.1e). One study in mink reported a morphologically unique ultrastructural characteristic in late-stage basophils.[9] A second population of narrow and dense cytoplasmic granules was observed in the late basophils and interpreted as secondary granules.[9]

PLATELETS AND COAGULATION

In observations by Thornton et al., platelets had a mean diameter of 1.7 µm (1.5–2.3 µm), and mean platelet volume of 19.8 µm[337] (Figure 115.1f,k). Platelets are rarely as large as RBCs (<1% of total platelets).[37] It is unknown if the large platelets (megaplatelets) represent immature cells as is assumed in some domestic animals.

In a study characterizing von Willebrand factor (vWF) in ferrets, the findings were comparable to those of other mammalian species in that a similar differential distribution of von Willebrand factor was observed along the vascular tree.[14,19] Two unique differences are noted in ferret vWF compared to other species.[14,19] Rather than ciliated bronchial epithelial cells, the bronchial mucous goblet cells stained positive for vWF.[14,19] In addition, the multimeric distribution of platelet vWF was skewed toward the smaller–molecular-weight multimers and larger-molecular-weight multimers were not released following 1-deamino-8-D-arginine-vasopressin administration.[14,19] There are few published reports on mustelid coagulation values (Table 115.2). Mustelid coagulation pathways are reported to be similar to those of other mammalian species.[5,24,36]

A study on mink platelet function found that normal mink have unique platelets that contain less ADP than

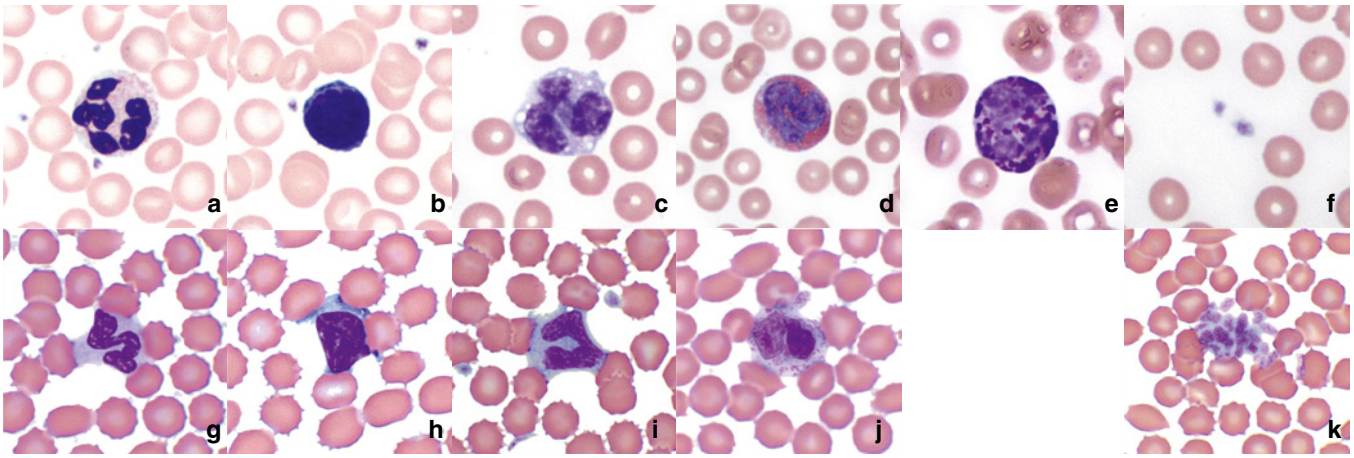

FIGURE 115.1 Comparative WBC and platelet images from selected mustelids. Modified Wright stain on 100× objective unless otherwise noted. Ferret (*Mustela putorius furo*): (a) neutrophil; (b) small lymphocyte; (c) vacuolated monocyte; (d) eosinophil; (e) basophil; and (f) individual platelets. Sea otter (*Enhydra lutris*): (g) neutrophil; (h) lymphocyte; (i) monocyte; (j) eosinophil; (k) platelet aggregate. All slides were stained using a Midas III Automated Slide Stainer with Harleco Wright–Giemsa stain. Siemens Autoslide Buffer with Harleco stain and tap water were used for ferret slides. Buffer pH 6.4 (Merck, Germany) with Harleco stain and distilled water were used for otter slides. (**Source:** Sea otter photos courtesy of Dr. Kendal Harr.)

humans and pigs, but more than in guinea pigs, rabbits, and cattle.[30] Normal mink platelets aggregated in response to stimulation with collagen, exhibited irreversible aggregation with ADP, were nonresponsive to epinephrine, and secreted more ATP than ADP when treated with thrombin.[30] After administration of serotonin and arachidonate, only shape change was observed.[30]

BONE MARROW COLLECTION AND HEMATOPOIETIC EVALUATION

The proximal femur is the most common site for bone marrow aspiration or core biopsy in ferrets; other sites of collection include the proximal humerus and the wing of the ilium.[14,35] Mink bone marrow can be obtained from the femur or the humerus, as in the domestic ferret.[9,21] In sea otters, bone marrow can be collected from the pelvis or femoral trochanter[7] (see Chapter 141).

The M:E ratio of healthy ferrets is 1.1 to 3.4:1.0. Unique morphologic features or maturation patterns of the erythroid, myeloid, and megakaryocytic lineages have not been reported in normal mustelids at the light microscope level.[21] Characteristic ultrastructural features of granulopoiesis are reported in mink.[19]

Extramedullary hematopoiesis (EMH) occurs in almost all ferrets older than 2 years, and in some can lead to splenomegaly. It is a compensatory reaction in response to either inadequate bone marrow function or increased blood cell needs, although the exact process is often undetermined. Splenomegaly found prior to anesthetic administration should be noted as a clinical finding and etiologies pursued, as splenic cysts, nodules, splenitis, and neoplasia are also etiologies. Splenectomy should not be undertaken without bone marrow evaluation, as the spleen may be the sole source of blood cells.[14,35]

REFERENCE INTERVALS

Complete blood count and coagulation data from various mustelid species are presented in Tables 115.1 and 115.2. Many factors can affect the results of hematologic profiles of normal mustelids including stress, age, gender, reproductive status, anesthesia, nutrition, and environment.

Ferrets exhibit an increase in neutrophils and a decrease in lymphocytes as they age, similar to age-related changes in other species.[20] In general, ferrets younger than 5–7 months can normally have lymphocyte predominant hemograms.[20] Younger ferrets have lower PCVs than older ferrets, similar to the known lower PCVs in young animals.[16,20] Male ferrets can have higher Hgb levels than female ferrets.[37] Young male ferrets aged 10 weeks to adult age were observed to have an age-related increase in RBC count, Hgb concentration, and Hct.[14] Young female ferrets exhibited a PCV decrease from 12 to 18 weeks old potentially due to reproductive maturation.[20] Mink experience age-related changes in the total WBC count and differential similar to other animals.[21] The total WBC count, neutrophil, and monocyte counts are higher in adult river otters than juveniles, although capture stress may contribute.[38] Adult Eurasian otters are thought to have higher platelet counts than juveniles.[12]

While one study did find increased mean PCV and Hgb concentration in male mink, no significant differences in PCV, RBC count, and Hgb concentration were observed between males and females in more recent

[a] Anesthetized, healthy, adult, captive, brown mink (n = 160). Data acquired using a Coulter S-Plus IV counter with manual differentials using Wright staining.[39]
[b] Anesthetized, healthy, 6-month-old black mink (n = 20). Data acquired using a Sysmex KX-21 without manual differentials. Results reported as mean ± standard error.[32]
[c] Eleven weeks to 9-year-old, mixed sex, unanesthetized, healthy pet ferrets (n = 106). Data acquired using a Cell-Dyn 3500 with manual differentials using modified Wright staining. Statistics and RI generation done in accordance with ASVCP guidelines.[15,16] Significant differences in age, sex, and fasted status were noted by the authors, but details were not provided.
[d] Ferrets 10–12-week-old, mixed sex, anesthetized, using cardiac puncture. Data supplied by Marshall Farms (Marshall BioResources, North Rose, NY).[14]
[e] Adult, mixed sex, apparently healthy ferrets (n > 500). Anesthetic status unknown; however, from the comparatively decreased PCV and WBC, it is possible that many of the ferrets were anesthetized. Data acquired using Sysmex XN technology, with manual differentials and PCV. RI generated in accordance with ASVCP guidelines and verified[15] (Harr, personal communication).

TABLE 115.2 Coagulation values of ferrets and mink using select methods.

Parameter	Mean ± SD	Range	Animal
Clotting time (seconds)	120 ± 0.5[a]	–	Ferret[24]
	240 ± 1.0[a]	–	Mink[24]

[a] Glass. Ferrets (n = 6) and mink (n = 3) of unspecified age, sex, and anesthetic status.[24]
[b] Fibrometer (coagulation analyzer, Becton Dickinson, Franklin Lakes, NJ). Anesthetized, healthy, adult, mixed sex ferrets (n = 18), using cranial vena cava venipuncture.[5]
[c] ACL 3000 (coagulation analyzer, Beckman Coulter, Brea, CA). Anesthetized, healthy, adult, mixed sex ferrets (n = 18), cranial vena cava venipuncture.[5]
[d] Ellagic acid added. Anesthetized, healthy, adult, mixed sex ferrets (n = 18, cranial vena cava venipuncture.[5]
[e] Lee–White method. Adult, healthy, anesthetized mink (n = 6). Sex unknown.[30]

studies.[13,32,39] In a reference population of 160 healthy, adult, captive mink, there was more variability in females: 729.58 ± 125.40 × 10^3/μL in males and 840.70 ± 259.36 × 10^3/μL in females.[39] No notable sex differences were observed in the hematologic profiles from river otters, despite trapping season coinciding with postbreeding or early gestation.[38] Moran et al. observed higher platelet counts in male Eurasian otters than females, though this was not clinically relevant.[12] Capture stress likely contributes to lymphocytopenia observed in Eurasian otters.[12]

Hematologic changes are observed in response to sedation and restraint. Ferrets anesthetized with isoflurane have significant decreases in Hct, RBC count, Hgb concentration, and WBC count; isoflurane causes splenic sequestration of RBCs.[27] The Hct is reduced by approximately 35% using isoflurane, and all of the values return to within 7–14% of baseline within 45 minutes after anesthesia.[27] Sevoflurane causes a similar drop in PCV, likely caused by a similar mechanism.[23] Weiss et al. observed that Hct, Hgb concentration, and RBC counts are 10–20% lower in anesthetized mink when compared to previously reported unanesthetized mink.[39]

The nutrition and environment of the different mustelid species also play a role in hematologic difference. The addition of a dietary antioxidant, phenozan, results in increased Hgb content of RBCs as well as a higher RBC count; although the exact mechanism is unclear, nutrition plays an important role in reducing oxidative stress levels in mink, which is important for fur quality.[3] In another study, river otters adapted to high altitudes are observed to have higher Hct, total Hgb, and RBC counts than sea-level populations.[8] Although Eurasian otters have similar diving behavior to river otters, their RBC counts are reported to be lower than river otters, and their MCV values are also higher.[12]

Platelet reference intervals are variable depending on the study possibly due to the relatively quick clotting time in ferrets of 1–3 minutes, as well as several publications that are not in accordance with American Society for Veterinary Clinical Pathology (ASVCP) guidelines. Platelet values in 106 clinically healthy, nonanesthetized, pet ferrets are 171.7–1280.6 × 10^9/L using a Cell-Dyn 3500.[16] This has more variation than earlier literature reporting ranges from 245–910 × 10^9/L in fitch and albino ferrets, 297–910 × 10^9/L in male and female albino ferrets, and 297–730 × 10^9/L.[20,37] Rui et al. presented a mean platelet value of 274.38 ± 97.34 × 10^9/L in male and female healthy minks.[32] There are a few published reports on mink coagulation values[24,30] (Table 115.2).

HEMATOLOGIC DISEASE

Anemia

Aplastic anemia (pancytopenia) is commonly associated with hyperestrogenism in ferrets due to prolonged estrus in females, exogenous estrogen administration, or in ferrets with estrogen-secreting adrenal neoplasms.[14] Bone marrow suppression of the erythroid, myeloid, and megakaryocytic lineages occurs secondary to estrogen-induced damage, and, consequently, anemia, neutropenia, and thrombocytopenia are common hematologic findings.[22] Normocytic normochromic nonregenerative anemia is a consistent initial finding in estrogen-induced anemia in ferrets. [22] Aplastic anemia was observed in 100% of ferrets in estrus without copulation in one study, with a 100% mortality rate.[22] In this same study, hemorrhages were noted in 83% of ferrets due to severe thrombocytopenia.[22] Females with severe anemia may have platelet counts <20 × 10^9/L, and one ferret had a platelet count as low as 7 × 10^9/L.[20,22]

A juvenile ferret was reportedly diagnosed with immune-mediated pure red cell aplasia.[25] The ferret presented with a severe nonregenerative anemia, lymphocytosis, and a hypercellular bone marrow with an erythroid maturation arrest.[25] In the editor's experience, this is seen with some frequency predominantly in Marshall Farms ferrets. The hypercellular description of the marrow in Malka's report is incongruous with aplasia. The editor typically interprets this fairly common presentation as nonregenerative immune-mediated anemia (NRIMA) and describes the erythroid population as having a maturation arrest to be consistent with diagnosis in dogs[34] (Figure 115.2d–f).

Splenic extramedullary hematopoiesis often plays an important role in ferrets with anemia and is a common diagnosis from splenic aspirates, particularly in ferrets with splenomegaly (Figure 115.2a).[14,35]

Oxidative hemolytic anemia was identified in a river otter that presented with an acute anemia (PCV = 29%) and red-brown urine containing numerous Hgb casts.[31] More than 90% of the otter's RBCs contained single large Heinz bodies and eccentrocytes were frequently observed on blood smear evaluation.[31] The toxin exposure was determined to be minnows containing methylene blue.[31]

Leukogram Changes

Lymphocytic and myeloid leukemias are rarely observed in ferrets and are poorly characterized. The authors and editor have observed a case of probable myelogenous leukemia in a 6-month-old spayed female ferret that presented for lethargy and weight loss. Hematologic findings include a nonregenerative anemia, thrombocytopenia, and a marked leukocytosis (WBC 79,670/μL). The differential WBC count was comprised primarily segmented neutrophils without toxicity, metamyelocytes, band neutrophils, monocytes, and myelocytes. Small lymphocytes and eosinophils were <1% of the count (Figure 115.2c). A touch impression of the bone marrow was of variable preservation, but myelogenous leukemia was supported by a monomorphic infiltrate of a left-shifted myeloid series (M:E ratio approximately 10:1). The infiltrate consisted predominantly of myelocytes and metamyelocytes with few bands and an apparent maturation arrest at the myelocyte-metamyelocyte stage with a storage pool depletion. Immunophenotypic and cytochemical characterization for leukemia classification in ferrets is needed. Cross-reactive and partially

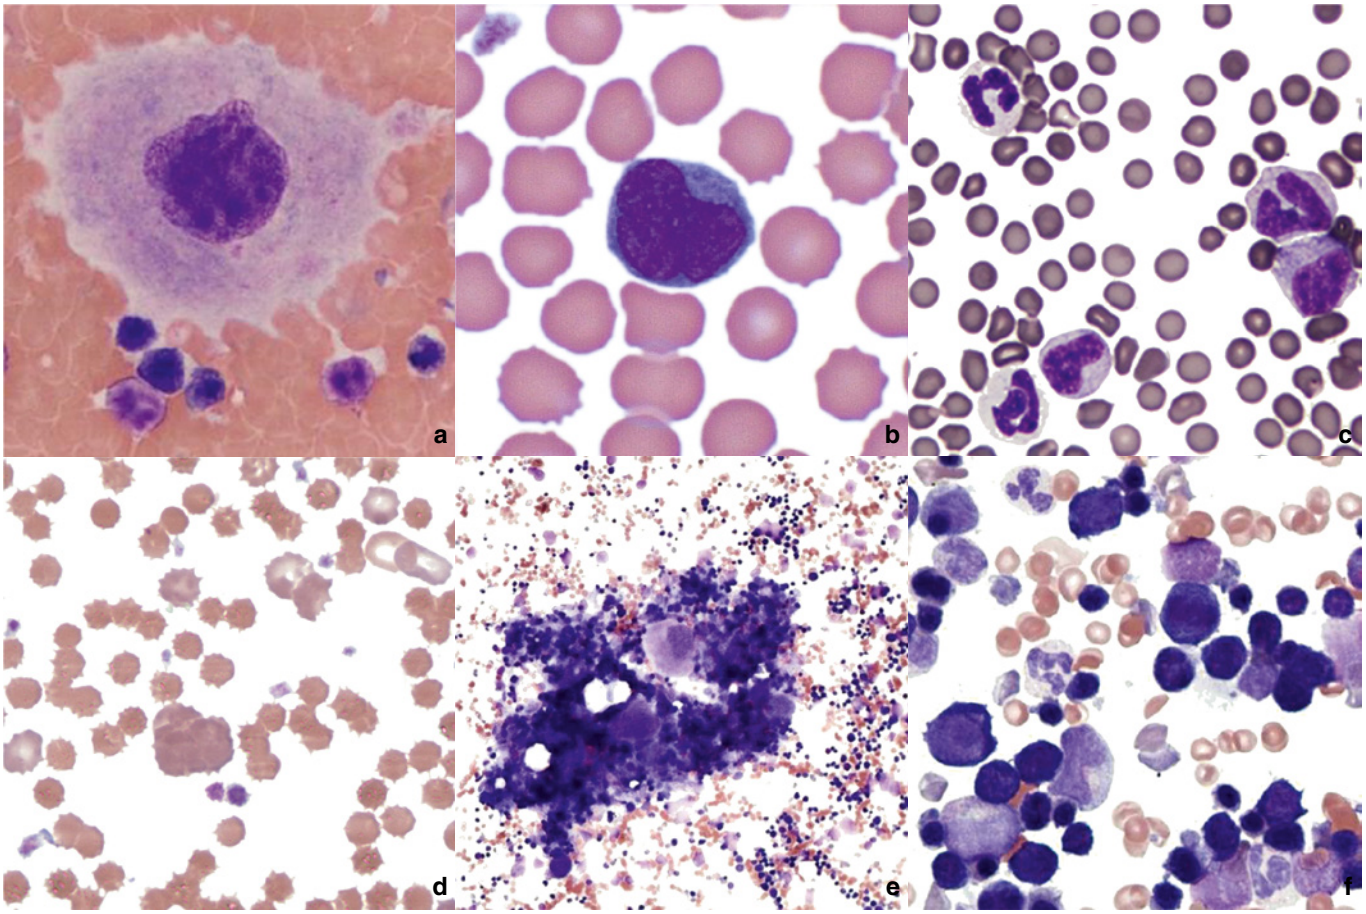

FIGURE 115.2 Abnormalities seen in ferret peripheral blood or spleen. (a) Megakaryocyte indicating extramedullary hematopoiesis, splenic aspirate, 100× objective; (b) Lymphoblast in circulation in apparently healthy ferret; (c) Probable myelogenous leukemia. Neutrophils are left-shifted to myelocyte in image. Myeloblasts were also found (not pictured) 50× objective; (d) Reticulocyte agglutination occasionally found in ferret peripheral blood exhibiting immune-mediated anemia; (e) and (f) Bone marrow aspirate from a ferret with nonregenerative anemia (presumed immune-mediated) exhibiting erythroid hyperplasia and apparent maturation arrest, 20× and 50× objectives. validated CD3, CD20, CD14, and CD18 antibodies (Veterinary Diagnostic Laboratory, Michigan State University, Lansing, MI) are available.[28]

The most common clinicopathologic finding in ferrets with lymphoma is anemia. Lymphocytosis and atypical lymphocytes in peripheral blood are relatively uncommonly reported, though occasionally found in lymphoma-afflicted ferrets.[1,11] In young ferrets with lymphoma, a lymphocytosis is more commonly observed than a lymphopenia, which is more commonly noted in older ferrets.[11,14] Atypical circulating lymphocytes are occasionally observed in lymphoblastic lymphoma, but have low sensitivity for disease detection.[4,11] In young ferrets with mediastinal lymphoma, circulating lymphoblasts are a reported feature.[4] In ferrets with lymphoma over 3 years old, atypical lymphocytes are less commonly observed in peripheral blood.[11] Lymphoma diagnosis should include evaluation of lymph node and splenic and/or bone marrow biopsies.

Eosinophilic gastroenteritis in ferrets, though not commonly reported, can result in a peripheral eosinophilia.[14] The exact etiology of eosinophilic gastroenteritis in ferrets is unknown; no parasitic- or allergen-related associations have been identified to date.[14] In a study of ferrets with eosinophilic gastroenteritis, eosinophil concentrations ranged from 1190–3290/μL.[14] Ongoing monitoring of peripheral eosinophil counts can be an adequate method for determining response to treatment and disease progression.

Aleutian Disease Virus

Aleutian disease virus (ADV) is a parvovirus affecting primarily mink, though it rarely can affect ferrets. Ferrets with ADV may have variable clinical findings and hematology test results are nonspecific requiring further diagnostics (PCR) to confirm diagnosis. Experimental ADV infection of mink results in a severe anemia within several months of infection.[29] The proposed mechanism of the anemia is increased RBC destruction, which may be accompanied by decreased or inadequate erythropoiesis. Leukopenia and thrombocytopenia are observed in later stages of infection.[29] Characteristic findings of Aleutian disease in mink include hypergammaglobulinemia and histologic tissue infiltrates of lymphocytes and plasma

cells.[29] Similar lymphoplasmacytic tissue infiltrates were observed in a case report of a pet ferret with spontaneous Aleutian disease; however, interestingly, the hypergammaglobulinemia typically seen in infected mink was not noted.[41]

Hemoparasites

Blood parasites have been reported in mustelids. A *Hemobartonella*-like organism has been reported in a river otter.[17] The affected animal presented with a normocytic normochromic anemia (PCV 12%) with slight polychromasia and anisocytosis, and moderate numbers of parasites were observed on blood smear evaluation as in other species.[17] Microfilariae, most suggestive of *Dirofilaria lutrae*, were identified in approximately 20% of examined river otter blood smears over a 6-year period, though clinical disease was inapparent in those animals.[38] The same study reported lower median MCV of unknown significance in microfilaria-positive animals.[38] *Babesia microti*-like parasites were reported in a North American river otter without any clinical signs.[6] Intraerythrocytic piroplasms were observed in 1–2% of the RBCs; although no hematologic abnormalities were noted, the pathogenic potential of this parasite is unknown.[6] *Babesia sp. NV-1* was detected molecularly in an American mink in Japan.[18]

HEMOSTATIC DISORDERS

Approximately 30 cases of ferret hemorrhagic syndrome (FHS) in 8–24-week-old kits were reported in 2006.[35] They had all recently been shipped from a commercial breeder. Usually, the only clinical signs were acute hemorrhage and death. The disease is now rarely reported; however, the author (CJD) sees about one case a month in recently shipped ferrets from 6–8 weeks of age. The few affected ferrets that had coagulation panels analyzed showed prolonged prothrombin time (PT) and partial thromboplastin time (PTT). Unfortunately, sampling for coagulation panels has not been possible as the ferrets are found dead, having no previous signs. Live animal testing is necessary to further document this disease and elucidate its pathogenesis. Epistaxis, bleeding from mucosal surfaces, and body cavities filled with hemorrhage are found at necropsy. No etiologic agents have been found upon histologic examination of tissues. Once severe hemorrhage has started, it is usually fatal. Ferrets who seem to recover may relapse. Based on this, and the age of the affected ferrets, a genetic component is strongly suspected.[35]

Rodenticide intoxication should be included as a differential diagnosis for any hemostatic disorder. Rodenticide in wild populations is a significant cause of anemia and hemorrhage. Anticoagulant rodenticides reduce the synthesis of vitamin-K-dependent coagulation factors through inhibition of vitamin K epoxide reductase (see Chapter 89).

Mink are one of the species affected by Chédiak–Higashi syndrome (CHS), an inherited platelet disorder. Chédiak–Higashi syndrome is characterized by altered pigmentation, abnormal giant neutrophil granules, and platelet-related bleeding due to abnormal platelet granulation (see Chapters 82 and 146). Anistoroaei et al. found the *LYST* gene to be responsible for the Aleutian (color) phenotype and associated Chédiak–Higashi syndrome.[2] Hematologic findings include markedly prolonged bleeding and prolonged coagulation times.[30] In a study characterizing platelets from mink with CHS, platelets from affected animals have an impaired aggregation response to collagen as well as a lack of serotonin.[30] They have a near absence of the nucleotide storage pool, comprising 38% of ATP and 9.6% of ADP found in normal mink platelets.[30] In CHS-affected mink, the release of Ca^{2+} and Mg^{2+} was 56% and 28% of normal, respectively.

CHAPTER 116

Hematology of Cavies

SAMANTHA J. M. EVANS and KURT L. ZIMMERMAN

Introduction
Erythron
Leukon
Platelets and Coagulation
Bone Marrow
Reference Intervals
Partitioning Factors
Hematologic Disease

Acronyms and Abbreviations

F, female; KC, Foa-Kurloff cells; M, male; NS, not specified; PLT, platelet; SD, standard deviation; SE, standard error; WG, Wright–Giemsa.

INTRODUCTION

Caviidae is a family of rodents native to South America, which includes domestic and wild guinea pigs (*Cavia sp.*) along with the capybara (*Hydrochoerus hydrochaeris*), mara (*Dolichotis patagonum*), and rock cavy (*Kerodon rupestris*). The vast majority of what is known about cavy family hematology is due to study of the domestic guinea pig (*Cavia porcellus*). Guinea pigs have been used extensively in biomedical research, and additional information for laboratory strains used in research can be found in Chapter 118. This chapter focuses on clinical aspects of hematology for the exotics, zoo, or wildlife practitioner.

Blood collection from guinea pigs can be challenging and is a balancing act of determining the blood volume needed for analysis and selecting a vessel or method that will supply the required quantity without threatening the animal's well-being. Up to 100–400 µL of blood can be obtained from the lateral saphenous or tarsal veins by filling microhematocrit tubes from the clear hub of a sterile hypodermic needle (23–27 gauge), or using gentle aspiration into a 1 cc syringe.[5] Larger volumes (1–2 mL) can be obtained from the jugular or femoral veins, or cranial vena cava (personal communication, Angela Lennox), in sedated or anesthetized animals.[5,28] For research purposes, blood collection methods that yield significantly larger volumes of blood include cardiac, abdominal aorta, or cranial vena cava punctures (generally used as a terminal procedure in anesthetized animals).[29,35] The blood volume of the adult guinea pig is approximately 69–75 mL/kg of body weight, and about 8–10% of the blood volume (0.5–0.7 mL/100 g of body weight) can be safely drawn in a single collection from a healthy guinea pig.[28]

ERYTHRON

Guinea pig RBCs have mild to moderate anisocytosis with a diameter ranging between 7.1 and 8.3 µm (Figure 116.1).[39] The guinea pig RBC is the largest in comparison with other common laboratory rodents, with a mean cell volume (MCV) of approximately 85 fL.[22,24] Best estimates of guinea pig RBC life span range from 60 to 80 days.[39] RBC indices in normal guinea pigs (i.e., RBC count, hemoglobin (Hgb), and PCV) are relatively low when compared with the values observed in other laboratory rodent species, and are more similar to those seen in rabbits.[24,39,41] Historical RBC indices tend to be lower than values observed in specific-pathogen-free (SPF) guinea pigs from more contemporary studies. Along with historically higher mean WBC counts, this suggests that subclinical disease may have contributed to a mild anemia and leukocytosis in previous reports.[24]

LEUKON

Cavian heterophils are varyingly referred to as neutrophils, depending on the source, and are the functional counterpart of the neutrophil in other species.[42] Heterophils are approximately 10–12 µm in diameter, have a condensed, segmented nucleus (with up to five or more segments), and fine, variably eosinophilic cytoplasmic granules, causing some to refer to them as "pseudoeosinophils" (Figures 116.1, 116.2a, and 116.3a).[27,34,41] As with other mammals, a "drumstick" X chromosome lobe (Barr body) may be present on heterophil nuclei in female guinea pigs.

Lymphocytes are the predominant leukocyte, and small lymphocytes (Figures 116.2b and 116.3c), which are present in greater numbers than large lymphocytes, are not much larger than RBCs. Cavian small lymphocytes have a round, condensed nucleus surrounded by a narrow rim of cytoplasm. Intermediate (approximately 1.5× the size of a RBC) and large lymphocytes (up to double the size of a small lymphocyte), with a less condensed, more oval-shaped nucleus and an expanded amount of pale to moderately basophilic cytoplasm, are also observed.[41] These larger lymphocytes may contain variably sized azurophilic granules (Figure 116.2c).[34] Large granular lymphocytes from the peripheral blood of guinea pigs have been shown to demonstrate cell-mediated cytolytic activity in vitro.[14]

Occasional Foa-Kurloff cells (or Kurloff cells, KC), which are unique to cavian species, may be observed in circulation, accounting for up to 3–4% of the differential leukocyte count in guinea pigs.[23,27] The KC is a specialized mononuclear leukocyte that contains a large (1–8 µm), intracytoplasmic, finely granular to fibrillary, eosinophilic inclusion body consisting of mucopolysaccharide (Figures 116.2g–i and 116.3a).[23,29] The inclusion is membrane-bound, displaces the nucleus, and is metachromatic and periodic acid–Shiff (PAS)-positive.[29] KCs are known to be estradiol-dependent with increased numbers found in the peripheral blood of females compared with males.[30] Among females, their numbers also increase with pregnancy and fluctuate with different stages of the estrous cycle.[3,23] In addition to peripheral blood, they are found in large numbers in the spleen, thymus, bone marrow, and pulmonary capillaries, rarely in lymph nodes, and within vascular channels of the placenta, where they may help prevent maternal rejection of the fetal tissues.[24,30,3] KCs are counted as lymphocytes in the leukocyte differential count in peripheral blood. The exact origin and function of these cells are unknown, although it has been speculated that they may function similarly to natural killer cells.[24,42] These cells have been observed in the peripheral blood and organs of capybara (Figure 116.3a), as well as other species found in the family Caviidae.[19] They are also found in paca (*Cuniculus sp.*), which is in the superfamily, Cavioidea, but separated into the family, Cuniculidae (personal communication, Kendal Harr).

The morphology of cavian monocytes is very similar to that of common domestic species and humans. They are usually larger than the large lymphocytes (about 13–17 µm in diameter), have an oval to reniform or amoeboid nucleus with a dispersed chromatin structure, and have a gray-blue, occasionally vacuolated cytoplasm that is darker than the cytoplasm of large lymphocytes (Figures 116.2d and 116.3d).[35,42]

Cavian eosinophils are easily distinguished from heterophils ("pseudoeosinophils"). They are larger than heterophils (about 10–15 µm in diameter), have a less-segmented nucleus with a less-clumped chromatin, and dense, round, brightly eosinophilic granules that almost completely fill the cytoplasm (Figures 116.2e and 116.3b).[35,42]

As with many mammalian species, basophils are uncommonly found in guinea pig blood except in association with parasitic infection, along with eosinophilia.[37] They are slightly larger than heterophils (about 10–14 µm in diameter) and have a lobulated nucleus. Their cytoplasm is closely packed with round, dark purple granules of varying size (Figure 116.2f).[28,42]

PLATELETS AND COAGULATION

Guinea pig platelets are typically quite small (2–3 µm), with an oval, irregular, or spindle shape and fine purple granulation (Figure 116.1). By electron microscopy, their platelets contain many dark granules (dense bodies) and an open canalicular system.[25] Reference values for circulating platelet counts have been reported to vary from about 250 to 850 × $10^3/\mu L$[24] and tend to be lower than in other laboratory rodents.[35] Coagulation studies demonstrate that the guinea pig has a longer prothrombin time than other domestic species, and a relatively

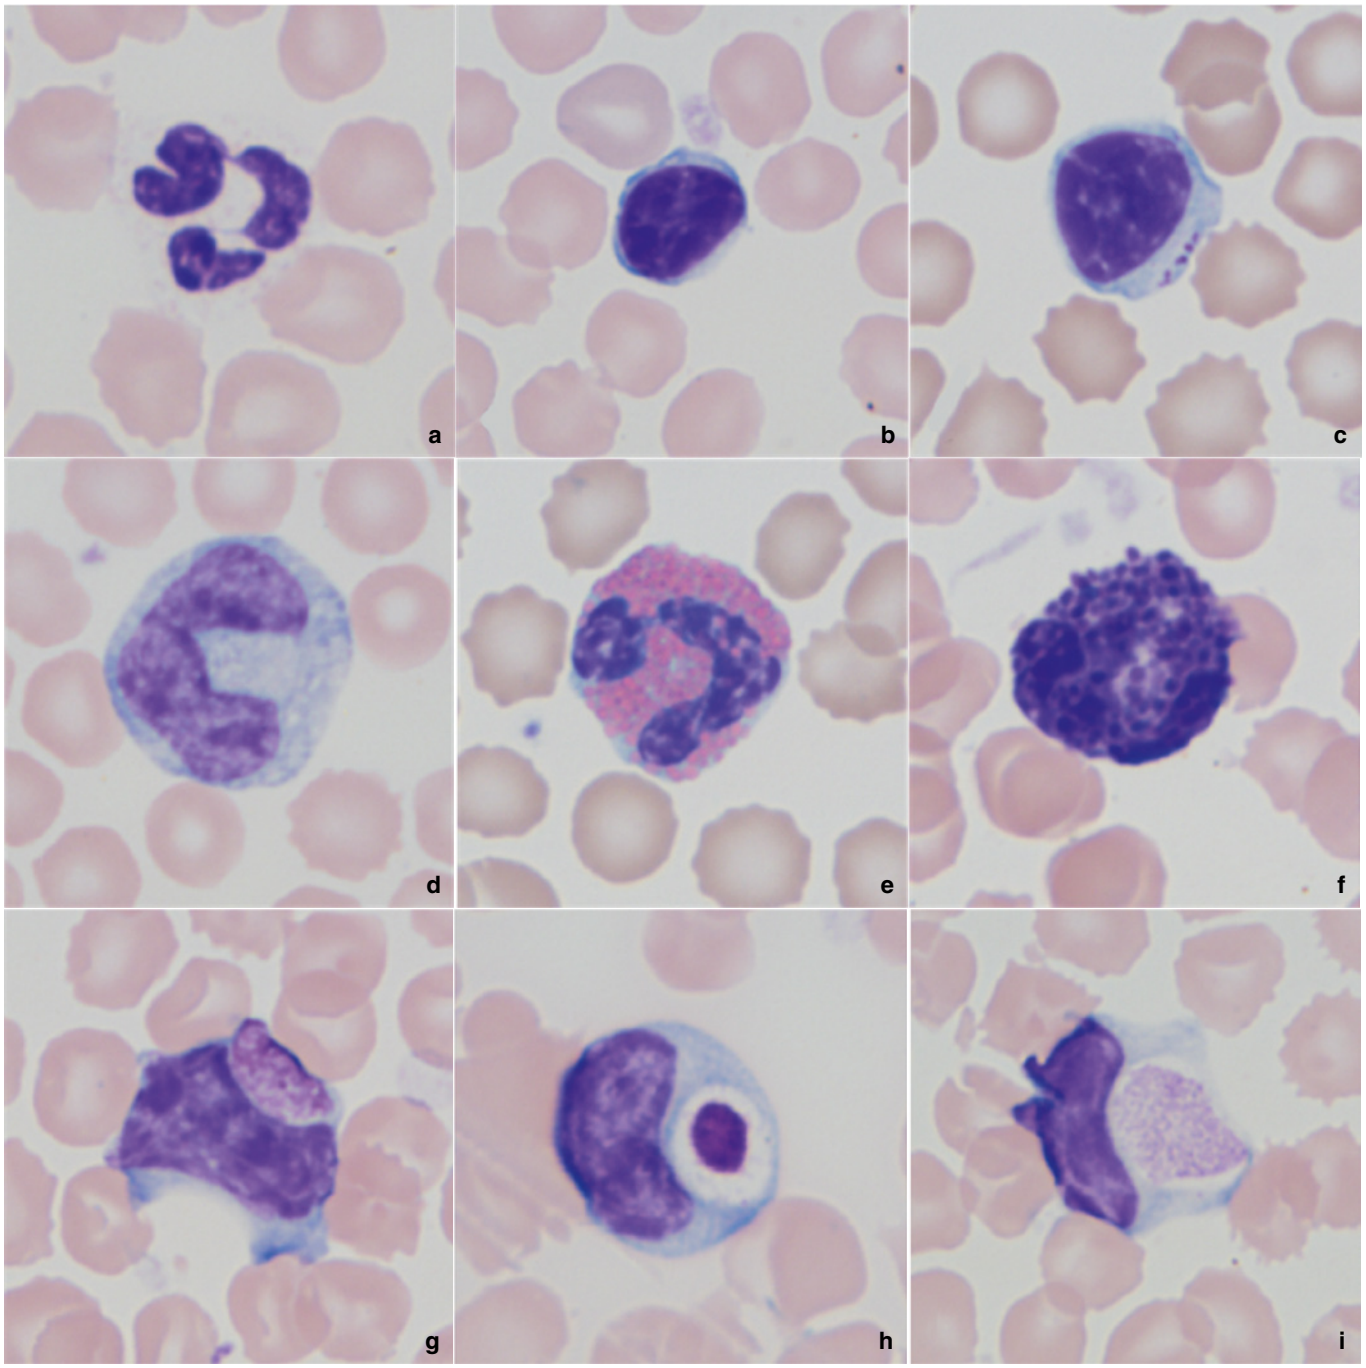

FIGURE 116.2 Normal leukocytes found in guinea pig blood. (a) Heterophil with faint, fine eosinophilic granulation; (b) Small lymphocyte with scant cytoplasm; (c) Intermediate-size lymphocyte with expanded cytoplasm and azurophilic granules; (d) Monocyte with irregular nucleus and foamy basophilic cytoplasm; (e) Eosinophil with numerous small, round, brightly eosinophilic, slightly refractile granules; (f) Basophil with numerous small, round to oval, deeply basophilic granules; (g)–(i) Variable appearance of Foa-Kurloff cells, each with a single, large, eosinophilic, cytoplasmic inclusion. Modified WG stain (1000× magnification).

long partial thromboplastin time.[21,39] Variability in reported coagulation parameters is undoubtedly derived in part from the variety of methods that have been used. Thromboelastography (TEG) has also been reported in guinea pigs which were shown to have a shorter *r* (time to initial clot formation), shorter *k* (time to reach an amplitude of 20 mm), and higher maximum amplitude (MA), indicating that guinea pigs are hypercoagulable and have increased clot stability compared with humans.[21]

BONE MARROW

Bone marrow can be obtained from the femur, tibia, or iliac crest in live guinea pigs under general anesthesia.[34,35] Collection of a small volume of marrow (3 µL) into a glass capillary is recommended to avoid excess blood contamination, and use of anticoagulant is usually not necessary if slides are made quickly. Postmortem collection can also be obtained by splitting the femur (or another bone) with bone cutters and using a paint brush to spread the marrow across a glass slide[35] (see Chapters 141 and 118).

Bone marrow components in guinea pigs are similar to those observed in other species (Figure 116.4), with the addition of Kurloff cells found as scattered individual cells or small clumps, particularly in the metaphyseal region.[14,30] The M:E ratio has been estimated to be between 1.5 and 1.9 in normal guinea pigs.[9,14,28] As in many mammals, the cellularity of guinea pig bone marrow decreases proportionally with age, and appears to vary slightly based on location (i.e., guinea pig femur and tibia marrow is less cellular than rib, sternum, and vertebrae).[17,39] Indications for bone marrow evaluation in guinea pig patients include cavian leukemia, unexplained peripheral cytopenia(s), or suspicion of other infiltrative bone marrow neoplasia; however, at the author's institution, the latter two are rarely encountered clinically. Although bone marrow evaluation is relatively common in the research setting for a variety of purposes,[39] reports in clinical practice are not widely available.

REFERENCE INTERVALS

It is difficult to find hematologic studies on cavies which fully comply with the guidelines for reference interval generation set forth by the American Society for Veterinary Clinical Pathology (ASVCP).[11] Guinea pig hematology studies were performed in the 1950s and so analytical methods are now significantly different.[2,4,14]

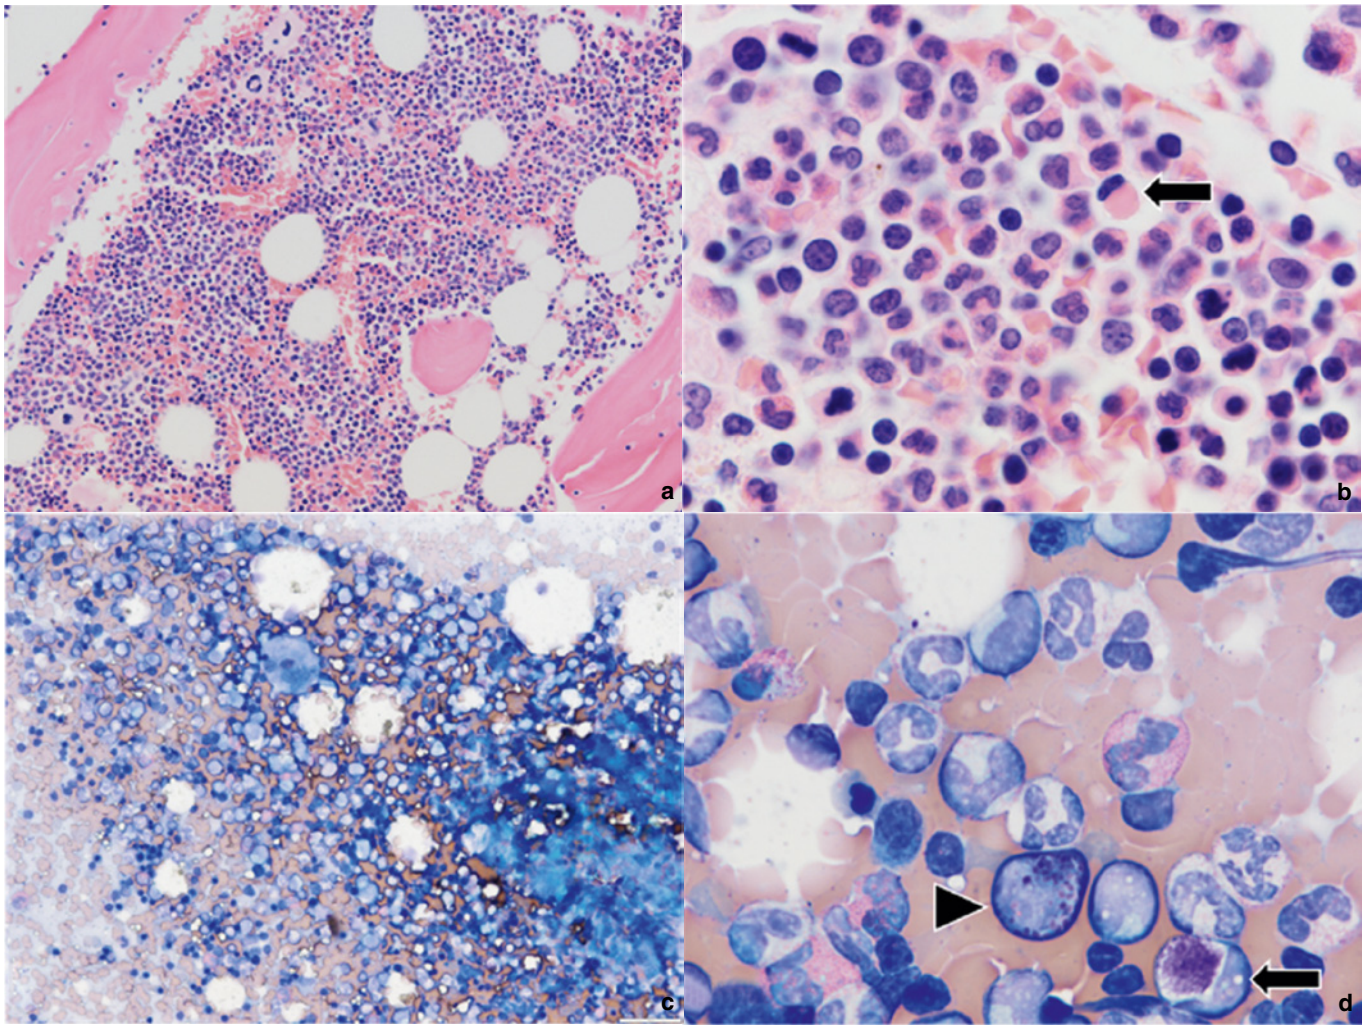

FIGURE 116.4 Normal bone marrow from an adult (7-month-old) female Hartley guinea pig demonstrating a heterogenous combination of megakaryocytic, granulocytic, erythroid, and monocytic lineages; lymphocytes; plasma cells; histiocytes; and Kurloff cells (KC). (a) and (b) Histologic section of the femur. (a) Several megakaryocytes, lipid vacuoles, and bony trabeculae are seen at low magnification; (b) A KC (arrow) admixed with various hematopoietic cells is seen from higher magnification. H&E stain ((a) = 200×; (b) = 1000× magnification). (c) and (d) Cytologic smears. (c) A large megakaryocyte can be seen on the periphery of a cellular bone marrow particle at low magnification; (d) Several heterophil precursors, four eosinophil precursors, one basophil precursor (arrowhead), a KC (arrow), and varying stages of erythroid precursors seen at higher magnification. Modified WG stain ((a) = 200×; (c) = 1000× magnification). Slides courtesy of Dr. Kelly Santangelo and Dr. Mary Afzali at Colorado State University.

Therefore, this chapter aims to represent the best data available for these species with the recognition that the information may be imperfect.

Partitioning Factors

As in many species, age may be a significant partitioning factor. PCV is lower in young (<30-day-old) animals than in adults, except in the first few days postnatal, in which the PCV is reported to be equal to or higher than adult levels.[26,39] Reticulocyte counts are generally higher in immature guinea pigs relative to adults, which have average estimates between 0.9% and 2.3%, depending on the study.[22,26,39] Reference interval studies from client-owned patients are not readily available; descriptive statistics from one study of laboratory animals are presented (Table 116.1).

Data are conflicting with regard to differences between sexes, with some studies reporting a significant difference in some values and others reporting no differences.[22,39,42] Even when sex differences are found, discrepancies exist in the literature as to the direction of difference (e.g., some reports find Hct/PCV is greater in females than males, and others find the opposite).[22,42] Perhaps differences in reproductive status at the time of sampling could explain some of these discrepancies. Nevertheless, sex does not appear to be a consistent partitioning factor of guinea pig hematology.

TABLE 116.1 Hematologic parameters for the guinea pig (Cavia porcellus).[22]

Number of animals (sex)	83 (M) Mean (± SD)	53 (F) Mean (± SD)
RBC (× 10^6/μL)	5.7 (± 0.5)	5.5 (± 0.3)
PCV/Hct (%)	48 (± 4)	47 (± 3)
Hgb (g/dL)	14.6 (± 1.1)	14.5 (± 1)
MCV (fL)	83.5 (± 2)	84.4 (± 1.7)
Mean corpuscular hemoglobin (MCH, pg)	25.4 (± 1.3)	26.3 (± 1.5)
Mean corpuscular hemoglobin concentration (MCHC, g/dL)	30.4 (± 1.8)	30.9 (± 2)
Reticulocytes (%)	1.2 (± 0.9)	0.9 (± 0.8)
WBC (× 103/μL)	6.1 (± 2)	5.6 (± 1.8)
PLT (× 10^3/μL)	427 (± 63)	448 (± 75)

HEMATOLOGIC DISEASE

Guinea pigs are common laboratory animal models, and the myriad of hematologic diseases experimentally induced in this species is beyond the scope of this chapter (see Section 2 and Chapter 118). Primary hematologic disease is uncommon as a presenting concern for guinea pigs in clinical practice.[23] However, the following clinically significant conditions have been reported.

Nonregenerative anemia is a common finding in aged guinea pigs affected by chronic renal disease secondary to advanced nephrosclerosis.[3,24] Flea-bite anemia has been reported secondary to infestation with *Ctenocephalides felis*, the cat and dog flea, and *Nosopsyllus fasciatus*, the northern rat flea.[24,40] Anemia is also associated with vitamin C deficiency.

Guinea pigs appear to be relatively resistant to the effects of steroids in that the numbers of circulating lymphocytes are not markedly reduced by corticosteroid injection.[24,39] Thus, a corticosteroid-induced stress leukogram characterized by lymphopenia is not expected in this species. As with many other species, eosinophilia with or without basophilia have been documented secondary to a number of parasitic infections, including mites, ticks, nematodes, and others.[24,37] Heterophilia, monocytosis, eosinophilia, and basophilia have been reported to rise between two and four times preinfection values in guinea pigs experimentally infected with *Trixacarus caviae* (guinea pig mange).[33] Neutrophilia (heterophilia) and/or lymphocytosis have been reported in response to experimental bacterial and viral infections as well.[13,36]

Lymphocytic leukemia has been well-described in guinea pigs, with leukocyte counts of 200,000/μL or greater.[3,8,16] At the author's institution, cavian leukemia is the most common hematologic disease encountered in pet guinea pig patients. Guinea pigs possess an endogenous type C retrovirus which has been associated with leukemia and exogenous transmission in an inbred strain of guinea pigs,[12,20] but spontaneous viral-induced leukemia has not been well-established in a natural setting. An immunocytochemical assay for immunophenotyping of leukemia and lymphoma (as T-cell or B-cell phenotype) has been developed for this species.[10]

Hypovitaminosis C (also known as scurvy) is a multisystemic disease affecting guinea pigs and other species (primates, bats, and others) that lack the hepatic enzyme l-gulonolactone oxidase to produce ascorbic acid (vitamin C).[24] Vitamin C is an antioxidant and a necessary cofactor in collagen biosynthesis. A spectrum of clinical findings, due to defective collagen and capillary fragility, manifest as subcutaneous, periarticular, and possibly pericardial hemorrhage. These patients may develop both anemia, secondary to blood loss, and coagulopathy, manifested as a high normal to increased prothrombin time.[29,32,43] Somewhat paradoxically, vitamin-C-deficient guinea pigs have also been reported to have normal platelet concentrations up to significant thrombocytosis.[3]

Guinea pigs are important natural reservoirs of *Trypanosoma cruzi* (Chagas disease in humans) in South America,[6] though clinical signs and pathologic findings in naturally infected guinea pigs have not been well characterized. Experimentally, guinea pigs demonstrate infection kinetics and pathologic changes, especially myocarditis, similar to those found in the human disease.[7] Capybara are considered to be asymptomatic reservoirs of *Trypanosoma evansi*,[1] an important pathogen of horses, and have been shown to be seropositive for antibodies against *T. cruzi*.[38] *Leishmania enriettii* is a parasite mainly found in guinea pigs which causes cutaneous leishmaniasis.[27] Although the parasite is thought to be spread hematogenously, detection in the blood has not been reported. Similarly, naturally acquired toxoplasmosis, infection with *Toxoplasma gondii*, has been described in guinea pigs[24] and is potentially hematogenously spread. Experimental infections with many other hemotropic organisms have been performed in guinea pigs, which are beyond the scope of this chapter.

INTRODUCTION

European rabbits (*Oryctolagus cuniculus*) are frequently used as an experimental model in human and veterinary research, are raised for meat, and are popular pets. In addition, there are numerous wild hare species which are not covered in this chapter. The effects of clinical diseases on rabbit hematology and diagnostic test application, especially as prognostic indicators, are increasingly being explored. Hematologic assessments are an essential tool for clinicians and researchers alike in the evaluation of health and potential clinical disease.

BLOOD COLLECTION

Rabbit blood hemolyzes easily and clots quickly, which may negatively affect the accuracy and precision of hematology results. Postprandial lipemia may cause artifactual changes in hematologic parameters and it is usually not possible to obtain a truly fasted sample from rabbits due to cecotrope ingestion. Fasting of cecal herbivores should be done with caution in sick animals. Mechanisms of lipemia interference are numerous and depend on the methodology (e.g., turbidity affecting spectrophotometric analyses, volume displacement effect impacting electrolyte measurement).[43] Physicochemical interference on electrophoretic and spectrophotometric methods is the most common and, as lipoproteins absorb light, Hgb and the values calculated from it (MCH, MCHC) may be affected.[64] Interference with the sample's light scatter properties may result in spurious WBC and platelet counts and lipid interference should be suspected when WBC scattergrams demonstrate high numbers of low- to moderate-sized particles.[64] Because lipemia can interfere in numerous tests and methods, the minimum degree of lipemia sufficient to cause interference is variable, and manufacturer guidelines should be followed.[50]

Rabbits can be restrained in a commercial rabbit restrainer, a zippered cat bag, or by securely wrapping the rabbit in a large towel. Common recommended sites for venipuncture in rabbits include the lateral saphenous, cephalic, and jugular veins. Cardiac puncture may be used in research in anesthetized rabbits, typically during a terminal procedure. The ear vessels are not recommended, particularly in small-eared breeds, due to the propensity of hematoma formation, bruising, thrombosis, and skin sloughing.[5] The jugular vein is convenient and allows for a larger volume of blood (up to 6 mL) to be drawn quickly, though obese rabbits with a substantial dewlap may present a challenge.[6] For collection

from the jugular vein, rabbits are restrained similarly to cats, with the neck gently extended upward and the feet drawn straight down over the edge of the table. The neck should not be fully extended to prevent damage to the spine. The rabbit should have a towel placed over its back and secured on each side to ensure that struggling and kicking, which can damage the spine, are prevented. The jugular furrow may be clipped to improve visualization of the jugular vein and improve sterility, especially if repeated venipuncture is expected. The lateral saphenous vein can be accessed easily for smaller blood volumes (0.5–2.0 mL) with minimal stress. It is away from the animal's head and its use preserves cephalic veins for potential catheterization.[5] Rabbits can be restrained with the head between a restrainer's elbow and body, and the leg extended over the table's edge, held at the stifle to occlude venous return. The lateral saphenous vein is superficial and is prone to hematoma formation, therefore, gentle pressure is recommended after phlebotomy.[6] When collecting large volumes of blood in research, direct cardiac venipuncture may be performed using an 18-gauge or larger needle, 1.5–2 in (3.8–5.1 cm) in length, which is inserted in the third left intercostal space, lateral to the sternum.[35] Cardiac blood collection is reserved for terminal procedures and should not be used for clinical patients because it can result in myocardial damage, hemothorax, pericardial tamponade, and death. Rabbits should be anesthetized before cardiac blood collection is attempted.[32]

The total blood volume in healthy rabbits is estimated to be 4.5–8.1% of total body weight, or approximately 56 (44–70) mL/kg.[11,35] However, there may be inaccuracies in calculating blood volume based on body weight. Therefore, one should consider correlating blood volume with lean body weight or body surface area in obese or emaciated animals.[25] Approximately 6–10% of the blood volume can be collected,[38] and the recommended maximum blood volume that can be safely collected during one sampling is 7.7 mL/kg of body weight.[39]

ERYTHRON

The rabbit RBC is a typical mammalian, anucleated, biconcave disc with a diameter of 5.0–7.8 μm.[45] This variation results in significant anisocytosis appreciated in blood smears from rabbits (Figure 117.1), with microcytes of one-quarter the diameter of normal-sized RBCs sometimes seen in smears from apparently healthy rabbits.[8] Anisocytosis can be more prominent in male rabbits,[45] resulting in higher RDW values than female rabbits. Anisocytosis is also, in part, attributed to the increased size of reticulocytes, and polychromasia is found in up to 2% of RBCs[8] (Figure 117.1). This is likely a reflection of a high RBC turnover and a predicted random destruction rate of 0.5% per day. The average life span of rabbit RBCs is 57 (45–70) days.[25] Poikilocytosis is a normal feature of healthy rabbit RBCs. Most rabbits have mild (<3%) poikilocytes appreciable on blood smear, the majority of which are acanthocytes and echinocytes. Fragmentation morphology (low numbers of schistocytes, microcytes, keratocytes, and spherocytes) is rarely observed in blood smears from healthy rabbits, while diseased rabbits exhibit mild to moderate fragmentation, often associated with septic and inflammatory disorders or malignant neoplasms.[8]

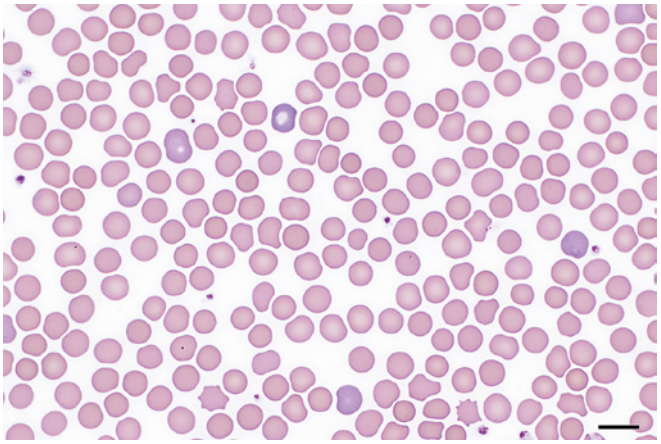

FIGURE 117.1 Photomicrograph of a representative blood smear from a healthy rabbit. Anisocytosis, a few larger, polychromatophilic cells, and rare RBCs containing small, basophilic Howell–Jolly bodies are illustrated. 1000×, aqueous Wright–Giemsa. Bar = 10 μm.

Reticulocytes account for approximately 1–7% (median of 2.7% [168 K/μL], minimum of 0.8% [54 K/μL], and maximum of 7.8% [413 K/μL]) of RBCs in healthy adult rabbits.[10] Automated reticulocyte counts may be higher in samples collected in lithium heparin when compared to EDTA-anticoagulated blood, and there is good correlation between manual reticulocyte counts and quantification by the ADVIA 2120i hematology analyzer.[30] Interestingly, rabbit blood is considered to be an excellent quality control material for flow cytometric reticulocyte enumeration in humans, since the reticulocyte concentration and reticulocyte fluorescence intensity distribution are similar to those of human blood.[48] Nucleated RBCs and RBCs containing Howell–Jolly bodies are found in low numbers in healthy rabbits,[37,38] and do not indicate a regenerative response (Figure 117.2k).

Rabbit Hgb has high oxygen affinity.[7] Neonatal rabbit Hgb has a higher oxygen affinity than that of the dam with the difference gradually disappearing over time.[57] While the general pattern of membrane proteins is similar in all mammalian RBCs, the polypeptide pattern of the rabbit RBC membrane is unique in exhibiting decreased amounts of bands 2.1–2.3 and 6, a band 4.1 which appears splitting into two sub-bands, and higher amounts of band 4.9.[36]

LEUKON

The rabbit heterophil is approximately 10–15 μm in diameter[49] and contains a segmented nucleus that stains variably purple with a darker nuclear membrane. Rabbit

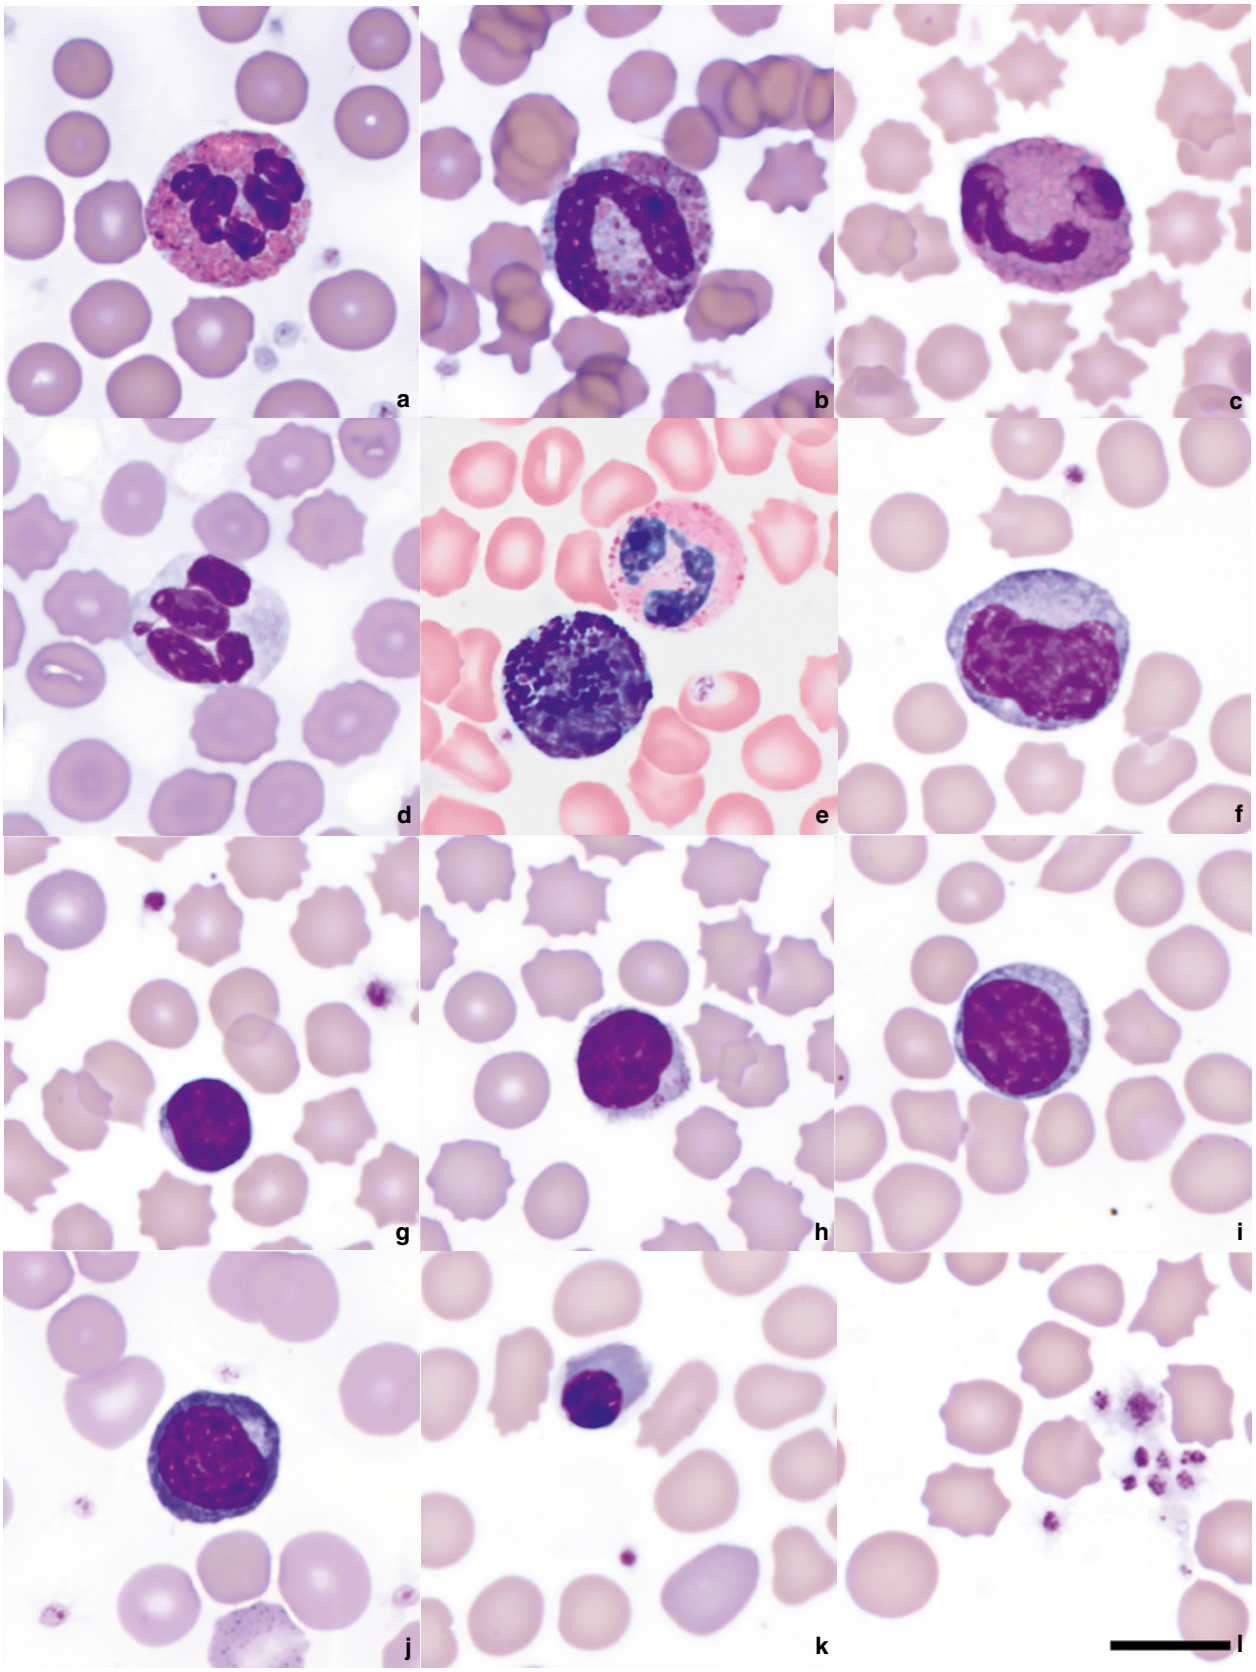

FIGURE 117.2 Photomicrographs of blood elements from pet rabbits (*Oryctolagus cuniculus*). (a) Heterophil; (b) Toxic band heterophil; (c) Eosinophil; (d) Basophil using aqueous Wright-Giemsa stain; (e) Heterophil (upper right) and basophil (lower left) using methanolic Wright-Giemsa stain; (f) Monocyte; (g) Small, well-differentiated lymphocyte; (h) Granular lymphocyte; (i) Intermediate-sized lymphocyte; (j) Reactive-appearing lymphocyte; (k) Polychromatophilic metarubricyte (nucleated RBC); (l) Small platelet clump; 1000×, aqueous Wright–Giemsa. Bar = 10 μm.

heterophils contain acidophilic granules within a colorless to lightly basophilic cytoplasm. Small, azurophilic (primary) granules may give these cells a light purple color, while variable numbers of larger, bright red (secondary, specific) granules are typically present in normal heterophils (Figure 117.2a).

Lymphocytes are the predominant leukocytes in peripheral blood from healthy, unstressed rabbits. The rabbit lymphocyte nucleus is round, condensed, and occasionally indented. The nucleus of the small, well-differentiated lymphocyte (7–10 µm in diameter) is surrounded by a narrow band of pale-blue-staining cytoplasm (Figure 117.2g). Intermediate-sized lymphocytes (10–15 µm in diameter) are commonly found and their slightly more abundant, pale to medium basophilic cytoplasm may occasionally contain a few azurophilic granules[46] (Figure 117.2h,i). Reactive-appearing lymphocytes exhibiting increased cytoplasmic basophilia and a prominent paranuclear (Golgi) clear zone are occasionally identified, and likely reflect antigenic stimulation (Figure 117.2i).

The rabbit monocyte is a large cell (15–18 µm in diameter)[49] with a pleomorphic nucleus (lobulated, horseshoe, or bean-shaped) and diffuse, lightly stained nuclear chromatin. The pale basophilic to light gray cytoplasm is abundant and may contain a few to numerous vacuoles (Figure 117.2f).[46] Morphology is dependent upon response to antigen.

The rabbit eosinophil is slightly larger than the heterophil (12–16 µm in diameter) and has a segmented nucleus that may appear bilobed or horseshoe-shaped.[49] The cytoplasm stains slightly darker blue than the heterophil, and its acidophilic, dull, round pink-red granules are more numerous and larger, up to four times the size of heterophil granules (Figure 117.2c).

Rabbit basophils are generally more numerous than in other vertebrates; while there are lower numbers of tissue mast cells, which are sparsely distributed compared to most other animals and most numerous in the skin, paws, nose, and ears.[22] Basophils measure 10–15 µm in diameter.[49] The nucleus stains light purple and the pale basophilic cytoplasm is packed with deeply purple metachromatic granules.[46] The granules of rabbit basophils typically do not stain with aqueous Romanowsky stains, giving these cells a similar appearance to neutrophils in other species[1] (Figure 117.2d,e). Interestingly, while canine and feline basophils are typically not identified by hematology analyzers, the ADVIA 2120i (Siemens Healthineers AG, Erlangen, Germany) is capable of enumerating rabbit basophils.[34]

PLATELETS AND COAGULATION

Rabbit platelets appear as small clusters of azurophilic granules surrounded by pale blue cytoplasm,[35,46] and measure 1–3 µm in diameter with occasional larger forms seen in blood smears from healthy animals[49] (Figure 117.2l). Previously reported platelet reference intervals varied considerably, from tight to broad ranges, but were not generated in accordance with American Society for Veterinary Clinical Pathology (ASVCP) guidelines (Table 117.1).

TABLE 117.1 Hematologic reference intervals for mixed sex, adult rabbits ($n > 500$). Results generated using Sysmex, Vetscan 5, and manual methods are combined. Outliers are removed and statistics are performed in accordance with ASVCP guidelines. As blood samples from healthy animals were collected in-clinic, a component of stress induced leukograms may be present in the data.

	SI units	Reference interval
WBC	10^9/L	3.4–12.3
RBC	10^{12}/L	4.9–7.5
Hgb	g/L	105–158
Hct	L/L	0.32–0.47
MCV	fL	52–72
MCH	pg	19–24
MCHC	g/L	305–363
Band	10^9/L	0
Heterophil	10^9/L	0.8–8.0
Lymphocyte	10^9/L	0.8–7.6
Monocyte	10^9/L	0–0.8
Eosinophil	10^9/L	0–0.3
Basophil	10^9/L	0–0.7
Platelets	10^9/L	200–1060

Source: Harr, personal communication.

Rabbit hemostasis is, generally, very similar to other mammals and rabbit thromboplastin is often used to construct commercial prothrombin time (PT) assays. Rabbits have a lower factor VII activity and comparatively slow fibrinolytic response compared to humans. Factor VII circulates as a relatively long-lived protein in the healthy rabbit in comparison to the reported shorter half-life for factor VII in the human circulation.[20] Rabbits are known models for venous thrombosis,[59,62] and a study using thromboelastometry identified a comparable maximum clot firmness (MCF) between rabbits and humans, explained by their similar platelet count and fibrinogen levels, supporting the usefulness of rabbits as an animal model for examining platelets.[51] Rabbits have a more active intrinsic system of coagulation and higher clotting factor activities than humans. Rabbit platelets contain 20–25 times the amount of serotonin in human platelets and fail to aggregate in the presence of epinephrine. These and other differing biologic characteristics of rabbit hemostasis warrant caution in extrapolating results of studies in this species to humans.[2,14]

REFERENCE INTERVALS

When assessing rabbit diseases, hematologic reference values are helpful in health status evaluation, providing important information for clinicians. However,

numerous factors such as age, sex, diet, environmental conditions, disorders, stress, pregnancy, and circadian rhythm may influence hematologic values. There are several published rabbit reference intervals which are derived from data collected from homogeneous laboratory animals. These do not reflect the myriad of rabbits housed in laboratory medical facilities, farms, and private homes kept as companion animals.[35] These homogeneous rabbit groups contain animals of the same breed, strain, age, housed in the same environmental conditions, and their reference intervals can be very different from a heterogeneous population of pet rabbits. Additionally, a few texts combine reference intervals from different sources to create ranges too wide to be clinically useful,[38] and/or that do not address the use of different methodologies.[58] Reference intervals generated in accordance with ASVCP guidelines are presented in Table 117.1.

Partitioning Factors

RBC and WBC counts in New Zealand white rabbits undergo significant postnatal change and become comparable with those of adult rabbits by 6 weeks of age. Rabbit RBC counts increase linearly with time after birth.[27] Erythrocyte counts are low in newborn kits, whereas MCV and MCH values are typically higher than in adults.[4,41] New Zealand white rabbits (1–2-month-old) also have reticulocyte counts of 7.4 ± 4.7%, with a 50% reduction in those counts occurring during the third month of life and a subsequent smaller decrease to 3.0 ± 1.3% in adult rabbits.[24] Total WBC counts are lowest in newborn and juvenile rabbits.[27] The absolute lymphocyte concentration sharply increases during the first month of life.[27] In newborns, the initial heterophil:lymphocyte (H:L) ratio (58:31) is reversed in comparison to adults declining to approximately (31:59) by 2 weeks of age. The ratio at 2 months of age is reported as 33:60, increasing to 45:45 after 12 months of age.[25] The increased H:L ratio in neonatal rabbits has been attributed to higher corticosteroid concentrations in neonates.[26] Rabbits delivered by caesarean section on day 29 of gestation showed a comparable H:L ratio to adult rabbits.[4]

The WBC count in rabbits may vary due to age, sex, breed, circadian rhythms (diurnal fluctuations), nutritional status, diet, age, sex, and breed. Additionally, the differential WBC count in a healthy rabbit fluctuates considerably when evaluated over a single month.[39] Total WBC numbers demonstrate diurnal variation, with the lowest counts in the late afternoon and evening. Lymphocyte numbers are typically highest in the early morning and lowest in late afternoon and evening, whereas heterophil numbers are lowest in the early morning and increase to peak numbers in late afternoon and evening.[38]

Progressive alterations in several hematology values of pregnant does occur during gestational development. Platelet concentration increases progressively from organogenesis through the stages of fetal growth.[40] A shortened PT and increased antithrombin III concentration are noted during the late period of pregnancy, and are thought to represent physiologic responses to prevent excessive hemorrhage and/or hypercoagulability at parturition.[40] Progressive decreases in RBC count, Hct, and Hgb concentration are also seen during pregnancy, and are attributed to hemodilution, although a decreased RBC life span during pregnancy has been documented.[31] Dams may also have an initial increase (during organogenesis) followed by a decline in reticulocyte count,[40,60] probably associated with increased demand at this stage. While the WBC count also increases progressively during pregnancy, the changes are typically not statistically significant.[31]

BONE MARROW COLLECTION AND EVALUATION

Bone marrow evaluation is indicated in cases of pancytopenia, nonregenerative anemia, leukemia, and/or gammopathy.[35] Bone marrow aspirates may be obtained from an anesthetized rabbit from the wing of the ilium, the proximal femur, or the proximal humerus. An 18-gauge Rosenthal pediatric biopsy needle can be used for bone marrow collection from the humerus and femur (see Chapter 141).

The morphology of most cells and the maturation sequence in rabbit bone marrow are similar to that in humans and other mammals,[37] and excellent color photomicrographs of rabbit bone marrow are available elsewhere.[49] The M:E ratio of rabbit bone marrow is approximately 1:1.[49] The M:E ratio in rabbits from birth to 5 months of age is reported in older references.[12] Mitotic figures are rarely identified. Lymphocytes compose 3–5% of the nucleated cells in rabbit bone marrow, with occasional plasma cells seen.[49]

Few nonexperimental conditions affecting rabbit bone marrow are reported in the literature. Toxicosis with benzimidazole, a compound used to treat nematode and trematode infections and routinely used in the treatment of *Encephalitozoon cuniculi*, produces histopathologic changes including radiomimetic lesions such as hypoplasia and necrosis.[18] Bone marrow neoplasms are more commonly reported, lymphoma being most prevalent.

HEMATOLOGIC ABNORMALITIES

Physiologic

Rabbits respond to adrenocortical stress or exogenous steroids by mounting a leukocytosis characterized by mature heterophilia and concurrent lymphopenia and eosinopenia.[37] Rabbit lymphocytes are particularly susceptible to the effects of stress. Administration of exogenous epinephrine results in a lymphocyte shift from the spleen and bone marrow to peripheral blood. Epinephrine causes splenic contraction through stimulation of α and β receptors in the splenic capsule.

The mechanism of lymphocyte mobilization from bone marrow is uncertain.[56] Corticosteroid administration results in a redistribution of lymphocytes from the peripheral blood, bone marrow, and spleen to the lymphatic tissue, though the exact mechanism for this process is not fully elucidated.[55] Prolonged stress results, ultimately, in heterophilia and lymphopenia.[58] Transportation or handling stress, if prolonged, can cause an inverse H:L ratio that persists for 24–48 hours.[38]

Pathologic

Rabbits are used as a disease model for drug and vaccine development, in studies of cellular and molecular immune mechanisms underlying many human diseases, including syphilis, tuberculosis, HIV–AIDS, and viral diseases, which is beyond the scope of this chapter[15] (see Chapter 118). Inflammatory and neoplastic diseases are the most common etiologies of anemia in rabbits with severe dental disease, encephalitozoonosis, and neoplasia (commonly lymphoma) diagnosed most frequently.[10] Chronic infections (e.g., otitis, abscesses, endometritis, pyometra) or neoplastic diseases (e.g., uterine adenocarcinoma, lymphoma) may lead to nonregenerative anemias. Rabbits with pneumonic tularemia exhibit leukopenia characterized by monocytopenia and lymphopenia, which are identified on day 4 postexposure. Granulocytes remained largely unchanged. A significant thrombocytopenia was also noted, an interesting finding given that coagulopathies are not reported in humans with this disease.[47] Hematology can be useful in differentiating *E. cuniculi* from *Pasteurella multocida* infection. No known hematologic changes are associated with encephalitozoonosis, while rabbits with pasteurellosis often develop heterophilia and left shift.

Hemorrhage is the second most common cause of anemia in rabbits and is associated with trauma and genitourinary diseases.[10] Erythroid regeneration induced by blood loss will occur after approximately 4–5 days, if not impacted by an inflammatory response. Lead toxicosis is a fairly common known cause of regenerative anemia in rabbits. Reticulocytosis, nucleated RBCs, hypochromasia, poikilocytosis, anisocytosis, and basophilic stippling may occur with lead toxicosis,[29] along with overall anemia and thrombocytopenia.[54]

There are several potential etiologies for leukocytosis, heterophilia, and granulocyte immaturity. Pelger–Huët anomaly, a noninflammatory autosomal dominant disorder characterized by abnormal segmentation of blood granulocytes, was previously documented in rabbits[42] (see Chapter 146). Rabbits affected by infectious disease may present with leukocytosis, but mild inflammatory disease typically results in a shift to a heterophil-predominant differential cell count. Commonly, rabbits with acute infection present with an H:L ratio greater than one. H:L ratio inversion may also occur with transport and handling stress, so this must be interpreted cautiously with clinical signs. Though possible, rabbits generally do not develop severe leukocytosis in response to bacterial infections. Occasionally, rabbits with an infectious process present with leukopenia with toxic change (Figure 117.2b).

The most sensitive and specific indicators of systemic inflammation are acute phase proteins. Normal rabbits typically have <20 mg/L of C-reactive protein which has been described as a biomarker of inflammation in rabbits with suspected encephalitozoonosis.[9] Serum amyloid A is currently being investigated in rabbits and shows promise, though further investigation is necessary.[33] Transferrin and ceruloplasmin are additional candidates.[16]

Lymphocytosis, often associated with viral disease, can also be associated with nonspecific immunologic responses. Paradoxically, some viral infections may induce lymphopenia. Experimental infections of cottontail rabbits (*Sylvilagus fioridanus*) with herpesvirus induce lymphocytosis with proliferation of atypical lymphocytes,[21] while a profound lymphopenia is observed in New Zealand white rabbits experimentally infected with influenza, human immunodeficiency, or Myxoma viruses.[19,28,52] Lymphoproliferative disorders are relatively uncommon in pet rabbits. Multicentric lymphoma is the most common, having been reported in several rabbit breeds. Some rabbits may develop a leukemic phase and circulating neoplastic lymphocytes will cause lymphocytosis in these patients.[23] Lymphoid and myeloid leukemias are rarely reported in rabbits.

Eosinophilia may be caused by parasitic disease such as ascariasis, hepatic coccidial infestation with *Eimeria stiedae* in rabbits housed on the ground, or, most commonly, *E. cuniculi* infestation.[38] Eosinophilia associated with hypersensitivity reactions is less common in pet rabbits than in the laboratory setting where rabbits have been used for cosmetic and drug-safety testing. Cutaneous eosinophilic granulomas have been associated with mite infestation (*Cheyletiella* sp. or *Psoroptes cuniculi*) in the pet rabbit.[61]

There are a few reports of hemoparasites in lagomorphs. Molecular detection of *Babesia* sp. and *Anaplasma phagocytophilum* was reported in black-tailed jackrabbits (*Lepus californicus*), desert cottontail (*Sylvilagus audubonii*) rabbits, and eastern cottontails (*Sylvilagus floridanus*) from the Southern USA. A large piroplasm (3.8 μm × 1.9 μm) was observed in the blood smear from one of the PCR-positive jackrabbits.[63] Parasites morphologically consistent with *Babesia divergens*, the agent of bovine redwater and of European human babesiosis, were identified on blood smears from PCR-positive cottontail rabbits (*S. floridanus*) in Massachusetts.[17] Circulating microfilariae have been rarely reported in rabbits.[13]

Hemostatic Disease

Thrombocytopenia and marked hypofibrinogenemia, along with other indicators of disseminated intravascular coagulation (DIC), including prolonged PT and activated partial thromboplastin time (APTT), are associated with rabbit hemorrhagic disease (RHD) caused by a calicivirus.[3,44] RHD is highly infectious and fatal, resulting in significant economic losses and heavy

mortality among wild and domestic rabbit populations.[53] The mortality is believed to result from circulatory dysfunction associated with DIC and necrotizing hepatitis.[44] Three main RHD virus groups with subtle differences in morbidity and mortality have been characterized based on their genetic, antigenic, and epidemiologic properties at the time of publication. Introduction of rabbit hemorrhagic disease virus 2 (RHDV2) in North America is of significant concern in naïve populations and has resulted in significant mortality across the west coast of the USA.[3]

Clinical pathology end points are a standard component in many types of nonclinical (preclinical) studies, e.g., toxicology studies, and are included as deemed applicable in others, e.g., efficacy studies. This chapter reviews recommendations and industry standards for hematologic evaluation in laboratory animals. Regulations regarding preclinical toxicologic safety assessments are discussed in Chapter 10.

NORMAL HEMATOLOGY OF NONHUMAN PRIMATES

In preclinical toxicology and drug development studies, cynomolgus monkeys or crab-eating macaques (*Macaca fascicularis*) are the most commonly evaluated nonhuman primate (NHP) species. Marmosets (Callitrichidae family) are becoming increasingly popular due to their small size. Rhesus macaques (*Macaca mulatta*) are used for xenotransplantation and human immunodeficiency virus research due to their similarity to humans and presence of a naturally occurring immunodeficiency virus (simian immunodeficiency virus). Other species studied in research include chimpanzees (*Pan troglodytes*), baboons (*Papio sp.*), squirrel monkeys (*Saimiri sp.*), owl monkeys (*Aotus sp.*), and tamarins (*Saguinus sp.*).

Blood from NHPs may be collected from a number of venipuncture sites depending on the animal's size, method of restraint, and sample volume required. The femoral vein is the most common site for collection of large volumes (>0.5 mL). The cephalic, saphenous, coccygeal, and jugular veins also can be used. For smaller sample volumes, a sterile lancet may be used to puncture the marginal ear vein, a finger, or a heel. The

average circulating blood volume of rhesus macaques, cynomolgus macaques, and marmosets have been estimated at 56, 65, and 70 mL/kg, respectively, making them relatively volume-rich versus rodent species, but not without limitations.[9]

ERYTHRON

Erythrocytes (RBCs) from NHPs are anucleate, biconcave disks with central pallor. Some species, such as macaques, have a large area of central pallor. A high degree of variability between NHP species exists for RBC diameter and mean cell volume (MCV). Macaque RBC diameter ranges from 6.5–7.5 μm, and RBC diameters across NHP species range between 3.5 and 8.5 μm.[82] Similar to humans, the circulating life span of macaque RBCs is approximately 100 days, and normal reticulocyte counts are relatively low (0–80,000/μL).

Similar to felines, marmoset RBCs may be more susceptible to Heinz body formation during times of stress and disease. Heinz bodies have been described frequently in blood smears from healthy captive marmosets and occasionally from healthy captive tamarins.[36,37] The clinical significance of these inclusions has been debated. Heinz body hemolytic anemia has caused significant morbidity and mortality in marmoset colonies and has been linked to a frequently fatal disease, Wasting Marmoset Syndrome.[36] Wasting Marmoset Syndrome is considered a form of inflammatory bowel disease, but there is no known etiology.[88] Vitamin E supplementation has been reported to decrease the incidence of anemia.[12]

Low numbers of nucleated RBCs, typically one to two per 100 WBCs, are frequently seen in healthy captive New World monkeys (marmosets, tamarins, owl monkeys, squirrel monkeys) and probably reflect the relatively high RBC turnover rate of these species.[36,37,60] Similarly, slight to mild anisocytosis, polychromasia, and Howell–Jolly bodies are also commonly described in owl monkeys, squirrel monkeys, and tamarins.[14,36,37,60]

Stomatocytosis is a frequent finding in blood smears from normal squirrel and owl monkeys. The cause is not known, and the number of stomatocytes varies. A study performed on a colony of seven captive squirrel monkeys identified 9–89% stomatocytes (average 52%).[23] In addition, this study documented an association between increased numbers of stomatocytes and elevated hematocrits (Hct) that was probably caused by alterations in the normal packing characteristics of RBCs. Unlike many inherited and acquired forms of stomatocytosis in other species, squirrel monkey RBCs do not show increased osmotic fragility or shortened survival time.[23]

LEUKON

In rhesus, cynomolgus, stump-tailed, and pig-tailed macaques, neutrophils and eosinophils measured 10.7–13.3 μm, lymphocytes measured 9.5–12.5 μm, monocytes measured 12.5–15.5 μm, and basophils measured 10.5–13.0 μm.[81] With regard to absolute number, neutrophils generally exceed lymphocytes in the peripheral blood of healthy adult NHPs, including chimpanzees, baboons, cynomolgus monkeys,[17] and cotton-top tamarins.[86] Lymphocytes exceed neutrophils in healthy adult rhesus monkeys[16] and in many New World monkeys including owl monkeys, squirrel monkeys, marmosets, and some species of tamarins.[9] In general, similar to other mammalian species, monocyte, eosinophil, and basophil counts are low in healthy NHPs, typically ranging from 0% to 4% of the total WBC count. The typical NHP neutrophil contains a condensed, twisted, or segmented nucleus that commonly has five to six lobes, but may possess as many as 10–12. A small drumstick-shaped appendage (Barr body) may extend from the neutrophil nucleus of females. The cytoplasm varies from pale to light pink, and fine granulation is a feature of most, if not all, neutrophils from NHPs (Figure 118.1). Lymphocytes from NHPs have scant basophilic cytoplasm and large round nuclei. Lymphocyte morphology is variable and "atypical" or "reactive cells" may be seen. Monocytes in NHPs are larger than lymphocytes and may appear in two forms. The first form has a broader band of cytoplasm than is observed in the lymphocytes, with a mottled gray-blue color with a foamy appearance or with discrete vacuoles. The second type of monocyte, a transitional form, has a large oval nucleus devoid of depressions, and its cytoplasm appears darker adjacent to the nucleus and often has delicate pale reddish granulation (Figure 118.1a).

As compared to other mammalian species, eosinophils and neutrophils have an equivalent size and both may have azurophilic or eosinophilic granules. Eosinophils can be confidently identified using the following criteria: (1) eosinophil granules are almost twice as large and rounder than those of neutrophils; (2) eosinophil granules have a brighter yellow-red color, and may be superimposed on the nucleus; (3) the cytoplasm of eosinophils is slightly more gray-blue; and (4) the eosinophil nucleus is not as condensed or segmented.[82] Marmoset eosinophils contain irregular spherical granules which often have a bluish tinge and create a "muddy" gray-blue cytoplasm that can be confused with basophils. The color of eosinophil granules has been reported to vary from eosinophilic to azurophilic to basophilic in cotton-top tamarins, squirrel monkeys, and chimpanzees, respectively, though type of stain was not always reported[13,14,37] (Figure 118.1e, f, and h).

Idiopathic eosinophilia has been described for specific owl monkey karyotypes. K-I (*Aotus nancymaae*) and K-VI (*Aotus azarae boliviensis*) are associated with low and high levels of eosinophils, respectively. The results indicated that the genetic basis of the eosinophilia in K-VI monkeys was likely a function of heightened eosinophilopoiesis and depressed recruitment kinetics from the peripheral circulatory pool in response to Regulated on Activation, Normal T Cell Expressed and Secreted (RANTES).[2]

Basophils contain dull gray cytoplasm with dull gray rods and additional pale violet to dark purple, round or rod-like granules of varying sizes. The granules typically do not obscure the nucleus, but the morphology and number of the granules may vary significantly between species (Figure 118.1c,g).

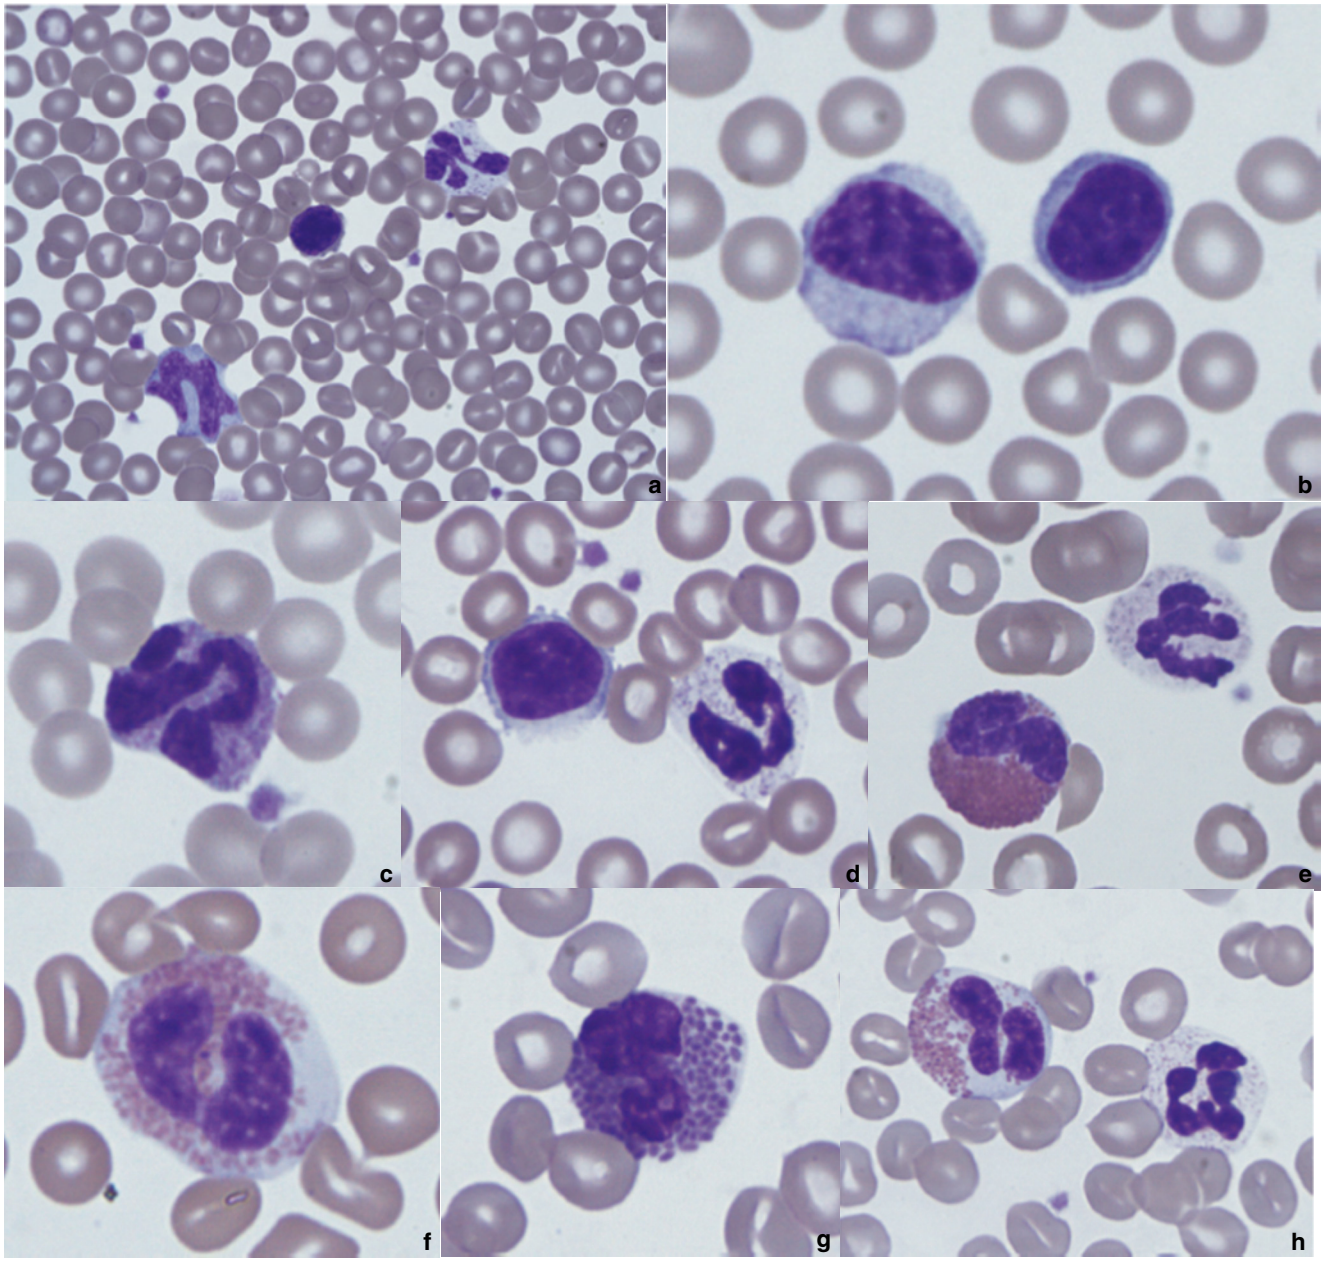

FIGURE 118.1 Peripheral blood cells: (a) Owl monkey (*Aotus nancymae*)—from left to right a monocyte, lymphocyte, and neutrophil; (b) Bolivian squirrel monkey (*Saimiri boliviensis*)—two lymphocytes; (c) Bolivian squirrel monkey (*S. boliviensis*)—basophil; (d) Bolivian squirrel monkey (*S. boliviensis*)—lymphocyte and neutrophil; (e) Chimpanzee (*Pan troglodytes*)—eosinophil and neutrophil; (f) Guyanese squirrel monkey (*Saimiri sciureus sciureus*)—eosinophil; (g) Rhesus macaque (*Macaca mulatta*)—basophil; (h) Rhesus macaque (*M. mulatta*)—eosinophil and neutrophil. Modified Wright–Giemsa stain.

PLATELETS

Platelet morphology in NHP blood smears is similar to platelets from other species. They display an amorphous pale blue ground substance and pronounced violet granulation. Transmission electron micrographs of chimpanzee and monkey platelets show that most of the internal structures are similar to those seen in many mammalian species with the exception of large clumps of glycogen and structures of unknown character circumscribed with fibrous strands.[53] Platelet numbers vary between species, and are generally higher in macaques and lower in chimpanzees among common NHP species.[28] Although few reports on platelet activity in NHPs exist, platelets from baboons and chimpanzees reportedly aggregate with collagen, ristocetin, and ADP. Biphasic aggregation (i.e., aggregation followed quickly by disaggregation) to ADP is common

in both species; however, chimpanzee platelets are not responsive to arachidonic acid.[53] Platelets from rhesus monkeys aggregate in response to collagen, ADP, and arachidonic acid.[45,96] Marmoset platelets aggregate with arachidonate, ristocetin, and collagen at high concentrations, but not with epinephrine. In addition, they have a monophasic response to ADP[55] (see Figure 118.1d and h).

BONE MARROW COLLECTION AND EVALUATION

In larger NHPs, bone marrow can be collected from a number of sites including the iliac crest, the ischial tuberosity, the trochanteric fossa of the femur, the tibial crest, or the proximal humerus.[30] The trochanteric fossa and the proximal humerus are useful for collection from smaller animals. Bone marrow constituents are reportedly similar when sampled from three separate sites: sternum, ribs, and femur[82] (see Chapter 141).

With regard to bone marrow evaluation, the myeloid to erythroid (M:E) ratio ranges from 1.1–1.3 in cynomolgus macaques (mainland China or Vietnam) with no significant differences between sexes.[15] The morphology of hematopoietic cell populations has been described for cynomolgus and rhesus monkeys with strong similarity between the two species.[73,90] A unique feature of bone marrow from rhesus and cynomolgus macaques is the presence of "giant" band neutrophils and metamyelocytes (Figure 118.2g), which is important to recognize as a difference from other species[73,90] (Figure 118.2).

COAGULATION

In general, coagulation values for most species are similar to those reported for humans. Comparisons of the clotting system of rhesus macaques, cynomolgus macaques, and humans concluded that both NHP species are suitable for studying human coagulation defects. Specific differences included higher concentrations and activities of factors II, VII, VIII, and XII in rhesus macaques and lower factor IX activity in both rhesus and cynomolgus macaques as compared to humans.[8,87] Activation of fibrinolysis, intrinsic coagulation, prothrombin consumption, and functional levels of most coagulation factors in cynomolgus macaques were very similar to humans.[8] Clotting times for baboons, chimpanzees, and macaques are typically short, with clots being retracted partially or completely by 4 hours.[30] A recent comparison of 18 analytes that assessed excessive thrombin activation, clotting inhibition, endothelial damage, and fibrinolysis between normal baboons and humans showed a high level of concordance. Exceptions included elevated thrombin/antithrombin complex and fibrinopeptide A and lower plasminogen activity in NHPs.[27]

HEMATOLOGY OF LABORATORY ANIMALS

The Regulatory Affairs Committee (RAC) of the American Society for Veterinary Clinical Pathology (ASVCP) recently published a best practice paper that made clear recommendations on hematology values to assess in toxicology studies[92] (see Chapter 10). Briefly, CBC should include Hct, total and differential WBC counts, Hgb, blood smear collection, RBC, bone marrow smear collection (case-by-case basis for carcinogenicity studies), MCH, MCHC, MCV, RDW, and reticulocyte count. Absolute counts (concentrations) are more relevant than relative counts (percentages). Blood films should be evaluated if cell morphology evaluation, platelet clumping, left shifts to immature cells, presence of nucleated or atypical cells, and confirmation of automated cell counts or other variables are necessary. These criteria need to be defined in standard operating procedures (SOPs). These recommendations apply to all preclinical studies and all species; however, in general less commonly used species are more likely to require manual review of a blood smear. Particularly for mice, even though they are the most often used laboratory animal species, automated counts often do not match manual counts.[65] There may be changes in the list of values to assess depending on anticipated changes related to both the species and the model being studied. Preanalytical factors that can affect hematologic test results are outlined in Table 118.1.

PREANALYTICAL FACTORS AFFECTING HEMATOLOGIC TEST RESULTS

Blood Collection Site

During the course of a study, care must be taken to be aware of body-weight and species-specific requirements (maximum blood volumes) for both single time points and total volume over time with multiple collections. Clinical pathology samples should be collected prior to other study-specific blood samples to more accurately reflect in vivo hematologic values.[72] There are differences in hematologic values and quality of samples for hematologic analyses, as well as effects on animal welfare and behavior, depending on the method and site of blood collection. Standardizing the venipuncture technique for each study is recommended. Venipuncture techniques are discussed in species-specific chapters found in Section IX. In general, the same venipuncture sampling site should be used throughout the study to minimize increased variation in hematologic values due to sampling site whenever possible.

In mice, blood collection sites for in-life assessments include the tail vein, submandibular vein, and sublingual vein (under anesthesia); and for terminal assessments, direct cardiac puncture (Table 118.2).[83] Bleeding from the retrobulbar sinus is no longer recommended in light of tissue trauma, contaminated and clumped samples,

post collection morbidity, postprocedural complications including blindness and induction of chronic stress, and the need for anesthesia.[25,65,92]

In rats, similar to mice, higher RBC indices (RBC count, Hgb, and Hct), leukocyte, and platelet concentrations are observed in blood collected from more peripheral vessels as compared to more central vessels or the heart.[6,26] Lower basophil counts, total RBC counts, Hgb, Hct, MCH, and MCHC values were observed in rat vena cava blood samples as compared to sublingual samples.[84] In guinea pigs, many collection sites have been used including, most recently, the gingival vein with no notable changes in hematologic values.[79] In rabbits, the auricular vein was the most commonly used, but recently the jugular vein has been used as a practical alternative for repeat sampling, as a subcutaneous sampling port can be placed for blood collection from the jugular vein. No changes in hematologic values have been reported.[63] Site of collection has less of an impact in larger species such as pigs, dogs, and NHPs, though changing the collection site may increase result variation.

Frequency and Time Points

Blood collection for hematology in rodent preclinical studies will have an overall study design that takes into account their limited blood volume, larger group size, and decreases variability (see Chapter 10). Large animal (dog and nonhuman primate) preclinical studies, because of their increased variability, smaller group sizes, and larger blood volume, will generally have baseline blood collection(s). These are performed once or twice before dosing to account for day-to-day variability in individual animals. These prestudy baseline samplings also allow for exclusion or inclusion criteria, if they indicate or support other evidence that an animal is not clinically normal and, therefore, not appropriate to use in the study.

Interim blood collections are generally used for studies longer than 7 days duration and can be tailored based on known or anticipated mechanism of action and pharmacology of the test article. Once again, species and blood volume requirements must be considered when determining the most appropriate time points and frequency of blood collection. For many types of preclinical studies, the need for hematology end points must be balanced with the need for blood collection(s) to evaluate toxicokinetics, pharmacokinetics, and pharmacodynamic markers.

The FDA Redbook 2000 states that blood samples obtained in preclinical toxicity studies should be analyzed individually, and not pooled.[11] Pooling results in averaging the variability and eliminating the range and outliers. It dilutes or masks effects that would be observed when analyzing individual specimens and precludes identification and investigation of changes occurring in individual animals.[1]

Age

Age has a significant impact on hematologic values in all species. When setting up RIs for in-house hematologic evaluations, attention should be given to ages of the reference animals to ensure they are representative of anticipated ages of study animals.

In one study of C57BL/6 mice, hematologic RI were determined using facial vein blood collection with diluted blood samples analyzed on the Sysmex XT-2000iV (Sysmex Corp., Kobe, Japan) and indicated an increase in RBC and platelet concentrations from birth to 35 days of age, with a decrease in Hgb, MCH, and MCV between 7 and 14 days of age before rising to adult values. At birth, there were equal proportions of neutrophils and lymphocytes. As they aged, the differential count was dominated by lymphocytes. Basophils were present in low numbers at birth and were rarely seen after 14 days of age; however, no manual cell counts were performed in this study.[101] In C57BL/6 mice, there is a decline in lymphocytes and increasing neutrophil concentrations with age, and a lower Hct due to expanded plasma volume.[65,71]

Published RI for growing and aging male Wistar rats (from 1 to 24 months of age) noted that: Hct progressively increased and then stabilized at 12 months of age. Reticulocyte count declined and then stabilized at 6 months of age. The relative numbers of lymphocytes decreased and neutrophil increased with age.[29]

New Zealand white rabbits (1–2-month-old) were found to have reticulocyte counts of 7.4 ± 4.7%, with a 50% reduction in those counts occurring during the third month of life. A subsequent smaller decrease to 3.0 ± 1.3% in adult rabbits occurred.[43] RBC counts are low in

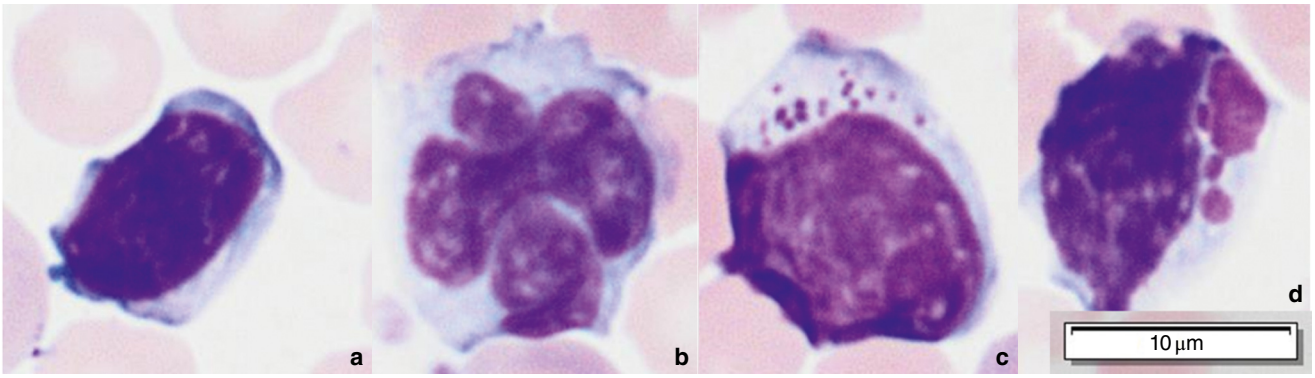

FIGURE 118.3 Hartley guinea pig peripheral blood cells: (a) Small lymphocyte; (b) Lymphocyte with clover-leaf nucleus; (c) Granulated lymphocyte; (d) Lymphocyte with Kurloff body. Wright–Giemsa stain, 100× objective.

newborn rabbits, but attain adult reference intervals by 6 months of age, whereas the MCV and MCH values are higher than in adults.[4] Total WBC counts were lowest in newborn and juvenile rabbits, reaching adult levels after 6–12 months of age (see Chapter 117).

Weiser-Maples guinea pigs had increasing WBC and neutrophil concentrations with decreasing lymphocyte concentration with age as measured on the ADVIA 120 (Siemens Healthineers AG, Erlangen, Germany) with an 18 hour fast and abdominal vein collection under methoxyflurane anesthesia at ages up to 886 days.[50] Possible lymphocyte morphology in Hartley guinea pigs is presented in Figure 118.3.

In a study of Large White Italiana × Duroc × Landrace commercial pig hybrids, where blood was collected via the femoral vein under sevoflurane anesthesia and analyzed on the ADVIA 2120 (Siemens Healthineers AG, Erlangen, Germany), changes from 5 to 30 days of age consisted of increased RBC mass (Hgb, Hct, and RBC) with increased RDW and decreased MCV, as well as decreased platelet concentrations with decreased mean platelet volume.[97] RBC, Hgb, Hct, MCHC, and MCV were also significantly lower in young specific-pathogen free minipigs when compared to adults when collected by cardiac puncture[103] (Figure 118.4).

In laboratory Beagles aged 6–9 months with blood collected from the cephalic vein and analyzed on the T540 Coulter counter, age-related changes included increased RBC, Hct, and Hgb, increased neutrophil concentrations, and decreased lymphocyte concentration. Another study showed similar trends from 9–36 months.[10]

In healthy cynomolgus infants, PCV, MCV, and Hgb concentration dropped significantly from 1–3 months after birth.[89] Changes noted with age in Chinese-origin rhesus macaques aged 3–5 years included increased total WBC, lymphocyte, and platelet concentrations.[16] In cynomolgus macaques under manual restraint with blood collection from the cephalic veins and analyzed on the Sysmex XT-2000iV (Sysmex Corp., Kobe, Japan), decreases in RBC, Hct, and Hgb concentration were observed for females only from 4 to 6 years of age.[102]

Sex

In mice, a sex-associated difference in recovery from blood collection has been observed, with female mice having a more robust recovery from serial blood collections.[74] In general, female mice (and rats) have a lower measured RBC concentration as compared to males,

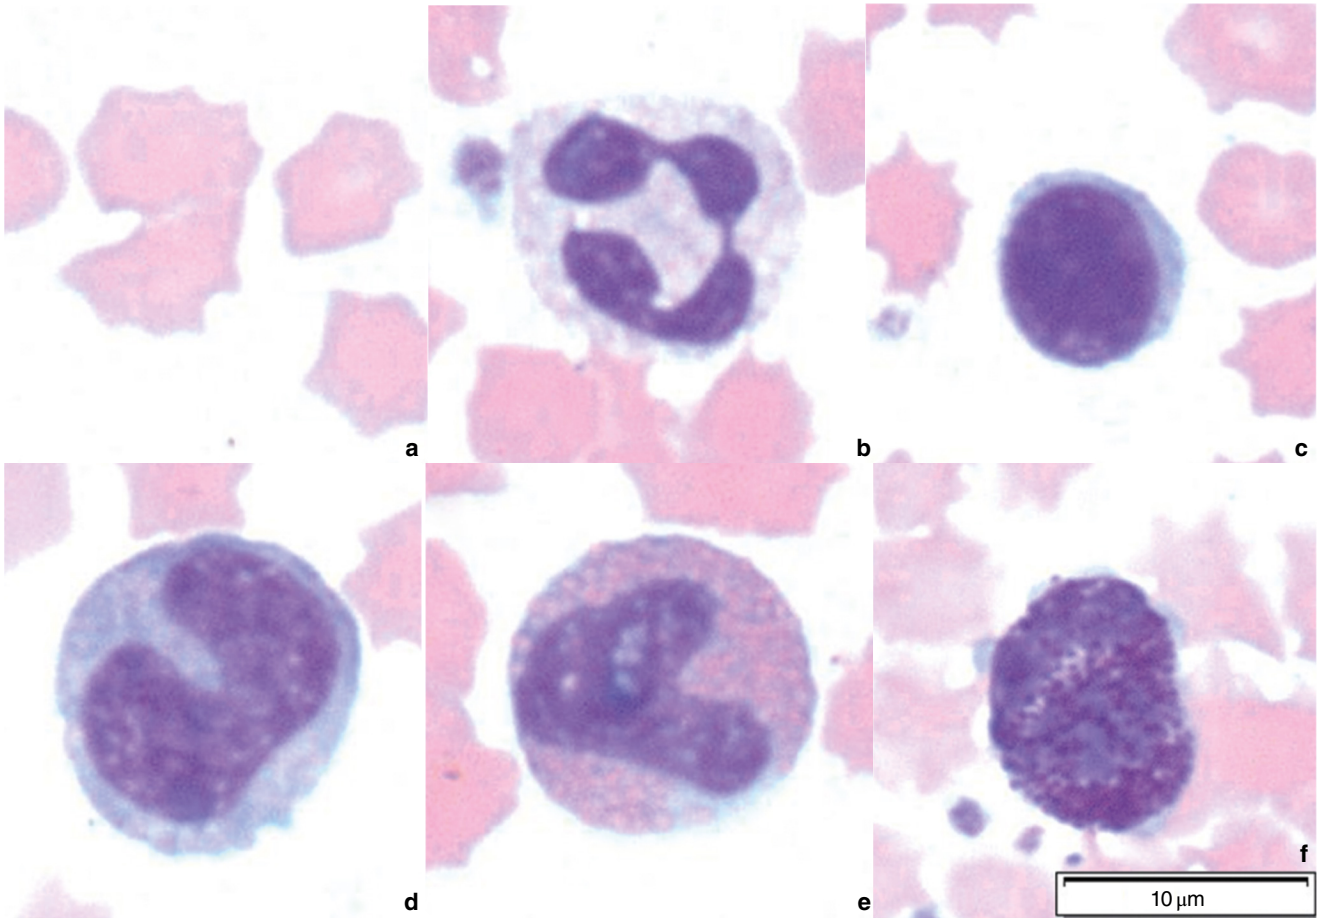

FIGURE 118.4 Yorkshire pig peripheral blood cells: (a) RBCs frequently appear as acanthocytes; (b) Neutrophil; (c) Lymphocyte; (d) Monocyte; (e) Eosinophil; (f) Basophil. Wright–Giemsa stain, 100× objective.

though values may be affected by strain, age, gender, and environment.[71] It should be kept in mind, however, that there are always multiple variables at play.[20]

Male Sprague–Dawley rats have higher Hgb concentration, Hct, RBC concentration, MCV, MCH, WBC, neutrophil, lymphocyte, and monocyte concentrations, while females have higher MCHC, platelet, and eosinophil concentrations when assessed following collection from the abdominal vena cava under sodium pentobarbital anesthesia prior to euthanasia.[38] In contrast to serial blood collections, male Sprague–Dawley rats have a more robust recovery after acute blood collection procedures than did female rats.[61]

In rabbits, RBC count and Hgb concentration are slightly higher in males and reticulocyte counts slightly higher in females.[82] Albino large white (JW-AKT) rabbits with blood collected after 15 hour fast from the auricular vein and analyzed on the Celltac MEK-5258 (Nihon Kohden Corp., Tokyo, Japan) had increased RBC, Hgb, platelet (PLT) in males versus females.

In 5-month-old beagles, PLT concentrations were higher in females.[10] WBC concentrations are reported to increase after 30 days and RBC decrease during the second half of pregnancy.[49]

In studies of adult and juvenile cynomolgus macaques, RBC, Hgb, and Hct were lower in females.[102] In juveniles, reticulocyte concentration was higher in females. In Chinese-origin rhesus macaques under cage restraint, lower extremity veins analyzed on the hematology analyzer XE-2100 (Sysmex Corp., Kobe, Japan) showed that females had lower RBC and Hgb, and higher neutrophil and eosinophil concentrations.[16] In a study of cotton-top tamarins, blood was collected from the femoral vein under anesthesia after an overnight fast, and analyzed on the ADVIA 120 (Siemens Healthineers AG, Erlangen, Germany), PCV, Hct, Hgb, and RBC concentrations were all lower in females than in males and reticulocyte concentrations were higher.[86]

Old World monkeys and great apes have a true menstrual cycle, which can affect RBC indices because a significant amount of blood may be lost during menstruation. Reported changes include decreased RBC mass with increased reticulocyte concentration, MCV, and RDW, as well as increased WBC and platelet concentrations. These changes are most notable with menstruation of >7 days duration.[70] In addition, baboons and chimpanzees display marked turgescence and detumescence of the sex skin in association with the follicular and luteal phases of the menstrual cycle, respectively. These fluid shifts can affect RBC indices causing decreased Hgb, Hct, RBC, and WBC concentration, and increased PLT concentration in the luteal phase.[34]

Pregnancy and Lactation

Hormonal changes through cycling and pregnancy have effects on hematology. RBC counts, Hgb, and Hct values are lower in pregnant Wistar Hannover and Sprague–Dawley rats.[54] Female rats may exhibit leukopenia during estrus.[100] Ovariohysterectomy in female rats results in an increase in the number and percentage of circulating T and B lymphocytes.[71]

In pregnant New Zealand white rabbits, RBC, Hgb, and Hct increased up to day 13, then decreased until day 25 of a 28-day gestation period. Reticulocyte concentrations increased up to day 16, then decreased. Platelets increased up to day 10, and started to decrease on day 13.[99]

In Danish sows at midgestation with blood collection from the jugular vein under manual (snare) restraint and analyzed on the ADVIA 2120i (Siemens Healthineers AG, Erlangen, Germany), changes in laboratory results were consistent with blood volume increases including decreased Hgb concentration and Hct, increased reticulocyte concentration and increased MCV.[7]

Strain

Strain has a major impact on hematologic analyses. It is important that laboratories develop reference intervals that are specific to not only species but also strains of laboratory animals; during studies, appropriate controls must consist of animals of matching strain and vendor/origin. There are notable differences in WBC between BL/6 and BALB/c mice for example.

Differences in circulating mast cells were found between the Th2-prone BALB/c mice and Th1-prone C57BL/6 mice.[18] C57BBL/6 mice have higher RBC counts versus BALB/c or Institute of Cancer Research (ICR); ICR mice have higher platelet concentration than either; C57BL/6 had higher lymphocytes; BALB/c had more granulocytes.[51]

The effects of enrichment are highly variable between strains. A/J and C57BL/6 mice in enriched environments had higher total WBC concentrations than those in nonenriched cages, whereas BALB/c mice had higher WBC concentrations in a nonenriched environment.[95]

Vendor/Geographic Source

Significant differences were found for MCV, MCH, PLT, mean platelet volume, plateletcrit, and WBC, RBC, lymphocyte, monocyte, eosinophil, and reticulocyte concentrations for male and female Wistar rats obtained from two different vendors.[47] Hematologic analysis of eight different outbred stocks and two separate inbred strains of mice from three vendors demonstrated that RBC-dependent values (RBC concentration, Hgb concentration, Hct, MCV, MCH, and MCHC) exhibited less variability than did the WBC concentrations (total WBC, neutrophils, and lymphocytes).[85]

Geographic source is also an important factor in laboratory animal hematology, especially if considering wild-caught animals. One of the most notable examples is the variation of hematologic values between cynomolgus monkeys that originate from Mauritius and those from South-East Asia. Specific differences include higher RBC counts with decreased MCV, MCH, reticulocyte counts, and lower WBC counts in Mauritian monkeys.[21] Differences in cynomolgus monkeys from Cambodia include higher neutrophil, monocyte, and eosinophil concentrations, higher MCHC, and lower lymphocyte concentrations, Hct, and MCV.[17]

Diet

In general, overnight fasting is recommended in all laboratory animal species except mice. Fasted mice do not consume as much water, resulting in hemoconcentration and increased Hct.[24] Fasting of rats can cause increased erythroid indices as well.[100]

Male Wistar rats fasted for 0–48 hours had increased Hgb concentration at 16 hours.[46] Restricted diet provided during evening hours maintains diurnal rhythm, while diet restriction in the morning disrupts the diurnal rhythm of cortisone and adrenocorticotropic hormone.[5] In a 2-year dietary restriction study in Sprague–Dawley rats, decreased total WBC, neutrophil, lymphocyte, and platelet concentrations were identified and were linked to decreased hematopoiesis.[42] Copper-deficient diets provided to male rats resulted in lowered Hgb concentration and MCV as well as increased reticulocyte concentrations. Combined copper and iron deficiencies yielded lowered Hgb concentration and increased reticulocyte, nucleated RBC, and platelet concentrations.[78]

Environment

RBC indices generally increase with environmental heat, and decrease with cold.[100] Warming the whole body or warming the tail is used to induce peripheral vasodilation to facilitate blood sample collection. Warming the tail has been shown to reduce the numbers of WBCs, neutrophils, and lymphocytes observed as compared to nonwarmed tail blood samples.[41] In both warmed and nonwarmed tail blood collection methods, RBC indices and platelet concentration were elevated when compared to both cardiac and retroorbital sinus collection.

Exposure to electromagnetic fields has been studied extensively in mice and rats with variable results consisting of changes in RBC counts, Hgb concentration, Hct, MCV, MCH, and MCHC that depend on exposure frequency, duration, and other parameters.[44] A recent study in C57BL/6NCrl mice showed no changes in hematology or other biologically or clinically relevant values after up to 1 year of exposure.[77]

In rabbits where blood was collected from the ear vein using a commercial restrainer and analyzed on the CELL-DYN 3700 (Abbott Laboratories, Abbot Park, IL, USA), heat stress (hot tropical conditions) caused increased PCV (dehydration) and lymphopenia (stress).[62]

Handling and Restraint

Mouse lymphocyte concentrations decrease with handling and other stressors, while neutrophilia is associated with stress or excitement.[65] To minimize generation of a stress leukogram, handling and restraint for other procedures, electrocardiograms, behavioral testing, physical examinations, and other room disturbances should be conducted after the collection of clinical pathology samples.[26] Blood collection via the submandibular vein in mice has been shown to be more stressful in the absence of anesthesia.[39] Acute stress induces lymphopenia in rodents by changing the distribution from the circulation into peripheral organs such as the skin or lymph nodes and bone marrow.[67] Long-term restraint for infusion studies or nose-only inhalation studies can impact hematologic results, resulting in decreased lymphocyte and eosinophil concentrations, and increased neutrophil concentrations.[68]

Transport

Movement of animals to treatment or procedure rooms, over both short and longer distances, can result in hematologic changes. In BALB/c mice, a decrease in lymphocyte concentrations at 4 hours after transport was observed, consistent with a stress-induced leukogram.[22,67] In F344/N rats that had blood collected for hematologic assessment on the day of shipment receipt versus 12 days later, the newly arrived rats had neutrophilia, eosinopenia, and monocytosis.[19] There were no notable differences in lymphocyte or platelet concentrations. Rhesus macaques had increased platelet counts during the acclimatization period, so 3 months acclimatization was recommended.[35]

Circadian Rhythms

Just as circadian rhythms impact toxicity and treatment effects, they can also affect hematologic results. For example, in rodents, peak numbers of mature circulating WBC and lymphocytes are seen during the light phase, with lowest numbers observed during the dark phase.[105] In mice, WBC, lymphocyte, and eosinophil concentrations peak in morning, and are 3× higher than in the evening. In rats, WBC numbers are lower during periods of activity than during rest periods.[100] Thus, if rodents are maintained on a reverse light cycle and blood is collected during the dark phase, their WBC concentrations will not correspond to RIs from animals on a normal diurnal cycle. To reduce variability in experimental groups when blood sampling takes several hours to complete, it is best to randomize sampling across groups rather than to complete each group one at a time (i.e., random selection of group order and animals within groups, or one animal from mid-dose, control, high dose, low dose, then repeat). Since setting up and initiating blood collection in the animal or procedure room may cause excitement in the first animals sampled, randomization of sampling order by group will reduce this temporal bias associated with excitement.[75]

Although many prosimian NHPs are nocturnal, owl monkeys are the only nocturnal species of simian NHPs and the only nocturnal NHP species commonly used in research. Diurnal variation in both RBC and WBC parameters is due to circadian rhythms and alterations in hydration.[9] These factors should be taken into consideration when sampling blood from owl monkeys.

Anesthesia and Analgesia

Any drug can have effects on hematology values and therefore effects of anesthetic or analgesic agents to be used in laboratory animals should be understood before such treatments can be administered during a study.

One study evaluating the effects of subcutaneous analgesic administration on hematologic values in mice using blood collected by cardiocentesis and analyzed on the Hemavet HV950 (Drew Scientific, Erba Diagnostics, Inc., Transasia Biomedical Ltd, East Mumbai, India) found that after 6 hours, WBC concentrations were higher in mice treated with carprofen and Hct values were lower in mice treated with either buprenorphine or tramadol compared to untreated controls.[40] In albino male mice administered oral aspirin acutely (600 mg/kg 3×/day for 7 days) or chronically (150 mg/kg daily 6 days per week for 25 weeks), blood collected by tail vein was assessed by manual methods. Effects consisted of decreased RBC count, Hgb concentration, and PCV, and increased WBC, neutrophil, eosinophil, and lymphocyte concentrations with acute or chronic doses of aspirin as compared to controls.[57] In this study, ferritin expression in the liver was also measured to assess potential for altered iron uptake from the gastrointestinal tract (as reported in humans), but was similar between dosed and control animals.

In Wistar rats, use of an injectable combination of medetomidine, midazolam, and butorphanol for anesthesia resulted in transient (<24 hours) increases in Hct values and Hgb levels, and transient decreases in total WBC counts, when assessed on the Sysmex XT-2000iV (Sysmex Corp., Kobe, Japan) after jugular vein collection.[66] In Sprague–Dawley rats (Charles River Laboratories), changes in clinical pathology values induced by carbon dioxide (CO_2) inhalation consisted of increased lymphocyte concentration in males following CO_2 inhalation, consistent with an adrenaline response. In this study, blood was collected from the orbital sinus or via cardiocentesis (terminal samples) and evaluated by automatic cell counter with manual slide differentials.[98] In a study using Wistar rats that compared hematologic results associated with three different methods of anesthesia (intramuscular injection with detomidine or ketamine, isoflurane delivered by an anesthetic vaporizer, or isoflurane-soaked cotton ball in a nose cone), blood was collected at euthanasia via the caudal vena cava and analyzed on the ADVIA 120 (Siemens Healthineers AG, Erlangen, Germany). While there was no control group, Hct values were higher than reference intervals for all anesthetic methods, and were lower with vaporizer administration compared to intramuscular and nose cone administration.[52] Increased WBC concentrations were observed in albino rats treated with indomethacin orally when blood was collected by cardiocentesis at euthanasia and analyzed using hemocytometer and manual slide differential.[1]

In pigs, RBC count, Hgb concentration, and Hct measured at 24 hours after experimental femoral fracture repair surgery were increased in the control group (fentanyl only) compared with the treatment group (fentanyl and local bupivacaine).[80]

In a study of beagle dogs, samples collected from the jugular vein and analyzed on Celltac Alpha (Nihon Kohden Corp., Tokyo, Japan) showed that isoflurane anesthesia caused a decrease in RBC and lymphocyte concentration at 2 hours, consistent with blood dilution seen with anesthesia in humans.[91]

In NHPs, the most commonly used anesthetic agent is ketamine, but other agents such as Telazol®, isoflurane, and sevoflurane are frequently used.[48] A physiologic leukocytosis, characterized by lymphocytosis and sometimes a mature neutrophilia, typically occurs when blood is collected from nonanesthetized and untrained macaques. Ketamine anesthesia reportedly reduces lymphocyte concentrations and MCV, but increases the RBC counts, Hgb concentration, and MCHC in macaques of both sexes.[48]

Euthanasia

For most laboratory animal species, blood for hematologic analysis at terminal time points is collected prior to euthanasia. For small rodents, blood is often collected during or immediately following euthanasia in order to maximize the available blood volume. During CO_2-induced euthanasia in mice, when blood was collected by cardiocentesis at the time of euthanasia and analyzed on the Vet ABC Hematology Analyzer (Scil Animal Care Company, Henry Schein, Inc., Melville, NY, USA)-exposure to 100% CO_2 resulted in leukocytosis.[69] Ideally, antemortem blood samples should be collected, prior to euthanasia, as samples collected following death may contain artifacts.

ANALYTICAL CONSIDERATIONS FOR LABORATORY ANIMAL HEMATOLOGY

Automated Hematology Analyzers

The ASVCP Regulatory Affairs Committee recommends all hematology data be generated using automated instruments.[92] If the instrument flags a potential error, a manual smear should be reviewed. When considering acquisition of an automated hematology analyzer, clinicians should assess the abilities and limitations of available commercial units, to ensure that the unit has the capability to recognize and appropriately enumerate cells from the variety of species seen in the preclinical or research laboratory.[11,59]

An industry survey on blood volume requirements for hematology panels using automated analyzers noted that most respondents used sample volumes greater than the minimums recommended by the manufacturer.[72] Issues arise when hematologic analyses are required for small rodents with limited blood volumes. Substantial differences in RBC indices (MCV and MCHC), WBC, and PLT concentrations were observed with 1:5 dilution of rat and mouse blood samples with Cellpack (diluent for Sysmex XT-2000iV, Sysmex Corp., Kobe, Japan) in comparison to nondiluted samples.[59] Different anticoagulants were used in this study, which also induced significant differences, but no other diluents were used. Siemens ADVIA 120 (Siemens Healthineers AG, Erlangen, Germany) analyzer found that several variables were unacceptably altered by dilution of rat blood.[104]

Automated devices used for mouse hematology may have several problems resulting in inaccurate

identification and decreased precision. These are due to the nature of mouse blood components, e.g., small RBC diameter, relatively high numbers of circulating immature and nucleated RBC, variable WBC morphology, platelet clumping, undercounting monocytes, and inability to differentiate atypical lymphocytes, granulocyte types, bands and early myeloid precursors, nRBC, and neoplastic cells.[65] Since accuracy may be compromised, it is recommended to make blood smears for mice for manual microscopic counts (Figure 118.5).

USE OF CONTROL GROUPS, REFERENCE INTERVALS, AND HISTORICAL CONTROLS

Control groups in preclinical studies may include a control article, a vehicle-dosed group, or a sham surgery/procedure group as indicated. It is appropriate to compare test-article-dosed animals to control group animals at the same time points. When possible, generally in dogs and NHPs, individual and group baseline values should be considered and may be used for statistical analyses. Typically, in clinical pathology reports, changes are discussed using descriptive terms such as higher, increased, lower, or decreased as opposed to diagnostic terms (see Chapter 11). Factors such as repeated blood collections can have effects that occur in both dosed and control animals. In this case, having the control animals' data provides weight of evidence that a decreased RBC mass, e.g., is not a test-article-related occurrence. In the case of most rodents, control groups are particularly necessary, since blood volume almost never allows baseline sampling.

At most contract research organizations (CROs), records are kept of control animal values for as many values as is feasible at that given site. This is analogous to a reference interval at a diagnostic laboratory. Few CROs have applied ASVCP's reference intervals guidelines and so the intervals supplied are quite variable. Intervals would be stored with metadata and so ideally could be broken down by age, sex, type of control article, type of study, etc. However, because there can be shifts in values over time, these are not always useful and should never replace real-time, study-specific control animals and baseline values for individual animals where feasible.

Historical control data are useful in some situations. When a dosed individual or group has a value that is different than a control individual or group, historical controls could be used to support that change as being related or not. If the animals' value is out of the controls' range for a particular study, but lacks any other evidence that the change in question is real, having historical control data can be used to help rule it out as a true drug effect if the value is within the historical control data interval.

In general, site-specific reference intervals should be developed for each laboratory and should follow the ASVCP guidelines.[31] Reference intervals should be used

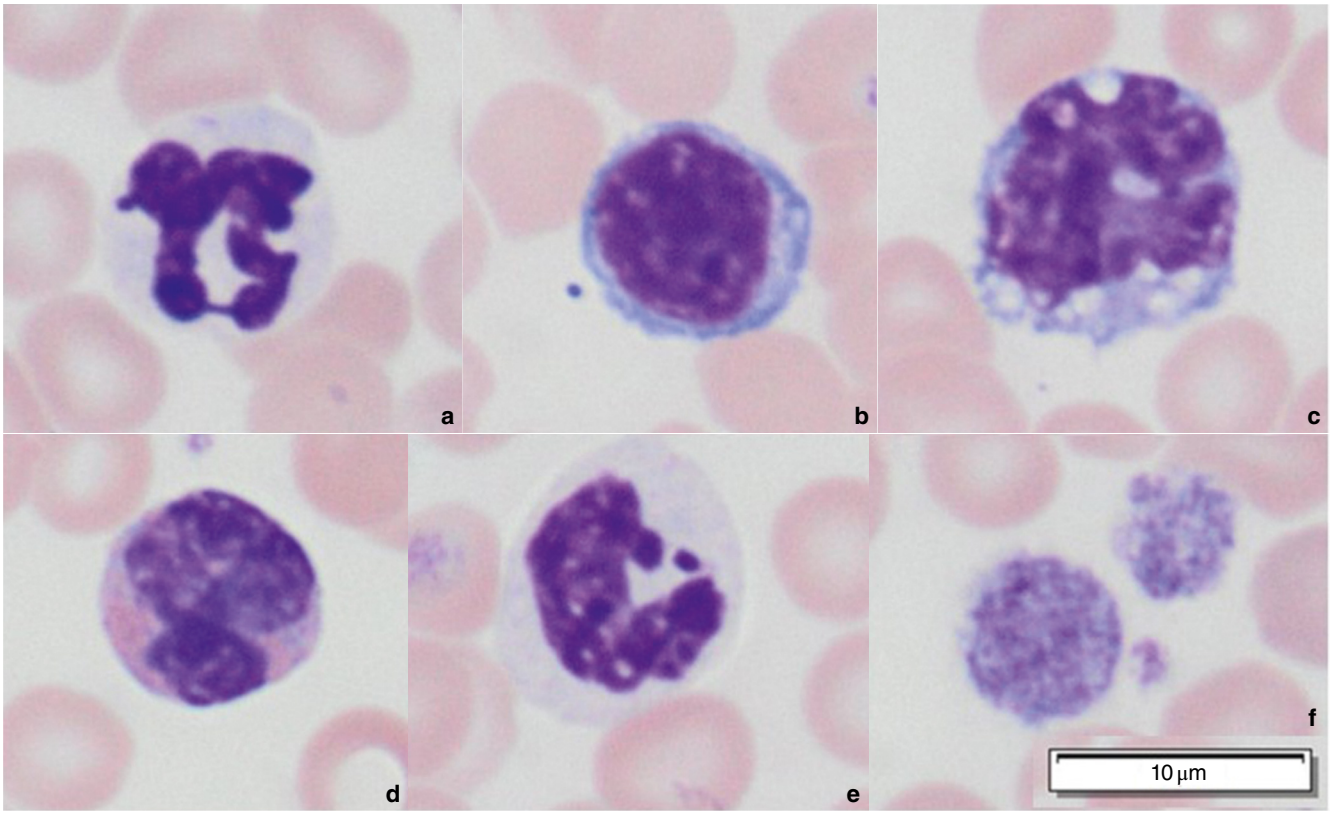

FIGURE 118.5 CBA–CaJ mouse blood peripheral blood cells: (a) Neutrophil with dense chromatin; (b) Lymphocyte; (c) Monocyte; (d) Eosinophil; (e) Neutrophil with open chromatin; (f) Three platelets with variable sizes. Wright–Giemsa stain, 100× objective.

as a tool, but not as the sole guide to determine if values are normal or abnormal, or to determine whether hematologic changes are the result of an experimental procedure. See species-specific chapters in Section IX for available control data.

POSTANALYTICAL CONSIDERATIONS FOR LABORATORY ANIMAL HEMATOLOGY

Data Presentation

Hematologic data can be presented as spreadsheets or graphs depending on personal or institutional preference. Color coding and variations in level of detail shown in tables and reports are also highly variable and often site-specific.[94] Hematologic data are nearly always numerical, and as such represented as either a percent difference or a fold change with a corresponding text modifier.[3,33] Consistent data presentation methods should be maintained throughout a particular report or program.

Data Interpretation

When interpreting hematologic data from laboratory animals, there are some inherent differences from interpreting clinical data. For example, it is important not to overinterpret results in individual animals, as there is often variability in the population. As part of the overall process of hematology data interpretation, comparisons between groups and statistically significant differences need to be critically assessed.[33]

There are also some species-specific hematologic differences that should be considered during study design. Rodent species have more reticulocytes, so will have more polychromasia and anisocytosis on blood smears. Howell–Jolly bodies and nucleated RBC are also commonly observed in blood smears from normal mice.[58] Differential counts vary in different species; mice have relatively more lymphocytes, while dogs and some species of NHPs have more neutrophils. See species-specific chapters in Section IX.

Numerous software packages can aid in streamlining data interpretation and improving consistency and standardization. The simplest data visualization tool may be Excel (Microsoft Corporation, Redmond, Washington, USA) spreadsheets. GraphPad Prism (GraphPad Software, San Diego, California, USA) and Spotfire (TIBCO Spotfire, Somerville, MA) also offer visual displays with color coding and more advanced options that can automate data correlations. Formulas can be created to determine group effects and highlight changes in individual animals.

BONE MARROW

Bone marrow histology is performed as part of any standard preclinical study and includes assessment of H&E-stained slides from all animals. Bone marrow cytology slide preparation is typically performed at necropsy and slides are stained with a Romanowsky-type stain.[76] Smears are only evaluated if indicated by hematology and bone marrow histopathology.[93] Bone marrow cytology is often collected but not evaluated unless there is a specific reason. These situations include a need to differentiate early hematopoietic precursors, investigation of incompletely characterized changes in hematopoietic cellularity on bone marrow histology, determination of whether changes in bone marrow cellularity reflect erythroid or lymphoid cell lineages, and uncharacterized atypical or abnormal cells in the peripheral blood.[76] In the bone marrow, many special stains can be employed including Giemsa to highlight bacteria or erythroid cells, new methylene blue to highlight reticulocytes or Heinz bodies, toluidine blue for mast cells and basophil granules, periodic acid schiff to detect and differentiate erythroid, lymphoid, and myeloid precursors, Masson trichrome for collagen, Prussian blue for ring sideroblasts, and reticulin for collagen III reticulin fibers.[65]

Bone marrow samples from rodents are collected at necropsy for histology as well as cytology (evaluated if indicated). Most frequently, a sagittal section of the sternum is used; a sagittal section of the femur is often also evaluated and sometimes cross-sections of the vertebrae.[76] See species-specific chapters in Section IX for bone marrow evaluation and Chapter 141 for collection techniques. An in vivo evaluation of bone marrow at an interim time point prior to necropsy is required to understand the kinetics of the hematologic response. Core biopsies or fine needle aspirates may be obtained from the iliac crest in dogs and nonhuman primates.[76]

TABLE 118.3 Reference intervals for laboratory beagle dogs.

Age and sex (number of animals)	9–34 months, both sexes (340)[10]	
	Mean	Reference interval
RBC (× 10^6/μL)	7.1	5.7–9.0
Hct (%)	47.1	38–58
Hgb (g/dL)	16.5	12.9–20.4
MCV (fL)	66.9	58–74
MCH (pg)	23.4	20.9–25.8
MCHC (g/dL)	35.1	32.2–37.5
WBC (× 10^3/μL)	9.5	4.9–18.7
Neutrophils (10^3/L)	5.9	2.2–12.2
Lymphocytes (10^3/L)	2.6	1.2–4.5
Monocytes (10^3/L)	0.5	0.1–1.5
Eosinophils (10^3/L)	0.4	0.1–1.5
Basophils (10^3/L)	–	–
PLT (× 10^3/μL)	333	192–538

TABLE 118.4 Reference intervals for cynomolgus monkeys. It is likely that there is a component of a steroid induced leukogram in these values.

Age and sex (number of animals)	19–72 months, both sexes (119)[17]	
Parameter	**Mean**	**Reference interval**
RBC (× 10^6/μL)	5.5	4.6–6.4
Hct (%)	38.0	29–47
Hgb (g/dL)	13.2	11.2–15.2
MCV (fL)	69.6	54.9–84.3
MCH (pg)	24.2	21.3–27.1
MCHC (g/dL)	35.1	27.4–42.8
WBC (× 10^3/μL)	10.3	2.52–18.08

REFERENCE INTERVALS FOR LABORATORY ANIMALS

The ASVCP has published guidelines for development and use of RIs.[31] It is strongly recommended that institutions develop their own RIs for age- and sex-matched control animals from specific colonies/vendors, to ensure accurate, reliable comparison to hematologic values from test group animals. General reference intervals that are available may be found in the species-specific chapters in Section IX and in Tables 118.3 and 118.4.

Reference Intervals
Partitioning Factors
Bone Marrow Collection and Evaluation
Hematologic Disease

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathologists; MPV, mean platelet volume; N:L ratio, neutrophil to lymphocyte ratio; TEG, Thromboelastography.

The biological family Camelidae includes two Old World species, the Bactrian (*Camelus bactrianus* and *C. ferus*) and dromedary camels (*C. dromedarius*), and four New World species, the domestic llama (*Lama glama*), alpaca (*Vicugna pacos*) and the wild guanaco (*Lama guanicoe*) and vicuna (*Vicugna vicugna*). In their respective environments, the camels adapted to severe, dry deserts and the South American camelids adapted to the high-altitude Altiplano.

Llamas and alpacas are sometimes considered to be the same with respect to laboratory reference intervals and interpretation, but there are differences between these species and separate reference intervals should be used.[5]

Venipuncture of the jugular vein is the most common blood collection method. The jugular vein lies deep in the jugular furrow and is not easily visualized in camelids, but with occlusion of the vein and ballottement, a fluid ripple may be seen. The overlying skin is thicker over the anterior neck than it is toward the forelimb, but there is more of a separation between the jugular vein and the carotid artery, so the possibility of arterial puncture is less. Posterior on the neck, the overlying skin is thinner, but a carotid artery stick is more likely. The left jugular vein is very close to the esophagus, so sampling from this side occasionally results in accidental puncture of the esophagus.

ERYTHRON

Camelids' RBCs are elliptical in shape, unlike those of any other mammals.[7,9,13] These elliptical erythrocytes are flat and thin with no central pallor. Because of their shape, they sometimes appear folded on blood smears. Hgb crystals that appear as darkly eosinophilic, dense, rhomboid-shaped structures are frequently seen on blood smears from healthy, nonanemic camelids. The cause and significance of these structures are not known.[34] Cabot rings are also occasionally seen in RBCs from clinically healthy camelids. These are narrow, thread-like structures in the form of rings or figure eights within RBCs. They are thought to be remnants of mitotic spindles and have no known clinical significance in camelid blood.[13]

As in bovids, reticulocytes are present in the normal animal, but typically in lower relative numbers than found in other mammalian species. Normal, nonanemic llamas may have reticulocyte concentrations in the range of 12,000–79,000/μL (0.2–0.6% or 0–0.4%).[9,34] Mean reticulocyte percentages for normal alpacas and vicunas are reported to be 1.4% and 1.2%, respectively. As many as two to three nucleated RBCs per 100 WBCs may be seen in nonanemic llamas.[9]

Several structural and physiologic features of camelid RBCs contribute to their high resistance to osmotic lysis,

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

decreased deformability, and high affinity for oxygen. These attributes are adaptive for life in areas of low water availability or lowered oxygen availability. Camelid erythroid membranes contain higher concentrations of the integral membrane protein, band 3, compared to other species.[16] In addition, increased cross-linking of band 3 with other membrane proteins in camelid RBCs probably contributes to their decreased deformability and resistance to hypotonic lysis.[25] Although decreased RBC deformability could be disadvantageous for animals facing a variety of environmental pressures, the disadvantage is minimized by the shape and small size of camelid RBCs that allow them to easily pass through capillaries without having to deform.

The size and shape of camelid RBCs facilitate oxygen diffusion by providing a higher effective surface area for gas exchange.[36] Goat RBCs that are of similar size, but with a smaller surface area, have a much lower oxygen capacity as well as a decreased oxygen affinity in blood.[36] Another adaptation to life at high altitude and low oxygen tension is an oxygen–hemoglobin dissociation curve that is shifted to the left, especially at lower partial pressures of Po_2, facilitating uptake of oxygen by the lung.[36] In addition, the percentage of alkali-resistant (fetal) Hgb with increased oxygen affinity is higher in adult alpacas than in adults of other species.

LEUKON

Camelid leukocytes do not have the unique features of their RBCs and are generally similar to other mammals (Figure 119.1). Neutrophils have a typical segmented nucleus and may have fine pink to purple stippling in normal cells. The neutrophil to lymphocyte (N:L) ratio in adult llamas and camels is about 1.5, which is more similar to humans, dogs, cats, and horses than it is to ruminants.[9,11,34] The N:L ratio was reported to be lower (0.5–2.9) in a group of 29 alpacas, but these were 10–18 months old, so the difference may be based more on age than species.[12] In a study of acute inflammation, the baseline mean N:L ratio in 12 healthy adult alpacas was 4.6.[26] Many published reference intervals do not include an N:L and the relatively small group sizes on which older values are reported suggest that better information is needed to make valid species comparisons. Rare band neutrophils may be seen in peripheral blood from normal animals, but they are more commonly seen in response to inflammation and their morphology is like that of other species.

Camelid lymphocytes vary in size as they do in ruminants. The percentage of granular lymphocytes in circulation in healthy llamas has been reported to be higher than that seen in cattle and horses. In four different studies, the percentage of granular lymphocytes was 7–29%, 1–19%, 0–14%, and 10–30% of blood lymphocytes.[5,11,34] Granules also vary in size.

Low numbers of monocytes are typically found in healthy camelids and have similar morphology to other species including thick band nuclei with coarse chromatin, which may round as the cell matures and reacts to antigen (see Tables 119.1 and 119.2). Cytoplasm is blue to gray and may contain numerous vacuoles (Figure 119.1c,h).

Eosinophil numbers tend to be higher in healthy adult llamas than in other species.[9,13] Eosinophils are usually hyposegmented with band-shaped to bilobed nuclei. The cytoplasm contains numerous fine to small round eosinophilic granules in light blue cytoplasm (Figure 119.1d,i).

Basophils are occasionally found in peripheral blood smears from normal camelids and can be easily identified by their copious blue granules which may obscure the banded nucleus (Figure 119.1e,j).

PLATELETS AND COAGULATION

Platelets from camelids are round to irregular and contain azurophilic granules. Camelid platelets are generally small in volume and platelet counts are higher than in many other species.[5] A study of alpaca platelet indices using the ADVIA 2120 showed that the average mean platelet volume (MPV) in healthy alpacas is lower than that of other species. The same study showed no significant difference between the ADVIA platelet counts and blood-smear-estimated platelet counts suggesting that automated counts are acceptable for this species.

Coagulation testing may be performed in camelids using instruments and reagents that are used in other mammalian species. Thromboelastography (TEG) has been investigated in adult animals and in crias. Mean values of TEG parameters (± standard deviation) for adult alpacas and neonatal crias were, respectively, R = 7.7 (±2.9), 5.6 (±2.2); K = 3.53 (±1.43), 2.55 (±1.18); α = 48.1 (±11.2), 56.2 (±10.4); maximum amplitude (MA) = 55.5 (±8.35) and 59 (±3.21) mm. Mean prothrombin time (PT) and partial thromboplastin time (PTT) were 8.6 (±0.6) and 18.9 seconds (±1.9) in adults versus 9.4 (±0.6) and 18.1 seconds (±1.96) in neonates. A significant difference was not observed between age groups.[2]

REFERENCE INTERVALS

Published reference intervals for New World camelids have been based on relatively small numbers of animals and have been obtained from animals living in a variety of situations including altitude and with different management conditions such as diet and deworming protocols.[7,8,12,34] Values presented in Tables 119.1 and 119.2 have been generated and/or verified using apparently healthy mixed-sex animals by the author in the Pacific northwest region of the United States.

Because camelid Hct and mean cell volume (MCV) cannot be accurately measured with automated hematology analyzers due to the unique RBC shape, reference intervals have most often used data generated with manual methods. Comparisons between manual methods and automated methods are now being made.[5,35] The resulting variability in published intervals highlights the value of both using reference intervals specific to a laboratory/instrument and of having information about the populations from which reference intervals are derived. In using automated hematology analyzers for camelid blood, use of the equine setting with modifications is most often reported.[5,35]

A recent study of 65 healthy adult alpacas showed that automated differential WBC counts correlated well with manual counts for neutrophils, lymphocytes, and eosinophils, and correlated poorly for monocytes and basophils. Comparisons of analyzer-based RBC reference intervals with previous reported intervals for alpacas and llamas showed differences in PCV, Hgb concentration, and RBC counts; but these were somewhat herd-dependent.[5] In a comparison of a

TABLE 119.1 Hematologic reference intervals of alpacas (*Vicugna pacos*). Reference interval is generated from 37 apparently healthy adult, mixed-sex alpacas using an ADVIA 120 on the equine setting. Pcv and differential wbc counts were performed manually.

	Oregon State University Clinical Pathology Lab
PCV (%)	25–37
RBC (× 10^6/μL)	9.5–17.02
Hgb (g/dL)	11.5–16.4
MCV (fL)	19–28
MCH (pg)	8.5–13.9
MCHC (g/dL)	41.9–48.9
WBC (× 10^3/μL)	10.5–23.4
Neutrophils (× 10^3/μL)	2.9–15.3
Bands (× 10^3/μL)	0–0.36
Lymphocytes (× 10^3/μL)	2.8–10.1
Monocytes (× 10^3/μL)	0–1.3
Eosinophils (× 10^3/μL)	0.3–6.3

point-of-care blood gas analyzer (Element POC, Heska Corp., Loveland, CO) with both a manual PCV method and automated hematology analyzer (ADVIA 120, Siemens Inc., Malvern, PA), in analyzing blood from 104 alpacas and 20 llamas, there were strong correlations between the point-of-care method and both of the two other methods, but constant and proportional biases were present for both comparisons.[35] This indicates reference intervals should be method-specific when optimized.

Reference intervals for adult, mixed-sex, alpacas and llamas for PT and PTT based on mechanical clot detection have been published, but were not generated or verified in accordance with American Society for Veterinary Clinical Pathologists (ASVCP) guidelines.[5,10,14,29] The reported PT reference intervals for llamas were all <13 seconds. There is more variation between the species in the reported PTT reference intervals: 8.8–16 seconds for llamas and 17–22.3, 12.3–21.8, and 8.85–15 seconds for alpacas, again without outlier removal and statistics in accordance with ASVCP guidelines.[5,10,14,29]

Partitioning Factors

Some of the more frequently reported age-related differences in camelids include lower PCV and Hgb concentration, and higher absolute lymphocyte and platelet numbers in juvenile llamas and guanacos compared to adults.[9,13,20] Juvenile alpacas have fewer absolute eosinophil numbers compared to adults in one report.[9]

There are few reported significant differences in camelid reference intervals between males and females. Packed cell volume is reported to be higher in adult male llamas than in adult female llamas.[20] Eosinophil numbers were reported to be significantly higher in females than males in a group of 29 10–18-month-old alpacas.[12] The median MPV of female alpacas is significantly lower than that of males.[5]

The reported effects of altitude on hematologic values in camelids are not clear. For example, Ellis reported a PCV interval of 33–42% for 40 alpacas at the La Raya, Peru, experimental station located at an altitude of 4200 meters, but Tornquist reported a mean PCV of 30.4% for 64 healthy llamas and 30.7% for 171 healthy alpacas at this same station.[7,33] Fowler reported a PCV interval for 116 alpacas at 3900 meters as 24–45%.[9] The PCV interval for 37 healthy Oregon alpacas living at an altitude of approximately 68 meters was 25–37% and for 29 alpacas in Australia (altitude not reported) was 30–42%.[12,33] Hydration status and centrifugation technique may also contribute to the reported differences.

Other environmental factors such as seasonality have not been well-documented. A study of apparently healthy free-ranging (n = 20) versus captive guanacos (n = 17) showed a higher total WBC count and higher PCV interval in the free-ranging population than in the captive population, but factors such as handling and stress could not be standardized.[15]

BONE MARROW COLLECTION AND EVALUATION

Bone marrow is most frequently obtained from the sternum or ribs of camelids with the animals standing or in left lateral recumbency. Intravenous xylazine is often used for sedation.[1,18] A good marrow sample may be obtained from the midline of the sternum at the level of the caudal aspect of the elbow when positioned naturally.[18] The site is aseptically prepared and an 11–16 gauge bone marrow biopsy needle is used to obtain samples. Bone marrow samples are most frequently aspirated into EDTA, but may be collected with no anticoagulant if bone marrow smears are prepared immediately. Slides are air-dried and stained with appropriate stains including Wright or Wright–Giemsa for general evaluation or with Perls iron stain to assess iron stores (see Chapter 141).

Cellularity of normal camelid bone marrow is reported to be similar to or somewhat increased in comparison with other mammals. In studies of seven llamas and 20 dromedary camels, cellularity of 50–85% was noted.[1,24] The morphology and maturation of erythroid cells in bone marrow was similar to that seen in other species in both llamas and camels. Erythroid cells started to change from round to elliptical as they became less polychromatophilic.[1] No dacryocytes, spindle-shaped RBCs, or uneven Hgb distribution were reported in bone marrow samples. No unique features of WBC morphology or maturation have been reported in camelid bone marrow samples. Percentages of bone marrow eosinophils are increased in comparison to other species, which parallels the higher percentages seen in blood.[1] Megakaryocyte numbers and morphology appear to be similar to those of other species. Stainable iron was present in moderate amounts in macrophages in the bone marrow of both llamas and dromedary camels.[1,24] The average M:E ratio in bone marrow of healthy camelids is similar to that of other species. It is reported to average 1.2 in dromedary camels,[24] 0.9–2.9 in llamas,[1,8] and 0.5–1.0 in alpacas.[18]

HEMATOLOGIC DISEASE

Anemia is common in sick camelids and is often hard to classify. The morphologic features of a regenerative response to anemia are less predictable in camelids than they are in many other species. Anisocytosis, polychromasia, reticulocytosis, and nucleated RBCs may be seen in response to anemia, but also may be present in nonanemic animals. In alpacas made acutely and severely anemic by phlebotomy, reticulocyte percentages increased, but only to a maximum of 1.5%, with the peak reticulocyte response occurring at a mean of 10.4 days after induction of anemia.[33] Other morphologic features of camelid RBCs that are occasionally observed in anemia include dacryocytes (tear-drop-shaped cells), spindle-shaped erythrocytes, and uneven

Hgb distribution in the RBCs.[21,22] Although these have been reported in association with iron deficiency anemia, they are seen in moderate to marked anemias of other etiologies in camelids. Anemia due to gastrointestinal and external parasites may be quite severe due to blood loss, inducing an associated iron deficiency.

Anemia of chronic disease is likely to be a factor in many sick camelids with no identifiable cause of anemia. As in other species, the anemia is most likely mild to moderate with little evidence of bone marrow response. The pathogenesis involves the influence of inflammatory mediators, including the acute phase protein hepcidin, on iron transport and erythropoietin responsiveness. In a study of 22 anemic and 22 nonanemic alpacas, no difference in serum hepcidin levels was found.[33]

Hemoparasites have been documented in camelids. *Candidatus Mycoplasma haemolamae*, a hemotropic mycoplasma, may be observed as small, round, or ring-shaped basophilic organisms on the RBC membrane, or in the background, if blood smears are not made promptly after blood collection.[19,27,31] While infection with this organism can certainly be associated with mild to marked anemia, there are many infected animals that are not anemic.[32] The prevalence of this infection in camelids in the USA is around 30% in both llamas and alpacas, with the majority of infections being subclinical.[33] Diagnosis by PCR is the most sensitive method, though some infected animals may have organism numbers that drop below the detection limit at times.[31] *Anaplasma phagocytophilum*, a tick-borne organism that infects granulocytes, has been reported rarely in alpacas, llamas, and one camel, and was associated with mild to moderate anemia.[17,30] In one of those cases, concurrent infection with *M. haemolamae* was present[17] (Figure 119.2f).

Other causes of anemia reported in other species may occur in camelids, but have not been well-documented. These include chronic renal failure, hypothyroidism, and copper deficiency. Hemolytic anemia with Heinz bodies has been reported in two alpacas ingesting red maple leaves.[6] A few reports of bone marrow neoplasia and myelodysplastic syndrome have been associated with severe, nonregenerative anemia in camelids.[3,23,28]

In addition to hemoconcentration due to dehydration as a common cause of relative polycythemia, there is evidence that camelids have a large splenic RBC reserve that may be released into circulation in response to excitement. Miller and Banchero showed that llamas given injections of epinephrine to simulate stress or excitement had increases in PCV of approximately 10% at 3 and 6 minutes postinjection. The PCV typically dropped to resting level in 20 minutes.[20]

Physiologic neutrophilia, a shift of marginated neutrophils to the circulating pool in response to catecholamine release during handling and blood sampling, may account for at least some of the discrepancies reported in N:L in healthy camelid.[7,8]

Hematologic responses to inflammation appear to be similar in camelids to those in other species. In studies where acute inflammation was induced with lipopolysaccharide or inoculation with *Streptococcus zooepidemicus*, neutrophilia and increased band numbers were noted, along with a decrease in lymphocyte counts and an increased N:L.[4,26] In the study using lipopolysaccharide

to stimulate acute inflammation, a significantly increased N:L ratio was noted as early as 12 hours.[26] This was accompanied by serum iron levels that were significantly lower than baseline.

Very few cases of leukemia in camelids have been published. They include an acute myeloid leukemia in an alpaca and one case of lymphocytic leukemia.[3,28] A published case of myelodysplasia in an alpaca described no circulating blast cells or leukocytosis, but with atypical erythroid and myeloid cells in the bone marrow (<30% blasts).[23] Considering the lack of publication, it is likely that leukemia occurs uncommonly in these species.

CHAPTER 120

Hematology of Cervids

BRIDGET C. GARNER

Erythrocytes
Leukocytes
Platelets
Reference Intervals
Hematologic Disease

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathology; LGL, large granular lymphocyte.

The Cervidae family (order Artiodactyla) is a diverse group of animals that has adapted to tropical to arctic climates, and consists of elk, white-tailed deer, mule deer, brocket deer, reindeer, chital, and red deer, among others.[15] Factors including the animal's age, sex, reproductive status, and concurrent disease(s), as well as the methods of capture and blood collection used, can affect cervid hematologic parameters as is seen with other species. As a result, defining normal hematology for such a wide range of species and subspecies can be challenging, but there are noticeable trends.

ERYTHROCYTES

Cervid RBCs are round in vivo and similar in size to, or slightly smaller than, bovine red cells (Table 120.1). More specifically, reindeer RBCs have an average diameter of 5.5 µm, whereas discoid RBCs in white-tailed deer measure 3.5–4.5 µm in diameter.[32,25] Once the blood is collected, RBCs from many cervid species assume a sickle shape, which is described as crescent or holly leaf, and called "drepanocytes" (Figure 120.1a). Other morphology variants include the matchstick (Figure 120.1b) and burr cell.[24,26] The matchstick-appearing cells may transform after initially sickling.[25] The cells are not sickle-shaped in vivo, but change their shape if the blood is alkalinized, oxygenated, or left to stand at 4°C.[23,25,26,45] This peculiarity was first described by Gulliver in 1840, and since that time sickle cells have been observed in a variety of cervids such as barasingha (*Rucervus duvaucelii*), barking deer (*Muntiacus muntjak*), chital (*Axis axis*), fallow deer (*Dama dama*), hog deer (*Axis porcinus*), mule deer (*Odocoileus hemionus*), Père David's deer (*Elaphurus davidianus*), red deer (*Cervus elaphus*), Reeves's muntjac (*Muntiacus reevesi*), rusa deer (*Rusa timorensis russa*), sambar deer (*Rusa unicolor*), sika deer (*Cervus nippon*), and white-tailed deer (*Odocoileus virginianus*).[2,8,9,15–17,33,45] At pH 7.4, most RBCs are sickled, whereas at pH 7.0, few exhibit this shape; thus, the sickling can be reversed by acidifying the blood.[45]

Some Cervidae family members do not exhibit RBC sickling; the RBCs of European reindeer (*Rangifer tarandus*) known as caribou in North America, European elk (*Alces alces*) known as moose in North America, and some North American wapiti (*Cervus canadensis*) do not adopt the sickle shape when exposed to oxygen (Figure 120.1c).[17,45,46] A standard peripheral blood smear from a healthy reindeer shows discoid RBCs with mild anisocytosis, but polychromasia is rare. Central pallor, although present, is often indistinct, and rouleaux formation is uncommon.

Deer RBCs contain several morphologic forms of hemoglobin (Hgb), each of which has different electrophoretic properties, and is associated with a distinct morphologic red cell shape.[25] "Hemoglobin heterogeneity" is not unique to cervids, but the white-tailed deer greatly exceeds the low level of polymorphism reported in other species.[24] An individual deer may contain a

mixture of one to six of 21 structurally different Hgb molecules due to variability in the up to three alpha and up to seven beta chains, whereas most other species have less than three different Hgbs.[24,26]

The sickling effect noted in cervid RBCs is due to the formation of spindle-shaped bodies from variant forms of oxygenated Hgb.[25] This phenomenon is an interesting laboratory observation, but it does not appear to have a deleterious effect on the deer or lead to shortened RBC survival.[26,33] Hemoglobin types I and III are the most commonly identified Hgb types in white-tailed deer.[25] These are associated with RBC sickling, or the formation of the crescent or holly leaf shape.[24] Hemoglobin type II, alone or in combination with Hgb types I, III, or IVb, is often associated with the development of a matchstick shape.[24,25] Red cells that contain Hgb type IVa may assume a burr or thorn-apple shape.[24] Sickling does not occur if Hgb type V or VII is present.[24,25]

The average RBC life span varies among cervids. The circulating RBCs of five white-tailed deer persisted for 125 days, one North American wapiti for 149 days, and one sika deer for 159 days.[33] A direct relationship between RBC volume and body size and an inverse relationship between RBC volume and RBC count have been recognized.[18] Such guidelines may be useful for data interpretation when reference intervals are not available.

LEUKOCYTES

Many similarities in cervid WBC morphology are seen upon review of Romanowsky-stained blood smears (Figures 120.2–120.4). The most comprehensive description of cervid leukocyte cytochemical staining and ultrastructural properties has been performed for reindeer (Figures 120.5 and 120.6).[32,19]

Neutrophils, which comprise nearly half of all WBC in reindeer,[4,32] are typically 18–25 μm in diameter with pale eosinophilic cytoplasm.[19] Reindeer neutrophils may occasionally exhibit a low number of basophilic cytoplasmic granules (Figure 120.5). The nuclei resemble those of other species, but they may be more segmented with up to seven lobes.[19]

Lymphocyte diameter ranges from 15 to 35 μm, and these cells may be round, oval, or angular, with variable nuclear to cytoplasmic ratios.[19] The cytoplasm, which is usually lightly basophilic, may contain a few fine azurophilic granules. This cellular morphology is consistent with that of large granular lymphocytes (LGLs). Neutrophil to lymphocyte ratios are typically less than, or equal to one,[1,18,44] but some studies indicate that neutrophils are the most abundant leukocytes in cervids (Table 120.1).[32,43,48]

Monocytes have reniform to oval nuclei with light, blue-gray cytoplasm on peripheral blood smears. Occasionally, there are clear cytoplasmic vacuoles and a small quantity of red-to-pink cytoplasmic granulation.[19]

Eosinophils are slightly larger than neutrophils at 25–30 μm in diameter. The red-orange cytoplasmic granules are typically small and round, with an electron-dense appearance via electron microscopy.[19] The granules frequently group and form aggregates on one or both sides of the nucleus.[19]

Two distinct basophil populations may be seen in some cervids, reindeer in particular (Figure 120.7).[19] The

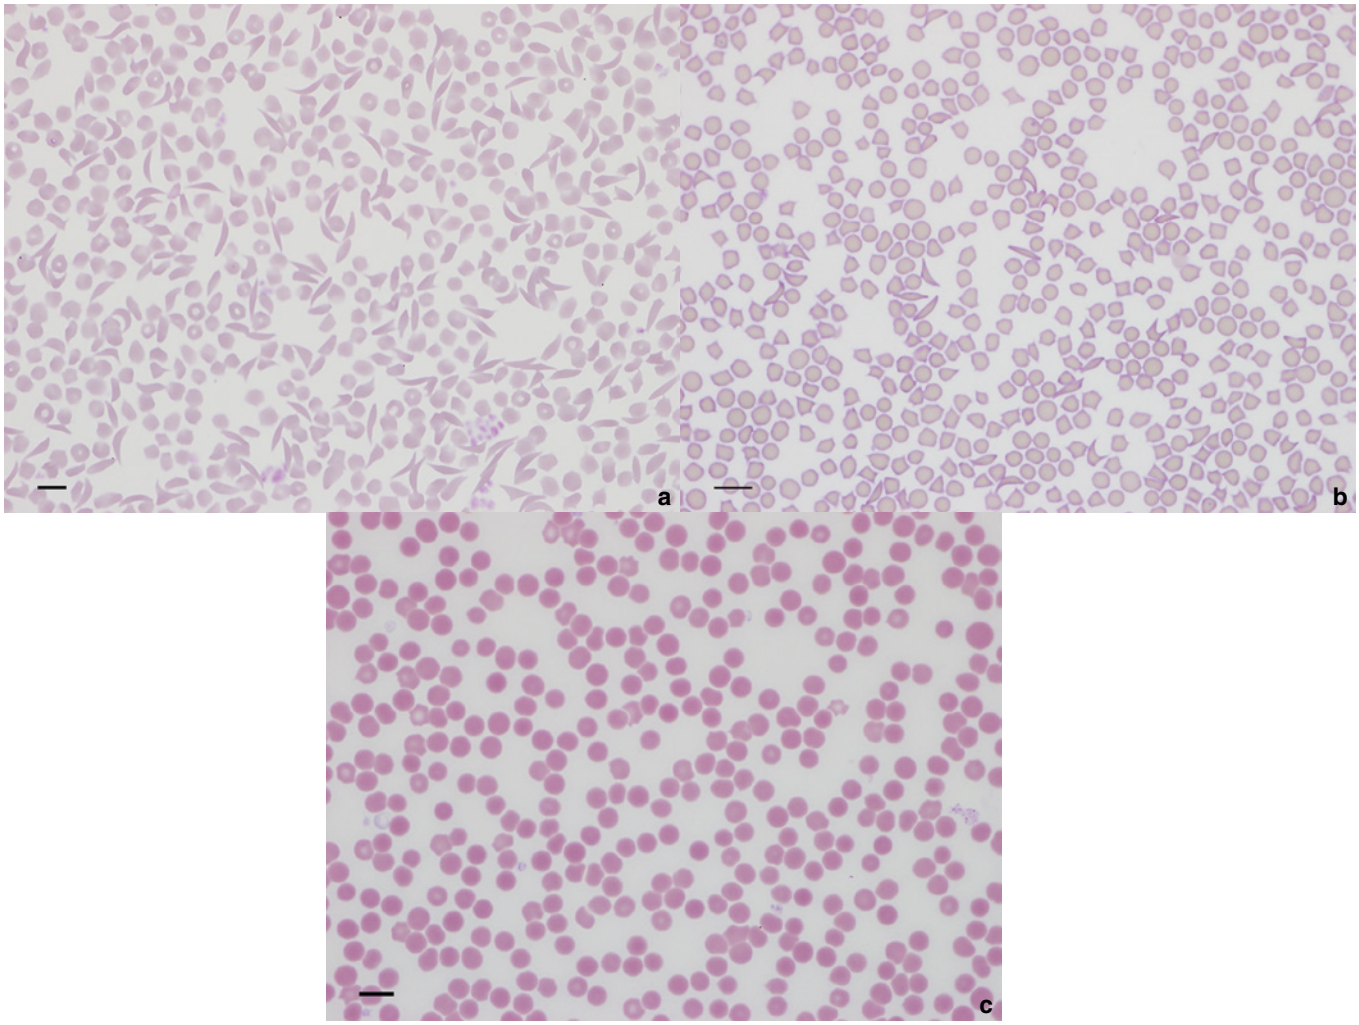

FIGURE 120.1 Normal cervid erythrocytes. Modified Wright stain. Scale bar = 10 µm. (a) Deer, RBCs with normal sickled appearance. Platelets are small and moderately granulated; (b) Deer, RBCs with sickled and matchstick appearances; (c) Reindeer, non-sickled RBCs. Platelets are small and moderately granulated.

first type has the typical appearance noted within most other mammals. These basophils have numerous, pale to dark basophilic granules disseminated throughout the cytoplasm. The second population is cytologically similar to "gray" basophils seen in limited other species. These cells have variable numbers of clear cytoplasmic granules (or vacuoles) that are less than 1.0 µm in diameter interspersed with variable numbers of intensely basophilic, perinuclear granules of similar size. The perinuclear granules may obscure a portion of the nucleus and make it appear ragged or deformed. Both basophil populations can be identified within the same blood smear, and the relative proportions of each can vary between individuals.[19]

PLATELETS

Cervid platelets, including reindeer, are relatively small (Figure 120.1), but the reference intervals for platelet counts are wide with much variability between studies (Table 120.1).[18,30,40] Platelet morphology has not been studied extensively in cervids.

REFERENCE INTERVALS

Complete blood count data are depicted in Table 120.1 that generally followed American Society for Veterinary Clinical Pathology (ASVCP) guidelines for reference interval generation including outlier removal and appropriate statistics. Medical management of cervids should employ species-specific and likely method-specific reference intervals with appropriate outlier removal and statistics. Given the effects of age, sex, reproductive status, season, and the manner in which the blood is collected, there are many variations of reported reference intervals for cervids.

Age has several effects on hematologic values in cervids. There is a direct correlation between age and RBC values. Newborn chital deer have lower RBC counts than juveniles and adults, and newborn reindeer have

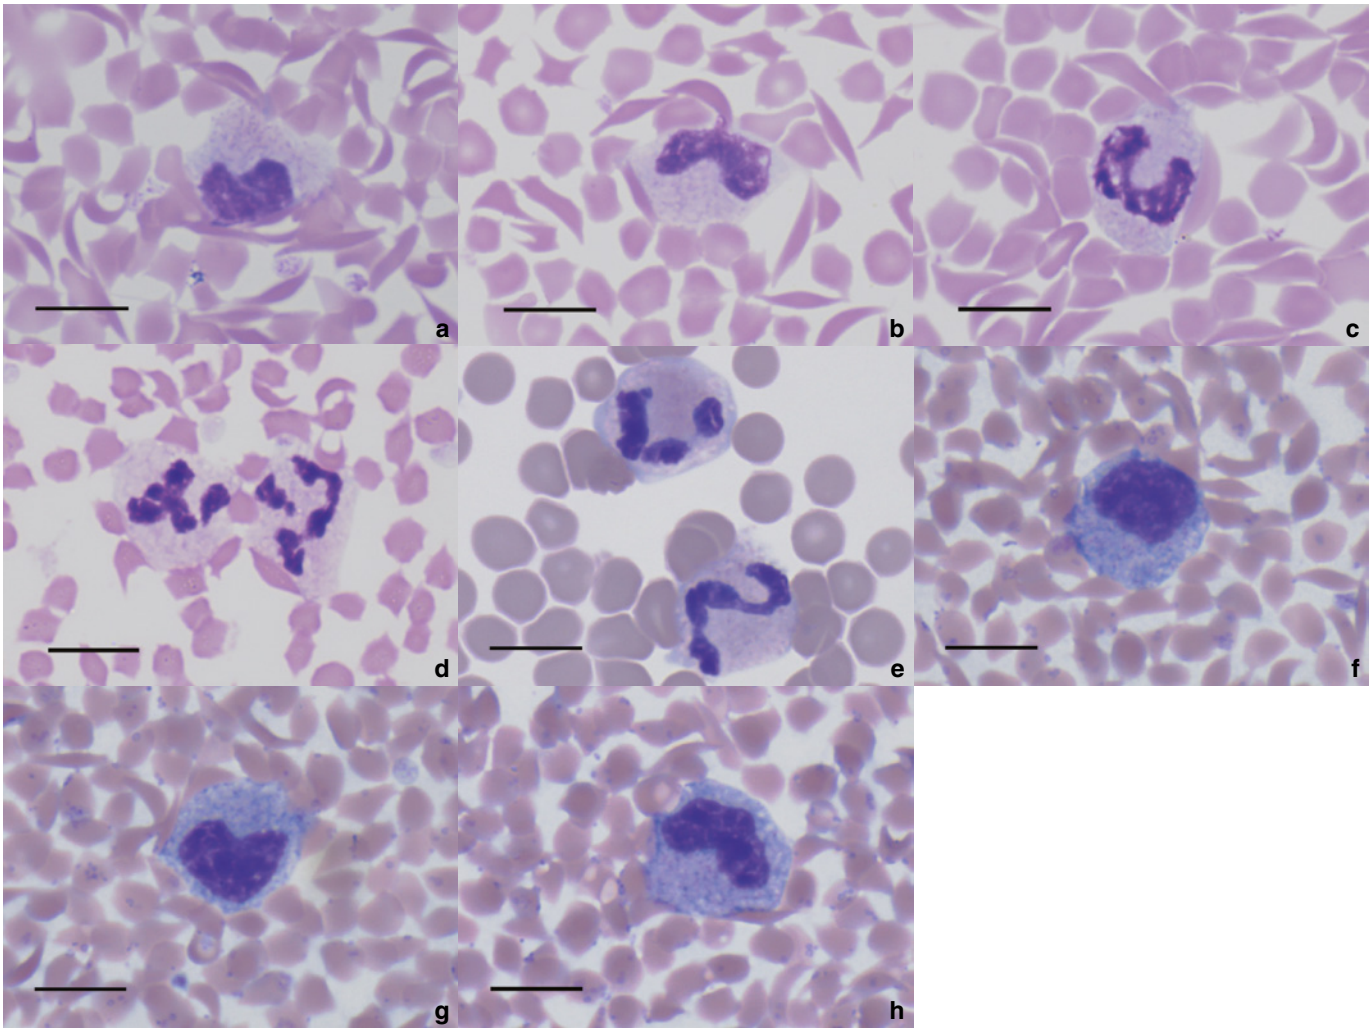

FIGURE 120.2 Normal and toxic circulating cervid neutrophils and neutrophil precursors. Modified Wright stain. Scale bar = 10 µm. (a) Deer, metamyelocyte neutrophil; (b) Deer, early band neutrophil; (c) Deer, late band neutrophil; (d) Deer, segmented neutrophils; (e) Wapiti (elk), segmented neutrophils; (f) Deer, toxic myelocyte neutrophil and *Mycoplasma* infection; (g) Deer, toxic metamyelocyte neutrophil and *Mycoplasma* infection; (h) Deer, toxic band neutrophil and *Mycoplasma* infection.

RBC counts, PCV, Hgb, and mean cell hemoglobin concentration (MCHC).[4,5,43] As white-tailed deer fawns age, their energy requirements increase, as do their RBC counts and their Hgb concentration.[5,36] In chital deer, RBC counts and Hct increase by 40–60% from birth to 10 months of age.[6] Similar findings have been reported for captive reindeer and white-tailed deer.[4,36] In contrast, reticulocyte and platelet counts are higher in newborn reindeer.[4] Reindeer hematologic values stabilize at approximately 5 months of age; therefore, adult reference intervals may be useful when interpreting data from animals 5 months or older if juvenile reference intervals are not available.[32,43]

Anisocytosis, poikilocytosis, basophilic stippling and sickling vary between young animals and adults. Marked anisocytosis and poikilocytosis are found in blood smears from healthy newborn reindeer, but only mild anisocytosis is expected in normal adults. Basophilic stippling and a small number of nucleated RBCs may also be identified in the neonates.[4] Neonatal and juvenile deer RBCs are unlikely to sickle due to the predominance of fetal Hgb (approximately 95% of total Hgb at birth).[22,25] Over time, fetal Hgb is replaced by adult Hgb, and sickling is expected to appear by 8–12 weeks of age if the appropriate adult Hgb forms are present.

There is an unclear connection between age and WBC parameters in cervids, which may be due to species, variation in the measurands, or reference interval generation. Some studies have established a correlation between age and WBC counts, but others have found conflicting results or no correlation at all.[34,36,44] One study that identified an association between age and WBC count determined that neonatal chital deer had significantly greater WBC counts than juveniles or adults.[6] In another study, white-tailed deer WBC counts were highest at 1 month of age.[21]

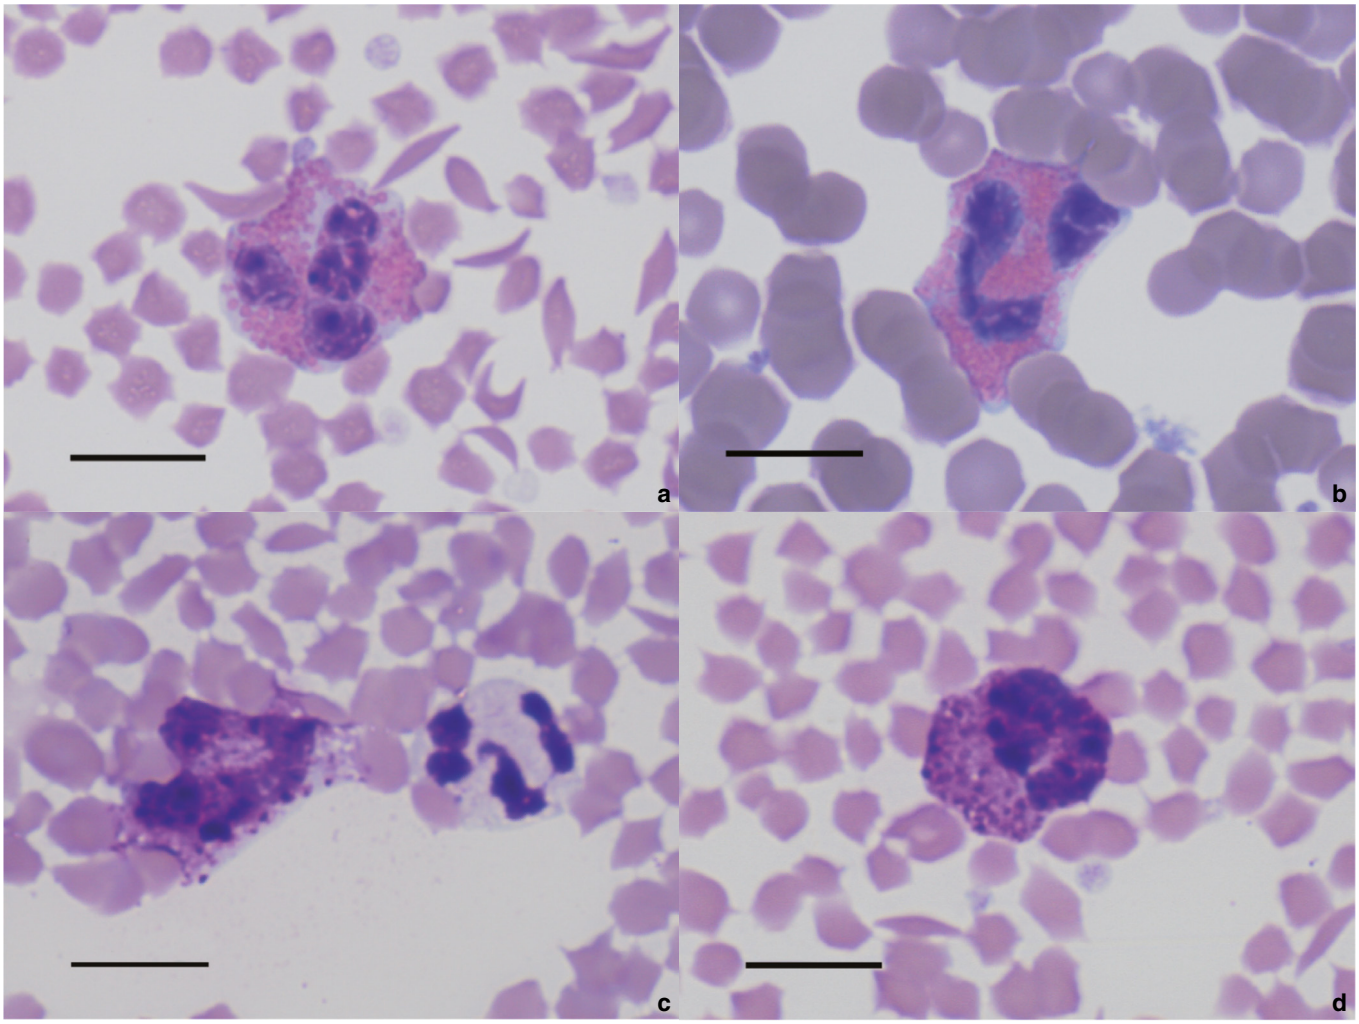

FIGURE 120.3 Normal circulating cervid eosinophils and basophils. Modified Wright stain. Scale bar = 10 µm. (a) Deer, eosinophil; (b) Wapiti (elk), eosinophil; (c) Deer, basophil (left) and segmented neutrophil (right); (d) Deer, basophil.

Meanwhile, WBC counts were typically lower in newborn than juvenile reindeer.[4] The total WBC count is not the only discrepancy found between age groups. In adult chital deer, lymphocytes predominate, but an increased number of neutrophils and a neutrophil:lymphocyte ratio of 2:1 were found in neonates.[6] In rusa deer <90 days old, the neutrophil:lymphocyte ratio was also greater than one, but in older deer, the ratio was less than one.[44]

Sex-related changes in hematologic patterns are most evident in adult cervids.[6] Significant differences between newborn and juvenile male and female reindeer are not typically found, since sex-related variations in hematologic parameters are more significant with sexual maturity and adulthood.[4] RBC count, Hgb concentration, and Hct as well as total WBC count were higher in chital stags than in chital hinds.[5] Similar patterns were noted in male and female rusa deer.[2] However, this observation does not appear to be absolute, since studies did not observe these RBC or WBC variations in mule deer or red deer.[1,30] Adult female reindeer living in zoological parks had higher Hgb, PCV, mean corpuscular volume (MCV), and neutrophil and lymphocyte counts than adult males.[43]

Changes in the erythron due to reproductive status are reported in both male and female cervids. As mating season approaches, RBC, Hct, and Hgb increase to maximum values in male red deer (*C. elaphus*), and decrease thereafter.[12] In female tule elk, pregnancy results in increases in Hgb, RBC count, Hct, and MCV.[40] In female reindeer, PCV, MCV, and Hgb values are higher (and may peak) during the autumn months and then decrease with parturition and the early lactation period.[43] In particular, the Hgb concentration of pregnant reindeer decreases by approximately 3 g/dL or more leading up to and following parturition.[43] The decreases in RBC count, Hgb concentration, and PCV seen in female reindeer in the early stages of lactation were attributed, at least partially, to iron deficiency.[32]

An animal's reproductive status can also affect the WBC and platelet concentrations. During the annual

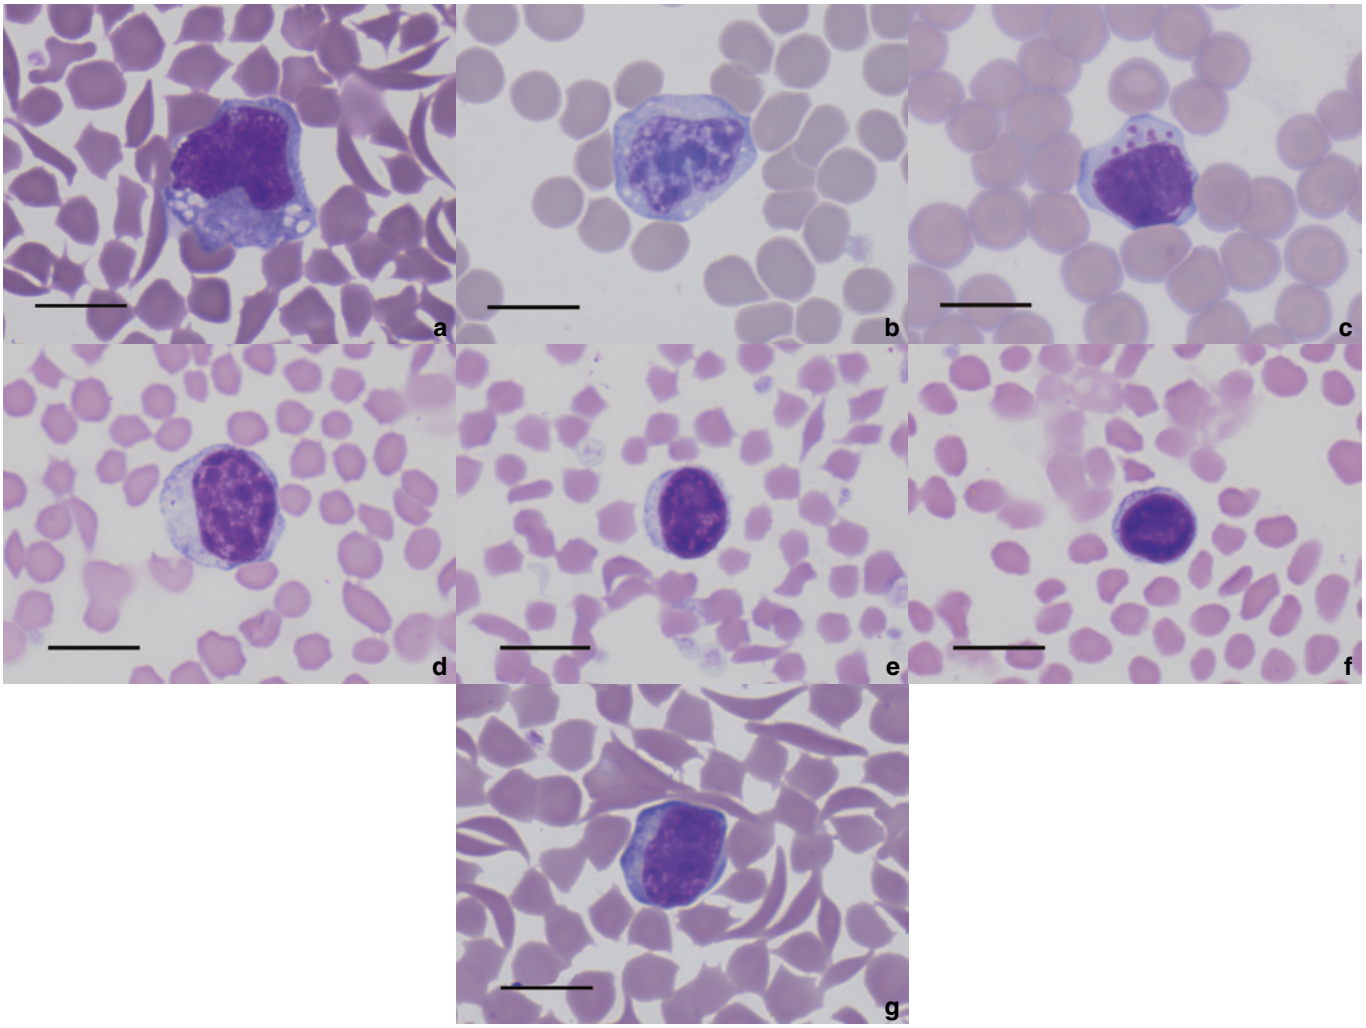

FIGURE 120.4 Normal circulating cervid monocytes and lymphocytes. Modified Wright stain. Scale bar = 10 μm. (a) Deer, monocyte; (b) Wapiti (elk), monocyte; (c) Wapiti (elk), large granular lymphocyte; (d) Deer, large lymphocyte; (e) Deer, medium-sized lymphocyte; (f) Deer, small lymphocyte; (g) Deer, reactive lymphocyte with basophilic cytoplasm.

rutting period, chital deer stags had altered differential leukocyte counts. The WBC count increased in pregnant tule elk due to increased lymphocyte numbers.[40] The mean platelet count in red deer (*C. elaphus*) peaked twice throughout the year.[12] The most significant peak (reaching a mean platelet count of 607.94 ± 54.18 × 10^9/L) occurred in October, during mating season, whereas a smaller peak occurred in the spring.[12]

Cervids are easily excitable, and this is demonstrated by the hematology data. As a result, caution should be used when applying captive animal reference intervals to free-ranging populations and vice versa.[34] Red and white cell values are significantly higher in nonanesthetized deer than in chemically restrained animals.[42] A greater stress response is evidenced by increased plasma cortisol and noradrenaline concentrations. Subsequent splenic contraction contributes to the changes in the awake, physically restrained cervids, but drug-specific effects may be present in sedated animals.[30,28,38,42] A stress response to various handling conditions is repeatedly demonstrated in reindeer.[37,38] Reindeer stressed during venipuncture demonstrate increased WBC counts and decreased lymphocyte numbers, as well as moderate increases in PCV, Hgb, and RBC count.[37]

Changes in the erythron and leukon due to handling and restraint are not consistent across species and sex. Chital does had significantly greater increases in PCV and RBC and WBC counts than chital bucks when both groups were physically restrained for blood collection.[6] Nonanesthetized male marsh deer had higher PCV than females.[42] In contrast, little or no difference in WBC count was seen between excited and resting male sika deer or between farmed male and wild female sika deer.[28]

Intermittent handling of cervids may decrease their stress and subsequently decrease stress-induced hematologic changes. In chital hinds, Hgb, RBC count, and Hct values rose 10–20% during early restraint periods, but declining values suggested that hinds adapted to

repeated handling within 4 weeks.[5] Stags did not show these distinct and sequential erythron changes with handling, although the relative percentages of WBCs changed after the initial period.[6] The annual male reproductive cycle may have confounded hematologic alterations associated with adaptation to handling stress.[6]

HEMATOLOGIC DISEASE

Infections from epizootic hemorrhagic disease virus, bluetongue virus, and *Yersinia pseudotuberculosis*, among others, contribute to hematologic changes in cervids.[7,20,35] Lymphopenia is commonly identified, and it may be an indicator of decreased survival.[7,35] Acute bacterial infections or other inflammatory conditions contribute to neutrophilia in reindeer similarly to that seen in other species.[4] Two North American elk infected with *Babesia odocoilei* (Figure 120.8a) presented with a normocytic normochromic nonregenerative anemia, but the leukogram abnormalities differed between animals.[10]

Multiple hemoparasites are reported in cervids, but direct connections between these infections and clinical signs are rarely made. A *Mycoplasma ovis*-like organism was initially recognized in a farm-raised white-tailed deer fawn due to the presence of many coccoid, bacillary, and ring-shaped organisms on the blood smear

(Figure 120.8b).[3] Concurrent respiratory and gastrointestinal diseases were confounding factors in the fawn, but multiple affected females from the herd were subclinical.

DNA screening of free-ranging white-tailed deer showed a high prevalence of *Mycoplasma sp*. infections comprised of multiple species.[29] Clinical abnormalities were not detected during PCV measurement or on postmortem analysis. Free-ranging and captive Brazilian deer also had a high prevalence of hemoplasma infections that contained multiple genetically distinct species, but the pathogenic potential was not elucidated.[13,14] A hemomycoplasma species was identified in a herd of reindeer.[41] These animals were often anemic (characterized by either microcytosis or macrocytosis), with abundant poikilocytosis and visible organisms on the blood smear. Concurrent nematode infection may or may not have contributed to the anemia and RBC morphology changes.

Theileriosis was confirmed in a farmed reindeer with anorexia and weight loss.[11] Ring-shaped organisms were found on blood smear review, and PCR confirmed the organism was closely related to, albeit distinct from, *Theileria cervi* (Figure 120.8c). Both *Trypanosoma cervi* (Figure 120.8d) and *Theileria cervi* were seen on a blood smear from a white-tailed deer fawn.[47] Lesions associated with systemic trypanosomiasis and theileriosis were not found on necropsy.

ACKNOWLEDGMENT

The author wishes to acknowledge Dr. Katie Boes for her contribution to this chapter in the previous edition.

Acronyms and Abbreviations

ANAE, alpha-naphthyl acetate esterase; ANBE, alpha-naphthyl butyrate esterase; APTT, activated partial thromboplastin time; ASVCP, American Society for Veterinary Clinical Pathology; AT, antithrombin; CAE, chloroacetate esterase; CSS, cold stress syndrome; DIC, disseminated intravascular coagulation; EEHV, elephant endotheliotropic herpesvirus; HAB, harmful algal bloom; LAP, leukocyte alkaline phosphatase; MA, maximum amplitude; PAS, periodic acid–Schiff; PT, prothrombin time; SBB, Sudan Black B; SAA, serum amyloid A; TEG, thromboelastography.

The Paenungulata clade contains the extant mammal orders of Sirenia (manatees and dugongs), Hyracoidea (hyraxes), and Proboscidea (containing the family Elephantidae, or elephants). This clade is distantly related to the horse. As well as sharing genomic and morphological similarities[52], some members of this clade display similar and unusual hematologic characteristics: very large RBCs, the presence of heterophils instead of neutrophils, and the existence of a unique bilobed monocyte.

ELEPHANTIDAE

The Asian elephant, *Elephas maximus*, is found naturally in south-east Asia and the Indian subcontinent. Asian elephants do occur in the wild, but have also been commonly used for work and ceremonial purposes. The African elephant, *Loxodonta africana*, does not have a close history of association with humans.

Erythron

With recently reported mean cell volume (MCV) ranging from 104–138 fL, and an average cell diameter of 9 µm, the elephant RBC is the largest among terrestrial mammals.[1,25,30,51,65] The hematocrit (Hct) or PCV ranges from 27% to 47%, with an average of 35%.[1,25,30] Because of the large RBC size, the RBC count tends to be lower than in other mammals, with reported ranges of 1.4–6.6 × 10^{12}/L.[1,25,30,65] RBC, PCV, hemoglobin concentration (Hgb), and RBC indices appear to be fairly similar when comparing African and Asian elephant data, taking different analytical methodologies and reference populations into account.

Anisocytosis is mild and occasional schistocytes and acanthocytes may be present. Reticulocytes and nucleated red blood cells (nRBCs) are generally absent from the blood of healthy elephants.[1,30,12] Elephant RBCs exhibit strong rouleaux formation, similar to that seen in horses, and the RBC sedimentation rate is high.[51,53] Both Asian and African elephant RBCs display greater osmotic resistance compared to those of humans and domestic animals, probably due to the high surface area to volume ratio of the elephant RBC.[55,65]

Leukon

Leukocytes have similar morphology and cytochemical staining characteristics in both elephant species (Figure 121.1). A unique feature of the elephant leukon is the bilobed monocyte, which has been described in both African and Asian species. In addition, like the rest of the Paenungulata clade, the elephant "neutrophil" contains many pink cytoplasmic granules, and has inconsistently been called a heterophil by some authors and will be referred to as such here.[25,53]

Elephant heterophils are 12–16 μm in diameter, with many fine, round to oval, variably sized reddish granules and a nucleus containing three to five lobes.[25,30,51] The heterophil of the Asian elephant shows variably positive staining for peroxidase, strong positivity for Sudan Black B (SBB), moderate positivity for leukocyte alkaline phosphatase (LAP) and chloroacetate esterase (CAE), and negative staining for alpha-naphthyl acetate esterase (ANAE), alpha-naphthyl butyrate esterase (ANBE), and periodic acid–Schiff (PAS).[25,51] When viewed with electron microscopy, these cells are round with short microvilli and small pores, and contain larger electrolucent primary granules and smaller secondary granules, which can be either round or oblong.[25,30]

Lymphocytes have a similar appearance to those of domestic livestock, and small, medium, and large lymphocytes are seen on blood smears, with the latter two being most common. The nucleocytoplasmic ratio is high, with a round to oval to slightly indented nucleus and a thin rim of pale blue cytoplasm.[25] Purple granules may rarely be present. Elephant lymphocytes stain variably positive with ANAE and ANBE and negative with SBB, peroxidase, CAE, and LAP.[1,25,51]

Monocytes in both elephant species have variable morphologies, ranging from a large cell similar to that seen typically in domestic animals with a polymorphic nucleus and vacuolated blue cytoplasm, to a bilobed cell, to a monocyte with a round to oval nucleus. The bilobed monocyte measures 16–18 μm in diameter, with a pale blue, occasionally vacuolated cytoplasm. The nucleus is horseshoe-shaped with two lobes; trilobed forms have been described.[25,51,53] Monocytes may also display a round to oval nucleus when spread out on a smear, and these forms have been confused with lymphocytes. Discriminating features include the presence of cytoplasmic vacuoles and a coarser, more clumped chromatin pattern in the monocyte.[25] Both of these unusual leukocytes have been conclusively shown to be monocytes in both African and Asian elephants, using cytochemical staining and electron microscopy. They stain weakly or focally positive for peroxidase, indicating a phagocytic function.[1,25,53] Further cytochemical staining characteristics include variable positivity for ANAE, SBB, and CAE and negativity for LAP and ANBE.[1,25] When viewed with the electron microscope, both bilobed and round nucleus monocytes contain a low number of small round variable electron dense granules (100–300 nm in diameter), numerous mitochondria, and variable numbers of tubulovesicular structures.[25]

Eosinophils are slightly larger than heterophils with a 14–18 μm diameter and have a pale blue cytoplasm filled with small but distinct, round, red-orange, refractile granules. Nuclear shape ranges from band to bilobed to trilobed, with coarsely clumped chromatin.[25,51] They stain strongly positive for peroxidase, ANBE, and ANAE and moderately positive for SBB; while being negative for alkaline phosphatase and CAE.[25,51] Ultrastructurally, granules are round to oval to rod-shaped.[25,51]

Basophils have a band-shaped to bilobed nucleus and contain numerous small lavender to magenta granules. They stain moderately positive with ANAE and negative with SBB and peroxidase.[25,51]

Disparities in elephant differential cell counts are present in the literature. Old publications tend to count the bilobed monocytes as lymphocytes, or as a separate population of cells, resulting in highly variable results.[1,16,45,65] Even when reviewing only studies from the last 20 years, where the bilobed monocyte has been counted as a monocyte, or as a separate population, there are discrepancies. This is partially due to the difficulty in differentiating reactive monocytes with round to oval nuclei from lymphocytes; however, the correct identification of these cells with round nuclei as monocytes has been confirmed with special stains. For example, in one study the lymphocyte (all cells with round nuclei, likely incorrectly categorized) was found to be the dominant cell type in both captive (not immobilized) and free-ranging (immobilized) Asian elephants from Sri Lanka, making up an average of 40–44% of the differential, with heterophils and monocytes (including bilobed cells) each around 25–30%. Percentages of eosinophils were roughly 5% and basophils were generally less than 1%.[53,54] This is different to results from a small group of captive elephants in Thailand, where bilobed monocytes (counted separately) had a mean differential percentage of 37%, with lymphocytes at 27%, heterophils at 29%, and "normal" monocytes at 1%.[51] This is in turn completely different to another recent study from Thailand in which hematology data from 149 male and female Asian elephants in tourist camps in Thailand were analyzed; bilobed monocytes were not identified at all.[30] Samples were measured on an automated hematology analyzer with manual differential counting; the authors attempted to count bilobed monocytes as a separate population but did not find any. (These data are not presented in this chapter.) Leukocyte counts using cytochemical staining on blood smears from a

group of captive Asian elephants in the USA, where all cells described here as monocytes (bilobed and round nuclei) were counted as such, revealed that monocytes are the dominant cell type, followed by heterophils, lymphocytes, eosinophils, and basophils[25] (Table 121.1). Current automated techniques cannot be expected to correctly identify elephant leukocytes and manual differential cell counts are always required. It is vital that monocytes are identified correctly, as described here, and that appropriate reference intervals are used.

TABLE 121.1 Hematology reference data for Asian elephants (*Elephas maximus*) and African elephants (*Loxodonta africana*). Note that in the first case, sample size was small and therefore the minimum–maximum range is reported. The Asian elephant reference population comprised 25 adult, predominantly female animals, from zoological collections in the USA.[1,25,58] The free-ranging African elephant population comprised 48, mostly male adult animals, from the Kruger National Park in South Africa.[58] Only 23 samples from the automated hematology analysis were finally included after applying the QA screening process.

Platelets and Coagulation

Platelet counts in 22 wild caught African elephants ranged from 229–622 × 10^9/L and in captive Asian elephants from 106–719 × 10^9/L.[25,30,17] Ultrastructural examination, using transmission and scanning electron microscopy, has shown that platelets from both species do not have a surface open canalicular system.[14,17] They do contain α-granules, dense bodies, mitochondria, Golgi bodies, glycogen, and filamentous structures of unknown function.[14,17] Elephant platelets show reversible aggregation in response to a low dose of an agonist such as platelet-activating factor or adenosine diphosphate.[14] Activated platelets demonstrate numerous cytoplasmic protrusions, rather than pseudopodia, and there is no interaction between adjacent platelets.[14] As has been observed in bovines, gaps form in the cell membrane during activation, which may provide the route of granule extrusion in the absence of a canalicular system.[14]

Activity of Asian elephant coagulation factors VII, IX, X, and XI and antithrombin (AT) was found to be similar to that of humans. Activity of factor VIII was about twice that of humans. Commercially available reagents (in particular recombinant tissue factor) can be used for coagulation testing in Asian elephants, but results will differ between different manufacturers. For seven elephants, prothrombin time (PT) ranged from 8.8–12.3 seconds and activated partial thromboplastin time (APTT) from 52.1–83.5 seconds. Although factor XII activity was higher than in humans, APTT was up to two times longer than in humans, using the same analytical system. The reason for this is not clear.[20]

Asian elephants have hypercoagulable tracings using thromboelastography (TEG), in particular high maximum amplitude (MA) and α-angle with minimal clot lysis, compared to domestic species, although similar to manatees.[46]

An Asian elephant originating in Malaysia and housed in an Australian zoo was found to have persistently elevated PT. Factor VII deficiency caused by a homozygous missense mutation in the gamma-carboxyglutamic-acid-rich domain of the factor VII gene, resulting in arginine for glycine substitution, was identified. This elephant did not show any clinical signs of a hemostatic disorder, and the mutation was not found in the rest of the Australian zoo elephant population.[35]

Reference Intervals

Multiple publications presenting hematology data from healthy elephants of both species exist.[1,16,25,30,46,53,54,58,65] Very few studies, however, have followed accepted guidelines, e.g., those from the American Society for Veterinary Clinical Pathology (ASVCP), for reference interval generation.[18] Additionally, all of the older papers and some recent ones use manual and not automated methods, which are subject to a high degree of analytical imprecision. In studies where automated hematology systems were used, there is usually no information about analytical performance or validation of the method, which is likely to be important in these animals with very large RBCs as well as very different WBC morphologies. As discussed in the earlier text, there are also huge discrepancies in monocyte identification, leading to significant variation in monocyte and lymphocyte reference intervals.

The hematology data presented in Table 121.1 for 20 captive Asian elephants were generated using an automated hematology analyzer, with manual differentials using modified Wright–Giemsa staining and cross-checked using cytochemically stained slides. Bilobed and round nucleus monocytes were counted as monocytes. A recent study generated clinical pathology reference intervals according to ASVCP guidelines for free-ranging apparently healthy African elephants from the Kruger National Park, South Africa.[58] After a strict outlier elimination procedure, hematology reference intervals were derived from 24 EDTA whole blood samples analysed on the scil Vet abc (Scil Animal Care Company, Henry Schein, Inc., Melville, NY, USA) or Horiba ABX Micro ESV60 (Horiba Ltd., Kyoto, Japan) automated analyzers. Reference intervals were also generated for manual PCV from 48 samples. Other studies on African elephants used samples from culled animals and manual counting methods and are not reported here.[16,65] Hemostasis reference intervals for TEG, clotting times, and fibrinogen were generated according to ASVCP guidelines for up to 26 captive Asian elephants.[46] Data and methods used are presented in Table 121.2.

Partitioning Factors

Hematologic values appear to be similar for African and Asian elephants, apart from the WBC differential cell count, which is highly method-dependent. Various studies have shown few differences between subgroups of elephants. There was no difference in results between a group of captive, nonimmobilized Asian elephants and a group of free-ranging, immobilized individuals of the same species.[54] MCV and mean cell hemoglobin concentration (MCHC) were higher in female versus male Asian elephants in one study, but not in others.[30,53,54] No age or sex differences in hemostatic measurands have been identified; however, studied partitioned subgroups were small and the statistical testing lacked power.[46]

RBC counts and PCV have been reported to be slightly lower in pregnant versus nonpregnant Asian elephants, due to volume expansion associated with pregnancy.[45] Higher values for RBC, Hgb, MCHC, and lower values for MCV were found in free-ranging African elephants in the dry season compared to the wet season, probably due to dehydration.[65] Both young Asian and African elephants have higher WBC counts than adults.[12,65]

Biological variation of hematology or hemostasis measurands in elephants is minimally reported. One study concluded that there were no remarkable seasonal changes in hematology results collected from four captive Asian elephants every two weeks over a 12-month

TABLE 121.2 Hemostasis reference data for Asian elephants(*Elephas maximus*). The reference population comprised 8 male and 30 female captive animals from zoological collections in the USA and United Kingdom.[46]

Measurand (units)	Method	Sample size	Mean	SD	Min–max range	RI

period, but did not evaluate the data statistically.[44] The author of this chapter calculated intraindividual variation in a group of four captive female African elephants using data measured on a CELL-DYN 3500 (Abbott Laboratories, Abbot Park, IL, USA) hematology analyzer and found intraindividual coefficients of variation of 10.3% for WBC, 9.4% for RBC, 7.3% for Hgb, 7.4% for PCV, 3.3% for MCV, and 2.1% for MCHC. These values are similar to those found for dogs.[27]

Blood and Bone Marrow Collection

Many captive or working elephants are trained to allow blood collection without restraint or sedation. Blood is collected from the auricular veins on the medial surface of the ear, in a standing or laterally recumbent elephant. Vasoconstriction may occur in cold weather, making these veins difficult to visualize. A hair dryer may be used to warm up the area to promote vasodilation. The lateral auricular veins, cephalic vein (medial proximal forelimb), or saphenous vein (distal hindlimb) may also be used for collection. If these sites are chosen, a tourniquet (e.g., bungee cord) will be needed to raise the vein. A large bore needle is advised to prevent damage to the very large elephant RBCs.

Elephant long bones do not have open marrow cavities and are filled with dense trabecular bone.[43] Hematopoiesis may take place in the vertebral bodies; further research is needed.

Hematologic Disease

Elephants with inflammatory disease may not show leukocytosis, heterophilia, lymphocytosis, and/or monocytosis. More common and specific changes include left shifted heterophilia, heterophil toxicity, reactive lymphocytes, plasmacytosis, and marked monocytic activation.[56] A left shift may include the presence of giant toxic heterophils and precursors as early as myelocytes. Toxic heterophils exhibit Döhle bodies and cytoplasmic basophilia. Serial blood smear examination in elephants with inflammatory disease is important, as resolution of the abovementioned morphological changes is associated with clinical improvement, while increasing heterophil toxicity indicates an increasing severity of disease.[56]

Elephant endotheliotropic herpesviruses (EEHV) belong in the Proboscivirus genus of the beta herpesvirus subfamily. Multiple EEHV strains have been recognized in both Asian and African elephants; and the strains appear to be species-specific with large intrastrain genetic variation. African elephants are naturally infected with EEHV2, EEHV3A, EEHV3B, EEHV6, EEHV7A, and EEHV7B, which are usually nonpathogenic or of low pathogenicity in this species.[34] EEHV1A, EEHV1B, EEHV4, EEHV5A, and EEHV5B naturally infect Asian elephants globally and infections are generally not clinically significant in most elephants.[34] Captive Asian elephant calves between the ages of 1 and 4 years can, however, develop a severe hemorrhagic disease, which is often fatal. Up to 20% of captive calves may be affected.[48] The majority of cases have been caused by EEHV1A, followed by EEHV1B, EEHV3A, EEHV4, and EEHV5A. The disease is rare in African elephant calves in similar husbandry situations, although two lethal cases of EEHV2, one mild case of EEHV3B, and one of EEHV6 have been reported.[48] EEHV1 infection in Asian elephants is not a crossover infection from African elephants as previously thought, but has been a natural infection of Asian elephants at least since evolutionary divergence between the two species.[34] Affected elephants present with lethargy and anorexia, edema of head, neck, forelimbs, and trunk, and cyanosis that begins at the tongue tip and moves caudally.[47] Characteristic pathologic lesions include herpetic inclusion bodies within endothelial cells, particularly of tongue, myocardium, and liver; extensive microhemorrhage in the heart and tongue muscle leading to microscopic and macroscopic edema, including pericardial effusion and ascites, macroscopic cardiac hemorrhage, and petechiation of visceral and parietal serous membranes.[47,48] Endothelial cell

necrosis and fibrinoid degeneration of blood vessel walls leads to thrombosis, edema, and hemorrhage. These lesions may also be found in renal, brain, and retinal tissue.[19] Hematologic changes may include lymphopenia, thrombocytopenia, and anemia.[48] One African elephant calf that survived an infection with EEHV3B showed an initial leukopenia with a left shift, lymphopenia, monocytopenia, and mild anemia. Over the course of the 14 days of viremia, lymphocytosis, monocytosis, and neutrophilia developed, the left shift was absent by day 11 and the leukogram was normal by day 30. There was an initial drop in platelets over the first five days of infection followed quickly by return to normal.[11] Serum amyloid A (SAA), although not disease-specific, is increased in Asian elephants with nonpathogenic EEHV viremia and decreasing viral titres are associated with return of SAA to normal levels.[57] SAA concentrations in the elephant calf described in the earlier text increased to 12-fold of the elephant's baseline values by day 12 and returned to baseline by day 14.[11] In a suspected case, blood and trunk wash fluid should be submitted for PCR examination based on Association of Zoos and Aquariums protocols. More information can be found on eehvinfo.org.[22]

Mycobacterium tuberculosis has been isolated from captive and working Asian and African elephants across the globe.[39,40,49,62] The prevalence of *M. tuberculosis* in the captive North American elephant population has been estimated to be between 3 and 4%.[39] Clinically apparent disease is not seen in most infected elephants. When present, clinical signs include weight loss, anorexia, exercise intolerance, dyspnea, and coughing.[39] Pathology occurs primarily in the lungs and draining thoracic lymph nodes, and occasionally in extrathoracic locations. Lesions range from granulomatous, caseous, and/or mucopurulent solitary nodules to coalescing areas in affected locations.[40] Captive Asian elephants with tuberculosis may have a moderate normocytic, normochromic anemia and hypoferremia, and have also been found to have lower MCHC and higher band neutrophil and eosinophil concentrations than tuberculosis-negative elephants, as well as a lower albumin to globulin ratio.[24,51] Serological tests are available for screening but do not indicate clinical disease, which must be confirmed by interferon-γ release assay, trunk wash culture, and PCR according to United States Department of Agriculture protocols when in the United States.[40,42] Transmission is probably from humans to elephants, but this disease can be zoonotic.[39] Cases of mycobacteriosis caused by *Mycobacterium avium* and nontuberculous mycobacteria have also been reported.[33,67]

Microfilaria, in most cases *Dipetalonema sp.*, have been identified in blood smears from both African and Asian elephants.[7,12,36] *Dipetalonema gossi* was found to be associated with intrahepatic vasculitis and hepatitis in free-ranging elephants in South Africa.[7,12] *Trypanosoma evansi* (surra) has been reported in Asian elephants, and causes fever, progressive anemia, edema of dependent parts, and petechiation of mucous membranes.[29] Parasites may be seen in blood smears of affected animals, but this method is insensitive. *Trypanosoma congolense* and *Trypanosoma brucei* have been identified in African elephants.[61]

SIRENIA

This order contains four species in two families: *Dugong dugon* (dugong), *Trichechus manatus* (West Indian manatee), *Trichechus senegalensis* (African manatee), and *Trichechus inunguis* (Amazonian manatee). There are two subspecies of the West Indian manatee: *Trichechus manatus latirostris* (Florida manatee) and *Trichechus manatus manatus* (Antillean or Caribbean manatee). The sirenians are large aquatic herbivorous mammals that inhabit various fresh water and marine habitats.

Erythron

Like elephants, sirenians have similar Hgb and PCV values to domestic species, but a higher MCV and lower RBC (Table 121.3). MCVs of 105–140 fL and 116–167 fL have been reported in Florida manatees and dugongs, respectively, using different automated methods.[26,66]

Typical blood smear findings for Florida manatees include mild polychromasia, mild to moderate rouleaux (less than cats and horses), stomatocytosis, low numbers of schistocytes, echinocytes, nRBCs (in 40% of animals), Howell–Jolly bodies, and <15% Heinz bodies.[26] A manatee nRBC is shown in Figure 121.1. The presence of schistocytes and Heinz bodies may suggest a degree of inefficient removal of abnormal RBCs by the spleen. Unlike elephants, reticulocytes are present in the blood of healthy Florida manatees, with mean relative reticulocyte count of 2%.[26] Reticulocytes were not detected in healthy Antillean manatees in one study, although low numbers of nRBCs may be present.[37] Extramedullary hematopoiesis occurs normally in the sirenian spleen, liver, kidney, and vertebrae, which may explain the presence of circulating nRBCs in healthy animals.[8] Erythron findings in dugongs are similar, with mild anisocytosis, rare schistocytes, low numbers of Howell–Jolly bodies, and low numbers of nRBCs in around 70% of animals, especially pregnant females.[66]

Leukon

Sirenian WBC counts are slightly lower than most domestic mammals, although similar to other marine mammals.[26] Dugongs have lower WBC concentrations than manatees.[66] The heterophil to lymphocyte ratio in manatees is around 1.0–1.6.[26,37] In a hematologic evaluation of dugongs, lymphocytes were predominant in one half of animals, heterophils in one third of animals, with equal proportions of the two cell types in the remainder.[66] This variation may have been due to stress during capture. Free-ranging dugongs have higher eosinophil counts than manatees, possibly due to the presence of internal parasites.[66] Ultrastructural images of dugong blood cells are available in the literature.[66]

TABLE 121.3 Hematology and hemostasis reference data for Florida manatees (*Trichechus manatus latirostris*) and dugongs (*Dugong dugon*). The reference populations of Florida manatees were: hematology, 52 free-ranging animals and 62 captive animals from institutions in the USA; coagulation, 21 male and 19 female free-ranging animals; TEG, 17 male and 12 female free-ranging animals. The dugong reference population consisted of 92 free-ranging animals from Australia.[5,6,26,66]

Like the elephant, manatees and dugongs have heterophils rather than neutrophils. The heterophil of the Florida manatee and dugong measures 9–12 μm in diameter, contains numerous pink to red-staining round to oval to rod-shaped granules in a pale blue cytoplasm, and has a nucleus with three to five lobes (Figure 121.1).[26,66] These cells stain strongly positive for PAS and myeloperoxidase (like neutrophils of domestic animals, but unlike heterophils of rabbits and birds) and show weak staining with CAE; but are still called heterophils due to their appearance.[31,66]

In all species, lymphocytes are small to medium in size (diameter 7–10 μm), occasionally with magenta cytoplasmic granules (Figure 121.1).[26,37,66] In approximately half of dugongs, lymphocytes are the predominant cell type. While most lymphocytes exhibited negative staining, a subset of dugong lymphocytes had mild to moderate granular focal cytoplasmic reactivity with ANBE and PAS consistent with a T-cell subset.

Sirenian monocytes are similar to other mammals with a large diameter of 16–18 μm, polymorphic nucleus, and occasionally vacuolated blue cytoplasm. Unusual monocyte morphology, in particular the bilobed monocyte of elephants and hyraxes, has not been reported in sirenians. Cytochemical staining of dugong monocytes revealed moderate patchy cytoplasmic staining with ANBE, scant staining with alkaline phosphatase, and diffuse pale granular cytoplasmic staining with PAS. Monocytes did not stain with ANAE, peroxidase, SBB, and napthol AS D chloroacetate esterase.

The eosinophil has a reported diameter of 9–13 μm with a more basophilic cytoplasm and less lobulated nucleus, as shown in Figure 121.1. [26,37,66] Granules are bright pink or dark red, larger, and more uniform than those of the heterophil. Dugong eosinophils all stained positive with ANBE, some stained positive with peroxidase, PAS, and SBB, similar to elephants and domestic ungulates.[66]

Basophils (Figure 121.1) range in diameter from 10–11 μm and tend to have a band-shaped nucleus and purple granulation, which is minimal in manatees but abundant in dugongs.[26,66] Basophils are uncommonly observed in sirenian blood and have not been identified in cytochemical stains to date.[66]

Platelets and Coagulation

Platelet counts are similar to those in domestic mammals; platelets are small (2–3 μm), ovoid to irregular in shape, with light blue to pink granules.[26,66] Platelet clumping is often observed on sirenian blood smears.

Several studies have evaluated hemostasis in healthy and debilitated Florida manatees.[5,6,21,37] APTT is fast compared to other species, and like the elephant, manatees have comparatively high concentrations of factors VIII and XII, compared to humans.[5,37] TEG studies in clinically normal manatees have demonstrated shorter R and K and greater α and MA compared to other species, indicating a relative hypercoagulability.[6,21] The adaptive advantage of this relative hypercoagulability is not known; however, it has been speculated that these animals may be naturally predisposed to thromboembolic disease.[6]

Reference Intervals

Recent publications have focused on Florida manatees with a single study reporting hematology results for dugongs.[5,6,21,26,66] Most studies were either published prior to, or did not explicitly follow ASVCP guidelines. Hematology data generated for 52 free-ranging and 62 captive healthy Florida manatees are presented in Table 121.3.[26] This study compared results between free-ranging and captive animals, as well as between different life stages, but did not generate reference intervals. Free-ranging manatees had significantly higher MCV than captive animals and calves had lower MCV than adults. Heterophil numbers were lower in free-ranging versus captive, with higher values in calves compared to adults, possibly due to a longer, stressful restraint period before blood sampling in captured animals. Eosinophils were lower in captive animals. Automated reticulocyte count was higher in free-ranging manatees. Calves tended to have more reticulocytes and metarubricytes than adults.

Studies presenting hemostasis data included between 29 and 40 Florida manatees.[5,6,21] Due to the low number of animals, recommended statistical methods for reference interval generation were not always possible and results are generally reported as mean, standard deviation, and minimum–maximum range. Data for coagulation profiles generated from 40 free-living healthy Florida manatees are presented in Table 121.3.[5] Reference intervals, generated by the robust method for PT, APTT, fibrinogen, and D-dimers from up to 29 rehabilitated Florida manatees, are available but not presented in the table, as the authors neglected to report any methods used to produce the results.[21] Results for all clotting profile measurands apart from D-dimers appear to comparable in both studies. Kaolin-activated TEG was studied in 29 free-living healthy Florida manatees (Table 121.3).[6] Resting times between blood collection and TEG analysis ranged from 3 to 12 hours. No differences were found for sex or size class in any of these hemostasis studies.

Hematology data were collected from 82 free-living Antillean manatees, caught off the coast of Belize.[59] The reference sample group included adults, subadults, and calves of both sexes. The analytical methods and outlier detection used are not described; the sample size differs between measurands and data presented are not always plausible, e.g., MCV minimum–maximum range starts at zero. If these data are accessed, they should not be used for medical diagnosis.[59]

Reference intervals have been generated, according to ASVCP guidelines, for a population of free-living dugongs in southern Queensland, Australia (Table 121.3).[66] The reference population consisted of 42 males and 50 females (11 pregnant), 56 adults and 36 subadults. WBC and lymphocyte counts were higher in

(**Source:** Photos courtesy of Dr. Nicole Stacy.)

subadults versus adults. PCV, MCV, and nRBC were higher and platelet count lower in pregnant females. Results were generated from two hematology analyzers, and differences were found between analyzers for some measurands (Table 121.3).[66]

Blood and Bone Marrow Collection

Manatees and dugongs are docile, gentle animals and can be captured without sedation using nets or stretchers.[59,66] Blood is collected in a nonsedated animal from the brachial plexus between the radius and ulna from either pectoral flipper, using a 18–22 gauge needle and a butterfly extension, or wing-tipped blood collection set.[5] There is a vascular bundle here formed by axillary and brachial arteries.

This order has amedullary pachyosteosclerotic long bones which contain loose connective tissue rather than sites of hematopoiesis. Hematopoiesis occurs primarily in the inner, cancellous bone portion of the vertebral bodies. Myeloid, erythroid, and megakaryocytic precursors have been identified. No lymphoid precursors were observed.[8]

Hematologic Disease

nRBCs increase in Florida manatees with inflammatory disease and a mild leukocytosis may also be present. Both changes are specific, but poorly sensitive and other inflammatory markers such as SAA or plasma albumin:globulin ratio have better diagnostic accuracy.[23] Band heterophils and toxic change are indications of active immune response (Figure 121.2).

Cold stress syndrome (CSS) is one of the most common causes of fatalities in Florida manatees and results after prolonged (>72 hours) exposure to water with a temperature of <20 °C. Manatee with CSS suffer from metabolic and nutritional disorders, systemic inflammation, infectious disease, and hemostatic derangements, specifically thromboembolic disease.[23] Animals commonly present with epidermal lesions ranging from skin bleaching to ulceration and orthokeratotic hyperkeratosis.[23] These lesions frequently occur at the extremities, probably due to small vessel vasoconstriction combined with localized inflammation and activation of coagulation leading to endothelial dysfunction.[6] Using TEG, manatees with CSS were found to have longer R and shorter K times, and increased fibrinolysis at LY30, suggesting a procoagulant excess with activation of the fibrinolytic pathways. MA and α-angle were not different, indicating that final clot strength is not affected in CSS.[6] The use of TEG as a prognostic tool has not been examined. APTT and PT are extended in cold-stressed manatees. Seven out of 10 cold-stressed manatee samples did not clot by 90 seconds, while the normal

TABLE 121.4 Hematology reference data for 25 adult, mixed-sex rock hyrax (*Procavia capensis*) using an Abacus (Diatron, Vienna, Austria). Manual 400-cell differential cell counts were performed using modified Wright-stained blood smears. Statistical outlier removal was not performed.[2]

MCH, mean cell hemoglobin; MPV, mean platelet volume; RDW, red cell distribution width.

manatee PT reference interval is <12 seconds.[6] Mean D-dimer concentrations of cold-stressed manatees were around seven times higher than healthy animals. D-dimer values exceeding 1500 µg/L or increasing values over the course of rehabilitation were indicative of a poor prognosis.[6,21] ATIII was lower in CSS animals, suggesting a consumptive coagulopathy. Three CSS animals had ATIII <70% with PT and APTT prolonged beyond clot end points, indicating disseminated intravascular coagulation (DIC). Factor XI activity was increased in CSS manatees; this finding has been associated with an increased thrombotic risk in humans. Although the dataset was small, these findings all suggested that CSS is associated with hemostatic derangements.[6] Lymphocyte proliferation was decreased in manatees with CSS, indicating that immune dysfunction is a component of this syndrome, predisposing these animals to opportunistic infectious diseases such as bronchopneumonia, enterocolitis, and dermatitis.[64]

Brevetoxicosis or a harmful algal bloom (a.k.a. HAB) is another leading cause of death in Florida manatees, caused by a neurotoxin produced by a plankton, *Karenia brevis*, during algal blooms. Congestion, hemorrhage, and inflammation at multiple sites are major pathological findings.[9] Submucosal infiltration of lymphocytes, plasma cells, and macrophages, containing brevetoxin antigen, was present in the respiratory tract and leptomeninges. Hemosiderosis was seen in hepatic, splenic, and central nervous system tissues suggesting a chronic hemolytic process. The pulmonary congestion and hemorrhage suggest acute cardiovascular collapse from shock. The central nervous system changes could explain neurological signs seen clinically. It was theorized that brevetoxin-containing cells undergo apoptosis with a concurrent cytokine storm that leads to shock and death. Ongoing apoptosis could also lead to chronic immunosuppression. In addition to apoptosis, lymphocytes from animals with brevetoxicosis, exposed in vitro to brevetoxin, show decreased proliferative responses compared to lymphocytes from healthy animals.[63,64]

A DIC scoring system was developed for Florida manatees, based on platelet count (1 point 75–150 $\times 10^{9}$/L, 2 points < 75 $\times 10^{9}$/L), D-dimer (1 point 150–500 µg/L, 2 points > 500 µg/L), PT (1 point > 12 seconds), APTT (1 point < 14 seconds), and fibrinogen (1 point > 4.50 g/L, 2 points ≤ 3.00 g/L). DIC was present with a combined score of ≥4. DIC was diagnosed, based on the scoring system, in 56% of manatee afflicted with CSS and 51% with trauma, but was not diagnosed in manatee with brevetoxicosis. The presence or absence of DIC in CSS did not affect long term survival.[3] Manatee that had an increasing DIC score over the course of rehabilitation did not survive.[3]

HYRACOIDEA

The hyrax is a small, approximately 10-pound (4–5 kg), terrestrial herbivorous mammal which occurs naturally over most of Africa, the Middle East, and western part of the Arabian peninsula. There are five species within this order: *Procavia capensis* (rock hyrax or dassie), *Dendrohyrax validus* (eastern tree hyrax), *Dendrohyrax arboreus* (southern tree hyrax), *Dendrohyrax dorsalis* (western tree hyrax), and *Heterohyrax brucei* (bush hyrax). *P. capensis*, the rock hyrax, has the widest distribution and is commonly found in zoological collections worldwide.[13]

Erythron

Published information on hyrax hematology is scarce. One study obtained hematology data from 25 free-ranging clinically normal rock hyraxes, from the eastern Mediterranean region.[2] The reference population consisted of 18 female and 9 male, 17 subadult and 8 adult animals (Table 121.4). Males generally had higher values than females, apart from MCV, monocyte, eosinophil, and basophil counts, which were not different between the sexes. RBCs are similar in size and volume to the dog (MCV = 59–81 fL), and while not as big as those of elephants and sirenians, are large for a mammal of its size. PCV and Hgb concentration appear to be lower than other members of the Paenungulata clade. This may be linked to low iron intake from their natural diet, as this species is susceptible to iron overload in captivity. Blood smears from healthy rock hyraxes may exhibit mild hypochromasia, anisocytosis, schistocytosis, polychromasia, microcytosis, macrocytosis, and a variable number of codocytes. nRBCs are rare.[2]

Leukon

Neutrophils in hyraxes do show a variable amount of pink granulation similar to manatee and elephants, but have not been described as heterophils in the few reports available (Figure 121.1). Lymphocytes were mostly small. The prevalence of large granular lymphocytes ranged from 0.5–20% of the lymphocyte population. Eosinophils in this species contain many small, round brick red granules.

A low percentage (1–3%) of bilobed WBCs with a light to medium blue cytoplasm are found in blood smears. The nuclear lobes are connected by a thin filament of chromatin. The morphology of these cells is similar to the bilobed monocytes described for elephants, and were categorized as monocytes in the study, although no cytochemical staining was performed to confirm this.

Hematologic Disease

WBC and neutrophil counts were fairly high in some animals in one study, which may reflect an adrenaline and/or glucocorticoid response.[2]

Hemosiderosis is a common postmortem finding in captive rock hyrax, indicating iron overload. This is most likely due to suboptimum nutrition with excessive bioavailable iron in captivity, leading to excessive iron absorption.[32] No clinicopathological information is available.

Cases of tuberculosis due to the dassie bacillus (*Mycobacterium tuberculosis complex sp.*) have been reported in rock hyraxes living in or imported from South Africa and the United Arab Emirates.[15] This is the genetic clade of Mycobacterium which causes tuberculosis in people and elephants. Typical granulomatous inflammation caused by the bacteria was present in the lungs as well as other organs on postmortem. No hematology findings have been reported.

Hyraxes are reservoirs for leishmaniasis. The presence of and seropositivity for *Leishmania tropica* and *Leishmania aethiopica* has been demonstrated in rock hyraxes in Israel and Saudi Arabia, respectively.[41,58] Both organisms cause cutaneous leishmaniasis in humans.

Rare reports of hemoparasites exist in hyrax. *Babesia thomasi* has been reported to occur in free-ranging hyraxes in sub-Saharan Africa.[28]

CHAPTER 122

Hematology of Marine Mammals

NICOLE I. STACY and HENDRIK H. NOLLENS

Blood Sampling
Erythrogram
Leukogram
Platelets and Coagulation
Bone Marrow Collection and Evaluation
Reference Intervals
  Partitioning Factors
Hematologic Manifestation of Disease

Acronyms and Abbreviations

AID, anemia of inflammatory disease; aPTT, activated partial thromboplastin time; CD, cluster of differentiation.

BLOOD SAMPLING

Hematology is a well-established and essential diagnostic tool in marine mammal medicine and is used in a variety of research and clinical settings, from individual animal monitoring in managed care to stranding situations and population-level health assessments. The bottlenose dolphin (*Tursiops truncatus*) is the best studied marine mammal species regarding hematology, with studies published as early as 1964.[20]

Given the unique anatomic features of marine mammals, a physical examination is more limited in comparison to terrestrial mammals. However, blood sampling is often feasible and easily obtainable, providing an opportunity to pursue a suite of diagnostics, of which hematology is considered minimum baseline data. General principles of hemogram interpretation across mammalian species apply to marine mammals. The hemogram is useful for detection of systemic inflammation, guidance for additional diagnostic testing, and patient monitoring during treatment.

Blood collection in marine mammals can be challenging and trained behaviors have become essential tools. Venipuncture sites of marine mammals are well described in the literature. Common blood sampling sites include ventral fluke vasculature, the ventral peduncle where the fluke veins converge, and the central vein of the dorsal fin in cetaceans (dolphins and whales);[25] the caudal gluteal vasculature and jugular vein in otariidae (true sea lions); the plantar veins and the extradural sinus in phocidae (seals); the extradural sinus and interdigital hind flipper veins in odobenidae (walruses);[9,21] and jugular and sublingual veins in polar bears (*Ursus maritimus*).[3] Anticoagulants include EDTA or lithium heparin which may be used for blood collection for CBC, with EDTA preferred. Sodium citrate is used for fibrinogen and hemostasis testing. Given the incomplete intrinsic coagulation pathway in cetaceans, thrombin-activator blood sampling tubes are recommended when serum is to be collected, since blood samples without thrombin additive may clot slowly, resulting in potential artifactual changes and variability in test results.[27] In situations in which only a small blood volume can be acquired (e.g., logistical challenge, difficult restraint), a whole blood sample of minimum 1.25 mL can be collected in sodium citrate. Considering the dilution factor of 1.1, this sample can be used for CBC, excluding erythrocyte sedimentation rate, and then centrifuged to obtain plasma for fibrinogen and serum chemistry excluding calcium, sodium, and total carbon dioxide.[27]

ERYTHROGRAM

Marine mammals have the largest mammalian erythrocytes (RBC) compared to terrestrial mammals, with only elephant RBCs ranging similarly in size to pilot whales (*Globicephala sp.*).[34] RBC sizes range from a minimum mean cell volume (MCV) of 106 fL in bottlenose dolphins

up to MCV 183 fL in beluga whales (*Delphinapterus leucas*) in the toothed whales (Figure 122.1a–c). No information is available to date in the baleen whales. Compared to other marine mammal species, northern elephant seals (*Mirounga angustirostris*) have higher MCV, mean cell hemoglobin (MCH), mean cell hemoglobin concentration (MCHC), and lower RBC counts, which is presumptively associated with their physiologic adaptation to deep diving requiring increased oxygen storage, a need that develops at time of weaning.[15] Polychromasia, assessed by blood film evaluation, appears to be mild in clinically normal pinnipeds, sea otters, and walrus, but is absent to minimal in clinically normal cetaceans. Erythrocyte morphology in health may include up to 50% codocytes in walrus[27] and occasional Howell–Jolly bodies and nucleated RBC (nRBC) in healthy cetaceans. Heinz bodies are uncommon in healthy marine mammal species other than the manatee (see Chapter 121).

Erythrocyte morphology in health at different life stages versus changes in disease and clinical significance have yet to be determined in marine mammal species. For example, prominent metarubricytosis in two captive-born neonatal bottlenose dolphin calves that died from different causes was associated with regenerative anemia of undetermined etiology; these two animals also showed increased erythropoiesis in bone marrow, liver, and spleen, and erythrophagocytosis, but it was unknown whether the erythroid regenerative response was normal for the life stage or could be attributed to disease.[4]

The erythrocyte sedimentation rate is readily available, cost-effective, and routinely included in marine mammal CBCs at in-house laboratories, as its clinical value in the diagnosis and monitoring of inflammatory disease in marine mammals has been anecdotally documented.[25,27] Erythrocyte sedimentation rate is reportedly higher in pilot whales and false killer whales compared to other cetaceans;[27] therefore, it is essential to consider species-specific ranges as for other diagnostic tests when interpreting results.

LEUKOGRAM

Leukocyte (WBC) morphology in marine mammals is generally comparable to other mammals, though there is some variability. Neutrophil morphology is similar across marine mammals and all have segmented nuclei. While pinnipeds, walruses, and polar bears have clear cytoplasm, bottlenose dolphins and other cetaceans may exhibit variable numbers of fine dust-like pink or orange-colored secondary granules similar to other ungulate species, e.g., giraffe, equine foals (Figures 122.2 and 122.3). The conventional band versus mature neutrophil definition of no segmentation being <66% of the width of the neutrophil nucleus is an established method of defining bands in mammalian hematology.[13] A stricter method that identifies a band neutrophil if any chromatin broader than a thin filament spanning between lobules has been established in marine mammals, particularly cetaceans[27] (Figure 122.4). Furthermore, a segmented neutrophil may be defined as having at least two lobes separated by filament(s)[25] (Figures 122.2–122.4). Given that more band neutrophils are identified by this method, clinically healthy cetaceans commonly have 1–3% band neutrophils, which may vary up to 5%.[27] This method of quantifying bands is believed to be more sensitive in detecting early inflammation and in monitoring cetaceans during treatment by marine mammal clinicians.

Small lymphocytes are similar in size and morphology to other mammalian species with clumped chromatin and scant pale basophilic cytoplasm. Atypical or reactive lymphocytes and plasma cells are infrequently found in healthy marine mammals (Figure 122.5).

Monocytes typically exhibit a reniform, bi or multilobed nucleus with smooth chromatin and pale to medium basophilic cytoplasm (Figures 122.2 and 122.3). Some monocytes may appear reactive or activated, i.e., have a variable number of cytoplasmic vacuoles with bluer cytoplasm, in apparently healthy marine mammals.

Eosinophils in marine mammals vary in size, number, and color. The cytoplasm may be slightly basophilic in bottlenose dolphins and Hawaiian monk seals which may be confused with toxic neutrophils (Figures 122.2d and 122.3d). Basophils are typically present in very low numbers or possibly absent in marine mammals. They vary significantly in granule number, size, and color intensity, but can be easily differentiated from neutrophils and eosinophils (Figures 122.2 and 122.3).

PLATELETS AND COAGULATION

Platelet concentrations in marine mammals are interpreted similarly to their terrestrial counterparts. Significant differences in platelet physiology are likely adaptations to diving (see Section VI). For example, although killer whales produce concentrations of thromboxane similar to other mammals, the low response of their platelets to thromboxane is presumed to be a protective mechanism for deep diving marine mammals that prevents clotting.[27] Pressure changes associated with diving do not result in platelet activation or changes in platelet numbers in killer whales.[26]

The predominant coagulation pathway in cetaceans is the extrinsic pathway through tissue factor activation, since most cetaceans are reportedly deficient or lacking factor XII (Hageman factor), thus resulting in a nonfunctional intrinsic pathway.[29,32] Consequently, activated partial thromboplastin time (aPTT) and activated coagulation time are comparatively prolonged when compared to other mammalian species, and both tests are considered inaccurate.

BONE MARROW COLLECTION AND EVALUATION

Due to the difficulty in accessing active representative bone marrow (especially in adult animals) and the

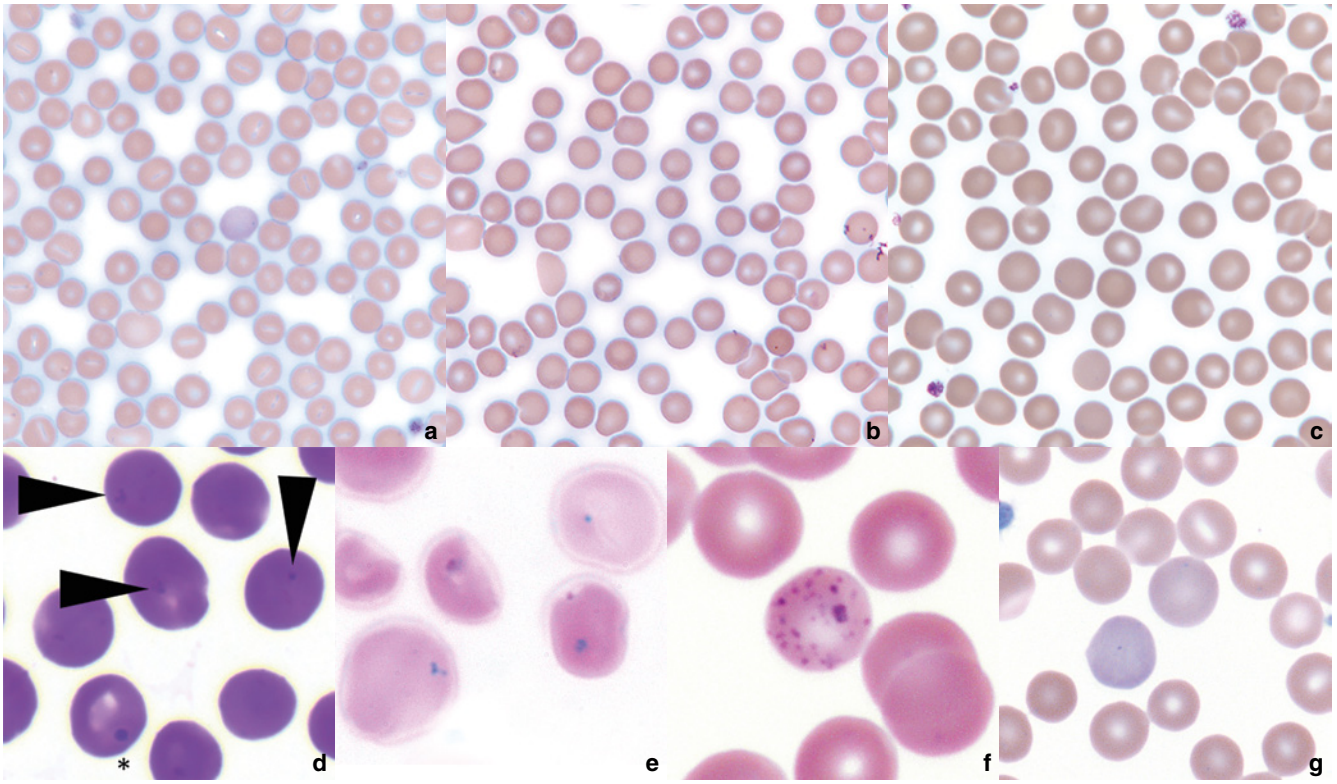

FIGURE 122.1 Erythrocytes from marine mammal species. (a) Bottlenose dolphin (*Tursiops truncatus*) RBCs; (b) Killer whale (*Orcinus orca*) RBCs; (c) Beluga whale (*Delphinapterus leucas*) RBCs. Bottlenose dolphin (*T. truncatus*): (d) Focal fine granular basophilic aggregates (arrowheads) and a Howell–Jolly body (asterisk) suggestive of siderocytes; (e) Turquoise-colored positive-staining aggregates consistent with siderotic inclusions using Prussian blue stain in the same patient sample; (f) Basophilic stippling; (g) Anisocytosis and polychromasia in a regenerative anemia. 1000×, modified Wright–Giemsa stain (unless otherwise indicated).

potential to cause harm to the marine mammal patient, bone marrow sampling should be performed only if considered clinically useful, under anesthesia, and in species in which bone marrow is more readily accessible, such as pinnipeds. Indications for bone marrow sampling are uncommon and include persistent cytopenias, leukocytosis with the suspicion of neoplasia, or presence of circulating cells with abnormal morphology as in other mammals. The underlying causes for such conditions may often be explained using clinical and medication history, and other clinicopathological changes. Sampling in live animals has the potential to cause harm to the patient and is invasive at the anatomic sites, including ribs and vertebra, and has only been used in pinnipeds under anesthesia.

Bone marrow sampling can be performed postmortem. Autolytic changes in carcasses >1 day old, bone marrow sample preparation technique, and the animal's age have to be considered when interpreting the specimen's quality for use in diagnosis. The proximal appendicular or axial skeleton is a common collection site in any mammalian species throughout life. Cetacean bone marrow can be challenging to obtain, since active bone marrow is mainly located in the axial skeleton, and vertebral bodies are difficult to access due to their dense internal structure. Bone saws are useful to access the bone marrow. Imprints for cytology and tissue sections for histopathologic evaluation may provide useful diagnostic information (Figure 122.6).

REFERENCE INTERVALS

Although there is abundant literature on hematology data from various marine mammal species in managed care and wild populations, few publications report hematologic reference intervals established in accordance with American Society of Veterinary Clinical Pathology guidelines.[10,24,30] Blood analyte databases with summarized data from various institutions with animal populations of the same species but exposed to different extrinsic factors, e.g., husbandry, nutrition, environment, etc., and likely using different analytical methodologies should not be used for medical interpretation. As in other species, any hematology data of an individual marine mammal needs to be interpreted in the context of history, administration of recent or current medications, and clinical examination findings. Many extrinsic and intrinsic factors in published hematology data have to be considered when applying data from published studies to an individual, such as analytical methodology and biological

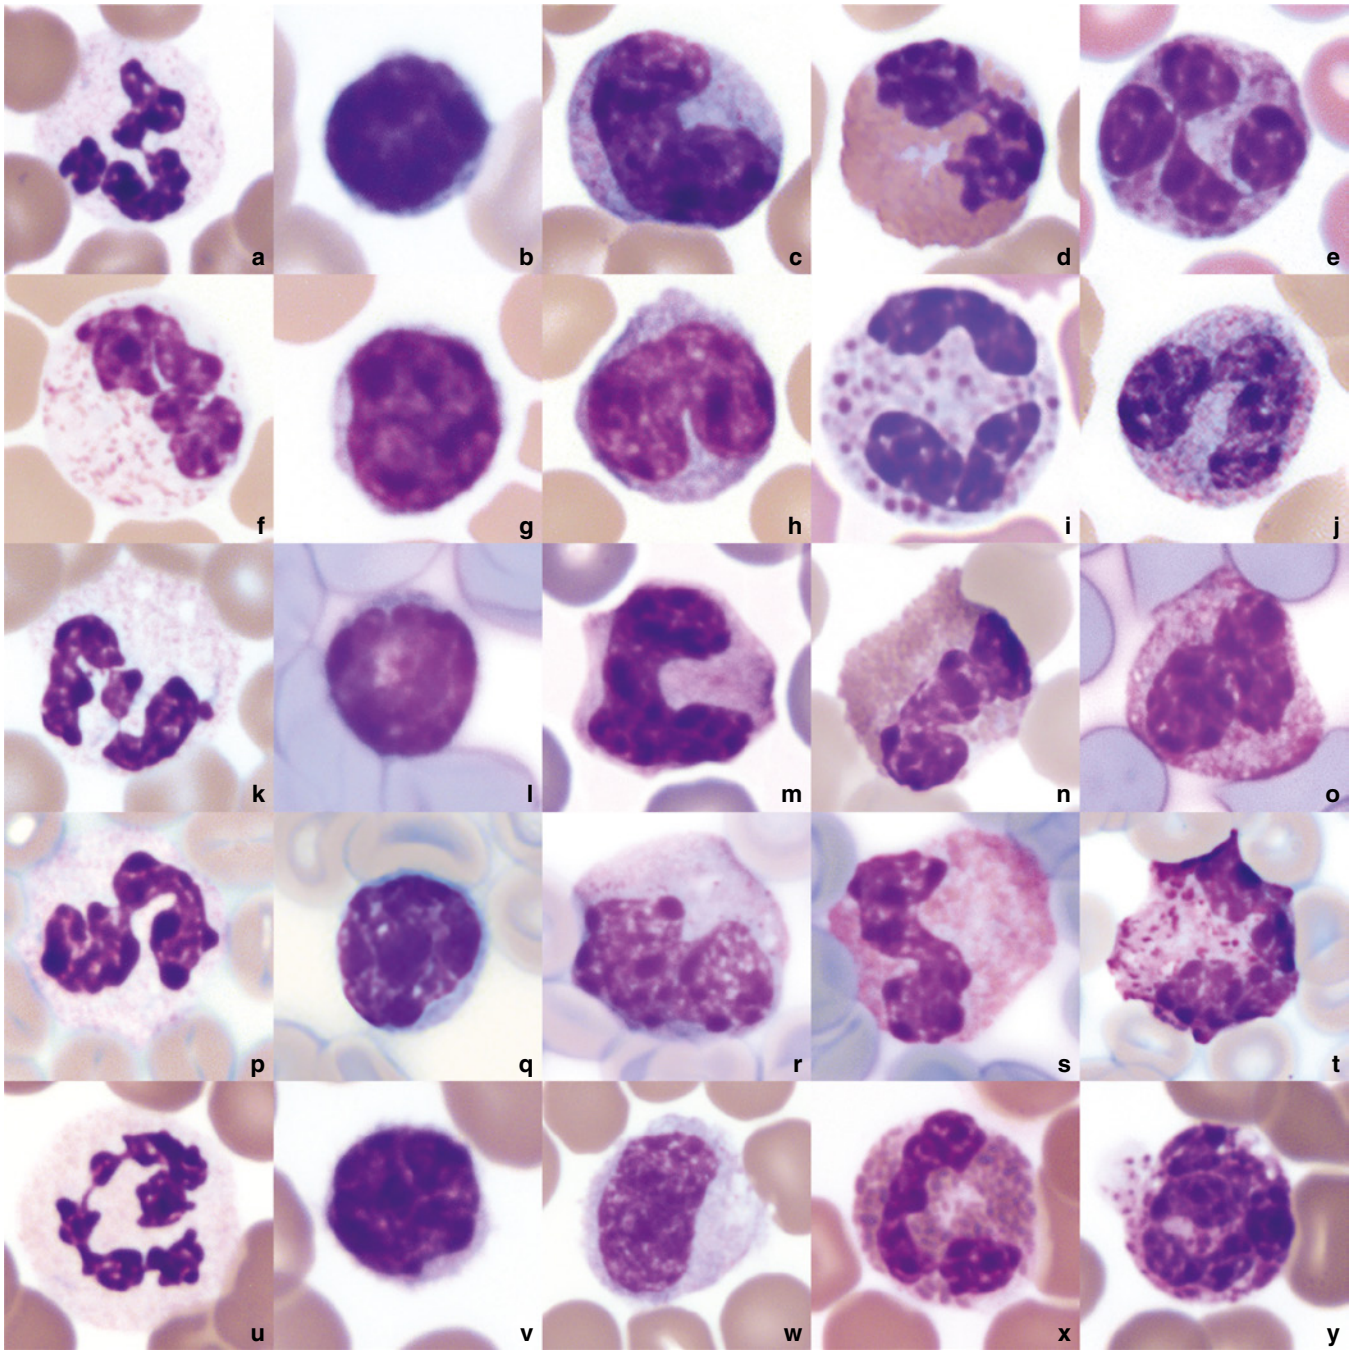

FIGURE 122.2 Normal cetacean leukocytes. Bottlenose dolphin (*Tursiops truncatus*): (a) Segmented neutrophil; (b) Small lymphocyte; (c) Monocyte; (d) Eosinophil; (e) Basophil. variables,[11] as well as inclusion criteria of animals in a study. Various partitioning factors have been documented in marine mammals, with the clinically relevant factors including age, sex, season, and habitat,[11,24] and physiological factors, e.g., fasting in northern elephant seals.[39]

Consistent methodology allows for the generation of population- and subject-based reference intervals, and the trends found over continuous routine wellness examinations can be evaluated. The use of subject-based reference intervals offers the best opportunity for close monitoring of an individual, observation of

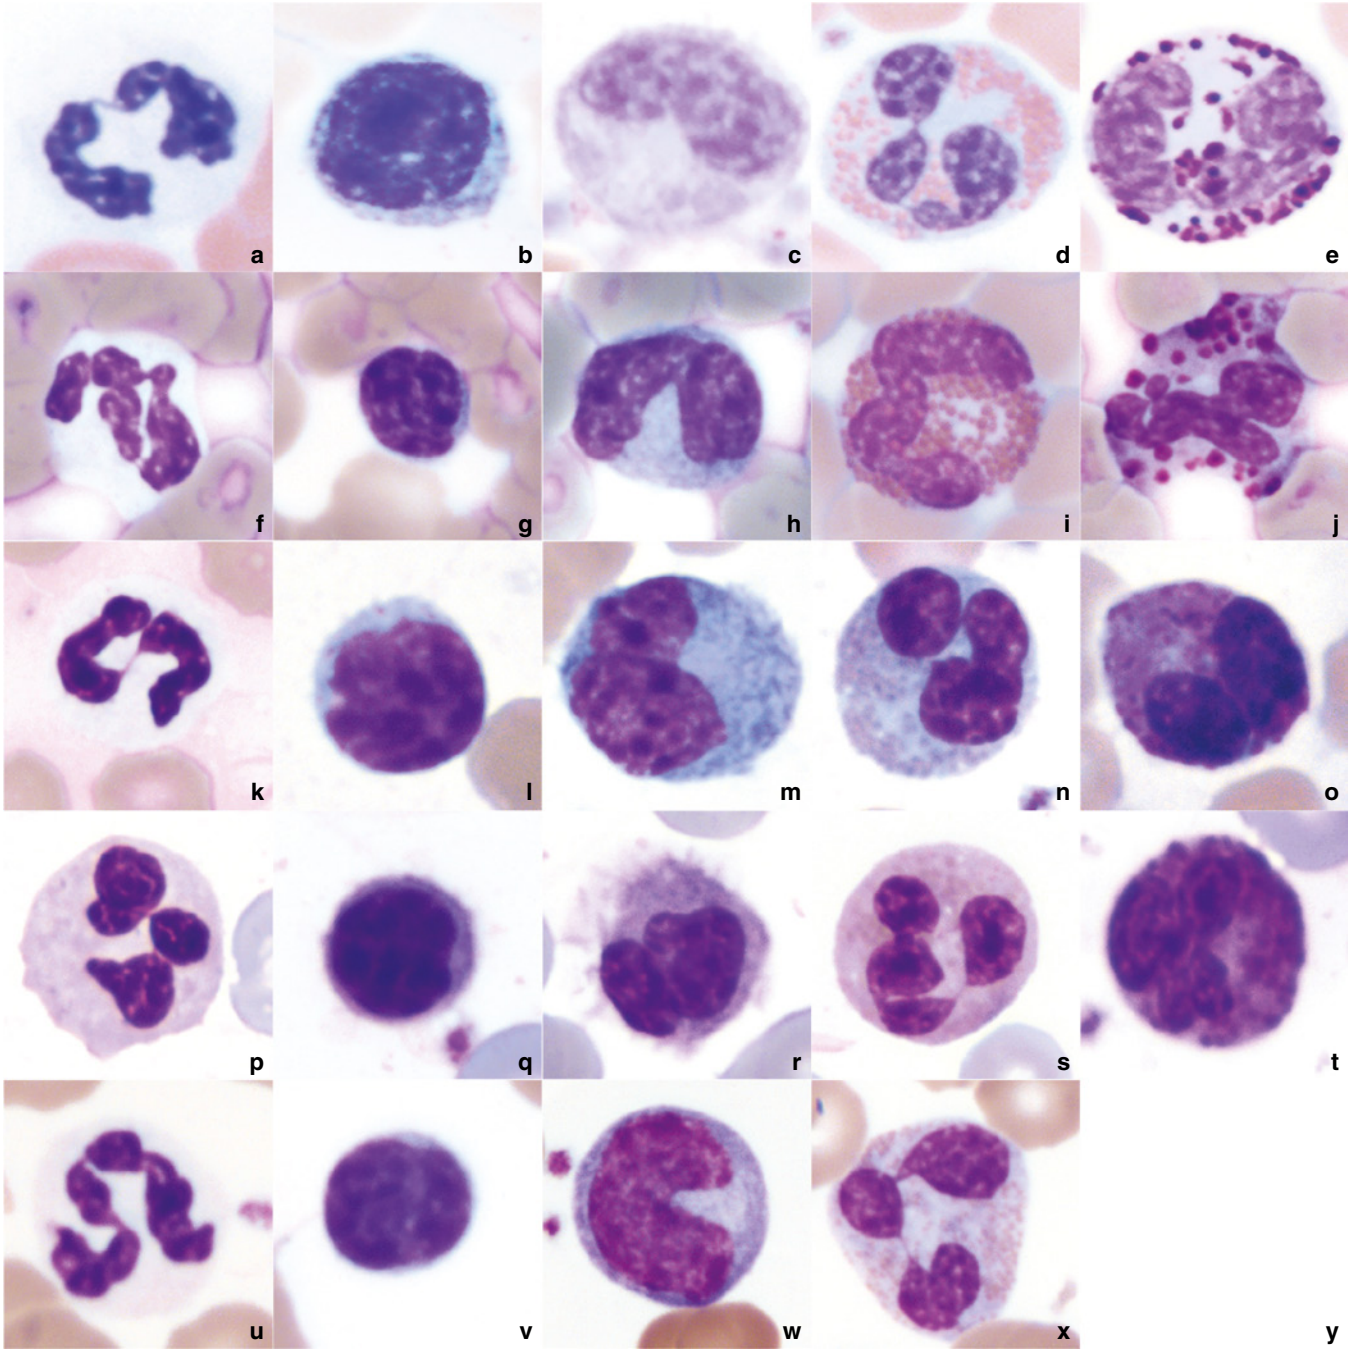

FIGURE 122.3 Normal pinniped leukocytes. Monk seal (*Neomonachus schauinslandi*): (a) Segmented neutrophil; (b) Small lymphocyte; (c) Monocyte; (d) Eosinophil; (e) Basophil. individual variability, and early detection of hematologic abnormalities during suspected illness. However, reference intervals created from a single animal's data may result in increased false positives (type 1 error), i.e., diagnosis of disease which is not present. Broader population-based reference intervals can be applied in the initial assessment of stranded animals, and then trends of the individual observed, with consideration of analytical error, e.g., allowable total error (see Chapters 138 and 140).

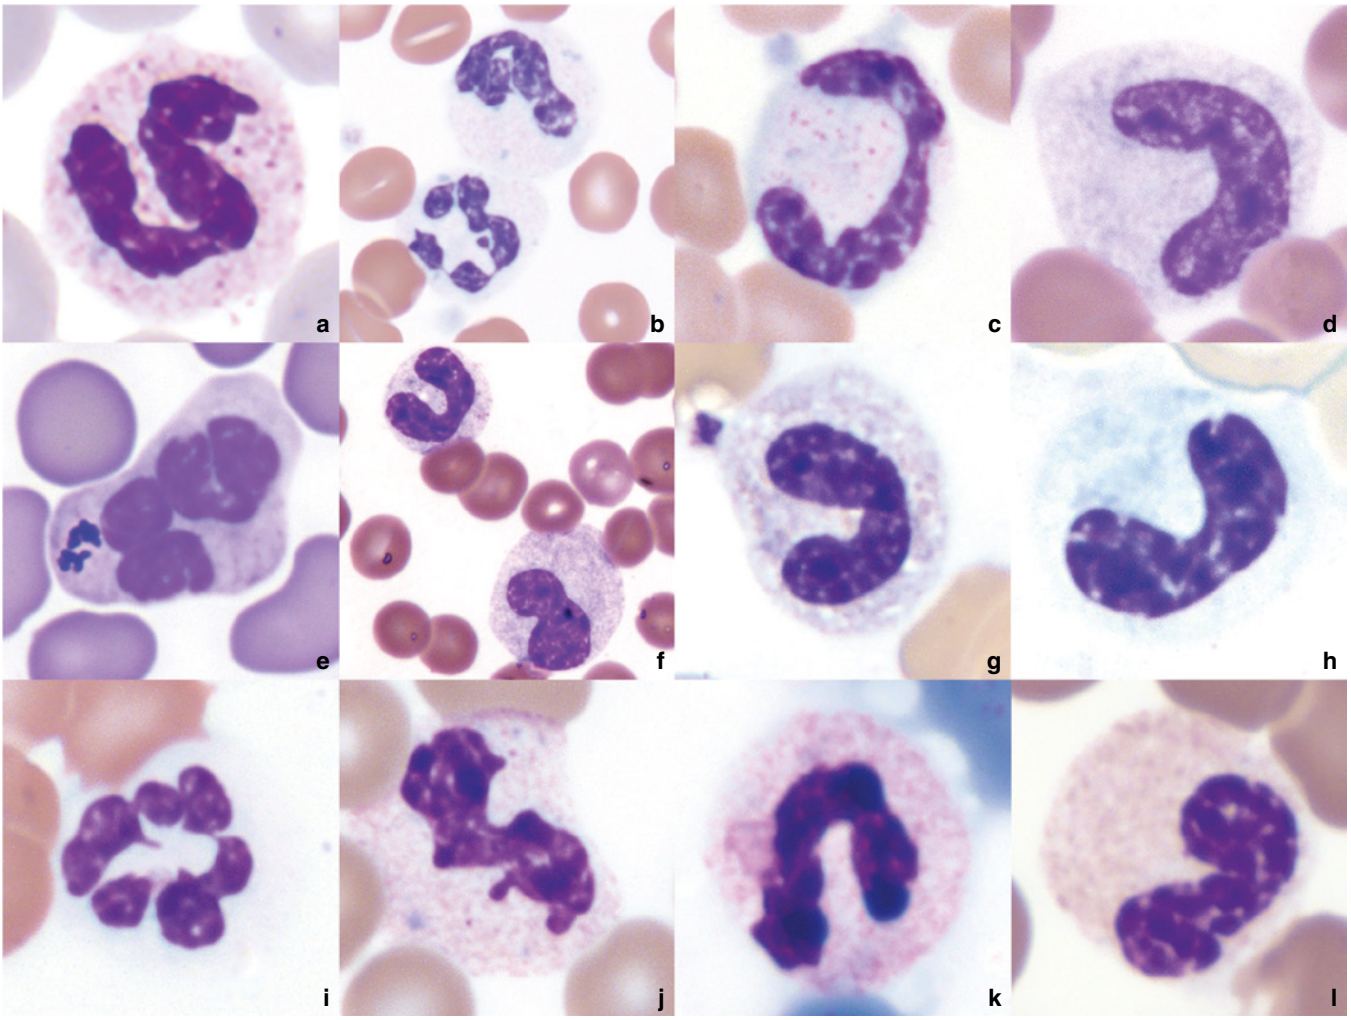

FIGURE 122.4 Abnormal neutrophil morphology in cetacean and pinniped blood. Partitioning Factors

The growing embryo and fetus induce significant hematologic changes in the mother. In killer whales (*Orcinus orca*), decreasing Hct, Hgb, and RBC concentration during gestation were linked to plasma volume expansion prior to parturition, which resolved postnatally.[28] Physiologic leukocytosis around parturition has been attributed to increased neutrophil concentration in killer whales, with a sharp drop after parturition.[28] In bottlenose dolphins, while WBC counts remain stable, lymphocytes and platelets reportedly decrease during the 2nd and 3rd semester, and evidence of hemoconcentration may be observed including increased RBC count, Hgb, and Hct.[1] These nonpathologic hemogram changes need to be considered when interpreting blood data from pregnant killer whales and bottlenose dolphins.

HEMATOLOGIC MANIFESTATION OF DISEASE

Mild anemia of chronic disease associated with inflammation is seen in marine mammals. Underlying mechanisms and causes for anemia are presumptively similar to those of other mammals and interpretation is based on similar principles (see Section III). Anemia of inflammatory disease (AID) is typically nonregenerative; however, mild increases in anisocytosis, polychromasia, nRBC, and mild basophilic stippling reflect slight

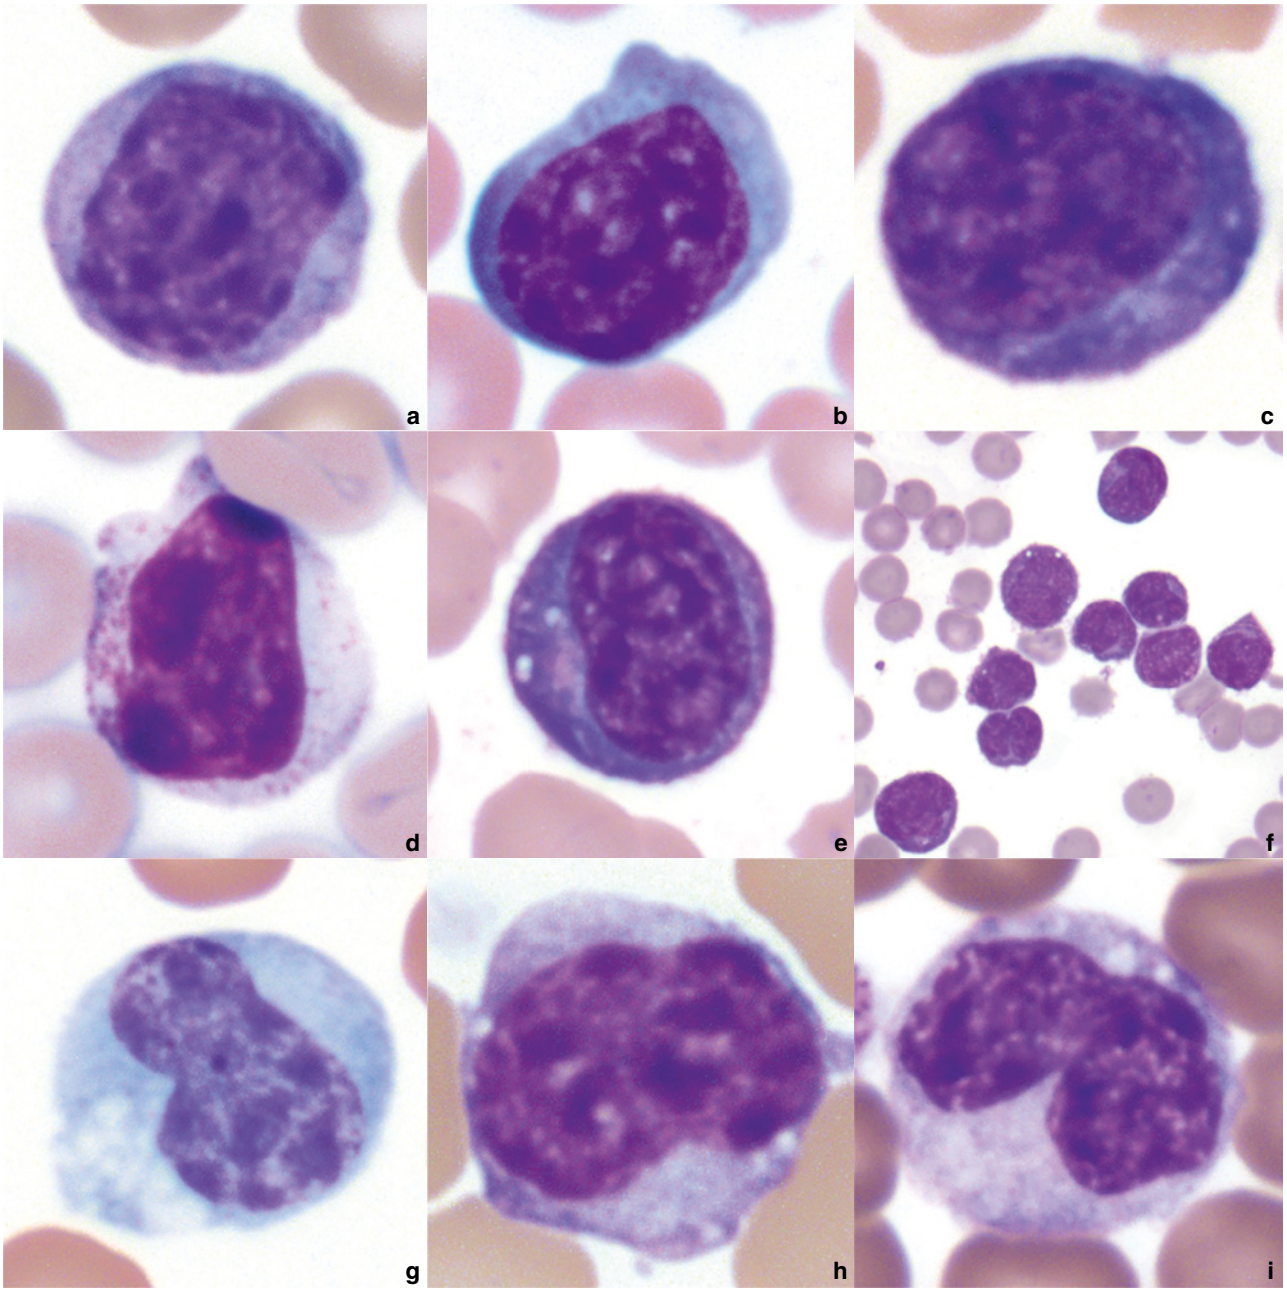

FIGURE 122.5 Abnormal lymphocyte and monocyte morphology in cetacean and pinniped blood. Bottlenose dolphin (*Tursiops truncatus*): (a) Reactive lymphocyte; (b) Atypical lymphocyte; (c) Atlantic spotted dolphin (*Stenella frontalis*): reactive lymphocyte; (d) Killer whale (*Orcinus orca*): granular lymphocyte; (e) California sea lion (*Zalophus californianus*): reactive lymphocyte; (f) California sea lion (*Z. californianus*): circulating neoplastic lymphocytes in patient with confirmed intestinal lymphoma, 20× objective; (g) Bottlenose dolphin (*T. truncatus*): reactive monocyte; (h) Atlantic spotted dolphin (*S. frontalis*): reactive monocyte; (i) Long-finned pilot whale (*Globicephala melas*): reactive monocyte. 1000×, modified Wright–Giemsa stain.

increases in reticulocyte counts, which may become evident during recovery from anemia of inflammatory disease in the cetacean patient (Figure 122.1f,g). Since speed, degree, and confounding factors of erythroid regenerative responses are not well understood in marine mammals and difficult to study given the lack of controlled research settings, trends of the individual patient may be followed over time during treatment. Blood loss anemia is a rather rare condition in marine mammal medicine, but may result in prominent reticulocytosis after several days of blood loss, similar to other mammalian species, as observed by the authors in bottlenose dolphins. Bone marrow depression is diagnosed based on exclusion of other etiologies of anemia. Bone marrow aspirate and/or biopsy is possible in pinnipeds, but is often not feasible in other taxa (see Chapter 141).

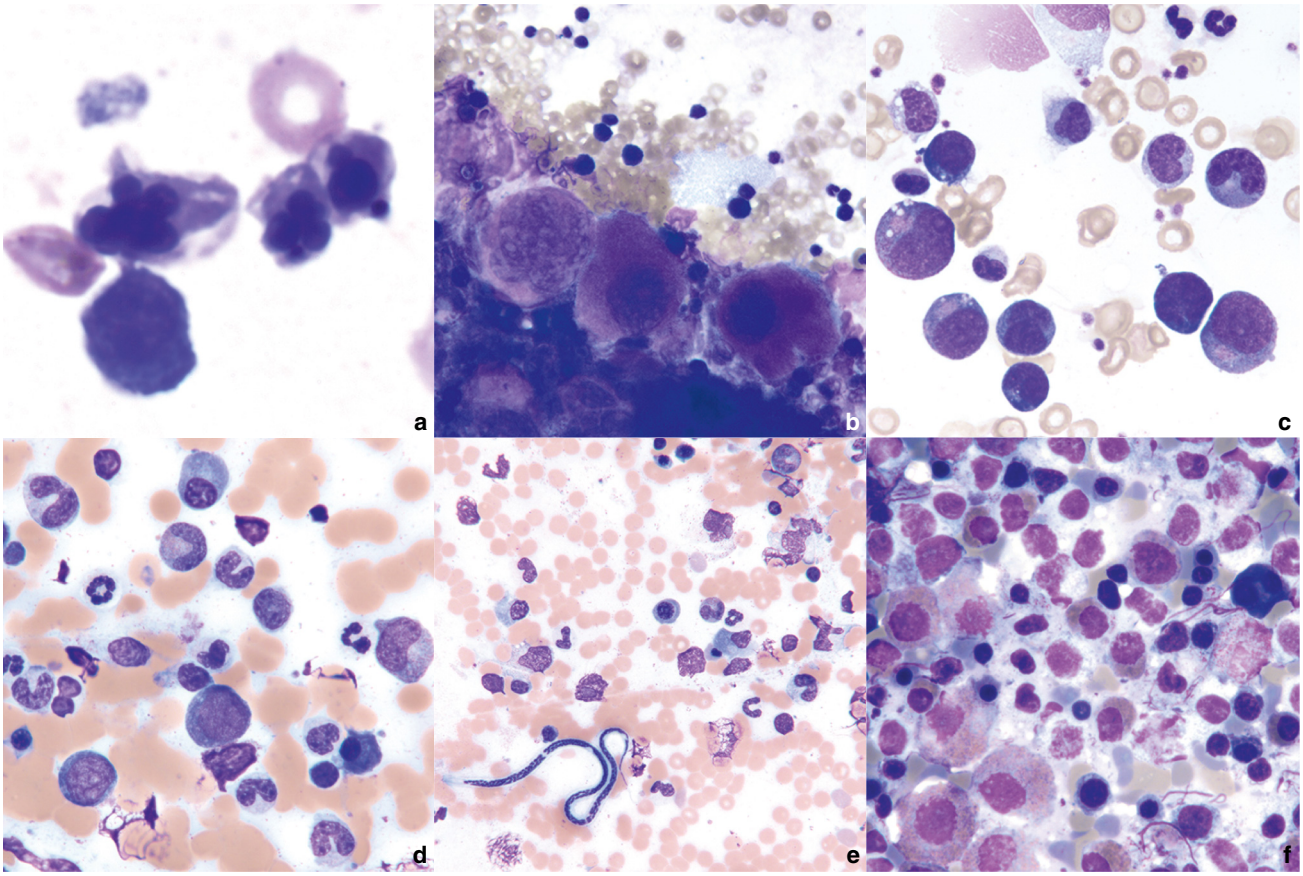

FIGURE 122.6 Bone marrow cytology. Guadalupe fur seal (*Arctocephalus townsendi*): (a) Dysplastic changes in erythroid precursors, possibly from antimicrobial effects and/or nutritional deficiencies; (b) Megakaryocytic hyperplasia in patient with inflammatory leukogram and peripheral thrombocytosis; (c) and (d) Myeloid hyperplasia; (e) California sea lion (*Zalophus californianus*): microfilaria likely from hemodilution; (f) Bottlenose dolphin (*Tursiops truncatus*) with confirmed brevetoxicosis: postmortem collected bone marrow imprint showing cell lysis from autolysis, yet overt eosinophilic hyperplasia. Modified Wright–Giemsa stain.

Increased numbers of Heinz bodies in two bottlenose dolphins were presumptively attributed to oxidative damage from liquid amber tree toxicity and/or hydrogen peroxide administration by the authors. Bottlenose dolphins in managed care can develop iron storage disorder, which is not believed to be hereditary and associated with diet, among other factors.[18] The authors have observed low numbers of siderocytes, confirmed by Prussian blue, in blood smears from captive dolphins with clinically suspected or confirmed iron storage disorder (Figure 122.1d,e). The presence of siderocytes should prompt evaluation of serum iron indices.

The leukogram is a key CBC component in marine mammals, as it assesses inflammation from infectious and noninfectious causes. Common infectious causes of inflammation include secondary bacterial infections, pneumonia, and gastrointestinal disorders in marine mammal species.[25,35] Considerations for noninfectious causes include urogenital carcinoma in California sea lions, oral carcinomas in bottlenose dolphins, or other noninfectious causes of tissue necrosis. In response to inflammatory disease, marine mammal leukocyte morphologic changes may include neutrophil left-shifting, toxicity, monocytic reactivity, atypical or reactive lymphocytes, and plasmacytoid cells.

Given the importance of early diagnosis of inflammation in clinical settings, inflammatory markers are routinely included during wellness examinations and treatment monitoring. The most important inflammatory markers include all leukogram analytes, especially WBC count, polymorphonuclear bands, toxic change, platelets (e.g., inflammatory thrombocytosis), Hgb, PCV, fibrinogen, erythrocyte sedimentation rate, serum alkaline phosphatase, acute phase proteins, and serum iron.[25,28] Serum amyloid A (SAA) has been proven clinically useful in the diagnosis of systemic inflammation in northern elephant seals.[33] The clinical utility of SAA and other acute phase proteins to detect systemic inflammation in cetaceans is still under investigation.[6] Toxic change in neutrophils is frequently observed with inflammatory disease or other causes of accelerated neutrophil activation or production and is evaluated as for other mammals. Harvey (2012) proposed a scale of

1+–3+ for the evaluation of toxic changes, which appears to introduce less interobserver variability than other grading scales published in the literature (e.g., 1+–4+)[13] (Figure 122.4).

Inflammatory disease in marine mammals often results in leukocytosis. However, cetaceans with clinically suspected low-grade inflammation frequently only display mild left-shifting and minimal toxicity without neutrophilia. Identification of these mild changes can be important. For example, low-grade pneumonia in cetaceans can be life-threatening.[25] Anecdotally, leukopenia in cetaceans can be a poor prognostic indicator when observed as a trend in an individual, reflecting acute, overwhelming inflammation and possible sepsis. Drug reaction should be considered in patients with anemia of undetermined cause, neutropenia, and bone marrow dyscrasia as documented in other mammals.[36] Neutropenia has been observed in cetaceans after sulfadiazine administration; similarly to dogs in which aplastic anemia has been documented.[37]

Algal toxin exposure has resulted in increased eosinophil concentrations with domoic acid exposure in sea lions.[9] Eosinophilic hyperplasia has been seen in the bone marrow of a bottlenose dolphin with confirmed exposure to brevetoxin (Figure 122.6f). Hemoparasitic agents described in the following text should also be ruled out in cases presenting with eosinophilia.

Increasing trends in platelet concentrations and large platelets are often observed with inflammatory disease, similar to terrestrial mammals in which one of the most common causes of thrombocytosis is cytokine production in inflammatory disease[23] (Figure 122.6b). Thrombocytopenia is uncommon in marine mammals. Thrombocytopenia may be artifactual resulting from platelet clumping, and blood film evaluation should be performed before considering differential diagnoses. It has been observed by the authors in a few northern elephant seals with disseminated intravascular coagulation from *Otostrongylus circumlitis* infestation, in cetaceans reacting to sulfadiazine,[37] and as a sequelae to bone marrow suppression in various species.

Clinically significant infectious agents may be observed upon blood film review. Filaroid parasites in seals, specifically *Acanthocheilonema (Dipetalonema) spirocauda*, the so-called seal heartworm, can cause clinical disease and mortality. *Acanthocheilonema odendhali* is found in sea lions (*Otariidae*), but considered an incidental finding, similar to canine heartworm infection, which is rarely observed in phocidae and otariidae under managed care[19] (Figure 122.6e). Additionally, the authors observed an intracytoplasmic focal aggregate of cocci in a neutrophil from a bottlenose dolphin that became suddenly anorexic with a WBC count change from 6.2 to 14.9 × 10^9/L within 24 hours (Figure 122.4e). This observation prompted blood culture from which *Peptostreptococcus sp*. was isolated. After adjustment of antimicrobials based on the sensitivity panel, the dolphin recovered rapidly. The definitive cause of the septicemia was not determined, but was presumably associated with chronic pulmonary disease.

Few case reports of leukemia in marine mammals exist. Lymphoma has been documented in cetaceans and pinnipeds, with a description of leukemic manifestation in two harbor seals; herpesvirus-associated B-cell lymphoma in California sea lions; eosinophilic leukemia in a Pacific white-sided dolphin (*Lagenorhynchus obliquidens*); and myelogenous leukemia in a walrus (*Odobenus rosmarus*) and a bottlenose dolphin (*T. truncatus*).[23,36] Reactive lymphocytes, which exhibit increased size, dark cytoplasmic basophilia, smooth chromatin, rare to occasional nucleoli, and a heterogenous appearance, are frequently observed in marine mammals with inflammatory disease (Figure 122.5). When atypical lymphocytes with similar morphologic features are observed during blood film evaluation, the challenge is similar to other mammalian species. The differentiation of reactive (heterogenous lymphoid population) versus neoplastic (monomorphic) lymphocytes is challenging at best with light microscopy alone and any diagnosis must be based on morphologic features, absolute lymphocyte counts, and other laboratory, clinical, and imaging findings (see Section V). Currently, there is no published literature on the use of cluster of differentiation (CD) markers in the diagnosis of leukemia; although, in the authors' experience, CD markers that are functional in dogs are often cross-reactive in pinnipeds. Markers have been used to assess immune functions in cetacean species and could potentially be used in the diagnosis of leukemia.[8,30]

ACKNOWLEDGMENTS

The authors thank Dr. Thomas Reidarson for the "Marine Mammal Hematology" chapter in the previous (6th) edition of this textbook, Laurie Adler for technical assistance, and the medical technologists at SeaWorld San Diego, San Antonio, and Orlando, especially Sherry Dickerson.

Acronyms and Abbreviations

AGP, α_1 acid glycoprotein; ALV, avian leukosis virus; ASVCP, American Society for Veterinary Clinical Pathology; CV, coefficient of variation; H:L ratio, heterophil:lymphocyte ratio; HSC, hematopoietic stem cell; IL, interleukins; SAA, serum amyloid A.

Members of the order Galliformes are heavy-bodied, ground-feeding birds, referred to as gallinaceous birds. There are hundreds of birds in this order including chicken (*Gallus gallus*), turkey (*Meleagris gallopavo*), quail (*Coturnix sp.*), pheasant (subfamily Phasianinae), grouse (subfamily Tetraoninae), peafowl (*Pavo sp.*), ptarmigan (*Lagopus sp.*), partridge (subfamily Perdicinae), and guinea fowl (family Numididae). They are often raised for egg and meat production or used for recreational hunting. Backyard poultry flocks are increasing in the USA and are typically maintained for food production, show, or as companion animals. These backyard operations can be a source of zoonotic infectious diseases and may have detrimental effects on neighboring food animal operations, as biosecurity protocols may be inadequate.[20] Hematologic evaluation of these animals is a relatively inexpensive method to evaluate health.

HEMATOPOIESIS

The majority of research on avian hematopoiesis has been performed in gallinaceous birds, mostly chicken and quail-chick chimeras. In the embryo, hematopoiesis begins in the yolk sac with a single wave of hematopoietic stem cells (HSC) that will then colonize developing organs, including, in approximate chronologic order, the intra-aortic clusters, para-aortic foci, spleen, liver, bursa of Fabricius, thymus, and bone marrow.[57] Even though the bone marrow is the last organ colonized by hematopoietic precursor cells in the embryonic period, it contains multiple cell lineages by day 12 of embryogenesis. Embryogenesis lasts approximately 21 days in the chicken. Definitive HSC that maintain hematopoiesis during the bird's life will develop within the chicken embryo (versus yolk sac, as previously thought).[16]

In the first 2–5 days of embryogenesis, HSC are originally derived from the yolk sac.[57] During this early stage, these HSC are committed primarily to erythropoiesis.[57,67] However, the yolk sac will also contain primitive lymphoid cells, granulocytic and macrophagic precursor cells, and likely thrombocytes within 10 days of embryogenesis.[16,67] These cells will eventually enter circulation and colonize other organs and locations (e.g., bone marrow, spleen, liver).

Within the chicken embryo, hematopoietic cells are first confidently identified in the para-aortic foci and intra-aortic clusters around day 3 of embryogenesis.[57,67] Para-aortic foci are groups of cells located in loose mesenchymal tissue ventral to the aorta.[16] These para-aortic foci provide cells for the first wave of thymic colonization and for bone marrow colonization. Interestingly, definitive para-aortic foci have not been identified in mammals.[16] Intra-aortic clusters are areas of hematopoietic cells protruding into the aortic lumen. These cells are CD45- and CD41-positive (pan-leukocytic antigen and HSC marker, respectively).[16] They appear to be predominantly erythroid precursors; however, myeloid and thrombocyte precursors are also present.[57,67]

Between days 8 and 15 of embryogenesis, a rudimentary spleen is colonized by stems cells from the yolk sac, intraembryonic para-aortic foci, and intra-aortic clusters. The spleen then begins to support erythropoiesis, granulopoiesis, and lymphopoiesis.[57,67] After hatching, the spleen will become one of the major secondary lymphoid organs. During this same time period, epithelial cells in the bursa of Fabricius (primary lymphoid organ) attract stem cells from the yolk sac, spleen, liver, bone marrow, and blood.[57,67] The bursa is responsible for the amplification and differentiation of B-lymphocytes via bursin, which is the major differentiating hormone of B cells.[16] After sexual maturity, the bursa will involute and B-cell amplification and differentiation will primarily occur in the spleen and intestinal germinal centers.

The thymus, the other primary lymphoid organ in birds, is responsible for T-lymphocyte differentiation. T-cell progenitors colonize the thymus in three waves. The first wave occurs at day 6 of embryogenesis, with T cells traveling from the para-aortic foci to the thymus.[16] The bone marrow supplies the progenitors for the second and third waves of thymic colonization, which occur at days 12 and 18 of embryogenesis, respectively.[16] T-cell differentiation is regulated by thymopoietin, which is synthesized by thymic epithelial and dendritic cells.[16] Certain T-cell lymphocyte populations can also be found in the spleen and intestinal epithelium during embryogenesis.[16,57]

The bone marrow contains multiple cell lineages by 12 days of embryogenesis, and after hatching it is the primary site of hematopoiesis. Bone marrow contains specialized niches for different areas of hematopoiesis, likely based on cell–cytokine interactions.[57] The bone marrow primarily produces erythroid cells; however, granulocyte and lymphocyte development also is initiated and may occur here.[67] Unlike in mammals, the liver plays only a minor role in embryonal hematopoiesis, supporting erythropoiesis and granulopoiesis until shortly after hatching.[57] However, the liver does serve as an important organ for extramedullary hematopoiesis in post-hatched gallinaceous birds.

Cytokines are small proteins that are secreted by one cell and cause an effect on another cell. Cytokines involved in hematopoiesis are better defined in mammalian species than in birds. Colony-stimulating factors (CSF) have been shown to act on pluripotent HSC and initiate the development of myeloid cells in chicken. Similar to mammals, there are three identified CSFs in chicken: granulocyte CSF, macrophage CSF, and granulocyte–macrophage CSF.[32] Interleukins (IL), specifically IL-2, IL-15, and IL-21, regulate T-cell proliferation.[32] IL-18 stimulates proliferation of CD4+ T cells.[22] Other cytokine function is poorly defined or varies between manuscripts. A detailed review of cytokines and chemokines is provided elsewhere.[32,57]

In mature gallinaceous birds, erythropoiesis occurs in the vascular sinuses of the bone marrow (medullary sinus lumen), primarily in the vertebrae and long bones.[67] Erythropoiesis is stimulated by avian erythropoietin, which is structurally distinct from mammalian erythropoietin. Similar to other birds, RBCs develop from rubriblasts to prorubricytes to rubricytes to polychromatophils to mature RBCs (metarubricytes). Rubricytes may be separated into basophilic rubricytes followed by early and late polychromatophilic rubricytes.

As discussed in the earlier text, avian bone marrow is primarily dedicated to erythropoiesis and the number of reserve mature granulocytes is very low compared to most mammals. Granulocytes develop in the extravascular space of bone marrow. Due to limited granulocyte reserves, left shifts in the heterophil line occur frequently with inflammation. In adults, the spleen is presumed to be one of the primary locations for lymphopoiesis and granulopoiesis; however, extramedullary hematopoiesis can also occur in the liver and kidney. The role of bone marrow in avian lymphopoiesis is unclear, but there may be small stem cell populations originally from the thymus and bursa that are capable of self-renewal.[67] Granulocyte maturation appears to be similar in gallinaceous birds as in other birds with the following stages: myeloblasts, progranulocytes, myelocytes, metamyelocytes, band granulocytes, and mature granulocytes. Monocytopoiesis is not well described in gallinaceous birds and monocyte precursors are likely similar in appearance to granulocytic precursors.

There is limited literature on thrombocyte proliferation and maturation in gallinaceous or other birds. Thrombocytes are presumed to mature in the vascular sinus of bone marrow and are derived from thromboblasts, which are difficult to differentiate from other blast cells with light microscopy alone. In general, thrombocytes are most commonly found in areas of hemodilution in bone marrow samples. Further study is needed.[67]

BLOOD COLLECTION

The brachial (wing) vein is the most commonly used vessel for blood collection in chicken and turkeys. The wing vein is superficial and easily visible in animals over 2 weeks of age. A quick reference for assisted or unassisted venipuncture in poultry can be found on the Food and Agriculture Organization of the United Nations' website (http://www.fao.org/docrep/005/ac802e/ac802e0a.htm). The maximum blood volume that should be collected is 1% of the body weight (e.g., absolute maximum of 23 mL in 5 lb/2.3 kg chicken). Blood smears should be prepared at the time of collection by well-trained staff. Both wedge (a push preparation using two glass slides) and coverslip (a pull preparation using two square glass coverslips aligned catty-corner) techniques are appropriate for gallinaceous birds (see Chapter 137).

The use of anticoagulants is necessary for hematologic evaluation. In general, EDTA and lithium heparin are the most common options in veterinary medicine, and both are considered appropriate for gallinaceous species, as no significant lysis has been documented to date. PCV and plasma protein can be lower and lymphocyte numbers and platelet clumping can be higher in lithium heparin versus EDTA samples.[25] Therefore, the same anticoagulant should be used to decrease variation.[25] Cellular morphology and staining are adequate with both EDTA and lithium heparin, though EDTA may be preferred to avoid heparin artifact.[25]

ERYTHRON

In general, RBC mass in gallinaceous birds can be evaluated through PCV, hemoglobin (Hgb), or with RBC counts. Packed cell volume is determined by centrifugation of microhematocrit tubes. Hemoglobin can be measured by standard instrumentation after cell lysis and removal of nuclei. Manual RBC counts can be performed with standard erythrocyte Unopette® methods using a hemocytometer. When using automated methods, both WBCs and RBCs will be counted; however, WBC numbers are small in comparison and will likely not skew RBC counts.[67] Mean cell volume (MCV) and mean cell hemoglobin concentration (MCHC) can be calculated from the PCV/RBC count and Hgb/RBC count, respectively. Mean cell hemoglobin (MCH) does not provide diagnostic information.

Mature Galliform RBCs are oval to elliptical with smooth eosinophilic cytoplasm and a centrally located, oval nucleus with clumped to condensed chromatin (Figure 123.1). Chicken RBCs have a more rounded nucleus compared to other gallinaceous birds. The vast majority of RBCs should be mature and relatively uniform in appearance. Minimal anisocytosis (variation in RBC size) is expected and clinically insignificant. Mature chicken RBCs average 12x6 μm.[67] RBCs in white-breed and bronze-breed turkeys average 14x8.5 μm.[6] In Japanese quail and adult peafowl, RBCs average 11x7 μm and 14x7 μm, respectively.[51,65] Most papers cite an older reference reporting that chicken RBC life span has a maximum of 35 days. It does not appear that this has been confirmed experimentally in recent times.[64]

Polychromasia is common on blood smears due to the shorter half-life of avian RBCs. Blood smears from normal gallinaceous birds typically contain 1–5% polychromatophils.[67] With standard Romanowsky stains, polychromatophils are slightly larger and more oval than mature RBCs with increased cytoplasmic basophilia and a round to slightly oval, lighter staining nucleus with less-condensed chromatin. In addition, due to intravascular and intrasinusoidal erythropoiesis, rubricytes are seen in low numbers on peripheral blood smears.[67] Circulating rubricytes also appear to be more common in chicken and turkeys than in other birds, though are uncommon in blood smears from the normal animal and increase with erythroid regeneration.[67] Rubricytes are round and contain basophilic to grayish cytoplasm with a centrally located round nucleus with clumped chromatin.

LEUKON

Nonmammalian RBCs and thrombocytes are nucleated, limiting the use of automated analyzers. Although some studies have shown good agreement between manual and automated granulocyte counts, lymphocyte and monocyte counts are considered inaccurate.[36] Therefore, manual WBC-counting methods (hemocytometer) are primarily used in the diagnostic setting.[12] Natt–Herrick solution can be used to provide a direct WBC count.[11] The eosinophil Unopette® method can provide an indirect WBC count when used in conjunction with WBC differential counts. WBC estimates can also be calculated from the monolayer during blood smear examination. WBC estimates should not be performed by novice microscopists. Estimates should only be used when there is even WBC distribution in the blood smear.

The avian WBC count can be determined directly with a Neubauer-ruled hemocytometer, pipettes, and Natt–Herrick solution. The advantage of this technique is that all WBCs are visualized and enumerated. The disadvantages are that this WBC counting technique is labor intensive, care must be taken to differentiate thrombocytes from small lymphocytes, and WBCs may be swollen and distorted if analysis of the diluted specimen is delayed. This method works well for an in-house laboratory, but may prove difficult with samples that are mailed to a diagnostic laboratory due to increased lysis over time.

The WBC count can be quantitated indirectly with the Unopette® system. In this technique, heterophils and eosinophils are selectively stained by phloxine dye and counted in a hemocytometer. Based on the WBC differential cell count of a stained blood smear, the combined heterophil and eosinophil hemocytometer count is mathematically corrected to account for basophils and

mononuclear cells (e.g., lymphocytes and monocytes) that were not counted. Thus, the total WBC count per microliter of blood has been determined indirectly. Advantages of this system are that heterophils and eosinophils are directly identified and counted in a hemocytometer; thus, there is no confusion between lymphocytes and thrombocytes because they are not counted with the hemocytometer. However, hemocytometer counts are labor-intensive, a greater potential for mathematical errors exists, and WBC distribution on stained blood smears may not be random.

One can estimate WBC counts from the stained blood smear by multiplying the average number of WBCs per field of view by a given factor; the factor is usually approximately the square of the objective's magnification, e.g., 2500 for the 50× oil-immersion objective. This factor can vary with the optics of different microscopes. Advantages include the stability of the blood film and the labor-efficient process of WBC count estimation. The major disadvantage is that the WBC count is estimated instead of quantitated. Thus, poor smear technique resulting in cell lysis and maldistribution may influence the estimate, and the coefficient of variation (CV) may be significantly higher. Coefficient of variation for hemocytometer-derived WBC counts (eosinophil Unopette® method) is approximately 13% as opposed to 30% for estimated WBC counts from stained blood smears.[35] The variation reported with these techniques may vary with some labs reporting CV that are significantly higher. However, the latter technique may be useful when the lability or specimen volume would otherwise preclude hematologic study. Ultimately, the future of avian hematology depends on the development of semi-automated or automated techniques to determine avian WBC counts in a rapid, accurate, economical, and labor-efficient manner.

Heterophils follow lymphocytes in abundance and an H:L ratio <1 is expected in most gallinaceous birds (except guinea fowl). Heterophils should have colorless cytoplasm with numerous eosinophilic, slightly muddy-appearing to refractile elliptical granules. Nuclei are less lobulated than expected in mammalian specimens; mature heterophils have two to three lobes and coarse chromatin[65,67] (Figure 123.1). Mature heterophils are approximately 13 μm in diameter in chicken and approximately 10 μm in diameter in turkeys, quail, and peafowl.[6,51,65,67]

Lymphocytes are the predominant leukocyte in most gallinaceous birds, which is in contrast to other avian species.[30,52,54,67] Guinea fowl do appear to be heterophil predominant, though a steroid induced leukogram should be ruled out.[46,47] Both small and medium lymphocytes may be found in blood smears from normal animals.[65,67] In adult quail, small lymphocytes and medium lymphocytes measure approximately 5 and 8 μm in diameter, respectively.[65] Small lymphocytes have a scant amount of medium basophilic cytoplasm, a round nucleus with condensed chromatin, and a high nuclear to cytoplasmic ratio (Figure 123.1). In contrast to small lymphocytes, medium-sized lymphocytes have increased amounts of pale to light basophilic cytoplasm and a round to slightly indented nucleus with coarse to condensed chromatin. No clinical significance is typically ascribed to the proportion of medium to small lymphocytes. However, it is important to ensure that small lymphocytes are not classified as thrombocytes and that medium lymphocytes are not classified as monocytes. Rare reactive lymphocytes, with dark blue cytoplasm and clear Golgi zones, are also expected in circulation in normal birds, especially after vaccination.

Monocytes are the largest cells in circulation. They contain a modest amount of light to medium basophilic to blue–gray, often vacuolated cytoplasm and a round to kidney-shaped to pleomorphic nucleus with clumped or smooth chromatin (Figure 123.1). Fine azurophilic cytoplasmic granules may be seen.[67] In chicken and quail, monocytes are 13–14 μm in diameter, while peafowl and turkey monocytes are smaller averaging 11 μm in diameter.[6,51,65,67]

Eosinophils in gallinaceous birds are similar to other mammalian and avian species in that they have pale blue cytoplasm with numerous eosinophilic round granules and a lobulated nucleus with condensed chromatin (Figure 123.1). Eosinophil granules stain very pale with Wright–Giemsa in some gallinaceous birds, such as certain turkeys, pheasants, and grouse. Variation with types of Romanowsky stain may also occur. Eosinophils in gallinaceous birds are approximately 10–12 μm in diameter.[6,51,65,67] Eosinophils can be differentiated from heterophils by their distinct granules, lack of refractile appearance, and typically darker-staining or more visible nucleus.

Basophils contain numerous dark basophilic granules, which often obscure the nucleus (Figure 123.1). Basophils are more commonly observed in blood smears from avian species than mammalian species and may be morphologically similar to mast cells. Basophils in gallinaceous birds are typically smaller than other WBC, measuring 9–12 μm in diameter.[6,51,65,67]

When needed, cytochemical stains can be used to distinguish WBCs in chicken and likely other gallinaceous birds. Acid phosphatase, peroxidase, Sudan Black B, and Luna methods may be used to differentiate chicken eosinophils from heterophils. Periodic acid–Schiff and Grimelius stains differentiate chicken thrombocytes from small lymphocytes, as thrombocytes stain positively with periodic acid–Schiff and Grimelius, while lymphocytes do not.[63] The ultrastructural features of blood cells in select gallinaceous birds have been discussed extensively in other sources.[37–40]

Studies using conventional flow cytometry with fluorescent markers to perform WBC counts and differentials in chicken and quail have generally shown good correlation with blood smear evaluation and manual differential counts in research settings.[8,41,56] In one study, there was poor correlation between monocyte counts obtained with flow cytometry versus manual differentials.[8] Use of fluorescent markers is not common in diagnostic and clinical settings, likely due to cost and long-term instability of cell markers during shipping and transit.

THROMBON

Thrombocytes are smaller and rounder than RBCs and contain a small amount of clear to pale blue cytoplasm with occasional small clear vacuoles or pink granulation surrounding a small round, condensed nucleus (Figure 123.1). Thrombocyte counts in gallinaceous species appear to be consistent with other avian species at approximately 30,000 cells/μL.[24,33] During blood smear examination, it is important to view the feathered edge for large thrombocyte clumps which falsely decrease the thrombocyte estimate. Thrombocytes are reported to be approximately 4 μm in diameter in quail.[65]

REFERENCE INTERVALS AND PARTITIONING FACTORS

The American Society for Veterinary Clinical Pathology (ASVCP) has published guidelines for the determination of de novo reference intervals in veterinary species.[19] Deviations from the published recommendations

may occur due to study publication prior to ASVCP guidelines, inclusion of low numbers of target species, difficulty in proving health in avian species, inappropriate statistical analysis, inclusion of outliers, etc. Baseline blood profiles from individual animals in times of health may aid in interpretation of future blood profiles. This would likely only be practical in well-managed, small backyard flocks or zoo settings.

Variations in hematologic values can be seen with many partitioning factors (species, breed, sex, age, environmental conditions, reproductive status, etc.). It should be noted that many studies evaluating reference intervals and partitioning factors were performed in different areas of the globe and published in various journals. A detailed review of this literature is beyond the scope of this chapter; however, some guidelines are provided in the following text.

Chicken

There are several CBC changes that are expected during growth of chicken. From 1–7 weeks of age, Hgb, PCV, and MCV increase and WBC count decreases with increasing age.[23] Following this, PCV and Hgb appear clinically similar in Polbar chicken (Poland) across three time points: 8, 12, and 18 weeks of age.[24] By contrast, RBC counts, PCV, and Hgb concentration increased substantially between 10 and 35 weeks of age in clinically normal breeding cocks.[34] In the Polbar chicken, WBC counts decreased from 37 × 10^3/μL to 27 × 10^3/μL between 8 and 18 weeks of age due to decreases in absolute heterophil and lymphocyte counts.[24] A steroid-induced leukogram is possible. In the breeding cocks, WBC counts also decreased substantially, mostly due to decreases in lymphocyte counts.[34]

Significant differences in CBC values between male and female chicken have been found. Hgb concentration and PCV are higher in male than female chicken for several breeds.[7,49,58] Studies evaluating total RBC counts, MCV, MCH, and MCHC in males versus females offer no clear consensus.[24,49] The differences between these values may not be significant or clear between breeds, testing modalities, and environments. In general, total WBC counts are often statistically higher in male versus female chicken.[7,49] However, clinically significant differences may only be apparent in some breeds (e.g., American Red Cornish and Vanaraja breeds).[7,49] Multiple studies have shown that absolute or relative lymphocyte numbers are higher in female chicken than in male chicken.[24,58] In the peak egg-laying period, RBC counts, PCV, Hgb, and WBC counts have been shown to decrease in hens.[62]

Hemoglobin concentration and PCV have been shown to be statistically and clinically different between different breeds (as well as geographic locations) of chicken.[7,48] For example, average Hgb in Aseel (Indian) chicken was 12.9 g/dL compared with 8.7 g/dL in Rhode Island Red (English) chicken with both sites using a comparable cyanmethemoglobin method.[48]

Turkey

One reference interval study published prior to ASVCP guidelines had no mention of outlier removal, and the reported intervals should not be used for medical diagnosis.[9] Although sex has been shown to be a major partitioning factor in CBC findings of chicken, clinically significant differences have not been found between male and female turkeys.[21,54] When both male and female turkeys aged from 19–23 weeks to 30–32 weeks, heterophil numbers increased, lymphocyte counts decreased, and thus the H:L ratio increased.[54] PCV may decrease during egg production/laying and a PCV greater than 45% may be an indicator of poor egg production.[50] PCV in turkeys can drop substantially in the summer (41% to 35% in male turkeys between winter and summer, respectively).[21]

Quail

In some studies evaluating presumably healthy quail, there are substantial discrepancies in total WBC count, with means ranging 2.6–16.8 cells × 10^3/μL.[4,13,43] MCV decreased dramatically at 2 weeks of age, followed by a steady increase until at least 6 weeks of age in Japanese quail (*Coturnix japonica*), similar to a pattern seen in chicken.[4,23] Also similar to chicken, PCV is higher in adult male than female quail.[3,18] PCV differences between sexes are also clinically significant with males averaging 42–52% and females averaging 33–46%.[3,18]

Pheasant

Selected reference intervals for 6-week-old farm-raised Chinese ring-necked pheasants (*Phasianus colchicus*) are provided in Table 123.1.[15] While this study followed guidelines recommended by the ASVCP, some limitations to consider include: cardiac collection, administration of euthanasia solution, and unspecified anticoagulant (presumed EDTA).[19] In addition, while all animals were considered clinically healthy and gross and histopathologic evaluation of many tissues was unremarkable, some animals had substantial abnormalities in serum chemistry results.[15] It is possible that the low reference values represent a mild anemia due to chronic disease.

RBC count, PCV, and WBC count increase as pheasants age from around 30–360 days, which contrasts somewhat with other gallinaceous birds.[24,33,34,53] These changes can be clinically significant with average PCV increasing from 28% to 36% and 34% to 44%, depending on the study.[33,53] However, WBC counts may substantially decrease within time points between 30 and 360 days of age.[26,33,52] Interestingly, one study showed markedly increased WBC counts in both males and females in November (averaging 26 × 10^3/μL) versus March (averaging 9 × 10^3/μL).[26] However, these animals were also aging from approximately 180 to 300 days during this comparison, so the variables were not isolated.[26]

Table 123.1 Selected Galliformes hematology reference intervals. RBC counts were determined using hemocytometer, PCV by centrifugation of microhematocrit tube, Hgb using the cyanmethemoglobin method, and MCV was calculated. Reference interval generation was in compliance with ASVCP guidelines.

	Japanese quail[a] (*Coturnix japonica*)	Chinese ring-necked pheasants[b] (*Phasianus colchicus*)
RBC (× 10^6/μL)		2–3.6
PCV (%)	34–55	28–40
Hgb (g/dL)	9.6–18.4	
MCV (fL)		91–164
Activated coagulation time (sec)	<180	
Prothrombin time (sec)	10–14	

[a] 12 male and 12 female (n = 24), 22-week-old, clinically healthy Japanese quail were housed in British Columbia, Canada and had unremarkable postmortem histopathology. Blood was collected from unsedated birds' jugular veins and the sample was placed in heparinized tubes or tubes with no anticoagulant.[68]
[b] 84 or 107 (depending on analyte), 6-week-old, male and female Chinese ring-necked pheasants were housed in Minnesota, USA and had clinically healthy and unremarkable postmortem histopathology. Blood was collected from the heart after sedation with euthanasia solution given IM and was placed in tubes with unknown anticoagulant (presumed EDTA).[15]

Similar to chicken, male pheasants have higher RBC counts, PCV, Hgb, and MCHC than females.[26] Significant decreases in PCV, RBC counts, and Hgb and increases in total WBC, lymphocyte, and basophil counts can be seen during peak egg laying.[30,55] These changes are likely clinically significant; in one study, average RBC count decreased from 3.5 × 10^{12}/L to 2.6 × 10^{12}/L).[30] The decrease in RBC values during peak egg-laying has also been observed in chicken; however, in contrast to pheasants, chicken appear to have decreased WBC counts during peak egg-laying.[62]

Guinea Fowl and Peafowl

In contrast to other gallinaceous birds, guinea fowl appear to be heterophil-predominant, not lymphocyte-predominant.[46,47] Additionally, WBC counts of guinea fowl appear to be lower than other birds with two studies demonstrating average WBC counts of 1.4 and 3.7 × 10^3/μL in apparently healthy birds of different ages.[46,47] As guinea fowl age from 8 to 24 weeks, Hgb and WBC count increase significantly.[46] Unlike chicken, there are no consistent differences in RBC count, PCV, Hgb, or total WBC counts between male and female guinea fowl.[1,46,47] One study of guinea fowl from two different countries (Belgium and Ghana) showed statistically significant differences in RBC counts and PCV.[46] Another study showed significant differences between all hematologic values between five different varieties of guinea fowl in Nigeria.[1] Different guinea fowl production systems also appeared to cause variations in WBC counts as well as heterophil and lymphocyte proportions.[47] One study in peafowl, published before ASVCP guidelines, has no mention of outlier removal and the reported intervals should not be used in medical diagnosis.[51]

BONE MARROW COLLECTION AND EVALUATION

Bone marrow evaluation can provide valuable information in cases of nonregenerative anemia, heteropenia, persistent thrombocytopenia, pancytopenia, and dysplastic changes. The proximal portion of the tibiotarsal bone is most commonly used for antemortem bone marrow aspiration in gallinaceous birds. The femur and sternum may also be used, but may have variable quantities of fat and there is the concern for perforation of the air sacs at the sternum/keel. Fresh smears should be prepared at the time of collection by well-trained staff. When utilizing a diagnostic laboratory, the following samples should be submitted to provide the most accurate results: freshly prepared bone marrow smears, recent CBC data (within 24 hours) or whole blood for CBC, and bone marrow in EDTA (large birds) (see Chapter 141).

There are limited studies on the cytologic evaluation of bone marrow aspirates in the chicken; however, the composition of chicken bone marrow has been extensively evaluated.[10] In healthy adult chicken, the bone marrow cellularity is high (>70% cells to fat in marrow particles) (Figure 123.2a). The M:E ratio in healthy adult chicken is approximately 1:1 (Figure 123.2b). Mature cells should outnumber immature cells in all cell lines (Figure 123.2c). Certain cell types are difficult to definitively identify in bird bone marrow, such as early thrombocyte and monocyte precursors. Aggregates of variably sized lymphocytes are more commonly identified in birds than in some mammals.[16,44] Other cells that may be visualized in bone marrow aspirate samples include osteoblasts, osteoclasts, plasma cells, and macrophages. Cell distribution can vary with disease; examples are provided in the following text (Figure 123.2d).

Bone marrow cytologic evaluation has also been evaluated in clinically healthy Japanese quail and partridge with no overt hematologic abnormalities.[44,66] The mean M:E ratio is 0.4 in Japanese quail and 1.3 in partridge.[44,66] Erythroid cells predominate (76%) in Japanese quail, while slightly more than half of the cells (52%) are myeloid in the partridges studied.[44,66] The cellularity of samples is typically high, ranging from 60–90% cells to fat.[44,66] In Japanese quail, bone marrow findings can vary by age, with increasing RBC and thrombocyte precursor cells with advanced age.[44] There are no significant

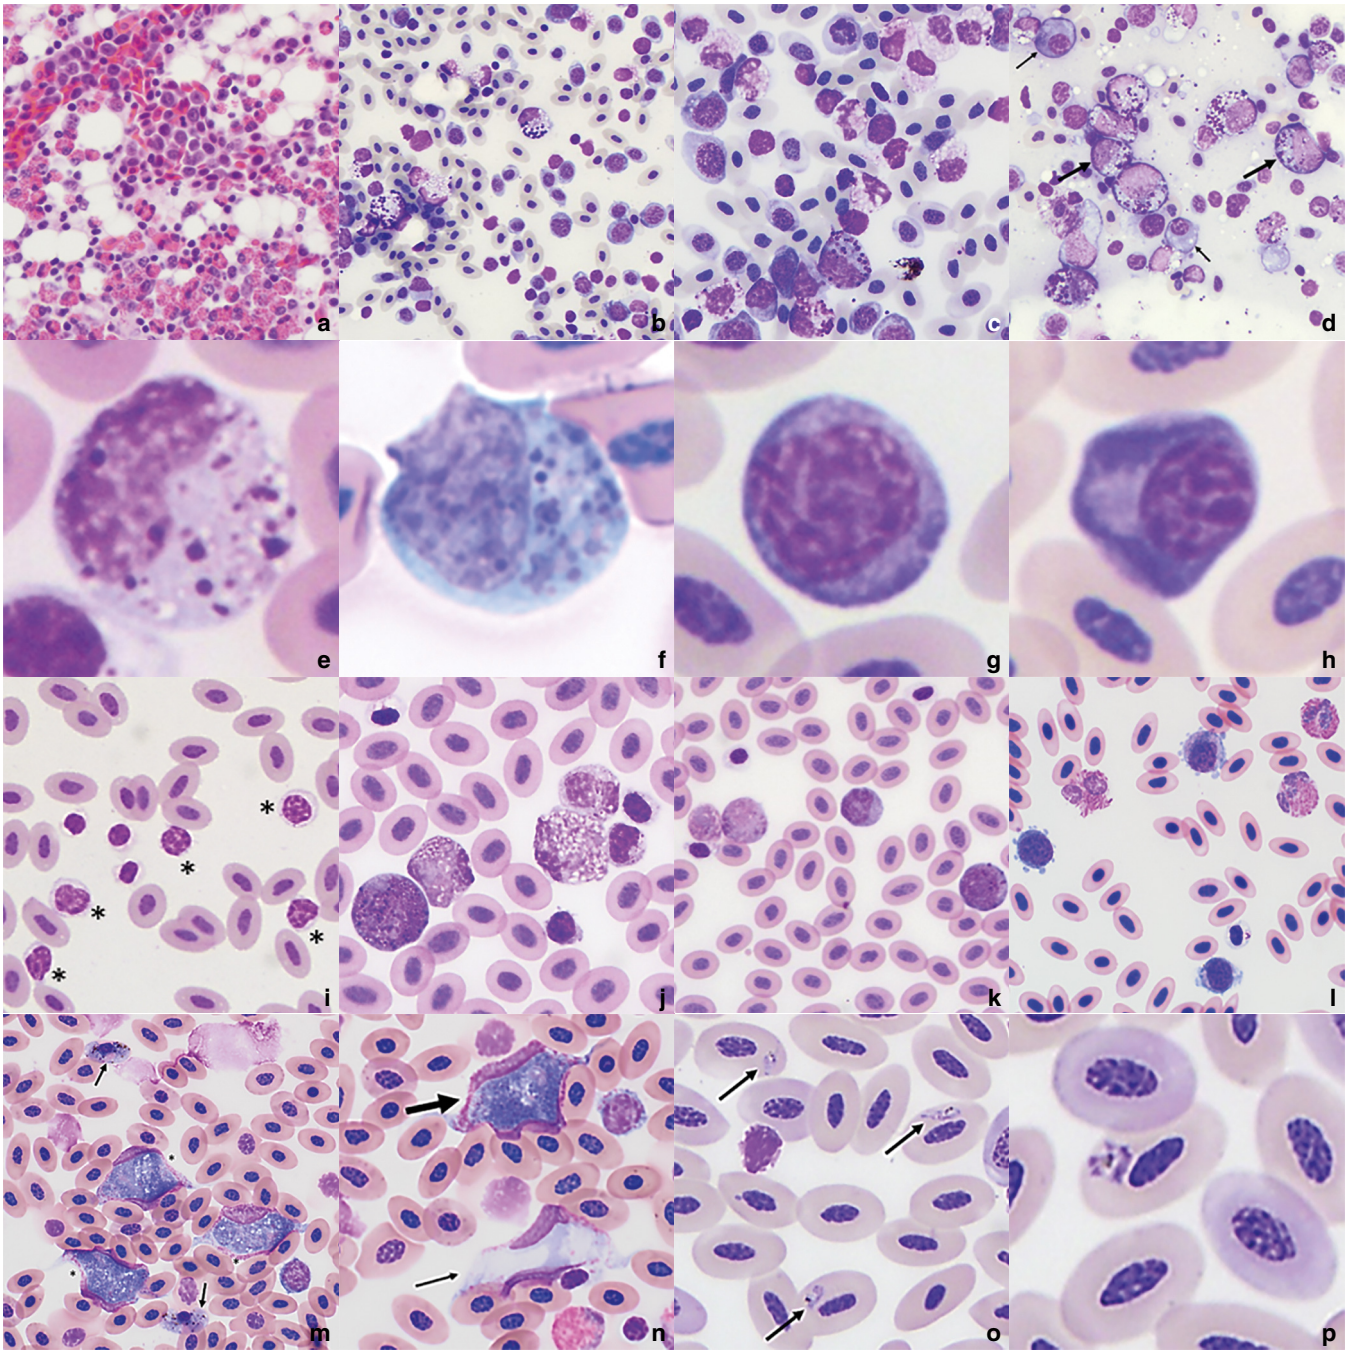

FIGURE 123.2 Bone marrow and abnormal cytomorphology from Galliformes. Samples are stained with Wright–Giemsa unless otherwise noted. Chicken (*Gallus gallus domesticus*): (a) Normal bone marrow, core biopsy, H&E; (b) and (c) Normal bone marrow impression; note M:E ratio is approximately 1–1.5 (Source: Samples provided by Dr. Erin Edwards); (d) Myeloid hyperplasia and plasmacytosis secondary to *Staphylococcus sp*. synovitis and osteomyelitis, bone marrow. Myeloid precursors (large arrows) and plasma cells (small arrows) are increased (Source: Sample provided by Dr. Erin Edwards); (e) Toxic heterophil metamyelocyte with increased basophilic cytoplasm and dark purple granules; (f) Toxic heterophil myelocyte (Sources: images provided by Drs. Nina Zitzer and Gregory Having). Golden pheasant (*Chrysolophus pictus*): (g) Reactive lymphocyte; (h) Plasma cell (Source: Sample provided by Gladys Porter Zoo). Chicken (*Gallus gallus domesticus*): (i) Lymphoid leukosis in an ALV-positive chicken; note increased numbers of small to intermediate lymphocytes (*) and mild to moderate anemia (Source: Slide provided by Dr. Holly Minard); (j) and (k) Myelocytic myeloid leukosis; note immature myeloid precursors and dysplastic change in the heterophils; (l) T-cell leukemic lymphoma in a chicken with confirmed Marek's disease; note immature lymphocytes and anemia (Source: Image provided by Dr. Gary Lee). Turkey (*Meleagris ocellata*): (m) *Leukocytozoon* gametocytes (*) and *Hemoproteus* (arrows); (n) *Leukocytozoon* macrogametocyte (thick arrow) and *Leukocytozoon* microgametocyte (thin arrow) (Source: Images provided by Dr. Francisco O. Conrado). Kristin J. Bondo and Blake Grisham).

differences between bone marrow findings in male and female Japanese quail or partridge.[44,66]

HEMATOLOGIC DISEASE

Anemia

When PCV and/or Hgb concentration fall below an accurate reference interval, the anemia should then be classified as regenerative or nonregenerative by quantifying immature RBCs. Immature RBCs can be seen on standard blood smears, as polychromatophils and polychromasia can be documented. When a more accurate indicator of regeneration is needed, reticulocyte counts can be performed with new methylene blue preparations (see Chapter 23). With new methylene blue, reticulocytes show a distinct cytoplasmic ring of granular basophilic material (aggregates of RNA) surrounding the nucleus.[65] Rubricytes may also be enumerated either in percent or per 100 WBC. A nonregenerative anemia is presumed when gallinaceous birds have <5% polychromatophils, <3% reticulocytes, or <3 rubricytes per 100 WBC. It can take up to 3 days for a regenerative response to be detected in peripheral blood, so the duration of anemia should be considered prior to classification. In strongly regenerative anemias or certain hematopoietic disorders, rubriblasts, prorubricytes, and rarely mitotic figures may also be seen in circulation.

In general, regenerative anemias are seen with blood loss and hemolysis. Blood loss can be caused by trauma, internal and external parasitism, intestinal disease, and toxins (e.g., brodifacoum rodenticide).[68] Common internal parasites that may cause anemia in gallinaceous birds include capillariasis, severe ascaridiasis, cecal threadworms (*Trichostrongylus tenuis*), and chronic coccidiosis (*Eimeria tenella*, *Eimeria necatrix*, or *Eimeria brunetti*).[29] External bloodsucking parasites of poultry are numerous and include various species of fleas (e.g., *Echidnophaga gallinacea*), ticks (e.g., *Argas persicus*), mites (e.g., *Dermanyssus gallinae*, *Ornithonyssus sylviarum*), mosquitoes, biting midges (e.g., *Culicoides sp*.), certain flies (e.g., *Simulium spp*.), and bedbugs (*Cimex lectularius*).[29] Causes of hemolysis include *Plasmodium sp*. infestation, bacterial sepsis, and toxins (lead, zinc, etc.). Nonregenerative anemias can be seen with anemia of chronic inflammation, certain bacterial diseases (salmonellosis, chlamydiosis, aspergillosis, avian tuberculosis, *Mycoplasma gallisepticum*), iron deficiency due to chronic blood loss, viral disease (chicken anemia virus, reticuloendotheliosis virus, avian leukosis virus (ALV), Marek's disease), and leukemia.[27,42] Polycythemia, or increased PCV above an accurate reference interval, is rarely reported in gallinaceous birds. Mildly increased RBC counts and PCV can be seen with excitement, stress, or dehydration and are nonspecific clinical changes seen with many etiologies, including poor management. Significant erythroid regeneration in the face of a normal to mildly increased PCV may be observed as a sequela of significant respiratory disease.

Inflammation

Inflammation can cause several changes in peripheral blood such as leukocytosis or leukopenia, altered WBC differential (including heteropenia, heterophilia, lymphocytosis, monocytosis), left shift of heterophils, toxic change, and reactive lymphocytes. In general, band heterophils should be very rare in healthy adult gallinaceous birds. Increased H:L ratio in gallinaceous birds can be seen with inflammation, stress, egg-laying, or in certain age groups and should not be used as the sole indicator of inflammation.[4,5,30,49,50] H:L ratios are also reported to vary between different chicken breeds when determined by conventional flow cytometry using the fluorescent markers anti-CD45-PE, anti-CD4-Alexa 700, and anti-macrophage-fluorescein isothiocyanate (KUL01).[8] Studies using automated analysis should be replicated prior to interpretation.

Increased band heterophils (left shift) can be seen with severe, and often acute, inflammatory diseases of gallinaceous birds. Band heterophils have a more bilobed or horseshoe shaped nucleus with mild cytoplasmic basophilia and possibly decreased cytoplasmic granules. In addition, primary granules (round, purple granules) may be seen in the cytoplasm of band heterophils or earlier precursors such as myelocytes (Figure 123.2e,f). Quail under 1 week of age, and possibly other young birds, may have bilobed nuclei in their heterophils.[65] Toxic change in heterophils can occur with significant inflammation and increased peripheral demand for heterophils. In brief, toxic changes in heterophils can include increased cytoplasmic basophilia, decreased cytoplasmic granulation, indistinct vacuolation of the periphery of the cell, and primary basophilic rounded granules (Figure 123.2f).

Heterophilia is seen with a variety of etiologies including, but not limited to, stress, bacterial pneumonia or sepsis, chlamydiosis, systemic fungal infections, necrosis, and parasitic infestations (e.g., *T. tenuis*).[35] Severe heterophilia (>70 × 10^3/μL) may be associated with pneumonia, chlamydiosis, coelomitis, *Mycobacterium* infections, systemic aspergillosis, and, less commonly, leukemia.[27] Heteropenia is seen with acute, severe, or chronic infections (e.g., bacterial sepsis), certain medications (e.g., cyclophosphamide) or with bone marrow failure due to chicken anemia virus, leukosis, etc.[17,35,42]

Considerations for lymphocytosis include chronic fungal or parasitic disease, chronic viral infections, or lymphoid neoplasms. Increased numbers of reactive lymphocytes and plasma cells can be seen with antigenic stimulation from a variety of etiologies (e.g., infection, inflammation, and vaccination). Reactive lymphocytes are slightly larger and have a small amount of deeply basophilic cytoplasm. The nuclear chromatin of reactive lymphocytes remains mature (coarse to condensed) and there are no visible nucleoli (Figure 123.2g). In comparison, plasma cells have a small nucleus with clumped chromatin and a moderate amount of deep blue cytoplasm with a perinuclear clear zone or Golgi zone; and may also be counted in a differential cell count

(Figure 123.2h). Lymphopenia can be observed in gallinaceous birds with severe stress or with certain medications such as cyclophosphamide and corticosteroids.[17]

Monocytosis in gallinaceous birds is observed with chronic inflammatory processes. *Mycobacterium avium* infections, chlamydiosis, aspergillosis, and necrosis may produce severe increases in monocyte counts.[27,35] Eosinophilia is observed with parasitic infestations, foreign bodies, fungal disease, and chronic antigenic stimulation.[35] Basophilia is seen with parasitic infestations and with acute inflammation from a variety of etiologies.[35] Monocytopenia, eosinopenia, and basopenia are considered clinically insignificant.

The principal acute phase proteins that have been used to identify the acute phase response in chicken, and thus the innate immune response, are serum amyloid A (SAA), α_1 acid glycoprotein (AGP), and ovotransferrin.[45] Ovotransferrin and α_1 acid glycoprotein have long been established using radial immunodiffusion (Mancini method) or ELISA. The majority of investigations have studied the acute phase protein response in experimental models of infection or in response to bacterial endotoxin. For instance, Adler used *Salmonella typhimurium* lipopolysaccharide to demonstrate a response in AGP levels in chicken, which increased fourfold within 24 hours post treatment.[2] More recent investigations have shown that SAA has the greatest and most rapid increase in chicken with systemic inflammation of several etiologies, including to natural red mite infestation.[31] The ELISA assay for chicken AGP and SAA can be obtained from Life Diagnostics Inc (Westchester, USA). Validation according to the ASVCP guidelines is recommended (see Chapter 139).

Neoplasia

Leukemia in gallinaceous birds is often induced by viruses and referred to as leukosis. Common viral causes include ALV and Marek's disease virus. CBC findings vary dramatically depending on the virus, disease stage, species, patient age, etc. Additional diagnostic tests are typically needed to confirm which virus caused the neoplastic transformation. Although case reports of natural, spontaneous leukemia (nonviral induced) are lacking in gallinaceous birds, arguably they could occur.

The leukosis/sarcoma group encompasses a variety of retroviruses that induce neoplasms in chicken.[42] ALV is the most common virus in this group and can cause significant losses in poultry flocks. The most common neoplasm observed is lymphoid leukosis, followed by myeloid and erythroid leukosis. There are six subgroups based on differences in viral envelope glycoproteins (A, B, C, D, E, and J). Lymphoid leukosis is a neoplasm of B-cell (bursa) lymphocytes, which can be small or large lymphocytes (Figure 123.2i). These neoplasms typically do not occur before 14 weeks of age, which can help differentiate an ALV etiology from Marek's disease. Mortality usually occurs closer to 24–40 weeks of age in commercial operations.[42] However, ALV and related leukosis can also been seen in older animals (2–5 years of age) in backyard flocks (K. Harr, personal communication). Rubriblasts are commonly observed in circulation with erythroid leukosis (erythroblastosis).[42] However, it can be difficult to differentiate rubriblasts, lymphoblasts, and myeloblasts on standard blood smears alone. Severe anemia and thrombocytosis can also be observed with erythroid leukosis.[42] Myeloblastic myeloid leukosis (myeloblastosis) and myelocytic myeloid leukosis (myelocytomatosis) are induced by ALV subgroup J. Immature myeloblasts are the predominant cell type in circulation with myeloblastic myeloid leukosis. These large cells contain a small amount of basophilic cytoplasm that lacks cytoplasmic granules, immature chromatin, and variably prominent nucleoli. Promyelocytes, myelocytes, metamyelocytes, and mature heterophils will be present, but likely in smaller proportions. Anemia and thrombocytopenia are often present.[42] In myelocytic myeloid leukosis, granulated myelocytes predominate; however, cellular atypia and immature cells are also observed (Figure 123.2j,k).[28,42]

Marek's disease is caused by an alphaherpesvirus and is common worldwide in chicken. However, natural infections have been documented in quail and turkeys as well.[42] Marek's disease induces lymphoproliferative neoplasms. Lymphoma is far more common (e.g., lymphoid tumors in nervous system, spleen, liver, eyes, or skin); however, large T-cell leukemia may also be seen (Figure 123.2l).[42] Unlike lymphoid leukosis, Marek's disease may occur as early as 4 weeks and the mortality peaks in chicks from 10–20 weeks of age.[42] Anemia may also be observed with Marek's disease, whether leukemic cells are present or not. Marek's disease may be differentiated from leukosis due to a characteristic leg paresis, atherosclerosis, and persistent neurologic disease.

Coagulopathy

There is a paucity of literature on clinical coagulation disorders, thrombocytopenia, and thrombocytosis in gallinaceous birds. Many of the original avian coagulation studies used chicken and were reviewed in the "Avian Hematology" chapter in the 6th edition. Thrombocytosis is thought to occur secondary to inflammatory disorders (*Mycobacterium* infections, etc.) or neoplastic disorders (erythroid leukosis, etc.).[27,42] In gallinaceous birds, thrombocytopenia may be seen with increased thrombocyte destruction or consumption (sepsis, etc.) or with bone marrow disease (myeloid leukosis, chicken anemia virus, cyclophosphamide administration, etc.)[17,42] (see Chapter 95).

Hemoparasites

In general, hemoparasites are uncommon in well-maintained commercial flocks of gallinaceous birds. However, hemoparasites may be observed in backyard flocks, wild animals, and companion animals. The protozoan parasites commonly seen in avian blood smears include *Plasmodium*, *Hemoproteus*, and *Leukocytozoon sp*. These agents share a similar life cycle, with sporogony (asexual spore formation) in the midguts of *Simulium*

flies or *Culicoides* midges. In infected birds, merogony/schizogony (asexual reproduction) occurs in the tissue and sexual differentiation occurs in peripheral blood.[69] *Hemoproteus* and *Leukocytozoon* organisms can be observed in RBCs from apparently healthy wild and companion gallinaceous birds. Infection with multiple agents is common in wild birds.

Hemoproteus gametocytes are occasionally observed in RBCs of gallinaceous birds (Figure 123.2m). Gametocytes are basophilic, oval to elongated, with occasional yellow-brown iron pigment. Large organisms will mold around the RBC nucleus without displacing it. Most commonly, the presence of *Hemoproteus* gametocytes is considered an incidental finding; however, increased numbers may be observed with concurrent systemic illness. In one study of wild grouse and ptarmigan in Alaska, prevalence of *Hemoproteus sp*. detected by PCR was 21%.[59] In another study of wild sage-grouse from Colorado, *Hemoproteus sp*. were detected by blood smear examination in 9% of birds.[60]

Leukocytozoon sp. infestations also occur in gallinaceous birds. Leukocytozoon gametocytes dramatically alter the appearance of the nucleated cells they infect, replacing normal cytoplasm and displacing the nucleus peripherally (Figure 123.2m,n). A recent study in chicken used cell-type-specific antibodies to identify thrombocytes as the primary cell infected by *Leukocytozoon sabrazesi*.[69] Prevalence of *Leukocytozoon* in wild sage-grouse, as determined by blood smear examination, varies from approximately 10% to 45%, with some variation between state and breeding season.[14,60] In one study of wild grouse and ptarmigan in Alaska, prevalence of *Leukocytozoon* detected by PCR was 53%.[60] The true prevalence of *Leukocytozoon* likely varies between species, locations, and environments. Leukocytozoonosis can cause economic loss, especially with concurrent illness.[14,69] In chicken, *L. caulleryi* has been reported to have tropism for the reproductive tract, causing inflammation, edema, and decreased egg production.[14] In sage-grouse, *L. lovati* may cause decreased productivity even though only low numbers of organisms were detected.[14] *L. lovati* in wild grouse appears to be more prevalent during the brood-rearing season (July–August) than in the breeding season (March–May).[14]

Plasmodium sp. can be clinically insignificant or cause mortality. In one study of wild grouse in Alaska, prevalence of *Plasmodium sp*. detected by PCR was 17%.[59] Prevalence of *Plasmodium sp*. is <1% in wild sage-grouse from Nevada, Oregon, and Colorado, when determined by blood smear examination.[14,60] *Plasmodium pedioecetii* has been identified in several species of gallinaceous birds including sage-grouse, greater prairie chicken, and gray partridge.[14,61] *P. pedioecetii* is also seen in Attwater's prairie chicken in Texas (Figure 123.2o,p). *P. pedioecetii* appears to be incidental with no overt clinical signs in the gallinaceous birds studied. *Plasmodium* and *Hemoproteus* gametocytes can be difficult to differentiate (see Chapter 126).

Other hemoparasites that may be observed in gallinaceous birds include *Trypanosoma sp*., microfilaria, *Isospora sp*., *Hepatozoon sp*., *Aegyptianella sp*., and spirochetes (*Borrelia anserina*). These organisms have similar appearances in other animals (see Chapter 125).

ACKNOWLEDGMENTS

The authors wish to acknowledge Sarah Eide, Joseph C. Essler, and poultry pathologists Drs. Gabriel Senties-Cue, Martin D Ficken, and Erin Edwards, at the Texas A&M Veterinary Medical Diagnostic Laboratory (TVMDL), for their contributions to this chapter. The authors also acknowledge Dr. Patricia S. Wakenell for her previous contributions to this section and Dr. David Eckersall for his contribution on acute phase proteins.

Acronyms and Abbreviations

K-EDTA, potassium-ethylenediaminetetraacetic acid; G:E ratio, granulocytic to erythroid ratio.

The order Psittaciformes includes four families: the Psittacidae (African and New World parrots and parakeets), the Cacatuidae (cockatoos), the Strigopidae (New Zealand parrots), and the Psittaculidae (other Old World parrots and parakeets). Most psittacine birds are colorful birds that have a strong beak for cracking nuts, seeds, and woody foodstuffs and are commonly kept as pets.

BLOOD COLLECTION AND PREANALYTICAL FACTORS

Most parrots are prone to stress during manual restraint and large parrots may be difficult to safely restrain for blood sampling. In general, blood collection should be done as early as possible, even before a complete physical examination is performed. This limits stress-induced changes on the hemogram and biochemical profile. General anesthesia induces various hematologic changes and intramuscular injection of sedatives may lead to acute local inflammation and biochemical changes lasting several days. Therefore, reversible intranasal sedation is a safe and reliable alternative to either manual restraint or general anesthesia prior to venipuncture. An intranasal combination of midazolam and butorphanol induces safe and reliable conscious sedation in healthy parrots.[14,35]

Blood is typically collected from the right jugular vein in most Psittaciformes regardless of their size. This site is the easiest to sample from while the bird is manually restrained. A large apterium (featherless tract) is present in all parrots and this avian order, being tropical, generally has a large jugular apterium with less adjacent down feathers than birds from temperate ecozones. The skin is particularly thin and the vein is readily visible. Obesity is common in pet birds, especially in Amazon parrots (*Amazona sp*.), and may result in subcutaneous fat deposition around the neck that may complicate venipuncture. Alternatively, the left jugular vein may be used, but is smaller than the right and sometimes too small to sample. The ulnar vein is prone to hematoma formation and is only recommended for venipuncture in anesthetized parrots. Additionally, it is more challenging to restrain parrots for venipuncture at this site than other birds, such as raptors. The medial metatarsal vein is generally too small in most parrots to obtain a large enough volume except in larger parrots such as macaws. A volume of 1% of body weight can safely be collected in most psittacine birds.

A 25–22-gauge needle, depending on the animal size, is typically used with a 1–3 mL syringe. Preheparinization of the needle and syringes is not recommended, as it will result in overheparinization of the sample, cytologic artifacts, dilution artifacts, and is unnecessary when proper techniques are employed. However, blood sampling is

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

dependent upon the venipuncturist's experience level and needle heparinization will usually result in adequate, though not optimal, samples. The needle should be removed from the syringe prior to transferring the blood to the collection tube to limit hemolysis. Hemolysis is rarely encountered during blood collection performed by the authors. As avian blood clots quickly, it needs to be transferred as soon as possible into the collection tube. If a hematoma develops during collection, the blood will clot faster in the syringe. Toenail clipping is not recommended, as it leads to bacterial contamination and samples of suboptimal quality.

There are several preanalytical factors that may affect hematologic results. Basic factors associated with psittacine biologic variability such as season, age, sex, comorbid chronic stable diseases (such as feather-damaging behavior, common in Psittaciformes), and stress (induced by transport, restraint, degree of socialization) need to be considered when interpreting the hemogram. Proper collection techniques and anticoagulant choice are also important. K-EDTA is the anticoagulant of choice in most psittacine birds and has not been shown to lead to hemolysis within 12 hours of sampling in any psittacine species unlike in some other avian orders (notably some Passeriformes, Gruiformes, and Struthioniformes). It is superior to heparin for hematologic analysis as it inhibits thrombocyte and WBC aggregation, has slightly better preservation of cellular elements in stored samples, and superior cytologic staining. In a study on anticoagulants in macaws (*Ara sp.*), K-EDTA and heparin resulted in similar hemograms with significant cell lysis at 24 hours in both anticoagulants, rendering blood smear assessment more challenging. Citrate resulted in profound hematologic changes (dilution effect and hemolysis) and is not recommended for hematology in psittacine birds. However, the main drawback of this study was the collection method with all syringes being preheparinized, thereby confounding the results comparing the anticoagulants.[25] In another study in Hispaniolan Amazon parrots (*Amazona ventralis*), PCV was significantly lower and lymphocyte concentrations were significantly higher (although still within expected reference intervals) in lithium heparin samples compared with K-EDTA, although there was similar preservation of cell morphology and staining for both heparinized and K-EDTA samples.[21] Therefore, in small psittacine birds, it is still acceptable to use heparin when performing both hematology and biochemistry from the same collection tube to maximize small sample volume. Insufficient or delayed mixing in blood collection tubes with anticoagulant may cause small clots, which will affect blood cell counts. Prolonged storage of psittacine whole blood is also not recommended, as significant hemolysis and WBC lysis were seen after 12 hours in macaws.[25]

LABORATORY EVALUATION

All WBC counting techniques in birds are manual, which results in increased analytic variability, decreased accuracy, and a decreased ability to transfer reference intervals established within one laboratory to another. Because RBCs greatly outnumber WBCs and thrombocytes, general automated techniques can be used for RBC counts.

Psittacine blood cells tend to be more fragile compared to other avian species such as raptors and poultry. Consequently, blood smears may have more artifacts, especially in the small psittacines, possibly due to substandard preanalytical techniques. Experience may be the largest factor in producing quality blood smears. Specifically, the wedge technique (push preparation) may result in excessive cell lysis in psittacine birds. Other techniques to minimize cell lysis, such as the pull preparation and cover slip techniques, can be used to improve blood smear quality.

Blood cell counting is performed either through hemocytometer-based techniques or by performing an estimate from a blood smear. While estimation from the smear is the least precise and accurate technique, it is relatively quick and easy. Thus, it is still widely performed by practitioners in-house and by commercial laboratories. Hemocytometer counts are performed using a stain such as phloxine B, eosin, Natt–Herrick solution, or Rees–Ecker solution. It is noteworthy that some Psittaciformes, such as cockatoos, have deeply basophilic granules in their eosinophils using Wright's stain, which may not stain positively with eosin or phloxine B. The agreement between different counting methods is generally poor in birds, which has been demonstrated in various avian species including macaws. In particular, a significant disparity has been reported between hemocytometer total cell counts and WBC estimates of blood smears in cases of marked leukocytosis. While hemocytometer cell counts are typically considered more accurate than blood smear estimates, phloxine-B staining protocols may be less accurate when there are increased numbers of monocytes and/or lymphocytes, and in cases where heterophil degranulation and eosinophilia may interfere with phloxine stain uptake.[45]

Early attempts at automation of total WBC and differential cell counts used techniques such as high-throughput digital image cytometry in parrots and antibody-independent flow cytometry protocols in Galliformes[2] (see Chapter 123). None of these techniques are currently available for diagnostic use in psittacines. While flow cytometry has been used successfully in chicken for differential cell counts, it is unlikely that the technique will be efficacious in Psittaciformes because of the large number of species seen in practice in which most antibodies may not cross-react.

ERYTHROCYTE MORPHOLOGY

Psittacine RBCs are large elliptical cells that have abundant orange-red cytoplasm and condensed ovoid nuclei with dense homogenous chromatin when stained with Romanowsky-type stains. Mild anisocytosis and slight poikilocytosis are found in blood smears from healthy birds. Additionally, mild variations in nuclear morphology can be normal; e.g., symmetrically centrally constricted nucleus, nuclear microlobulation, and, less

commonly, binucleation (Figure 124.3d). The presence of these nuclear abnormalities does not correlate with PCV.[7]

As in other avian species, psittacine RBCs compared to mammalian RBCs have a shorter circulating half-life, ranging from 25–45 days in different species, thus have a higher percentage of circulating polychromatophilic RBCs in health.[38] Polychromatophilic RBCs are large elliptical cells and contain a large volume of purple-red cytoplasm compared to the orange-red of mature RBCs. Nuclear morphology is like that of mature RBCs, although the chromatin may be less densely clumped (Figure 124.3c). The use of supravital stains (e.g., new methylene blue) to identify visible reticulum has demonstrated that a high percentage (>90%) of erythrocytes contain some amount of visible reticulum; thus, only cells with a complete ring of reticulum that encircles the nucleus (i.e., ring form) should be classified as reticulocytes in avian species. The recommended staining protocol for avian reticulocyte assessment is a dilution of 1:3 parts blood to new methylene blue, with an incubation time of 10 minutes. The same procedure may be used to identify Heinz bodies and denatured organelles caused by oxidative damage.[24] This mixture can be stored refrigerated for up to 24 hours.[28] Supravital stains require incubation with whole blood, and secondary staining of already prepared blood smears is of low quality and often nondiagnostic. The number of polychromatophilic RBCs observed on a Romanowsky-stained blood smear typically corresponds with the number of ring-form reticulocytes on a new methylene-blue-stained preparation. Variations in staining techniques and counting protocols for avian reticulocytes have resulted in a high degree of variation in published reticulocyte percentages in birds with reports ranging 0.4–6.8% in healthy psittacine species.[38] Additionally, absolute reticulocyte concentrations are superior to reticulocyte percentages, which can be influenced by the PCV. Reference intervals generated using 44 healthy psittacine birds of varying species for absolute polychromatophil count were 5,670–227,640 cells/μL (mean: 131,204 cells/μL).[28] More immature erythroid cells (e.g., early and late polychromatophilic rubricytes) may be seen in low numbers in healthy birds and in increased numbers as part of a regenerative response in anemic birds. Early and late polychromatophilic rubricytes are ovoid to round with a smaller volume of blue-gray to pale purple cytoplasm. These cells can be distinguished from mature and polychromatophilic RBCs by their small round nuclei and more open chromatin pattern. Rubricytes may also be counted, in lieu of reticulocyte counts, to assess regeneration on a Romanowsky preparation (Figure 124.3c,d).

Blood group antigens have not been described in psittacine species, although studies in poultry have identified as many as 28 different blood group antigens.[27] Preformed antigens to blood groups have not been described in birds, and homologous major crossmatches in a small group (n = 15) of untransfused cockatiels (*Nymphicus hollandicus*) were all compatible, as were heterologous crossmatches with blue-fronted Amazon parrots (*Amazona aestiva*).[13] That being said, care must be used when considering blood transfusions between different avian species (i.e., heterologous transfusions), which may result in agglutination and/or hemolysis.[13,27] There are no published reports of transfusion reactions in psittacines, although the clinical features of transfusion reactions in birds have not been well-defined. The half-life of homologous transfused RBCs was much longer (11–17 days) compared with the heterologous transfused RBC (0–3 days) using fluorescent-labeled RBCs. Additionally, nearly all the donor–recipient pairs in the heterologous groups of cockatiels became crossmatch-incompatible after one transfusion.[13] Based on these findings, homologous transfusions are recommended, although single heterologous transfusions may be clinically tolerated in psittacines.[27] Heterologous transfusions are not recommended, as the circulating half-life of the transfused RBC is relatively short and the metabolic effects resulting from clearance of transfused RBC in already debilitated birds can have a negative clinical impact. Only fresh whole blood transfusions are available for psittacines, as high potassium concentrations develop in avian blood products maintained with currently available storage media.[38] Cryopreservation techniques for avian packed RBCs have shown some promise in in vitro pilot studies. However, some protocols result in poor post thaw RBC viability and in vivo studies are lacking, limiting the practical use of these techniques currently.[18] Avian erythropoietin is structurally unique compared to mammalian erythropoietin, and there is no in vivo cross-reactivity when mam-malian erythropoietin is administered to birds[38] (see Chapter 103).

LEUKOCYTE MORPHOLOGY

As in other avian species, psittacine WBCs consist of granulocytes (i.e., heterophils, eosinophils, and basophils) and mononuclear cells (i.e., lymphocytes, monocytes) (Figure 124.1). Heterophils are the most numerous WBC in most parrots (said to be heterophilic predominant), and are largely analogous to mammalian neutrophils. Heterophils have abundant clear cytoplasm filled with numerous secondary granules which are typically rod-shaped to round and a dull reddish-orange, sometimes with a faint refractile quality, when stained with Romanowsky-type stains. Nuclei are segmented to lobulated with dense, condensed dark chromatin and inapparent nucleoli. Assessment of nuclear morphology in mature avian granulocytes can be challenging with the high degree of cytoplasmic granulation. Additionally, some species may have relatively hyposegmented nuclei in health, which can also make determination of a left shift challenging. Evidence of toxic change can help provide support for a suspected left shift. Increased cytoplasmic basophilia and vacuolation should be present, but may be difficult to appreciate in mild cases of toxic change due to cytoplasmic granulation. Other toxic changes reported in avian heterophils include the presence of primary granules (round, metachromatic to magenta cytoplasmic granules), degranulation, and/or consolidation of heterophil granules, although care must

be taken to avoid misinterpreting smear artifact[38] (Figure 124.4a,b). Although functionally like mammalian neutrophils, avian heterophils have decreased activity of some enzymes including myeloperoxidase, alkaline phosphatase, and catalase.[15] It has been suggested that the differences in antimicrobial enzyme composition between avian heterophils and mammalian neutrophils account for the development of caseous rather than liquid necrosis in response to heterophilic inflammation in avian tissues.[38]

Lymphocytes are often the second most numerous of all leukocytes, following heterophils, in most psittacine species. Some psittacine species are lymphocytic predominant, with lymphocytes being the most common WBC type; e.g., some Amazon parrots (*Amazona sp.*), some Pionus parrots (*Pionus sp.*), and Quaker parrots (*Myiopsitta monachus*). Avian lymphocytes are morphologically comparable to those described in mammals. Small mature lymphocytes should predominate with scant pale blue cytoplasm, clumped chromatin, and inapparent nucleoli. Granular lymphocytes with azurophilic cytoplasmic granules may be present in varying, typically low, numbers. Reactive lymphocytes with increased amounts of deeply basophilic

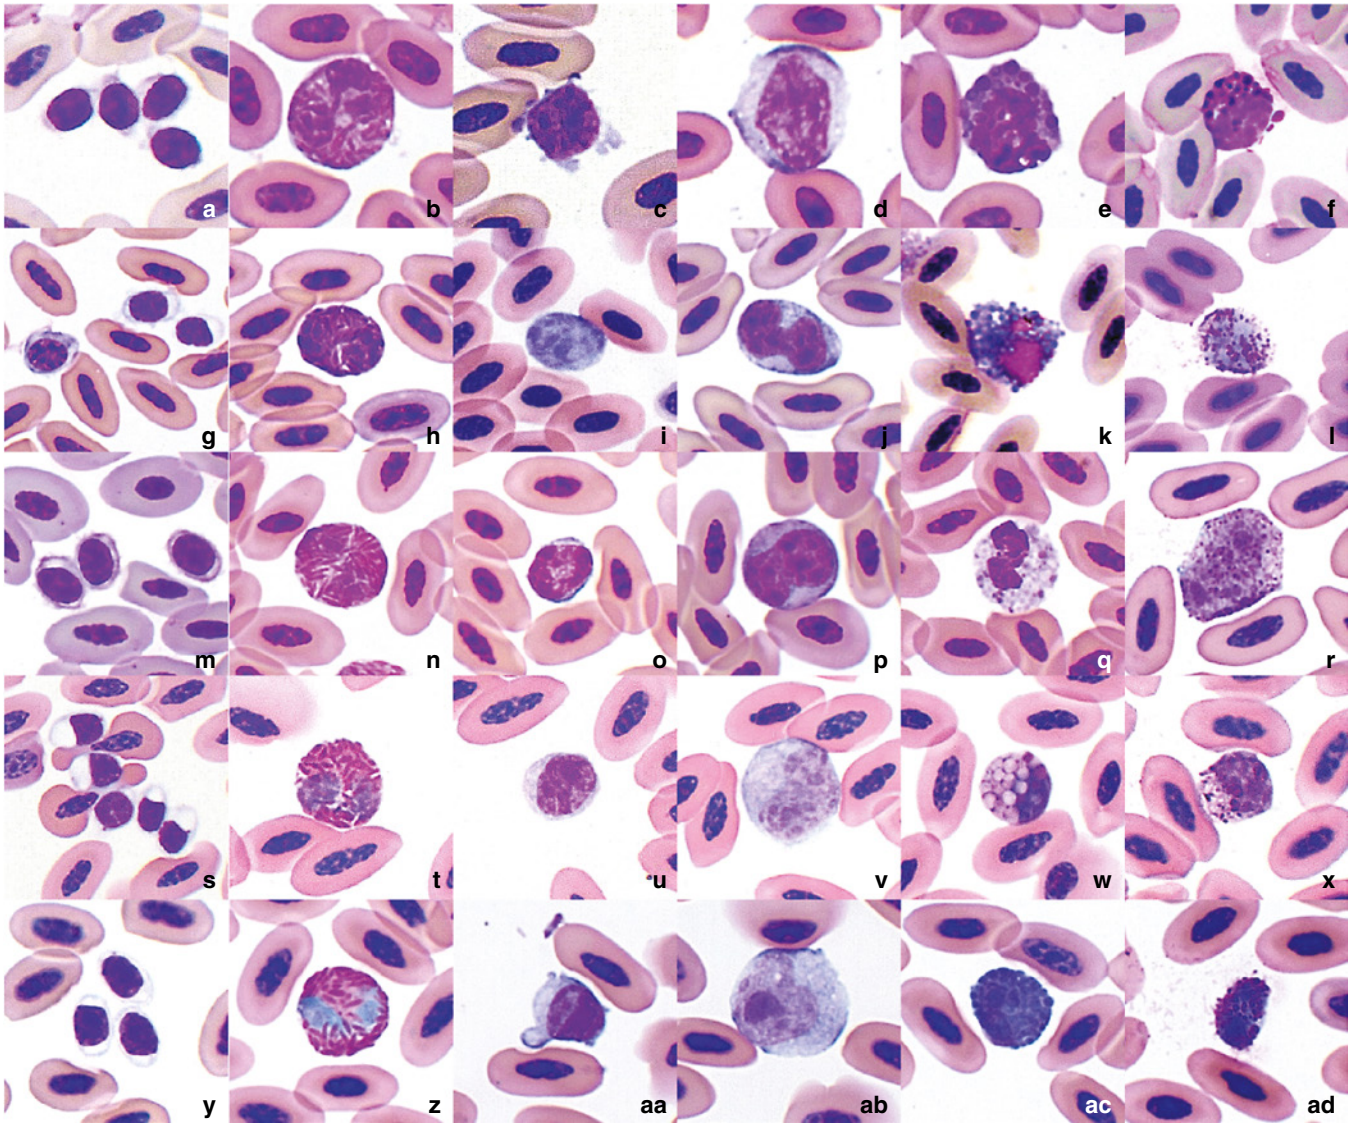

FIGURE 124.1 Comparative WBCs, RBCs, and thrombocyte morphology of selected psittacines. 1000× using modified Wright's stain unless indicated. African grey parrot (*Psittacus erithacus*): (a) Thrombocyte; (b) Heterophil; (c) Lymphocyte with classic cytoplasmic blebbing; (d) Monocyte; (e) Eosinophil; (f) Basophil. Cockatiel (*Nymphicus hollandicus*) stained using Diff-Quik stain: (g) Thrombocyte and a polychromatophil; (h) Heterophil; (i) Large lymphocyte which can be periodically found in normal birds; note the scant tag of basophilic cytoplasm; (j) Monocyte which is larger than surrounding RBCs; (k) Blue eosinophil which raises questions regarding granule pH; (l) Basophil. Eclectus parrot (*Eclectus roratus*): (m) Three thrombocytes; (n) Heterophil; (o) Intermediate-sized lymphocyte; (p) Monocyte; (q) Eosinophil with gray and occasional pink and purple round granules; (r) Basophil. Macaw (*Ara sp.*): (s) Five thrombocytes with variable spreading on the glass slide; (t) Heterophil; (u) Intermediate-sized lymphocyte; (v) Monocyte; (w) Eosinophil; (x) Basophil. Amazon parrot (*Amazona sp.*): (y) Three thrombocytes; (z) Heterophil; (aa) Lymphocyte with cytoplasmic blebbing; (ab) Monocyte; (ac) Blue-gray eosinophil; (ad) Basophil. (**Source:** All photos contributed by Dr. Kendal Harr.)

cytoplasm may also be observed under circumstances of antigenic stimulation and must be distinguished from neoplastic lymphocytes based on other hematologic abnormalities, clinical history, and other diagnostic findings. Finally, avian monocytes are morphologically and functionally comparable to mammalian monocytes (Figure 124.1).

Eosinophils are much less numerous than heterophils and contain abundant pale blue cytoplasm with numerous round cytoplasmic granules. Eosinophil granule morphology varies in different psittacine species. Psittacine eosinophils may have gray to bright blue to pale purple granules, while others have the more typical reddish-orange-colored granules (Figure 124.1). Nuclei are segmented to lobulated, though less so than heterophil nuclei, with dense dark chromatin and inapparent nucleoli. Similar challenges assessing eosinophil nuclear morphology exist, as described for heterophils. The eosinophil granule content of different avian species has not been thoroughly explored with cytochemical stains and ultrastructure, and functionally the exact role of eosinophils is poorly understood. Avian eosinophils are less responsive to parasite antigens compared with mammalian eosinophils, and may be a more general component of inflammation in these species.[38]

Basophils may be smaller than heterophils and eosinophils with a large amount of clear to pale blue cytoplasm and many small, dark purple cytoplasmic granules. Basophil nuclei are like eosinophil nuclei, although may be even less-lobulated. Granules may dissolve or coalesce with the alcohol-based stains routinely used for hematology, such as Romanowsky-type stains. Alcohol-based stains can stain quite differently than aqueous-based stains (see Chapter 117). Some of the basophil granule constituents are similar to those in mammals (e.g., histamine), and, while the function of avian basophils is not known, it is thought to be similar to that of mammalian basophils.[38]

THROMBOCYTES AND HEMOSTASIS

Thrombocytes are analogous to mammalian platelets and morphology can vary from species to species. In general, thrombocytes are small, round to oval cells with clear to light blue cytoplasm, sometimes with a few pink cytoplasmic granules and clear vacuoles (glycogen) (Figure 124.1). When activated, as during collection, storage, and inflammation, they can undergo a shape change resulting in the development of elongated cytoplasmic processes or a more spindloid appearance. Nuclei are round to oval with dense smudged, homogenous chromatin and inapparent nucleoli. Distinguishing thrombocytes from lymphocytes can be challenging but, in general, lymphocytes have a larger more complex nucleus and darker blue cytoplasm compared to the condensed nucleus and clear cytoplasm of thrombocytes. It can be helpful to initially assess thrombocyte morphology near the feathered edge of a blood smear where thrombocyte clumps allow the viewer to easily identify thrombocytes and become familiar with their morphology.

Absolute thrombocyte counts in psittacines are rarely determined due to the tendency of thrombocytes to clump. A direct thrombocyte count can be performed using a hemocytometer and Natt–Herrick solution; however, visual assessment from a blood smear may be sufficient for diagnostic purposes. In general, 10–15 thrombocytes per 1000 RBCs are considered adequate. Quantitative thrombocyte estimation from a blood smear is prone to error due to uneven distribution and thrombocyte clumps in most smears.

Commercially available reagents for hemostasis assessment in humans and other mammals interact with avian coagulation factors, but do not bind with the same affinity; thus, self-made, avian-specific reagents are often required. This limits the availability and practicality of running coagulation assays in a commercial diagnostic laboratory. Additionally, the intrinsic coagulation pathway may be less significant in birds which lack factor XII, although activated clotting time can be activated with diatomaceous earth, resulting in shorter times to clot. The need for avian specific reagents and methods is supported by coagulation times exceeding the upper limit of the reaction time (500 seconds) observed for partial thromboplastin time in many species of birds, including macaws (*Ara sp.*) and African grey parrots (*Psittacus erithacus*), when plasma was analyzed using nonspecific commercially available reagents.[19] The optimum anticoagulant for coagulation analysis in birds has not been determined, as only trisodium citrate has been evaluated. As stated in the earlier text, trisodium citrate causes increased hemolysis in psittacine blood within hours of sampling (see Chapter 95).

Thromboelastography is a more holistic tool for coagulation assessment in mammals, as it incorporates coagulation factors and cellular elements, as well as assessment of fibrinolysis. This assay has been successfully modified for use in avian species, although normal tracings vary in different species.[32,44] As no current reports of thromboelastography performance in birds with coagulopathies exist, the diagnostic value of this assay in psittacines is still unknown.

BONE MARROW COLLECTION AND EVALUATION

Bone marrow collection in psittacines is like that in other avian species. Bone marrow can be collected from any nonpneumatized long bone. The most common site for collection of clinical bone marrow samples is the tibiotarsus proximate to the cnemial crest. Bone marrow samples should be collected into an anticoagulant to prevent clotting, and 1% EDTA has been demonstrated to be superior to heparin in the authors' experience. Preparation of bone marrow smears is also like those described for mammalian bone marrow aspirates, and techniques to minimize excessive hemodilution (e.g., petri dish technique) should be used to maximize the diagnostic yield of the sample. Routine Romanowsky stains are recommended for air-dried bone marrow aspirate smears (see Chapter 141).

Hematopoietic cells of granulocytic and erythroid lineages at all stages of development (Figure 124.2) can be identified in psittacine bone marrow aspirate smears, although cells of the thrombocyte lineage cannot be reliably identified by morphology alone. As in other species, the distribution of hematopoietic precursors favors many more mature than immature forms. Maturation stages in normal psittacine erythropoiesis are largely like those in mammals with the obvious distinction of nuclear retention in mature forms. The six recognized stages of erythroid development in birds are rubriblasts, prorubricytes, basophilic rubricytes, early polychromatophilic rubricytes, late polychromatophilic rubricytes, polychromatophilic RBCs, and mature avian RBCs (metarubricytes). Late-stage rubricytes can be distinguished from polychromatophilic RBCs by the nuclear shape, round in rubricytes and ovoid in RBCs. By convention, mature RBCs are not included in bone marrow cell differentials. Late-stage erythroid precursors (early and late polychromatophilic RBCs) are the predominant cell type observed in psittacine bone marrow aspirates.

Psittacine granulopoiesis is also largely like that observed in mammals with a gradual decrease in cell size and cytoplasmic basophilia as cells mature, and a gradual decrease in nuclear size with development of nuclear segmentation and lobulation in mature granulocytes. The stages of granulocytic development are also similar and include myeloblasts, progranulocytes, myelocytes, metamyelocytes, bands, and mature segmented granulocytes. Unique to avian progranulocytes are multiple different granule types, while mammalian progranulocytes contain only primary granules. Avian progranulocytes contain granules ranging in color from orange to basophilic to metachromatic, and in shape from spherical to ring forms.[5] It has been speculated that these different granule morphologies may represent a unique organelle or potentially different intermediary stages of granulocyte development.

Avian thrombocytes are derived from a line of mononuclear precursors in the bone marrow (see Chapter 123). The thrombocyte series includes early-, mid-, and late-immature thrombocytes. While thrombocyte precursor morphology has been described in psittacines,[5] a recent assessment of bone marrow morphology in Hispaniolan Amazon parrots (*A. ventralis*) revealed discordance in thrombocyte precursor classification between experts in avian hematology. It was concluded that morphologic assessment alone is insufficient to distinguish thrombocyte precursors from later-stage erythroid precursors. Regardless, in the previous studies where thrombocyte precursors were identified, they accounted for <3% of all nucleated cells, and thus omission of this cell lineage is unlikely to change clinical assessment of bone marrow aspirates, unless there is a peripheral thrombocytopenia.

Like other avian species, low numbers of lymphocytes (<2%), plasma cells (<1%), macrophages (<1%), and osteoclasts may be observed in bone marrow aspirates from psittacines. Iron has not been observed in Romanowsky stained bone marrow aspirates from psittacines. The mean G:E ratio derived from 17 clinically healthy, adult Hispaniolan Amazon parrots (*A. ventralis*) was 0.4 ± 0.2. It is possible that the unique histologic organization of avian bone marrow, with erythropoiesis occurring in the medullary sinus lumen and granulopoiesis within hematopoietic chords in the extravascular space, may predispose avian bone marrow samples to biased sampling of erythropoiesis over granulopoiesis (data submitted by authors).

REFERENCE INTERVALS

Partitioning Factors

Reports on the effect of various physiologic, analytic, and environmental factors on hematologic results in psittacines are highly variable largely due to the small numbers of individuals from which these observations were made, with resultant wide confidence intervals around reported reference limits. Additionally, WBC differentials in psittacines have been historically reported as percentages rather than absolute concentrations, which limits the ability to extrapolate this data without concurrent total WBC counts. Current guidelines put forth by the American Society for Veterinary Clinical Pathology require minimum numbers of individuals within partitioned reference intervals, which are largely absent from the current published data in psittacines. Furthermore, statistically significant differences between partitioned groups of individuals may not be clinically relevant.

Preanalytical sampling factors and analytical methodology can influence hematologic results in psittacines. PCV was lower in jugular samples collected from anesthetized Carnaby's cockatoos (*Calyptorhynchus latirostris*) compared to samples collected with manual restraint from the metatarsal vein.[34] Circulatory alterations associated with gas anesthesia are assumed to occur in psittacines. Additionally, many published reference interval studies in psittacines utilize different methodology to generate the hematologic data, and given the high degree of imprecision inherent to manual techniques used for avian CBCs, results obtained using different techniques should not be considered equivalent.

Partitioning factors are typically important biological variability factors, although partitioned reference intervals are not routinely used for diagnostic assessment of psittacines. With these caveats in mind, the following observations have been reported. In general, erythroid parameters tend to increase with age from the neonate stage, and this finding has been reported in both captive and wild psittacines.[1,6,23,31,47] The PCV is often lower in neonates and fledglings than in adults.[5,9,10] There are progressive increases in MCV and hemoglobin (Hgb) concentration in some species.[23,47] In general, WBC counts decrease with age, which is also reported in both wild and captive psittacines.[14,31,47] In some species (African grey parrots, Amazon parrots, and macaws),

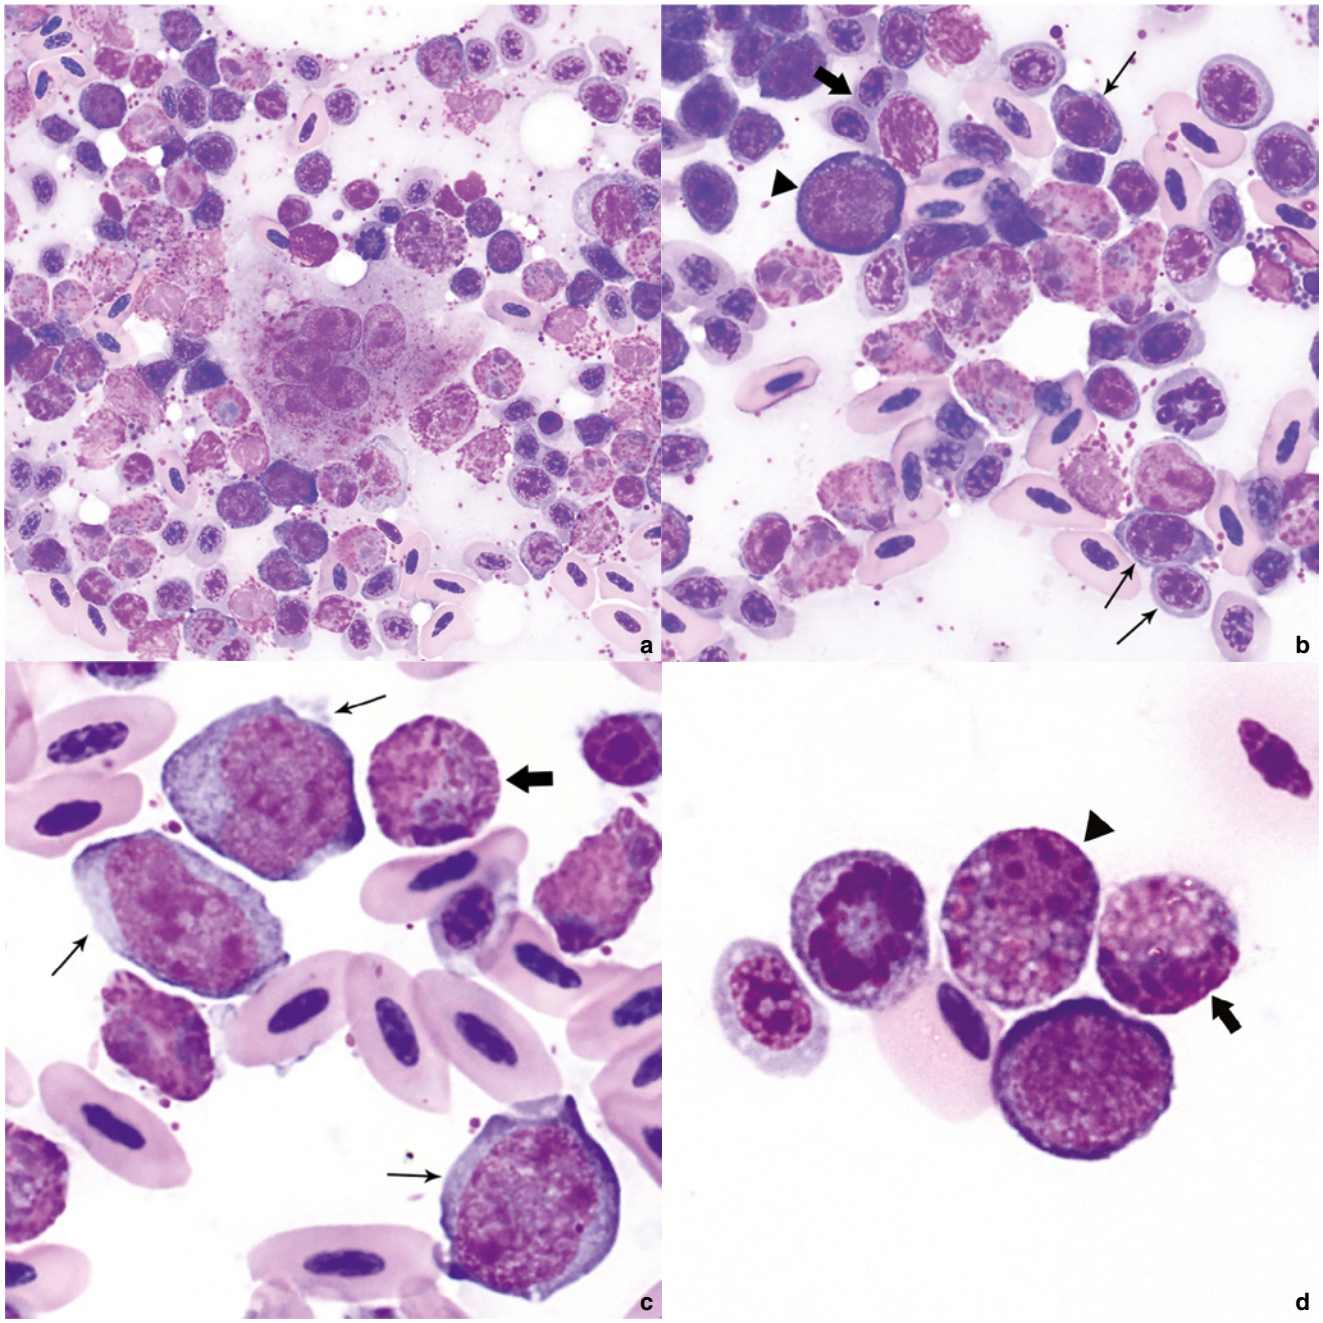

FIGURE 124.2 Erythroid and granulocytic precursor morphology in bone marrow from a Hispaniolan Amazon parrot (*Amazona ventralis*). (a) Large osteoclast surrounded by many proliferative- and maturative-stage granulocytic and erythroid precursors; (b) Representative stages of erythrocyte development including a rubriblast (arrow head), basophilic rubricytes (thin arrows), and early polychromatophilic rubricytes (thick arrow); (c) Representative stages of granulocytic development including myeloblasts (thin arrows) and a heterophil myelocyte (thick arrow); (d) Heterophil myelocyte (thick arrow) and a heterophil progranulocyte with round reddish-orange secondary granules and round magenta primary granules (arrow head) a mitotic figure, polychromatophil, and blastic precursor. 1000× Modified Wright–Giemsa stain.

WBC counts transition to expected adult values at 2–3 months of age.[5,9,10,14] There are inconsistent and often contradictory reports of WBC differential variation with age in psittacines. Lymphocyte concentrations were higher in a population of juvenile, captive Spix's macaws (*Cyanopsitta spixii*) compared to adults, although in other species (cockatoo, Eclectus parrot, macaw) lymphocytes are reported to increase with age and, in some species, may be the predominant leukocyte in adult individuals.[14]

Few reports regarding the effect of sex on hematologic values in psittacines exist, in part due to the challenges in distinguishing individuals of different sexes, as these species often lack significant sexual dimorphism. Higher

RBC, PCV, and Hgb concentrations have been reported in male budgerigars compared with females. In a population of fledging wild hyacinth macaws (*Anodorhynchus hyacinthinus*), females had higher total WBC and heterophil concentrations compared to males.[1] Higher WBC counts due to increased lymphocyte concentrations were observed in female orange-winged Amazon parrots (*Amazona amazonica*) compared with males.[48] Other variables such as stress should also be considered in these studies.

Environment can also influence hematologic data. PCV was higher in winter months relative to autumn in a population of captive Spix's macaws.[14] Species that form large flocks had lower total WBC counts compared to solitary species. Higher total WBC counts due to higher heterophil and eosinophil concentrations were observed in a population of wild blue-fronted Amazon parrots (*Amazona aestiva*) compared to captive individuals of the same species, although these findings were attributed to an epinephrine response as a result of capture and sampling. Lymphocyte and monocyte concentrations were higher in the captive blue-fronted Amazon parrots in this study.[12] Wild nestling burrowing parrots (*Cyanoliseus patagonus*) with higher body condition scores had higher WBC counts due to increased heterophil concentrations, compared to those with low body condition scores[36] (see Table 124.1).

HEMATOLOGIC DISEASE

The most common hematologic abnormality reported from a population of ill pet psittacines presenting to a tertiary referral center was leukocytosis, which was observed in 28% of individuals, followed by anemia, which was present in 26% of individuals. Noteworthy is that over 50% of sick psittacines in this study had no hematologic abnormalities.[4] That being said, a number of important and relevant hematologic abnormalities may be observed in ill psittacines.

Anemia

As in other species, anemia in psittacines should be assessed for evidence of regeneration, which can help in prioritizing potential underlying etiologies. Nonregenerative anemia is a nonspecific finding and can develop more quickly in birds compared to mammals due to the shorter circulating RBC life span in birds. Nonregenerative anemia has been most commonly reported in association with a wide range of chronic infectious diseases, such as chlamydiosis, aspergillosis, and mycobacteriosis. Other diseases associated with nonregenerative anemia in psittacines include egg yolk peritonitis, chronic air sacculitis, chronic liver or renal disease, hypothyroidism, hyperestrogenism, iron deficiency, starvation, self-mutilation, and neoplasia.[6] Mild nonregenerative anemia is frequently observed in African grey parrots (*P. erithacus*) with Psittaciform 1 bornavirus, the putative causative agent of proventricular dilation disease.[26] Severe nonregenerative anemia was reported in an adult hyacinth macaw (*A. hyacinthinus*) secondary to a nutritional vitamin-B12 deficiency. Occasional folded dacryocyte-like RBCs were observed and the anemia gradually resolved with vitamin-B12 supplementation and transition to a balanced commercial pelleted diet.[20] Severe nonregenerative anemia, as a component of pancytopenia, is commonly seen in juvenile old world parrots infected by psittacine circovirus. Hypochromasia and/or microcytosis has been reported in poultry secondary to iron

TABLE 124.1 Reference intervals for psittacine birds, in accordance with ASVCP guidelines for sample size and statistical analysis.

Species	Captive orange-winged Amazon parrot ($n = 29$)[48]	African grey parrot	Amazon parrot	Budgerigar	Cockatiel	Cockatoo	Conure	Macaw
RBC ($\times 10^{12}$/L)	2.4–3.7	3.0–4.0	2.0–4.5	–	2.5–5.0	–	–	2.2–3.9
PCV (L/L)	0.42–0.60	0.40–0.53	0.39–0.54	0.40–0.57	0.40–0.60	0.38–0.52	0.40–0.55	0.38–0.54
Hgb (g/L)	–	142–186	130–160	–	–	–	125–190	129–193
MCV (fL)	138–193	–	–	–	–	–	–	–
WBC ($\times 10^9$/L)	0.7–16.4	3–15	5–15	2.5–8	3.5–11	4–14	3.5–11	5–20
Heterophils ($\times 10^9$/L)	0.7–7.2	1–12	1.5–11	0.9–5	1–9	1.5–10	1–6	1.1–15.0
Lymphocytes ($\times 10^9$/L)	0–10.8	0.6–7	1–10	0.9–4.5	0.4–4	1–7	1–5.5	0.7–8.7
Monocytes ($\times 10^9$/L)	0.1–0.9	0–0.8	0–0.6	0–0.6	0–0.9	0–0.7	0–0.7	0–0.8
Eosinophils ($\times 10^9$/L)	–	0–0.2	0–0.3	0–0.1	0–0.2	0–0.2	0–1.0	0–0.1
Basophils ($\times 10^9$/L)	–	0–0.5	0–0.4	0–0.4	0–0.6	0–0.3	0–0.4	0–0.4

All values except those from the orange-winged Amazon parrot were generated from >500 adult, mixed-sex birds, retrospectively deemed healthy based on clinical history. WBC counts determined via hemocytometer or direct smear estimate, 200 cell WBC differential cell counts. Hgb by cyanmethemoglobin without centrifuging to remove erythrocyte nuclei.

deficiency and presumably could develop in psittacines to do chronic external blood loss, although primary reports are lacking (see Chapter 123).

Other morphologic abnormalities in the erythroid line in psittacines are occasionally striking. An alkylating chemotherapeutic agent (Mitomycin-C) was shown to experimentally induce RBC nuclear abnormalities in conures (*Aratinga canicularis*), resulting in a dose-dependent increase in RBC numbers with micronuclei and/or nuclear budding. A time-dependent increase in numbers of polychromatophilic RBCs was also noted.[17] Therefore, prominent or progressive erythrocyte nuclear atypia should warrant further investigation for potential drug or toxin exposure in psittacines. Marked erythroid dysplasia resulting from apparent loss of nuclear anchoring and orientation has been observed by the editor in lovebirds (*Agapornis sp.*) and cockatiels (*N. hollandicus*), though other bird species may be affected (Figure 124.3).

Hemorrhage is the most common cause of regenerative anemia in psittacines and is most often the result of trauma, ulcerative internal lesions such as gastrointestinal ulcers, or bleeding neoplasms. Less commonly, blood-sucking parasites or coagulopathies (secondary to toxins, bacterial or viral infections, neoplasia, inherited factor deficiencies, or severe hepatic disease) may result in hemorrhage and a regenerative anemia.[6] Conure bleeding syndrome is an uncommon and poorly characterized disease typified by variably acute to chronic recurrent episodes of hemorrhage from the upper respiratory tract, gastrointestinal tract, and body cavities of several species of conures and other small psittacines. The clinically appreciable external hemorrhage induces a marked regenerative response (see Chapter 95).

Presumed immune-mediated hemolytic anemia has been reported infrequently in captive psittacines.[29,30] Anemia in these cases was moderate to severe (PCV of 28% and 17%, respectively) with variable changes in RBC morphology including moderate numbers of anucleated RBCs (erythroplastids) and marked macroscopic agglutination, as well as a subtle rounding to erythrocyte

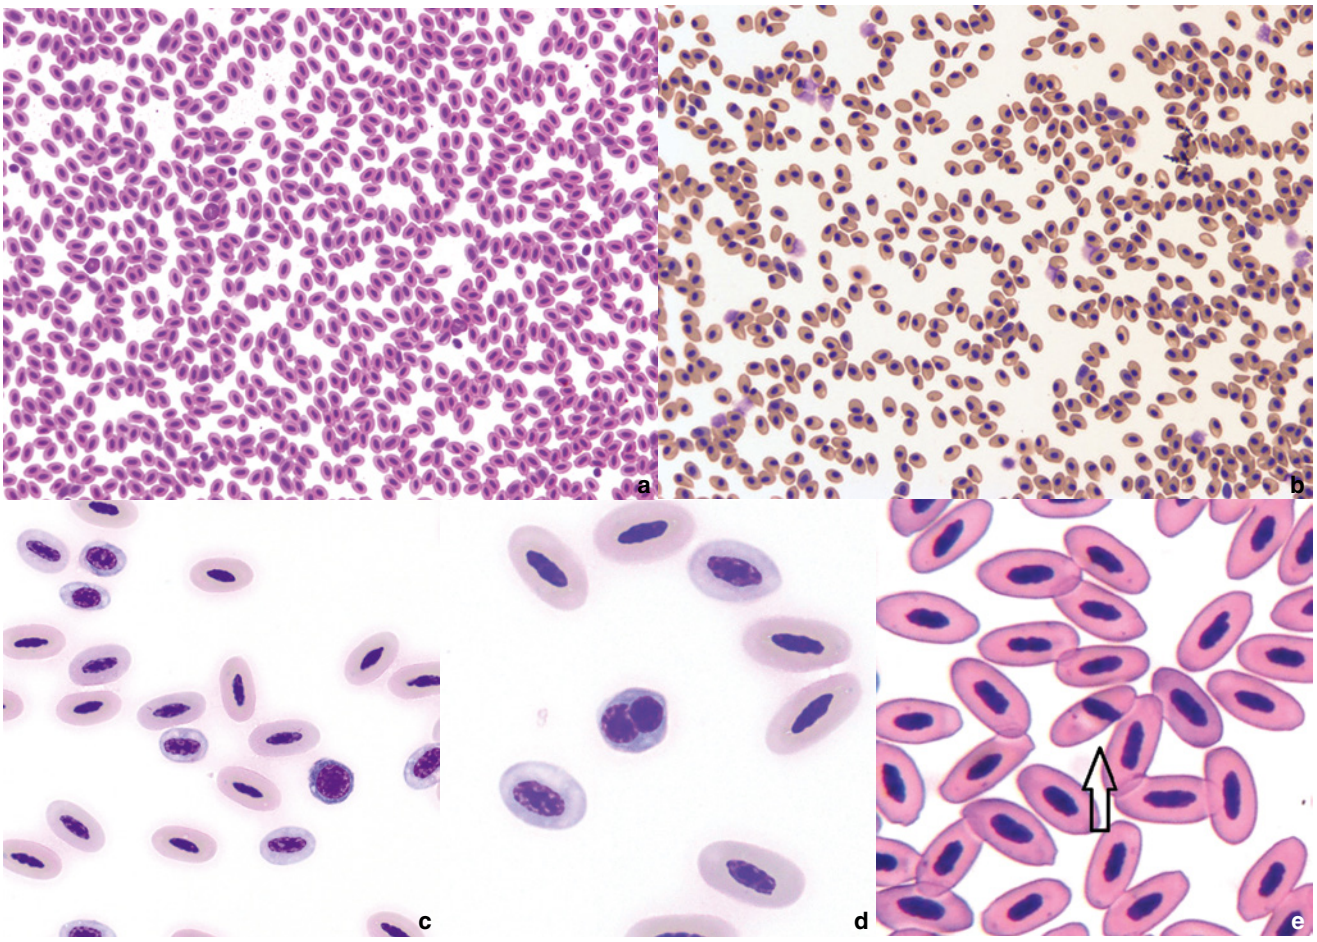

FIGURE 124.3 Erythroid morphologies found in psittacines. (a) A normal blood smear from a lovebird (*Agapornis sp.*) for comparison, 10× objective; (b) Erythroid dysplasia with loss of nuclear anchoring and orientation in a blood smear from a flockmate of the normal bird pictured in (a), 10× objective; (c) Regenerative anemia with increased numbers of polychromatophilic RBCs, late polychromatophilic rubricytes, and one basophilic rubricyte in an Amazon parrot (*Amazona sp.*); (d) Binucleated early polychromatophilic rubricyte in an Amazon parrot. 1000× (e) High magnification view of an RBC nucleus that has inappropriate orientation and is almost perpendicular to the cell (open arrow). (**Source:** Photos courtesy of Dr. Kendal Harr. Modified Wright–Giemsa stain unless otherwise specified.)

cell margins, suggestive of spherocytes.[29,30] Leukocyte findings were inconsistent. Both birds had normal total WBC counts on presentation; although one developed a mild heterophilia,[29] while the other had a heteropenia with a marked left shift.[30] Additionally, bone marrow findings in these birds ranged from unremarkable to erythroid hyperplasia with left shift. Anemia improved in one of the birds following corticosteroid administration, but this individual ultimately relapsed and died of suspected aspiration pneumonia.[30] Intravascular hemolysis with hemoglobinuria has been reported secondary to lead toxicity in Amazon parrots (*Amazona sp*.) and African grey parrots (*P. erithacus*).[41]

As in other species, absolute erythrocytosis due to increased circulating RBC mass must be distinguished from relative erythrocytosis due to hemoconcentration. This can typically be accomplished via physical examination and evaluation of biochemical values that support hemoconcentration, such as increased total protein concentration. Primary absolute erythrocytosis due to polycythemia vera, an idiopathic myeloproliferative disease, has not been reported in psittacines at this time. Secondary erythrocytosis in these species is most often attributed to chronic respiratory disease, especially aspergillosis, pulmonary neoplasia (primary or metastatic), and cardiovascular disease. Erythroid regeneration may be seen in the face of normal to increased PCV in birds with respiratory disease. PCVs ranging from 55–74% have been reported in older Amazon parrots (*Amazona sp*.) with idiopathic chronic pulmonary interstitial fibrosis. Affected individuals also had higher MCV and mean cell hemoglobin concentration compared with unaffected control birds.[49] Chronic obstructive pulmonary disease, also called macaw asthma, is associated with a marked erythrocytosis and has been reported in macaws (*Ara sp*.) housed in poorly ventilated aviaries and exposed to feather dust from cockatoos and African grey parrots.[46] Inappropriate secondary erythrocytosis due to erythropoietin-producing neoplasms has not been reported in psittacines.

Leukocyte Changes in Disease

Physiologic leukocytosis must be distinguished from pathologic leukocytosis in psittacines as in other species, and hematologic manifestations of epinephrine and corticosterone release associated with transport, physical restraint, blood sampling, and secondary to excess endogenous or exogenous corticosteroids are largely similar to those describe in other avian and mammalian species.[37,38,43]

Inflammation is the most common cause of leukocytosis in psittacines. Inflammatory leukocytosis in psittacines is typified by heterophilia, which may also be accompanied by a left shift and toxic change. The magnitude of the heterophilia can vary, typically in the range of 20–50,000 cells/μL,[29,30,41] but may be pronounced, especially in association with systemic mycobacteriosis, which can incite total WBC counts exceeding 100,000 cells/μL.[3,11,16,40,45] Monocytosis, lymphopenia, and reactive lymphocytes may also be observed in association with inflammatory disease in these species.[9,11,40,45] Granulocytic hyperplasia and left shift (increased numbers of myeloblasts and progranulocytes) were reported at necropsy in the bone marrow of a mature female lesser sulfur-crested cockatoo (*Cacatua sulphurea*) with an acute severe heterophilia and left shift with marked toxic change secondary to esophageal perforation from gavage feeding.[3] Infectious agents that have been reported to result in inflammatory leukograms in psittacines include bacterial (avian chlamydiosis,[40] avian mycobacteriosis, salmonellosis,[45] avian coxiellosis, sepsis), fungal (aspergillosis),[45] and protozoal (*Toxoplasma gondii*)[11] diseases. Mild leukocytosis may be observed associated with viral (Pacheco's disease) infections as well.[16] Non-infectious inflammatory diseases have also been associated with leukocytosis and include neoplasia, metabolic disease, intestinal foreign bodies, orthopedic disease, lead or zinc toxicities, and trauma.[6,8]

Lymphocytosis in psittacines typically reflects antigenic stimulation, which may be secondary to viral infections (e.g., herpesvirus, psittacine circovirus), although this may reflect a temporal response, as lymphopenia has also been reported in birds with these viral infections.[38,43] Chronic antigenic stimulation and vaccinal response should also be considered. Eosinophilia and basophilia are less common in birds and have been reported secondary to tissue necrosis, trauma, respiratory disease, intestinal parasites, and presumed primary immune mediated hemolytic anemia.[6]

Leukopenia is less commonly reported in psittacines. Leukopenia with or without concurrent nonregenerative anemia and thrombocytopenia is common in parrots with psittacine circovirus infections, the causative agent of psittacine beak and feather disease. Viral antigen was recovered from the bone marrow and circulating WBCs in a group of affected African grey parrots (*P. erithacus*) indicating a direct viral cytotoxic effect.[43] Leukopenia secondary to bone marrow toxicity from drugs (e.g., fenbendazole, chlorambucil) is a well-established finding in other species of birds and presumably in psittacines as well. Leukopenia due to overwhelming tissue demand for WBCs, as observed in cases of endotoxemia, also occurs in psittacines and is typically characterized by concurrent toxic change and left shift.[6] Finally, care should be taken to assess blood smears with apparent leukopenia for evidence of WBC rupture, as poorly prepared blood smears may be associated with prominent cell lysis and artifactual leukopenia.

Thrombocytosis has been reported concurrent with a marked regenerative response to anemia.[6] Thrombocytopenia, as a component of pancytopenia due to decreased bone marrow production, is observed with viral infections (psittacine circovirus and polyomavirus), lymphoid leukemia, and drug/toxin administration (e.g., chlorambucil).[22,38,39] Thrombocytopenia may also be secondary to peripheral consumption/sequestration,

as a sequela of disseminated intravascular coagulation, or endotoxemia.[6,38]

Hemic Neoplasia

Expected hematologic findings in psittacines with hemic neoplasia have been poorly characterized. Individual case reports indicate that a wide range of hematologic abnormalities may be observed, including lack of any hematologic abnormalities (Figure 124.4d,e). As in other species, leukemia and lymphoma with a leukemic phase can be challenging to distinguish in some cases; however, attempts to determine the primary site of disease burden, blood for leukemia and tissue for lymphoma, may be helpful in classifying the underlying disease process in many cases. Psittacines lack organized lymph nodes found in mammals and so lymphoma is often derived from scattered lymphoid aggregates in organs.

Marked leukocytosis due to a mature lymphocytosis with few slightly larger more immature-appearing lymphocytes, and no other hematologic abnormalities, has been reported in a double yellow-headed Amazon parrot (*Amazona oratrix*) and a green-winged macaw (*Ara chloropterus*) with chronic T-cell lymphocytic leukemia. Marked bone marrow infiltration by small mature lymphocytes was noted in both cases with concurrent marked peripheral lymphocytosis.[21,38,39] The leukemic phase of lymphoma is common in many avian species, and has been reported secondary to cutaneous, nonepitheliotropic B cell lymphoma in an umbrella cockatoo (*Cacatua alba*).[42] This patient had a moderate heterophilia and mild eosinophilia at the time of diagnosis. Heterophilia and a left shift were also reported in a yellow-collared macaw (*Primolius auricollis*) with retrobulbar and multicentric B cell lymphoma. No leukemic phase of lymphoma, i.e., no atypical circulating cells,

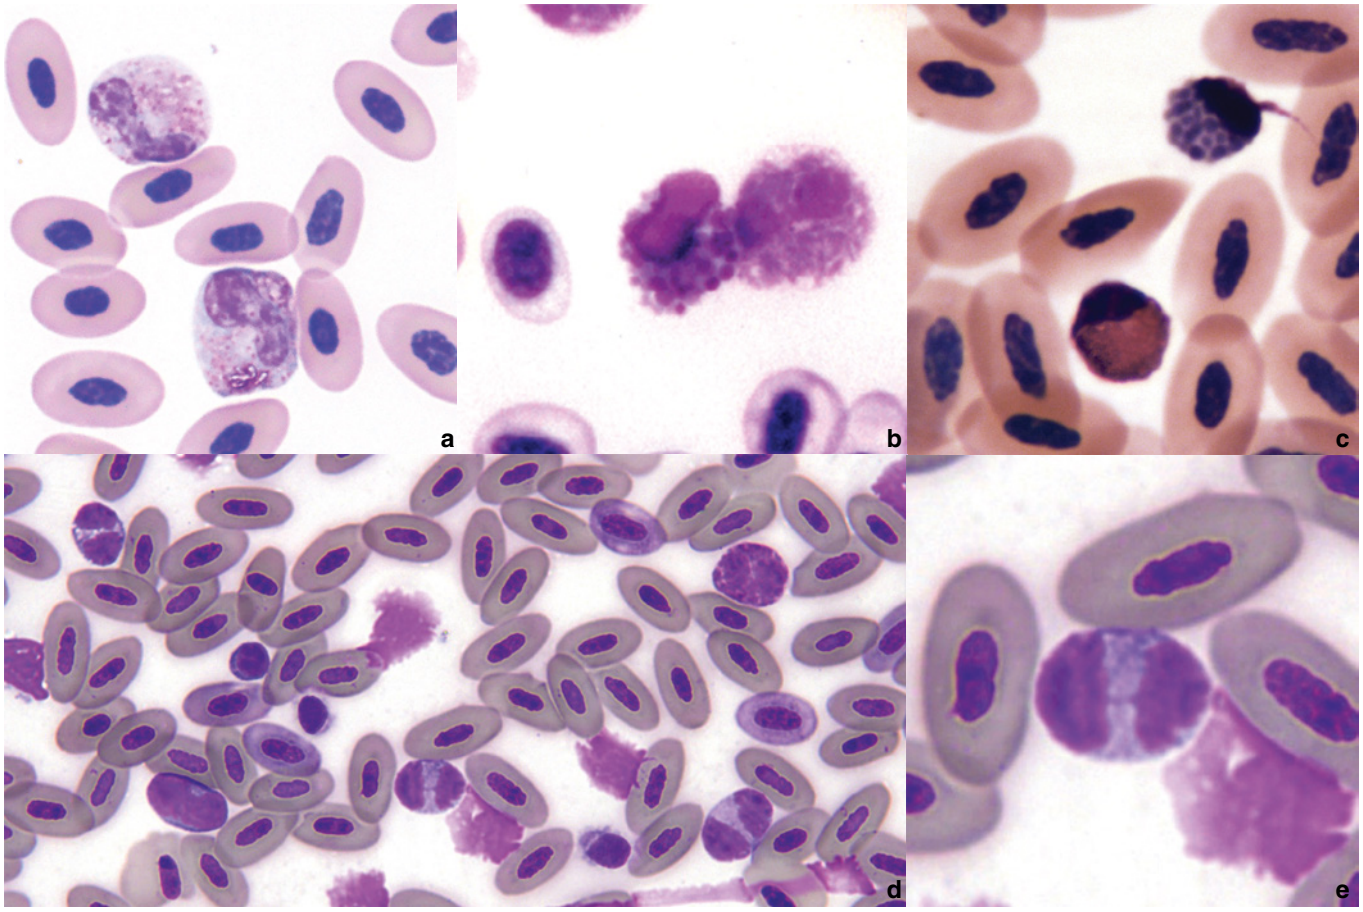

FIGURE 124.4 Leukocyte morphology found in sick psittacines. Wright–Giemsa or modified Wright's stain. RBCs may be used as internal size markers. (a) Toxic band heterophils with increased cytoplasmic basophilia and degranulation from a cockatoo; (b) Metamyelocyte from an African grey parrot (*P. erithacus*) showing distinct round, purple, primary granules next to a heterophil with mild degranulation. The total WBC count was estimated to be 100,000 cells/μL and the bird died within 48 hours of sampling due to intestinal perforation; (c) A heterophilic myelocyte in comparison to an eosinophil in a lilac-crowned Amazon (*Amazona finschi*) with ulcerated fungal dermatitis; (d) and (e) Probable lymphocytic leukemia in a blue-fronted Amazon parrot (*Amazona aestiva*) that presented repeatedly for CBCs with approximately 50,000 lymphocytes/μL for 2 years. The neoplastic cell morphology, which almost appears binucleate with a strand of nuclear material, was a consistent finding.

was noted in this individual despite the observation of 5–20% neoplastic lymphocytes in a patchy distribution throughout the bone marrow at necropsy.[33] In this case, erythroid and granulocytic lineages were admixed with the neoplastic cells and showed normal maturation.

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathology; H:L ratio, heterophil:lymphocyte ratio.

The Anseriforme order of birds is composed of at least 180 waterfowl species within three families. These include the largest family, Anatidae, which houses ducks, geese, and swans, and two smaller families, Anhimidae (screamers) and Anseranatidae (of which the only living species is the magpie goose, *Anseranas semipalmata*). These birds are all adapted to an aquatic existence. Members of Anatidae are commonly used for meat production and hunted for sport, but are also companion animals and housed at zoo facilities. Hematology is a rapid, inexpensive, and relatively minimally invasive method to evaluate some aspects of health in these species.

BLOOD COLLECTION

When collecting blood from large waterfowl, use of a 3 mL syringe with a 20–25-gauge needle is recommended. Visualization of the jugular vein can be difficult in these species due to lack of the apterium (featherless tract over the jugular vein); therefore, the basilic vein (medial aspect of the elbow) and the medial metatarsal vein (medial aspect of the hock) are recommended as more accessible sites. Accessing the basilic vein can be difficult and stressful; of course, this is dependent on user experience. The medial metatarsal vein may be easier to access and less stressful for the animal, especially if a light towel or cloth is used to cover the face and eyes, without blocking the airways, to reduce visual sensation. The medial metatarsal vein is more resistant to hematoma formation than the basilic vein. A wrap may be used to ensure hemostasis.[10]

ERYTHRON

The erythron is assessed by the same means as other birds, using total RBC count, PCV, hemoglobin concentration (Hgb), mean cell volume (MCV), mean cell hemoglobin concentration (MCHC), and evaluation of RBC morphology (see Chapter 123). Normal Anseriforme RBCs are oval with eosinophilic cytoplasm and a centrally located oval nucleus with densely clumped basophilic chromatin (Figure 125.1). Mallard (*Anas platyrhynchos*), canvasback (*Aythya valisineria*), and lesser scaup (*Aythya affinis*) RBCs are oval measuring 12–14 µm in length and 6–8 µm in width with nuclei that vary from 5–6 µm in length and 2–3 µm in width.[9,23] These are larger than RBCs of domestic mammals, with an average calculated MCV of 192 fL noted for Indian runner ducks (*Anas platyrhynchos domesticus*), 164 fL for wood ducks (*Chenonetta jubata*), and 145 fL for black ducks (*Anas superciliosa*).[6,29,30]

Normal RBCs of healthy waterfowl display minimal to mild anisocytosis and anisokaryosis. Erythrocyte life span is estimated at a maximum of 42 days in

healthy white Pekin ducks (*A. platyrhynchos*). Polychromatophils are more rounded and slightly larger than mature RBCs with increased cytoplasmic basophilia (Figure 125.1). In most healthy ducks of a variety of species, the average PCV is approximately 45% which is similar to tundra swan (*Cygnus columbianus*).[2,28,34] Indian runner ducks have a reported average RBC count of $2.5 \times 10^6/\mu L$ and average Hgb of 13.8 g/dL.[6] The clinician should be aware that calculated hematocrit as determined by the i-STAT 1 (Abbott Point of Care Inc., Abbott Park, Illinois, USA) is consistently lower than PCV determined by microhematocrit tube centrifugation. This discrepancy was demonstrated in mottled ducks (*Anas fulvigula*)[34] and is similar to findings in other avian species. The authors of the study do not recommend direct comparison of i-STAT determined Hgb and hematocrit with other analyzers as these are likely falsely decreased in ducks and other avian species.

LEUKON

The leukon is assessed by the same means as other birds and includes a total WBC count, differential WBC counts, and morphologic evaluation (see Chapter 123). Average total WBC count has been reported between $6.3–20.9 \times 10^9/\mu L$ in ducks.[6,34] Circulating Anseriforme WBCs are composed of the same cell types as other avians and include heterophils, lymphocytes, monocytes, eosinophils, and basophils. Most studies of healthy Anseriformes have found lymphocytes are the predominant leukocyte type and the heterophil to lymphocyte (H:L) ratio is less than 1.[11,15,29,30,40] However, this was inverted in ferruginous ducks (*Aythya nyroca*), mottled ducks, and tundra swans, which had H:L ratios greater than 1 (e.g., H:L was approximately 1.3 in mottled ducks).[2,28,34] Importantly, this H:L inversion may be due to species differences, capture stress, or undiagnosed inflammatory conditions in the population.

Heterophils are round to oval with clear cytoplasm that is filled with elongated to fusiform eosinophilic granules that are slightly refractile in appearance. They contain a bi to multilobed nucleus with condensed chromatin (Figures 125.1 and 125.2). In ducks, heterophils were described as approximately 10 μm in diameter.[36] Rod-shaped heterophil granules can be distinguished from eosinophils by their lack of distinct granule borders and refractile, slightly muddied appearance.

Lymphocytes are predominantly small, ranging from 4–8 μm in diameter with scant amounts of light blue cytoplasm visible on one side of a round to slightly cleaved nucleus with condensed chromatin (Figures 125.1 and 125.2). Low numbers of intermediate-sized lymphocytes with a slightly increased amount of cytoplasm are commonly seen in Anseriforme blood smears as well. Additionally, a few reactive lymphocytes might be seen as part of an antigenic response with deeper blue cytoplasm, pseudopods, and purple cytoplasmic granules.

Monocytes, the largest WBC in circulation, are similar in appearance to other birds and mammals. They are round to irregular in shape with a moderate amount of basophilic to gray cytoplasm that is often vacuolated. They contain a round to lobed to irregular nucleus with variably condensed chromatin (Figures 125.1 and 125.2).

Eosinophils are round with pale blue to clear cytoplasm and many distinct eosinophilic, fine, round to oval granules. They contain a bi to trilobed nucleus with condensed chromatin (Figure 125.1). Eosinophils are reported to average 9.7 μm in diameter in ducks.[36] Duck eosinophils have been reported to have rod-shaped granules, but this has not been confirmed with ultrastructure or cytochemical stains at this time.

Basophils are round to slightly irregular in shape with numerous basophilic round granules that often obscure the nucleus. These average 6.4 μm in diameter in ducks[36] (Figure 125.1).

THROMBON AND COAGULATION

There is a paucity of information regarding thrombocytes and coagulation in Anseriformes. Thrombocytes are nucleated round to oval cells with a small amount of clear cytoplasm that surrounds the ovoid nucleus. The cytoplasm frequently contains one to several round azurophilic granules at one pole (Figure 125.1). Transmission electron microscopy has demonstrated that thrombocytes in ducks are 4.5–6 μm in diameter with large vacuoles.[4] Thrombocyte counts were low in 5-day-old mallards (fewer than five per 10 high-powered fields) and increased to a plateau of approximately 20 thrombocytes per 10 high-powered fields at 18 days old, which is consistent with adult thrombocyte counts.[11] Thrombocytes are also commonly seen in large clumps, mostly on the feathered edge as well as in the body of the smear. Thrombocyte clumping is typically interpreted to indicate an adequate thrombon mass.

REFERENCE INTERVALS AND INFLUENCING FACTORS

Only one study of ferruginous ducks in Israel adheres to the American Society for Veterinary Clinical Pathology (ASVCP) guidelines for correctly establishing and reporting de novo reference intervals in veterinary species.[2,13] The authors of this study reported that guidelines for establishing reference intervals were followed for PCV (38–54%), total WBC count ($0.5–9.2 \times 10^3/mL$), and WBC differentials. However, this study only reported relative values for quantifying polychromasia, and total WBC concentration was estimated. Furthermore, the low reference values for all WBC types (heterophils, lymphocytes, monocytes, eosinophils, and basophils) were $0.0 \times 10^3/mL$; therefore, these data were not included in this text. Articles that did not adhere to reference interval guidelines are cited.[28,34] Deviations from the guidelines included publication of the study

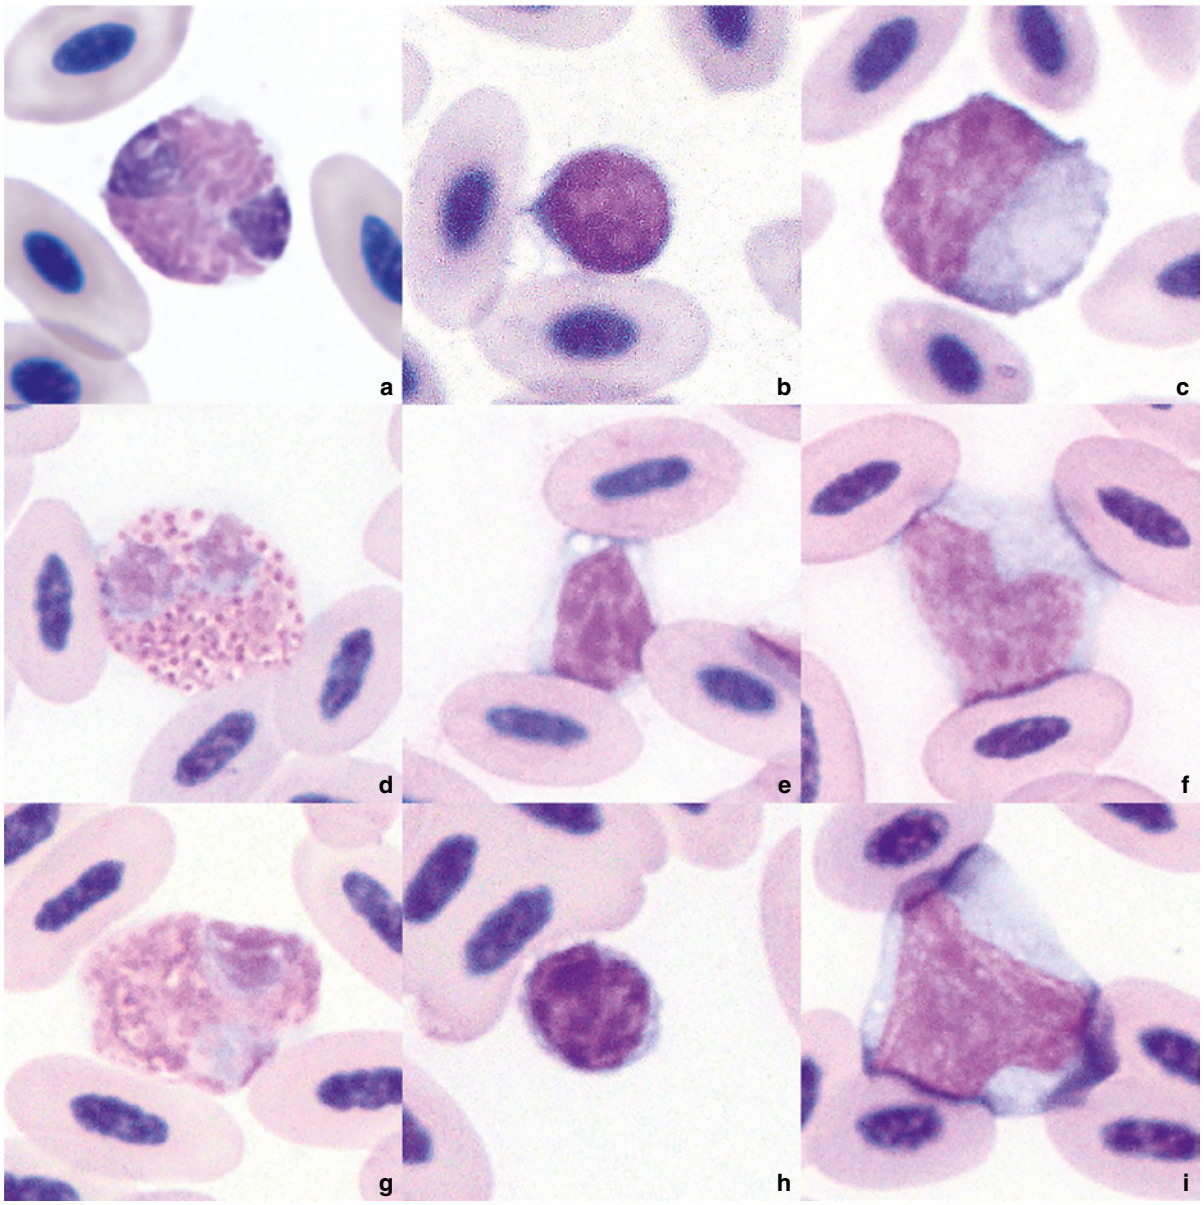

FIGURE 125.2 Selected normal leukocytes from three species of healthy, adult Anseriformes: Canada goose (*Branta canadensis*): (a) Heterophil; (b) Lymphocyte; (c) Monocyte. (**Sources:** Samples provided by the Ohio Wildlife Center and the Cameron Park Zoo.)

prior to ASVCP guidelines, insufficient number of target species, inability to prove health, limited statistical analysis, and/or inclusion of outliers.

Pre-analytical factors can affect reference intervals, and pre-analytical conditions (e.g., sampling method) must be reported and reviewed when establishing reference intervals. Capture method and time of day likely had stress-related and diurnal effects on hematologic values of mottled ducks. Ducks captured by hand net at night had significantly lower PCV and H:L ratio and significantly higher absolute WBC, eosinophil, and lymphocyte counts compared with ducks caught by rocket net during the day. The increased H:L ratio in the latter group suggests increased stress, but the effect of capture method and stress on hematologic values cannot be separated from a diurnal effect.[34]

Several biologic factors influence reference intervals in Anseriformes and these must be considered when designing or reviewing a reference interval study (Table 125.1). Reported effects of age on RBC, WBC, and thrombocyte concentrations vary. Increased PCV has been reported with aging in canvasback ducks (4–10-week-old ducklings versus adults >1 year) and trumpeter swans (*Cygnus buccinator*) (3–4 months versus 5–8 months).[21,32] Ferruginous ducks had a higher proportion of polychromatophils as juveniles than as adults.[2] This pattern is consistent with erythroid turnover and regeneration in neonates and juveniles. While

TABLE 125.1 Effect of sex on hematologic values in selected Anseriforme species. No significant differences in hematologic values between sexes in Anseriformes are reported, except those related to seasonal influences and breeding. Differences in WBC types between sexes were not reported.

juvenile and adult wild tundra swans did not differ in their total WBC counts and differentials, juvenile mottled ducks and trumpeter swans demonstrated a significant decrease in total WBC count with aging toward adulthood.[32,28,34] Furthermore, a greater H:L ratio in adult versus juvenile mallards and ferruginous ducks has been reported.[2,11] It was suggested that a postjuvenile decrease in lymphoid organ activity might contribute to a decrease in peripheral lymphocytes.[2] Absolute eosinophil counts were significantly greater in adult ferruginous ducks than in first-year ducks, and it was presumed this was due to increased parasite exposure with increasing age.[2] Juvenile mottled ducks had significantly greater average absolute monocyte counts (1.1 × 10^9/L) compared with adults (0.7 × 10^9/L).[34] Only one study has explored aging changes in thrombocyte counts of Anseriformes. Five-day-old mallards had lower thrombocyte counts than adults, with thrombocyte counts reaching a plateau consistent with adult values (approximately 20 thrombocytes per 10 high-powered field) by 18 days of age.[11]

The literature overwhelmingly shows that there are no significant differences in hematologic values between sexes in Anseriformes, except those related to seasonal influences and breeding which will be discussed later. Wood ducks, black ducks, upland geese (*Chloephaga picta*), tundra swans, and trumpeter swan cygnets did not show significant differences in hematologic values between males and females.[28–30,15,32] Few studies have evaluated hematologic differences due to reproductive activity in Anseriformes. Both male and female mallards had significantly increased thrombocyte counts during pre-egg-laying and egg-laying stages compared with incubation, molting, and postreproductive stages.[11] Loss of a social partner had a stress-related effect on hematologic values in greylag geese (*Anser anser*), with decreased PCV during mate removal in both males and females. Isolated males also demonstrated elevated total WBC count and H:L ratio.[26]

Seasonal variation in hematologic values is common in Anseriformes and should not be confused with pathologic change. A few species have demonstrated higher RBC, PCV, Hgb, and MCHC and lower MCV during prenesting periods (winter and spring) compared with postnesting periods (summer and fall).[33,37] For male and female Canada Geese, RBC averaged 2.67–2.78 × 10^9/L, PCV averaged 51–52%, Hgb averaged 16.2–17.1 g/L, MCHC averaged 31.6–33.0 g/L, and MCV averaged 188.5–193.3 fL in the pre-nesting period (January to March), while in the post-nesting period (June to October) RBC averaged 2.18–2.30 × 10^9/L, PCV averaged 45–46%, Hgb averaged 13.6–14.0 g/L, MCHC averaged 29.9–30.7 g/L, and MCV averaged 198.8–210.1 fL.[37] For male and female mallards, RBC averaged 3.35–3.71 × 10^9/L, PCV averaged 49–50%, Hgb averaged 15.0–15.6 g/L, MCHC averaged 30.3–31.6 g/L, and MCV averaged 135.2–148.4 fL in the pre-nesting period (January–March), while in the post-nesting period (July–October) RBC averaged 2.01–2.51 × 10^9/L, PCV averaged 39–45%, Hgb averaged 11.4–13.5 g/L, MCHC averaged 29.2–29.9 g/L, and MCV averaged 186.6–199.6 fL.[37] Canvasback ducks in midmigration (November) were found to have lower average RBC (2.63–2.87 × 10^9/L) and higher average MCV (202–209 fL) than over-wintering ducks during December–January (RBC, 2.99–2.96 × 10^9/L; MCV, 186–187 fL) and February–March (RBC, 3.09–3.28 × 10^9/L; MCV, 165–168 fL).[21] It is suggested that these differences are due to hormonal changes that occur with altered photoperiod and nutritional changes during migration and nesting.

BONE MARROW COLLECTION AND EVALUATION

Bone marrow collection from the proximal tibiotarsus has been described in Canada geese (*Branta canadensis*), using a 14–16-gauge, 3-inch needle and a 10 mL syringe following sterile technique. Syringes and collection tubes should contain EDTA. Birds were restrained on their backs, and the needle was inserted 0.5 cm below and slightly to the right of the tibiotarsal anterior crest. This technique yielded adequate marrow cellularity for cytologic analysis and resulted in minimal, if any, lameness after the procedure.[8,39]

Very little work has been done to characterize normal bone marrow in Anseriformes. It is recommended to perform at least a 500-cell differential, as in other species. One study that evaluated 10 apparently healthy ducks (unstated species) native to Northern Iran found that precursor morphology and blood cell formation were similar to gallinaceous birds (see Chapter 123). Mean myeloid to erythroid ratio was 1.0. The erythroid series was composed predominantly of late polychromatophilic rubricytes (mean, 20.5%) with a low percentage of rubriblasts (mean, 0.8%). The myeloid series was composed predominantly of heterophilic myelocytes (mean, 14.8%). The specific myeloid series could be identified by secondary granules seen at the myelocyte stage. Lymphocytes were not observed in ducks, but plasma cells were present at a mean of 2.0%.[39] The authors surmised that peripheral blood lymphocytes likely arise from the spleen and gut-associated lymphoid tissue in many adult birds, as reported by Zinkl 1986.[41]

HEMATOLOGIC DISEASE

Heavy Metal Toxicity

Heavy metal toxicity is an unfortunate result of waterfowl and humans' coexistence and can occur via ingestion of or penetration by zinc or lead shot or ingestion of fishing weights. Ingestion of zinc-contaminated vegetation and sediment is another route of exposure. Experimentally induced zinc toxicity in mallards, which causes abnormal hematopoiesis and decreased RBC life span, caused a regenerative anemia characterized by decreased PCV and Hgb concentration (anemia) and increased reticulocyte counts (erythroid regeneration) compared with blood samples from control birds. Abnormal erythroid morphology included increased polychromasia, immature RBCs (basophilic and polychromatophilic prorubricytes), poikilocytosis, and binucleated RBCs.[14,25]

Lead toxicity typically results in microcytic, hypochromic anemia due to inhibition of enzymes involved in heme synthesis, including aminolevulinic acid synthase, aminolevulinic acid dehydratase, and ferrochelatase. Lead toxicity effects on hematologic values have been studied in a variety of free-ranging ducks in Argentina, trumpeter swans, and Canada geese. High blood lead concentrations were associated with significantly decreased PCV, RBC, Hgb, MCV, and MCHC and abnormal RBC morphologies including anisocytosis, poikilocytosis, polychromasia, hypochromasia, basophilic stippling, and increased numbers of immature rubricytes (Figure 125.3a,b).[3,12,18] Maturation arrest of erythroid precursors was also seen in the bone marrow of mallards.[3] Experimental lead intoxication in mallards caused increased mean total WBC counts, absolute heterophil counts, numbers of toxic heterophils and reactive lymphocytes, and decreased absolute lymphocyte counts compared with controls.[3,25] Similarly, increased blood lead concentrations in trumpeter swans were associated with a significantly increased total granulocyte count.[18]

Crude Oil Toxicity

Oil pollution is a serious hazard to waterfowl health. Oiling of plumage results in loss of thermal regulation and decreased feather integrity may hinder or prevent flight. Ingestion of oil-contaminated food, water, and preening of oiled feathers can affect metabolic function, suppress adrenocortical function, and induce hemolytic and/or hemorrhagic anemia in ducks and other aquatic birds.[16,17,24,35] Heinz bodies, which are microscopic evidence of oxidative damage to Hgb, and damaged organelles have been reported in RBCs of various species of aquatic and marine birds and likely also occur with crude-oil ingestion in Anseriformes.[17,24] In wild sea ducks

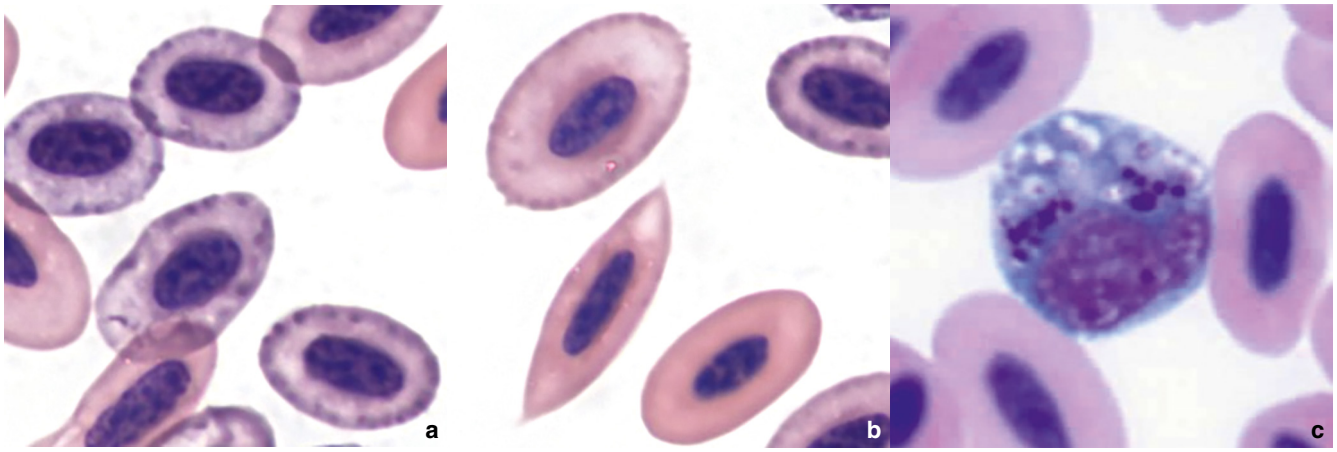

FIGURE 125.3 Abnormal erythrocyte and leukocyte morphology in Anseriforme blood. naturally affected by an oil spill, birds demonstrated regenerative anemias evidenced by reduced RBC count, PCV, and Hgb with increased polychromatophils. Marked multiorgan hemosiderin deposition on necropsy was presumed to be due to hemolysis.[40] It should be noted that other bird species had documented hematochezia due to coagulopathy, which may also induce regenerative, blood loss anemia.

Other anemias have been documented in research studies. Experimentally induced hypothyroidism in barnacle geese (*Branta leucopsis*) had significantly decreased PCV, by 18%, and Hgb concentration, by 22%, compared with control geese.[7]

Inflammatory Leukogram

Inflammatory changes in the leukogram of Anseriformes are similar to other species. Depending on severity and duration of the inflammatory process, either heterophilia or heteropenia may be seen, and both can be accompanied by a left shift and/or toxic change (Figure 125.3c). In some cases, lymphocytosis and monocytosis are seen with inflammatory response; or lymphopenia might occur concurrently as a stress response. Bienzle et al. reported cases of wild Anseriformes with hematologic abnormalities related to infectious and inflammatory processes. These included a septicemic teal (*Anas sp.*) with heteropenia, severe left shift, and toxic change; an Aleutian Canada goose (*Branta canadensis leucopareia*) with a mild left shift and moderate toxic change due to osteomyelitis and aspergillosis; and a black-bellied whistling duck with marked heterophilia, left shift, and toxic change due to septic osteoarthritis, valvular endocarditis, and hepatic necrosis. In the latter case, the total WBC count was 278 × 10^9/L and mature and immature heterophils each exceeded 100 × 10^9/L. Lymphocytosis, monocytosis, and eosinophilia were also present. This demonstrates the severe hematologic changes that can occur with inflammation in these species and the risk of misdiagnosis of leukemia if blood smears and complete case information are not evaluated appropriately.[5]

Leukemia

Few reports of leukemia in Anseriformes exist, especially in comparison to reports in domestic animals. Chronic T-cell lymphocytic leukemia was diagnosed in a black swan (*Cygnus atratus*) after severe lymphocytic leukocytosis was found incidentally on a health exam (reported as >1,000,000 total WBCs/μL [?] with 98% lymphocytes). Immunocytochemistry and immunohistochemistry confirmed CD3+ neoplastic lymphocytes in the peripheral blood, bone marrow, liver, spleen, heart, lungs, and kidneys. Neoplastic lymphocytes were described as small, round, and mature with a high nuclear to cytoplasmic ratio, mature condensed chromatin, and no overt nucleoli. The swan did not have a concurrent cytopenia of other cell lines and survived 433 days after initial evaluation.[38] This case contrasts with that of a 4-year-old Pekin drake diagnosed with lymphocytic leukemia and malignant lymphoma after presentation with depression, anorexia, and coughing; anemia, thrombocytopenia, and extreme leukocytosis (estimated at 2,000,000 total WBCs/μL) characterized by a marked lymphocytosis (99% lymphocytes) were found on clinicopathologic evaluation. Circulating lymphocytes were predominantly small. The duck survived 1 month after initial diagnosis, and on necropsy, well-differentiated, cleaved lymphocytes diffusely involved the liver, spleen, intestines, lungs, air sacs, kidneys, heart, ventriculus, proventriculus, and bone marrow. Erythroid hypoplasia was noted in the marrow at necropsy.[31]

Hemoparasites

Ducks, geese, and swans are found to be commonly infected with species of *Hemoproteus*, *Leukocytozoon*, and *Plasmodium* with one study reporting a >75% infection rate with at least one hemotropic parasite in surveyed waterfowl[1] (Figure 125.4; see Chapters 123 and 126). There are fewer reports of *Trypanosoma sp*. in waterfowl, and microfilaria are also occasionally seen in peripheral blood smears (Figure 125.4). *Plasmodium* and *Leucocytozoon sp*. are capable of causing severe anemia, weight loss, and death in susceptible birds, of which juveniles are often more susceptible than adults. Infections are typically

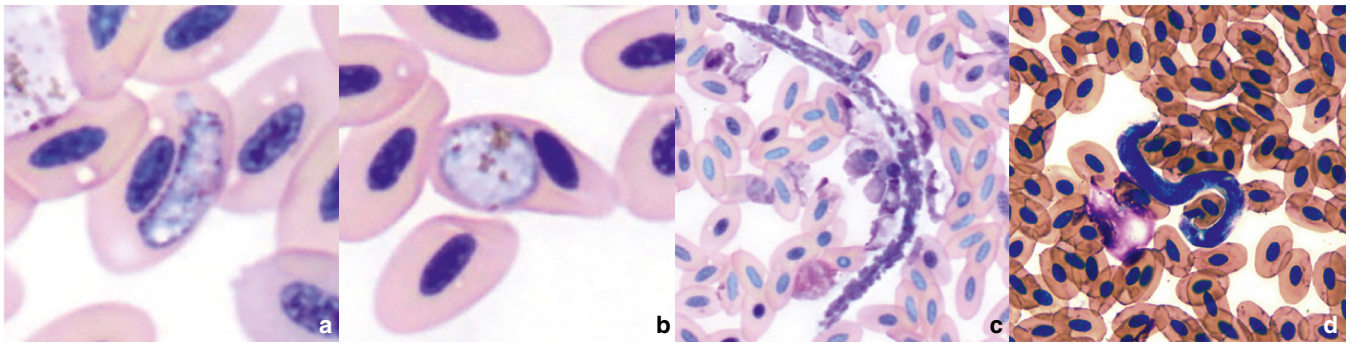

FIGURE 125.4 Hemoparasites of Anseriformes. (a) *Hemoproteus spp*. in a wood duck (*Aix sponsa*); (b) *Plasmodium spp*. in a northern pintail (*Anas acuta*); (c) *Microfilaria* in a wood duck. seasonal because transmission is vector-dependent: (*Hemoproteus sp*. via *Culicoides* and *Ornithomyia sp*. flies; *Plasmodium sp*. via *Culex* and *Aides sp*. mosquitoes; *Leukocytozoon sp*. via *Simulium sp*. black flies). Potential clinical signs include weight loss and anorexia or hyporexia, lethargy, weakness, lameness, and dyspnea.[1] Of particular importance, *Leucocytozoon simondi* appears to be a significant cause of anemia due to intravascular hemolysis in several duck species.[19,20,22,27]

Acronyms and Abbreviations

CI, confidence interval; LD50, median lethal dose; LRL, lower reference limit; NA, not available; R, robust method; RI, reference interval; RT, robust method after Box–Cox transformation; TS/TP, total solids/total protein concentration; URL, upper reference limit.

The term "raptor" encompasses birds of prey, generally defined as carnivorous birds with a hooked beak and sharp talons that consume vertebrate species. Raptors include the families of generally diurnal birds Accipitridae (hawks, eagles, buzzards, harriers, kites, Old World vultures), Cathartidae (New World vultures, condors), Falconidae (falcons, forest falcons, kestrels, caracaras), Pandionidae (ospreys), and Sagittariidae (secretary bird, *Sagittarius serpentarius*); and the nocturnal owl families, Strigidae and Tytonidae.

BLOOD COLLECTION

Sample sites for blood collection in raptor species vary with patient size and potential use of sedation or anesthesia. The medial metatarsal vein, cutaneous ulnar vein, basilic vein, and jugular vein are common peripheral blood collection sites. The largest bore vein possible should be chosen to improve sample quality. Sample hemolysis can result from patient movement during collection, and hematomas may form. Lipemia is an uncommon sample condition for raptor species, but is reported as a postprandial effect. Capture, transport, confinement, and physical restraint may all contribute to a stress response that can alter hematologic values. In birds as a whole, blood volume is estimated at 6–12% of a bird's total body mass, with a recommended maximum blood collection volume of 1% of the patient's body weight to avoid deleterious effects.[8]

The anticoagulant of choice for hematologic evaluation of raptor blood is EDTA, as there is less leukergy and it does not result in staining artifact. In vitro hemolysis is reported infrequently and EDTA-anticoagulated blood is acceptable for smear preparation in raptors. However, as with other avian species, a common collection method is to place blood in a heparinized tube (preferably lithium heparin). A single sample can then be used for both hematologic and biochemical evaluation with maximal use of the sample volume. The minimum blood volume necessary for hematologic evaluation is removed, then the remaining sample is centrifuged to yield heparinized plasma for biochemical analysis. The potential downsides of heparin use are interference with smear staining and increased cell clumping which impairs accurate counting and morphologic evaluation. Small blood collection tubes for pediatric use (microtainers) are useful to ensure the correct ratio of blood to anticoagulant. A blood smear should be made prior to placing the blood sample in heparin anticoagulant, as staining artifacts can result in smears of heparinized blood and impair hematologic analysis. However, if very small blood volumes are collected,

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

this may not be practical as the risk of the sample coagulating quickly is higher. Coverslip smears can be useful to reduce cell lysis due to blood smear preparation, but reference laboratories vary in their policies of accepting coverslip smears.

ERYTHRON

The average raptor mean red cell volume (MCV) ranges from 168–188 fL in different species, with RBC elliptical dimensions in blood smear evaluation reported as approximately 8 × 15 μm.[33] RBC life span is generally assumed to be similar to other avian species, ranging between 28 and 45 days.[39] As in other avian species, PCV measurement is used to measure oxygen-carrying capacity in raptors. Plasma from the spun hematocrit tube is then used to measure protein concentration via refractometry. Refractometers vary in accuracy of avian plasma protein measurement when compared to the biuret method standard; correlation to standard protein measurement is recommended prior to use of refractometers for samples from nonmammalian species.[7] Erythrocyte manual counting may be performed to calculate the mean cell volume using a hemocytometer-based Natt–Herrick staining technique or commercially available disposable pipette systems (see Chapter 123). Hemoglobin (Hgb) measurement is performed in some laboratories by lysing RBCs, centrifuging the sample to pellet nuclei and membranes, then measuring Hgb in the supernatant using the cyanmethemoglobin method. The Hgb concentration is then used to calculate the mean cell hemoglobin concentration (MCHC). Reticulocyte staining is performed using a 3:1 dilution of 0.5% new methylene blue stain to whole blood, incubating the blood for 10 minutes, and then preparing a smear. Ring-form reticulocytes are defined as RBCs containing aggregates of stained reticulum that form a ring, contiguous or discontiguous, around at least half of the nucleus. Ring-forms correlate more closely with polychromatophils in a Wright's-stained smear than other defined reticulocyte types[9] (See Chapter 123). Evaluation of RBC morphology includes semiquantitative assessment of polychromatophils (Figure 126.1a,b), anisokaryosis, and poikilocytosis including specific morphologic abnormalities, and hemic parasites (Figure 126.4). Polychromatophil and reticulocyte percentages in raptors generally range up to 5% in health; increased percentages indicate increased erythroid regeneration. Rubricytes are occasionally found and RBC more immature than rubricytes (Figure 126.1b,c) are generally not found in blood smears from healthy raptors.

LEUKON

As with other nonmammalian species, avian hematologic methods generally rely on manual counting of WBCs and thrombocytes. Three common methods of manual leukocyte counting are the two hemocytometer-based techniques using either Natt–Herrick or phloxine B stain, and a manual estimate from a stained blood smear. References vary as to the comparative accuracy of the three techniques for WBC counting in raptors and other birds.[8] Thrombocytes and RBCs can also be quantified via the Natt–Herrick technique; a 60-minute stain incubation improves differentiation between lymphocytes and thrombocytes.[3] Alternately, toluidine blue staining using a 1:100 ratio of blood to 0.01% stain can permit quantification of RBCs, WBCs, and thrombocytes. Smear estimation of thrombocyte concentration can be performed, but thrombocyte clumps (Figure 126.1d) and lysis can render the estimate useless. Leukocyte concentration estimate can be performed and substantial changes such as heterophilia and monocytosis can often be detected. Evaluation of WBC morphology may detect abnormalities such as immaturity and toxicity in heterophils, reactive changes in lymphocytes, and hemic parasites.

Heterophils have lobulated nuclei and contain orange-pink to brownish, rod-shaped to fusiform granules (Figure 126.2a–g). A mean diameter of 8.8 μm is reported for avian heterophils.[25]

Lymphocytes in healthy raptors vary from small to intermediate in size and generally have scant volumes of basophilic cytoplasm and rounded nuclei (Figure 126.2h–n). Thrombocytes can generally be distinguished from lymphocytes by their clear to pale blue cytoplasm, oval to slightly elongated nuclei, and smaller nuclear size. Monocytes are morphologically similar to those in other avian species and often have more rounded nuclei than the mammalian form (Figure 126.2o–u); vacuolated cytoplasm may be prominent if activated.

Eosinophils have bilobed nuclei and contain orange-pink granules that are generally round, but may be oblong and are more refractile (Figure 126.2v–ab). Eosinophils and heterophils are roughly the same size; a mean avian eosinophil diameter of 7.9 μm is reported.[25] Rare raptors (e.g., king vultures) have eosinophils with grayish granules, and raptors in the genus *Falco* have eosinophils with bluish cytoplasm that can appear vacuolated and poorly granulated and/or contain basophilic granules.[9,42] Owl eosinophils have been reported to have variable granulation, though cytochemistry and electron microscopy have not been used to confirm identification. For example, owls in the genus *Strix* have eosinophils with rounded bluish to dull pink granules and owls in the genera *Asio* and *Otus* have eosinophils with round bright pink/orange granules that often appear smaller than heterophils.[9] Basophils contain deep purple granules, but can appear hypogranulated or degranulated (Figure 126.2ac–ai), and are similar in size to heterophils.

REFERENCE INTERVALS

Many reference intervals (RI) used for raptors were not created in accordance with American Society for Veterinary Clinical Pathology guidelines and medical

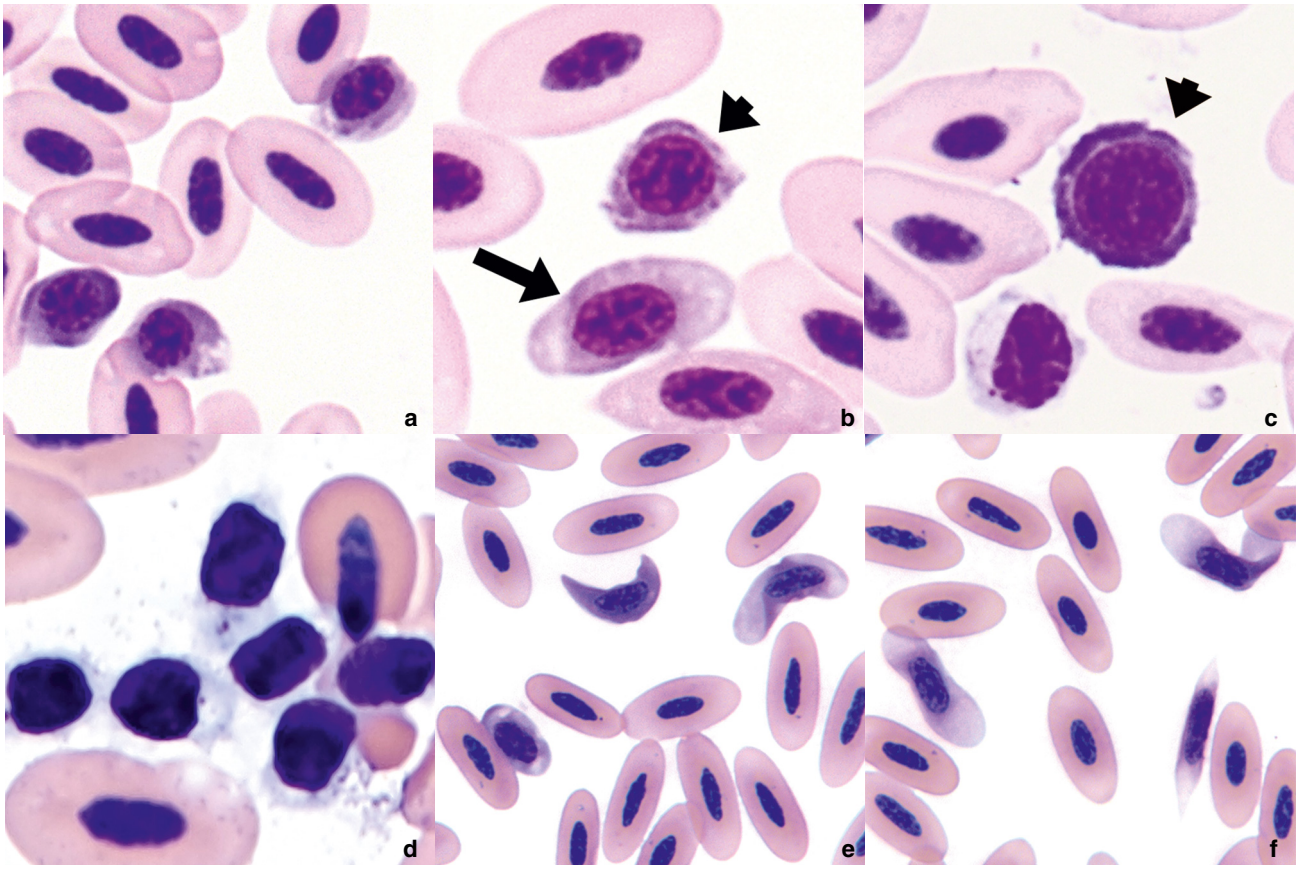

FIGURE 126.1 Normal and abnormal RBC morphology. All images taken using 100× (oil) objective with modified Wright–Giemsa stain. (a) Three polychromatophils (American kestrel, *Falco sparverius*); (b) Larger polychromatophil (arrow) and smaller polychromatophil (arrowhead) (red-tailed hawk, *Buteo jamaicensis*); (c) Immature erythroid cell (arrowhead) and thrombocyte (lower left) (red-tailed hawk, *B. jamaicensis*); (d) Thrombocyte clump (red-tailed hawk, *B. jamaicensis*); (e) and (f) Polychromasia and RBC morphologic abnormalities in confirmed lead poisoning (bald eagle, *Haliaeetus leucocephalus*). care may be affected. Age is the most significant partitioning factor, affecting both erythroid and myeloid cells lines. Other partitioning factors may be masked by the stress response that is often present in raptor CBCs and additional significant factors may be identified as data that have been impacted when stress is identified, partitioned, and analyzed.

Reference intervals for PCV in raptor species vary with age. Age-related differences are consistently noted throughout the literature, with younger birds having lower PCV, Hgb concentration, and/or total protein concentrations than older birds.[6,10,17,23] This finding is commonly reported in other avian species and is hypothesized to reflect higher tissue oxygen demands in older, flighted birds. Younger birds have higher percentages of reticulocytes, rubricytes, and immature erythroid cells. Environment (e.g., altitude) can also affect erythroid values.[22]

Age-related differences are reported in total WBC count and other WBC parameters. Younger raptors often have higher WBC counts than older birds with increased heterophils accounting for a substantial part of the difference, but findings vary between species.[10,17,23] Owls generally have higher lymphocyte percentages than other raptors (Table 126.1), while heterophils generally predominate in other raptor species (Tables 126.2 and 126.3). The stress response should be considered when evaluating reference intervals for use diagnostically, as it likely impacts many of the published reference intervals. Boreal owl species tend to have lower WBC counts than temperate/tropical owls.[1]

Thrombocyte estimates based on smear evaluation are similar in raptors to those reported in other avian species, generally ranging from 20,000–50,000/µL. However, estimates are often impeded by clumping and cell lysis. Reference intervals for whole-blood clotting time in raptors range from roughly 2–10 minutes.[28] Species-specific reference intervals are suggested in one publication, as the reference interval for prothrombin time in barn owls (*Tyto alba*; 17–29 seconds) differed from that for Japanese quail (*Coturnix japonica*; 10–16.2 seconds), with the same method using avian kephalin.[49]

Conv. Units, conventional units; RI, reference interval; LRL, lower reference limit; URL, upper reference limit; CI, confidence interval; R, robust method; RT, robust method after Box–Cox transformation; NA, not available; NR, not reported by the editor; TS/TP, total solids/total protein concentration.
Editor's note: Reference intervals for monocytes, eosinophils, and basophils are withheld, as the standard deviation exceeds the median for these values. Readers are advised to look at minimum and maximum values with the caution that reference interval statistics have not been performed. Lymphocytes are retained so that readers note that animals with a significant stress response are included in these values. It is possible that anemic animals were included in this population. Communication from the Journal of Veterinary Clinical Pathology.

TABLE 126.2 Reference intervals for 41 adult, mixed-sex bald eagles (*Haliaeetus leucocephalus*).[20] Authors state that outliers were removed, but no detail as to how this was done is provided in the manuscript. Data should be used with caution in medical settings.

Conv. Units, conventional units; Dist., distribution; RI, reference interval; LRL, lower reference limit; URL, upper reference limit; CI, confidence interval; G, Gaussian distribution; NG, non-Gaussian distribution. NA, not available.
Editor's note: Reference intervals for eosinophils are withheld, as the standard deviation exceeds the median for these values. Readers are advised to look at minimum and maximum values with the caution that reference interval statistics have not been performed. Readers should note lymphocytes lower values indicate that animals with a significant stress response are included in these values.

HEMATOLOGIC DISEASE

Stress leukograms are occasionally reported in raptors and are similar to corticosteroid-mediated stress leukograms in mammals, with heterophilia and lymphopenia noted. California condors (*Gymnogyps californianus*) are reported to have unusually pronounced stress leukograms with total WBC counts of 25–30 × 10^3/μL, potentially masking infection-related leukocytosis. A typical corticosteroid response is evident in Table 126.3. Without additional evidence (e.g., heterophil toxicity and immaturity) to support inflammatory disease, the diagnosis of concurrent inflammation is difficult in the face of a corticosteroid response.

Anemia

Anemia is common in debilitated raptors and has numerous known etiologies. Hypochromasia is often noted with severe or chronic anemia. Increased reticulocytes and appearance of more immature erythroid cells (Figure 126.1a–c) are consistent with regenerative anemia due to hemorrhage and/or hemolysis. Hemolytic anemia can be caused by acute intoxication (e.g., lead toxicity), hemoparasitism (e.g., *Plasmodium* or *Aegyptianella* infestation), and septicemia. Abnormalities including hypochromasia, microcytosis, basophilic stippling, nuclear abnormalities, and ballooning cytoplasm can raise suspicion for heavy-metal toxicosis (see Chapter 125 and Figure 125.3).

Editor's note: Reference intervals for monocytes, eosinophils, basophils, and H:L ratios are withheld, as the standard deviation exceeds the median for these values. Readers are advised to look at minimum and maximum values with the caution that reference interval statistics have not been performed. Lymphocytes are retained so that readers note that animals with a significant stress response are included in these values. It is possible that anemic animals were included in this population. Communication from the Journal of Veterinary Clinical Pathology.

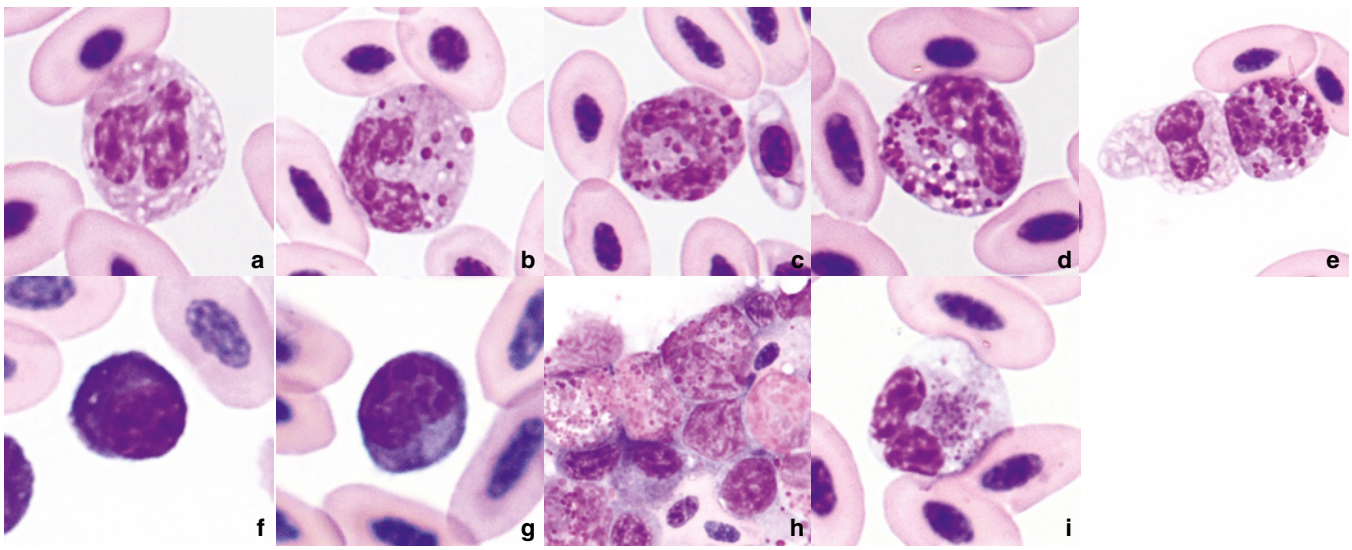

FIGURE 126.3 Abnormal WBC morphology. All images taken using 100× (oil) objective with modified Wright–Giemsa stain. (a)–(e) Toxic heterophils in red-tailed hawk (*Buteo jamaicensis*); (a) Mildly (1+) toxic heterophil; (b) Moderately toxic (2+) band heterophil; (c) Markedly toxic (3+) band heterophil; (d) Markedly toxic metamyelocyte; (e) Two variably toxic and immature heterophils; (f) Reactive lymphocyte in red-tailed hawk (*B. jamaicensis*); (g) Reactive lymphocyte in turkey vulture (*Cathartes aura*); (h) Bone marrow cytology with heterophilic hyperplasia in red-tailed hawk (*B. jamaicensis*); (i) *Chlamydia psittaci* in a toxic heterophil in red-tailed hawk (*B. jamaicensis*).

Nonregenerative anemia may be due to chronic/inflammatory disease, nutritional imbalance, viral infections, or chronic toxicosis and can be accompanied by hypochromasia. Anisocytosis and poikilocytosis are also seen in raptors with inflammatory disease.

Inflammation

Toxic changes in heterophils include sparse granulation, basophilic and/or foamy cytoplasm, and toxic granulation (small magenta-staining primary granules) (Figure 126.3a–e). Immature heterophils have

hyposegmented nuclei and are interpreted as a left shift when present (Figure 126.3). Heterophilia and increased heterophil:lymphocyte ratios are common in raptors with inflammatory disease and heavy-metal toxicosis. Monocytosis is common in subacute to chronic infectious and inflammatory disorders. Reactive lymphocytes have expanded pale to deep blue cytoplasm (Figure 126.3f,g) and may be plasmacytoid with perinuclear clearing. Bone marrow evaluation may be performed ante mortem or at fresh necropsy to assess the etiology of hematologic changes (Figure 126.3h).

Common Disease Conditions

Vultures (including condors) and bald eagles (*Haliaeetus leucocephalus*) are particularly prone to heavy-metal toxicoses due to carrion-scavenging behavior, but numerous nonscavenger raptor species are also affected. Experimental lead toxicosis induced in turkey vultures (*Cathartes aura*), Andean condors (*Vultur gryphus*), and other raptor species resulted in a substantial drop in PCV.[32] Marked reticulocytosis and basophilic stippling of RBCs are inconsistently reported possibly due to the stage of toxicosis, the blood smear staining and fixation method, and prolonged exposure to anticoagulants such as EDTA.[26] Hypochromasia, poikilocytosis, microcytosis, increased circulating immature erythroid cells, and bone marrow dyserythropoiesis are also reported in lead-poisoned birds (Figure 126.1e,f). Asymmetric cytoplasmic enlargement, aka ballooning or D cells, can be noted. Similar findings including hypochromasia, reticulocytosis, and dyserythropoiesis have been seen by the author and the editor with zinc toxicosis, presumably due to functional iron deficiency.

Methylmercury poisoning can occur in aquatic and piscivorous birds due to environmental contamination. As apex predators, raptors are vulnerable to secondary mercury poisoning with substantial accumulated concentrations due to the high bioavailability of mercury in consumed prey.[12] Experimental dosing of kestrels resulted in increased heterophil and total WBC concentrations, with heterophil counts exceeding reference intervals in the higher-dose group. Additionally, similar species may be exposed to petroleum toxicants after oil spills when bioaccumulation will occur. Petroleum intoxication causes anemia and WBC dyscrasia in all species of birds studied to date.[30] Heinz body hemolytic anemia has been identified in both natural and experimental petroleum exposure of birds; ultrastructural evaluation was required for accurate identification of avian Heinz bodies.[13,16]

Chlamydia psittaci is a gram-negative, obligate intracellular bacterium in the order Chlamydiales and the family Chlamydiaceae. Infection occurs in many avian species and is called chlamydiosis, previously termed ornithosis or psittacosis. *C. psittaci* was previously categorized by some in the controversial genus *Chlamydophila* along with other organisms, but reunification under the single genus *Chlamydia* is now generally accepted.[40] *Chlamydia avium* and *Chlamydia gallinacea*, two recently described infectious agents in poultry, pigeons, and psittacines, are not reported yet in raptors.[41] Clinical signs involve the respiratory and gastrointestinal tracts, e.g., anorexia, nasal discharge, coughing, dyspnea, and diarrhea. Hematologic abnormalities are not specific and indicate severe chronic inflammation, including heterophilia with evidence of left shift and minimal toxicity and monocytosis. Mild nonregenerative anemia consistent with anemia of chronic disease is typical. The infectious stage of *Chlamydia*, the elementary body, is approximately 0.2–0.3 μm in diameter. Host cells internalize the elementary bodies into membrane-bound vacuoles where they differentiate into coccoid to pleomorphic reticulate bodies approximately 0.6–1.0 mm in diameter. Chlamydial microcolonies then form via binary fission of reticulate bodies. Reticulate bodies subsequently transform into elementary bodies. Stains such as Giemsa, Gimenez, Macchiavello, methylene blue, and modified Ziehl–Neelsen can be used to detect chlamydial inclusions in smears or swabs. Elementary bodies are small, red/purple inclusions using Giemsa stain; larger, deep blue staining inclusion bodies may be seen in mononuclear cells or heterophils using Giemsa stain in blood smears or tissue samples (Figure 126.3i).[19] PCR is recommended as the most sensitive test for chlamydiosis, though quality assurance statistics will vary with primer sets.

Aegyptianella pullorum is a rickettsial infection that is most closely related to *Anaplasma sp*.[38] Argasid (soft) ticks serve as the biologic vector. Intraerythrocytic inclusions appear as smaller rounded, basophilic inclusions or as larger clusters or morulae composed of tiny cocci. Clinical disease due to *Aegyptianella*, including anemia, weakness, and hepatosplenomegaly, are described in several avian species, but reports of clinical disease in raptors are sparse.[45,46]

Aspergillus sp. infection is reported in numerous raptor species, with gyrfalcons (*Falco rusticolus*), immature red-tailed hawks (*Buteo jamaicensis*), goshawks (*Accipiter gentilis*), golden eagles (*Aquila chrysaetos*), bald eagles, and rough-legged hawks (*Buteo lagopus*) potentially more susceptible to clinical illness; prairie falcons (*Falco mexicanus*) and Harris's hawks (*Parabuteo unicinctus*) may be more resistant.[21] Concurrent disease and immunosuppression can predispose birds to clinical aspergillosis; lead poisoning of bald eagles and other raptor species is one example. Clinical illness may present either acutely or as a more chronic onset of clinical signs that can include dyspnea, exudative rhinitis, keratitis and periorbital swelling, and unilateral wing droop. Right ventricular dilation due to pulmonary hypertension may be detected during imaging with ascites and/or pulmonary congestion as potential sequelae. The typical hematologic profile reported with fungal infection of raptors is a mild to moderate nonregenerative anemia and leukocytosis characterized by moderate to severe heterophilia and monocytosis, with lymphocyte counts normal to decreased. Immature heterophils (left shift) can be seen, and increased plasma protein concentration, likely due to antibody production, is also reported. These hematologic abnormalities are nonspecific to

aspergillosis and other infectious/inflammatory disorders cannot be excluded. Additionally, immunosuppressed birds may have hypoproteinemia and lack leukocytosis.[5]

Coagulopathy

In avian species, coagulopathy is most commonly documented in raptors and usually due to intoxication (petroleum, heavy metals, rodenticides, other), though infectious causes and disseminated intravascular coagulation are possible (see Chapter 95). Anticoagulant rodenticides are a well-described threat to raptor species through both primary and secondary exposure routes. Biological action differs substantially between groups of anticoagulant rodenticides. The first-generation compounds include warfarin, chlorophacinone, and diphacinone. The need for multiple feeding exposures of these compounds for lethal toxicity led to the development of resistance in target rodent species. Second-generation anticoagulant rodenticides (e.g., brodifacoum, bromadiolone, difethialone, difenacoum, and flocoumafen) were subsequently developed and require only a single feeding exposure to kill target rodents. Potential for bioaccumulation in predatory wildlife differs by specific rodenticide type, with lower bioaccumulation risk for first-generation compounds and bromadiolone and flocoumafen, and higher risk for difethialone, difenacoum and brodifacoum.[36] Lower LD50 (median lethal dose) for a second-generation compound (brodifacoum) versus a first-generation compound (diphacinone) is reported in raptor species.[29] Of note, avian metabolism of anticoagulant rodenticides differs from that of mammals, and raptors (particularly owls) appear to have greater risk of bioaccumulation and toxicity due to limited detoxification ability.[35,48]

Anticoagulant rodenticide poisoning of raptors can result in hemorrhagic shock and blood-loss anemia with severe decreases in PCV and plasma protein.[28] Unlike mammalian species, a minority of poisoned birds present with excessive bleeding from minor wounds or pulmonary hemorrhage.[43] Confirmation of coagulopathy may be attempted clinically using either a whole-blood clotting time or activated clotting time. In rodenticide-poisoned birds, clotting times of 27 minutes and >60 minutes are reported (RI = 2–10 minutes).[28] Prothrombin time measurement can also be diagnostic for sub-lethal rodenticide poisoning, but avian-specific reagents and species-specific reference intervals are needed.[18] With appropriate medical support including vitamin K supplementation, PCV and plasma protein values steadily recover. PCV may normalize within a week's time.

Hemoparasites

Raptors are commonly infested with one or more hemic parasites depending on species and geographic location. The following parasites are commonly found in the peripheral blood of free-ranging raptors, though captive raptors may also have parasite burden.

Leukocytozoon is an apicomplexan parasite in the order Achromatorida, family Leucocytozoidae. *Simulium sp*. black flies serve as the definitive host of this avian parasite. Sporozoites are transmitted during insect feeding on birds and infect hepatocytes to become first trophozoites, then schizonts progressing to merozoites. Endothelial cells may also become infected at this stage. Merozoites then infect (a) macrophages and endothelial cells to become megaloschizonts, progressing through cytomere, schizont, and merozoite stages; and (b) circulating blood cells to become gametocytes. The gametocyte "sail" stage markedly distorts the host cell, impairing cell identification (Figure 126.4a–c). Staining differences between male and female gametocytes may be noted.[37] Organisms in both RBCs and WBCs are reported, and highly deformed, infected host cells typically appear to have nonlobulated nuclei. Interestingly, *Leukocytozoon sabrazesi* has been shown to infect thrombocytes.[50] A smaller, spherical form of *Leukocytozoon* organisms may also be seen in blood cells. While *Leukocytozoon* is often ubiquitous and nonpathogenic in adult raptors, it can cause intravascular hemolytic anemia and immature raptors tend to have heavier parasite burdens.[22] Hepatosplenomegaly and granulomatous inflammation have been reported in various avian species.[47] Combined hemoparasite infestations including *Leukocytozoon* have had severe consequences in raptors such as snowy owls (*Bubo scandiacus*).[11]

Hemoproteus is an apicomplexan parasite in the order Hemosporidia, family Hemoproteidae. Hemoproteus species identified in raptors include *Hemoproteus noctuae*, *Hemoproteus syrnii*, and *Hemoproteus tinnunculi*; infestation is most commonly reported in Strigiformes.[22] Avian *Hemoproteus* infection is frequently reported as an incidental finding and historically has been considered nonpathogenic in many avian species, but *Hemoproteus*-associated disease has been reported in several raptor species including snowy owls and goshawks.[24] As with other hemic parasites, *Hemoproteus* has the potential to cause anemia.[7] Deleterious clinical effects may be subtle, e.g., infestation is negatively correlated with weight in female American kestrels (*Falco sparverius*).[2] Treatment of a naturally infected population of female blue tits (*Cyanistes caeruleus*) resulted in increased survival to the next breeding season;[34] long-term effects on breeding and fitness may occur in raptors as well. The degree of parasitemia may reflect immune status in raptors, as reduction in parasite burden can occur following recovery from injury or illness.[8] Blood-sucking insects serve as both mechanical vectors and biologic intermediate hosts. Insect vectors inoculate sporozoites during feeding on birds; sporozoites develop into schizonts in numerous tissues including vascular endothelium, muscle, heart, spleen, and liver. Released merozoites can reinfect tissues becoming secondary schizonts or infect RBCs to become gametocytes. Pigmented gametocytes can be detected in peripheral blood smears where they appear as elongated structures, either microgametocytes or macrogametocytes. They occupy more than half of RBC cytoplasm and often wrap slightly around the erythrocyte nucleus, though typically the nucleus is still aligned along the axis of the cell (Figure 126.4d–f).[27] In aged or stored blood,

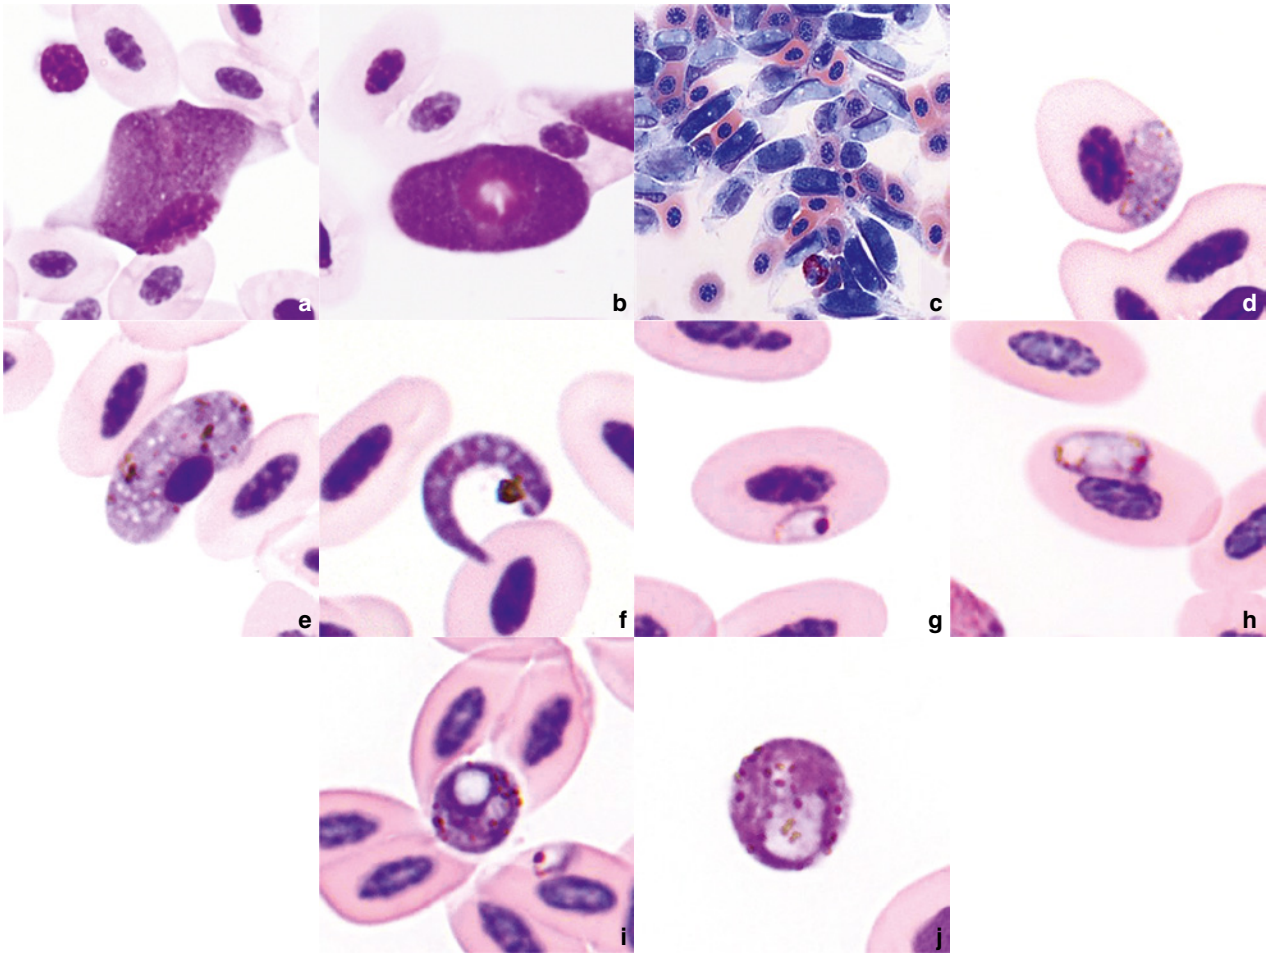

FIGURE 126.4 Hemic parasites in raptor species. All images taken using 100× (oil) objective with modified Wright–Giemsa stain. (a) and (b) *Leukocytozoon sp*. (Cooper's hawk, *Accipiter cooperii*); (c) *Leukocytozoon sp*. in owlet blood smear (barn owl, *Tyto alba*); (d)–(f) *Hemoproteus sp*. (American kestrel, *Falco sparverius*); (g)–(j) *Plasmodium sp*. (short-eared owl, *Asio flammeus*). (**Source:** Image (c) courtesy of Dr. Kendal Harr.)

gametocytes can appear in blood smears as either round and/or elongated extracellular structures (Figure 126.4f).[7]

Plasmodium is an apicomplexan parasite in the order Hemosporidia, family Plasmodiidae. Over 200 species of *Plasmodium* are characterized. *Plasmodium* infestation occurs in many avian species including various raptor species and is often reported as an incidental finding, but infection can be lethal especially to nonadapted species. Fatal hemolytic anemia caused by *Plasmodium relictum* infection is reported in raptors, with falcons (e.g., gyrfalcons) particularly affected.[22,37] Concurrent disease or immunosuppression (e.g., from captivity stress) may worsen parasitism levels. Conversely, parasitism may worsen immune compromise leading to co-infection. For example, in several captive snowy owls, *Plasmodium* was hypothesized to contribute to fatal outcome following infection with West Nile virus, due to impairment of T-cell function.[15] In a common buzzard (*Buteo buteo*) presenting for an open humeral fracture, severe *Plasmodium* parasitism was found with associated morbidity, including anemia and marked intraperitoneal hemorrhage due to splenic rupture.[14] *Culex sp*. mosquitoes are the primary insect vectors and serve as an intermediate host. In the initial stage of infection, an infected female mosquito feeding on a bird transmits *Plasmodium* sporozoites that parasitize host tissues and replicate into schizonts. The resulting merozoites infect RBCs, WBCs, and thrombocytes to become trophozoites that can mature into schizonts and gametocytes. Any or all of these stages may be seen in peripheral blood smears (Figure 126.4g–j). Gametocytes are irregularly rounded to elongated, often contain golden-brown granular iron pigment, and frequently displace the RBC nucleus. Trophozoites frequently contain a large vacuole that displaces the parasite nucleus eccentrically, resulting in the characteristic signet-ring morphology. Schizonts are rounded structures that contain fused to individual merozoites.

Babesia is an apicomplexan parasite in the order Achromatorida, family Babesiidae. Scattered reports of babesiosis in raptors describe infection with either of two species: *Babesia shortti*, potentially specific to

Falconidae, and *Babesia moshkovskii*, potentially specific to Accipitridae. Infestation may be subclinical, but fatalities are reported in several falcon and kestrel species; co-infection is often reported as a contributor to morbidity.[37] Ixodid ticks are presumed to serve as a biological vector. Sporozoites are transmitted from tick salivary glands during feeding and directly infect RBCs, becoming trophozoites. Trophozoites develop into merozoites, lysing-infected host cells in the process and releasing extracellular merozoites to infect additional RBCs. In peripheral blood smears, organisms appear as small, rounded to piriform inclusions that lack pigment.

Isospora (*Atoxoplasma*) is a coccidian parasite transmitted via the fecal–oral route. *Atoxoplasma* is now considered a junior objective synonym of *Isospora* and the genus name *Isospora* is recommended for use.[4] *Isospora* is a rare diagnostic finding in raptors and has been reported in spotted owls (*Strix occidentalis*).[31,37] Infestations are often fatal in passerine birds, but the pathogenicity is currently unknown in raptors. Following ingestion of sporulated oocysts by the avian host, organisms enter the bloodstream via the intestinal vasculature and infect mononuclear WBCs. Schizogony occurs in both tissue and circulating mononuclear cells, as well as in intestinal epithelial cells. They may be found in peripheral blood smears as rounded, pale-staining inclusions indenting the host cell nucleus.

Immature microfilariae may be noted extracellularly in peripheral blood smears from raptors, but are usually considered to be nonpathogenic.

Trypanosomes are unicellular, flagellated protozoa that may be found extracellularly in blood smears. A variety of blood-sucking arthropods serve as biological vectors for different *Trypanosoma* species. No clinical importance is currently ascribed to infection in raptors. Co-infection is more common with other microorganisms transmitted by *Simulium sp.*; thus, those that share the same insect vector.[44]

INTRODUCTION

The term ratite is a functional classification of birds that are flightless and have evolved with skeletal characteristics in which a keel is absent on the sternum, as there are no major flight muscles that require attachment. Taxonomically, these birds represent four orders within the Aves; namely, Apterygiformes, Casuariiformes, Rheiformes, and Struthioniformes. Tinamiformes are also considered by some authors to be ratites, but have not been considered in this chapter. Within these four orders, the International Union for Conservation of Nature (IUCN) currently recognizes five kiwi species, three cassowary species, three rhea species, two ostrich species, and a single species of emu[3] (Table 127.1). Each of these groups of ratites occurs naturally in distinct geographic regions with kiwi being restricted to New Zealand, cassowary to New Guinea and far north Australia, rhea to South America, ostrich to Africa, and emu to mainland Australia.

Several ratite species have been commercially produced. A boom in the farming, and associated value, of these birds occurred in the 1990s, which has subsequently subsided.[4] Many of these species are also held in zoological collections throughout the world. Consequently, hematologic assessment of ratites may be undertaken for health assessment of individuals or of a flock.

BLOOD COLLECTION AND HANDLING

Blood collection from ratites requires assessment of the species, situation, and in all instances the safety of the operator should be a paramount consideration. The large adult size and fractious nature of many ratites often necessitates chemical immobilization to allow safe blood collection.[21,32] Blood may be collected from standing, hooded, habituated ostriches with minimal physical restraint, from the brachial vein on the medial wing surface. Alternatively, blood can be collected from the medial metatarsal or jugular vein. The latter has been used to collect blood from emus physically restrained in sternal recumbency. In large adult ratites, blood is collected using a 21-gauge, 1-inch needle or 21-gauge butterfly catheter. In smaller ratites and juveniles of larger species, the jugular vein is the preferred site for venipuncture[4] using a 23–25-gauge needle. In most ratite species, blood volume is not a limiting factor with rhea weighing up to 25 kg, emu up to 55 kg, and ostrich up to 150 kg.[21]

EDTA causes hemolysis of ostrich blood and has been reported to cause hemolysis in other ratite species.[18] Consequently, EDTA is not recommended as an anticoagulant for ratites with the preferred anticoagulant being 3.2% buffered sodium citrate solution (blue top vacutainer tube), with the correct ratio of 1:9 anticoagulant to blood and correction for the dilution effect that liquid anticoagulant has on subsequent analyses. Alternatively,

TABLE 127.1 Bird species considered to be ratites.

Common name	Scientific name	Order
Southern brown kiwi	*Apteryx australis*	Apterygiformes
North Island brown kiwi	*Apteryx mantelli*	Apterygiformes
Little spotted kiwi	*Apteryx owenii*	Apterygiformes
Great spotted kiwi	*Apteryx haastii*	Apterygiformes
Okarito kiwi	*Apteryx rowi*	Apterygiformes
Northern cassowary	*Casuarius unappendiculatus*	Casuariiformes
Southern cassowary	*Casuarius casuarius*	Casuariiformes
Dwarf cassowary	*Casuarius bennetti*	Casuariiformes
Emu	*Dromaius novaehollandiae*	Casuariiformes
Greater rhea	*Rhea americana*	Rheiformes
Lesser rhea	*Rhea pennata*	Rheiformes
Puna rhea	*Rhea tarapacensis*	Rheiformes
Common ostrich	*Struthio camelus*	Struthioniformes
Somali ostrich	*Struthio molybdophane*	Struthioniformes

heparin can be used as an anticoagulant; however, it typically interferes with staining and causes leukocyte clumping.[4] In all instances, it is recommended that blood smears be made immediately after blood collection to maintain the optimal morphology of ratite hematologic cells. A range of Romanowsky stains have proven suitable for staining blood films of ratites.

Analysis of blood should be undertaken according to standard techniques for handling avian blood.[6,7] Automated analysis is complicated, as with all avian samples, by nucleated erythrocytes (RBCs) and thrombocytes, as well as nucleated leukocytes (see Chapter 123).

ERYTHRON

Ratite RBCs, when examined using Romanowsky-stained blood films and light microscopy, are ovoid cells containing a centrally located ovoid nucleus composed of dense, darkly staining (dark blue-purple) chromatin and a moderate amount of evenly colored eosinophilic cytoplasm (Figure 127.1). Erythrocytes have an average length of 13.3–16.2 µm and width of 7.5–11.3 µm in the common ostrich,[26–28] the greater rhea,[14] and the emu.[11] Blood film examination of most ratites reveals a small proportion of polychromatophilic RBCs and occasional rubricytes.[4,15] Additional variant RBCs[9] have been reported in health including binucleated RBCs from a greater rhea,[14] anucleated RBCs (erythroplastids) from the southern cassowary and emu,[8] and multinucleated RBCs from a North Island brown kiwi.[19]

LEUKON

Ratite leukocytes (WBCs), when examined using Romanowsky-stained blood films and light microscopy, exhibit the general types of avian leukocytes; namely, heterophils, lymphocytes, monocytes, eosinophils, and basophils (Figures 127.2 and 127.3). The average length and width for heterophils are 13 × 12 µm (emu[11]) and 13 × 12 µm (greater rhea[14]); for lymphocytes 9 × 8 µm (emu) and 9 × 7 µm (greater rhea); and for monocytes 12 × 11 µm (emu) and 16 × 13 µm (greater rhea).

Heterophils are the most commonly encountered leukocyte in ratites. Typically, heterophils are irregularly round leukocytes with a lobed, basophilic nucleus and prominent acidophilic cytoplasmic granules. The nucleus is strongly basophilic (blue to purple) when adequately stained, but may exhibit an aqua-blue color with inadequate staining; and is commonly partially obscured by the presence of cytoplasmic granules. The cytoplasm contains robust, fusiform, red granules that are typically evenly distributed at moderate to high density. In some heterophils, these granules may exhibit a refractile central body in the granule's mid-section. There are no significant distinguishing differences in heterophil morphology between ratite species (Figures 127.2a and 127.3a,c,e).

Lymphocytes are usually the second most commonly encountered leukocyte in ratite blood. Morphologically, lymphocytes may vary in appearance. Typical small lymphocytes are the smallest WBC and have a round nucleus composed of dense, coarsely clumped chromatin, and a small, often incomplete cytoplasmic rim that is moderately to deeply basophilic. Larger and more variably shaped lymphocytes may also be encountered in the blood of healthy birds. These larger lymphocytes may be similar in size or larger than granulocytes and approach the size of monocytes. They have an irregularly round nucleus composed of moderately dense, irregularly clumped chromatin with a moderate amount of agranulated, moderately basophilic cytoplasm. Some lymphocytes may exhibit several punctate, azurophilic to basophilic cytoplasmic granules (Figures 127.2d,e and 127.3a). There are no significant distinguishing differences in lymphocyte morphology between ratite species.

Ratite monocytes are large, pleomorphic leukocytes with nuclei that may be ovoid, indented, horseshoe, or irregularly shaped and composed of fine to reticular chromatin. There is typically a moderate to large amount of gray to basophilic cytoplasm. Granules are typically not evident in the cytoplasm; however, small eosinophilic granules may be observed in some cells. One to several small vacuoles may be evident in the cytoplasm of some monocytes (Figure 127.2b). Although monocyte morphology in an individual's blood is often quite varied, there are no significant distinguishing differences in monocyte morphology between ratite species. As monocytes and large lymphocytes have a similar size and morphologic appearance when viewed in Romanowsky stained blood films, it may be difficult to distinguish between these two WBCs.

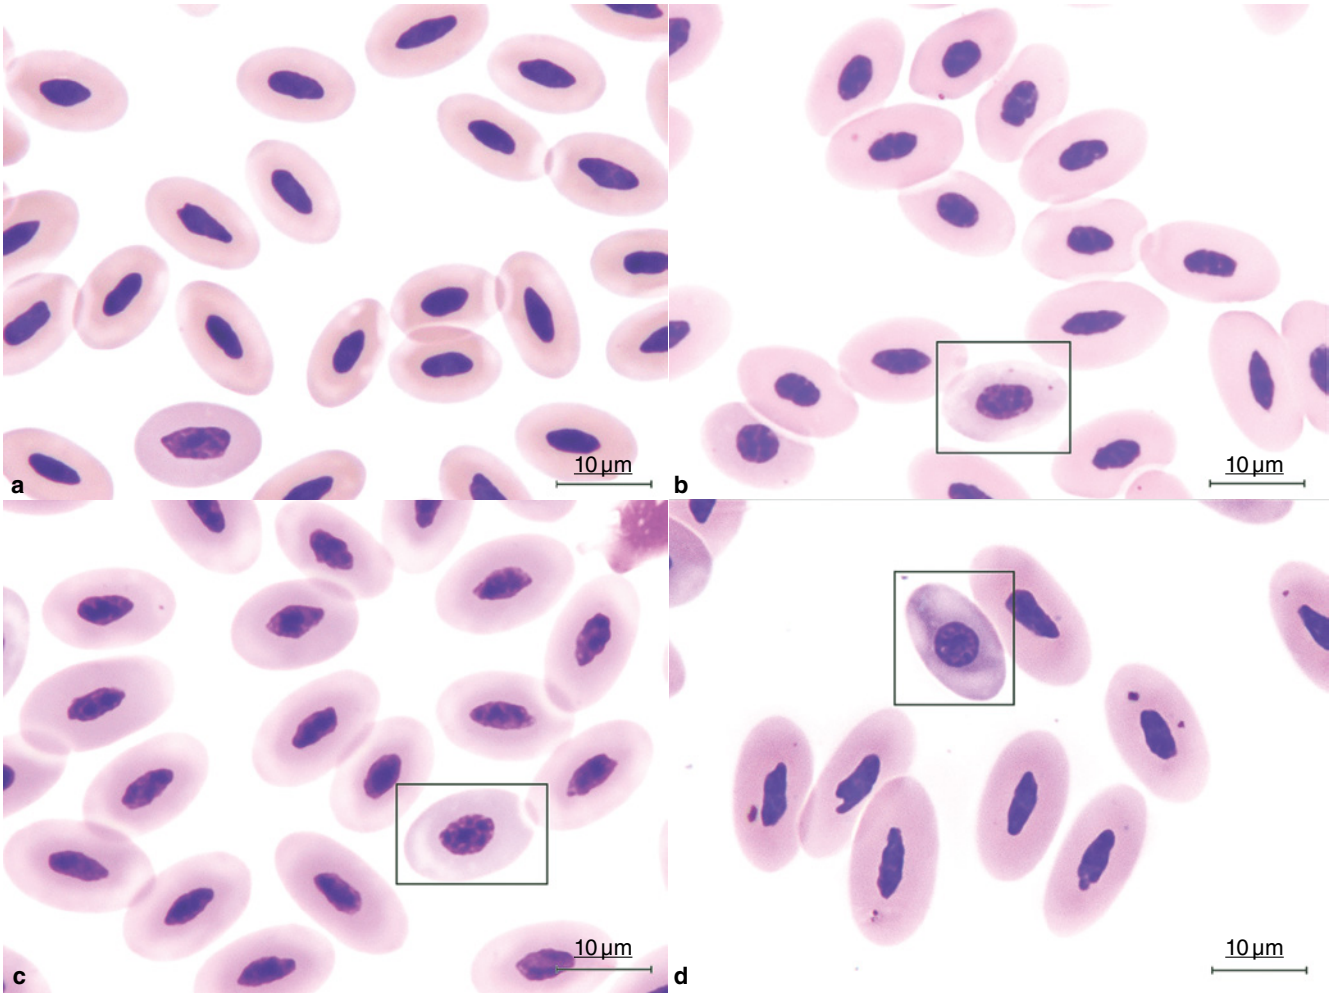

FIGURE 127.1 Erythrocytes. (a) Greater rhea (*Rhea americana*) erythrocytes with mild overlap; (b) Common ostrich (*Struthio camelus*) erythrocytes; (c) Emu (*Dromaius novaehollandiae*) erythrocytes; (d) Southern cassowary (*Casuarius casuarius*) erythrocytes. Bar = 10 µm. Boxes indicate polychromatophilic erythrocytes. Modified Wright's stain.

Eosinophils are far less commonly encountered in ratite blood than heterophils. Typically, eosinophils are irregularly round leukocytes with a lobed, basophilic nucleus and brightly acidophilic cytoplasmic granules. Eosinophils typically have two to three nuclear lobes that are partially obscured by cytoplasmic granules and commonly exhibit more darkly stained chromatin than the chromatin of adjacent heterophils. The cytoplasm is moderately basophilic and contains a moderate to high density of round to ovoid cytoplasmic granules that are more brightly eosinophilic than heterophil granules. Overall, eosinophils have a similar appearance in all ratite species with subtle variation in the shape and hue of the cytoplasmic granules (Figures 127.2c and 127.3d,f).

Typically, ratite basophils are irregularly round with prominent darkly staining, purple to black, round to ovoid basophilic granules that obscure the cytoplasm and much of the nucleus of the cell. When apparent, the basophilic chromatin of the nucleus often appears pale in comparison to the color of the cytoplasmic granules. However, in some birds, granules may fail to stain. In these cases, basophils exhibit regular, round vacuoles (or nonstaining granules) in a pale cytoplasm with occasional basophilic granules. In such cases, the round to ovoid or bilobed nucleus is apparent and composed of moderately dense chromatin. There are no significant distinguishing differences in basophil morphology between species of ratites (Figure 127.3b,c).

Leukocyte ultrastructure has been described for the ostrich.[5] Notably, heterophils had two granule types, type I were fusiform and type II had heterogenous shape and density and were smaller than type I. Ostrich eosinophils exhibited three granule types with the most common type being round in shape. The nucleus of both these acidophils was composed of peripheral heterochromatin and central euchromatin. Basophils were not observed in this study. Lymphocyte and monocyte ultrastructure revealed a similar distribution of peripheral heterochromatin in the nucleus of both cell types; however, monocytes had more invaginations of the membrane.

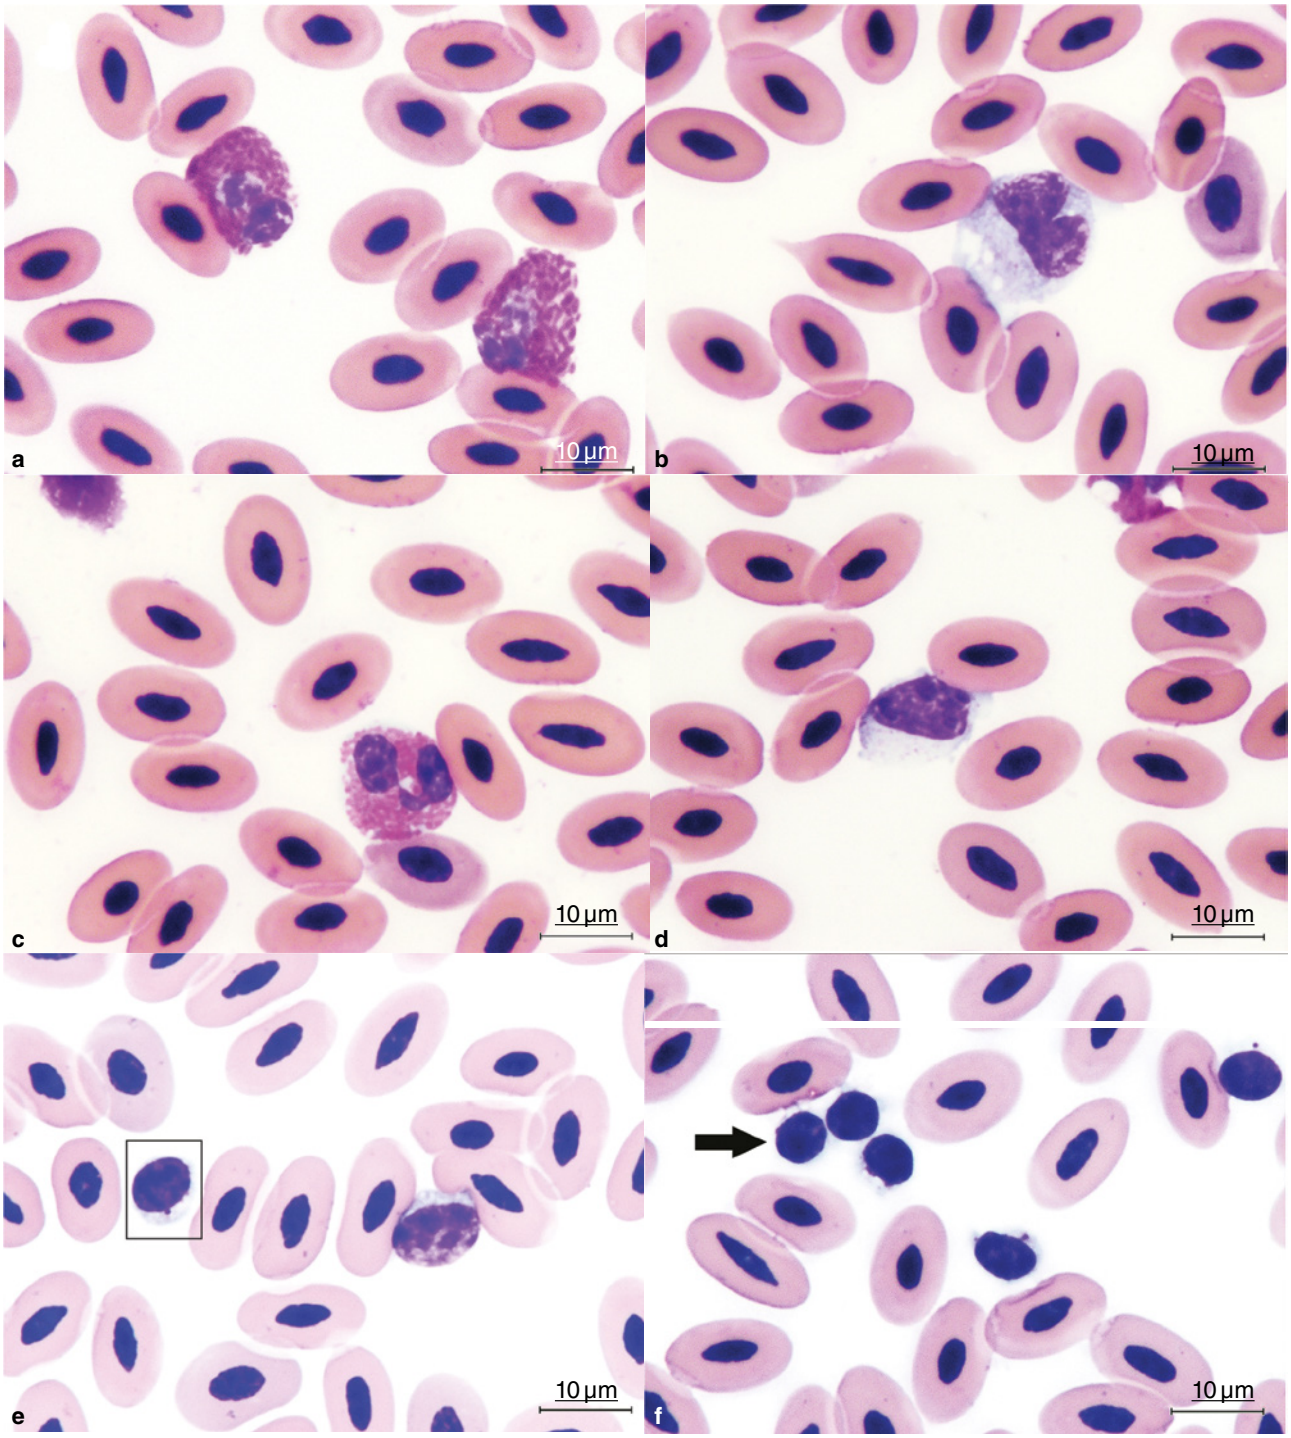

FIGURE 127.2 Hematologic cells from a common ostrich (*Struthio camelus*). (a) Two heterophils are shown amid RBCs; (b) A monocyte is portrayed amid RBCs; (c) An eosinophil is illustrated amid RBCs; (d) A lymphocyte is present amid RBCs; (e) A thrombocyte (box) and lymphocyte are demonstrated amid RBCs; (f) An aggregate of three thrombocytes (arrow) and two individual thrombocytes are evident amid RBCs. Bar = 10 µm. Modified Wright's stain.

THROMBON AND COAGULATION

Ratite thrombocytes, when examined in Romanowsky-stained blood films using light microscopy, are small, round or elongated, nucleated cells (Figure 127.2). The nucleus is either rounded or fusiform, reflecting the overall shape of the cell, composed of very dense chromatin giving a darkly basophilic, almost black appearance. A small amount of colorless to palely basophilic cytoplasm may be present in a thin rim around the rounded cells or tapers along the long axis of the fusiform cells. In some cases, fine cytoplasmic projections (pseudopodia) may be evident. Several small, punctate, eosinophilic, or azurophilic granules may be observed in

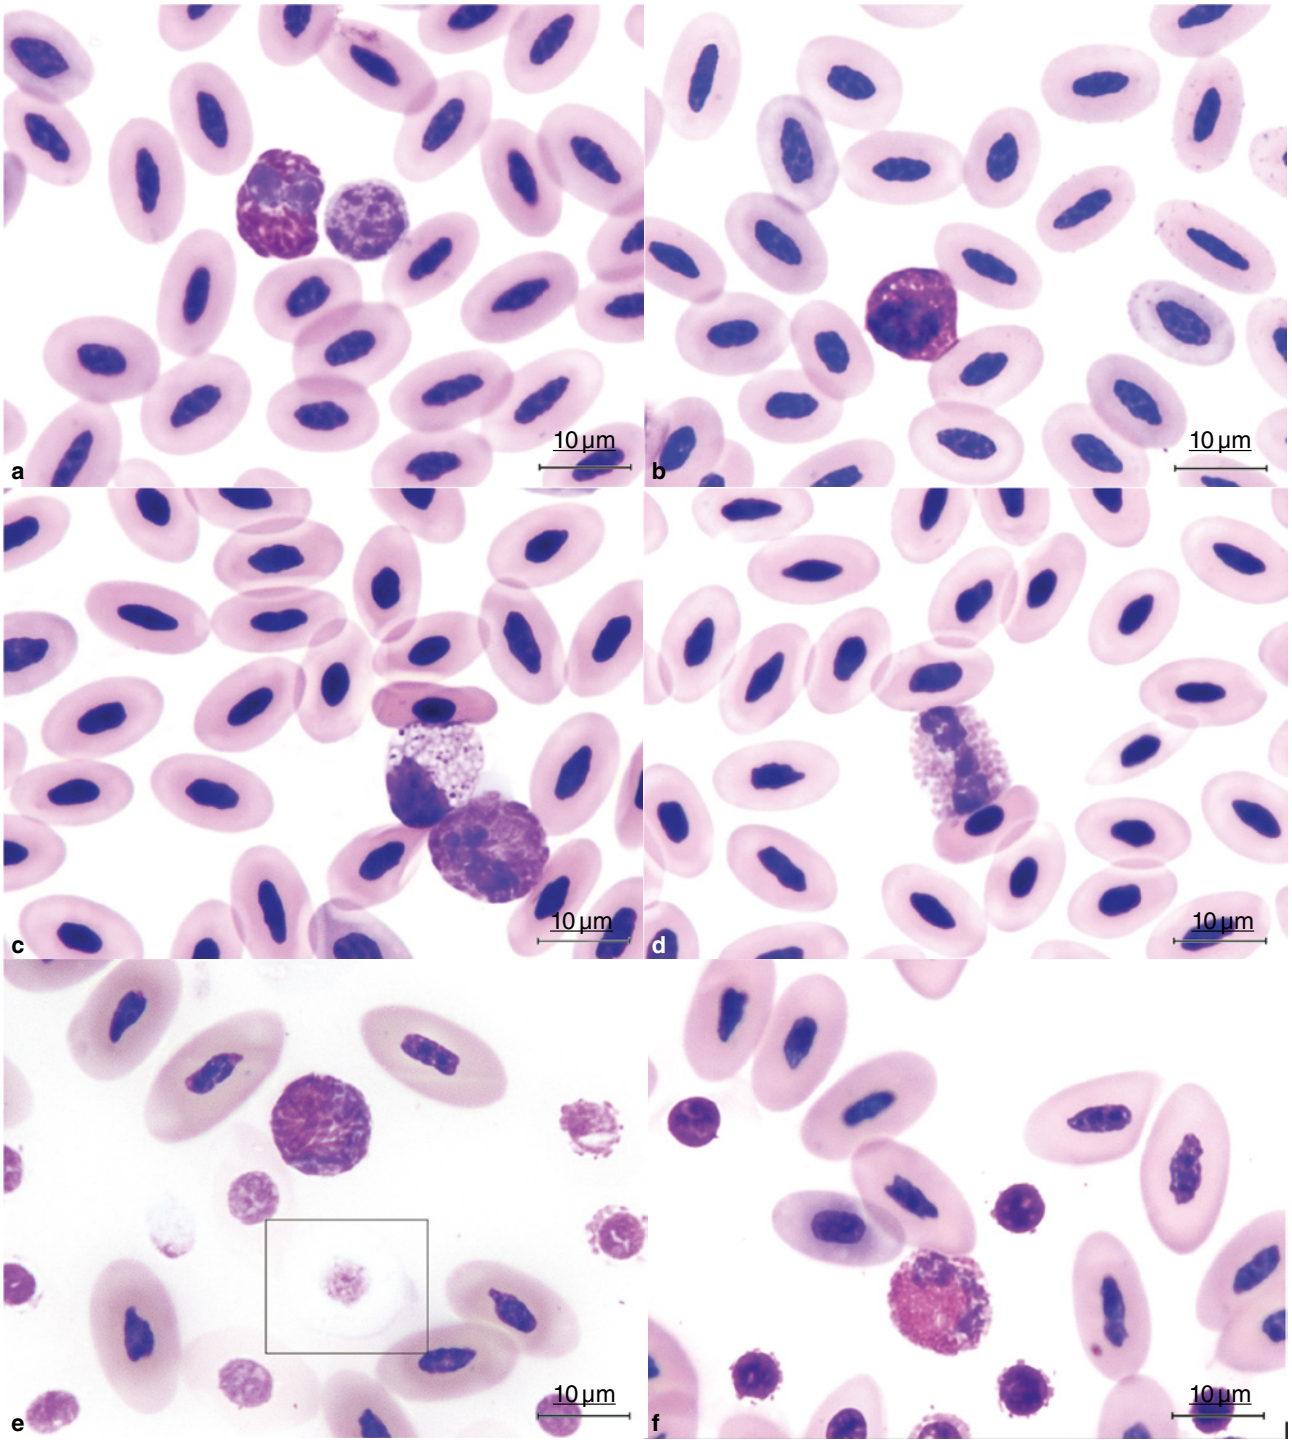

FIGURE 127.3 Comparative morphology of hematologic cells from ratites. (a) Blood from an emu (*Dromaius novaehollandiae*) showing a heterophil and lymphocyte amid erythrocytes; (b) Blood from an emu (*D. novaehollandiae*) showing a basophil amid erythrocytes. Note the dense basophilic cytoplasmic granules; (c) Blood from a greater rhea (*Rhea americana*) showing a basophil and a heterophil amid erythrocytes. Note the small number of basophilic granules and the large number of clear vacuoles or nonstaining granules evident in the basophil; (d) Blood from a greater rhea (*R. americana*) showing an eosinophil amid erythrocytes; (e) Blood from a southern cassowary (*Casuarius casuarius*) showing a heterophil amid erythrocytes including lysed cells devoid of hemoglobin (one illustrated by a box); (f) Blood from a southern cassowary (*C. casuarius*) showing an eosinophil amid erythrocytes and lysed cells. Bar = 10 µm. Modified Wright's stain.

the cytoplasm of some thrombocytes (Figure 127.2e,f). Importantly, individual thrombocytes must be distinguished from small lymphocytes. Typically, individual thrombocytes have a chromatin pattern that is more homogeneous and darker than that of lymphocytes; while thrombocyte cytoplasm is less basophilic than that of lymphocytes. Commonly, thrombocytes become aggregated during collection, transport, and storage.

Large aggregates at the leading edge of blood films or small aggregates distributed throughout the body of the blood film can be identified. Distinct, individual cell outlines may be difficult to discern in these aggregates.

REFERENCE INTERVALS

Most published studies on ratite hematology predate current American Society For Veterinary Clinical Pathology (ASVCP) guidelines for reference intervals and are not generated as medical reference intervals. Hematology data for some hematologic analytes have been published for a number of ratite species including the common ostrich,[4,26,28,31,34] emu,[24] southern cassowary,[34] lesser rhea,[30] greater rhea,[4,14,37] and three species of kiwi.[25]

Hematologic values are broadly similar across ratite species. Observed differences may be due to species as well as a range of preanalytical, analytical, and postanalytical factors.

The general characteristics of birds are typified by the mean erythrocyte values determined for 1240 individual birds encompassing 204 species which found an average PCV of 0.46 L/L, an average mean corpuscular volume (MCV)of 169 fL, and an average RBC concentration of 2.79×10^{12}/L.[17] In comparison to these general values, adult ratites are reported to have lower numbers of larger erythrocytes that result in an average PCV that is similar to the general avian average of 0.46 L/L. Ratite leukocyte values are characterized by a heterophil predominance with lesser numbers of lymphocytes and small numbers of monocytes, eosinophils, and basophils. It is rare for studies to report an accurate thrombocyte concentration due to the very common phenomenon of aggregation (clustering) affecting the accuracy of counts.

A number of physiologic partitioning factors have been reported to affect hematologic characteristics, including age, sex, and season.[7] However, it may be difficult to isolate the effect of a single physiologic factor; e.g., age, season, and nutrition may all be interrelated. The effect of age on hematologic values has been reported for the common ostrich by several authors.[26,31] Common ostrich chicks had a mean PCV of 0.37 L/L compared to adults that had a mean PCV of 0.48 L/L.[28] In contrast to some birds,[7] differences in hematologic values were not observed between sexes for emu[24] or lesser rhea.[31] Interestingly, two male emus, while incubating eggs, had a decrease in hematocrit from 0.57 to 0.47 L/L and 0.54 to 0.46 L/L, respectively.[4,10] In 2011, Samour et al.[31] reported increased total leukocyte concentration in ostrich chicks from $11.9 \pm 0.7 \times 10^9$/L at 1 month to $23.0 \pm 1.1 \times 10^9$/L at 12 months of age. By contrast, no statistical difference in total leukocyte concentration or heterophil concentration was detected for greater rhea; however, lymphocyte concentration was greater in juvenile birds.[31]

HEMATOLOGIC DISEASE

The hematologic response to disease is complex and depends on the inciting cause, magnitude, and duration of the disease process, as well as the bird's intrinsic hematologic characteristics and its ability to respond to a particular challenge. Notably, the effect of transport as a stressor of ratites has been investigated[2] with an increase in the heterophil:lymphocyte ratio (H:L) noted post-transport. While there have been a number of studies that documented hematologic values of ratites in health, there have been few published reports of the hematologic response to disease by ratites. Consequently, there are many ratite diseases that are yet to have the hematologic characteristics fully documented.

Anemia has been observed as the sole hematologic abnormality and also with other hematologic changes; notably with increased WBC concentration. Lesser rheas infested with the nematode, *Deletrocephalus dimidiatus*, had anemia (0.22 L/L) as the sole abnormality.[12] An emu with mucopolysaccharidosis IIIB had anemia (0.28 L/L), leukocytosis (33.6×10^9/L), heterophilia, and lymphocytosis.[15] A rare case of leukemia/lymphoma in an emu presented with an anemia (0.17 L/L) and an associated leukocytosis (112.6×10^9/L) including lymphocytosis (47.3×10^9/L) and many immature cells (54.0×10^9/L).[16]

Inflammation in ratites spans diverse etiologies, illustrating that ratites mount an effective leukocyte response often with significantly increased heterophil concentrations. An emu with a tarsometatarsal sequestrum and osteomyelitis following blunt trauma to its leg initially had a total WBC concentration of 41.7×10^9/L that subsequently increased to 68.9×10^9/L and then decreased after surgical removal of the bone fragments.[36] An emu infected with the bacteria, *Erysipelothrix rhusiopathiae*, had a total WBC concentration of 50.0×10^9/L with marked toxic changes in the heterophils and bacteria evident on blood smear evaluation.[20] Emus with encephalitis due to a filaroid nematode had total WBC concentrations of between 19.1 and 80.0×10^9/L.[22] A southern cassowary with serologic evidence of toxoplasmosis had a heterophil concentration (17.8×10^9/L) and a decreased lymphocyte concentration (0.6×10^9/L).[27]

In some cases, leukocytes may be consumed or sequestered at a severe inflammatory nidus, or not produced at all. Common ostriches with stomach impaction had a mean WBC concentration that was significantly less before (10.4×10^9/L) versus after (16.6×10^9/L) treatment.[40] Similarly, a common ostrich was reported with a leukopenia of 3.7×10^9/L and left shift with granule immaturity.[18] Exertional myopathy did not increase the total leukocyte concentration in emu[35] or greater rhea.[33]

HEMOPARASITES

A few hemoparasites have been recognized in ratite blood.[38] A number of hemosporidian species have been reported for Apterygiformes, Casuariiformes, Rheiformes, and Struthioniformes. *Leukocytozoon struthionis* has been described from Struthioniformes. Hemosporidians, yet to be identified to a species level, have been recognized in Casuariiformes and Rheiformes. Additionally, *Babesia kiwiensis* and *Hepatozoon kiwi* were found in the North Island brown kiwi.[29]

The clinical consequences of *Plasmodium sp*. are poorly characterized but may be significant. A 5-month-old emu, in Florida, with a *Plasmodium sp*. had a severe anemia (0.10 L/L) with 35% polychromatophilic RBCs and a 4% parasitemia.[13] *Plasmodium matutinum* has been recognized in a wide range of avian hosts including in North Island brown kiwi and great spotted kiwi in New Zealand.[39] *Plasmodium sp*. have been reported to cause the death of kiwi but no hematologic values were available.[1]

ACKNOWLEDGMENTS

I thank Dr. Christine Bayley, Gribbles Veterinary Pathology, Melbourne, Australia for providing case material.

  Pathologic Response

Acronyms and Abbreviations

CEG (G1), coarse eosinophilic granulocyte; ER, endoplasmic reticulum; FEG (G3), fine eosinophilic granulocyte; G2, neutrophil; GT (G4), granulated thrombocyte.

Elasmobranchii is one of two subclasses of the class Chondrichthyes (cartilaginous fishes), the extant representatives of the jawed fishes. More than 800 species are divided into two superorders: Selachimorpha (sharks) and Batoidea (rays and skates).

SAMPLE COLLECTION AND ANALYSIS

Phlebotomy sites for hematology specimens include the caudal vein (sharks, skates, and rays) and the pectoral fin (wing) veins (skates and rays). Other phlebotomy sites may be used; however, hematologic values from different sites vary and may not be comparable.[18] Commercial blood collection tubes are appropriate for most species; however, EDTA may cause lysis in samples from some ray species.

Manual CBCs are performed as for teleost species except some cell counting diluent formulas may need to be adjusted for higher osmolality to prevent lysis. The stock formula of Natt and Herrick[19] (3.88 g NaCl, 2.50 g Na^2SO^4, 2.91 g $Na^2HPO^4{\cdot}12H^2O$, 0.25 g KH^2PO^4, 0.10 g methyl violet 2B, and 7.5 mL 37% formaldehyde) can be modified to simulate the physiologic conditions of marine elasmobranchs (E-NH diluent). The original formula supplemented with 31.5 g/L urea and 13.5 g/L sodium chloride (NaCl) will yield a final osmolality of 1190 mmol/kg.[2] An aliquot of the original formula (stable 2 years) is passed through low-ash, grade-42, filter paper before adding NaCl and urea (final solution stable approximately 24 hours). A 1:100 dilution is prepared by mixing 20 µL whole blood in 1980 µL E-NH diluent and loaded into the two chambers of an improved Neubauer hemocytometer. WBC counts (/µL or $\times10^9$/L) are determined by averaging the number of cells tallied in all nine large squares of both chambers and multiplying by 110. RBC counts ($\times10^6$/µL or $\times10^{12}$/L) can be determined from the same hemocytometer preparation by tallying the five small RBC squares, within the central large square, from both chambers, and multiply the average by 5000. Thrombocyte counts (/µL) can also be obtained from the same preparation by averaging the tallies of the central large square and multiplying by 1000. Elasmobranch blood is stable for up to 5 hours in EDTA, or a whole blood aliquot can be preserved at the time of collection in 10% neutral buffered formalin (1:5) for a month or longer for hemocytometer counts.[2,3] For formalin preserved samples, the 1:100 dilution for the hemocytometer is prepared by adding 20 µL of fixed cells (1:5) to 380 µL E-NH diluent (1:20), and cell counts are determined using the above mentioned formulas for whole blood. Total dissolved solids by refractometer and PCV using a microhematocrit centrifuge are performed using standard methods. Historically, fish hemoglobin (Hgb) was determined by spectrophotometer using Drabkin's cyanmethemoglobin

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

method, followed by centrifuging to remove RBC nuclei; however, this method may not be readily available due to the hazardous chemical reagents. In 1990, HemoCue (HemoCue America, Brea, CA, USA) introduced the Hb201+ azide-methemoglobin whole blood portable analyzer which yielded higher hemoglobin concentrations in sandbar shark blood compared to the cyanmethemoglobin method;[2] therefore, method-specific reference intervals should be generated. Automation of differential cell counts is not currently possible for elasmobranchs.

ERYTHROCYTES

Elasmobranch nucleated RBC morphology is comparable to the avian counterpart except for much larger size (20–25 μm in length).[9] Mature cells have an ellipsoid shape, smooth cytoplasm uniformly filled with hemoglobin, and a central oval nucleus of condensed chromatin. Less mature, polychromatophilic cells are commonly observed on blood smears as well as occasional immature forms, including RBC in mitosis (Figure 128.1a). Compared to dogs, elasmobranch RBCs are much larger (approximately 7 μm in diameter for dogs vs ≥20 μm in sharks) and subsequently fewer in number ($5.9–8.4 \times 10^6$ cells/μL for adult dogs vs 0.5×10^6 cells/μL for sharks, respectively).[9,21,23] Erythropoiesis in adult sharks occurs in the splenic red pulp in the species studied.[9,27]

LEUKOCYTES

Elasmobranch lymphocytes, monocytes, neutrophils, and basophils resemble their mammalian counterparts in morphology, while there are some distinct differences in the eosinophilic granulocytes (Figures 128.1 and 128.2). WBC differentials typically reveal abundant lymphocytes, often the predominant cell type, and a small number of monocytes. Neutrophil numbers vary; commonly observed in shark species, but typically rare or not observed in rays and skates. Basophils are rarely observed on shark blood smears, but often found in low numbers in blood smears from ray species (Tables 128.1 and 128.2).

Elasmobranch granulocytes have been given multiple names in the literature. Neutrophils, similar to those in most mammals, have clear, colorless cytoplasm. The nucleus may be lobed or nonlobed, with both morphologies commonly observed on the same blood smear from apparently healthy animals (Figure 128.2). Mainwaring et al. describe this cell as granulocyte 2, or G2, in their G1–4 series.[17,21]

Several nomenclature systems for the eosinophilic cells have been proposed since the 1980s and this lack of a standardized naming system has led to confusion, especially for the two cells containing eosinophilic granules.[6] Cells with cytoplasm containing abundant elongate, reddish granules resemble avian heterophils. They have been termed fine eosinophilic granulocytes, or FEG, based on granule morphology, and as granulocyte 3 or G3 cells by Mainwaring et al., based on ultrastructure (Figure 128.3b).[13,17,21] Cells containing oval to round cytoplasmic granules, often with differing tinctorial properties than the heterophil, resemble avian eosinophils. They have been termed coarse eosinophilic granulocytes, or CEG, and as granulocyte 1 or G1 (Figure 128.3a).[13,17,21] Variations in size, shape, and tinctorial properties of the eosinophilic cells on Romanowsky-stained blood smears are observed in different elasmobranch species. The granule shape and color in the eosinophil vary by species more so than the heterophil and either have granules that are brighter red-orange than those in the heterophil (Figure 128.2j),granules that are lighter reddish-pink than the heterophils (Figure 128.2b), or show similar tinctorial properties to the heterophil but differ in shape (Figure 128.2f). The nuclei of elasmobranch eosinophilic granulocytes may be round, indented, or multilobed on the same blood smear (Figures 128.1c–e and 128.2c).

Lymphocytes are typically small with dark condensed chromatin and a small tag of blue cytoplasm. Low numbers of intermediate and large lymphocytes (>10 μm) may be found in blood smears from apparently healthy sharks. Antibody classes and structure are different than mammalian types and currently under investigation. Monocytes (phagocytes) are similar in morphology to those found in mammals and are differentiated from lymphocytes by more copious dark blue cytoplasm that is occasionally vacuolated.

THROMBOCYTES AND COAGULATION

Sharks, skates, and rays possess thrombocytes of similar size and morphology to those found in avian species. On Romanowsky-stained blood smears, thrombocytes appear as oval cells, with clear cytoplasm and a central oval nucleus of condensed chromatin. Rounded and spindle forms are sometimes observed. Like erythropoiesis, thrombocytopoiesis occurs in splenic red pulp. Pica studied thrombocyte form and function in torpedo rays (*Torpedo marmorata* bottom-dwelling rays) and a catshark (*Scyliorhinus stellaris*) and concluded that these cells appear functionally like mammalian platelets, although less abundant.[20] Thrombocytes form aggregates and adhere to glass. A study of hemostasis using five shark species, one skate, and one guitarfish found that elasmobranch blood clotted very slowly in glass tubes, often >48 hours; adding calcium chloride accelerated the clotting process but caused cell lysis.[15] Interestingly, thrombocytes from a Port Jackson shark (*Heterodontus portusjacksoni*) phagocytized latex particles.[22] The function of elasmobranch thrombocytes in response to infectious agents is unknown.

A second type of thrombocyte, first described by Mainwaring and Rowley as granulocyte type 4, or G4 cells, may be found in some elasmobranch species.[17] This cell resembles the typical thrombocyte in size and shape; however, the cytoplasm is filled with abundant azurophilic granules (Figures 128.2d and 128.3d). The

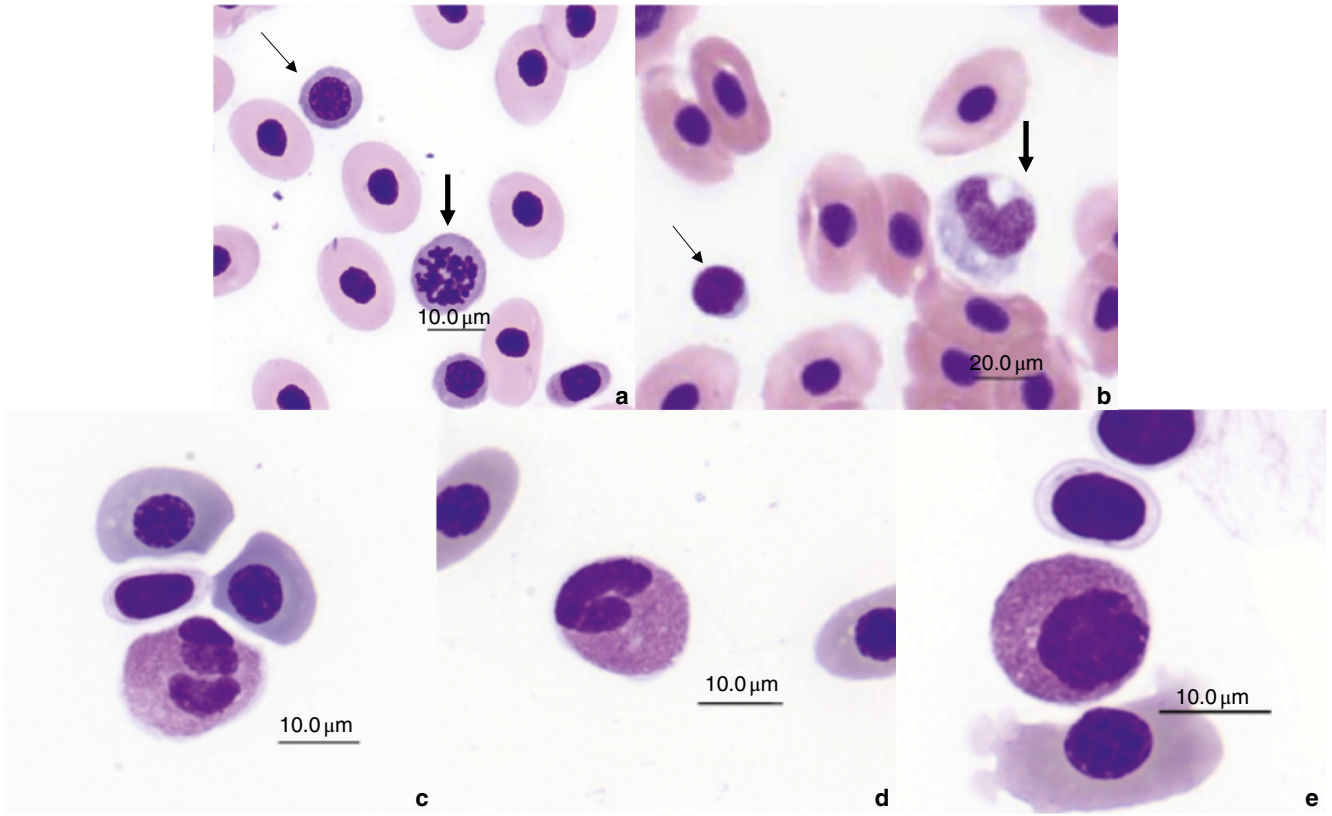

FIGURE 128.1 Elasmobranch blood cells. Blacknose shark (*Carcharhinus acronatus*): (a) Normal erythrocytes, polychromatophilic RBC or rubricyte (thin arrow), mitotic erythrocyte (thick arrow). Mitotic figures may be found in blood smears indicating erythroid regeneration and are not indicative of neoplasia. Cownose ray (*Rhinoptera bonasus*): (b) Lymphocyte (thin arrow), monocyte (thick arrow). Honeycomb stingray (*Himantura uarnak*): (c) Mature heterophil with segmented nucleus; (d) Heterophil band; (e) Immature heterophil. Modified Wright–Giemsa stain. 1000× magnification.

clinical significance of this cell is not known, and further investigation of this cell's identification and function is warranted.

CYTOCHEMISTRY AND ULTRASTRUCTURE

Multiple studies in elasmobranch blood cell cytochemistry were published in the mid-1980s, including the comprehensive observations by Hine, Wain, and Boustead for 24 elasmobranch species.[13] Hine summarized granulocyte cytochemistry findings as weak or negative for peroxidase, alkaline phosphatase, and beta-glucuronidase, but often strongly positive for acid phosphatase, and periodic acid–Schiff.[12] Reports vary for different species and future studies will aid in cell descriptions.

Ultrastructural studies (Figure 128.3) have described RBC cell maturation within the hematopoietic tissues, e.g., splenic red pulp, beginning with round cells containing a large nucleus with small amounts of condensed chromatin. The cytoplasm contains mitochondria and ribonucleoproteins, rough endoplasmic reticulum (ER), vacuoles, and Golgi complex. Successive developmental stages show maturation to an ellipsoid shape and the nuclear chromatin condenses.[27,28] Lymphocytes are described as having a central nucleus with dense patches of heterochromatin and occasional nucleolus. The limited cytoplasm contains few vesicles, vacuoles, mitochondria, rough ER, and occasional Golgi complex.[21] Monocytes have a prominent eccentric nucleus and the cytoplasm contains rough ER, Golgi complex, Golgi-derived vesicles, and heterophagosomes. Protoplasmic extensions are common.[21]

Rowley et al. summarized the granulocytes of dogfish (*Scyliorhinus canicular*) as G1 (eosinophil) with an irregular, sometimes bilobed nucleus, one population of unstructured electron-dense round-ovoid granules.[21] Hyder reported the presence of large, crystalline, membrane-limited granules containing

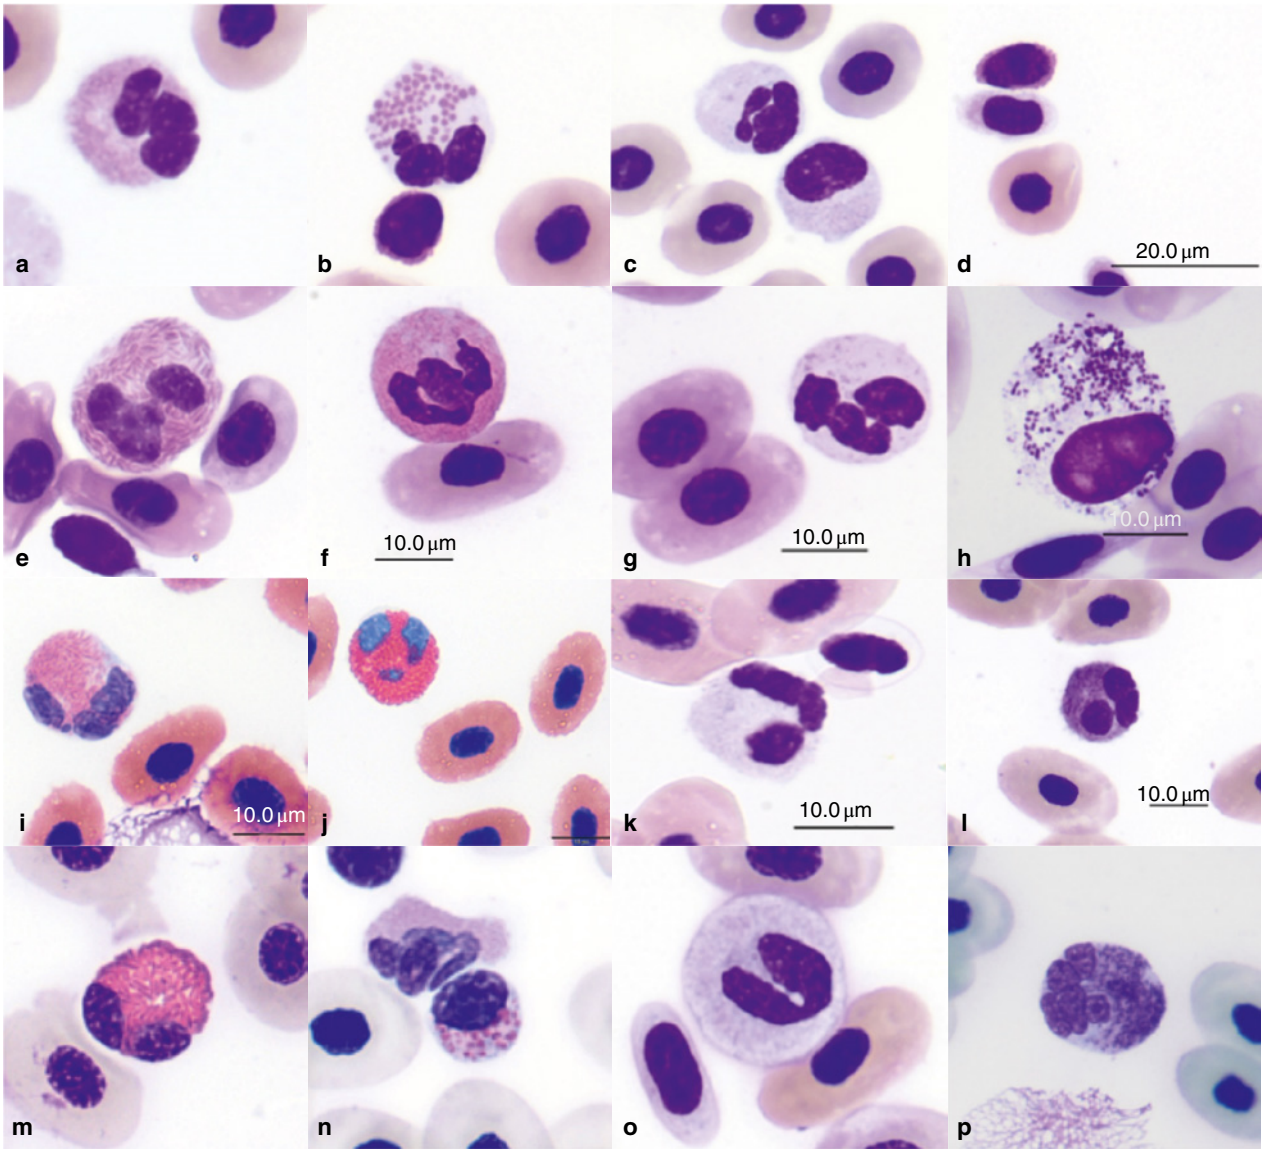

FIGURE 128.2 Normal elasmobranch granulocytes. Modified Wright–Giemsa stain. 1000× magnification.

elongated crystalloids in the nurse shark (*Ginglymostoma cirratum*) eosinophil, and compared these rhomboidal inclusions to the characteristic crystalline inclusions in mammalian eosinophil granules.[14] The G2 (neutrophil) nucleus typically appears clefted, or horseshoe-shaped, and the cytoplasm contains small heterogenous granules. The nucleus of the G3 (heterophil) is typically lobed and the granules are unstructured, electron-dense, and rod-shaped. Dogfish G4 granulocytes (granulated thrombocytes) have an elongate nucleus and cytoplasm filled with one population of square/cuboid electron-dense, unstructured granules.[21] Further investigation of the granulated G4 (granulated thrombocyte) is warranted to determine clinical significance. Editor's note: Further investigation of the G4 (granulated thrombocyte) as a granular lymphocyte is warranted.

Thrombocytes of nurse shark (*G. cirratum*) cytoplasm contain numerous agranular vesicles and small vesicles with electron-dense material.[14] Shark species that possess the second type of thrombocyte, G4 or granulated thrombocyte, such as the lesser-spotted dogfish (*S. canicula*) have cytoplasm filled with electron-dense granules (Figure 128.3d). Specific cytochemistry and ultrastructure studies may use different methods and have been misquoted in the literature. The reader is advised to access the original studies for accurate information and evaluation.

TABLE 128.1 Reference intervals for 33 adult, mixed-sex free-ranging sandbar sharks (*Carcharhinus plumbeus*) and 22 adult, mixed-sex aquarium-housed cownose rays (*Rhinoptera bonasus*).

REFERENCE INTERVALS

Interpretation of elasmobranch hematology results may be difficult for a variety of reasons including a lack of reference intervals for most species, preliminary identification and understanding of function of each leukocyte type, and individual species response to a variety of environmental factors. Additionally, results may be affected by different processing techniques or variation between technicians performing the CBCs. Biological factors such as age, sex, and season are essentially unexplored, though differences in species and in captive versus wild have been documented. For example, wild carpet sharks have higher PCV than captive carpet sharks (*Chiloscyllium punctatum*).[7] This finding demonstrates that it is important to generate reference intervals for wild and captive

populations, as they may not be interchangeable. Although established reference intervals may not be available for an individual, the clinician may find serial CBCs to be a useful diagnostic tool. When interpreting hematology results for an individual or group of elasmobranchs, it is helpful to analyze trends.

Reference intervals were calculated for 33 free-ranging sandbar sharks (*Carcharhinus plumbeus*) and 22 aquarium-housed cownose rays (*Rhinoptera bonasus*), following American Society for Veterinary Clinical Pathology guidelines (Table 128.1). Animals were briefly manually restrained following the National Aquarium Animal Care and Welfare protocols. The sandbar sharks were collected via bottom-set longlines or gill nets in the Delaware Bay near Cape May, NJ and Lewes, DE, during summer months of 1985–1999. The baited lines or nets were set for no more than 30 minutes. Immediately upon landing, the sharks were manually restrained briefly for blood collection, body measurements, and tagging. All sharks sampled were active and appeared healthy. Samples for the 22 cownose rays were obtained during regularly scheduled physical examinations at the National Aquarium between 2007 and 2009. Each ray was netted individually, transferred to a holding tank, and manually restrained for blood collection and examination.

Blood samples were collected from the caudal vein and immediately transferred to EDTA (sharks) or lithium heparin (rays) tubes. Hemocytometer counts were determined using the modified Natt and Herrick diluent described in the earlier text. PCV using a microhematocrit centrifuge (>11,000 g) was determined for all but one sandbar shark, due to a broken capillary tube. Total plasma solids were read by refractometer. Hemoglobin

for the sandbar sharks was measured using a hand-held Spencer-AO hemoglobinometer (American Optical). This device was discontinued mid-1990s, as was the Unopette 5859 HGB (Becton Dickinson Corporation). RBC evaluation for the cownose ray samples was restricted to PCV, per National Aquarium laboratory protocols. Blood smears were stained either with Wright–Giemsa, or a combination of May–Grünwald and Wright–Giemsa. WBC differentials were determined for all but one sandbar shark, due to a broken slide.

Reference intervals were generated de novo using the robust method with MedCalc® statistical software version 19.5 (MedCalc Software Ltd, Ostend, Belgium; https://www.medcalc.org; 2020) after outliers were removed for leukocytosis or anemia, detected by the Tukey method. Data were tested for normal distribution using the Shapiro–Wilk test. Double-sided 90% confidence intervals for the lower and upper reference limits were determined.

HEMATOLOGIC RESPONSE TO DISEASE

Physiologic Response

Dogfish (*S. canicular*) exposed to confinement stress have decreased PCV, Hgb concentrations, and WBC counts.[24] Mako sharks (*Isurus oxyrinchus*) and sandbar sharks (*C. plumbeus*) have increased hematocrit due to capture stress.[4,25] In contrast, no change in PCV is noted after capture in gummy sharks (*Mustelus antarcticus*).[10] The differences in response to capture stress illustrate the importance of evaluating elasmobranchs on an individual basis and caution should be used when making assumptions between species. Leukocytosis attributed to stress is common in clinical settings.

Pathologic Response

Decreased PCV (anemia) has been reported in several cases. In clinical practice, anemia has been noted due to parasitism, trauma, gastrointestinal ulcerations, cardiac disease, and other chronic disease (Delaune, personal communication). Lesser-spotted dogfish (*S. canicula*) treated with enrofloxacin had decreased PCV, possibly due to oxidative stress.[26] Spiny dogfish (*Squalus acanthias*) and cownose rays (*R. bonasus*) had decreased PCV after a 30–40-day quarantine period.[16,8] Mandelman and Farrington hypothesize that the reason for the apparent decreased PCV in spiny dogfish may be attributed to an artificially increased PCV postcapture and transport, due to RBC swelling.[16]

Multiple causes for elevated PCV (polycythemia) have also been posed. Lemon sharks (*Negaprion brevirostris*) have increased PCV during exercise.[5] Wild and captive epaulette sharks (*Hemiscyllium ocellatum*) and grey carpet sharks (*Chiloscyllium punctatum*) have increased PCV after exposure to anoxic conditions.[7] Both captive and wild carpet sharks have increased Hgb concentrations immediately post exposure to anoxic conditions, though wild and captive epaulettes demonstrate no change in Hgb concentration after exposure to anoxic conditions.[7] The authors hypothesize that polycythemia (increased PCV and Hgb concentrations) post anoxia exposure may be attributed to RBC release from hematopoietic organs, hemoconcentration, accelerated RBC maturation in circulation, or an increase in oxygenated RBC, as blood is diverted from muscles and/or gastrointestinal tract into the peripheral blood.[7]

Interpreting WBC counts and differentials is difficult, as the function of leukocyte types is not entirely understood. In clinical practice, leukocytosis may be observed due to stress, parasitism, bacterial or fungal infections, and trauma. Male whitespotted bamboo sharks (*Chiloscyllium plagiosum*) with amputated claspers had a heterophilic leukocytosis with toxic changes, while with sharks with normal claspers did not.[1] Heterophils (FEGs) and monocytes from nurse sharks (*G. cirratum)* demonstrated in vitro phagocytosis).[14] With suspected inflammatory or infectious conditions, a shift in the WBC differential results to a heterophil predominant differential versus the expected lymphocyte predominant differential, i.e., an inverted heterophil:lymphocyte ratio, may occur. Some elasmobranchs that are apparently healthy will have an acute leukocytosis of unknown origin. It is important to note that not all clinically ill elasmobranchs will respond with a leukocytosis or shifted differential. As stated in the earlier text, trends in individual hematology results are often helpful when managing clinical cases.

ASVCP, American Society for Veterinary Clinical Pathology; MS-222, tricaine methanesulfonate; ICM, intermediate cell mass; PAS, periodic acid–Schiff; PRV, piscine orthoreovirus.

Many of the most commonly farmed fishes are salmonids, particularly Atlantic salmon (*Salmo salar*) and rainbow trout (*Oncorhynchus mykiss*).[17] While the use of automated hematology in these species is limited by nucleated erythrocytes and thrombocytes, hematology can be a useful diagnostic technique in fisheries management. Unfortunately, the paucity of valid baseline clinical information including for salmonid hematology has limited its diagnostic utility.

BLOOD COLLECTION

As most fish respond poorly to handling, sedation is frequently required. Salmonids, like many other teleosts, have somewhat soft oval-shaped cycloid scales and, as such, should be handled gently in order to mitigate associated trauma. Cutaneous mucus is important as both a physical barrier to invading organisms and as a part of humoral immunity, with IgM found in the cutaneous mucus of Atlantic salmon (*S. salar*);[42] handling trauma may damage or remove cutaneous mucus, predisposing to potentially fatal secondary infection. Tricaine methanesulfonate (MS-222) is the only anesthetic approved for use in food fish and requires a 21-day withdrawal period. MS-222 is typically administered by immersing fish in a water bath, prepared with water similar to living conditions, preferably from the same tank. Recommended added concentrations are broad as are buffering recommendations, and other sources should be referenced for dosing guidelines. It is important to note that MS-222 is acidifying and the preparation should be buffered with sodium bicarbonate.[10]

Salmonids are most commonly bled from the caudal tail vein.[8] Cardiac puncture should be limited to individuals that will not be recovered after blood collection. Blood should be collected into a heparinized or EDTA-treated container to prevent blood clotting and maintain cellular morphology. Heparin best maintains WBC morphology in these species, though it can induce both thrombocyte and WBC clumping, affecting differential counts. Erythrocytes in EDTA-stored samples tend to swell, affecting the PCV.[13] Serum will quickly gel in a significant number of samples within half an hour and so plasma is required to ensure that the sample taken can be analyzed for biochemistry.

LABORATORY ANALYSIS

As all salmonid blood cells are nucleated with significant overlap in cell size between cellular lineages, automated methodologies utilized in mammalian

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

samples have limited use in fish. Instead, manual counting methods with a hemocytometer are needed (see Chapters 123 and 128). Sources of error in manual counting methods include dilution with anticoagulant and other matrices, sample settling, variable hemocytometer filling, cell identification, and counting of low cell numbers. Differentiation between activated thrombocytes and WBCs, particularly lymphocytes, may be difficult. While thrombocytes are typically oval, they become small and round when activated, resembling a lymphocyte. These manual methods utilize a diluent that differentially stains RBCs and WBCs. Natt–Herrick (Bioanalytic GmbH, Umkirch, Germany) and Rees–Ecker (RICCA Chemical Company, Arlington, TX) diluents are both effective in salmonids. A 1:100 or 1:200 dilution of blood to filtered diluent is prepared, and cells are allowed to stand for at least 5 minutes prior to filling the hemocytometer. As in avian species, allowing the cells to stain longer may result in better staining and more accurate results (see Chapter 128).

Information regarding RBC density may be obtained from manual RBC counts or from a spun PCV, and hemoglobin (Hgb) concentration can be measured utilizing the cyanmethemoglobin method.[7] In manual hemocytometer methods, RBCs are counted in five secondary squares of the center primary square. This raw count is multiplied by 5000 for a 1:100 dilution or by 10,000 for a 1:200 dilution, providing the number of RBCs per microliter of blood. Leukocytes can be counted in the four corner primary squares. This raw count is multiplied by 250 for a 1:100 dilution or by 500 for a 1:200 dilution, providing a number of WBCs per microliter of blood. Repeating the described methods on both sides of the hemocytometer is recommended and only results that agree within <10% are accepted. Flow cytometry has been investigated for salmonid blood cell quantification.[34] Based on forward and side scatter, flow cytometry can sort blood into the following three groups: erythrocytes, lymphocytes and thrombocytes, and granulocytes.

A WBC estimation can be performed when examining a well-made blood smear with even cell distribution.[22] Blood film evaluation should only be done using a well-made smear in the monolayer with even WBC distribution. Care should be taken when preparing these smears, as non-mammalian WBCs tend to lyse, altering differential counts. A variety of gentle blood smear techniques have been described, including gentle push smear techniques and coverslip preparation. Salmonid blood film evaluation, as in other species, should initially be scanned on low power to ensure the slide is well-prepared with even WBC distribution, to assess thrombocyte clumping at the feather edge, and investigate for hemoparasites. The hematologist should become familiar with the cell types present as magnification is increased. A 200-WBC differential should be performed in the monolayer, and these percentages are then applied to the WBC count to provide absolute counts for each leukocyte type.

HEMATOPOIESIS

Primitive hematopoiesis begins in the yolk sac blood islands at 2 days post fertilization in rainbow trout (*O. mykiss*) and then in the intermediate cell mass (ICM), from days 7–12 to day 15 post fertilization in rainbow trout.[20] The ICM is ventral to the notochord and forms when the posterior mesoderm migrates medially to fuse at midline.[20] Hematopoietic production is higher in the ICM than in the yolk sac, and proerythroblasts form alongside primitive endothelial cells of the trunk vasculature.[20] These proerythroblasts proliferate before entering circulation. A second wave of myelopoiesis occurs in the posterior ICM.[30] Hematopoietic cells then colonize the pronephros, surrounding vessels between renal tubules and glomeruli. The pronephros is the primary site of adult erythropoiesis and myelopoiesis, with the spleen serving as a secondary site.[20] Erythroid precursors are released from the kidney into circulation at an immature stage and rubriblasts, prorubricytes, and rubricytes can all be seen on blood film evaluation, especially in fry.

The pronephros is the site of B-cell lymphopoiesis in salmonids.[20] As in all gnathostomes (jawed vertebrates), T lymphocytes develop in the thymus.[20] While thrombocytes are present in circulation early in development, the cellular equivalent to the megakaryocyte, the maturation stages, and the primary site of thrombopoiesis have not been identified.

ERYTHROCYTES

Salmonid RBCs resemble those of birds and reptiles, as they are oval with abundant pale eosinophilic cytoplasm and a central oval nucleus with clumped chromatin. They can be distinguished from other animal families by nuclear morphology (Figure 129.1). The cytoplasm is typically homogeneously pale pink (or salmon colored), though rare to occasional small pale staining or clear areas, associated with degenerating organelles as in other species, are occasionally observed. Small amounts of anisocytosis and polychromasia are present in normal salmonid blood smears. Polychromatophils have a slight blue tinge to the cytoplasm, appear slightly rounder, and have a more open nuclear chromatin pattern. Polychromatophils comprise <5% of total RBCs, while immature RBCs (rubriblasts, prorubricytes, and rubricytes) are typically <1% of total RBCs in blood samples from apparently healthy fish. These round erythroid precursors have variably basophilic cytoplasm with a central round nucleus that is larger in size than that in mature RBCs (Figure 129.1m–p). As in other nonmammalian species, erythroid precursors undergoing mitosis can be seen in peripheral blood.

Erythrocyte size can be evaluated with impedance technology or microscopically, by direct measurement of RBCs on a blood film, and is highly variable, even within the same family and species.[6,14] Erythrocyte size

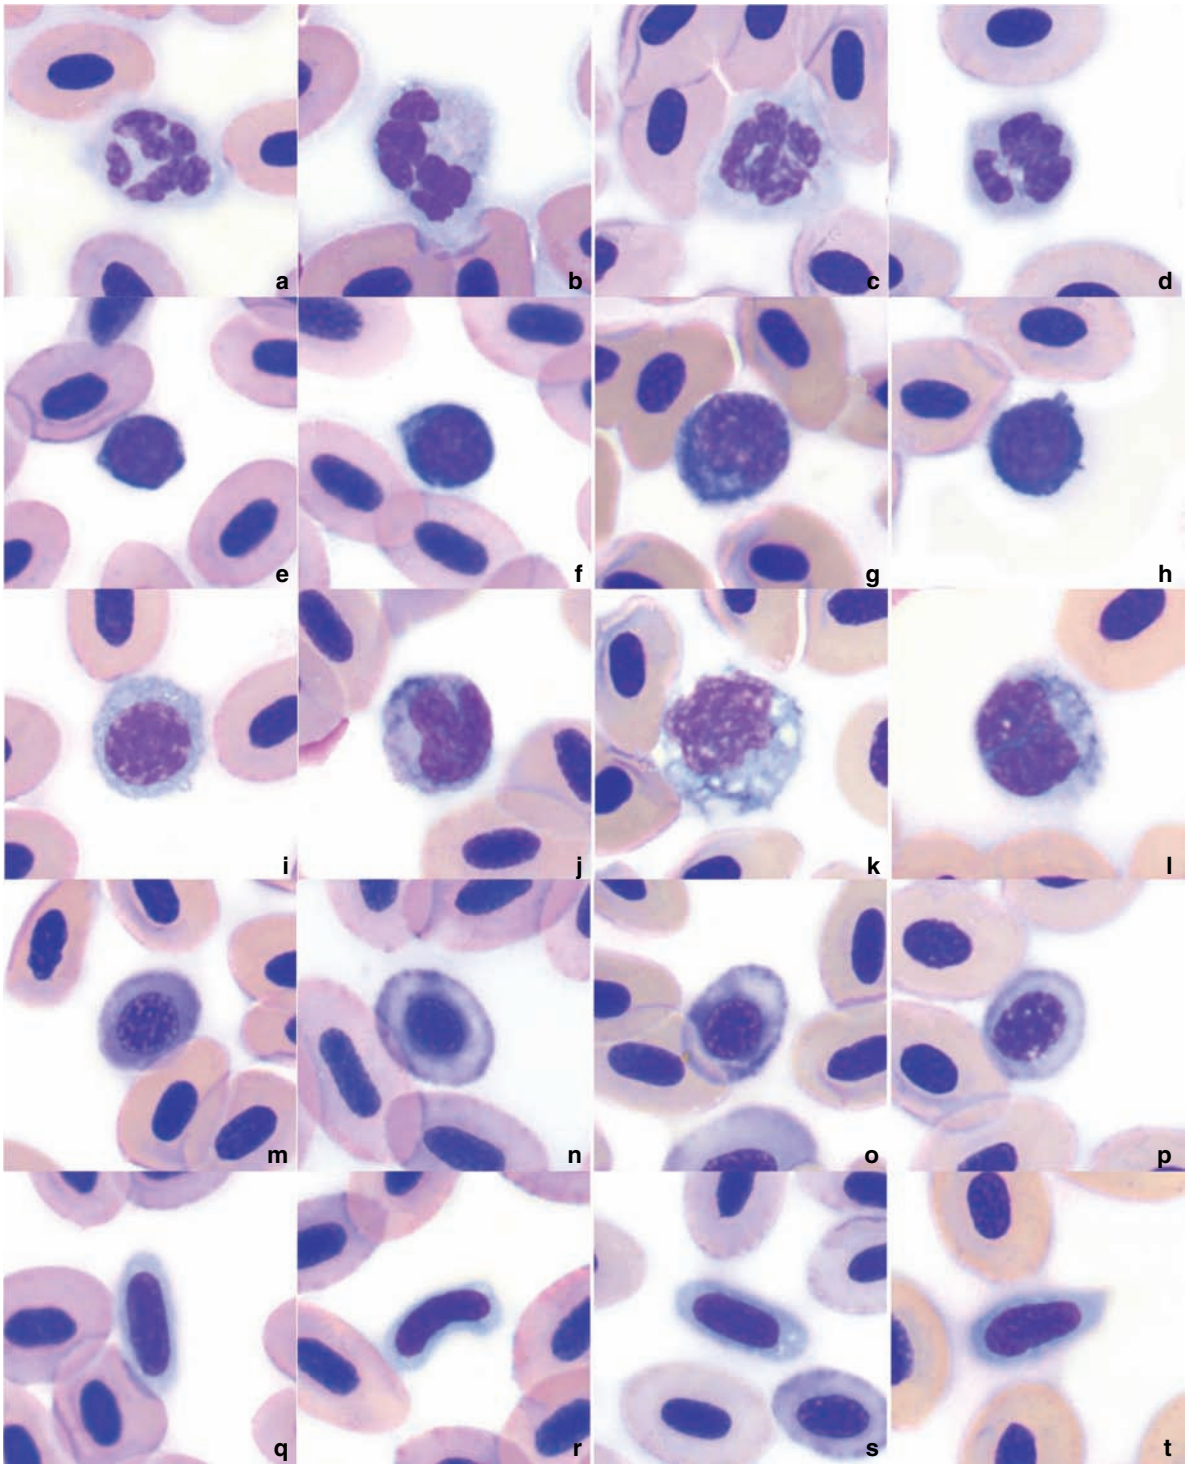

FIGURE 129.1 Leukocytes, immature erythrocytes, and thrombocytes from four salmonid species. King or Chinook salmon (*Oncorhynchus tshawytscha*): (a) Neutrophil; (e) Lymphocyte; (i) Monocyte; (m) Rubricyte; (q) Thrombocyte. Pink salmon (*Oncorhynchus gorbuscha*): (b) Neutrophil; (f) Lymphocyte; (j) Monocyte; (n) Basophilic polychromatophil; (r) Thrombocyte. in teleosts has been previously correlated to Hgb concentration, oxygen delivery, and, ultimately, aerobic swimming ability.[27] Fish with higher Hgb concentration have smaller RBCs. Additionally, triploid salmonids, or fish with three sets of chromosomes, have both longer and wider RBCs than those found in their

diploid counterparts (fish with two sets of chromosomes).[6,14] This difference is significant as induction of triploidy in farmed fish has been pursued as a method of sterilization, minimizing the impact of escaped farmed fish on wild populations.[5] Triploidy can be induced by duplicating the maternal genome using both heat and pressure treatments, among other techniques.[5]

LEUKOCYTES

The three types of WBCs documented in salmonids are neutrophils, lymphocytes, and monocytes[48] (Figure 129.1). Lymphocytes predominate with fewer but roughly equal numbers of neutrophils and monocytes.[48] Lymphocytes are round with a small amount of basophilic cytoplasm. Monocytes are larger with pale basophilic to gray, sometimes vacuolated, cytoplasm and a round to indented nucleus. Neutrophils are moderate in size with pale gray cytoplasm and a nucleus that varies in shape, but are typically segmented in apparently healthy salmon.

Neutrophils exhibit diffuse, weak to strong positive staining with periodic acid–Schiff (PAS), peroxidase, and Sudan black B stain with increased granular staining associated with cellular maturity.[7,48] Lymphocytic cells do not stain with Sudan black B or peroxidase, though some lymphocytes contain a few PAS-positive cytoplasmic granules, likely consistent with antibody.[7,48] Neither thrombocytes nor RBCs stain with Sudan black B, peroxidase, or PAS.[7,48]

Lymphocytes, the most common leukocyte in salmonid peripheral blood, are important for both innate and humoral immunity. B lymphocytes secrete antigen-specific antibodies with three heavy-chain immunoglobulin classes, IgM, IgT, and IgD, represented.[21] T lymphocytes may express either αβ- and γδ-T-cell receptors, and subpopulations include cytotoxic (CD8), helper (CD4), and regulatory (Treg, Th17).[40]

THROMBOCYTES

Thrombocytes are small, usually oval to spindloid cells with a small amount of colorless to pale basophilic cytoplasm and a small condensed nucleus (Figure 129.1o–t). Thrombocytes may be confused with lymphocytes, though thrombocytes have more condensed chromatin and lighter cytoplasm, and usually have a more oval shape. Thrombocytes can be enumerated on the hemocytometer and are easily differentiated from RBCs, as they are smaller and have a higher nucleus to cytoplasm ratio. Unfortunately, thrombocytes tend to clump, precluding an accurate estimate. If the sample is not clumped, the number of thrombocytes in the center primary square is multiplied by 1000 for a 1:100 dilution or by 2000 for a 1:200 dilution, providing a number of thrombocytes per microliter of blood.[2]

REFERENCE INTERVALS AND PARTITIONING FACTORS

Currently, no salmonid reference intervals generated in concordance with the American Society for Veterinary Clinical Pathology (ASVCP) reference interval guidelines exist for clinical use. Significant seasonal variations in RBC size are reported that are likely associated with the spawning season, though temporal associations with RBC size are not consistent across salmonid species.[15,39] For example, when the length of RBCs of rainbow trout (*O. mykiss*) were measured with an ocular micrometer, RBCs were largest in late summer and smallest in early spring.[15] On the other hand, RBCs of Atlantic salmon (*S. salar*) are largest during early summer and smallest during early autumn, based on a calculated mean cell volume (MCV).[39] Hematocrits also exhibit seasonal and inter and intraspecies variability. In general, less active fish have lower hematocrits, while more active fish have higher hematocrits.

HEMATOLOGIC DISEASE

Anemia

The regenerative response to peripheral anemia results in increased proportions and total numbers of polychromatophils and immature RBCs. A pre- or nonregenerative anemia is characterized by a lack of immature RBCs in the face of decreased erythroid mass. Decreased RBC mass has been associated with a variety of bacterial infections, including *Aeromonas* and *Streptococcus* species,[3] *Vibrio anguillarum*,[46] and *Renibacterium salmoninarum*.[9] *Aeromonas salmonicida* is the causative agent of furunculosis, which may result in septicemia, hemorrhage, and death. *V. anguillarum*, along with other *Vibrio sp.*, causes vibriosis. The virulence of *V. anguillarum* is, at least in part, associated with the production of hemolysins and other membrane-damaging toxins.[35] *R. salmoninarum*, the causative agent of bacterial kidney disease, causes diffuse granulomatous reactions within the reticuloendothelial tissues, resulting in a progressive infection that may ultimately result in death.[9]

Viral causes of anemia include infectious salmon anemia virus,[16] viral hemorrhagic septicemia,[37] and erythrocytic inclusion body syndrome.[44] Infectious salmon anemia virus, caused by an orthomyxovirus, is of economic importance in the farming of Atlantic salmon (*S. salar*) and causes severe anemia, leukopenia, and ascites.[16] In viral hemorrhagic septicemia, caused by a novirhabdovirus, endothelial cells are targeted by the virus, resulting in hemorrhage.[25] Erythrocytic inclusion body syndrome, caused by piscine orthoreovirus-2 (PRV-2), results in severe anemia in affected salmonids.[44] Both PRV-1 and PRV-2 have been shown to infect and replicate within salmonid RBCs, with resultant cytoplasmic viral inclusions, though only PRV-2 causes

anemia, while PRV-1 infection results in heart and skeletal muscle inflammation.[44]

Proliferative kidney disease, caused by the myxozoan *Tetracapsula bryosalmonae*, has been reported to significantly decrease RBC mass.[1,24] Vitamin-E deficiency may also result in anemia.[33] A variety of toxicants have been noted to result in anemia, with phenylhydrazine commonly utilized to induce hemolytic anemia in the research setting.[23] Other toxins associated with decreased erythrocyte mass include cadmium,[28] nitrites,[29] and bis(tri-n-butyltin) oxide[11] (see Chapter 130).

Stress

Sampling conditions must be considered, as stress may result in RBC and WBC redistribution. Splenic contraction in response to catecholamine release secondary to exercise or handling can increase PCV by up to 20%.[26] Increased catecholamine concentrations also induce an RBC sodium–hydrogen counter-transporter.[4] As sodium enters the RBC, water follows osmotically and RBCs swell.[4] Acutely stressed salmon with increased circulating cortisol concentrations have decreased circulating WBCs and/or lymphocytes and increased circulating neutrophils.[31,32,36] Antibody production by lymphocytes and reactive oxygen species production by neutrophils are reduced with increased concentration, as well.[38,45] A dorsal aorta cannulation technique for blood technique has been described to limit handling and stress during blood collection, though this method is impractical for use outside the research setting.[41]

Inflammation

Inflammatory responses in salmonids are characterized by a neutrophilia in the first 24 hours followed by an increase in monocyte numbers after several days.[18] Toxic neutrophils have increased cytoplasmic basophilia and vacuolization. Primary granules can be observed with severe toxicity.[43] Toxic neutrophils can be associated with both infectious (e.g., bacterial septicemia, mycotic infections) and noninfectious (e.g., tissue necrosis) causes of inflammation, though bacterial disease typically results in more severe toxic changes.

Hemoparasites

Several hemoparasites may be found in salmonid blood cells or hematopoietic precursors. Developmental stages of *T. bryosalmonae*, the causative agent of proliferative kidney disease, may be seen on peripheral blood evaluation.[24] These trypanosomes are leaf-like in shape with a single nucleus, kinetoplast, and flagellum. A diffuse granulomatous response affects the kidney and may affect other organs, including the spleen. Anemia results due to reduced erythropoietin production by the nephron.[1]

The hemoflagellate, *Cryptobia (Trypanoplasma) salmositica*, may be identified on blood film evaluation. Trypanoplasms are elongate and thin with two flagella and a kinetoplast.[47] Transmission occurs via the leech *Piscicola salmositica* or directly between fish. Clinical signs of cryptobiosis include anemia, anorexia, splenomegaly, ascitic distension (dropsy) and generalized edema.[47] The degree of anemia is directly related to the degree of parasite burden.[47] The cause of anemia is likely multifactorial, including secretion of hemolysins by *C. salmositica* and hematopoietic tissue necrosis.[47]

Developmental stages of the microsporidian, *Nucleospora* (*Enterocytozoon*) *salmonis*, may be seen in the nucleus of hematopoietic cells in the spleen, kidney, and peripheral blood.[12] Spores are oval and colorless to pale, with one nucleus and a coiled polar tube.[12] Affected fish are often anemic with a severe lymphocytosis, with death associated with heavy parasite burdens.[19] Circulating lymphocytes often contain intranuclear stages of the microsporidium.[19]

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathology; CCA, channel catfish anemia; MS-222, tricaine methanesulfonate.

The Ictaluridae family is primarily composed of 10 catfish species within the genus *Ictalurus*. The ictalurid catfish originated in the freshwaters of North America and include the commonly known blue, channel, flathead, and white catfish, as well as various species commonly known as bullheads (e.g., brown bullhead [*Ameiurus nebulosus*], black bullhead [*Ameiurus melas*], and yellow bullhead [*Ameiurus natalis*]). Three ictalurid catfish, *Ictalurus punctatus* (channel), *Ictalurus furcatus* (blue), and *I. punctatus*♀ × *I. furcatus*♂ hybrids, are the most commonly cultured catfish for food in the USA. Currently, over 75% of commercially raised catfish in the USA are channel–blue catfish hybrids, representing a sustainable food fish with faster growth rate and increased disease resistance. Catfish is the leading aquaculture industry in the USA. Commercial catfish production generates over 27% of the value of aquaculture production in the USA. From the first commercial production in ponds in the 1960s, catfish production has grown to reach annual sales of roughly 319 million pounds in 2016. Mississippi leads the USA in production with 34,700 acres in 2017.

To manage the health of ictalurid catfish in aquaria, natural, and commercial settings, veterinarians can utilize hematology as a nonlethal diagnostic test. Although a considerable amount of information on ictalurid hematology is available because of their commercial importance, additional information is still needed to define their hematologic responses.

BLOOD COLLECTION AND SAMPLE PREPARATION

To minimize handling, stress, and excitement, catfish are usually anesthetized prior to venipuncture. Anesthesia allows positioning of the fish and an unobstructed approach to a stabilized blood collection site. Tricaine methanesulfonate (MS-222) is the only anesthetic approved for use in fish in the USA. For a quick procedure, MS-222 is administered by placing catfish in a water bath with final concentration of 100–300 mg MS-222 per L water, preferably buffered. While alkaline water may not require buffering, American Veterinary Medical Association guidelines recommend that water with low alkalinity (<50 ppm) be buffered with sodium bicarbonate to a pH between 7.0 and 7.5. Once the catfish begins to enter stage two of anesthesia, with total loss of reaction to external stimuli and a slight decrease in opercular rate, it is removed from the water bath and immediately sampled. This anesthetic level is sufficient

in duration for an experienced phlebotomist to complete the venipuncture, with rapid return to the water environment and quick recovery from anesthesia. Anesthetic agents used in other countries for venipuncture include eugenol, benzocaine, and metomidate. All anesthetics should be used according to label directions in accordance with the country's regulations.

The most common venipuncture site for catfish is the caudal vein, which is approached laterally just ventral to the lateral line, or ventrally via the ventral tail region (Figure 130.1). An alternate site for venipuncture is the dorsal aorta, accessible via the buccal cavity. However, this blood collection site requires heavier sedation and a highly skilled phlebotomist. Cardiocentesis is another option for obtaining a blood sample, especially larger volumes, but there is a greater risk of fatal injury. The maximal, non-lethal sample volume is approximately 1% of body weight. Small blood volumes are collected using a small gauge needle (e.g., 21–23 g) attached to a 1–3 cc syringe. Small fingerling catfish may require a 25g needle. Collection using vacuum collection tube systems (e.g., Becton Dickinson Microtainers, Franklin Lakes, NJ, USA) can be used for larger volumes. Blood should be placed in an appropriately sized tube, to avoid an excessive K-EDTA to blood ratio, as soon as possible, thereby decreasing thrombocyte and coagulation factor activation. EDTA has not been associated with hemolysis in catfish, so heparin and other anticoagulants are typically avoided for hematologic analysis.

Blood smears should be prepared immediately with blood without anticoagulant, or as soon as possible with blood collected in EDTA. Blood prepared for hemocytometer blood cell counting methods, e.g., Natt–Herricks stain, should be counted as soon as possible. Blood can be preserved for later counting by transferring 100 µL whole blood to a tube containing 400 µL 10% neutral buffered formalin (1:5 dilution) and mixed well[3] (see Chapter 128). Blood cells are reportedly stable for counting with Natt–Herricks solution for up to 1 month following formalin fixation.[3] As a general reminder, formalin solutions and vapors should be kept away from unstained blood smears (during their preparation, storage, and shipping), as any fixation adversely affects the Romanowsky staining of blood cells.

ERYTHROCYTES

Mature RBCs (Figure 130.2k) are the most numerous blood cell and are oval to elliptical with eosinophilic cytoplasm using Romanowsky stains.[12,19] The nucleus is generally centrally located, round to oval in shape, and has condensed chromatin. Erythrocytes vary from 10–12 µm on their long axis. Immature RBCs, polychromatophils, appear rounder than mature cells, the cytoplasm stains more basophilic, and the nuclear chromatin is less condensed (Figure 130.2i,j). There are currently no standardized methods for evaluating the erythropoietic response in blood (e.g., reticulocyte staining, grading degree of polychromasia, rubricyte counts) of ictalurid catfish.

LEUKOCYTES

Neutrophils and lymphocytes are the predominant leukocytes in healthy catfish blood, followed by monocytes with rare basophils.[12,18] Eosinophils have not been definitively identified in healthy catfish. Functionally, catfish WBCs are analogous to mammalian WBCs. Channel catfish neutrophils are capable of bacterial phagocytosis and oxidative metabolite release. Monocytes exhibit in vitro phagocytosis of beads, but do not adhere well to plastic or glass surfaces. T and B lymphocytes have been identified.[7]

On Romanowsky-stained blood smears, neutrophils are round to oval and are approximately 11 µm in diameter.[18] The nucleus is eccentrically located and typically has minimal segmentation, so nuclear shapes range from oval to banded or irregular (Figure 130.2a–c). While catfish neutrophils may resemble mammalian bands and myelocytes because of their hyposegmentation, there is no current evidence that these represent abnormally immature cells. Low numbers of band neutrophils and rare myelocytes (identified using mammalian categorization) may be identified in blood smears of apparently healthy fish and do not necessarily indicate a left shift (Figure 130.2b,c). The moderate amount of cytoplasm on Romanowsky stains appears colorless to lightly basophilic, with low numbers of fine to coarse clear to lightly eosinophilic granules. Ultrastructurally, neutrophil cytoplasm contains many dense granules and small amounts of rough endoplasmic reticulum (ER).[6] On cytochemical staining, catfish neutrophils are strongly positive for peroxidase, periodic acid–Schiff (PAS), and Sudan black B.[7,18,21] Though pale staining granules may be found, heterophils have not been definitively identified in ictalurid catfish.

Lymphocytes (Figure 130.2d) are variable in size (small to large), with diameters that range from 5–9 µm.[7,18] The nucleus is more centrally located with variably condensed chromatin. The sparse to moderate cytoplasm typically stains lightly basophilic, with cytoplasmic blebs sometimes observed. Ultrastructurally, catfish lymphocytes have few cytoplasmic organelles as distinguishing features.[6] Lymphocytes from catfish do not stain with routinely used cytochemical stains.[18]

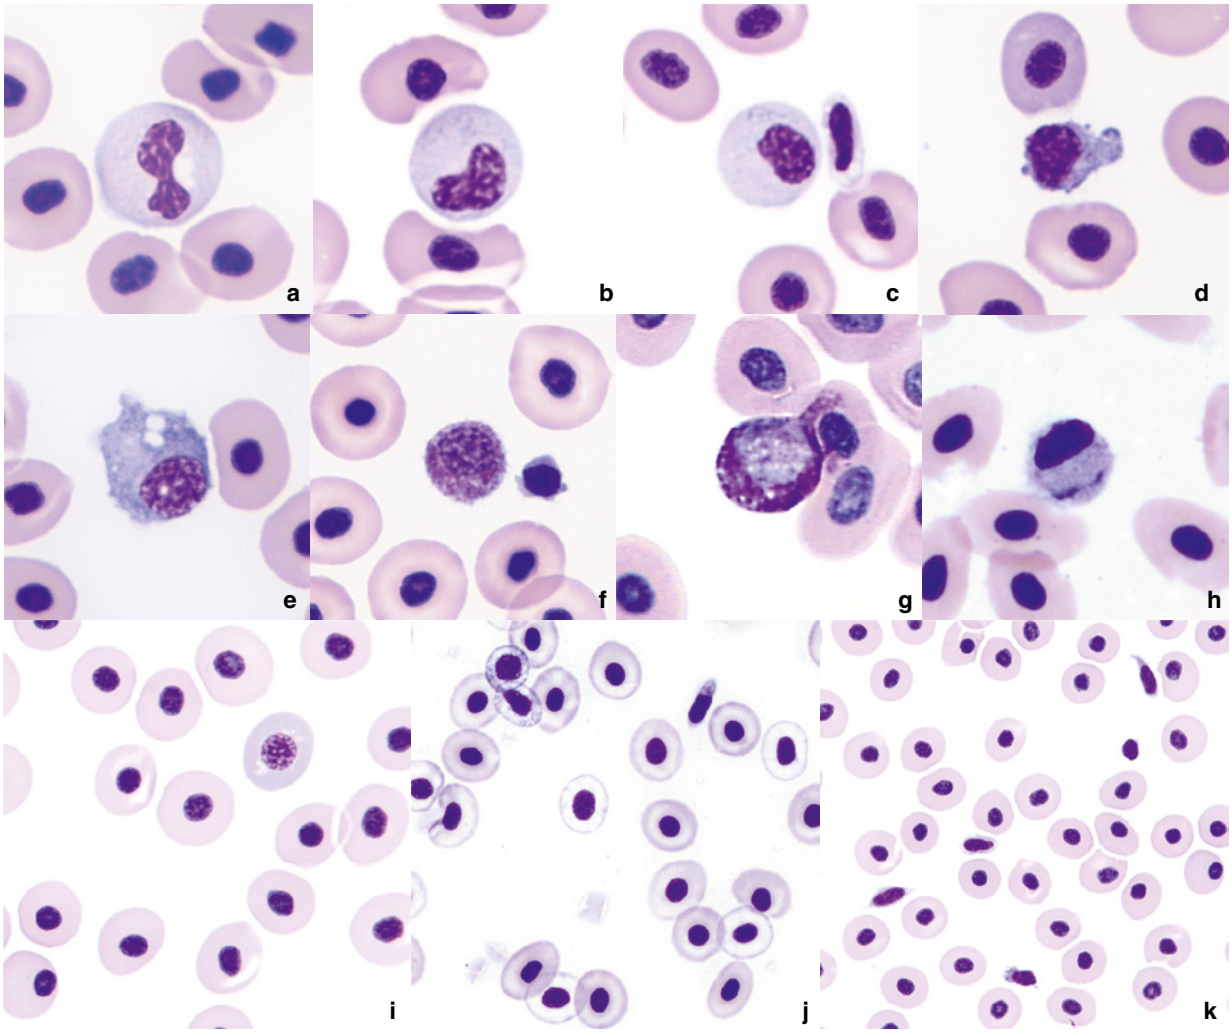

FIGURE 130.2 Blood cells of channel catfish (*Ictalurus punctatus*). Fish were assessed as healthy unless otherwise noted. (a) Neutrophil with irregularly shaped, bilobed nucleus; (b) Neutrophil with band-shaped nucleus; (c) Neutrophil with oval nucleus (possible metamyelocyte); (d) Small lymphocyte with cytoplasmic blebs; (e) Monocyte with cytoplasmic basophilia and clear vacuoles; (f) Basophil with round nucleus and cytoplasmic purple granules; (g) Basophil, Modified Wright-Giemsa stain (**Source:** Millipore Sigma, St. Louis, MO, USA); (h) Neutrophil with prominent linear basophilic inclusions in cytoplasm (possible Döhle bodies) and increased cytoplasmic basophilia from a catfish with acute *Edwardsiella ictaluri* infection; (i) Mature RBCs and a polychromatophil from a healthy fish; (j) Erythrocytes from an anemic catfish affected with channel catfish anemia (CCA) exhibiting hypochromasia; (k) Thrombocytes with oval to fusiform nuclei. Blood smears stained with Wright-Giemsa stain. All images are originally 1000× magnification except g which is 500× magnification. (**Source:** Images courtesy of Dr. Shannon Dehghanpir, Louisiana State University; (g) courtesy of Dr. Kendal Harr.)

Monocytes (Figure 130.2e) are oval with a diameter of approximately 12 µm, similar in size or larger than an RBC, and variably shaped nuclei that range from oval to indented to lobulated.[18] The nuclear chromatin has incomplete condensation. The cytoplasm is moderate in amount and stains basophilic, with few to absent clear vacuoles. Ultrastructurally, the cytoplasm contains ER, vacuoles, and granules.[6] Ictalurid monocytes are strongly positive for nonspecific esterase and reported as negative to weakly positive for peroxidase.[18,21]

Basophils (Figure 130.2f,g) occur in very low numbers in the peripheral blood and are relatively small leukocytes, with a diameter of 7 µm.[18] The nucleus is round in shape and centrally located, although the nuclear features are typically obscured by the granulated cytoplasm on Romanowsky stains. The cytoplasm is moderate in amount and contains many small purple-staining granules that vary in size and shape. In addition, the color of basophil granules may vary with aqueous versus alcohol-based Romanowsky stains (Figure 130.2g) (see Chapter 117). The cytoplasm of ictalurid basophils exhibits metachromatic staining reaction with toluidine blue, with conflicting reports of positive staining with PAS.[18,21]

THROMBOCYTES AND COAGULATION

Thrombocytes (Figure 130.2k) range in length from 9–11 μm and vary in shape from oval to elongate to fusiform.[18] The nucleus is oval to fusiform in shape with condensed chromatin, while the cytoplasm stains colorless with occasional clear vacuoles/granules. As in other vertebrates with thrombocytes, differentiating oval thrombocytes from small lymphocytes on Romanowsky smears can be challenging. One report indicated that catfish thrombocytes are less fusiform and more rounded when blood smears were prepared 2 hours or more after blood collection.[7] Ultrastructurally, the cytoplasm contains a canalicular system, glycogen granules, and vacuoles (some with phagocytosed debris).[18] Catfish thrombocytes are weakly positive for peroxidase, PAS, and nonspecific esterase.

There are no published studies that detail the physiology and diagnostic testing of the coagulation system in ictalurid catfishes. One preliminary study with citrated plasma from bullhead catfish indicated the presence of fibrinogen and rapid coagulation of plasma following addition of thrombin from other animals.[14] The prothrombin time (PT) and partial thromboplastin time (PTT) were dependent on the species origin (e.g., rabbit, dog, human, catfish) of thromboplastin used as reagent. The shortest times for PT and PTT in citrated catfish plasma were obtained using thromboplastin prepared from catfish brain. Catfish thromboplastin is not a standardized reagent, which limits studies of routine coagulation tests in catfish. Thromboelastographic studies of blood coagulation have not been reported in ictalurid catfish at the time of publication.

HEMATOPOIESIS

The primary sites for erythropoiesis, granulopoiesis, and thrombopoiesis in ictalurids are the head and trunk kidneys. The head kidney consists of bilaterally fused lobes that are anterior to the swim bladder.[12] It is composed primarily of hematopoietic, lymphoid, and inter-renal tissues. The inter-renal cells have an endocrine function similar to the adrenal glands of mammals.[9] Renal tubules and glomeruli initially form in the head kidney of ictalurids, but undergo degeneration during the fingerling stage and are absent in adult ictalurids. The fused portion of trunk kidney is posterior to the swim bladder and the bilateral lobes of trunk kidney extend cranially along the swim bladder. The corpuscles of Stannius are located on the lateral margins of the trunk kidney in ictalurids and are endocrine tissue. The trunk kidney is composed mostly of nephrons with glomeruli and tubules, and fewer hematopoietic and lymphoid aggregates. There is uncertainty as to whether the larger trunk kidney is equivalent in hematopoietic mass to the head kidney, and whether these two sites are similar in their ability to support basal and increased erythropoiesis, granulopoiesis, and thrombopoiesis. The spleen is primarily a lymphoid organ in ictalurids, but may contain low numbers of hematopoietic cells.[10]

The erythroid and granulocytic precursors in catfish are easily identified on Romanowsky-stained impression smears of the head and trunk kidney.[10] Some studies have applied a nomenclature system to the individual stages of these precursors, but this has not been formalized. The thrombopoietic precursors in catfish are not well described or identified on routinely stained smears, especially given their similarity to lymphoid cells. Hemosiderin granules are also present on smears of the head and trunk kidneys of ictalurids.

REFERENCE INTERVALS

While many reports of hematology reference values for ictalurid catfish are published, all are plagued by small sample sizes, some by misclassification of leukocyte types, inclusion of thrombocytes as a leukocyte subtype, and other issues. Seasonal variance of the circulating erythrocyte mass is a complicating factor in establishing reference intervals for pond-reared catfish. A study of channel catfish revealed a lower mean PCV (15%) in the winter compared to that (26%) in the summer months, reflecting the increased erythropoiesis and oxygen demand associated with a higher metabolic rate at warmer temperatures.[15] The two most recent reports on hematology reference values sampled 40 channel catfish, but utilized percentiles and statistics that are not in accordance with the published American Society for Veterinary Clinical Pathology (ASVCP) guidelines.[11,18,19] Therefore, there currently are no acceptable reference intervals for hematology values of ictalurid catfish.

HEMATOLOGIC DISEASE

Anemia

Channel catfish anemia (CCA) is a syndrome of severe anemia, including PCVs as low as 1%, in pond-raised channel catfish. Typically, the catfish with the most severe anemia are identified in ponds with lethargic and anorexic fish that exhibit marked pallor of lips, gills, and viscera. Channel catfish anemia is characterized by hypochromic erythrocytes (Figure 130.2j), hypoferremia, decreased hepatic iron concentrations, decreased transferrin saturation, absence of siderophages in the head kidney, and decreased hepatic expression of hepcidin.[5,13] Administration of parenteral iron to catfish with severe anemia attributed to CCA resulted in dramatic recovery from the anemia and abnormal iron status. All of these findings are consistent with iron deficiency, but the actual cause of altered iron metabolism in CCA remains unknown. Previously hypothesized causes of CCA included use of feeds with nutritional deficits, oxidized ingredients, toxins (e.g., mycotoxins, gossypol

from cottonseed meal), or iron chelation in pond water, but none of these have been definitively substantiated. Rare cases of severe anemia in channel catfish were attributed to commercial catfish feed.[16] Experimentally, severe anemia could be induced in healthy catfish by feeding the incriminated batch of feed, and the anemia resolved after feeding unaffected feed. No toxins, including heavy metals, mycotoxins, peroxides, pesticides, were identified in this feed, and there are no recent reports of feed-related anemia in catfish.

Anemia of inflammatory disease is likely common in fish, and has been documented in channel catfish with *Edwardsiella ictaluri* infection. This bacterial infection, known as enteric septicemia of catfish, initially causes intense neutrophilic and mononuclear cell infiltrates in the intestines.[9] In experimental *E. ictaluri* infections, PCV and RBC concentration are decreased by day 8, although the anemia was not characterized as nonregenerative.[2,16,17] Another study of *E. ictaluri* infection demonstrated a marked upregulation of hepcidin in hepatocytes within hours, and later in other tissues (e.g., intestine, olfactory sac).[13] Catfish hepcidin is considered to have the same role in iron regulation as in mammals, with iron sequestration likely contributing to the anemia. A similar pattern of hepcidin upregulation and hepcidin-induced iron sequestration likely occurs in the many other infectious and noninfectious inflammatory diseases reported in ictalurid catfish.

Hemorrhage is not commonly reported in ictalurid catfish and is not well-documented clinically with hematologic data. In a model of acute hemorrhage using bled catfish, increased numbers of polychromatophils and earlier erythroid precursors were present after 1 week in both the blood and head kidney, but less so on smears of trunk kidney and spleen.[10] Blood loss could occur in catfish from trauma (e.g., biting injury from other catfish, spearing injury from predatory birds) or even nosocomially from excessive venipuncture at research facilities. Moderate anemia occurs in channel catfish with proliferative gill disease caused by *Henneguya ictaluri*. This anemia was attributed to marked hemorrhage from damage to the vascular gill filaments, but was not characterized as regenerative.[4] However, the roles of other factors, such as iron sequestration due to inflammatory disease, were not ruled out as primary or contributing causes of this anemia.

Methemoglobinemia

Nitrite toxicosis is a major water quality concern of catfish farmers, since increased nitrite concentrations can occur in ponds, especially during the fall and spring. Nitrites from the fishes' nitrogenous wastes and protein breakdown products from uneaten feed, dead fish, and decaying algae accumulate in the ponds. Nitrites oxidize hemoglobin to methemoglobin with conversion of up to 90% of total hemoglobin in experimental fish, resulting in severe cyanosis and increased mortality rates.[5,19] In healthy catfish, methemoglobin concentrations are typically 5% or less of total hemoglobin. A moderate to severe anemia may also occur and is attributed to shortened RBC life span from oxidant-induced membrane damage and increased metabolic stress when pathways such as cytochrome b_5 reductase (NADPH methemoglobin reductase) are used to counter oxidants in the RBCs.[20] Anemia may exacerbate the hypoxic effects of methemoglobinemia. Diagnosis of nitrite toxicosis in catfish is based on clinical detection of methemoglobinemia by presence of chocolate-brown discoloration of the lips, gills, and viscera. On water quality testing, increased nitrite and decreased chloride concentrations with resultant increase in the nitrite:chloride ratio are confirmatory. The nitrite:chloride ratio in pond water should be 1:10 or less. Chloride plays a key role in preventing nitrite toxicosis, since chloride competes with nitrite for absorption from water by the gills, and thereby inhibits nitrite uptake. Chloride supplementation to lower the nitrite:chloride ratio of pond water is used as both a treatment and preventative of nitrite toxicosis, typically by adding sodium chloride (common salt) to the pond water.

Leukocyte Changes in Disease

Leukocyte changes attributed to stress have been documented in ictalurid catfish following presumed stressful circumstances (e.g., long-distance transportation from ponds to lab) and administration of cortisol.[7,8] These studies relied on relative neutrophilia and lymphopenia, based on changes in percentage differential counts from blood smears. Using flow cytometry, lymphopenia in cortisol-dosed catfish was attributed to decreased B-lymphocyte numbers.[1]

The primary inflammatory leukocyte changes identified in ictalurid catfish include leukocytosis, neutrophilia, monocytosis, and lymphopenia. These changes were documented in catfish with bacterial infections such as *Flavobacterium columnare*, *E. ictaluri*, and parasitic infections such as *Ichthyophthirius multifiliis*. Absolute neutrophilia, monocytosis, and lymphopenia have been documented.[7,17] It is difficult to assess the presence of immature neutrophils in blood due to hyposegmentation in blood smears from normal catfish. No standard exists for the morphologic determination of a "left shift" in catfish. However, the author has observed increased amounts of basophilic cytoplasmic inclusions in neutrophils from catfish with acute *E. ictaluri* infection (Figure 130.2h). These basophilic inclusions are more numerous and often linear, compared to the fine to coarse cytoplasmic granules observed in neutrophils of healthy catfish, and could represent Döhle bodies. The cytoplasm is also more diffusely basophilic, representative of another toxic change. There are no ultrastructural studies to confirm that these inclusions represent retained rough ER and increased free ribosomes. Other evidence of toxic changes such as vacuolization have not been reported in ictalurid catfish.

Acronyms and Abbreviations

ER, endoplasmic reticulum; FDA, Food and Drug Administration; HSC, hematopoietic stem cells; N:C, nuclear to cytoplasmic ratio; PAS, periodic acid–Schiff; SVC, spring viremia of carp; TMS and MS-222, tricaine methanesulfonate; USP, unit of potency.

Cyprinidae is the largest family of predominantly freshwater teleost fishes with over 350 genera and 2500 species (http://www.catalogueoflife.org), including such groups as carp, goldfish, zebrafish and related danios, true minnows, chubs, barbs, shiners, rasborines, and others. It is a morphologically diverse family with members ranging in size from a few centimeters to over 3 meters. They lack jaw teeth, but they have pharyngeal teeth, one to three rows with up to eight teeth per row, which are used for species identification. Their lips are thin and lack folds, ridges, or papillae. The mouth can be sucker-like which may be surrounded by sensory barbels, and often have a protrusible upper jaw. Fin rays are soft except in a few genera where they are fused and spine-like in the dorsal fin. They lack a true stomach and are physostomes with the gas bladder connected to the alimentary canal by a pneumatic duct. This enables the animal to gulp air to fill the gas bladder. Gills are the main respiratory organ in cyprinids, but also play a role in excretion of nitrogenous wastes, ion regulation, and osmotic balance. Cutaneous gas exchange is limited in this group. Hemoglobin is the oxygen-carrying protein.

Cyprinidae are native to North America, Africa, and Eurasia. They primarily eat invertebrates and vegetation, and are egg-layers, but most species do not guard the nest. They are important food fish, recreational angling sport fish, bait fish, and are popular in the aquarium hobby as well as used in research settings. Some, such as the Asian carp (several species collectively called Asian carp), have recently become invasive species in North America, whereas the zebrafish (*Danio rerio*) is an important model species for scientific research.[5,13]

RESTRAINT, BLOOD COLLECTION, AND STORAGE

Fish can be physically restrained without using anesthetics, but this can result in excessive stress which may affect blood values. Handling for as little as 20 seconds can increase PCV up to 25%.[4] If not using a general anesthetic, try to collect blood in less than 30 seconds. When possible, try to collect without completely removing the

fish from water, keeping head and gills submerged by using a sling. In the field, active collection methods involve moving sampling gear to collect fish including electrofishing, stunning, trawls, cast nets, and angling. Passive techniques are stationary and allow fish to move into them including gill nets, traps, and bait lines. All of these may induce a stress response.

Anesthetic agents can also result in physiologic changes, but, when used properly, can help lessen stress. Tricaine methanesulfonate (TMS, MS-222) is the most common and is currently the only United States Food and Drug Administration (FDA) fully approved anesthetic for finfish. Tricaine will acidify the water, which can damage gills, but adding sodium bicarbonate (baking soda) to buffer will reduce or eliminate adverse effects.[15] Specifically, a weight ratio of 1:1 or 2:1 bicarbonate to tricaine is often used. MS-222 concentration of 100–150 mg/L at an intermediate temperature range of 15–23 °C (41–73.4 °F) is recommended for most procedures in cyprinids[11] and typically achieves rapid induction. Ideally, stage 2 anesthesia (loss of equilibrium) is achieved within 20 seconds.[14] Lower concentrations are not recommended, as it takes longer to sedate the animal, which could lead to increased stress. It is important to note that induction time is inversely related to temperature. Other immobilization methods using chemical (quinaldine, benzocaine, metomidate, clove oil and its derivatives) and nonchemical (electrical currents, lower temperatures) options are reviewed in Ross and Ross[17] and may not be recommended. For prolonged procedures, keeping the gills perfused (water running over the gills) with well-aerated water using a pump or moving the fish forward (ram ventilation) is recommended. Fish can then be recovered in a container of fresh water, again well oxygenated with good branchial perfusion.

In larger fish (>8 cm), blood is usually collected using a ventral or lateral approach to the caudal vertebral vessels located ventral to the peduncular vertebrae. The artery and vein are in close proximity and either or both may be sampled. On a ventral approach, a 22–23 g needle attached to a 1–6 cc syringe is inserted (under the scale if necessary) along the ventral midline of the caudal peduncle posterior to the anal fin either at a slightly oblique anterodorsal angle or perpendicular angle, and directed toward the vertebral bodies. Once contacting the vertebrae, the needle is withdrawn slightly, and the plunger is gently drawn back. Vigorous aspiration should be avoided, as this may result in vessel collapse or hemolysis of fragile blood cells. On a lateral approach, the needle is inserted a few millimeters below the lateral line near the base of the caudal peduncle and directed toward the midline and under the vertebral bodies (see Chapter 130). The lymphatic system in fish is extensive and lymphatic fluid dilution will affect results, complicating diagnostic use. Blood can also be collected from the two-chambered heart or bulbus arteriosus of teleosts, but there is a greater risk of damage to the fish. Other collection sites include the Cuvierian duct (a vessel within the posterior oral cavity), dorsal aorta, and branchial vessels.

In smaller fish (<8 cm), collection of small blood volumes from the bulbus arteriosus of anesthetized fish with a small, 23 gauge needle attached to a 1 cc syringe or capillary tube after exposure of the body cavity is possible. Another suggested blood collection method in anesthetized fish is to sever the tail with a scalpel blade and apply a heparinized capillary tube to the caudal vessels.[12,15] However, this method not only results in death, it likely results in tissue fluid contamination and cell lysis. Diagnostic value of potential results should be assessed prior to use of this technique. For these methods, the fish should be immediately euthanized once blood has been collected.

Total estimated blood volume in teleosts is 5% of body weight (kg), which is less than the 10% estimate in many mammals. However, up to 30% of total blood volume from healthy fish could potentially be collected for a nonlethal sample due to differences in fish hemodynamics.[12] Lithium heparin and EDTA are both used as anticoagulants in fish. Fish blood tends to clot rapidly, so it may be necessary to coat the needle and syringe with an anticoagulant prior to collection. Heparin is more commonly used and appears to be effective at 50–100 USP units/mL or 0.3–0.75 mg/mL in most cases.[12,15] Cyprinid blood cells retain morphology with heparin, though some heparin artifact may be present.[14] Mixing rapidly is important and blood clots may form, as heparin does not prevent clotting initiated by the alternate coagulation pathway, which can result from vessel/tissue trauma during blood collection.[12] EDTA at 4–5 mg/mL final concentration is sometimes used as an alternative, as it more reliably prevents clotting, but it is not recommended when using MS222 because the combination of these compounds often causes hemolysis.[5]

Samples should be processed rapidly, as clinically significant changes can occur in whole blood after 1 hour at room temperature or 1–3 hours when refrigerated. Storing whole blood can result in artifactual results. Hematologic counts should be completed within hours of collection. A recently described method which has been evaluated for elasmobranch and several teleost species uses formalin fixation with blood evaluation days to weeks later[1] (see Chapter 128). This method remains to be validated for other species.

LABORATORY ANALYSIS

Nucleated RBCs complicate automated hematologic analysis and while newer techniques are starting to address this issue, they are not readily available.[8] Total RBC and WBC counts are performed similarly to bird and sharks (see Chapters 123 and 128). Packed cell volume is determined using a microhematocrit tube and manual centrifugation. In a study specifically designed to establish reference intervals for koi (*Cyprinus carpio*), samples were spun at 19,000 g for 5 minutes, though >11,000 g is likely satisfactory (Table 131.1).[19]

Hemoglobin (Hgb) concentration is measured using the cyanmethemoglobin method. RBC indices, including

TABLE 131.1 Minimum and maximum hematologic values for 19, 4–5 year, mixed-sex, healthy koi (*Cyprinus carpio*) held at 20–22°C at the University of Minnesota with outliers removed according to ASVCP guidelines.

mean cell volume (MCV) and mean cell hemoglobin concentration (MCHC), are calculated from the total RBC count, PCV, and Hgb concentrations using standard formulas. Blood smears can be stained with either Wright's or Diff-Quik™ stains for differential counts and blood cell morphology evaluation. WBC morphologic and cytoplasmic characteristics, particularly the granulocytes, are variable between fish species. Cytochemical staining using commercial kits for human WBCs and transmission electron microscopy to evaluate cellular ultrastructure can be used to delineate appropriate identification,[20] but standardization is still far from complete.

ERTYHRON

Cyprinid RBCs are oval, with a centrally located, irregularly oval basophilic nucleus with densely clumped chromatin and pale eosinophilic cytoplasm using Romanowsky stains. Koi RBCs measure 10–12 µm by 3–4 µm[19] and those in zebrafish are smaller, approximately 7 by 10 µm[13] Reticulocytes are often smaller in size, with larger, rounded nuclei, a higher nuclear to cytoplasmic (N:C) ratio, and more basophilic cytoplasm (Figure 131.1a). Erythropoiesis can occur in the peripheral blood, so immature forms can be present and can contribute to a mild to moderate degree of anisocytosis and polychromasia (Figure 131.1b,t). Maturation of RBCs is evidenced by increased cell size and Hgb content, and mature cells have higher MCV and MCHC values. The erythron may be affected by stress and environmental conditions.

LEUKON

The most abundant granulocytes have been called both heterophils and neutrophils in the literature.[19] Heterophils are defined as granulocytes with variably staining granules, while neutrophils have granules that appear white, clear, or are inapparent on Romanowsky stains. Cytoplasm is abundant and is often colorless to light blue or gray, and filled with abundant numbers of fine cytoplasmic granules. While granule color may vary with aqueous versus alcohol-based stains, apparently healthy cyprinids may have both cell types on the same slide (Figure 131.1k–o). These cell types are counted separately, though the clinical significance, especially of the neutrophil, is unknown. Cytochemical stains and ultrastructural analysis are warranted to determine underlying functional differences and appropriate classification. Polymorphonuclear cells typically measure 10–12 µm in diameter in koi[19] and 9–10 µm in zebrafish,[13] and are the predominant granulocyte involved in inflammation. They are generally round and contain eccentric nonsegmented to bilobed nuclei with moderately condensed chromatin. The nuclei have less lobation than in mammals and these should not be mistaken for band or immature cells, as this has not been confirmed and may vary by species. Heterophils with round nuclei are presumed to be more immature, consistent with mammals; but this has not been confirmed.

Lymphocytes, typically the predominant leukocyte, function in both humoral and cell-mediated immunity in cyprinids[13] (see Chapter 129). They are usually small, round cells with a rim of light to medium blue cytoplasm, but may be elongated (Figure 131.1e,f). They frequently have pseudopods or blebs along the cell margin (Figure 131.1g). The nucleus is typically rounded with deeply basophilic condensed chromatin, but may occasionally be oval, elongate, or pleomorphic. Lymphocytes have the highest N:C ratio of all leukocytes. As they become reactive, they increase in size and the nucleus may contain large amounts of clumped chromatin (Figure 131.1h). Koi lymphocytes can be classified as small (<8 µm), medium (8–10 µm), or large (>10 µm) based on their diameter.[19] In zebrafish, they average 5–8 µm in diameter.[13]

(**Source:** Photo credits: Dr. Nicole Stacy, Dr. Kendal Harr, and Ms. Jill Arnold. Basophil picture is courtesy of NC State Veterinary Teaching Hospital, Clinical Pathology Laboratory.)

Monocytes are usually the largest leukocyte, measuring 14–16 µm in koi[19] and 12–18 µm in zebrafish.[13] They are round to irregular in shape with a large, often eccentric heterochromatic indented round to horseshoe-shaped nucleus. Monocytes are phagocytic cells, termed macrophages when they migrate into tissue, with round, oval, or lobed nuclei, moderately condensed chromatin, and abundant gray to moderately basophilic cytoplasm (Figure 131.1i). There may be clear or variably colored, round vacuoles in the cytoplasm. Reactive cells may have numerous vacuoles which distort the cell (Figure 131.1j). Cellular margins may appear ragged, due to presence of pseudopodia. Larger amounts of cytoplasm, lower N:C ratio, nuclear morphology, and presence of cytoplasmic vacuoles help differentiate monocytes from large lymphocytes.

Eosinophils are less common than heterophils, though similar to slightly smaller in size. Nuclei are round, multilobed, or irregular and contain fine, mildly condensed chromatin. Cytoplasm is slightly to moderately basophilic with pink, distinct round to rarely elongate granules. The larger granule size and color differentiate them from heterophils (Figure 131.1p). They may not be found in blood smears from healthy fish and there may be species variation in normal eosinophil counts.

Basophils are rare. In koi, they are round and are typically smaller than heterophils, measuring 8–10 µm.[19] They contain large round, eccentrically located nuclei with condensed chromatin. Cytoplasm is abundant and on Wright's stain it is light blue-gray and contains moderately large, round to ovoid, dark basophilic granules that may obscure the nucleus (Figure 131.1q). But again, there can be stain variation with basophil granules staining more poorly with Diff-Quik™. Degranulated basophil granules may appear as empty vacuoles.

THROMBOCYTES AND HEMOSTASIS

Thrombocytes are involved in coagulation and clot formation. They are smaller than RBCs, oval, and have a central, elongate nucleus with clear or light blue-gray-staining cytoplasm. The N:C ratio is higher than in RBCs. Cell shape does vary with species, maturity, and degree of reactivity, from fusiform to oval to irregularly round. They are 3–4 µm in length in zebrafish.[13]

CYTOCHEMICAL AND ULTRASTRUCTUAL FEATURES

Cytochemistry, marker gene expression, immunohistochemistry, flow cytometry, fluorescent stains, and transmission electron microscopy are some methods that can be used to elucidate cell lines; however, use is limited on a routine basis. Upon cytochemical staining of koi whole blood, heterophils (as designated in this chapter) had strong peroxidase activity and reacted with acid phosphatase, periodic acid–Schiff (PAS), and Sudan Black B. Lymphocytes were positive for acid phosphatase and PAS. Monocytes were also positive for acid phosphatase and PAS, but were also positive for α-naphthyl butyrate esterase and β-glucuronidase activity. Eosinophils were positive for naphthol AS-D chloroacetate esterase activity. Basophils were reported to stain with PAS.[19]

Ultrastructurally,[19] koi RBCs contained a nucleus rich in heterochromatin and the cytoplasm was filled with electron-dense hemoglobin, a few mitochondria, and endoplasmic reticulum (ER). Heterophil nuclei contained peripheral heterochromatin and central euchromatin and there were numerous granules, mitochondria, and ER in the cytoplasm. The cytoplasmic granules were elongate, 0.2–0.4 µm in diameter, and consisted of a homogenous matrix with rare thin, needle-shaped crystalloids. In lymphocytes, the nucleus contained both heterochromatin and euchromatin. There were numerous free ribosomes, some mitochondria, and ER in the cytoplasm, and microvilli were often observed on the cell membrane surface. In monocytes, the peripheral rim and central area of the nucleus contained heterochromatin aggregates with strands of euchromatin. The cytoplasm was vacuolated and contained fewer free ribosomes than lymphocytes, numerous mitochondria, and some ER. Pseudopodia were often noted on the cell membrane surface. Eosinophil nuclei contained heterochromatin with small aggregates of euchromatin, and mitochondria and ER were present in the cytoplasm. Cytoplasmic granules were circular to oval, 0.5–1 µm, and had a fine granular matrix with one or more dense, bar-shaped crystalloids. Basophil nuclei contained abundant heterochromatin with small strands of euchromatin, and some mitochondria, ER, ribosomes, and granules were present in the cytoplasm. The granules were round to oval, 0.2–0.4 µm, with a core of dense crystalloid material. Small folds were noted in the cell membrane. Thrombocyte cytoplasm was filled with microtubules and large canaliculi and possible vacuoles with rare mitochondria, polyribosomes, and membrane-bound granules (Figure 131.2).

HEMATOPOIESIS

Fish hematopoiesis is similar to other vertebrates and occurs in several phases. However, cyprinids do not have bone marrow. The zebrafish model is highly conserved and can serve as a general overview for the cyprinids.[5,13] There are multiple phases or waves that take place in different locations. In the first wave, about 12–24 hours post fertilization, primitive myelopoiesis occurs in the anterior lateral mesoderm and primitive erythropoiesis occurs in the posterior lateral mesoderm, which subsequently forms the intermediate cell mass. Cells from these areas develop into either hematopoietic stem cells (HSC) or vascular endothelial precursors. Cell circulation begins after 24 hours post fertilization. The next waves are known as definitive and create erythromyeloid progenitors and pluripotent HSCs, which migrate to the embryonic anterior and caudal

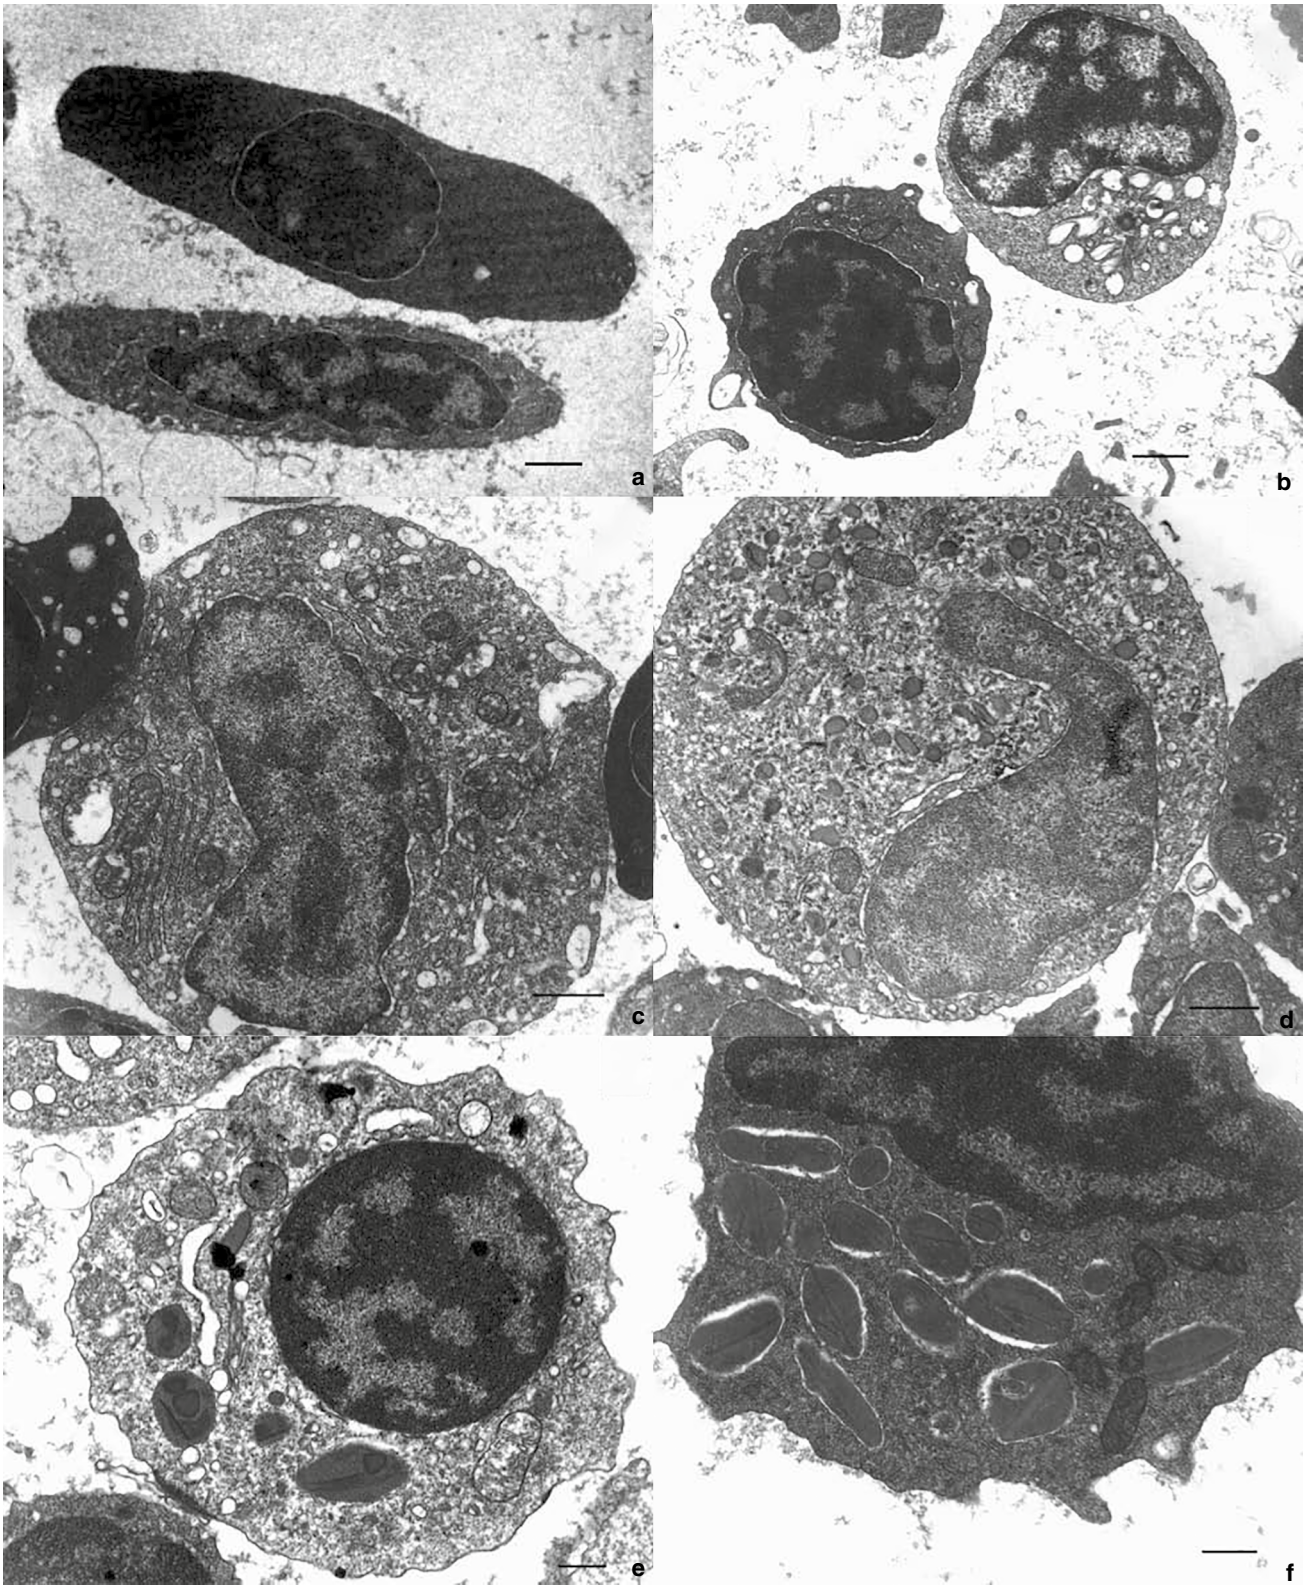

FIGURE 131.2 Ultrastructure of koi blood cells. (a) Erythrocyte with dense cytoplasm and a thrombocyte with an elongated nucleus and cytoplasmic microtubules (bar = 1lm). (b) Canaliculi are visualized as clear, membrane-bound vacuoles in the cross-section of a thrombocyte (left). The lymphocyte (right) has a thin rim of cytoplasm containing a few mitochondria (bar = 1lm). (c) Monocyte with large amounts of vacuolated cytoplasm containing scattered mitochondria and endoplasmic reticulum (bar 1 =lm). (d) Neutrophil with lobulated nucleus and numerous, small cytoplasmic granules (bar =1lm). (e) Basophil with numerous monoribosomes and fewer cytoplasmic granules with crystalloid cores (bar = 500 nm). (f) Eosinophil with densecytoplasm, scattered mitochondria, and large rice-shaped granules that have a characteristic needle-shaped crystalloid core (bar = 400). (**Source:** From [19], figure 3 (p.81) / with permission of John Wiley & Sons.)

kidney, becoming hematopoietic tissue. An HSC subset migrates to the developing thymus to become lymphoblasts. These become the primary hematopoietic sites in adult fish. The anterior or head kidney is predominantly hematopoietic tissue with few renal tubules, the trunk or posterior kidney contains more renal tubules with less interstitial hematopoietic tissue. The spleen, also a site of erythropoiesis, and anterior kidney filter foreign particles and degenerate blood cells.

REFERENCE INTERVALS

Further work on reference intervals in cyprinids is needed. There are multiple reference tables available, but many are compilations or do not meet recent American Society for Veterinary Clinical Pathology (ASVCP) reference interval guidelines.[9] Most do not state outlier removal, do not thoroughly describe the animal population or method which likely contributes to clinically significant variation between publications, or provide confidence intervals[19] instead of medical reference intervals. The issue is further complicated given the enormous diversity and numerous species in this family which inhabit a variety of warm water and temperate conditions. These poikilotherms can tolerate a wide variety of temperatures, which in turn impact hematologic variables. A recent paper[20] summarizes multiple studies on hematologic values of juvenile common carp, *C. carpio*, but authors express concerns on the limited number of individuals and variable genetic and environmental factors. To minimize variability, the authors generated a reference interval from a distinct population of juvenile carp, 5–8 months old, from rearing ponds sampled during a specific time frame, the end of September through October over 9 years. Ranges were wide indicating potential high biological variability. There is no mention of outlier removal, so diseased animals may have been included in the population. The authors note that some hematologic parameters of juvenile carp were quite stable (Hct, lymphocyte counts), some moderately variable (RBC, Hgb, MCV, MCH, and MCHC) and some highly variable (neutrophil, monocyte, and platelet counts). They suggest that the goal should be to develop ranges that are relevant for fish of similar age, size, reared under similar conditions, and sampled in similar time frames or seasons at the same temperature.

In light of the paucity of medical reference intervals for cyprinids in the literature, a de novo reference interval for a low number of koi was generated by the authors (Table 131.1). Blood was collected once in November from adult, healthy, mixed sex koi (4–5 years) held at the University of Minnesota as part of an aquaponics program. They were housed in three 1000 L rectangular tanks (50 animals divided among the three systems), each part of an A-frame nutrient film technique aquaponics system in an enclosed greenhouse. Filtration included a foam pad for mechanical filtration and a wet–dry biofilter with a plastic bio-ball substrate. The fish had been in these systems for at least 3 years and maintained on a standard commercial diet (Skretting, USA). They were originally obtained from a commercial breeder at approximately 2 years of age. Water temperature was 20–22 °C, pH was 7.2, and total ammonia nitrogen was 0.5 ppm. Fish were individually anesthetized in a separate holding container with buffered MS-222. Blood was collected from the caudal vessels by use of a lateral or ventral approach using a heparin-coated syringe and a 23 g needle into Li-heparin blood tubes. Blood smears, PCV, total protein values, and manual hemocytometer counts were done within 24 hours. Blood smears were stained with both Wright–Giemsa and Diff-Quik™ stains for comparison (Figure 131.1k,l). Differentials were conducted using Wright–Giemsa-stained slides, though both stains could be used diagnostically. Hemoglobin was analyzed using a HemoCue Hb 201+ Analyzer.

Partitioning Factors

Although much less is known about the factors that influence cyprinid blood values compared to mammals, some intrinsic and extrinsic factors that influence hematology include age, sex, breed, temperature, water quality, handling stress, hypoxia, reproductive status, season, nutrition, population densities, and disease.[2,3,6,7,8,10,11,12,16,18]

Both age and sex appear to affect hematologic values in common carp (*C. carpio*).[2] Hemoglobin, RBC, WBC, and MCHC increased in older fish (2–3 years) compared to younger fish (9 months to 1 year). Differences were correlated with the animal's length and size. White blood cell count, MCV, and PCV were noted to be higher in males than females. Hematologic profiles of common carp (*C. carpio*) spawners from eight breeds reared under identical conditions and collected during the breeding season revealed significant differences for Hgb, PCV, MCV, and MCH. However, values for RBC concentration, total WBC counts, and leukocyte differentials did not differ between breeds.[18] Hence, breed-specific reference intervals may be needed for some analytes.

Cyprinids compose a large, diverse group of fish capable of inhabiting highly variable environmental conditions. Age, sex, age, time of sampling, and other factors significantly impact hematologic reference values. Lack of method standardization and statistical evaluation further hinders comparison. While literature review is always a recommended starting point, the materials and methods of cyprinid reference interval studies should be thoroughly detailed, as most do not present true medical reference intervals, regardless of title. Establishing study-specific reference intervals is encouraged and standardization of testing and analytical specifications according to guidelines is advised.

HEMATOLOGIC DISEASE

Anemia

Anemia is a common sequela to disease and follows similar patterns of regeneration and lack thereof as found in mammals (see Chapters 129 and 130). However, as poikilotherms, cyprinids will have a decreased regenerative

response at colder temperatures and recovery may, therefore, be extended when the temperature is low. Immune-mediated hemolytic anemia has not been reported in cyprinids, though there is evidence that macrophages will phagocytize older RBCs. For example, a goldfish presented with recurrent buoyancy problems that were determined on radiographs to originate in the swim bladder, not the gastrointestinal tract as is more common. Surgery was performed to correct the swim bladder defect. The follow-up CBC revealed monocytes/macrophages exhibiting erythrophagia, presumed to be part of the postsurgical healing process (Figure 131.1r).

Physiologic Changes

In zebrafish, leukocyte differential cell counts changed depending on the type of stress.[11] Acute stress, simulated by alternating short intervals of air exposure by suspending the fish in a net or swimming at low water levels with the dorsum exposed to air, resulted in lymphopenia, monocytosis, and neutrophilia. Chronic stress, simulated with a combination of tank changes, overcrowding, chasing, and dorsal body exposure, for variable times intervals over 5 days, induced lymphopenia and monocytosis, but no significant change in neutrophil populations. Changes were postulated to be due to increased endogenous cortisol concentrations. Increased erythropoiesis was noted in the common carp (*C. carpio*) when exposed to air for up to 4 hours.[6] Approximately one-third of mature RBCs were replaced by immature RBCs and the authors suggest that this can increase the fish's tolerance to stress.

Inflammatory Disease

Cyprinids are susceptible to a number of viral, bacterial, parasitic, and fungal/oomycete infections which can impact hematologic values (Table 131.2). Several viruses

TABLE 131.2 Physiologic and pathologic factors that affect hematologic values in common carp (*Cyprinus carpio*) and goldfish (*Carassius auratus*).[12] NCR: Not clinically relevant.

Measurand	Increased value	Decreased value

are specific to cyprinids and likely impact hematologic values including: koi herpesvirus (Cyprinid herpesvirus-3), which causes disease in koi, common carp, and hybrids; carp pox (Cyprinid herpesvirus-1), which infects several cyprinid species; herpes viral hematopoietic necrosis disease (Cyprinid herpesvirus-2), which infects goldfish; carp edema virus aka koi sleepy disease (poxvirus), which infects carp, carp hybrids, and koi; and spring viremia of carp virus (rhabdovirus), which infects a number of cyprinid species.[16] There is a scarcity of published information on the hematologic effects of these diseases and further research is warranted. Spring viremia of carp may cause anemia and neutrophilia, monocytosis, eosinophilia, and basophilia, potentially for months after infection.[16] *Aeromonas salmonicida* or other *Aeromonas* species may cause severe ulcerative disease and mortality which can result in either leukocytosis or leukopenia, heterophilia or heteropenia, and monocytosis. Eosinophilia was noted in zebrafish with helminth infestation.[3]

ACKNOWLEDGMENTS

Many thanks to Dr. Nicole Stacy, Dr. Roy Yanong, Jill Arnold and Nicholas Jacob for assistance, advice, and reviews throughout the process.

The suborder Sauria (Lacertilia), within the order Squamata, is an assemblage of roughly 5600 lizard species, spanning more than 40 families.[64] All share a similar elongated quadrupedal body plan, although limbs may be reduced, vestigial, or even absent in some species. Lizards vary in size from the Jaragua dwarf gecko (*Sphaerodactylus ariasae*), weighing a mere fraction of a gram, to the Komodo dragon (*Varanus komodoensis*) that can weigh up to 200 kg.[64] Lizards occupy a wide range of habitats across all continents, except Antarctica, and have evolved a variety of biological and ecological adaptations to survive as ectotherms in different environments. The order Crocodilia includes the morphologically similar crocodiles, alligators, gharial, false gharial, and caimans. Crocodilians are ancient reptiles more closely related to birds than to lizards, but sharing some general anatomic and physiologic similarities to lizards including ectothermia. All 23 crocodilian species are aquatic and carnivorous, with the saltwater crocodile (*Crocodylus porosus*) being one of the world's largest predators. The tuatara (*Sphenodon punctatus*), native to New Zealand, is the only extant species of the Rhynchocephalia, a reptilian order distinct but closely related to lizards. Tuataras are long-lived, cold-adapted, lizard-like primitive reptiles that possess unique anatomical features among which is a parietal, or third, eye. For the purposes of this book, crocodilians and the tuatara will be treated alongside Sauria. Because sick reptiles display a limited array of nonspecific clinical signs, blood collection for hematology and biochemistry is particularly useful and provides valuable clinical information for health assessment of these rather stoic animals.

BLOOD COLLECTION AND PROCESSING

Venipuncture requires an understanding of anatomy, technical skill, and aseptic technique. Logistical considerations include body size, venipuncture sites, and both patient and handler safety. The small size of some species, such as geckos and anoles, may preclude blood sampling. Only limited research has been performed to assess total blood volume and safe volume parameters for blood withdrawal in lizards. The total blood volume likely approximates 5–8% body weight, based on data for snakes and turtles, yet values as low as 2–3% were reported from early experimental studies in sand lizards (*Lacerta agilis*).[17] Quick withdrawal of up to 10% total blood volume is empirically considered tolerable across vertebrates, and has been assessed directly in Siamese crocodiles (*Crocodylus siamensis*) without observed adverse effect.[5] In addition to hemodynamic compromise, potential complications of venipuncture include infection, vascular trauma, and collateral damage to surrounding soft or bony tissues. Some lizards and tuataras are capable of caudal autotomy (voluntary self-amputation of the tail) in response to

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

real or perceived attack. This potentially life-saving defensive mechanism, which may occur prior to the animal being restrained or the tail being grasped, comes with a variety of physiologic and social costs, even if the tail regenerates.[2,20]

Appropriate physical, and sometimes chemical, restraint is essential for successful venipuncture, and care must be taken to minimize risk to both the patient and the handlers. Reptiles are surprisingly strong, with powerful jaws and sharp claws. Helodermatid lizards, e.g., Gila monster (*Heloderma suspectum*) and beaded lizard (*Heloderma horridum*), are highly venomous, and other lizard species such as varanids likely have toxin-secreting glands.[16,65] Wounds (e.g., bites and scratches) incurred during handling of any lizard pose human health risks including blood loss, anatomic compromise, and potential infection that warrant immediate medical attention.[12] Handling of the larger crocodilians is best left to experienced staff.

Accessible venipuncture sites are limited in lizards and site selection is based on several factors, including animal size and behavior. In larger lizards, tuataras, and smaller crocodilians, the ventral caudal/coccygeal/tail vein is commonly used. This vein runs just ventral to caudal vertebrae and is accessed through a ventral midline or a lateral approach. In male lizards, the needle is inserted distal enough from the vent to avoid the hemipenes, which are absent in crocodilians and tuatara. Tail autotomy in many skinks, geckos, and other lizards is problematic, so the tail should be avoided in these species. In chameleons, tail discoloration may occur distal to the sampling site, but resolves within weeks.[37] A ventral abdominal vein, which runs along the ventral coelomic midline just beneath the coelomic membrane, is accessible for venipuncture in most lizards. However, this vessel cannot be visualized (blind stick). Careful and slow needle insertion in a sedated lizard is warranted to avoid lacerating the vein and causing a hemocoelom. Jugular venipuncture techniques have been described as an alternative for small lizards and chameleons.[9,14,47] Approaches for cephalic vein and brachial plexus sampling are uncommonly used. Blood sampling using digit lacerations or amputations, the postorbital sinus, and cardiocentesis are not recommended due to potential risks, including pain, infection, or damage to neighboring tissues.[60] In large crocodilians, blood can be collected from the postoccipital spinal venous sinus (supravertebral sinus, internal jugular vein, occipital sinus) caudal to the occiput and dorsal to the spinal cord, but risk exists for sample contamination with cerebrospinal fluid as well as for potential injury to the spinal cord.[48,50]

Lizards possess a closed circulatory system with a chambered heart and a circulatory tree distributed throughout the body. The blood of lizards is red, except for five species of aptly named green-blooded skinks in the genus *Prasinohaema*, native to New Guinea. In these lizards, the highest serum biliverdin level among any amniote species imparts a nonpathological bright lime-green color to the blood.[1] The lymphatic system differs from that of mammals in the absence of lymph nodes and existence of one or more lymph hearts, often located in the pelvic region.[32] Due to the close association of lymphatic and vascular networks, lymph-contaminated blood samples are common. This lymph component decreases erythroid density (decreased PCV, Hgb, etc.) and increases small lymphocyte numbers. A sample with visible lymph contamination, seen as clear or white fluid entering the needle hub and syringe upon venipuncture, is best avoided for hematologic assessment.

The anticoagulant of choice is dependent on test and species. For CBCs, either lithium heparin or K-EDTA is commonly used. EDTA has been used repeatedly in lizards, crocodilians, and tuatara blood samples with no hemolysis reported and is recommended at this time for CBC evaluation. Studies suggest that EDTA may be preferable to lithium heparin in green iguanas (*Iguana iguana*) and Chinese water dragons (*Physignathus concincinus*) due to better cell morphology, less WBC and thrombocyte clumping, and cell counts more similar to those from assessment of non-anticoagulated blood.[27,36] Anticoagulation with heparin is often linked to blue or pink discoloration of blood films and increased clumping of WBCs and thrombocytes versus EDTA-anticoagulated blood,[31] potentially affecting cell identification and quantification. Both EDTA and heparin anticoagulation are known to cause some changes to hematologic values in comparison to non-anticoagulated blood;[27] smear preparation from non-anticoagulated blood immediately after collection can negate potential artifacts and also yield information from patients of extremely small body size, in which collection of only a drop of blood is feasible. The coverslip method for blood film preparation is recommended by some authors due to perceived benefits in regard to reptilian blood cell fragility and cell distribution.[60] When a small blood volume is anticipated, heparin anticoagulation has the benefit of better facilitating plasma chemistry in addition to hematology. There is increased plasma yield in comparison to serum, and sodium- and potassium-EDTA salts confound electrolyte results.

A lizard CBC includes quantitative (PCV, RBC, Hgb, and WBC concentration) and qualitative assessment of RBC, WBC, and thrombocyte lineages, as in other vertebrates (see Chapter 123). Qualitative morphologic assessment is a key component of reptile health evaluation and requires well-made and representative blood films, with appropriate cell distribution and staining quality. Blood smears should be made as soon as possible after collection. Due to the risk of spurious findings, clotted samples should be avoided. A variety of Romanowsky-type stains (e.g., modified Wright–Giemsa) can be used for microscopic assessment, including rapid stains (e.g., Diff-Quik), though the latter may stain cell granules less reliably. Diagnostic accuracy and interpretation rely on the hematologist's familiarity with the specie's cell morphology under the stain conditions used.

ERYTHRON

Lizard RBCs are nucleated oval cells as in all vertebrates except mammals. When compared to birds and mammals, lizards have fewer circulating RBCs and lower

PCVs, but comparatively larger RBCs with lower corpuscular hemoglobin concentrations.[30] Lizard RBC sizes vary across species with dimensions reported in the range of 13–19 µm length and 8–12 µm width. These RBC sizes are generally smaller than that of snakes and turtles, and RBC numbers are reciprocally higher.[13,29] Crocodilian RBCs are on par with lizards, while the length and width of tuatara RBCs (mean 23 × 14 µm) exceeds that of squamates.[11,21] Mature RBC nuclei are centrally located and rounded to oval with variably irregular margins, dense chromatin, and surrounding eosinophilic cytoplasm (Figures 132.1 and 132.2). The nucleus of aged RBCs is smaller and denser (pyknotic).[60] Mild anisocytosis, polychromasia, and poikilocytosis are common in health (Figure 132.3). Erythroplastids (RBCs lacking nuclei) occur in low numbers and have no known clinical significance.[31] Low numbers (<2%) of circulating immature RBCs (e.g., rubricytes) are also common in health. Reptile RBCs are reported to be long-lived, though studies in lizards are lacking.[54]

Erythrocyte lineage maturation is similar to that in mammals with notable exceptions of nuclear retention and mild cell-size enlargement (versus progressive diminution) in terminal maturation. Polychromatophils are oval, but rounder than mature RBCs, with mild cytoplasmic basophilia and less-dense chromatin. Rubricytes are smaller round cells with a round nucleus, clumped chromatin, and a concentric ring of darker basophilic cytoplasm, which must be differentiated visually from similarly sized lymphocytes. Earlier erythroid precursors in circulation (prorubricytes and rubriblasts) are uncommon in health, but increase in pathologic states (e.g., erythroid regeneration) (Figures 132.3 and 132.4). These larger round cells with dark basophilic cytoplasm, round nuclei, looser chromatin, and, in blasts, a visible nucleolus, are similar to those of mammals. Mitotic rubricytes are occasionally present in circulation in health and increase in regenerative states.

LEUKON

Heterophils, lymphocytes, monocytes, basophils, and occasionally eosinophils are typically found in health (Figures 132.1 and 132.2). Other circulating WBCs, including plasma cells and macrophages (siderocytes, melanophages), are inconsistently seen and can indicate disease (Figures 132.3 and 132.4). The WBC differential of many lizards is primarily lymphocytic, although heterophils are reported as predominant in some species, such as Gila monsters.[8,60] Both heterophil- and lymphocyte-predominant leukograms are reported in crocodilians,[38,43,51,59] and lymphocytes are reported as predominant in tuataras.[11]

Mature heterophils are large, round granulocytic cells with colorless cytoplasm containing many eosinophilic pleomorphic granules (rod-, spindle-, or angular-shaped). Cell sizes in the range of 9–23 µm have been reported for various lizards as well as tuatara and the Nile crocodile (*Crocodylus niloticus*).[21] Heterophil granules range from neutral or muted to brightly eosinophilic depending on staining method. Degranulated-appearing heterophils are a relatively common finding and likely relate to sample handling or slide preparation factors, such as prolonged storage, underfixation, or staining.[28,60] Nuclear morphology varies across species: round to oval (e.g., most crocodilians, monitor lizards) or lobulated/segmented (e.g., green iguana, bearded dragon, tuatara). Chromatin in mature heterophils is densely clumped. Cytochemical staining patterns of lizard heterophils vary between species including variable reports of positive or negative staining for benzidine peroxidase (peroxidase).[8,11,28,43,46] For expected staining patterns, a thoughtful literature review is recommended. Heterophils are considered phagocytic, but may be capable of oxidative response in at least some species of lizards (e.g., green iguana, red-headed rock agama (*Agama agama*)).[4,28]

Lymphocytes are comparable to those in other vertebrates, consisting of predominantly small cells with high nuclear to cytoplasmic ratio and mildly basophilic cytoplasm (Figures 132.1 and 132.2). Size variation is common (5–15 µm).[21] Nuclear morphology is round with densely clumped chromatin. In many species, lymphocytes are the predominant circulating WBC in health. Differentiation of lymphocytes from thrombocytes is a frequent visual challenge (Figure 132.3). Distinguishing features of lymphocytes include mild cytoplasmic basophilia, slightly larger nuclei, and more clumped chromatin. Cytochemical staining with periodic acid–Schiff (PAS) typically stains reptile thrombocytes positively, likely staining glycogen, and most lymphocytes negatively. An exception to this pattern was seen in lymphocytes of American alligators, which stained PAS-positive, reflecting probable antibody production.[43] Reactive lymphocytes are characterized by larger size and more abundant deeply basophilic cytoplasm (Figure 132.3). Granular lymphocytes contain low numbers of distinct small eosinophilic cytoplasmic granules. Plasma cells are also occasionally identified (<1% of WBCs in health), and are classically characterized by deeply basophilic cytoplasm, paranuclear clearing, eccentric nuclear position, and coarsely clumped chromatin. Rarely, plasma cells containing clear or pale basophilic immunoglobulin Russell bodies (Mott cells) may be found (Figure 132.4g). The presence of reactive lymphocytes and/or plasma cells suggests immunologic stimulation. Circulating lymphocyte concentration in reptiles is also influenced by factors other than disease, such as seasonality and environmental conditions.[13,63]

Monocytes are often the largest leukocytes, with cell size ranging up to 25 µm diameter.[60] These cells are round with moderate to large quantities of pale-gray and subtly grainy cytoplasm. Nuclear shape is variably round, oval, indented, or mildly lobulated, with fine chromatin. Cytoplasmic vacuolation of occasional monocytes is common and may reflect cellular reactivity or in vitro artifact (Figure 132.3). Circulating monocytes containing phagocytized material can herald underlying pathology (e.g., hemolysis, inflammation), but must be interpreted in light of sample handling (Figure 132.4). Macrophages containing melanin pigment (melanomacrophages) are normally found in many reptilian tissues

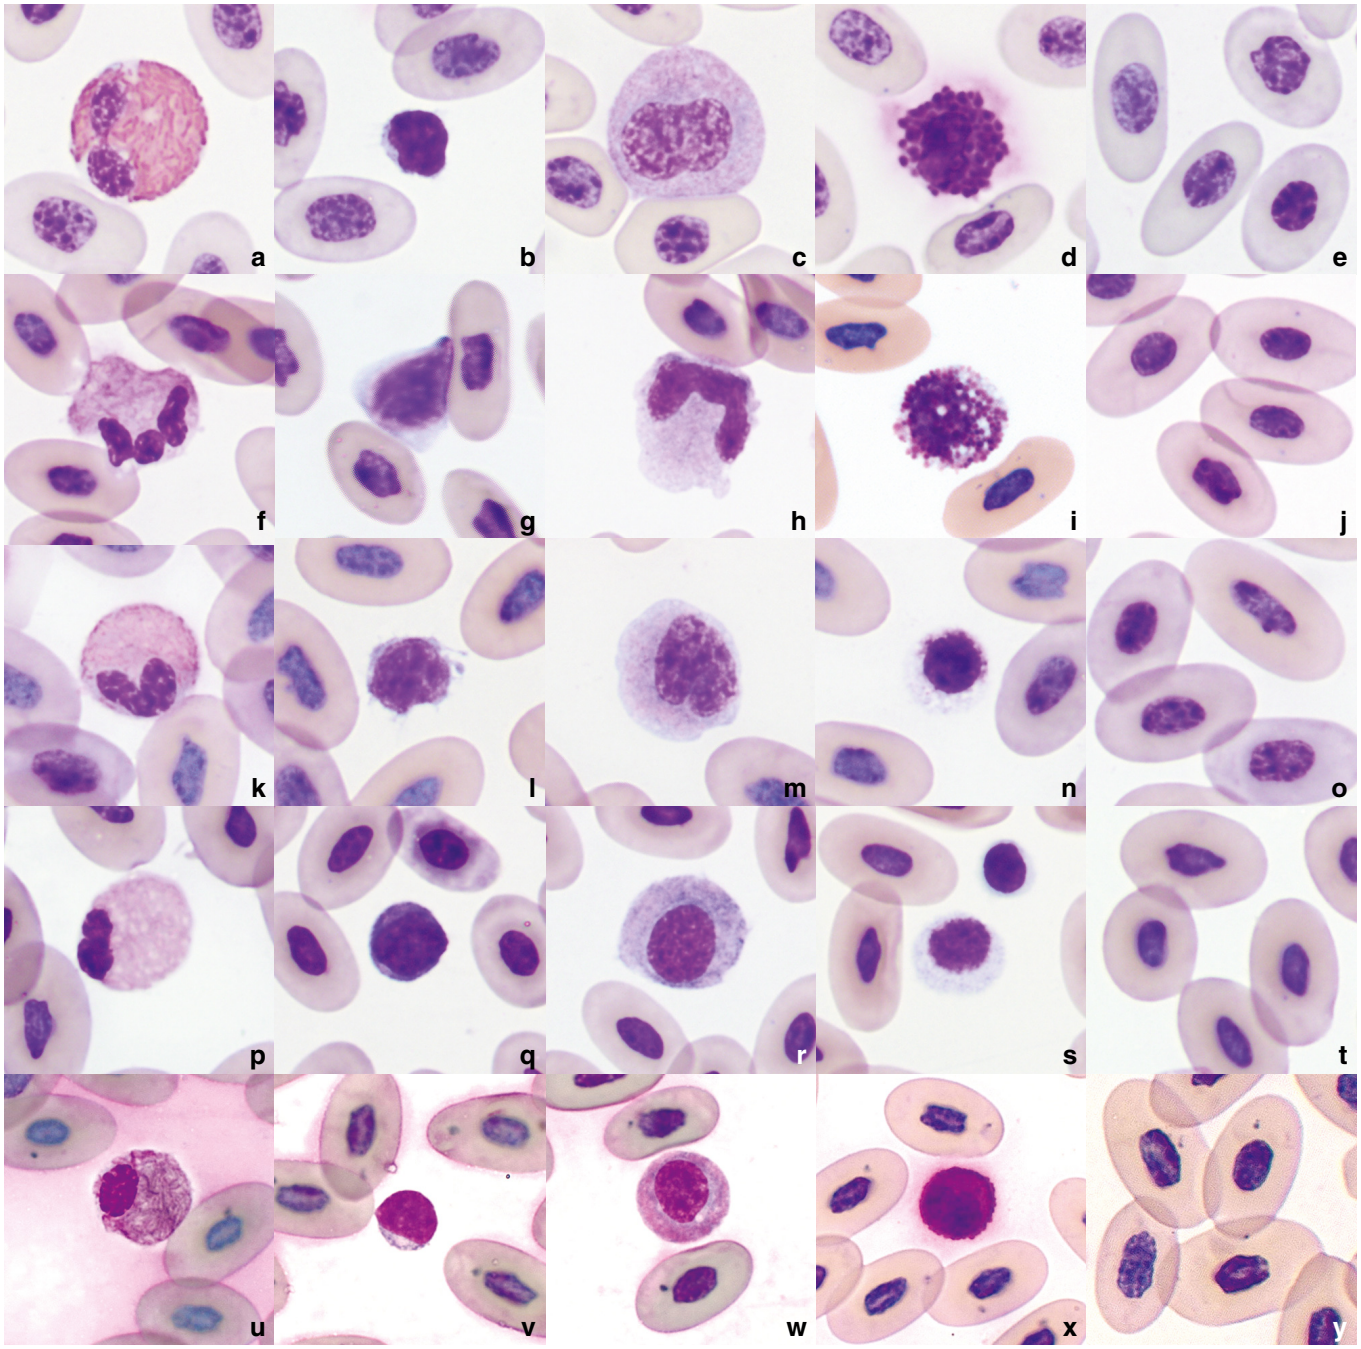

FIGURE 132.1 Common blood cells of iguanid and gekkonid lizards in health. and can rarely be found on blood films. When increased, melanomacrophages can indicate underlying nonspecific disease. Azurophilic monocytes are also identified occasionally in lizards and crocodilians, and are visually distinguished from standard monocytes by azurophilic cytoplasmic granules ranging from fine dust-like stippling to distinct purple granules (Figure 132.3). The nucleus is round to oval with clumped chromatin. The cellular origin of azurophils has been controversially classified as granulocytic or monocytic and may vary between reptile species. In most lizards and crocodilians, cytochemical stains support a monocytic lineage (azurophilic monocytes), being variably positive for acid phosphatase, alpha-naphthyl butyrate esterase, and PAS, and negative or only weakly positive for Sudan Black B and peroxidase.[28] Strong staining of azurophils for peroxidase and Sudan Black B, similar to that found in snakes and mammalian neutrophils, was a

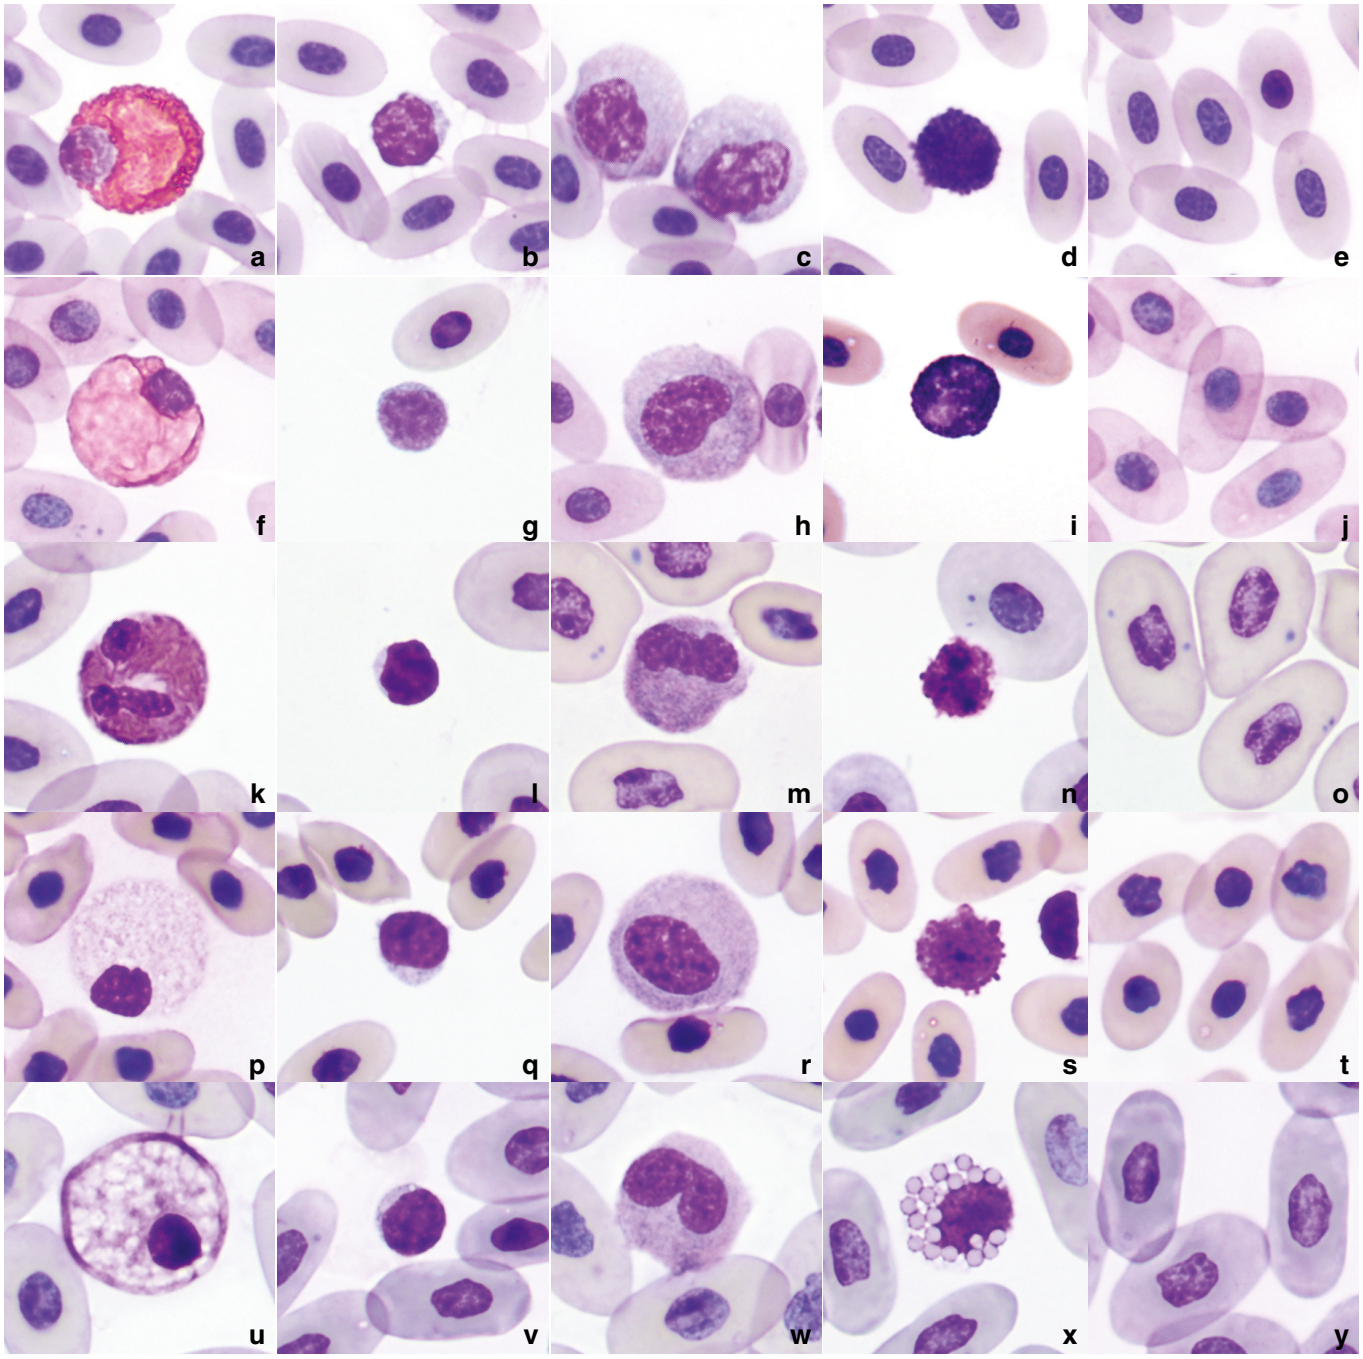

FIGURE 132.2 Common blood cells of monitor lizards, crocodilians, and Chinese crocodile lizards in health. (**Source:** Photo (i) is courtesy of Dr. Kendal Harr.)

unique finding in Gila monsters.[8] Due to unclear clinical significance and limited diagnostic value, separate classification and enumeration of azurophils in lizards is typically not necessary.

Eosinophils are present in low numbers or absent in health and are round granulocytic cells with clear to light blue cytoplasm containing many distinct round granules that stain variably eosinophilic, blue, or green across species. Eosinophil granule-staining properties are highly variable across species (Figure 132.3a–e). Cell sizes similar to heterophils (9–20 µm) are reported.[60] The nucleus is variably round to oval, lobed, central, or eccentric, depending on species. Though the distinction between heterophils and eosinophils ("eosinophilic granulocytes") is unclear in early references, eosinophils of lizards measured the smallest across reptile taxa.[21] Peroxidase staining has been suggested to help differentiate eosinophils from heterophils; however, variable

patterns are reported and review of species-specific literature is again recommended to assess expected cytochemical staining.[28]

Basophils are often present in low number, but vary substantially. They are smaller round cells (7–16 µm) with clear cytoplasm containing variably staining dark basophilic to purple or nonstaining granules.[21] Basophilic-staining granules often obscure the nucleus, which is round and central. Poorly staining granules appear as clear vacuoles and are commonly attributed to artifact from water-based stains or other components of rapid stains (Figure 132.3).

THROMBON

Thrombocytes are important in primary hemostasis of lizards and additionally have mild phagocytic activity. The cells are small and variably elliptical, with colorless to pale blue cytoplasm, central round-oval nuclei, and dense chromatin (Figure 132.3). Low numbers of small eosinophilic granules are occasionally present. Differentiation from lymphocytes can be difficult; thrombocytes generally have less basophilic to colorless cytoplasm, wispier or indistinct cytoplasmic margins, and denser nuclear chromatin. As mentioned in the earlier text, with few exceptions, PAS staining has been used to differentiate these cells; thrombocyte cytoplasm stains positive (pink) and that of lymphocytes typically does not stain.[60] Activated thrombocytes can show irregular margins with cytoplasmic extensions (pseudopodia) and vacuolation. Thrombocyte clumps in vitro are common and should be noted, as well as communicated in reporting of thrombon mass adequacy.

Thrombocytopenia is recognized but uncommon; assessment must include blood smear evaluation for clumps causing pseudothrombocytopenia. As in other taxa, excess consumption, destruction, or decreased production are the primary underlying processes. Associations between nuclear polymorphism in thrombocytes and severe inflammatory disease as well as prolonged anorexia have been proposed.[31]

HEMATOPOIESIS AND BONE MARROW ASSESSMENT

There are few studies of lizard hematopoiesis. As in birds, the yolk sac is a primary site of embryonic erythropoiesis. The bone marrow is the primary site of postnatal hematopoiesis and consists of a reticular network and blood sinuses, in which erythropoiesis occurs intravascularly and granulopoiesis extravascularly.[67] Other organs such as the spleen, liver, and mucosal-associated lymphoid tissues can contribute substantially in some disease states.[40] Erythrocytes are physiologically removed by phagocytes, primarily in the spleen.

Though uncommonly performed, and complicated by lack of procedure optimization, poor cellular exfoliation, and impact of extramedullary hematopoiesis, bone marrow in lizards, crocodilians, and tuataras is most reliably collected from the femur or tibia. In smaller lizards, a spinal needle is inserted through the trochanteric fossa or through the tibial crest and bone marrow is aspirated with a similar method as in other species (see Chapter 141). Erythropoiesis, granulopoiesis, and lymphopoiesis follow cellular morphology and progression similar to that in other vertebrates. Low numbers of macrophages, lymphocytes, and plasma cells are also observed. Like mammals, T lymphocytes are derived from the thymus. B lymphocyte origin is unclear in lizards. Thrombopoiesis is comparable to that in birds, consisting of a developmental progression from thromboblasts, to immature thrombocytes, to mature thrombocytes. Thromboblasts resemble rubriblasts; developing thrombocytes become progressively smaller, less basophilic, and elliptical, with dense nuclear chromatin. Interpretation of hematopoietic abnormalities in these species follows mammalian classifications.

REFERENCE INTERVALS AND INTERPRETATION

Reference intervals for individual species are often not available or are incompletely described. Adherence to best practices for reference interval generation is only recently more common and published "reference intervals" must be critically evaluated.[15] When no appropriate reference interval is available, results from the same animal over time or similarly housed comparator animals of the same species may provide pertinent data for comparison.

In addition to familiarity with species variations and preanalytic factors common in homeothermic vertebrates, lizards are ectotherms that rely heavily on environmental parameters, having evolved behaviors and strategies to best utilize the specific biotopes they inhabit. Hematologic values may fluctuate, and the sparse sets of "reference interval" values published for lizard species seldom account for factors that would likely impact interpretation of cell counts. Factors include intrinsic (age, sex, reproductive status) and extrinsic (season, temperature, other environmental conditions, diet, and social dynamics) variables. Furthermore, preanalytic variables such as venipuncture site, lymph dilution, and sample handling play a large role. The requirement for manual methods yields inherent imprecision and error. Techniques used to determine cell counts vary and interobserver differences in cell description and identification are a concern. Chronic and acute stress related to captivity and capture may also impact hematologic variables,[10] though this is challenging to document, especially in wild populations in which health status and other variables are unclear. Examples of recognized differences in hematologic ranges generated from healthy populations based upon extrinsic and intrinsic variables other than disease include: differences in total and differential WBC counts in free-ranging versus managed Texas horned lizards (*Phrynosoma cornutum*), or captive green iguanas housed under different conditions;[28,44] effects on RBC density or lymphocyte concentration by manipulation of environmental temperature in Cunningham's skinks (*Egernia cunninghami*) and saltwater crocodiles;[39,63] differences in seasonal variations in RBC, lymphocyte, and eosinophil concentrations in various species; and many other differences in hematologic findings between life stages, sexes, and reproductive status in a wide variety of species.[13,59]

HEMATOLOGIC DISEASE

Quantitative and qualitative hematologic assessment contributes to health screening of lizards, crocodilians, and tuataras in the same manner as in other vertebrate

species. Clinically significant findings can include anemia, inflammation, atypical cell populations, and infectious agents. A working knowledge of species-specific or related genera-specific findings, natural history, and literature review is necessary for correct interpretation.

Anemia

The response of the erythrocytic lineage to disease manifests in lizards similarly to other vertebrates, though specific disease conditions are generally less well described in comparison to mammals (see Section III). The major pathologic mechanisms of anemia (common) and erythrocytosis (rare) are conserved across taxa. Increased erythroid precursors most commonly reflect a regenerative response (Figure 132.4). In lizards, this response decreases mean cell hemoglobin concentration and, unlike in mammals, may also decrease mean cell volume due to the smaller size of precursor versus mature RBCs. Mildly increased polychromasia due to precursor circulation (rubricytosis) is reported with ecdysis. Dyserythropoiesis with dysplastic maturation evident in circulating blood is uncommon as a primary pathology. However, dysplastic changes, including anisocytosis, binucleation, and mild poikilocytosis, may be seen with intense regeneration, or may be secondary to failure of erythropoiesis in pathologies such as inflammation, neoplasia, and sepsis. Fusiform to pyriform RBCs occur commonly in low numbers as preparation artifacts. Reticulocyte enumeration can be used to assess regenerative response. Reticulocytes are identified by a ring of aggregated reticulum encircling the nucleus with new methylene blue vital staining. Polychromatophils are expected to stain as reticulocytes, but, due to a maturation spectrum, not all reticulocytes are polychromatophilic with routine stains. The regenerative response of lizards is sluggish compared to that in mammals. Anemia persisting more than 1 month without regeneration is considered nonregenerative.[60]

Inflammation

Leukocyte responses in disease are comparable to those seen in other vertebrates, though cellular responses are more affected by extrinsic factors and may therefore seem less predictable, e.g., low temperatures are associated with lower WBC counts. The most common WBC shift is heterophilia due to inflammation. Overwhelming inflammation can cause heteropenia. Established inflammation can result in monocytosis. Other shifts include responses to physiologic states and stressors (e.g., catecholamines, glucocorticoids, reproductive cycles), infectious agents (e.g., parasitism causing eosinophilia), metabolic derangements (e.g., lymphopenia with starvation), and a variety of pathologic and extrinsic variables (neoplasia, toxins, environment, etc.).

With significant bone marrow stimulation, left shift of the heterophil lineage is characterized by progressively more immature precursors (bands, myelocytes, metamyelocytes, promyelocytes, and myeloblasts) displaying increasingly immature features: subtly larger cell and nuclear size, abnormal nuclear lobulation, increased cytoplasmic basophilia, immature (primary) or pleomorphic cytoplasmic granules, and a higher nuclear to cytoplasmic ratio (Figure 132.4). In species with lobulated mature nuclei, immature cells have progressively less segmentation (from band-shaped to indented to rounded). In species with round mature nuclei, changes with immaturity are more subtle and may be difficult to assess (i.e., larger nuclear size, looser chromatin).

Toxic changes signifying accelerated heteropoiesis are common in cases of severe inflammatory stimulation. These morphologic changes represent alterations in normal cell development in the bone marrow and are characterized by a spectrum of increased cytoplasmic basophilia, cytoplasmic vacuolation (foaminess), reduced and/or more variable cytoplasmic granules (degranulation), and increased abnormal, often purple or blue, cytoplasmic granules (Figure 132.4). Both the degree of the toxic morphology and proportion of cells affected provide insight regarding severity. Artifactual heterophil degranulation is distinguished from toxic change by the absence of other morphologic alterations characteristic of toxicity (e.g., cytoplasmic basophilia, abnormal granulation).

The presence of circulating bacteria is a critical hematologic finding (Figure 132.4). Care must be taken to exclude contamination from sampling or staining. With this exception of in vitro artifact, phagocytized bacteria signify bacteremia and typically a poor prognosis. Infection with extracellular spiral bacteria was recognized in a rhinoceros iguana (*Cyclura cornuta*),[57] and a molecularly confirmed *Helicobacter sp*. causes infection and disease in Grand Cayman blue iguanas (*Cyclura lewisi*) and introduced green iguanas.[7] A chlamydial infection with classic chlamydial bodies in monocytes is reported in a flap-necked chameleon (*Chamaeleo dilepis*) with concurrent poxviral infection.[35]

Neoplasia

Although infrequent by mammalian standards, hematopoietic neoplasms have been identified as one of the most common malignancies in lizards.[18,33] Of these, lymphoid neoplasms are most common. Leukemias are recognized by leukocytosis and either atypical cell morphology (acute leukemia) or well-differentiated morphology (chronic leukemia). Acute leukemias have been more commonly reported (Figure 132.4). Species diagnosed with lymphoid leukemia include the Egyptian spiny-tailed lizard (*Uromastyx aegypticus*), Savannah monitor (*Varanus exanthematicus*), green tree monitor (*Varanus prasinus*), inland bearded dragon (*Pogona vitticeps*), Gila monster, Northwestern alligator lizard (*Elgaria* [*Gerrhonotus*] *coerulea principis*), and a chameleon.[18,19,26,56] Myeloid leukemias affecting bearded dragons, unspecified geckos,[18,24] and unclassified leukemias are also reported.[23] Diagnostic classification of hematopoietic proliferations follows the same scheme as in mammals, though ancillary testing (immunochemistry, flow cytometry) is more limited and infrequently employed.[19]

Hemoparasites and Inclusions

Many commonly identified RBC inclusions in lizards are of no clinical significance, except to recognize and differentiate from pathology (Figure 132.3). These include: pleomorphic refractile cytoplasmic foci attributed to staining artefact; small, discrete, round, basophilic cytoplasmic inclusions corresponding ultrastructurally to degenerate organelles;[6] and rounded to angular pale crystalline inclusions linked ultrastructurally to polymerized Hgb.[60] The latter inclusions have been documented in both healthy and ill iguanas as well as other reptiles, and may increase with disease, but are not of clear clinical significance.[28,58] Larger intraerythrocytic distinct clear rounded vacuoles have occasionally been observed in ill reptiles. Ultrastructural assessment in a septic alligator showed the vacuoles to be empty or contain amorphous particles. An association with septicemia is proposed.[53]

Hemoparasites are a relatively common finding in lizards, particularly in wild or wild-caught animals, and also occur in crocodilians and tuataras. The clinical importance of hemoparasites must be interpreted considering both intrinsic factors (e.g., immunosuppression, concurrent disease) and extrinsic factors (e.g., husbandry, temperature, season, age).

Lizards are host to a variety of protozoal parasites. Hemogregarine gamonts are common incidental findings in the cytoplasm of low numbers of RBCs in health. The gamonts are oval elongated or plump (sausage-shaped) with pale basophilic to colorless cytoplasm and a small basophilic to purple nucleus. These variably displace the nucleus and contain no heme pigment. Genera include *Hepatozoon*, *Hemogregarina*, *Karyolysus*, and others,[42,60] but definitive identification by molecular or other methods is pursued in relatively few cases and they are often reported simply as "hemogregarines." These protozoa are host-adapted and usually considered clinically incidental; statistical associations of hemoparasitism with hematologic changes, such as increased circulating erythroid precursors or monocytosis, have been occasionally reported,[3,8] but are not consistent findings and may reflect other host factors or comorbidities. *Hepatozoon tuatarae* infestation in tuataras varied with body size and tick burden.[22]

Hemococcidia are eimerial parasites that are considered potentially pathogenic. The life stages of hemococcidia (e.g., *Schellackia*, *Lainsonia*, *Lankesterella sp*.) include sporozoites in the peripheral blood and schizogony in the intestine.[45] Zoites infect WBCs or RBCs, and are rounded to oval structures with colorless cytoplasm and a small nucleus (resembling systemic *Isospora* (*Atoxoplasma*) of birds).

Hemosporida (e.g., *Plasmodium*, *Hemoproteus*, *Saurocytozoon sp*.) are considered potential pathogens, though light infections may be clinically tolerated. The life cycles and related morphologies recognized on blood films in this group vary and resemble corresponding organisms in birds. *Plasmodium sp*. undergo both sexual and asexual replication in circulation, recognizable as zoites (merozoites, trophozoites), gamonts, and schizonts (meronts). While there are no *Plasmodium* species described from crocodilians or tuatara, malaria in lizards is common and often apparently subclinical, but may impact performance and therefore population health.[55] The intraerythrocytic stages of *Hemoproteus sp*. are limited to transient zoites and predominant gamonts. Hemoglobin breakdown pigment (hemozoin) is described in both *Plasmodium* and *Hemoproteus sp*. infections. By contrast, the circulating intracellular gamonts of *Saurocytozoon sp*. closely resemble *Leukocytozoon sp*. of birds, causing cellular distortion and lacking heme pigment.

Infection by hemoflagellates such as *Trypanosoma* or *Leishmania sp*. appears to be subclinical. Trypomastigotes are morphologically comparable to those seen in other taxa, with a kinetoplast and undulating membrane. *Leishmania sp*. can be recognized by extracellular flagellated promastigotes and/or amastigotes in circulating cells, including RBCs and thrombocytes. A kinetoplast is described, but appears variably apparent on light microscopy.[60]

Sauroplasma (*Aegyptianella*, *Sauroplasma sp*.) are piroplasmid parasites characterized by small round or ring-shaped inclusions in RBCs (resembling those of *Babesia* or *Theileria sp*. in mammals).[62] They must be differentiated from common nonparasitic inclusions and pathogenicity is uncertain.

Microfilaria are commonly identified organisms in lizard blood and a good reminder for low-magnification screening (Figure 132.4). A variety of filariid genera are reported, such as *Foleyella* in chameleons and agamas, but in many cases the parasites are not definitively identified.[49] The infestations are often subclinical, but a high parasite burden, inopportune anatomic location of adult worms, and other factors can lead to clinical disease.[34,41]

A few viral infections in lizards induce recognized hematologic findings. Intraerythrocytic iridoviruses have been documented in chameleons, agamas, skinks, geckos, bearded dragons, and other species.[25,52,61] Thought to be possible piroplasms (pirhemocytonosis) in early reports, infected RBCs contain variably sized and pleomorphic eosinophilic or basophilic cytoplasmic viral inclusions that enlarge as infection progresses, and may be accompanied by poorly staining globoid structures (vacuole, albuminoid body).[25,52,61] Iridoviral pathogenicity is incompletely understood and may be dependent on temperature, among other factors; polychromasia, hypochromasia, and anemia have been reported in some cases.[25] Poxviral infection, seen as eosinophilic to blue-green staining pleomorphic intracytoplasmic inclusions, has been reported in circulating monocytes, lymphocytes, and thrombocytes of free-ranging flap-necked chameleons.[35] Pale basophilic intracytoplasmic inclusions ultrastructurally linked to rhabdovirus infection have also been reported in a caiman lizard (*Dracaena guianensis*) with unknown clinical significance.[66]

Although not associated with inclusions, Agamid adenovirus-1, which is overrepresented in bearded dragons and associated with variable clinical signs, is also frequently associated with leukocytosis and anemia in clinically affected lizards (K. Harr, personal communication).

Snakes are part of the class Reptilia, order Squamata, and infraorder Serpentes. The idea that snakes are a group distinct of lizards is a common misconception. Snakes are part of the fourth divergent clade of squamate evolution (after geckos, skinks, plated lizards, night lizards and teiids, lacertids, amphisbaenids), called Toxicofera for their shared anatomical trait of venom glands.[36] Along with snakes, iguanids, agamids, chameleons, monitors, helodermatids, and anguids are also included in Toxicofera. Therefore, a ball python (*Python regius*) is more closely related to, and a better model for, a bearded dragon (*Pogona vitticeps*) than a prehensile-tailed skink (*Corucia zebrata*). More than 2900 snake species are currently recognized, inhabiting all continents except Antarctica. As of 2020, the International Union for Conservation of Nature's (IUCN) Red List of Threatened Species listed 126 snake species as endangered, and 63 as critically endangered.[16]

By understanding their taxonomy, one can better evaluate individual species' hematologic values and morphologic changes on a peripheral blood film. Additionally, understanding the biology of these ectotherms is important not only for the individual patient's well-being, but for insight into environmental changes associated with global climate warming and emergence of disease. Snakes, just like any reptiles, are often the victim of the human–animal interface crisis and are harmed by illegal trade, poaching, introduced and invasive species, habitat destruction, emerging infectious diseases, and global warming.

BLOOD COLLECTION AND PREANALYTICAL ERROR

Venipuncture sites in snakes are few and include the ventral coccygeal vein, the jugular veins, and the heart. Because of the close anatomic association of lymph and blood vasculature, lymphatic fluid contamination may occur during blood sampling. This can result in dilution of the sample, resulting in decreased PCV, WBC counts, and possibly low thrombocyte counts. Lymphocytes may appear significantly increased and caution should be used to not overinterpret as a lymphoid leukemia. Unlike other species, puncture of the three-chambered heart, with the intent of sampling the single ventricle, is often done in the awake animal by experienced reptile

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

practitioners. With cardiocentesis, pericardial fluid may be concurrently sampled and can also have a dilutional effect. As with any sample, if the findings and hematologic values do not correlate clinically, a repeat sample should be obtained and analyzed prior to diagnostic interpretation.

Hemolysis definitively due to K-EDTA has not been documented in snakes at this time and several species including the king cobra (*Ophiophagus hannah*), eastern diamondback rattlesnake (*Crotalus adamanteus*), Burmese python (*Python bivittatus*), and rat snake (family Colubridae, subfamily Colubrinae) have not shown significant hemolysis when preserved in EDTA.[1,3,13,26] Preservation with a minute volume of formalin in a Natt–Herrick stain preparation may decrease clumping of all cells and provide improved preservation, though this has not been tested with snake species. The procedure was originally done to preserve fish hematologic samples[2] (see Chapter 128). Any refrigerated whole blood samples should be warmed to room temperature (20 °C) prior to making blood films or mixing with reagents for cell counts or other analysis.[30]

ERYTHROCYTES

Mature, oval erythrocytes have a similar morphology to other reptile species with a central, irregularly oval, condensed nucleus and are larger than their mammalian counterparts. For example, yellow rat snake (*Pantherophis alleghaniensis,* formerly *Elaphe obsolete quadrivitatta*) RBC dimensions are 18 × 10 µm and side-striped palm viper (*Bothriechis lateralis*) RBC dimensions are 22 × 12 µm, while a dog (*Canis familiaris*) RBC averages 7 µm in diameter.[30] In one study of wild spectacled cobras (*Naja naja*), measured mean cell volume (MCV) was 300–400 fL.[9] Hemoglobin concentration (Hgb) and PCV tend to be lower than mammalian species and the larger MCV is inversely proportional to RBC count.[5] Significant variation in PCV in healthy snakes may be due to species, wild-caught versus captive-bred populations, seasonality, hibernation, reproductive status, ambient temperature, ecdysis, and sex.[10,19,26] Additionally, ophidian RBC life span is longer than mammalian erythrocytes, with averages up to 600–800 days.[29] Unlike other reptiles, erythroplastids (anucleate RBCs) are rarely found in snakes and have no known clinical significance.[28] As in turtles and other reptile species, RBCs may contain small, round or irregular, deeply basophilic cytoplasmic inclusions that have been determined to be degenerate organelles in most cases. These degenerate organelles also have no known clinical significance and must be differentiated from viral inclusions and breakdown products found in septic animals[5,28] (Figure 133.3d).

Low numbers of polychromatophils, rubricytes, and mitotic figures are normal in young snakes or in snakes undergoing ecdysis[5,29] (Figure 133.1m–o). Polychromatophils are smaller and have smoother chromatin than mature RBCs. These cells enlarge as their chromatin condenses during maturation, which is opposite of their mammalian counterparts.[28] Reticulocytes (polychromatophils) can be quantified in peripheral blood films with new methylene blue staining, which results in basophilic precipitated RNA that rims the nucleus. Samples from healthy snakes typically have <5% reticulocytes.[5] Rubricytes may be quantified on Romanowsky-stained smears to assess erythroid regeneration and are rare (<3 rubricytes/100 WBC) in healthy snakes.

LEUKOCYTES

The snake heterophil has a similar function to the neutrophil in innate immunity and phagocytic activity, though function may be decreased in comparison to mammalian neutrophils in that peroxidase staining is weaker to absent in snakes.[1] Heterophils are found in lower numbers than lymphocytes and often azurophils in some healthy snakes.[19,21,25,26] Heterophils (10–23 µm) are smaller in size than azurophils, but larger than lymphocytes.[28] Heterophils are round with colorless cytoplasm which contains few to many clear to pale pink-orange (heterophilic) rod-shaped granules (Figure 133.1a–c). These granules often occupy the majority of the cytoplasm, but the round nucleus is usually still visible. The nucleus has the same condensed chromatin pattern seen in mature mammalian neutrophils, but in mature cells, the nucleus is round to oval lacking elongation or segmentation. Immature heterophils, which correlate with left shifting indicating accelerated bone marrow release, cannot be readily identified using standard diagnostic light microscopy.

Upon ultrastructural evaluation of eastern diamondback rattlesnake (*C. adamanteus*) heterophils, partially or completely degranulated heterophils were identified in addition to fully granulated heterophils.[1] On Romanowsky stains, these partially granulated heterophils have colorless to slightly gray or blue, apparently vacuolated cytoplasm. This is thought to be a preanalytical artifact of the collection/storage process as these samples are commonly collected into lithium heparin anticoagulant, though toxic change is also possible.

Lymphocytes are the predominant leukocyte in circulation in most snake species.[6,19,21,25,26] Their nuclei may be round, oval, triangular, or pleomorphic containing condensed to lacy chromatin and usually no distinct nucleoli. Lymphocytes have a scant to moderate amount of typically pale basophilic cytoplasm and sometimes exhibit cytoplasmic blebs (Figure 133.1d–f). Small lymphocytes (8–10 µm) are often smaller than an RBC, with intermediate and large lymphocytes (12–18 µm) slightly larger. Small and intermediate sized lymphocytes predominate, but a few large lymphocytes may be found, particularly with antigenic stimulation. Some may contain a few small magenta granules, consistent with granular lymphocytes. Numbers of granular lymphocytes will increase with disease. When antigenically stimulated, lymphocytes may exhibit deeply basophilic cytoplasm and sometimes a perinuclear clearing (Golgi

Nicole Stacy and Ball python images courtesy of Kendal Harr.)

zone). Plasma cells or, rarely, Mott cells can be seen in peripheral circulation with antigenic stimulation and inflammation[32] (Figure 133.2d).

Azurophils are large, monocytoid circulating immune cells which may predominate in individuals with an inflammatory leukogram.[19,21,25,26] While they are monocytoid in appearance, they stain strongly with peroxidase and often lack positive staining with naphthyl butyrate esterase, making their cytochemical characteristics more similar to the mammalian neutrophil.[1] Cytochemically, snake azurophils commonly stain positive for benzidine peroxidase, Sudan Black B, and periodic acid–Schiff (PAS), though there is some variation in the literature.[1] The azurophil lineage is not yet clearly established. These leukocytes are most prominently found in snakes, compared with other reptilian species. Azurophils are round or oval with a moderate to large amount of basophilic cytoplasm that contains a significant diffuse dusting of azurophilic (fine, magenta) granules. The nucleus is round or oval and often eccentric with clumped chromatin, but not as condensed as that seen in granulocytes (Figure 133.1g–i). During inflammation, azurophils may become vacuolated, phagocytic, or even binucleated (Figure 133.2f,g).

Given that azurophils are cytochemically different from monocytes and therefore functionally different, they should be enumerated separately from monocytes on a differential cell count, if present. Monocytes are rarely found in circulation in snakes, and most commonly not counted in differential cell counts from healthy snakes.[1,6,19,21,25,26] They are similar in appearance to azurophils except lacking the fine magenta granulation and have similar morphologic characteristics to those found in mammals. When monocyte-like cells were identified in the blood of yellow rat snakes, they were assumed to be degranulated azurophils[3] and were not definitively identified in eastern diamondback rattlesnakes[1].

Eosinophils are absent in most snake species studied.[1,6,29] Presence in individual species should be confirmed with cytochemical stains and ultrastructural evaluation. These granulocytes are larger than heterophils with a rounded or sometimes elongated nucleus and condensed chromatin. They have pale blue-gray cytoplasm that contains many rounded or plump bright pink to salmon color granules which sometimes appear refractile. Eosinophils may not always have eosinophilic granules. Since eosinophils are quite rare in snakes (if present at all in certain species), their function and kinetics have not been well defined.[26]

Basophils may not be seen in some animals and are typically found in low numbers.[1,26] Increased basophil numbers may be found in diseased animals. They have the same cytologic appearance as mast cells, but as mast cells reside within solid tissues, the circulating cells are identified as basophils. Basophils are small and round with a moderate amount of colorless to pale blue-gray cytoplasm which contains many dark purple round granules that typically obscure the nucleus. Some cells may be degranulated or nonstaining (especially if stained with an aqueous Romanowsky stain), and the cytoplasm appears vacuolated. In these cells, the nucleus is readily visible and round or oval with condensed chromatin (Figure 133.2j–l). Cytochemically, basophils are similar to mammalian basophils and have been reported to stain PAS-positive.[1,26]

THROMBOCYTES AND COAGULATION

Thrombocytes are the equivalent of mammalian platelets, with some fundamental differences. Thrombocytes are whole cells which contain a condensed nucleus and mature from a distinct cell line with a thromboblast progenitor, not a megakaryocyte.[28] Thrombocytes are often easy to differentiate from lymphocytes in most snake species, as they are elongated or oval with colorless to pale basophilic cytoplasm and sometimes contain single or multiple cytoplasmic vacuoles, especially when activated (Figure 133.1j–l). They may exhibit cytoplasmic blebbing. Thrombocytes readily clump in heparinized samples, making them difficult to quantify, and K-EDTA is preferred for thrombocyte evaluation. On peripheral blood films or in hemocytometer preparations, thrombocytes may aggregate and comparison with the morphology of clumped thrombocytes may aid in differentiation of lymphocytes from individual thrombocytes (Figure 133.2n). Thrombocytes can become phagocytic when activated.[28]

Coagulation in snakes is considered similar to other reptiles; however, there is minimal literature regarding snake species specifically.

REFERENCE INTERVALS

Published ophidian hematologic reference values performed according to American Society for Veterinary Clinical Pathology Quality Assurance and Laboratory Standard (ASVCP QALS) guidelines are currently limited. Hematologic reference intervals can be significantly influenced by factors such as species, age, gender, reproductive status, season, ambient temperature, geographic range,[35] restraint method,[3] and ecdysis. In one study that compared hibernation and seasonal factors of captive and wild viperid snakes, no differences were observed in PCV or total and differential WBC counts in pre- versus posthibernation samples.[10] However, given that snakes do not drink or eat during hibernation, changes due to dehydration are possible. Hematologic values can vary between captive versus wild-caught animals of the same species. Underlying etiologies may include parasitism in wild animals, and stress and husbandry issues in captive animals. In a study comparing hematologic values of wild-caught versus captive-bred king cobras (*O. hannah*), captive-bred individuals had higher PCV (mean 33% vs. 20%), Hgb concentration (10 g/dL vs. 6.5 g/dL), and lymphocyte counts, while heterophil and azurophil counts were lower.[26] The captive cobras in this study also had lower prevalence of *Hepatozoon* infestation as detected by light microscopy.

(a) Heparin binds to background protein resulting in a dark pink to purple haze that distorts cell morphology; (b) Ethiopian viper (*Bitis parviocula*): Heparin artifact and a heterophil; (c) Emerald tree boa (*Corallus caninus*): Moderately toxic heterophil; (d) Ball python (*Python regius*): Mott cell; (e) King cobra (*Ophiophagus hannah*): Thrombocyte (left) and atypical lymphocyte (right); (f) Emerald tree boa: Binucleated azurophil typical of marked reactivity; (g) Rattlesnake (*Crotalus sp.*): Probable toxic heterophil (left) and a reactive azurophil (right); (h) Ethiopian viper (*Bitis parviocula*): Melanomacrophage; (i) Ball python (*Python regius*): Siderophage (lower left) and erythrophagia consistent with acute and chronic hemorrhage; (j) Ball python: Basophil; (k) Ball python: Basophil with nonstaining granules, Quik Stain; (l) Emerald tree boa: Basophil; (m) Ball python: Active erythrophagia; (n) Emerald tree boa: Microclot containing clumped activated thrombocytes and a heterophil; (o) Ball python: Mitotic figure in a probable RBC (left) and a probable nuclear inclusion (virus unidentified). (**Source:** Some images are courtesy of Drs. Nicole Stacy and Kendal Harr.)

It is not possible to differentiate disease state from housing and husbandry issues in many of these comparative studies.

Reference intervals are available through many sources including online databases, but caution in their medical use is recommended, as many neither have outliers removed, use incorrectly applied statistics, nor account for partitioning factors. Ideally, reference intervals should be developed utilizing the ASVCP QALS guidelines (https://www.asvcp.org/page/QALS_Guidelines). Concurrent sampling from a healthy individual with similar signalment (i.e., age, sex, housing/ambient temperature, restraint, reproductive status, etc.) may be compared to the suspected ill animal; however, this is not a replacement for medical reference intervals. Without reliable reference intervals, CBC interpretation can be challenging and potentially result in under- or overinterpretation when used without caution. Hematologic values for the same patient over time may also be used to monitor progression of disease or response to therapy.

Editor's note: In order to capture a perceived lymphocyte predominance in snakes, reference interval generation for ball pythons seen at a veterinary clinic was attempted prior to this chapter's publication. Upon review of history and follow-up clinical data, it was found that over half of the 28 pythons, originally included as they had been listed at the time of sampling as apparently healthy, were dead within 3 years. Additional pythons were lost to follow-up. Eight of the dead animals had confirmed arenavirus, nidovirus, or other disease. Reference interval generation was therefore suspended.

BONE MARROW AND COLLECTION

Hematopoietic cells are synthesized in the marrow spaces of adult snakes similarly to mammalian species. Snake bone marrow is typically quite fibrous and not readily amenable to fine-needle or core biopsy collection. There is minimal marrow in the ribs, leaving the vertebra as the only sampling site. If a sample is collected, an acellular or hypocellular sample should not be overly interpreted. Confirmed successful techniques for antemortem sampling have not been reported.

HEMATOLOGIC DISEASE

Anemia

Causes of anemia are the same for snakes as other vertebrate species and include hemorrhage, hemolysis, or decreased production.[5] Because of the long RBC life span, regenerative processes also take longer to develop and become apparent clinically. Signs of regeneration include increased polychromasia and erythroid precursors including rubricytes and may be as immature as rubriblasts[30] (Figure 133.1m). Mitotic figures within polychromatophils can be found in cases of active regeneration[28] (Figure 133.2o). In one case report, a corn snake (*Elaphe guttata*) was found to develop signs of regeneration approximately 20 days after mild intraoperative hemorrhage.[12] Erythrophagia after surgical and other trauma is seen with some frequency in practice (Figure 133.2i,m). Generally, a regenerative response may take up to several weeks[30] and can be dependent on other factors such as ambient temperature, concurrent inflammation, immunosuppression, or other stressors. Repeat manual evaluation of peripheral blood films and PCV is recommended to monitor the erythron, and if sufficient time has passed, a nonregenerative anemia may be diagnosed. Anemia of chronic disease is likely the most common cause of nonregenerative anemia in snakes and can develop from a number of factors including poor environment especially including suboptimal temperature, inappropriate diet, chronic infection, neoplasia, etc.

Hypochromasia, associated with decreased mean corpuscular hemoglobin concentration (MCHC), may be seen with iron deficiency or chronic inflammation. Iron deficiency can develop secondary to the same etiologies as in other species including malabsorption from gastrointestinal disease, inappropriate diets (iron-deficient), blood loss, and chronic inflammation. Basophilic stippling is rare and may point to a regenerative response such as seen in posthibernation reptiles. It is also reported in patients with lead toxicosis and iron deficiency.[3,5] Some forms of poikilocytosis will be seen secondary to similar disease processes as established in mammalian species. For example, schistocytes occur with conditions that result in erythrocyte fragmentation. Increased numbers of RBCs with fusiform or teardrop shapes have been associated with septicemia or chronic infectious disease.[28]

Physiologic Changes

Noninflammatory, physiologic causes of a heterophilia include gravidity, excess endogenous or administration of exogenous glucocorticoids, summer seasonality, and free-living status. Lymphopenia is expected in response to glucocorticoids, though this may be difficult to detect.

Inflammatory Changes

A standard inflammatory leukogram is usually represented by a heterophilia with or without toxic change, and azurophilia. Etiologies are many and commonly include bacterial or parasitic infections, tissue injury, or necrosis.[4,28] Heterophils will exhibit toxic morphologic change, related to accelerated release from bone marrow and activation in the peripheral blood.[5,28] These toxic changes consist of (in order of increasing severity): degranulation or partial degranulation with cytoplasmic basophilia, foamy vacuolation, retention of cytoplasmic round magenta primary granules, color change in ragged, activated lysosomes and vacuoles, and sometimes giantism (Figure 133.2c). The degree of toxicity may reflect disease severity; however, snakes with

bacterial infection may present with no evidence of toxic change.[28] Heteropenia may also be seen with acute, overwhelming inflammation. Often toxic changes are seen, but may be absent very early on.

Azurophilia, and less commonly melanophages and hemosiderophages, may be seen with inflammation or hemorrhage[11,32] (Figure 133.2h). Azurophilia in snakes is more commonly associated with acute as opposed to chronic inflammation. Azurophils can demonstrate phagocytic activity and were found in higher numbers in *Hepatozoon*-infected king cobras than in their *Hepatozoon*-negative counterparts. The azurophils contained phagocytosed-free *Hepatozoon* gamonts, documented by electron microscopy.[26] *Chlamydia* inclusions have also been identified in circulating phagocytes of emerald tree boas with pneumonia and confirmed by PCR.[28] Significant, though nonspecific, changes in WBC counts were found in corn snakes (*Pantherophis guttatus*) experimentally infected with three different genogroups of ferlaviruses, which are associated with highly pathogenic outbreaks of respiratory disease.[23] Total WBC, lymphocyte, and azurophil counts were significantly greater than at baseline starting at day 16 postinfection, whereas heterophilia was identified on days 28 and 49. Basophilia has also been reported in cases of viral infection and parasitism.[5]

Viral Disease

Inclusion body disease (IBD) is one of the most important diseases of captive boid snakes (families Boidae and Pythonidae) worldwide.[7] Antemortem IBD diagnosis can be challenging. In addition to the animal's signalment, history, and clinical signs, inclusion detection on blood smears may be diagnostic. Intracytoplasmic inclusions are characteristically found in lymphocytes of infected snakes and are diagnostic for IBD. In lymphocytes and other peripheral blood cells (heterophils, azurophils, thrombocytes, RBCs),[7,17] oval or round inclusions are homogenously pale blue to slightly aqua in color (Figure 133.3c–e). They vary in size and may take up the majority of the cytoplasm, pushing the nucleus to the periphery in a half moon shape. They can sometimes be difficult to differentiate from the background cytoplasm and care must be taken when evaluating peripheral blood films from snake species, even in patients with absent clinical signs (Figure 133.3a,b). A buffy coat preparation may aid in diagnosis. Not all IBD-positive snakes will display inclusions in peripheral blood cells and additional diagnostics such as RT-PCR or histopathology may be confirmatory. The DeRisi Lab at University of California San Francisco has ongoing research on IBD and the novel snake arenavirus[30] (http://derisilab.ucsf.edu/index.php?news=125). Affected snakes can have leukocytosis and lymphocytosis.[7] Additional information on antemortem and postmortem diagnosis of IBD is available elsewhere including details on histologic appearance and distribution of lesions.[20,22,24]

Boid snakes afflicted with IBD show high morbidity and mortality and over 10 boid species have been reported to be infected. IBD has also been suspected in a few viperid and colubrid species,[17] but has not been confirmed.[7,17] Clinical presentation spans from asymptomatic to severe neurological disease and death. The duration of latent infections varies between pythons and boas and remains unknown in many species.[7] After the onset of clinical signs, pythons will generally succumb from fatal neurological disease within a few weeks, whereas boas will mostly die within months.[14,20,34] Clinical signs include incoordination, disorientation, torticollis, disequilibrium, opisthotonus, loss of righting reflex, anisocoria, and flaccid paralysis.[7,24] Intermittent regurgitation followed by anorexia has been predominantly described in *Boa sp*.[7,24] Although little is known about the clinical course of the disease, IBD appears to be invariably fatal.[34] As a probable consequence of immunosuppression, affected animals usually die from secondary infections and septicemia with encephalitis, pneumonia, hepatitis, enteritis, or osteomyelitis, and from neoplastic processes, such as lymphoma and leukemia.[14,27]

Iridoviral infections (aka snake erythrocyte virus and formerly pirhemocytonosis) are frequently reported in chelonians and amphibians and less commonly in Serpentes. The family Iridoviridae is composed of two genera, Ranavirus and Iridovirus. A third group of iridoviruses known to infect reptiles are erythrocytic iridoviruses.[38] Long thought to be caused by protozoal hemoparasites (*Toddia* and *Pirhemocyton*), eosinophilic intraerythrocytic inclusions were first documented to be of iridoviral origin by electron microscopy in a fer-de-lance viper (*Bothrops asper*) and later confirmed by sequencing from a diseased peninsula ribbon snake (*Thamnophis sauritus sackenii*) in Florida.[18,20] Severe anemia is the hallmark of erythrocytic iridoviral infections. The fer-de-lance viper presented with macrocytic and hypochromic anemia, polychromasia, and immature circulating RBCs left shifted to the rubriblast stage.[18] Two types of intracytoplasmic inclusions can be seen in the erythroid series. The first consists of punctate, granular pink to dark purple (acidophilic) aggregates ultrastructurally consistent with iridoviral particles. The second inclusion type is a translucent hexagonal crystal, suspected to be lipid and protein representing cellular and viral by-products. In the fer-de-lance viper, 14% of erythroid cells contained both inclusion types, 0.5% had iridoviral particles only, 0.5% had crystalline material only, and 85% were unaffected.[18] In the ribbon snake, 60% of RBCs were hypochromatic, with 95% of these displaying either inclusion type.[20]

Coagulopathy

Causes of thrombocytopenia are more likely due to peripheral consumption than decreased production.[5] If a thrombocytopenia is suspected, correlation with clinical findings, thorough evaluation of a peripheral blood film, and gross examination of the collection tube for clots are recommended. Repeat sampling may also be indicated. Immature thrombocytes are larger with less-condensed chromatin. An increased number of

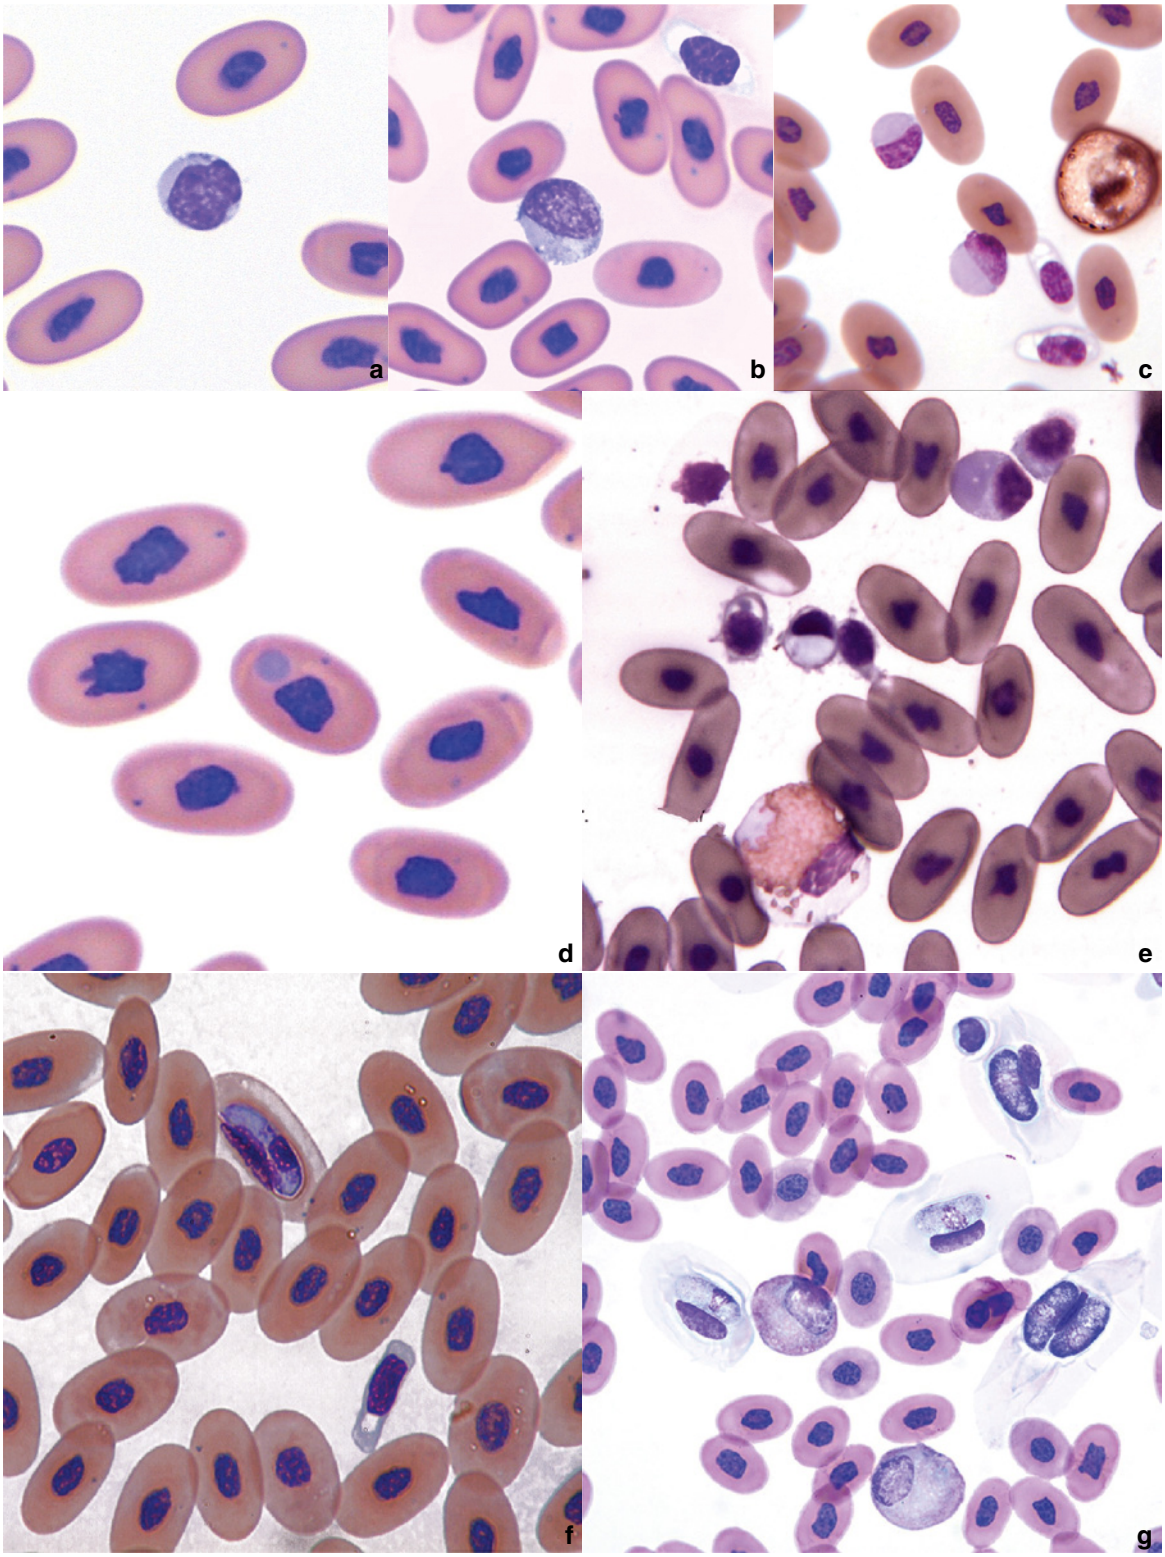

FIGURE 133.3 Infectious agents found selected snakes. Wright–Giemsa stain. Inclusion body disease caused by arenavirus may be diagnosed using hematology. The inclusions may be small and indistinct, but the large inclusions that push the nucleus into a half moon shape are pathognomonic. Boa constrictor (*Boa constrictor*) (note: all inclusions were not found in the same animal): (a) Small cytoplasmic inclusion in a lymphocyte; (b) Arenavirus inclusion is moderately sized and flattening the nucleus. Note the Golgi body to the right; (c) Large blue, ground-glass inclusions in two lymphocytes with the classic half-moon nuclear shape, two thrombocytes, and a heterophil also present; (d) Arenavirus-induced inclusions must be differentiated from the more common small punctate dark blue inclusion that is commonly seen in healthy snakes; (e) In severe infections, inclusions may be found in all cells including lymphocytes, thrombocytes, RBCs, and heterophils; (f) Wild python, species unknown (*Python sp.*): *Hepatozoon sp.* in a RBC; (g) Indigo snake (*Drymarchon sp.*): Five *Hepatozoon* organisms causing RBC lysis and two azurophils and one lymphocyte. (**Source:** Images a, c, and e are courtesy of Dr. Kendal Harr; f is courtesy of Dr. Nicole Stacy.)

immature thrombocytes correlate with a regenerative response to thrombocytopenia or increased thrombocyte demand (i.e., secondary to consumption or destruction).[29]

Hemoparasites

Most common reptilian hemoparasites have an indirect life cycle; therefore, they are more frequently seen in wild-caught specimens than captive-bred individuals, especially when housed indoors. Most are considered nonpathogenic and infestations usually have a good prognosis.

Hemogregarines are commonly found and often do not cause clinical disease. The term "hemogregarines" refers to four different genera, *Hemogregarina*, *Hepatozoon*, *Karyolysus*, and *Hemolivia*, which are morphologically similar and PCR is needed for differentiation.[29] However, *Hepatozoon* are more commonly found in snake species.[29] The intraerythrocytic, oblong gamonts have pale basophilic cytoplasm and a central round to oval nucleus with dark purple chromatin. They may displace or wrap around the RBC nucleus (Figure 133.3f,g). Otherwise, healthy individuals generally do not exhibit anemia and infection is subclinical.[26] Although anemia and inanition can be seen, reptilian hemogregarines only rarely cause clinical disease.

Hemoproteus sp. is a malaria-inducing hemoparasite seen in snakes. Gametocytes, meronts, and trophozoites can be found in RBCs or extracellularly. The gametocytes are round, oval, or elongated with pale basophilic cytoplasm and a round purple-blue nucleus. They characteristically contain brown or golden pigment consistent with hemoglobin breakdown products and this finding can help differentiate from *Hepatozoon* (hemogregarines).[29] Like hemogregarine infections, *Hemoproteus* infection generally does not produce clinical signs, but can contribute to hemolytic anemia in immunocompromised individuals.

Neoplasia

Hematopoietic neoplasia has not been commonly reported in snakes. Lymphoid neoplasia may be the most common hematopoietic neoplasia of snakes, but caution in interpreting increased lymphocyte counts is advised, as infectious conditions and general antigenic stimulation may result in marked lymphocytosis. Repeat sampling from different sites so as to avoid lymphatic dilution may be necessary. Other diagnostics such as cytochemical staining and flow cytometry are not currently readily available for reptile species, but may be offered by some laboratories. Cytomorphology, including visible nucleoli, mitotic figures in lymphocytes, and a monomorphic population, is important to determine neoplastic versus reactive lymphoid cells.

Myeloid neoplasms are rarely seen in snakes, though prevalence of neoplasia appears to be highest in snakes in comparison to other reptile groups.[11] A presumptive granulocytic leukemia in a hognose snake was further investigated with cytochemistry and found to be strongly positive for toluidine blue and periodic acid–Schiff and weakly positive for Alcian blue, supporting a basophilic leukemia.[33]

Acronyms and Abbreviations

N:C, nuclear:cytoplasmic; NBE, naphthyl butyrate esterase; ANAE, α-naphthyl acetate esterase; NaF, sodium fluoride; PAS, periodic acid–Schiff; ACP, acid phosphatase; PER, benzidine peroxidase; CAE, chloroacetate esterase; SBB, Sudan Black B; TB, toluidine blue; FP, fibropapillomatosis.

Testudines, also referred to as Chelonia, are poikilothermic nonmammalian vertebrates that belong to the class Reptilia. Over 300 species occupy terrestrial, fresh-water, and marine habitats worldwide, and include turtles, tortoises, and terrapins. Considered one of the most ancient reptiles, they are highly adapted to diverse environmental conditions and, therefore, there is marked inter- and intraspecies hematologic variability.

SAMPLE COLLECTION

The optimal site varies with size and species, level of sedation, medical condition, and skill of the phlebotomist. Possible locations include the jugular (preferred), femoral, brachial, and coccygeal veins, as well as the subcarapacial and postoccipital sinus.[11]

ERYTHROCYTES

As with other nonmammalian vertebrates, all circulating blood cells of testudines retain their nuclei. This precludes enumeration via an automated hematology analyzer and necessitates a manual method (see Chapters 123 and 128 for details on these techniques). On Wright-stained blood films, mature RBCs have an ovoid appearance with orange-pink cytoplasm and round to ovoid deeply basophilic nuclei (Figure 134.1). Testudine RBCs are relatively large compared to those of other species, achieving lengths approximating those of heterophils. Mean cell volume ranges from 310 fL, median in Hermann's tortoises (*Testudo hermanni boettgeri*), to 975 fL, mean in male green sea turtles (*Chelonia mydas*).[4,29] Unlike mammalian RBCs, mature testudine RBCs are larger than immature forms. Polychromatophilic RBCs contain faintly to deeply basophilic cytoplasm and more dispersed nuclear chromatin (Figure 134.1b,e). Rubricytes vary in size depending on the maturation stage, but typically have a round, less-elongate profile, with basophilic cytoplasm, indicating a lower Hgb concentration and relatively high nuclear to cytoplasm (N:C) ratio (Figure 134.1c,e,g). Nuclei are round to irregularly shaped and chromatin is coarsely granular to loosely clumped. Increased numbers of polychromatophilic cells, rubricytes, mitotic figures (Figure 134.1i), and binucleate cells (Figure 134.1h) may indicate an attempt at regeneration in anemic patients. The long RBC life span (up to 11 months) in Testudines may mute this response,

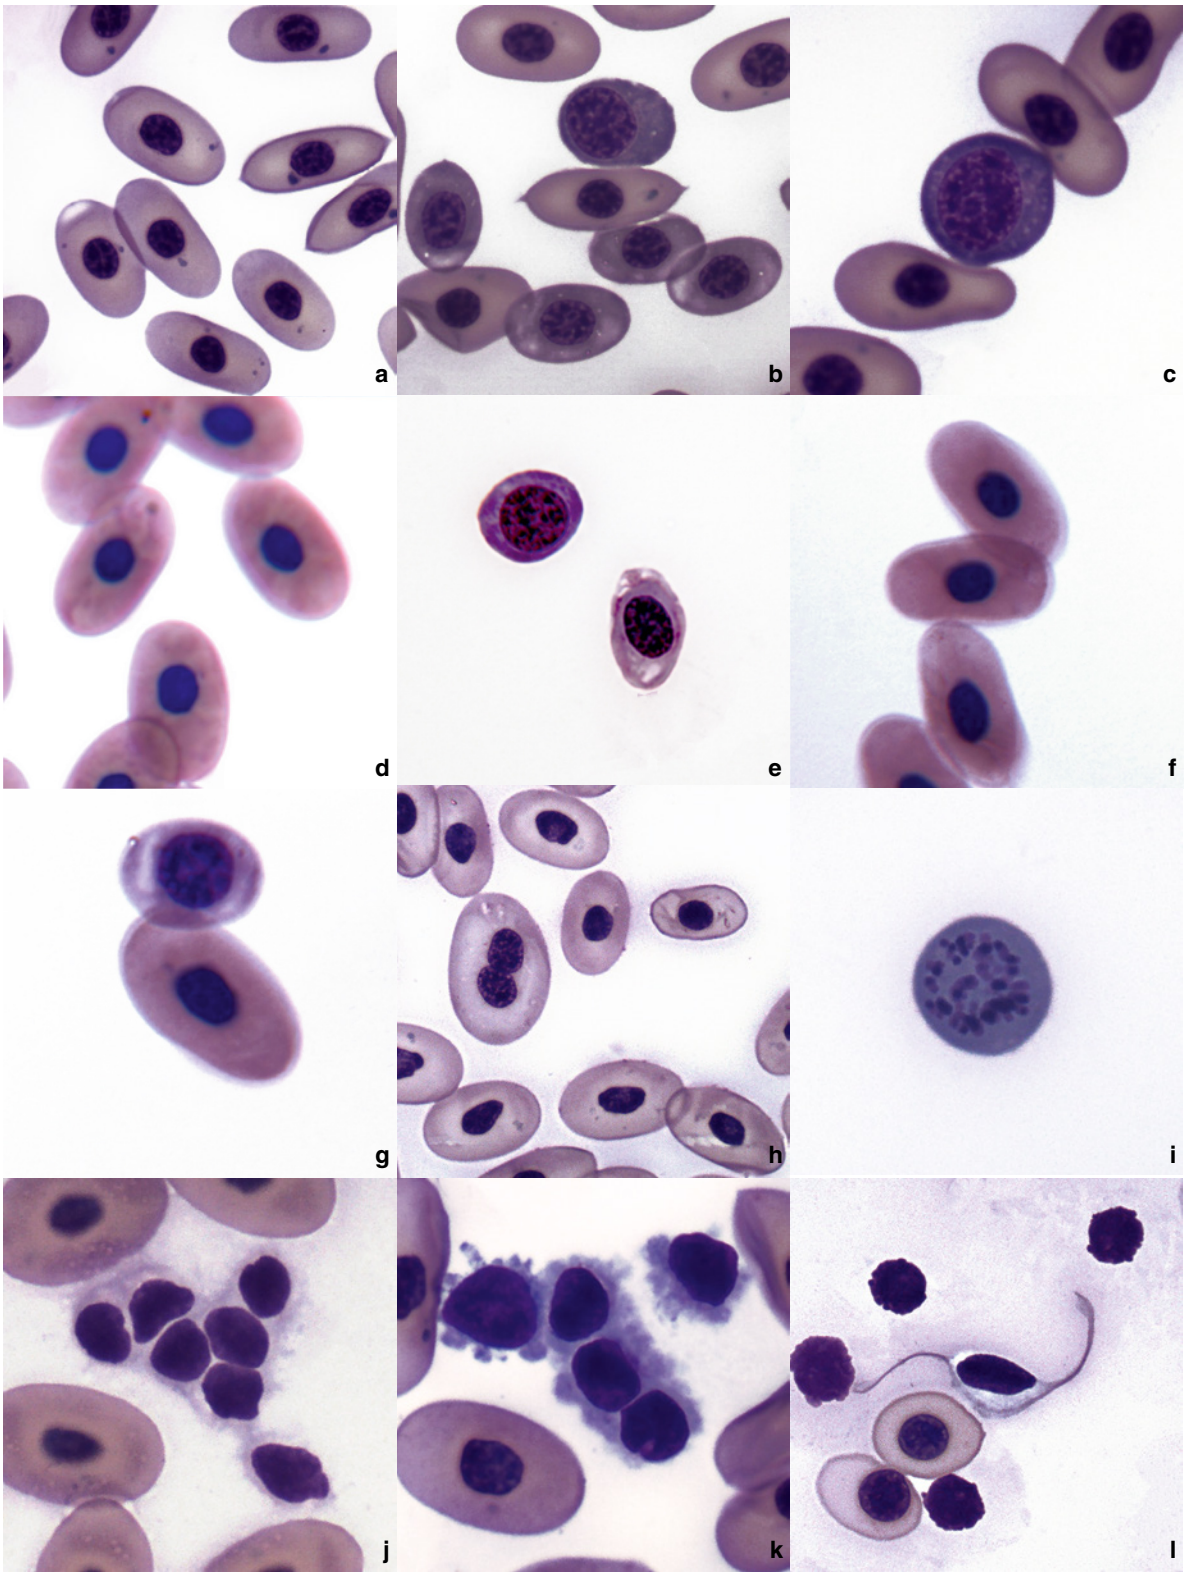

FIGURE 134.1 Erythrocytes and thrombocytes from selected Testudine species. Wright's stain, 1000× unless otherwise specified. Red-eared slider (*Trachemys scripta elegans*): (a) Normal RBCs, note the fully hemoglobinized cytoplasm, centrally located nuclei, and small basophilic inclusions; (b) Polychromatophilic RBCs are smaller and rounder, the chromatin is less-condensed, and the cytoplasm is more basophilic than mature RBCs; (c) Stage 1 rubricyte with a round profile, dispersed chromatin, and dark blue cytoplasm. Loggerhead sea turtle (*Caretta caretta*): (d) Normal erythrocyte; (e) Polychromatophilic RBC (lower right) and a stage 2 rubricyte (upper left). Yellow-footed tortoise (*Chelonoidis denticulatus*): (f) Normal RBC; (g) Stage 3 rubricyte. Box turtle (*Terrapene carolina*): (h) Binucleate RBC is slightly larger than normal RBCs. Annam leaf turtle (*Mauremys annamensis*): (i) Circulating mitotic figure which may be found during erythroid regeneration. Kemps Ridley sea turtle (*Lepidochelys kempii*): (j) Clumped thrombocytes with a high N:C ratio, scant nonstaining cytoplasm, and a round nucleus with densely clumped chromatin. *T. scripta elegans*: (k) Activated thrombocytes that appear to have pseudopodia and a more dispersed chromatin pattern. Desert tortoise (*Gopherus agassizii*): (l) Spindle-shaped thrombocyte amidst free nuclei with heparin artifact in the background. (**Source:** Photos (d)–(g): courtesy of Dr. Kendal Harr.)

however.[5] Erythrocytes from poikilotherms are believed to have significantly longer life spans than mammals, though there is little recent research on the subject. Erythrocytes from apparently healthy chelonians may contain small, punctate, basophilic cytoplasmic inclusions (Figure 134.1), thought to be either degenerating organelles or hemoglobin precipitates; neither having pathologic significance.[14,15]

LEUKOCYTES

Testudine leukocytes consist of heterophils, lymphocytes, monocytes, eosinophils, and basophils. Heterophils average 15.9 ± 2.8 µm and contain numerous linear, pink-orange, refractile granules that are acicular in shape and often appear to "melt" together[29] (Figure 134.2). Nuclei are round to ovoid and eccentrically located with densely clumped chromatin. In some cells, the granules obscure visualization of the nuclei. Cytochemical staining of leukocytes can vary among species. As an example, heterophils of the yellow-bellied slider (*Trachemys scripta scripta*) and loggerhead turtle (*Caretta caretta*) stain positively with acid phosphatase (ACP) with and without tartaric acid, peroxidase (PER), chloroacetate esterase (CAE), Sudan Black B (SBB), and periodic acid–Schiff (PAS); however, those of *T. scripta* are positive for naphthyl butyrate esterase (NBE), with and without sodium fluoride (NaF), whereas those of *C. caretta* are negative.[7,14] Heterophils in yellow-headed temple turtles (*Hieremys annandalii*) stain positively with PER, SBB, ACP, PAS, as well as α-naphthyl acetate esterase (ANAE).[8] These staining characteristics are similar to those of mammalian granulocytes implying similar functionality.

Lymphocyte appearance has been conserved among vertebrate species. Mature lymphocytes are generally approximately 7.5 ± 1.8 µm in diameter and contain a thin rim of basophilic cytoplasm and a round nucleus[29] (Figure 134.2). Distinguishing small lymphocytes from thrombocytes can present a challenge for the unseasoned and, occasionally, for the veteran hematologist. In general, lymphocytes have a more dispersed chromatin pattern and more deeply basophilic cytoplasm when compared to thrombocytes. Reactive change results in increased cytoplasmic basophilia, possibly with a perinuclear clear area (Figure 134.3h). Granular lymphocytes with eosinophilic to azurophilic cytoplasmic granules can be found on blood smears from normal chelonians (Figure 134.3i). Occasionally, larger, immature-appearing cells that contain more abundant cytoplasm, granular chromatin, and variably prominent nucleoli can be identified in the circulation from apparently healthy animals. While these reactive changes may be found in low numbers in blood smears from clinically healthy animals, the prevalence may increase significantly in sick animals and, thus, a search for a source of inflammation or antigenic stimulation is warranted.

Monocytes contain moderate amounts of blue-gray cytoplasm and a round to ovoid to reniform nucleus with loosely clumped to coarsely granular chromatin (Figure 134.2). They measure 13.4 ± 2.3 µm in diameter in green sea turtles.[29] Some cells may have an ameboid appearance, often attributable to pseudopodia. Monocytes in loggerhead turtles and yellow-bellied sliders stain positively with NBE with NaF.[7,14] Monocytes in the latter also stain positively with ACP with and without tartaric acid. When activated, monocytes often contain cytoplasmic vacuoles, possibly with phagocytized pigment (Figure 134.3k), and occasionally cellular components (Figure 134.3j-l). Azurophils, PER-positive phagocytic cells that contain magenta granules, are most often seen in snakes and are rarely encountered on chelonian blood smears; though they have been reported in desert tortoises (*Gopherus agassizii*)[6–9] (see Chapter 133).

Eosinophils are as large if not larger than heterophils, with a mean diameter of 18 ± 3.1 µm.[29] They contain a round to ovoid, eccentrically located nucleus and moderate to large numbers of round to ovoid, pink-orange granules. Eosinophil appearance seems to be the most variable among WBCs between turtle and tortoise species (Figure 134.2). The granules tend to be round, discrete, and less-refractile/duller in appearance when compared to heterophil granules. Eosinophil granules in *T. scripta*, *C. caretta*, and *H. annandalii* stain positively to varying degrees with ACP, NBE (with NaF), CAE, SBB, and PAS.[7,8,14] Eosinophil granules of *H. annandalii* also stain with PER.

Basophils are typically smaller (14.4 ± 1.3 µm) than heterophils and eosinophils and contain moderate to large numbers of fine, purple to deeply basophilic granules resembling mammalian mast cells[29] (Figure 134.2). Nuclei are round to ovoid, often centrally located with a dense chromatin pattern. Basophils can undergo degranulation between sample collection and slide preparation and may stain variably in aqueous-based and alcohol-based Romanowsky stain.

THROMBOCYTES AND HEMOSTASIS

Assessing primary hemostasis poses several challenges due to the tendency of thrombocytes to form clumps (Figure 134.1j,k) and their similar appearance to small lymphocytes. The latter becomes particularly important when preparing blood smears from chilled blood, as cell shrinkage makes differentiation between these two cells more difficult. Thrombocytes contain small amounts of nonstaining to pale basophilic cytoplasm and a round to oval nucleus. The chromatin is densely clumped, and nucleoli are not visible. Thrombocytes of loggerhead sea turtles and yellow-bellied sliders stain positively with PAS, presumably binding to glycoproteins.[7,14] Additionally, these cells also stain positively with NBE with and without fluoride in yellow-bellied sliders. When activated, the cytoplasm may become vacuolated or exhibit irregular cytoplasmic margins (Figure 134.1k). A study in healthy Hermann's tortoises (*Testudo hermanni*) demonstrated an average of 3–6 thrombocytes per 100× field; however, whether this value is appropriate for all Testudines remains to be determined.[2]

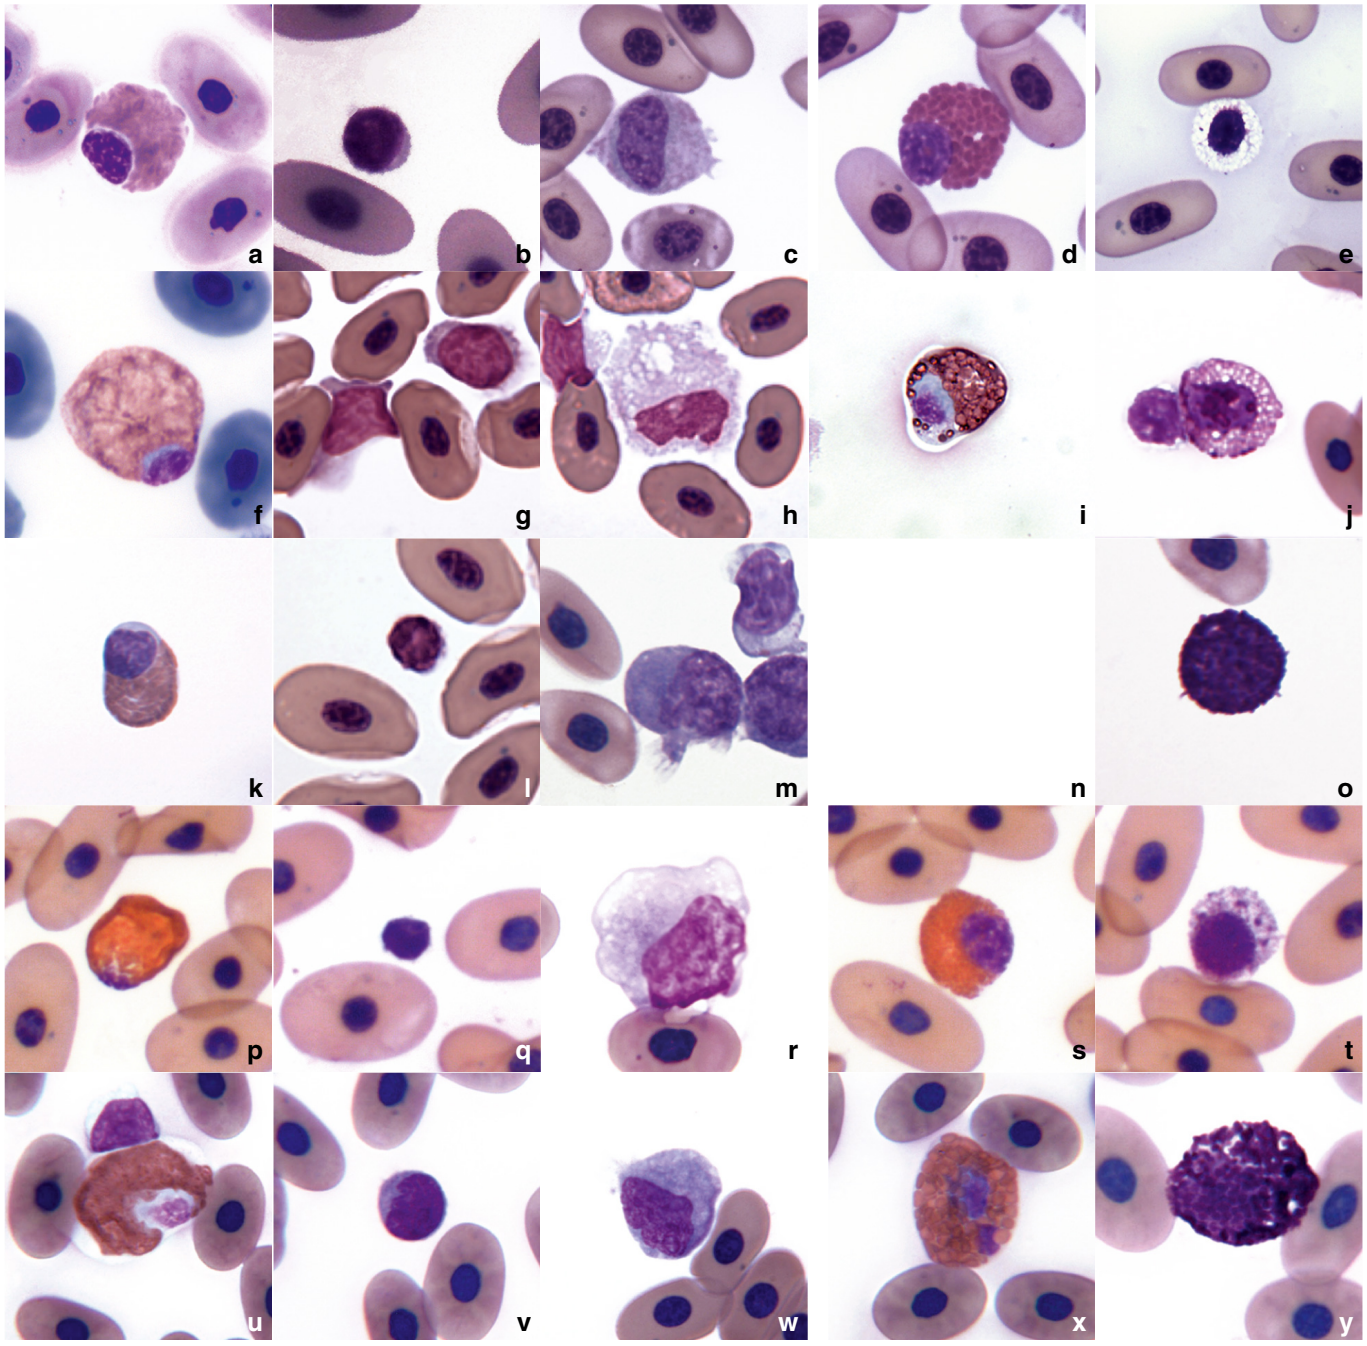

FIGURE 134.2 Normal leukocytes from selected Testudine species. Modified Wright's stain, 1000× unless otherwise specified. Red eared slider (*Trachemys scripta*): (a) Heterophil; (b) Lymphocyte; (c) Monocyte with blue-gray granular cytoplasm and slightly indented nucleus; (d) Eosinophil with easily discernible individual round granules versus those in the heterophil; (e) Degranulated or nonstaining basophil which appears "vacuolated" due to the lack of stained granules. Loggerhead sea turtle (*Caretta caretta*): (f) Heterophil; (g) Two intermediate-sized lymphocytes which can be found in samples from normal animals; (h) Monocyte with vacuolated blue-gray granular cytoplasm; (i) Eosinophil; (j) Basophil with clear granules and purple demarcation. Yellow-footed tortoise (*Chelonoidis denticulatus*): (k) Mature heterophil with a distinct round nucleus and muted pink/orange oblong to spindle granules, not classified as left shifted; (l) Small lymphocyte; (m) Monocytes with blue-gray cytoplasmic pseudopodia; (n) Eosinophil, not pictured; (o) Well-stained basophil such that the nuclear morphology is obscured. Snapping turtle (*Chelydra serpentina*) using Wright-Giemsa stain; (p) Heterophil with indistinct granulation; (q) Small lymphocyte; (r) Monocyte; (s) Eosinophil with round granules; (t) Partially staining basophil with a round nucleus, similar to a mast cell. Leopard tortoise (*Stigmochelys pardalis*): (u) Heterophil with indistinct granulation and a clear rim of cytoplasm with adjacent lymphocyte; (v) Lymphocyte with irregular, cleaved nucleus; (w) Monocyte; (x) Eosinophil with distinct round granules; (y) Basophil. (Photos a, f-q, s-y courtesy of Drs. Kendal Harr and Nicole Stacy.)

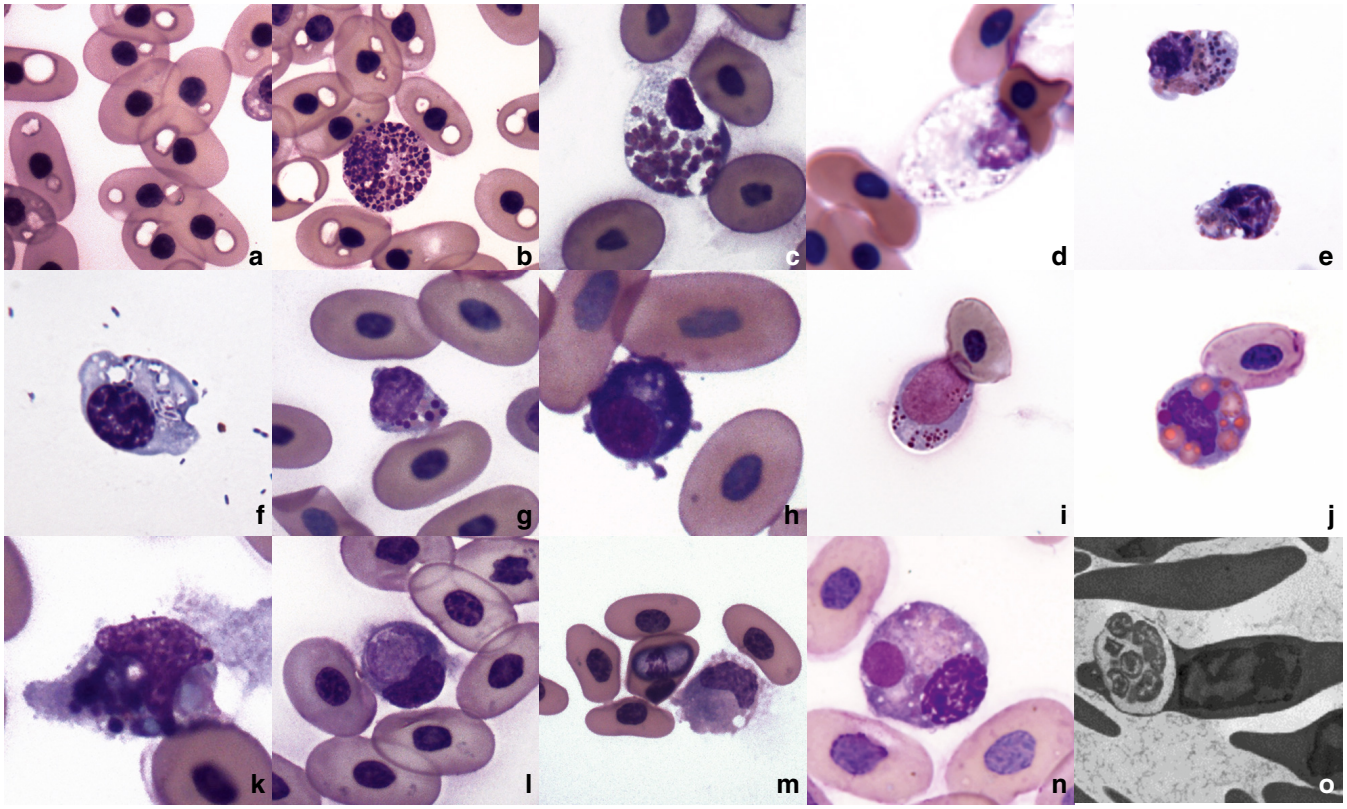

FIGURE 134.3 Abnormal cell morphology and infectious agents found in Testudines. Wright's stain, 1000× unless otherwise specified. Red-eared slider (Trachemys scripta elegans): (a) These non-staining refractile cytoplasmic structures in the RBC have been associated with sepsis in other species. These are not hemic parasites. See Chapter 133; (b) Toxic heterophil, marked. This cell contains almost exclusively primary granules and is found with aberrant RBC vacuolation described in (a). Loggerhead turtle (Caretta caretta): (c) Eosinophil for comparison. These should not be confused with toxic degranulation seen in heterophils; (d) Moderate toxic change with refractile degranulation and purple granule remnants. Leopard tortoise (Stigmochelys pardalis): (e) Markedly toxic heterophils in a tortoise with evidence of sepsis; (f) Monocyte with phagocytized bacteria from the same animal as in (e). Green sea turtle (Chelonia mydas): (g) Myelocyte with primary granules. (h) Plasmacytoid-reactive lymphocyte with deeply basophilic cytoplasm and perinuclear clear area in the same animal as (g). Loggerhead sea turtle (C. caretta): (i) Granular lymphocyte, found in higher numbers in virally infected turtles; (j) Circulating phagocyte which has vacuoles containing heterophilic debris. A dysplastic myeloid precursor could not be ruled out and NBE staining may have been useful in determining the origin of this cell. The sea turtle was afflicted with fibropapilloma virus; (k) Pigment-laden monocyte/macrophage (possible siderophage) containing abundant, globular, blue-black pigment. Box turtle (Terrapene carolina): (l) Cytophagic monocyte which has engulfed another leukocyte. Annam leaf turtle (Mauremys annamensis): (m) Intraerythrocytic basophilic, ovoid hemogregarine gametocyte fills and distorts the RBC cytoplasm. Adjacent activated monocyte. Eastern box turtle (Terrapene carolina carolina): (n) Monocyte containing a round magenta intracytoplasmic Iridovirus inclusion. Reprinted with permission from Dr. Michael Fry. Desert tortoise (Gopherus agassizii): (o) Presumptive intraerythrocytic apicomplexan in a desert tortoise, transmission electron micrograph. Courtesy of Dr. Sabrina Clark. BONE MARROW

On occasion, it may be necessary to submit bone marrow to permit a more detailed hematologic evaluation; however, there are very few descriptions of bone marrow cytology from healthy or diseased turtles. The bone marrow collection technique depends upon the size and nature of the patient. Diagnostic samples can be collected from the femoral or tibial medullary cavities of large chelonians; although many have limited medullary tissue.[11] A suitably sized Jamshidi or spinal needle with a stylette (or possibly a hypodermic needle for very small patients) can be placed into the medullary cavity and moderate aspiration used to obtain a sample. An alternative site is the plastrocarapacial bridge that laterally connects the plastron and carapace, but again the medullary tissue is limited. It is generally necessary to drill through the outer layer of keratin and bone to gain access to the medullary cavity and marrow beneath.

Hematopoiesis occurs primarily in bone marrow in adult turtles and tortoises with erythropoiesis localized to

blood sinuses and myelopoiesis to the extravascular spaces.[13] Maturation in both series in chelonian species follows a similar progression to those of mammalian and avian counterparts with the distinction that mature RBCs are larger than precursors. Though thrombopoiesis has been studied in avian, amphibian and fish species, the origin of thrombocytes in Testudine has yet to be elucidated.

The earliest identifiable erythroid precursor is the rubriblast, a round cell with deeply basophilic cytoplasm, a round nucleus, and relatively high N:C ratio. The chromatin pattern is dispersed, and nucleoli are round to ovoid and occasionally multiple. Reptilian rubriblasts have distinctive peripheral pinocytotic vesicles involved in ferritin acquisition for Hgb synthesis. Prorubricytes, the subsequent maturation stage, are similarly round and basophilic; however, the chromatin is more condensed, and nucleoli are absent. As maturation progresses to the rubricyte stage, cells maintain a round profile with paler cytoplasm due to Hgb synthesis. Nuclear size decreases, chromatin continues to condense, and rubricytes may be released into circulation. The rubricyte can be further subclassified as basophilic or stage 1 (Figure 134.1b,c,e,g) early polychromatic or stage 2 and late chromatic or stage 3 depending on N:C ratio and degree of hemoglobinization. At this point, cells increase in size to form the polychromatic erythrocyte. These cells are ovoid with nonuniform lightly basophilic cytoplasm and a rounded nucleus. The mature RBC (metarubricyte) is similar in size to the polychromatic RBC, but contains fully hemoglobinized, pink-orange cytoplasm and a round to ovoid, pleomorphic nucleus with condensed chromatin. Erythroid precursors and mature erythrocytes, when stained with SBB, had uniformly dark gray to black cytoplasm with scattered black cytoplasmic granules.[13]

Developing granulocytes originate from myeloblasts, cells characterized by a moderate amount of basophilic cytoplasm devoid of granules. Nuclei are large, often centrally located with granular chromatin and large, prominent nucleoli (Figure 134.3e). The progression to progranulocyte involves a decrease in cell size and cytoplasmic basophilia with increasingly condensed chromatin. Secondary granules specific to eosinophils and heterophils become apparent in myelocytes and metamyelocytes and increase in number as maturation progresses. Later stage precursors may be more difficult to differentiate than in mammals due to round nuclei in normal, mature cells. It can also be difficult to differentiate myeloblasts and monoblasts based on cytologic appearance on Wright-Giemsa stained preparations.[13]

REFERENCE INTERVALS

PCV varies with species, sex, age, nutritional status, disease status, and season[2,4,6,8,10,16,17,29,32,33] (Table 134.1). Chinese male yellow-marginated box turtles (*Cuora flavomarginata*) have higher PCVs than females of the same species.[33] There is a seasonal variation in polychromatophil and rubricyte numbers in certain species, with higher numbers in the winter, spring, and summer relative to autumn in geometric tortoises (*Psammobates geometricus*).[30] Juveniles of this species tend to have larger numbers of circulating rubricytes and polychromatophils relative to adult females.

Prior to reference generation, samples must be critically inspected to ensure quality. Blood vessel proximity to lymph and cerebrospinal fluid compartments often results in dilution, impacting the hemogram by falsely decreasing the PCV, Hgb, and RBC concentration, which can also vary with venipuncture site.[18] Inclusion of lymph-diluted samples in reference intervals results in increased variability and decreased diagnostic acuity. Additional and important factors must be considered, including health status information obtained after reference interval publication. While seasonal variation is

TABLE 134.1 Hematology data for adult, male and female, free-ranging desert tortoises (*Gopherus agassizii*) in the Mojave Desert over a 5-year period, divided by season and sex (PCV are presented), which were found to be statistically different.[9] Median PCV values generated in the field as sample quality issues during transport were noted by the author. Underlying endemic disease, including Mycoplasma, was further identified in this well-studied population after the reference intervals were published in 1999.[1,31]

	Winter	Spring	Summer	Fall
PCV (%), Males	30	30	29	28
PCV (%), Females	22	25	25	23
Total WBC/μL	970–10,520	1420–10,860	1500–10,920	390–10,120

Lymphocyte/μL	20–1880	0–3190	60–2750	10–3820
Monocyte/μL	0–570	0–340	0–320	0–320
Eosinophil/μL	0–560	0–860	0–950	0–710
Basophil/μL	0–2700	0–4360	60–3570	30–3760
Azurophil/μL	0–900	0–660	0–560	0–620

well illustrated in Table 134.1, ELISA testing for Mycoplasma endemic in the desert tortoise population has improved since reference interval generation.[31] It is likely, considering the outlier statistics used, that diseased animals were included in this population.[9]

Much like PCV, total and differential WBC concentrations vary with species, age, sex, reproductive status, and season (Table 134.1).[6,8,9,26,33,34] For example, juvenile loggerhead sea turtles have higher median WBC and heterophil counts than nesting adults[6] (Table 134.2). Absolute WBC counts decrease with age in red-eared slider turtles (*Trachemys scripta elegans*).[34] Heterophil numbers exhibit seasonal variations in certain species, with numbers increasing during the warmer, active season (spring through summer).[9]

Lymphocyte numbers tend to attain minimum values during brumation in hibernating species.[9] Peak lymphocyte counts occur in the summer in desert species and in years with ample rainfall.[6,9,33] Monocyte counts decrease during the summer months and reach peak values during the winter/periods of hibernation.[9,33] Conversely, in red-eared slider turtles, monocyte numbers increase from spring into late summer.[35] Monocyte counts also decrease with age in certain species.[2] Female yellow-marginated box turtles have higher monocyte counts than males.[33] Eosinophil and basophil numbers vary with species, season, and geographic location.[6,9] For example, eosinophils and basophils occur with higher frequency in freshwater than marine chelonian species. Male *C. flavomarginata* have higher eosinophil counts than females.[33] Like lymphocytes, basophil numbers decrease during hibernation and are often absent from blood samples from hibernating desert tortoises.[9] Given the aforementioned variability in cell counts, it is frequently more useful to review serial samples from an individual, rather than rely entirely on limited published values, especially those that are not in accordance with ASVCP guidelines (Table 134.3).

HEMATOLOGIC DISEASE

Anemia

Artifact must be differentiated from true anemia. Given the proximity of lymphatic or cerebrospinal fluid compartments to certain venous vessels, lymph dilution can occur with sample collection, but appears to be less common with jugular samples. Marked decreases in PCV (<20%) with minimal polychromasia in conjunction with increased small lymphocyte numbers are suspect for lymphatic contamination.[11] Phlebotomists can often, but not always, appreciate the clear to white lymphatic fluid and dilution during blood collection; such observations should be included with sample submission. Clinicians and biologists should consider discarding lymph diluted samples, as these may generate erroneous values that may lead to misdiagnosis.

Nonregenerative anemia occurs with a variety of disease processes in Testudines including parasitic infestation, bacterial and viral infection, poor husbandry, and chronic renal, hepatic, and gastrointestinal disease.[25] Stranded green sea turtles and chronically debilitated loggerhead sea turtles often present with anemia, either regenerative or nonregenerative, and an underlying cause must be appropriately identified and treated.[12,19,28] Fibropapillomatosis exacerbates this anemia, which worsens with tumor burden.[32] Fibropapillomatosis is a herpes-viral-induced neoplasm that affects all species of marine turtles. It results in the growth of single to multiple external and visceral fibroepithelial, plaque-like to verrucous growths. Lesions can impair vision, mobility, and feeding, depending on the anatomic location. As these animals have presumptive, concurrent vascular trematode infections, the anemia may be the result of peripheral consumption associated with vasculitis and chronic disease from spirorchid granuloma formation as well as the chronic disease that is FP. Several species of tortoises with intranuclear coccidian infection can present with anemia.[25] Anemia can also occur in tortoises infected with siadenovirus and other herpes strains.[24,28] Regenerative anemias can occur with nonfatal traumatic injuries (e.g., boat strikes, hit by car, predation). Severe ectoparasite burdens with ixodid and argasid ticks can cause blood loss anemia secondary to skin wounds, typically in terrestrial species.[25]

Inflammation

Leukocyte responses depend on the nature and severity of the disease process. Leukocytoses are most often associated with inflammation and antigenic stimulation, infection, and stress. For example, in addition to anemia, patients with intranuclear coccidian infection may present with leukocytosis.[25] Hematologic responses to siadenovirus infections vary as patients may present with leukocytosis or leukopenia.[24] Monitoring of serial CBCs can provide additional useful information regarding the patient's health status, as leukocyte trends may be as valuable as absolute values in evaluating responses to treatment. For example, there is an inverse relationship between total WBC count and health status in green sea turtles, as cell counts decrease with convalescence.[19]

Heterophilia occurs with inflammation, infection, and trauma as specifically documented in unhealthy stranded green sea turtles, presumably due to bacteremia and parasitism.[12,19,28] Disruption of bone marrow maturation due to severe inflammation and infection results in toxic change. Mild toxic change is characterized by increased cytoplasmic basophilia, and moderate to marked signs include retention of primary granules (Figures 134.3b,d,e). As heterophil nuclei are not lobulated, it is difficult to detect a left shift akin to those seen in mammals. With severe inflammation and infection, early myeloid precursors can enter the circulation. Heteropenia has also been documented in

TABLE 134.2 Loggerhead sea turtle (*Caretta caretta*) reference intervals. The population is wild-caught, male and female, juvenile turtles in the summer and fall months. These reference intervals were generated using previously published data shared by the authors,[17] with all outliers removed according to American Society for Veterinary Clinical Pathology (ASVCP) guidelines. Unfortunately, in the previous publication, outlier statistics were applied once, but not applied repetitively until no outliers remained.

Measurand	Units	n	Mean	SD	Median	Min.	Max.	Distribution	Reference Interval	CI 90% of LRL	CI 90% of URL

Testudines and is likely to occur in severe infection as in other species. Tortoises with siadenovirus infection can present with either heteropenia or heterophilia.[24] Heteropenia with toxic change, likely as a result of secondary bacterial infection, can occur with herpes viral infections in spur-thighed tortoises (*Testudo graeca)*, possibly due to secondary bacterial infection.[20] An asymptomatic, prolonged heteropenia associated with fenbendazole toxicosis has been reported in Hermann's tortoises.[21]

Lymphocytosis occurs with wound healing, spirorchid infection, and rarely siadenoviral infections. In addition to heteropenia, significant lymphocytosis has been reported in spur-thighed tortoises with herpes viral rhinitis infections.[20] It is likely that other viral diseases and chronic inflammation will also induce lymphocytosis. Lymphopenia is a feature of stress/glucocorticoid responses, and can also occur with malnutrition and immunosuppression.

Monocytosis occurs with acute and chronic infections, including fibropapillomatosis, fungal infections, and siadenovirus.[16,24,32] Eosinophilia has been reported in patients with helminthiasis and less commonly siadenovirus infections.[24] Allergic response has been minimally studied in Chelonia and further research is warranted.

Neoplasia

Lymphoid neoplasia occurs rarely in Testudines.[3,22,27] Both lymphomas and leukemias of B- and T-cell origin have been reported in turtles and tortoises. Patients with leukemia can present with marked leukocytosis and >140,000 lymphocytes/μL. Cells can be intermediate to large in size (8–18 μm in diameter) depending on immunophenotype. Immunocytochemistry using CD3 and BLA36 have been performed on air-dried blood smears to distinguish between T-and B-cell variants, respectively.[3,27] Quality assurance should include species specific controls.

N, individuals in study.

Hemoparasites and Inclusions

Care must be taken to distinguish between staining/preparation artifacts and true viral inclusions/parasites. Small basophilic inclusions thought to be degenerate organelles are commonly found in blood smears from apparently healthy Testudines and should not be interpreted as abnormal (Figure 134.1). Semiaquatic freshwater turtle RBCs and rarely WBCs may contain hemogregarine parasites, usually of the genus *Hemogregarina* (Figure 134.3m).[11] Though these parasites

are not host-specific, they rarely cause primary disease in infected animals. Iridoviral inclusions have been demonstrated in heterophils and monocytes in eastern box turtles (*Terrapene carolina carolina*) (Figure 134.3n). Intraerythrocytic *Anaplasma* morulae have been identified in the peripheral blood of anemic gopher tortoises[23] (Figure 134.3o).

ASVCP, American Society for Veterinary Clinical Pathology.

Amphibians (class Amphibia) are ectothermic, tetrapodic vertebrates and include 8177 known species of frogs and toads (order Anura), salamanders and newts (subclass Caudata, order Urodela), and caecilians (order Gymnophiona).[10] Their life cycle typically includes an aquatic stage followed by metamorphosis into an adult form. Many species are capable of regenerating lost limbs and degenerating body parts, which makes them interesting research subjects. Study of amphibian pathobiology is important for the preservation of wildlife populations, the health of captive animals kept as pets, and to aid in research studies.

Sample collection has been thoroughly described in a recent review article.[9] Contamination of the blood sample with lymphatic fluid during collection may decrease the erythroid mass and artifactually increase lymphocyte number.

In general, amphibian blood cell morphology is similar to that of reptiles; however, the cells are significantly larger. Comparative hematology studies have been performed only in a few species and the vast majority of reference intervals have low numbers or do not have outliers removed in accordance with American Society for Veterinary Clinical Pathology (ASVCP) guidelines.[5,9,12] These reference intervals cannot be used for medical use due to the risk of misdiagnosis.

HEMATOPOIESIS

Amphibian species vary in their sites of hematopoiesis, but common anatomic sites in adult amphibians include the spleen, liver, bone marrow, and kidney.[8] In most studied species of adult frogs, erythroid cells are produced in the spleen, while lymphoid, myeloid, and thrombocytic cell lines develop in the bone marrow.[8] In the South African clawed frog (*Xenopus laevis*), erythropoiesis and thrombopoiesis take place in the liver, while the granulocyte and monocyte/macrophage cell lines originate in the bone marrow.[16] In the axolotl (*Ambystoma mexicanum*), hematopoiesis is only found in the spleen and liver in adults.[11] In newts, hematopoiesis does not occur in bone marrow, but in the spleen, liver, kidney, and thymus.[8]

ERYTHRON

Mature amphibian RBCs are ovoid or elliptical in shape, biconvex with red to red-orange hemoglobin-containing cytoplasm and contain nuclei (Figure 135.1). Immature forms are rounded and have bluer cytoplasm. Occasional anucleate RBCs (erythroplastids) may be encountered on blood films, and lungless salamanders of the genus

African clawed frog (*Xenopus laevis*): (h) Neutrophil/heterophil; (i) Lymphocyte; (j) Monocyte; (k) Eosinophil; (l) Basophil; (m) Erythrocyte; (n) Thrombocyte. Eastern tiger salamander (*Ambystoma tigrinum tigrinum*): (o) Neutrophil; (p) Lymphocyte; (q) Monocyte; (r) Eosinophil; (s) Basophil; (t) Erythrocyte; (u) Thrombocyte. Axolotl (*Ambystoma mexicanum*): (v) Neutrophil; (w) Lymphocyte; (x) Monocyte; (y) Eosinophil; (z) Basophil; (aa) Erythrocyte; (ab) Three thrombocytes.

Batrachoseps have been found to have a majority of anucleate circulating RBCs (>90%)[6] (Figure 135.2e). The clinical significance of this finding is unknown.

Among amphibian species, RBCs exhibit considerable size variation, but their RBCs are generally larger than those of the birds and reptiles. The largest reported amphibian erythrocyte size is found in the amphiuma (*Amphiuma tridactylum*), with a measured RBC size of 70 × 50 µm.[14] Average RBC sizes reported vary between species in the same genus, e.g., 13 × 10 µm in Western clawed frogs (*Xenopus tropicalis*), 18 × 11 µm in African clawed frogs (*X. laevis*); though some of the variation may be due to measurement technique.[12] Other frog species have similar sizes reported, e.g., 18 × 11 µm in the white-lipped tree frog (*Litoria infrenata*). Typically, the urodele amphibians have larger RBCs than the anuran amphibians, but definitive, species-specific RBC sizes remain poorly defined. Some species have individuals with marked ploidy and either diploid, triploid, or tetraploid erythrocytes, which increases the RBC size variation as found in axolotl (*A. mexicanum*).[9,11] Erythroid mass and number may be measured by PCV and direct hemocytometer cell count (see Chapters 123 and 128). Amphibians typically have lower reported PCV values compared to birds and reptiles.[3,5,9,17]

Immature RBCs are recognized by increased cytoplasmic basophilia and a rounder cell shape (Figure 135.2a). These cells are typically smaller in size than mature RBCs.[1,4,9,15] The nuclei of immature RBCs (rubricytes) typically have more open (lighter-staining) chromatin patterns in comparison to mature RBCs (metarubricytes), and their chromatin becomes more condensed as the cells age[4] (Figure 135.2c). While occasional rubricytes may be found on blood smears from normal amphibians, increased numbers of immature RBCs are evidence of a regenerative response in anemic amphibians, those with hemoparasites (such as *Hepatozoon sp*. and hemogregarines), and those with secondary polycythemia due to decreased oxygen perfusion.[9,17]

LEUKON

Granulocytes observed in amphibians include neutrophils, eosinophils, and basophils. Amphibian neutrophils, or heterophils in some species, are granulocytes with myeloperoxidase-containing granules that do not stain or stain only weakly with typical hematology stains (e.g., Wright–Giemsa)[9] (Figure 135.1). In species in which these cells have visible red-orange granules, these cells may be referred to as heterophils (Figure 135.1a). Mature neutrophils typically have segmented or bilobed nuclei, but immature neutrophils may be seen in the peripheral blood in response to inflammation, and may have band-shaped, reniform, or oval nuclei (Figure 135.2f).

Amphibian lymphocytes have round to irregularly round or indented nuclei, small amounts of basophilic cytoplasm, with a high nucleus to cytoplasm ratio (Figure 135.1). Azurophilic granules may be found in lymphocyte cytoplasm in Ranidae frogs as well as axolotl, and the authors presume in many species of amphibians[4] (Figure 135.2d). Lymphocytes have been reported as the predominant leukocyte type in some species or individuals, including the American bullfrog (*Rana catesbeiana*), Australian tree frogs (*Litoria sp*.), the Western clawed frog (*Xenopus tropicalis*), and the California tiger salamander (*Ambystoma californiense*).[3,5,12,17]

Amphibian monocytes are similar in appearance to those seen in other species. They are large leukocytes with variably shaped nuclei (ranging from round to oval, bilobed, trilobed, or amoeboid). Monocytes have basophilic cytoplasm, which sometimes contains discrete vacuoles[1,4,9,15] (Figure 135.1).

Amphibian eosinophils display prominent, bright red-orange, round cytoplasmic granules with Wright–Giemsa stain (Figure 135.1). Eosinophils may show less segmentation than neutrophils/heterophils and contain bilobed or round nuclei, though they are not immature. Amphibian basophils are plentiful in aquatic species and may have a segmented or round to oval nucleus. Basophil granules are classically seen as round, dark purple/basophilic granules on blood films, but their granules may be nonstaining or clear, sometimes referred to as "degranulated" basophils, especially in aqueous stains (Figure 135.1). Clear or nonstaining basophil granules may be the result of partial dissolution of the granules when water-based hematology stains are used (Diff-Quik and similar stains).[4]

WBC counts may be estimated from cell density on a blood film, but this technique has limited accuracy due to the uneven WBC distribution on the blood film. These values should be considered an estimate and not a quantitative value as produced by automated hematology analyzers. Amphibian WBC counts are performed manually, utilizing Natt and Herrick stain to identify WBCs in a hemocytometer. A potential error source is the misidentification of thrombocytes for lymphocytes, thus artifactually inflating the WBC count.[15] Natt-and-Herrick-stained lymphocytes have more basophilic cytoplasm compared to thrombocytes, however.[4] Inactivated amphibian thrombocytes are oval to elongated and distinctly different than round lymphocytes which exhibit a higher nucleus to cytoplasmic ratio and more basophilic cytoplasm in comparison to thrombocytes.[1,4] Lymphocytes may be difficult to distinguish from thrombocytes in the blood film and hemocytometer in samples with activated cells. Phloxine staining may be used to visualize and count neutrophils/heterophils and eosinophils in a hemocytometer, which can then be used to calculate the total WBC count after a WBC differential is performed.[1] Using the phloxine method avoids the difficulty of differentiating thrombocytes and lymphocytes in the hemocytometer, as this is done while performing the differential cell count on a stained blood film. The phloxine method is less useful for species which have significant numbers of basophils and neutrophils (rather than heterophils), as these cell types stain minimally with phloxine dye.[1] Thus, the indirect calculation of total WBC count is more likely to be inaccurate and imprecise.

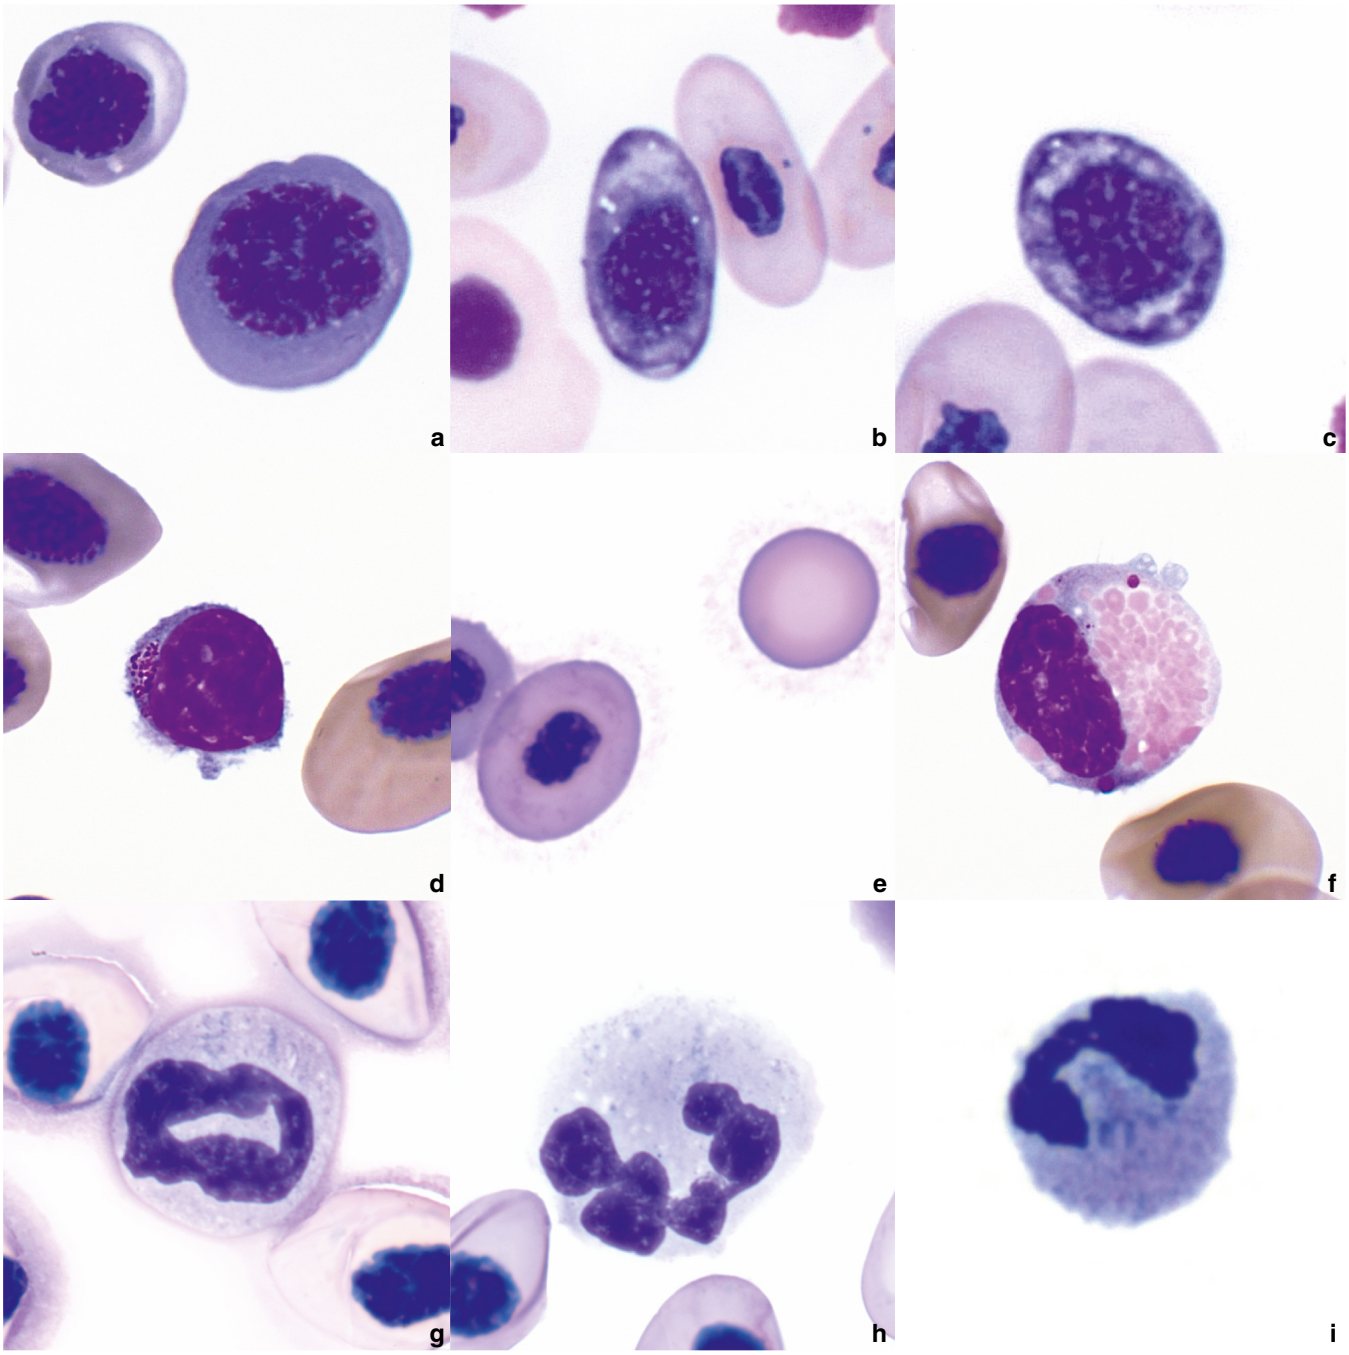

FIGURE 135.2 Abnormal amphibian blood cells. Axolotl (*Ambystoma mexicanum*): (a) Immature erythrocytes including probable rubricytes. Argentine horned frog (*Ceratophrys ornata*): (b) Immature, basophilic erythrocyte; (c) Rubricyte. American toad (*Anaxyrus [Bufo] americanus*): (d) Granular lymphocyte; (e) Anucleate erythrocyte or erythroplastid. Axolotl (*Ambystoma mexicanum*): (f) Toxic, immature heterophil/neutrophil with cytoplasmic basophilia, purple primary granules, and mild vacuolation with an oval nucleus. Eastern tiger salamander (*Ambystoma tigrinum*) with confirmed sepsis: (g) Toxic neutrophil with a circular nucleus exhibiting Döhle bodies and cytoplasmic basophilia; (h) Toxic neutrophil with a hypersegmented nucleus from the same salamander as (g). Mud puppy (*Necturus sp.*) with confirmed bacterial infection: (i) Toxic neutrophil.

THROMBOCYTES

Amphibians have nucleated thrombocytes, the functional equivalent of mammalian platelets. These are typically the smallest blood cells found on the blood film. They are round to oval or spindle-shaped and have small amounts of clear to pale blue cytoplasm[4,9] (Figure 135.1n,u). Activated thrombocytes may have increased numbers of eosinophilic cytoplasmic granules. Immature thrombocytes may be encountered, and these have rounder nuclei and more basophilic cytoplasm

than mature thrombocytes.[1,4,9] Thrombocytes often cluster together on the blood film, impairing estimation of their numbers (Figure 135.1ab). Enumeration of thrombocytes is uncommonly done, but is possible using a Natt-and-Herrick-stained sample on a hemocytometer, or they can be estimated on a stained blood film. With the Natt and Herrick stain, thrombocytes are smaller than RBCs and have pale basophilic cytoplasm, compared to the more deeply basophilic leukocytes.[9] If clotting occurs in the sample tube, thrombocytes will be trapped within the clot and are therefore less numerous on blood film preparations or in the hemocytometer.

HEMATOLOGIC DISEASE

Abnormalities of WBC number and morphology are not as well-studied as those of mammals or birds.[1] In general, leukocyte responses may be interpreted in a similar way to those of other species. Neutrophilia is generally expected in response to inflammation, though decreased numbers may result in severe, acute inflammatory disease. Toxic changes consistent with those found in mammals, including increased Döhle bodies, cytoplasmic basophilia, and vacuolation, are commonly seen in amphibian's immune response to infectious agents; especially typical gram-negative pathogens found in aquatic environments, such as *Vibrio* and *Aeromonas* (Figure 135.2f–i). The presence of circular neutrophil nuclei and hypersegmented nuclei has been found in diseased animals. The clinical significance of these findings, if any, is unknown.

Eosinophils may increase in parasitic disease, and lymphocytes may increase due to an immune response, fear/excitement, viral disease, or lymphoid neoplasia.[4] Hemoparasites identified in Amphibia include extracellular *Trypanosoma sp.*,[13] *Hepatozoon sp.*,[2] and intraerythrocytic rickettsial organisms.[7]

Current estimates of named living animal species are approximately 1,382,400, of which 58,000 (4%) are vertebrates and 1,324,400 (96%) are invertebrates represented in 30 phyla.[4] Corals, worms, snails, clams, lobsters, spiders, and sea stars illustrate the diversity of only a few representatives. Respecting the magnitude of this group of animals, only four selected phyla will be represented including Arthropoda/Crustacea (lobsters, crabs), Arthropoda/Chelicerata (horseshoe crabs, spiders), Mollusca/Bivalvia (oysters, clams), and Echinodermata/Echinoidea (sea urchins, sand dollars).

The United Nations Food and Agriculture Organization 2015 world aquaculture report described the global annual aquaculture production by relative percent, tons, and US dollar value by food category. Crustaceans (crabs, lobsters, and shrimp) represented 10% (7.4 million tons) and were valued at US$38.5 billion. Bivalves (clams, cockles, mussels, oysters, and scallops) represented approximately 21% (16.4 million tons), valued at US$17.9 billion. Nine species of invertebrates categorized as "other animals," which include the edible urchins, made up 1 million tons and were valued at US$3.9 billion.[25]

The commercial value of the horseshoe crab (*Limulus polyphemus*) is due to its hematologic characteristics and the unique ability of the hemocytes (often called amebocytes) to detect lipopolysaccharides and 1,3-β-D-glucan in the cell walls of bacteria and fungi, respectively. This high sensitivity is the basis of the Limulus Amebocyte Lysate test, used to assure safety of injectable drugs and implantable medical devices. Horseshoe crabs are also used in the eel and whelk fisheries industry as bait.[17] The combined fishing pressures have resulted in decreasing Atlantic populations which may also be impacted by climate change, resulting in an International Union for Conservation of Nature designation of vulnerable.

Hematology for health assessment is not widely practiced for invertebrates. Further development of hematologic techniques is needed to address the challenges of working with viscous hemolymph, the diversity of hemocyte characterization for so many species, and to consider the rapid changes in hemocyte distribution due to internal and external factors, as well as life stage for species that molt. Similar to early attempts to develop hematology methods for avian and reptilian species,

invertebrate hematology is becoming an important diagnostic tool as techniques are developed.

HEMATOLOGIC METHODS

Phlebotomy Sites by Body Type

Hemolymph, derived from Latin for blood/clear water, is comprised of cells, water, dissolved organic salts, and proteins. The cells, termed hemocytes, move freely in and around the tissues and organs. Circulatory systems vary in complexity with the general principal that a pumping organ, or developed heart, sends hemolymph to the gills and oxygenated hemocyanin is returned to the heart. The animals discussed in this chapter have an open circulatory system and lack vasculature.

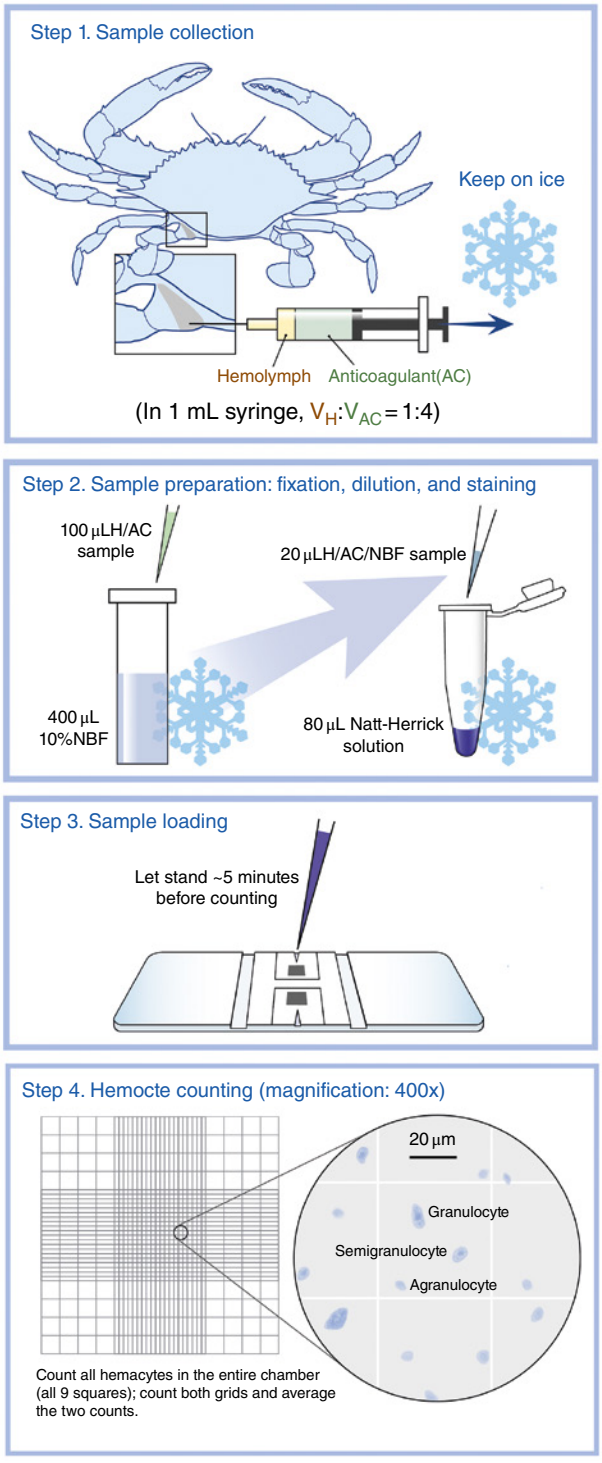
Typical phlebotomy sites for crustaceans are the ventral abdominal sinus, at the first or second abdominal segment in lobsters[3] (*Homarus americanus*) (Table 136.1a), and the arthrodial membrane at the base of the chelae (large claw) or swimming leg of crabs (Figure 136.1). Hemolymph is collected from the pericardial sinus of the horseshoe crab (*L. polyphemus*) through the arthrodial membrane between the prosoma and opisthosoma (Table 136.1c). Hemolymph is drawn from the adductor muscle of hard-shelled oysters and clams (class Bivalvia) after drilling a hole in the shell or directly from the heart after shucking the shell open (Table 136.1b). The adductor muscles of soft-shell clams (e.g., *Mya arenaria*) may be accessed from partially opening the shell. Coelomic fluid is collected from sea urchins and sand dollars (class Echinoidea) from the peristomal membrane adjacent to the mouth, with care to avoid damage to the internal organs by angling the needle 45° away from the oral/anal axis, directing the needle toward the body wall[22] (Table 136.1d).

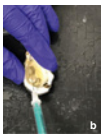
Anticoagulants and Sample Handling

Given the variety of terrestrial and aquatic invertebrate species, it is understandable that there are no standardized anticoagulants. Multiple formulations are found in the literature (Table 136.2). Techniques reported to prevent or slow cell aggregation include collecting hemolymph into syringes prefilled with ice-chilled solutions of anticoagulant or seawater, keeping syringes and sample tubes on ice (for marine species), and using formalin or formaldehyde to fix the cells.[2,3]

Laboratory Analysis

Hemolymph's viscous nature presents challenges for preparing smears and techniques for vertebrate blood must be modified. Various slide preparation techniques have been reported including staining a cytocentrifuged, hemolymph pellet with H&E, and toluidine blue. Lobster (*H. americanus*) hemolymph, drawn directly into a syringe containing cold formalin, was prepared using coverslips, methanol fixed, and stained with Giemsa for 30 minutes, followed by





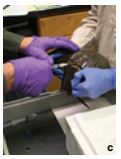


FIGURE 136.1 Blue crab (*Callinectes sapidus*) phlebotomy and hemocyte count. (Step 1) Hemolymph is drawn from the arthrodial membrane at the base of the swimming leg into a syringe containing chilled anticoagulant; (Step 2) Contents of the syringe are quickly transferred to vial (not shown) and a 100 µL aliquot is mixed with 400 µL 10% neutral buffered formalin to fix the cells. The final 1:100 dilution for cell counting is prepared by adding 20 µL fixed cells to 80 µL Natt and Herrick's solution; (Step 3) Neubauer hemocytometer is loaded; (Step 4) All hemocytes are tallied in the nine large squares from both grids and averaged. Cells × 110 = total hemocyte count/µL. (**Source:** Illustration by Wenjing Wu, CMI 2020©Wenjing Wu.)

rinsing in distilled water (pH 4) until the stain color transitions to pink.[9] Slides for lobster hemocytes can also be prepared using a cytocentrifuge, by loading 100–200 µL of hemolymph-anticoagulant solution or formalin-fixed cells into the sample cup, resulting in a diagnostic sample.[3] The slides can be stained with Wright–Giemsa or other Romanowsky stains. Formalin-fixed hemocytes stained in any Romanowsky stains may be very dark blue, and better viewing of cellular features can be obtained by diluting the methylene blue or similar purple stain in distilled water at a ratio of 1:50 (Figure 136.2).

Automated hemocyte counts using flow cytometry have been reported for Pacific oysters (*Crassostrea gigas*)[11] and purple sea urchins (*Strongylocentrotus purpuratus*).[22] Manual total hemocyte counts can be performed by standard methods using hemocytometers. If the hemolymph or coelomic fluid is collected directly into anticoagulant solution, this initial dilution must be included in determining the final multiplication factor for the number of cells tallied (Figure 136.1). Some reports employ no special cell counting diluent beyond anticoagulant for lobsters, blue crabs, and tarantulas.[3,27,23] Others have used formalin solutions for lobsters and Pacific oysters.[2,13] Cell counting diluents for birds, reptiles, and fish may be used.[18]

This chapter's author uses the Natt and Herrick formula, supplementing the stock solution with NaCl (0.14 g/10 mL) and urea (0.32 g/10 mL) for marine species whose hemolymph osmolality values approximate the surrounding seawater. Attempt to collect 0.5 mL hemolymph directly drawn into 1.5 mL chilled anticoagulant (0.3 M NaCl, 0.1 M glucose, 30 mM Na citrate, 26 mM citric acid, 10 mM EDTA; pH = 5.4)[27], for approximately 1:4 dilution. The sampling dilution factor may be variable based on hemolymph volume acquired. The syringe contents are quickly transferred to a chilled sterile vial. Then 100 µL anticoagulated hemolymph is immediately transferred to a vial containing 400 µL chilled 10% neutral buffered formalin (1:5 dilution). The second dilution factor, 5, is standard using this technique. The vials are brought to ambient temperature for transport to the lab. Prepare the 1:100 final dilution by adding 20 µL of the formalin-fixed cells to 80 µL Natt and Herrick stain. Load the Neubauer hemocytometer and tally all the hemocytes in the nine large squares of both grids, average, and multiply by 110 for hemocytes/µL (Figure 136.1).

Hemolymph total dissolved solids can be measured by refractive index as for vertebrate plasma. Hemocyanin is the respiratory pigment of cephalopods (octopus, squid, cuttlefish), gastropod mollusks (snails, slugs, limpets), and arthropods (horseshoe crabs and spiders) and can be measured by spectrophotometric methods.[7] Hemocyanin is an extracellular, copper-based oxygen-carrying protein that rapidly releases oxygen. In contrast to the gastropod mollusks, the bivalve mollusks (clams and oysters) and echinoderms

TABLE 136.2 Anticoagulant formulas for invertebrates, converted to per liter from the (published formula concentrations).

Chemical (per liter)	Lobster[3]	Blue crab[27]	Urchin[22]	Spider[23]	Horseshoe crab[7]
Calcium Chloride dihydrate ($CaCl_2$-$2H_2O$)	1.5 g				
Sodium chloride (NaCl)	28.4 g	17.5 g (0.3 M)	29.2 g (500 mM)	8.2 g (0.14 M)	3 g (3%)
Magnesium sulfate heptahydrate ($MgSO_4.7H_2O$)	8.7 g				
Magnesium chloride hexhydrate ($MgCl_2.6H_2O$)	5.5 g				
Potassium chloride (KCl)	0.7 g		1.9 g (26 mM)		
Tween 80	0.5 mL				
37–40% formaldehyde	1.25 mL				25 mL
Glucose ($C_6H_{12}O_6$)		18.0 g (0.1 M)		18.0 g (0.1 M)	
Dextrose ($C_6H_{12}O_6$)					18.16 g (100 mM)
Sodium citrate dihydrate ($C_6H_5Na_3O_7.2H_2O$)		8.8 g (30 mM)		8.8 g (0.03 M)	
Citric acid monohydrate ($C_6H_8O_7.H_2O$)		5.5 g (26 mM)		5.5 g (26 mM)

EDTA ($C_{10}H_{16}N_2O_8$)		2.9 g (10 mM)		2.9 g (10 mM)	2.9 g (10 mM)
EGTA ($C_{14}H_{11}N_2O_{10}$)			19 g (50 mM)		
TRIS ($C_4H_{11}NO_3$)			1.2 g (10 mM)		
Solution pH	7.6	5.4	7.4	4.7	4.6

Prepare solutions by adding the chemical amounts to a 1-liter volumetric flask and q.s. to mark with distilled or deionized water. Lobster (*Homarus americanus*), blue crab (*Callinectes sapidus*), urchin (*Strongylocentrotus purpuratus*), spider (*Lasiodora sp.*), and horseshoe crab (*Limulus polyphemus*).

(urchins) lack hemocyanin and utilize cell-bound hemoglobin within nucleated cells that are structurally like that of vertebrates.[8]

HEMOCYTES

Arthropoda/Crustacea—Lobsters, Crabs

While terminology varies somewhat in the literature, the consensus is that three cell morphology types, large granule, small granule, and hyalinocytes, can be consistently identified in crustacean hemolymph (Figure 136.2). Large granule hemocytes have a low N:C ratio and the cytoplasm is filled with granules (>1 μm), which store prophenol-peroxidase. The nucleus is usually eccentric. These cells have a primary role in phagocytosis of foreign material and fungal encapsulation. Small granule hemocytes also have a central nucleus, low N:C ratio and the cytoplasm contains fewer, smaller granules (<1 μm) that contain lysosomal enzymes. One main function of this cell is phagocytosis of bacteria. Hyaline hemocytes, in contrast, have a high N:C, and the cytoplasm contains abundant small electron-dense deposits in the cytoplasm. They serve a primary role in coagulation and are rich in transglutaminase activity, essential for clotting reactions.[3,15]

Hemocyte differential counts vary among species and are subject to rapid change depending on environmental factors, especially for species that molt. For example, the blue crab (*C. sapidus*) is reported to have changes in both total and differential hemocyte counts during the molting process. Intermolt crabs averaged $6 \times 10^3/\mu L$ hemocytes. Average total hemocyte counts increased to $14 \times 10^3/\mu L$ in late premolt and then returned to intermolt levels during ecdysis (molt). The differential counts showed marked

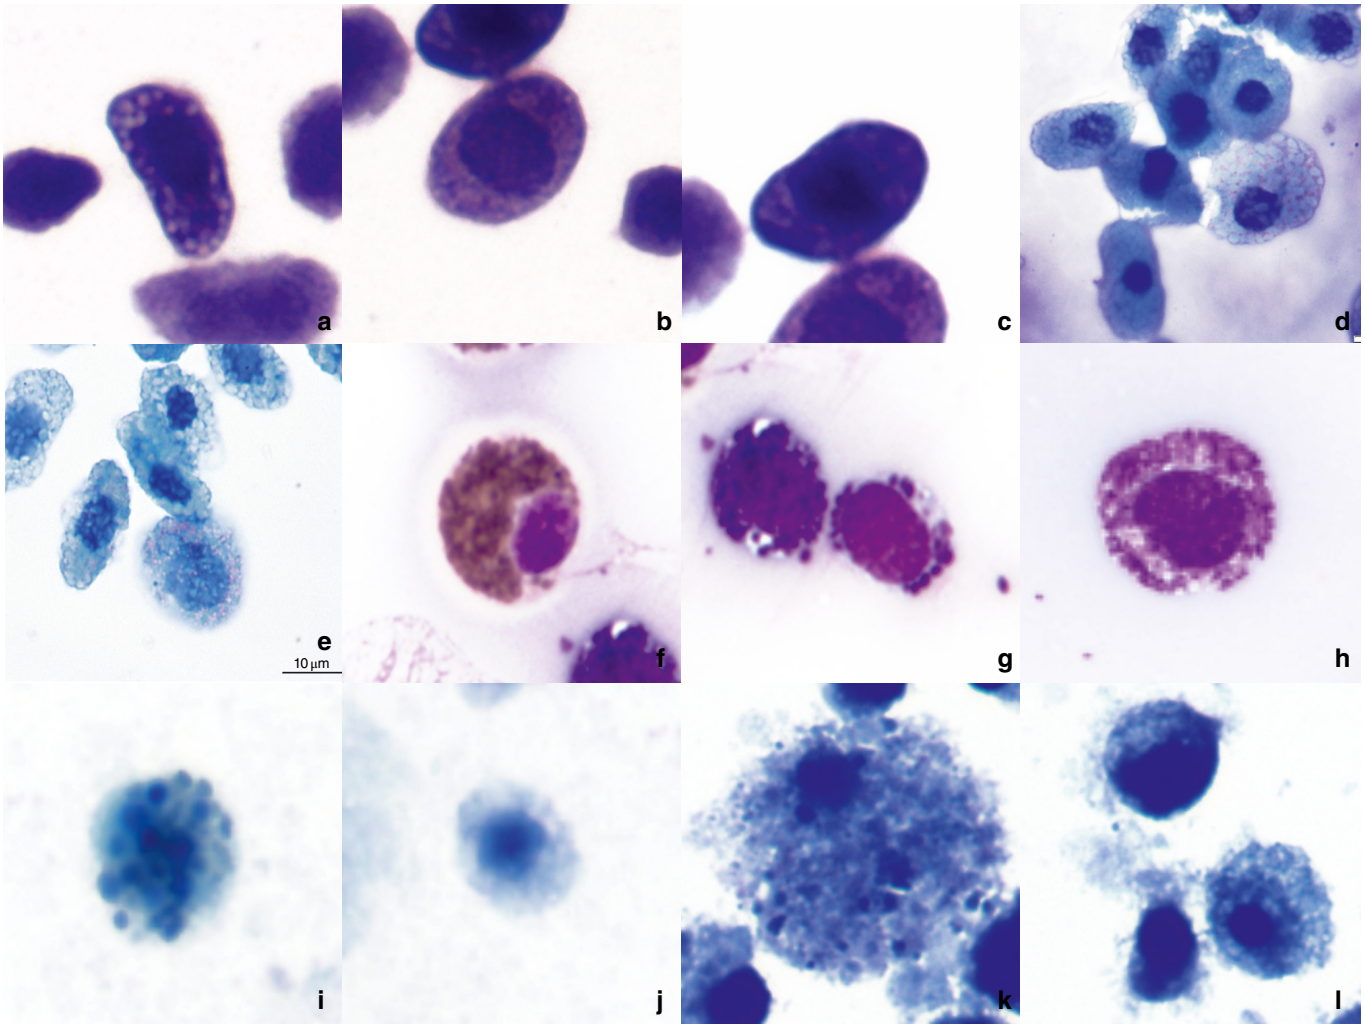

FIGURE 136.2 Hemocytes from selected invertebrates. All hemocytes are prepared using a formalin preservation technique and a Romanowsky stain, except for f-h. See text for approximate sizes. Apparently healthy blue crab (*Callinectes sapidus*): (a) Large granule hemocyte; (b) Small granule hemocyte; (c) Hyaline hemocyte (possible thrombocyte). Apparently healthy American horseshoe crab (*Limulus polyphemus*): (d) Amebocytes; (e) Amebocytes, noting slightly different granularity. Apparently healthy emperor scorpion (*Pandinus imperator*): (f) Unidentified granulocyte (possible heterophil); (g) Two cells with basophilic granules; (h) Larger granulocyte with basophilic granules. No formalin was used in the scorpion sample preparation, 100× objective, Wright–Giemsa stain. Courtesy of Dr. Nicole Stacy. Apparently healthy Pacific oyster (*Crassostrea gigas*): (i) Granulocyte; (j) Agranulocyte, aka hyalinocyte. Cell lineage is unknown. It should be noted that bivalves are reported to use cell-bound hemoglobin within nucleated cells similar to vertebrates. Diseased sand dollar (*Dendraster excentricus*): (k) Large, activated phagocyte; (l) Phagocytic coelomocytes with variable numbers of vacuoles. (Courtesy of Monterey Bay Aquarium.)

changes, with hyaline cells (possible thrombocytes) predominant during intermolt and small granular cells that phagocytize bacteria predominant through ecdysis, along with a moderate increase in all granulocyte concentrations. The differential cell counts shifted back to intermolt levels during the postmolt (shell hardening) period.[1] The highest mitotic activity is reported in the proecdysis/peeler stages (preparing to molt) in multiple species, which suggests need for increased hemocyte numbers during this vulnerable life stage.[24]

Arthropoda/Chelicerata—Horseshoe Crabs and Spiders

In contrast to the decapod crustaceans, there is a single type of hemocyte in the four extant species of horseshoe crabs; Atlantic, or American, horseshoe crab (*L. polyphemus*) found along the East Coast of North America, the mangrove horseshoe crab in Southeast Asia (*Carcinoscorpius rotundicauda*), the Indo-Pacific horseshoe crab (*Tachypleus gigas*), and the Japanese, or trident, horseshoe crab (*Tachypleus tridentatus*) found in

Southeast and East Asia. The cell is referred to as an amebocyte because it becomes motile and adherent when removed from the body or upon encountering foreign material. Inactivated amebocytes are large, approximately 20 µm in length, oval cells with cytoplasm that contains abundant large and small round granules (Figure 136.2). When exposed to bacterial endotoxin, the cells rapidly activate, markedly changing shape with numerous filopodia, and release granule contents.[26] This rapid response to endotoxin was the basis for the development of the Limulus Amebocyte Lysate assay in the 1960s, which is still a primary method for testing sterility of injectable drugs and implantable medical devices.[17]

In marked contrast to the horseshoe crab, spiders and tarantulas are reported to have multiple cell types, with varied nomenclature strategies proposed (Figure 136.2). Soares et al.[23] offered a comprehensive morphology and ultrastructure report of six cell types from the cardiac hemolymph from 16 Brazilian tarantula spiders (*Lasiodora sp.*). The cell names, sizes, and average abundance from the differential cell count are as follows: prohemocytes (10–15 µm; 8.1%) had a high N:C and homogenous cytoplasm filled with varied numbers of granules; granulocyte type I (25–30 µm; 35.2%) are elongate cells with a central lobed nucleus and cytoplasm filled with prominent granules; granulocyte type II resembles type I, but is larger (35–40 µm; 29.6%); spherules, or spherulocytes (15–25 µm; 11.1%), are round cells, with a round nucleus, a high N:C ratio, and large round cytoplasmic granules, postulated to be involved in coagulation; plasmatocytes (15–20 µm; 13%) were highly pleomorphic, from round to spindle-shaped and had no visible granules in the cytoplasm; oenocytoids (15–20 µm; 3%) are round cells with homogeneous cytoplasm. *Oenocytoids*, a term which may be unfamiliar, are cells present in low numbers in hemolymph of many insect species and their function is not known.[19] In contrast with the Brazilian tarantula (*Lasiodora sp.*), the wandering spider (*Cupiennius salei*) was reported to have a predominance of plasmatocytes (70–80%) with fewer granulocytes (20–30%) and only a few prohemocytes and cyanocytes.[16] Nomenclature for cells from spiders follows convention for other insects. More research, including exploration of cytochemistry and ultrastructural appearance, is warranted.

Mollusca/Bivalvia—Oysters, Clams

Marine bivalve hemocytes are characterized into two groups by light microscopy: granulocytes (cytoplasm contains abundant granules) and hyalinocytes (no visible granules) (Figure 136.2). Both phagocytic cell types aggregate and are motile using pseudopodia. A comparative study of hemocytes found in three Korean oysters (*Saccostrea kegaki*, *Ostrea circumpicta*, and *Hyotissa hyotis*) reported similar cell morphology and abundance. The hyalinocyte was most abundant and comprised approximately 60% of the cells followed by granulocytes (23–31%) and a third, much smaller (<10 µm), blast-like cell (3–5%).[14] Comparable hemocyte descriptions have been reported for the Pacific oyster (*C. gigas*) and authors suggest the blast-like cell may be a stem cell.[11]

Echinodermata/Echinoidea—Urchins and Starfish

The predominant hemocyte in the coelomic fluid of the purple sea urchin (*S. purpuratus*) are round phagocytes (small and large, approximately 30 and 50 µm, respectively). Rapidly motile round cells, termed vibratile cells (approximately 5 µm), move in a uniform direction by means of a single, long flagella. There are two types of spherule cells, or amebocytes (approximately 5 µm), one whose cytoplasmic vesicles contain the red pigment echinochrome A, with antibacterial properties, and the other amebocyte's vesicles lack this pigment.[22]

Hematopoiesis

Hematopoietic tissue of decapod crustaceans is found adjacent to, or enveloping, the ophthalmic artery (dorsal median artery) and on the dorsal and/or lateral sides of the cardiac stomach. The tissue comprises lobules, covered with fibrous connective tissue, with hemocyte precursors at different developmental stages within these connective tissue layers. Another hematopoietic tissue is situated between the stomach muscles and the anterior part of the hematopoietic tissue near the brain, initially termed the "cephalic gland" and later renamed the "anterior proliferation center". Early studies suggest that mesodermal cell masses on either side of the aorta may be the origin of hematopoietic tissue during embryonic and larval development in crayfish; however, the specific origins are not yet known.[24]

Giemsa-stained histologic sections of embryonic horseshoe crabs (*L. polyphemus*) showed the earliest appearance of hemocytes occurred at the 18th of 21-stage development. While no obvious hemopoietic tissue was found, the hemocytes were observed in the hemocoel cavities, usually in close association with connective tissue.[10] In contrast to the xiphosurans, hematopoietic sites are known for fellow chelicerates, e.g., scorpions and spiders. Scorpion hematopoiesis occurs in supraneural and lymphoid glands, while hematopoietic tissue in spiders is found in the heart wall.[16]

The site of hemopoiesis in bivalves remains unclear; however, immunohistochemistry has demonstrated hemocyte progenitor cells in the tubules and underlying hemolymph vessels of specialized regions of gill epithelium in the oyster (*C. gigas*).[20] A 2019 study induced coelomocyte proliferation in the echinoid purple sea urchin (*S. purpuratus*) after challenge with *Vibrio diazotrophicus* and by coelomic fluid depletion. Newly formed coelomocytes were detected both in the axial organ, a core of spongy tissue within the axial sinus of the hemal vascular system, and the pharynx, suggesting these are sites of hemopoiesis.[12]

HEMATOLOGIC RESPONSE TO DISEASE

Physiologic

There is little known regarding invertebrate response to physiologic stress.

Inflammation and Intoxication

A challenge study in lobsters showed that individuals in the treatment group in late-stage infection with gaffkemia (*Aerococcus viridans* var. *homari*) had immature hemocytes, suggesting a similar left-shift as observed in vertebrates. The total hemocyte count showed an initial increase at day 1 post inoculation with *A. viridans* (mean $26.6 \times 10^3/\mu L$). Then counts decreased to ranges comparable to the control group by day 4 ($16.5 \times 10^3/\mu L$).[3]

Mean total hemocyte concentrations from Pacific oysters (*C. gigas*) at an oil-spill site (345.2 hemocytes/μL) compared to those at an unpolluted reference location (401.2 hemocytes/μL) showed no significant difference. However, the proportion of granulocytes found in oil-spill oysters was half that of oysters sampled at the control site, suggesting the highly phagocytic granulocytes may be the cells most affected by petroleum intoxication. Oil-spill oysters had a slightly higher percent of blast-like cells (14.7% vs 10.7%) than control oysters.[11] Conversely, a report on parasitic infestation showed that mean total hemocyte concentrations approximately doubled in Pacific oysters (*C. gigas*) with the paramyxean protozoa (*Marteiliodes chungmuensis*) compared to the control group (410 hemocytes/μL and 210 hemocytes/μL, respectively). Differential cell counts differed as well, with infested oysters having increased granulocyte numbers.[6]

Spiders exposed to azadirachtin, a neem-tree extract used to control mosquitos, include reports for hemocyte counts because of the cell's role in phagocytosis of foreign material. Wolf spiders (*Schizocosa episina*) fed 10 ppm azadirachtin-treated prey showed a significant decrease in total hemocyte concentrations ($10.7 \times 10^3/\mu L$) compared to the control group (mean $37.3 \times 10^3/\mu L$).[21]

A 2019 study[5] of adult sea urchins (*Paracentrotus lividus*) challenged with bacterial lipopolysaccharide showed significantly higher total coelomocyte concentrations, and higher relative counts of phagocytic cells and red spherule cells, compared to control urchins. The test group of 12 urchins received an intracoelomic injection of *Escherichia coli* lipopolysaccharide suspended in a salt solution of similar composition to natural coelomic fluid, while the control group of 12 received a sham injection of the salt solution. Serial coelomic fluid samples were collected at 1, 3, 6, and 24 hours postinjection. Total coelomocyte counts were determined with a Burker hemocytometer. Differential coelomocyte counts from smears classified the cells as phagocytic cells, colorless spherule cells, red spherule cells, and vibratile cells. Results showed a significant rise in total cell concentrations 1 hour post-treatment ($10.4 \pm 0.74 \times 10^3/\mu L$; $p < 0.01$), compared to the control group ($8.1 \pm 0.65 \times 10^3/\mu L$) with peak levels at hour 3 ($11.6 \pm 0.65 \times 10^3/\mu L$), returning to the same level as the control urchins by 6 hours. The relative differential by cell type showed a rapid, significant increase in phagocytic cells and red spherule cells ($p < 0.001$), approximately twice that in controls. There was no significant difference in colorless spherule cells or vibratile cells compared with controls. The findings demonstrate the cellular defense mechanisms of specific coelomocytes in response to bacterial challenge.

ASVCP, American Society of Veterinary Clinical Pathology; CHCM, cellular hemoglobin concentration mean; CLIA, Clinical Laboratory Improvement Amendments; CV, coefficient of variation; ECVCP, European College of Veterinary Clinical Pathology; EFLM, European Federation of Clinical Chemistry and Laboratory Medicine; EQA, external quality assessment; ICSH, International Council for Standardization in Hematology; MPV, mean platelet volume; PDW, platelet distribution width; P_{ed}, probability of error detection; P_{fr}, probability of false rejection; POC, point of care; PT, proficiency testing; QA, quality assurance; QC, quality control; QCM, quality control material; RDW, red cell distribution width; RPT, repeat patient testing; SD, standard deviation; SOP, standard operating procedure; TE, total error; TE_a, total allowable error; TE_{obs}, total error observed; WHO, World Health Organization.

Many automated and manual techniques are used in veterinary hematology and quality management is an integral part of ensuring accurate and precise results. Different species with different hematologic properties complicate veterinary hematology and further increase the importance of comprehensive quality management. In recent years, the American Society of Veterinary Clinical Pathology (ASVCP) published several guidelines on quality management and control, providing tools to the veterinary community to achieve and improve quality in veterinary hematology.[2,21,50,11] Importantly, quality management does not only comprise analytical aspects, but also preanalytical and postanalytical factors.

EXTRA-ANALYTICAL FACTORS

Clinical, preanalytical, analytical, and postanalytical phases represent the "brain-to-brain loop"; a continuum of concepts relevant for laboratory testing starting when the clinician first makes a decision to order laboratory testing, through ordering, collection, identification, transportation, specimen preparation, analysis, reporting, interpretation, to taking appropriate actions for the patient via further monitoring, additional testing, and/or treatment.[38] Plebani has presented a paradigm for human laboratory testing, known as the "five rights" for patients, which provides valuable insight for veterinary patients. The five rights include: (1) appropriateness, (2) personalized and patient-centered service, (3) focus on outcomes, (4) value, and (5) diagnostic partnership. This paradigm addresses clinical and preanalytical factors such as ensuring that the right test is selected for the right patient, at the right time (with correct patient preparation), with the right specimen collection and handling, and the right transportation. The preanalytical stage within the laboratory includes the correct pretreatment

(if needed), sample separation, aliquoting, sorting, and routing through the laboratory. In the postanalytical phase, the "five rights" comprise the right turnaround time, data validation, units, reference intervals/decision limits, and interpretive comments to aid the clinician. In the clinical (postanalytical) phase, the "five rights" involve the right acknowledgment (e.g., timely review of laboratory results), interpretation, utilization (diagnosis/therapy), follow-up, documentation of results in the medical record, and actions initiated. These rights emphasize the joint responsibility of the laboratory and clinicians for the right/wrong utilization of laboratory information.

Preanalytical aspects of hematologic testing are related to animal status (e.g., fasting, physical exercise, drug intake), sampling process (e.g., animal handling, excitement, order of draw), and the sample itself (e.g., anticoagulant, tube fill, storage, labeling). Information concerning important preanalytical requirements should be provided to clients in writing to ensure appropriate sample quality.[50]

Although, the influence of fasting status is less pronounced for hematologic analyses than for biochemistry or hormone analyses, lipemic samples should be avoided, since turbidity will interfere with photometric hemoglobin (Hgb) measurement. In addition, lipids may form small droplets in vitro that cause spurious increases in platelet counts, mean cellular hemoglobin (MCH), mean cellular hemoglobin concentration (MCHC), and WBC counts (Figure 137.1).[54,55] In addition to analytical interferences, fasting status may also lead to in vivo variations in hematologic values. While severe food restriction for more than 48 hours has been shown to cause bone marrow and lymphoid depletion in rats,[30] less severe fasting for shorter time periods results in no or variable mild hematologic alterations in rats and monkeys.[34,56] While these alterations are clinically insignificant, they may be important in toxicology studies, requiring careful consideration of the fasting status.

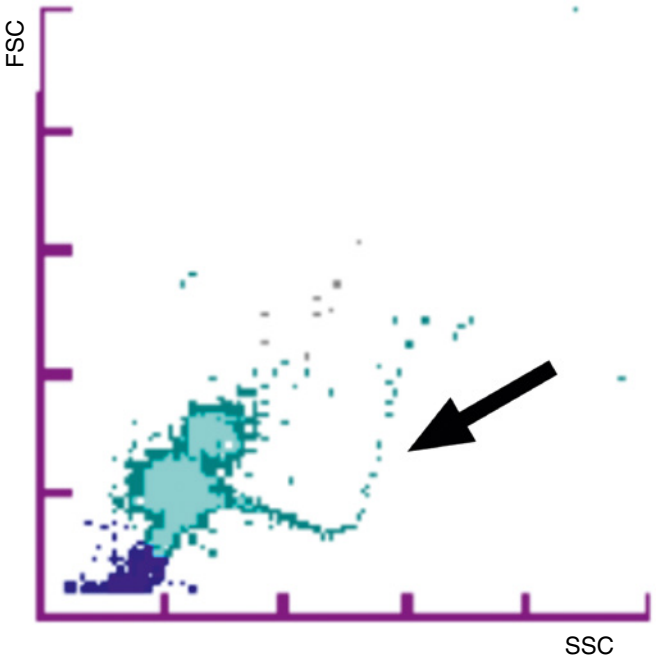

FIGURE 137.1 Sysmex XT-2000iV WBC/BASO scattergram of a canine blood sample (*x*-axis displays the side scatter; *y*-axis displays the forward scatter). Lipid droplets form a sigmoid curve on the scattergram (black arrow). (Source: Courtesy of Clare Doyle, SYNLAB VPG Hitchin.)

Before and during sampling, excitement should be avoided to reduce the presence of epinephrine-induced leukocytosis and spurious alterations in the WBC differential, due to shifting of neutrophils and lymphocytes from the marginal to the central pool.[44]

Hematologic analyses require K_2-EDTA- or K_3-EDTA-anticoagulated, citrated, or heparinized whole blood. Heparinized whole blood is only recommended for some birds, reptiles, and fish, since their blood may hemolyze when collected into EDTA (corvids, crows, jays, ravens, magpies, ostrich, brown kingfisher, pigeon, toucan, some species of ducks, cranes, hornbills and galliformes, chelonians, stingrays, and some bony fish).[26,10] In mammalians and other reptiles, birds, and fish, heparinized whole blood should not be used for hematology, since platelets and WBCs frequently clump and blood film staining quality is poor. Citrated whole blood is mainly used for coagulation assays and in rare cases with EDTA-induced platelet and WBC aggregates for hematology.[26] In other situations, citrated whole blood is not recommended, since lower platelet counts due to platelet aggregation commonly occur.[45] Except for the conditions above, EDTA is the anticoagulant of choice for hematological assays. It exists as spray-dried K_2-EDTA and liquid K_3-EDTA; statistically significant differences comparing tubes with spray-dried K_2-EDTA tubes and liquid K_3-EDTA tubes were considered to be clinically insignificant and due to the dilutional effect of the liquid anticoagulant.[48] Both types of salts can be used for hematologic analyses. Tubes filled in accordance with manufacturer-recommended volumes are more important. According to the Clinical and Laboratory Standards Institute (CLSI), the draw volume should be no more than 10% below the manufacturer-recommended volume and more pronounced underfilling of the tubes has the potential to affect accuracy[13] (e.g., decrease of spun PCV due to shrinking of RBC artifactually lowers mean cell volume (MCV)).[55] Comparable information is lacking for samples from veterinary species, but an effort should be made to achieve the recommended blood/anticoagulant ratio by filling to the line indicated on blood tubes. Specimen tubes should be labeled with a unique identifier that allows the laboratory to assess tube fill and sample quality.

Before sample shipment, blood films should be made in the clinic and protected from condensation, refrigeration, and extreme temperatures during transport to the laboratory.[50] Morphologic changes occurring as soon as 3 hours after blood draw are well described in humans.[57] Changes include nuclear swelling, decreased chromatin clumping, and cytoplasmic vacuolization in WBCs. In RBCs, crenation, sphering, fragmentation, and disappearance of nucleated RBCs may occur over time. Morphological changes in canine neutrophils during

storage have recently been described; when stored at room temperature, Döhle-body-like inclusions were observed after only 4 hours.[5] Hematologic sample stability has been assessed for different species and different analyzers.[8,6,39,23,12] Increased hematocrit (Hct) and MCV and decreased MCHC due to RBC swelling are commonly observed using different analyzers in multiple species and occur in as little as 6 hours after sampling. Inconsistent alterations, likely depending on species and hematology analyzer, are reported for platelet, WBC, and differential cell counts.[8,6,23,12] Most of the available information has been obtained using samples from healthy animals; but, one study in dogs showed that discrepancies due to sample storage were more pronounced in clinically ill dogs.[8] Laboratories should therefore provide guidance to clinicians regarding sample stability valid for their respective analyzer and careful evaluation of blood smears and scattergrams is needed to ensure accuracy of automated results.

Postanalytical procedures must provide legible and accurate results, transmitted in a timely manner to clients. Report formatting must be easily understood and, depending on the clients' expectations, explanatory comments might be needed. For example, an online survey showed important differences between clinicians' and clinical pathologists' understanding of the clinical relevance of RBC morphology terms.[32] Results should be released with validated or verified reference intervals. Details about reference intervals should be made available to clients upon request.[2]

The use of sophisticated laboratory information systems is the main driver reducing postanalytical errors. However, especially in veterinary hematology where many analyses are still performed manually, procedures should be in place to avoid manual data entry errors. Such procedures include double-verification procedures, medical validation of results by clinical pathologists, result review criteria, and δ checks. In human laboratories, efforts are made to implement automatic validation of test results to reduce subjectivity, time, and the need for a physician in the laboratory.[25]

Specimens should be archived under appropriate conditions or disposed of safely, according to biosafety regulations.[2] Except for stained hematology slides, hematologic samples can only be stored for a limited amount of time. Procedures for storage and disposal should be defined according to laboratory policies and accreditation requirements.[2] It is the responsibility of the laboratory management to define biosafety risks; all laboratory personnel must be educated of these risks and specimens must be handled and discarded according to state and national biosafety regulations.

ANALYTICAL FACTORS OF SPECIAL IMPORTANCE IN VETERINARY HEMATOLOGY

Point-of-care (POC) and large hematology analyzers used in reference laboratories have undergone major technical improvements in the last decades and large number of different methods are applied in veterinary hematology. Therefore, quality management of the analytical phase is of immense importance. It comprises general aspects applicable to all areas of veterinary clinical pathology and procedures specific to hematology. Automated hematology instruments must be validated prior to use with analytical quality requirements established as part of the instrument validation study.[21] Quality control (QC) procedures, statistical and nonstatistical, should be defined for all methods. Statistical QC refers to the analysis of control materials and interpretation of internal and external QC results.[21] Nonstatistical QC in hematology includes quality planning activities, the use of standard operating procedures (SOPs), definition of blood film and pathologist review criteria, δ checks (comparison of serial patient test results), correlation of Hgb concentration and Hct, correlation of automated hematology results and blood film findings, training and standardization among laboratory personnel, assessment of staining quality, and monitoring of increased MCHC. Additional specific QC procedures, such as calibration of pipettes and balances and monitoring of cell-counting reagent quality, are required for nonmammalian hematology.[50]

Quality Goals (Performance Specifications)

Historically, quality improvement in laboratory medicine focused mainly on analytical aspects, such as assay standardization, automation, information technology, and personnel training.[28] Introduction and monitoring of quality indicators, such as analytical performance specifications, were important milestones. In a conference of the European Federation of Clinical Chemistry and Laboratory Medicine (EFLM), held in 2014 in Milan, it was agreed that "for patient care, optimizing the quality of the total (preanalytical/analytical/postanalytical) examination process is the ultimate goal and, therefore, it would be desirable to go beyond setting analytical performance specifications and to establish examination performance specifications."[42] In veterinary hematology, only a few specific quality goals for the analytical phase are available, but more general goals and principles can be transferred from human medicine.

Milan Hierarchy

The "Milan hierarchy" is a consensus agreement defined during the 1st Strategic Conference of the EFLM in Milan in 2014. It describes three models to set analytical performance specifications (Table 137.1).[42]

1. The effect of analytical performance on clinical outcomes.
2. Components of biological variation.
3. State of the art, which is the highest level of analytical performance technically achievable.

TABLE 137.1 Summary of Milan hierarchy models for quality goals. Advantages and disadvantages are adapted to veterinary hematology.

Model	Key points	Advantages	Disadvantages
Model 1 Effect of analytical performance on clinical outcomes	Outcome studies investigate the impact of the test's analytical performance on clinical decisions or outcomes	Highly relevant to patients, since it addresses the influence of analytical performance on clinical outcomes	Can only be used if a strong link between the test and clinical outcome exists Actual test method may have different measurement quality than the method used in outcome studies Outcome studies may not be readily available
Model 2 Biological variation	Attempts to minimize the ratio of analytical noise of the biological signal	May be used for quality goals, as well as in analysis of patient results	The clinical relevance of biological variation data needs to be assessed Biological variation data are not available for all species
Model 3 State of the art	The highest achievable analytical performance based on current technology and methods	Information on state-of-the-art analytical performance is available for most hematology analyzers	Can only be used if a strong link between the state-of-the-art performance and clinical outcome exists State-of-the-art performance is not achievable by all laboratories using different methods

ASVCP Guidelines: Allowable Total Error Hematology

The ASVCP has released allowable total error recommendations as analytical quality specifications based on:

1. Clinical expert opinion on what is clinically desirable for dogs, cats, and horses.
2. Instrument performance derived from external quality assessment (EQA)/proficiency testing (PT) data.
3. CLSI guidelines.

The ASVCP guidelines provide an excellent reference for laboratory personnel and clinicians to objectively determine suitability of their analyzers and result interpretation (see Chapter 138).

Biological Variation

Biological variation data can be used to set analytical quality specifications. A database containing numerous analytes has been maintained on the Westgard website[37] and will now be expanded by the EFLM.[19,52] Since information on biological variation in animals is very limited, the human database was considered a useful tool to estimate biologic variation across species. However, concern has recently been raised about the data quality and the EFLM has created a task force to develop a critical appraisal list for evaluation of biological variation data.[1] This list focuses on details about the population and samples, preanalytical procedures, test method, estimates of analytical variation, outlier handling, and statistical analyses.[1] Implementation of these criteria will likely change human biological variation data substantially. A similar guideline for conducting biologic variation studies in animals is available[22] and should enable high-quality data collection for veterinary species. Available biological variation data in animals are maintained on the veterinary biological variation website.[3]

Nonstatistical Quality Control

Sample quality assessment of hematologic samples is a vital nonstatistical quality control tool. Lipemia, hemolysis, and clotted samples are the main interfering factors in hematologic samples. In accordance with ASVCP guidelines, any sign of clotting should result in a request for a fresh sample. Hematology results should not be reported for clotted samples. Evaluation for hemolysis and lipemia can be easily conducted if PCV is obtained for each patient. Hematology analyzers generally measure RBC counts, MCV, and Hgb concentration and calculate Hct, MCH, and MCHC from those measurements. Abnormal RBC indices, especially increased MCHC, therefore, can be used as a flag for detection of errors among measured RBC indices.[55] Common causes for

elevated MCHC include lipemia and Heinz bodies (spectral interferences in the Hgb assay), as well as in vitro and in vivo hemolysis (measured Hgb concentration includes Hgb from RBCs and free Hgb in plasma). Elevated MCHC results should always trigger assessment of plasma color and RBC morphology. Less common causes for elevated MCHC include extreme leukocytosis (spectral interferences in the Hgb assay) and true increases in MCHC due to eccentrocytes, pyknocytes, or spherocytes.[44] ADVIA analyzers provide a calculated and a measured MCHC, called cellular hemoglobin concentration mean (CHCM). Differences between MCHC and CHCM should prompt investigations regarding interfering substances; in addition, the CHCM can be used to calculate accurate Hgb concentrations. Sysmex analyzers offer a comparable calculation, called measured RBC Hgb content (RBC-He). In addition to an impedance RBC count used for calculation of MCHC, Sysmex analyzers provide an optical RBC count (RBC-O), which together with the RBC-He is used for the calculation of Hgb-O (optical). δ-RBC and δ-Hgb values (i.e., difference between RBC count or Hgb concentration of the impedance channel/photometric measurement and values derived from optical channel) can be used to distinguish underlying causes of elevated MCHC.[7] Increased MCHCs due to hemolysis require distinction between in vivo and in vitro hemolysis for clinical interpretation. RBC count and PCV correctly define the RBC mass available for oxygen transport when hemolysis occurs in the animal, whereas Hgb concentration provides information about available oxygen transport capacity in samples with in vitro hemolysis. RBC indices should be invalidated accordingly in these instances.

If undetected, clotted samples lead to erroneous hematology results. Therefore, macroscopic assessment of all samples is mandatory. If any doubts remain after macroscopic assessment or in cases of unexplained cytopenias, samples should be checked for small clots using a wooden stick to stir the anticoagulated blood in the submission tube. Small, red to tan, fibrin clots adhere to the wood and can be found upon gross inspection. Clotted samples should not be used for hematologic analyses.

RBC aggregation induces error in hematology results and may indicate important clinical information, e.g., immune-mediated hemolytic anemia (IMHA). RBC aggregation can be distinguished from rouleaux formation by a 1:9 dilution with saline. RBC aggregates due to immune-mediated mechanisms will persist and are visible macroscopically and/or microscopically, while stacking due to increased protein concentration in rouleaux formation will disperse. The agglutinin may be a cold-sensitive antibody and agglutination may interfere with electronic or optical RBC evaluation at room temperature. Small RBC aggregates are counted as a single large particle. If aggregates are larger than the upper threshold/gate, they are fully neglected by the hematology analyzer. This leads to spuriously low RBC counts, abnormally high MCV and MCHC, and erroneous Hct, while Hgb concentration is unaffected [55].

Manual Slide Evaluation

Manual blood smear review is the thorough microscopic analysis of a stained blood smear.[16] It is an integral part of veterinary hematology to ensure accuracy of automated hematology results and to detect morphological changes relevant for diagnosis.[16] For human hematology, the International Society of Laboratory Hematology (ISLH) has released criteria for action following automated CBC and WBC differential analysis.[4] Criteria include the age and sex, whether the request is for an initial or serial CBC, and whether there are significant differences between current and previous results. They are based on set thresholds and presence or absence of flags and aim to have a false negative rate of <5%.[15] Different studies in human medicine have, however, shown that institution-specific adaptations are needed.[16,15,24]

Comparable detailed guidelines are currently lacking in veterinary medicine. The ASVCP states that criteria should be established for microscopic blood film review and suggests confirmation of automated differential cell counts at predetermined thresholds.[50] Defined criteria should decrease the number of manual blood smear reviews as much as possible, for economic reasons and best use of technical and pathology staff. Veterinary experts' opinions concerning blood film reviews are diverse: some institutions review all blood films, whereas others have criteria triggering blood film review and/or manual WBC differentiation. The suitability of different approaches will depend on the patient population (i.e., sick patients, preanesthetic, or geriatric screenings), the available hematology analyzer (i.e., laser- or impedance-based instruments), and the knowledge base of laboratory personnel. In all instances, laboratory processes should ensure that accurate, automated WBC differentials are released and are not overwritten by manual WBC differentials with poor imprecision unless proven to be in error. Laser-based instruments provide, besides numerical results, sophisticated graphical result displays (cytograms); studies in animals demonstrating their usefulness as criteria for manual blood smear review are limited. For the ADVIA 120, cytogram sensitivity for left-shift detection was between 80 and 97% based on indistinct separation of polymorphonuclear and mononuclear cells and a shortened population of polymorphonuclear cells in the baso cytograms across the species studied. Specificities between 18 and 49% were poor.[43] For the Sysmex XT-2000iV, left shift, toxic changes, nucleated RBCs, and immature cells cause obvious changes in the cytograms.[29] However, no peer-reviewed information about cytogram sensitivity and specificity in the detection of morphological WBC changes is available. Considering the limited information currently available and the diversity of veterinary hematology, criteria for manual blood smear review should aim for a high sensitivity for the detection of morphologic abnormalities and inaccurate results. With further study and information, each laboratory will be able to reduce the number of slides reviewed and will increase analytical specificity. With a laser-based instrument, a safe approach would be

to release automatic results if they are within reference intervals and if cytograms are unremarkable. A blood smear should be reviewed when results are outside reference intervals or when abnormal cytograms are detected. See "Case Example" section in the following text. In addition to manual blood smear review, each laboratory should define criteria for pathologist's review. These criteria depend on knowledge base and training of technical staff and should be based on numerical and morphological results. Pathologist's review criteria should ensure that the clinical pathologist can confirm unusual and clinically highly relevant results. Interpretive comments should be provided to clinicians to ensure excellent communication that is required for correct diagnostic implementation in diagnosis and therapeutic choice.

With manual blood film review, plausibility of automated WBC, platelet, reticulocyte, and WBC differential counts should be assessed. Total WBC count (cells/μL) can be estimated at 100× magnification by multiplying the average number of WBCs present in 10 fields (total WBC number ÷ 10) × 100 to 150.[26] Accuracy of the WBC differential can either be estimated during overall slide review or 100 or 200 consecutive WBCs can be identified and counted at 400× or 500× total magnification. Considering the inherent imprecision of manual WBC differentials,[27] it is not advisable to define an exact cutoff for differences accepted between automated and manual WBC differentials. Rather, the manual WBC differential and cytogram review should confirm if WBCs were correctly classified by the hematology analyzer. Sysmex analyzers allow manual regating. Thus, if the analyzer was unable to separate cell populations, WBC differentials may be corrected by manual regating, providing highly precise WBC differential results (Figure 137.2).

Platelet counts can be estimated by multiplying the average number of platelets per field at 1000× (oil) × 15. This number may vary dependent on the microscope objectives. A recent study in dogs has shown that the variability of the platelet estimate is high, operator-dependent, and influenced by the area of the smear.[36] Plausibility assessment of the platelet count should, therefore, include evaluation of cytograms and histograms, platelet size, and plateletcrit. Neither automated nor manual platelet counts will be accurate if platelet aggregates are present.

Every laboratory should have procedures defining platelet aggregate assessment and reporting. Platelet aggregate presence must be clearly conveyed to the clinician on the report. Invalidating platelet counts in all samples with platelet aggregates will, especially in cats with platelet aggregates in up to 71% of samples, be frustrating for clinicians. When platelet counts are within reference intervals, platelet aggregates are clinically insignificant and laboratory procedures should focus on cases with automated counts indicating thrombocytopenia. Blood film review is required in all thrombocytopenic samples to assess platelet aggregates. An arbitrary five-tiered classification system (0–5) was introduced by Tvedten et al.,[47] scoring the number and size of platelet aggregates in the feathered edge and monolayer area. While 1+ and 2+ platelet aggregation appeared to have no significant effect on platelet count, 3+ and 4+ aggregation predicted a marked effect.

Modern laser-based hematology analyzers have flags for platelet clumps and, depending on number and size of platelet clumps, they might be visible in cytograms and histograms. These flags and graphical result displays negate the need for blood film assessment in clearly defined cases. It should be noted that the ADVIA platelet aggregate flag was less sensitive than manual blood film inspection.[47] Preanalytically, Iloprost, a synthetic analog of prostaglandin I2 can be added to EDTA tubes prior to blood sampling, to prevent platelet aggregation.[40,47]

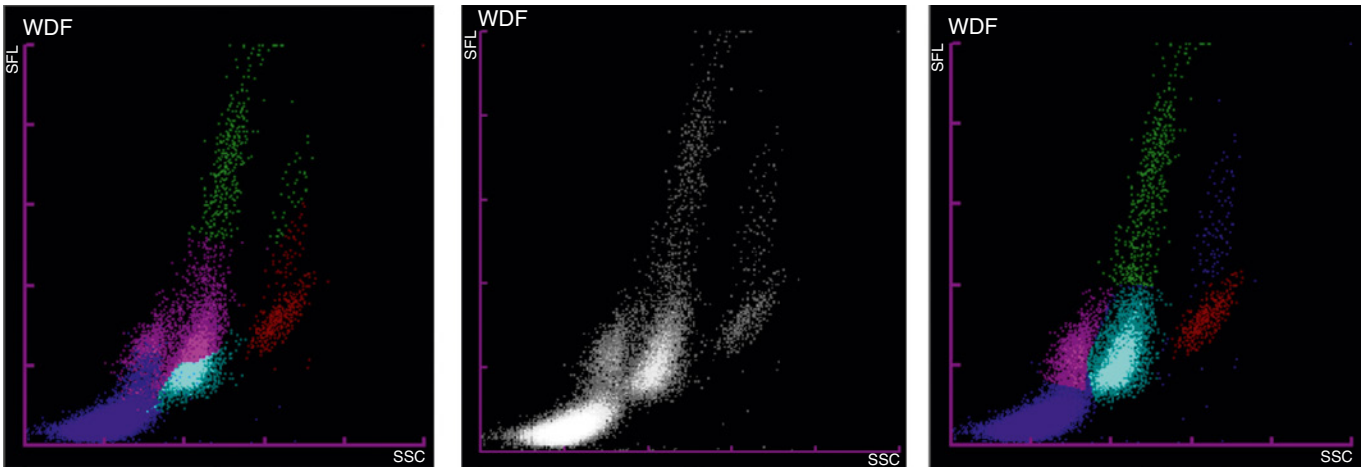

FIGURE 137.2 Sysmex XN WDF scattergrams of a feline blood sample with a WBC count of 10.3 × 10^3/μL and nine nucleated RBCs per 100 WBCs. The *y*-axis displays side fluorescence, *x*-axis displays side scatter. Lymphocytes are pink, neutrophils and basophils are light blue, monocytes are green, and eosinophils are red. The left scattergram represents the original gating of the Sysmex XN. It clearly indicates the instrument was not able to correctly classify WBCs. The middle scattergram is displayed in black and white to better visualize the nicely separated cell clusters. The right scattergram shows the separation attained after manual gating. A correct automated WBC differential with high precision was achieved.

Laser-based hematology instruments measure absolute reticulocyte counts utilizing a fluorescent dye staining RNA content. Pseudoreticulocytosis has been reported in humans and a dog with lymphoid leukemia due to misclassification of leukemic cells or particles thereof as reticulocytes[33] and accuracy of reticulocyte counts should be ensured (see Chapter 65). In addition to cytogram evaluation, blood films can be assessed for the degree of polychromasia. A semiquantitative assessment scheme for polychromasia has been published for dogs, cats, and horses,[26] and a study in dogs has shown a good agreement between polychromasia and automated reticulocyte percentages.[14] As a less-subjective alternative, a manual polychromatophilic cell count also correlates well with automated reticulocyte counts in dogs.[14] Due to high imprecision, manual reticulocyte counts using brilliant cresyl or new methylene blue-stained blood films may not be recommended for most mammalian species. Modern hematology analyzers are very sensitive and detect reticulocytes with little RNA content, which may stain similarly to adult RBCs on Romanowsky-stained blood films. A positive bias for automated counts compared to manual counts or estimates is therefore expected.

Plausibility Checks in Veterinary Hematology

Automated hematology analyzers either calculate Hct from the RBC count and MCV or determine Hct from the RBC pulse height. The PCV (aka microHct or spun Hct) is determined by high-speed centrifugation and is the most accurate and reproducible method. The World Health Organization (WHO) has released a recommended method for PCV determination by centrifugation[53] in which they consider sources of error including nonstandardized centrifugation time and force, inadequate mixing of the sample and filling of the capillary tube, and inaccurate reading. A recent study with veterinary students and clinicians showed: 25% of students made errors associated with inadequate mixing, 23% of the students read results incorrectly, and 91% of clinicians filled the tubes incorrectly according to recommended WHO standards (between two-thirds and three-quarters full).[9] The maximum absolute error in this study was 0.20 L/L (20%), emphasizing the importance of training and standardization. For every species, each laboratory needs to assess the optimal packing time.[53] This can be done using a well-mixed normal and a polycythemic blood sample. Two capillary tubes from each specimen are filled and centrifuged (between 10,000 and 15,000 g) for 2 minutes. The PCV is measured and recorded. With freshly filled capillary tubes, the process is repeated with increasing centrifugation time by 30 seconds until the PCV does not change with further increases in centrifugation time. The optimal packing time is equivalent to the second time interval at which there is no further reduction in PCV. PCV should periodically be measured in duplicate and results should not differ by more than 0.005 L/L (0.5%).[53] See Chapter 138 for information on total allowable error (TE_a).

Hgb concentration is approximately one-third of Hct in most species and this ratio was originally adopted from humans. Agreement within three units is considered acceptable.[26] In the author's experience, up to four units variation may be acceptable in cats. A study in cattle implies that a relationship of Hgb (g/dL) = 0.3 × PCV + 3 may provide a better estimate than the conventional estimate of one-third.[46] In birds, Hgb (g/dL) = 0.3 × PCV appeared to be a reasonable estimate of Hgb concentration in eight orders; however, in Phoenicopteriformes, a different relationship was found.[51] The "rule of three" is only an estimate and may vary in different species. If systematic deviations are observed for certain species, breeds, or strains, the laboratory should consider determining specific formulas to decrease the need for spun PCVs.

In general, the "rule of three" can be used in veterinary medicine as a plausibility check of automated Hgb concentration and Hct in most samples submitted. If the Hct is outside this range, then a spun PCV should be performed. If Hct differs more than three units, spun PCV should be reported and MCV and MCHC should be invalidated or manually calculated.

Standard Operating Procedures and Documentation

Documentation problems are the most common deficiencies identified during on-site inspections.[41] Documentation of processes is required by any certification standard, such as the ISO/IEC 15189, and the ASVCP also highlights the importance of documentation and provides detailed recommendations about SOPs.[21] All procedures performed in the laboratory should be included in SOPs, which can be organized as paper copies, electronically, or, preferably, both. They should be easily accessible by technicians, managers, and assistants as needed. A procedure for revision and document control should be in place. The outline of SOPs varies from laboratory to laboratory. A SOP detailing the correct format will ensure that all SOPs in an institution follow the same outline and that no information is forgotten. The ASVCP also provides an example for an SOP outline which can be modified for the laboratory accordingly (Table 137.2.).[21]

Personnel

Personnel training is vital in veterinary hematology. Laboratory personnel should be qualified and knowledgeable regarding cell identification, including species variations. Technologists must have more general and non-species-specific knowledge, such as use and maintenance of laboratory equipment, repair or replacement of inadequate equipment, and problem-solving procedures. According to the ASVCP quality assurance guidelines,[21] veterinary laboratory personnel should also understand linearity differences in animal samples, interfering substances, expected physiologic ranges and reference intervals, common problems encountered with veterinary samples, and appropriate use of species-specific criteria. Documentation of all available

TABLE 137.2 ASVCP Suggested General Standard Operating Procedure Outline.

- Purpose of the procedure.
- Principles of the assay.
- Details on sample management (e.g., patient preparation, specimen collection and handling, minimal volume, acceptable sample type).
- Operational aspects (e.g., interferences, reportable range, analytical sensitivity and specificity).
- Details on reagents (e.g., storage location and conditions, preparation, open shelf-life, manufacturer information).
- Details on equipment and supplies (e.g., necessary equipment, location of supplies).
- Calibration and quality control procedures.
- Step-by-step instruction of the process.
- Reference intervals for each appropriate species.
- Details on interpretation and reporting, including recommended actions for critical values, repeat criteria, review criteria, literature references, and documentation (e.g., name, date, and signature of author and review).
- Appendices may include logs or worksheets, package inserts, and quick reference guides.

relevant internal and external trainings should be accessible to all personnel, including a checklist with SOPs and demonstrated competencies.

Comparative smear evaluation to ensure standardization in blood film evaluation is a tool that documents competency of laboratory personnel. A prerequisite is the standardization of nomenclature and grading of morphological features. The International Council for Standardization in Hematology (ICSH) has released recommendations for such standardization in humans.[35] While a semiquantitative evaluation scheme, including grading number and severity of degenerative changes in neutrophils, is widely accepted and used in the veterinary field (see Chapter 45), a semiquantitative scheme for RBC morphology which grades anisocytosis, polychromasia, hypochromia, poikilocytosis, codocytes, spherocytes, echinocytes, and other shapes for dogs, cats, horses, and cattle, has not been widely adopted.[26] Grading of morphological features should provide the clinicians with clinically useful information. The ICSH therefore implemented a two-tiered grading system (2+ and 3+), except for schistocytes, where even the observation of small numbers is considered to be significant and 1+ may also be assigned.[35] In veterinary hematology, most laboratories use a three-tiered grading scheme (1+/few/mild/slight, 2+/moderate, and 3+/marked/many). Standard operating procedures may define poikilocyte numbers per field to aid in appropriate semiquantitative classification.

Comparative smear evaluation performed by all hematology technicians in the laboratory should be organized by the laboratory management. Comparative smear evaluation should be done on a regular basis (e.g., once per month) and include different species as well as different pathologic changes that are encountered in the laboratory. All laboratory personnel reading routinely smears should participate and results should be documented and discussed within the team.

Statistical Quality Control

Statistical quality control is an integral part of laboratory quality systems in veterinary hematology. It refers to the analysis of control materials and interpretation of the results with pre-established acceptance and rejection criteria.[21]

Quality Control Material (QCM)

QCM measurement monitors the entire test system and is used to monitor routine analytical performance.[31] The list of requirements for high quality control materials is long and includes: ethical origin, sufficient volume, homogenous, stable, pathogen free, cost effective, and QCM must span medical decision limits.[18] The latter is especially challenging across multiple species and disease states. QCM must be handled according to manufacturer instructions, labeled with the date received and opened, and discarded when expired. Each laboratory should also verify reagent stability over the maximum run length. Commercially available QCM for impedance and flow cytometry hematology instruments cannot be used interchangeably and the specific hematology analyzer must be considered when choosing an appropriate QCM. Discussion with the manufacturer's technical support is beneficial. Commercially available QCM used for hematology instruments are usually derived and optimized for the analysis of human specimens. Target values (e.g., MCV) may therefore not always be in the relevant range for veterinary species. In addition, a recent study has shown that quality control with human-based QCM resulted in a lower observed total error (TE_{obs}) compared to TE_{obs} calculated from meta-analysis where species-specific material was used.[17]

Due to cellular instability, the use of whole animal blood as the sole QCM is not advisable; but it may be used for assessment of within-run, same-day imprecision. Periodic repeat patient testing (RPT) may overcome some of the disadvantages of human-based QCM, including clinically relevant concentrations, patient matrix effects, and commutability.[49,20] Used together, stabilized commercially available QCM of known concentrations and repeated measurement of patient samples can be combined to answer the breadth of QA questions relevant to the diagnostic laboratory.

Selection of the type, number, and frequency of QCM is part of the QC validation process. For hematology, a minimum of two control materials with different target values and a maximum run length of 24 hours are generally recommended.[2,31]

QC Validation

QC validation consists of the selection of "rules" for the statistical monitoring of method performance.[21] While many laboratories still use the manufacturer's ranges as "rules," the use of Westgard rules, or similar statistics based on QC validation, is recommended. For determining candidate QC rules, an analytical quality requirement (TE_a or clinical decision interval) needs to be defined for each test, coefficient of variation (CV) needs to be estimated from replication studies, and bias needs to be assessed and compared to manufacturer target values for QCMs in method comparison studies or proficiency testing schemes. For example, normalized OPSpecs Charts or the computerized EZ RUNS or EZ RULES 3 calculators can be used to choose appropriate Westgard rules with a high probability of error detection (usually >90%) and a low probability of false rejection (<5%) (https://www.westgard.com/essay31.htm).

Repeat Patient Testing

Repeat patient testing is a statistical QC method using patient data. Advantages of RPT include low-cost, species-specific matrix relevant to the laboratory, and absence of deterioration that may affect commercial QCMs during transport and storage. Disadvantages include the availability of suitable samples for RPT, patient sample instability, and subjectivity in setting RPT control limits. Studies in veterinary hematology using canine samples for RPT showed that RPT-QC can achieve similar performance to commercial QCM-QC and that it is possible to detect deviations from stable performance based on desired quality requirements.[49,20]

Sample aging under defined conditions results in an expected degree of variation between baseline and repeat measurements over time. Acceptable time periods depend on the analyte, but 24 hours is acceptable for most analytes. Variations exceeding the expected variation indicate a problem with the test system.[20] Results of RPT-QC, like the results of commercial QCM, are interpreted with predetermined control limits. Control limits are determined by measuring a set of pilot data; based on these results, control limits are defined. According to Westgard, RPT data from at least 20 days should be collected. Differences between the original and repeat results are calculated and plotted on a control chart. Control limits containing about 95% of the data are graphically estimated.[20] Flatland et al. suggested that an additional 20 days of data should be evaluated to ensure that the initial estimate of control limits is accurate.[20] These control limits will be used to determine if future daily RPT-QC results are acceptable or not. In contrast to QCM-QC, where manufacturer target values can be used to calculate bias, RPT-QC bias is set to zero during QC validation. If RPT is applied in a laboratory, participation in proficiency testing schemes and comparative testing is therefore of immense importance in order to monitor bias.

External Quality Assessment and Comparative Testing

The ASVCP has released guidelines on proficiency testing/external quality assessment and comparative testing for reference and in-clinic laboratories[11] (see Chapter 138). ASVCP recommends that commercial and in-clinic laboratories participate at least quarterly in a proficiency testing program,[11] so that the accuracy of the laboratory's analyzers can be monitored on a regular, preventative basis. Prevention of misdiagnosis is imperative.

Comparative testing compares the results of two or more different instruments or methods, usually carried out independently and internally within a laboratory or network of laboratories. In-clinic laboratories may compare their results with those obtained by duplicate sample submission to a reference laboratory. Comparative testing is an important QC tool, especially for laboratories with POC analyzers, since most EQA programs do not have a sufficient number of participants with POC analyzers, resulting in weak peer groups which may produce erroneous proficiency testing comparisons. POC testing sites, therefore, often compare their test results to those from a reference laboratory by measuring a patient sample on their POC analyzer and sending it out to the reference laboratory. A lack of comparability between single samples may, however, only be due to imprecision and no conclusions about bias (systematic errors) can be drawn. Bias assessment requires more comprehensive comparisons with multiple samples over a range of results, measured repetitively. The same acceptance criteria used in proficiency schemes can be applied (usually within two or three standard deviations or within TE_a). However, interpretation of result comparability can be difficult if different methods and instruments are compared, which are not expected to be identical. If bias is expected due to different instruments or methods, reference intervals can be used to define clinical comparability of results. Placement within reference intervals (divided in quartiles) or the degree of variation above or below the reference intervals is compared; results are acceptable if they fall within the same area.[11] However, if the reference intervals have not been established according to recommended ASVCP guidelines, the results may be erroneously partitioned.

POC owners should be aware that comparative testing does not replace regular internal QC, nor does it replace PT. It is an additional statistical QC tool, which provides assessment of accuracy and precision, and should be considered to ensure that patient's results are comparable between the two laboratories. Comparative testing may be used if: unexpected results are obtained in patient samples, internal QC or PT results are unacceptable, analyzers have undergone major maintenance or repair, or if no PT program is available.

The CLSI recommends classifying unacceptable results as clerical errors, methodological problems, equipment problems, technical errors, problems with

EQA testing material, problems with evaluation of results, and no explanation. This should aid in the identification of the root cause.[11]

CASE EXAMPLE

History: Nine-year-old female boxer dog that presented for bloody diarrhea and vomiting.

Assessment of numerical results reveals an appropriate "rule of three" relationship for hemoglobin concentration and hematocrit. Besides the severe anemia, a severe microcytosis and hypochromia are striking. However, all results except Hgb concentration are flagged by the analyzer (Figure 137.3).

In this case example, impedance and laser light scatter do not accurately measure RBC, reticulocyte, and platelet counts. Manual regating, an option with Sysmex analyzers, cannot be accomplished, since RBCs,

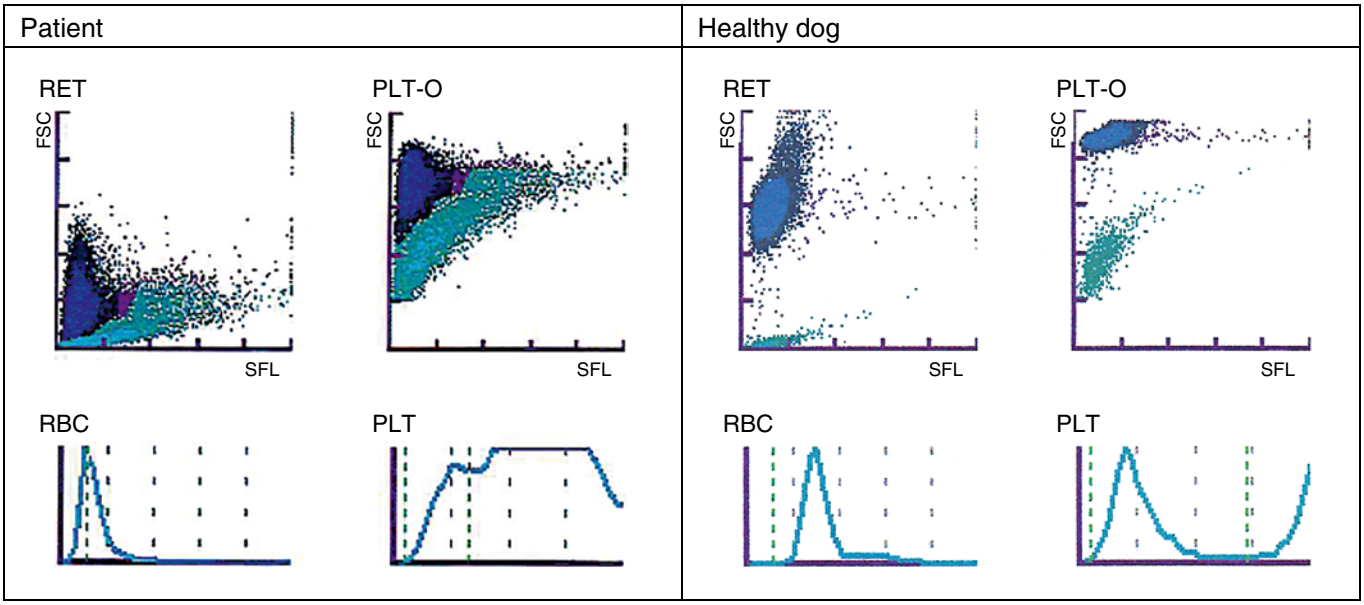

FIGURE 137.3 Cytograms and histograms. On both cytograms, forward scatter (FSC) on the *y*-axis reflects cell size, side fluorescence light (SFL) is depicted on the x-axis. The blue population shows RBCs, magenta-staining events are reticulocytes, and the lighter blue-green population represents platelets. In the patient, smaller RBCs and reticulocytes are shifted downward into the platelet population. Since platelets and RBCs, as well as platelets and reticulocytes, are not clearly separated, optical counts are not reliable and should not be released. The patient RBC histogram (patient, lower left) shows a distinct peak, shifted to the left compared to the RBC histogram for a healthy dog, reflecting the presence of small RBCs; however, the PLT histogram (patient, lower right) with lack of a well-defined peak, as seen in the healthy dog, indicates that platelets and RBCs cannot be distinguished by impedance technology due to the small RBC size. Impedance RBC and platelet counts are therefore not reliable and should not be released.

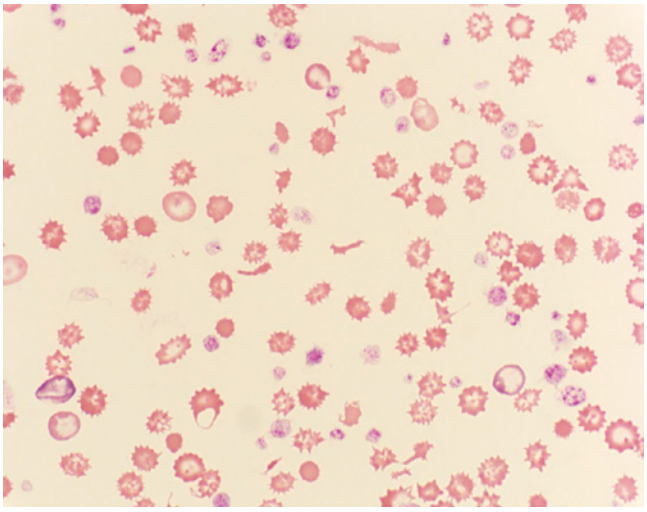

FIGURE 137.4 Blood film findings. Blood film examination confirms a severe microcytic, hypochromic anemia with only slight polychromasia; poikilocytosis is marked with presence of schistocytes, keratocytes, acanthocytes, and echinocytes. Platelet numbers are mildly increased. This is a typical case of iron deficiency anemia and was caused by chronic gastrointestinal bleeding from an intestinal adenocarcinoma.

TABLE 137.3 Hematology results.

Measurand	Result	Reference interval
RBC count (impedance)	1.7	6.1–8.1 × 10^6/μL
RBC count (optical)	–	6.1–8.1 × 10^6/μL
Hemoglobin	2.0	14.4–19.1 g/dL
Hematocrit	7	42–55%
MCV	41	64–73 fL
MCHC	29	34–36 g/dL
Reticulocyte count	43.9	10^3/μL
PLT count (impedance)	353	130–394 × 10^3/μL
PLT count (optical)	–	130–394 × 10^3/μL

platelets, and reticulocytes are overlapping in both channels. Hemoglobin concentration and PCV must be used to assess patients RBC mass; platelet counts can only be estimated on the blood film. Blood film examination is also required to evaluate RBC morphology and estimate regeneration (Figure 137.4).

CHAPTER 138

Total Error and Proficiency Testing

STEN WESTGARD and KATHLEEN P. FREEMAN

Why You Should Perform Proficiency Testing?
How Proficiency Testing Is Conducted and Judged
Graphs and Statistics in Your Proficiency Testing Report
Proficiency Testing Is Built on a Foundation of Allowable Total Error
Why Are There Different Allowable Total Error Goals?
Allowable Total Error Goals for Veterinary Hematology
The Challenge of the Future: Evolving Goals and Changing Practices

Acronyms and Abbreviations

ASVCP, American Society for Veterinary Clinical Pathology; %Bias, percent bias; CAP, College of American Pathologists; CLIA, Clinical Laboratory Improvement Amendments; CV, coefficient of variation; CVI or CV index, coefficient of variation index; EQA, external quality assessment; ISO, International Organization for Standardization; PT, proficiency testing; SD, standard deviation; QA/QC, quality assurance and quality control; TE_a, allowable total error; TE_{obs}, observed total error.

There is an apocryphal story about reaching your goals, numerously called the "Texas Sharpshooter Fallacy" or the "Story of the Master Archer," from the Torah, or even a fragment found in the texts of Cicero. It goes something like this: a warrior, desiring to master the bow and arrow, seeks out a mentor. As he wanders, the people he encounters point him in the right direction, and he begins to see arrows stuck into the bull's-eyes of targets, growing more numerous and numerous. Sometimes it's a bull's-eye in the trunk of a tree, or the side of a barn, or in a high branch, or the top of a steeple. Sometimes the targets are large, sometimes small. But always there is an arrow in the bull's-eye of each target.

Finally, he reaches the man responsible for all these bull's-eyes. He asks, admiringly, how the master archer has been able to be so accurate.

> "Oh, it's simple. I just shoot the arrow first, and **paint the target around the arrow** afterward."

This, then, is our conundrum with external quality assessment (EQA) in laboratory testing. Are we building the target first, and actually hitting a bull's-eye? Or are we shooting first, and merely painting the bull's-eye around wherever the arrow lands?[24]

WHY YOU *SHOULD* PERFORM PROFICIENCY TESTING?

Unlike many other industries and professions, laboratories never assume they are correct. Medical laboratories assure the quality of their results through continuous assessment activities. Therefore, not only do laboratories need to check that they are internally consistent, through the implementation of internal quality control (IQC), they also need to participate in EQA to confirm they are in alignment with the rest of the testing world. External quality assessment [EQA or proficiency testing (PT)] not only comprises interlaboratory comparisons focused primarily on the analytical quality of testing, but may also include all phases of the testing cycle, including interpretation of results.

Only by successfully completing both IQC and PT can laboratories assure their customers, clinicians, clients, and patients that they are delivering precise, accurate results.

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

IQC is not sufficient because it can only tell us if we are producing a *consistent* result. In order to know if we are obtaining the *right* result, we must have some comparison against an external value, preferably a reference value. Note that PT can tell us two things, depending on how it is structured: (a) It can tell us if we're getting the same result as other labs and instruments, if all we do is compare to a consensus value. That essentially confirms that we all deliver a similar result, even if it may still be the wrong result. Ideally, of course, we want more than that. (b) We want our PT program to tell us if we are reporting the right result, which requires that the PT program has some ability to determine what the correct value of each survey specimen is. This is a challenging task even in the human-based testing world with routine biochemistry analytes. When we enter the world of veterinary testing, with different species, the challenge is orders of magnitude higher.

While there is practical utility in performing proficiency testing, most medical testing laboratories working with human specimens participate in surveys because they must, not because they volunteer. Nearly every type of regulation and accreditation in the world requires proficiency testing as part of laboratory operation. Some important organizations mandating or recommending proficiency testing participation include the International Organization for Standardization (ISO), the global standard for quality. Clinical Laboratory Improvement Amendments (CLIA) regulations are required in the USA and CLSI recommendations incorporate global input from human laboratory experts.[16,5,3,6]

While no formal federal or international regulatory mandates exist for veterinary laboratories, American Society for Veterinary Clinical Pathology (ASVCP) has issued the following recommendations for EQA/PT:[2]

> "4.4.1 ASVCP recommends that both commercial and in-clinic laboratories participate in a PT program. . ..
> 4.4.2 EQA/PT participation should be used in addition to daily internal (meaning internal to the laboratory) quality assurance and quality control (QA/QC)
> 4.4.3 EQA/PT program participation for hematology and biochemistry testing is considered to be of highest importance."

HOW PROFICIENCY TESTING IS CONDUCTED AND JUDGED

While EQA programs vary considerably from country to country and program to program, there is essentially one common process: the program prepares specimens, sends them out to all participant laboratories, who then run these specimens as if they were actual patient samples, and those results are recorded and reported back to the survey organizers, who tabulate the data and perform a number of different calculations and assessments of the results. Participant laboratories can access the results in a variety of ways.

The ASVCP-recommended frequency of PT is quarterly or four times per year for in-clinic veterinary equipment regardless of waived status.[8] However, PT for all analysis in reference laboratories is not standardized and can be highly variable. In US human medical laboratories, PT frequency is largely regulatory driven. Regulated analytes must be tested four times per year, typically with five samples per challenge. Nonregulated analytes can be tested less frequently. The mandated judgment of PT is that the laboratory must pass with a score of 80%. That is, four out of five of the results must be considered acceptable and one result can be unacceptable. The first time a PT survey fails is bad, but a consecutive survey failure on the same analyte typically brings more dramatic consequences. Different PT programs enforce different success rates.

The consequences of failing a PT survey also vary. In countries like the USA and Germany, the CLIA regulations and the Rilibak regulations not only mandate the frequency and judgment criteria of PT, they also mandate significant consequences of failure, which can include loss of reimbursement or even the laboratory's operational license. Other PT programs are only educational and failure results in letters and warnings, but no actual operation or financial repercussions will occur. Eventually, if enough PT failures accumulate, any lab with ISO 15189 accreditation will find those failures are serious nonconformances that can jeopardize the entire laboratory's accreditation.

Historically, PT have had exceptionally low failure rates. In 1987, less than 1% of laboratories failed their College of American Pathologists (CAP) survey.[12] As the CLIA regulations came into effect, in 1994, that failure rate fluctuated between 1.3% and 5.6%.[22] Between 2007 and 2011, the CAP survey recorded failures rates between 3.0% and 3.74%.[15] Even the latest update proposed by CLIA in the USA was constructed with minimizing the failure rate of laboratories to only 1–2%.[5,23] Therefore, we expect that the goals of PT are attainable and only few laboratories would fail proficiency testing.

GRAPHS AND STATISTICS IN YOUR PROFICIENCY TESTING REPORT

Every PT report will generally provide the laboratory's mean in comparison to the reference mean and/or a peer group mean, dependent upon the program. These details may be included in a box plot, histogram, or Youden plot, which provide a visual display of the participating laboratory's results in the PT program.[2,21]

There are multiple statistics that can be displayed in a PT report, but the most common is the standard deviation index (SDI), which is simply:

$$\text{SDI} = (\text{reported value} - \text{expected/assigned value})/\text{group SD}.$$

This helps the laboratory understand how far away each value is from the expected or target value. SDI describes

the systematic error or bias of a method in terms of the variation of the group.

For example, an SDI of 0.0 indicates the lab mean is exactly the same as the group mean. An SDI of 2.0 indicates the lab mean is 2 group SDs higher or lower than the group mean, which indicates the laboratory is bordering on having an accuracy problem. Any SDI greater than 2.0 should be investigated by the laboratory.

Another statistic that may be included in the report is the coefficient of variation index (CVI or CV index) This is a comparison of the laboratory CV to the group CV using the equation:

$$\text{CVI} = \text{Lab CV}/\text{Group CV}.$$

A CVI of 1.0 indicates the laboratory CV is the same as the group CV. A CVI <1.0 suggests the laboratory's imprecision is better (less) than that observed for the group. A CVI >1.0 suggests the laboratory's imprecision is worse (higher) than that observed for the group.

Both the SDI and the CVI are crude statistics. They can certainly identify when laboratories are significantly different than the group. But if a laboratory has acceptable CVI and SDI, that is no guarantee they are providing clinically appropriate results. These are more appropriately thought of as negative indicators. They can tell you when you're doing badly, but can't give you assurance that you're doing well. A more demanding assessment would be needed for that.

PROFICIENCY TESTING IS BUILT ON A FOUNDATION OF ALLOWABLE TOTAL ERROR

For quantitative tests, in order to definitively determine whether a single PT result is acceptable or unacceptable, there must be a quantitative value that can be set around the "expected value," "consensus value," or "true value" (depending on which type of PT program you are participating in). It is unreasonable to expect, and impossible to achieve, the exact result in your PT challenge as the expected value of the survey due to both random and systematic errors. In every reported result both types of error are present. Some difference is inevitable, and indeed allowable. This is where the term "total error" is derived. The observed total error (TE_{obs}) represents the combination of random and systematic errors that is found in a single test result. There must be some amount of total error that is acceptable; that doesn't change the clinician's interpretation of the patient's health, doesn't alter the diagnosis, and doesn't impact the patient's treatment. This is what is called analytical allowable total error (TE_a) and is defined as an analytical performance specification that sets a limit for combined imprecision (random error) and bias (inaccuracy or systematic error) that can be present in a single measurement or single test result without confounding the clinical usefulness. Total error is calculated according to CLIA and ASVCP guidelines as 2CV + bias% (or 2SD + bias/units).[11] Implicitly, when PT surveys set goals for acceptability, they are defining analytical allowable total errors. The goals set by PT cannot, by definition, be more difficult to achieve than the clinically important quality of the results.

Once we accept the concept of TE_a, then we can compare our TE_{obs} against the TE_a. When the TE_{obs} is smaller than the TE_a, the PT result is a success. If this is applied to a routine testing result, the reported results can be used clinically with confidence. If the TE_{obs} is larger than the allowable total error, the laboratory has failed part of the PT challenge, and the results being reported may be generating false positives, false negatives, or other clinically significant errors.

WHY ARE THERE DIFFERENT ALLOWABLE TOTAL ERROR GOALS?

While the concept of TE_a is a simple one, the implementation of TE_a in the real world has been contentious and variable. Looking at different PT programs around the world, you will find that the TE_a goals for even routine biochemistry measurands, which have been tested for decades, are not standardized. In Germany, the Rilibak goals for albumin at 20%; while in the USA, CLIA sets them at 10% and ASVCP at 15%; while in China, they are set at just 6%. That's more than a threefold difference in performance specifications, and there is no known dramatic difference in clinical use in these three countries. The reasons behind the TE_a differences in the PT programs of different countries are the subject of an ongoing effort of a European Federation of Clinical Chemistry and Laboratory Medicine (EFLM) "Task and Finish" group dedicated to sorting out the best way to set performance specifications. They categorize the different kinds of acceptance criteria as regulatory, statistical, or clinical.[1]

Regulatory goals, e.g., the German Rilibak and US CLIA PT goals, are set primarily to identify poorly performing laboratories. They are often wider and based on "state of the art." Statistical acceptance criteria may also be based on "state of the art," but in a purely mathematical way, typically ±3 SD of the group of laboratories in the survey. This is a crude way of keeping all laboratories "in the herd" since 3 SDs are approximately 99% of the normal distribution. This type of approach was initially used commonly with laboratory testing, but in more modern versions of CLIA PT acceptance criteria, these group SD goals have been eliminated as much as possible.[23] This hierarchy of EQA/PT acceptance criteria is strikingly like the new hierarchy of analytical performance specifications that was ratified at the first Strategic Consensus Conference of the European Federation of Clinical Chemistry and Laboratory Medicine in 2014.[20] This created a three-tiered arrangement of performance specifications, simplified as clinical, biological, and state of the art.

Clinical limits are based on changes in test results that change the clinical decisions, diagnoses, and treatments. Kristensen and Meijer note: "These limits are desirable but may be difficult to implement because very few

clinical decisions are based solely on one particular test."[1] It is recognized that very few analytes have studies that can help define the goals at this level. Troponin and HbA1c are examples where clinical performance specifications have been determined in human medicine.

Biological performance specifications are derived from known biological variation for analytes. These are considered very evidence-based, since they are dependent not upon the regulators or state of the art, but on the scientific evidence of variation within the body. The drawback of these goals is that often variation is very small and the goals are difficult or impossible to achieve. A database of such goals was started in 1999 by Ricós et al. and updated biennially until 2014, reaching a total of more than 350 performance specifications.[18,4] At the 2014 EFLM conference, various shortcomings with the database were noted,[4] at which time the EFLM took over the task. As of this writing, however, no new update has been posted.

Obviously, for veterinary testing, the biologic variation approach poses a special challenge. While human-based testing can focus on numerous analytes and just one species, veterinary laboratories have multiple species with possibly quite different biological variation. Biologic variation data for multiple species have been collected in an online resource, http://vetbiologicalvariation.org. There is a healthy and vigorous discussion in the literature about the best way to collect and utilize this data to set performance specifications.[10,13]

Finally, the third type of performance specification in the Milan Hierarchy is the state of the art. In concept, this must be the highest technically achievable analytical performance of the moment. It does not mean every method's performance is acceptable.

ALLOWABLE TOTAL ERROR GOALS FOR VETERINARY HEMATOLOGY

Given the controversy and strong debate among the single set of well-studied human measurands, it's not hard to imagine that setting performance specifications for veterinary measurands is orders of magnitude more complex. Veterinary laboratory medicine is not focused on just one species, but multiple species (e.g., dogs, cats, horses, and livestock); and adding further complexity, even within species, there are different breeds, reproductive status, management, and other factors.

An additional complicating factor is veterinary hematology quality control material, which can be difficult to produce and may have a very short shelf-life. The ideal commutable IQC material for veterinary hematology is species-specific fresh whole blood with EDTA. Unfortunately, this is stable for a maximum of 72 hours for Hb and RBC, and significantly less (24 hours) for total and differential white blood cell and platelet counts. A control material that has a stability of 24 hours is not usable unless generated within the laboratory. Therefore, commutability is sacrificed for the more stable, commercially prepared control material. Vendors provide IQC material which is also often used as PT material, provided that different control lots are used. Out of practicality, we frequently find ourselves using controls and EQA/PT materials that are generated for the human medical market, then making a leap of faith that if our analyzer is acceptable for humans, it must also be acceptable for other species. When species-specific concerns must be addressed within the laboratory, whole blood from patient samples may be used to assess species-specific imprecision (CV) of the assay.[9] The instability and matrix effects of PT hematology materials, for any species, can be problematic. It may be difficult to separate out the matrix effects and degradation from any real method or instrument problems.[14]

ASVCP guidelines have summarized hematology TE_a in domestic species; though there are significant species differences (Tables 138.1 and 138.2). Of note are the unique challenges for feline samples, particularly due to tendencies of feline blood to clot quickly, clumps on blood smears, the presence of both punctate and aggregate reticulocytes, and higher imprecision for reticulocytes in cats. They also noted that reticulocyte counts in horses are "rarely clinically relevant."[17]

From a strict metrological perspective, we should calculate out all ATEs for each species, each breed, and at each key decision level. And then perform EQA/PT on each type. However, in practical terms, we will need to find a consensus goal for each analyte. One approach is to use the most stringent TE_a among the species commonly tested in the veterinary laboratory.[7] Thus, we may gravitate toward using a single performance specification, allowable total error, which is closer to a human goal than any particular animal goal.

THE CHALLENGE OF THE FUTURE: EVOLVING GOALS AND CHANGING PRACTICES

In 2016, a review of 10 veterinary in-clinic hematology analyzers using canine EDTA blood samples found that "these instruments often fail to meet quality requirements." At least 60% of analyzers reasonably determined RBC, WBC, Hct, and Hgb, when assessed by the ASVCP quality goal criteria. Platelets were less reliably measured, with 80% deemed suitable for low platelet counts, but only 30% for high platelet counts. Automated differential leukocyte counts were generally considered unsuitable for clinical use. Fewer than 50% of analyzers were able to meet requirements for statistical quality control for any measurand.[19]

This is a sobering conclusion about the current state of the art of veterinary hematology and underscores the critical need for better quality and more vigilant proficiency testing. EQA/PT, through an evolution of goal-setting, can gradually, incrementally pressure the improvement of hematology method performance by manufacturers of these instruments and drive better results for better care. Our current level of quality is not enough. Compliance to current practices is not adequate for the needs of our veterinary patients.

TABLE 138.1 Comparison of current hematology goals across veterinary and human testing. Note the variation of allowable total error between countries and organizations.

Hematology analyte	Total allowable error goal (TE_a%)	TE_a source
Hemoglobin	**±10%**	**ASVCP**

While veterinary hematology EQA/PT has a long way to go to catch up to the other laboratory testing fields, remember the oft-told saying about quality: It's a journey with no end. There are always improvements to be made. There will always be advances in technology, updated needs for diagnosis, and changes in treatment. The net result of these evolving changes will be a need to update and modify the acceptance criteria and performance specifications for EQA/PT. Just as soon as we get comfortable with one allowable total error, it may be time to retire the old goal and embrace a new goal.

INTRODUCTION

Diagnostic laboratory test performance can be divided into analytical performance, diagnostic performance, and clinical utility. The latter refers to how much a diagnostic test improves patient health outcomes relative to the current best alternative.[5] This chapter focuses on analytical and diagnostic performance and provides an overview of the study designs and statistical tools used in their assessment. Analytical performance assessment characterizes an assay's measurement performance through the study of analytical properties such as imprecision, bias, linearity, etc. Validation of analytical performance is the process of proving whether an assay can perform such that it is suitable for its intended clinical purpose.[45] The term verification is most often used in the context of proving particular analytical performance claims (e.g., verifying a manufacturer-reported linear range). Diagnostic performance addresses how successful an assay is at diagnosing a particular disease condition in a given patient population. Analytical performance must be validated before diagnostic performance can be assessed.

ANALYTICAL PERFORMANCE VALIDATION

Analytical Properties of Quantitative Tests

Quantitative measurement procedures possess properties that can be scientifically studied, in order to determine if an assay is performing as required (Table 139.1). Analytical performance validation is an integral part of the instrument and test kit manufacturing process. Factors that laboratories may consider in selecting an analytical instrument or method are given in Table 139.2.[11] Individual laboratories should carry out some assessment of analytical performance prior to implementing a new assay for routine clinical use. At a minimum, manufacturer analytical performance claims should be verified. Validation of assays developed internally by a

TABLE 139.1 Analytical properties of quantitative measurement procedures. Any or all of these properties may be assessed as part of analytical performance evaluation.

Property	Definition	Formula, if applicable
Bias	Represents trueness (systematic error) of a measurement. Bias is expressed as mean difference (in measurand units) or as %Bias (in units of percent). Bias is subcategorized as constant bias (constant throughout measurand concentration range) and proportional bias (changes with measurand concentration). Bias can be minimized using calibration procedures.	$\%\text{Bias} = \frac{\text{Mean}_{\text{test method}} - \text{Mean}_{\text{target}}}{\text{Mean}_{\text{target}}} \times 100,$ where "target" is mean from a comparative method, a peer group mean, or the known concentration of a control or reference material.[33] %Bias may be a positive or negative value.
Detection limit	Represents analytical sensitivity and is the smallest measurand concentration that an assay can distinguish from a blank specimen with a stated statistical probability.[17]	Limit of blank: $\text{LoB} = \text{mean}_{\text{blank}} + 1.65\ \text{SD}$ Limit of detection: $\text{LoD} = \text{LoB} + 1.65\ \text{SD}_{\text{spiked}}$
Imprecision	Represents random error. Expressed as the SD (measurand units) or the CV (%) of repeatability data. Conditions for studying repeatability should be clearly defined (see text). The clinical impact of imprecision on patient data can be minimized by performing replicate measurements and reporting the average result.	$\text{CV} = \frac{\text{SD}}{\text{Mean}} \times 100$
Interference	Analytical specificity—refers to analytical error caused by substances in the sample matrix, other than the measurand, that alter the results.	$\%\text{Change} = \frac{\text{Mean}_{\text{spiked with interferent}}}{\text{Mean}_{\text{equal volume of diluent added}}} \times 100$ Percent change refers to the change in measured concentration resulting from addition of interferent. Mean refers to the average of duplicate measurements.
Linearity (linear range)	Concentration range over which (predicted) known values for a specimen and measured values have a linear mathematical relationship. The linear range is delimited by the lowest and highest concentrations at which linearity exists.[43]	
Recovery	A method's ability to detect known quantities of measurand.	$\%\text{Recovery} = \frac{\text{Mean}_{\text{A}} - \text{Mean}_{\text{B}}}{\text{Measurand concentration added to A}} \times 100$ Mean: average of duplicate measurements. A is the aliquot spiked with measurand. B is the aliquot containing diluent (same as volume of measurand added to aliquot A). Means and added concentration are in measurand units.
Reportable range[a]	Range of measurand concentrations reported by an instrument or method.	
Total error	Observed total error (TE_{obs}) is the sum of random and systematic error, often used in clinical laboratories.	(1) TE_{obs} = Mean difference + 2SD (2) TE_{obs} = % Bias + 2CV (1) TE_{obs} in measurand units; (2) TE_{obs} in units of %. Absolute values for mean difference and %Bias should be used. The constant 2 is a Z-factor[b].[37]
Measurement uncertainty (MU, aka uncertainty of measurement, UM)	A metrological model for understanding measurement accuracy. Addresses dispersion of values and acknowledges that a quantity's "true" value is unknowable.[30] In clinical laboratories, MU is expressed as SD or multiples thereof.	Expanded MU = Measured result ± 2SD[37,27]

[a] Terminology and definitions vary. Related terms include working range, analytical measurement range, and clinically reportable range.[43]
[b] The Z-factor 2 is rounded from 1.96 and refers to bidirectional change and 95% statistical probability.[37]

TABLE 139.2 Considerations for choosing a laboratory method.

Consideration	Explanation or example(s)
Assay availability	Commercial assay versus developed internally
Instrument or test kit reputation	Anecdotal versus trade publications versus performance assessment as published in peer-reviewed medical literature
Acquisition options	Lease versus purchase versus loan
Service contract availability and details	
Instrument or test kit size ("footprint")	
Required environmental conditions	Temperature, humidity, water quality
Specimen type and volume	Whole blood versus serum versus plasma; acceptable anticoagulants
Turnaround time and specimen throughput capacity	
Test menu	Individual tests versus panels
Ease of instrument and software use	Patient and control data displays; patient and control data storage capacity and ease of retrieval; available flags and error notifications
Instrument connectivity	Ability to connect to electronic patient health record
Instrument maintenance	How often, how complex
Reagent and control material cost and shelf-life	Consider closed- and open-container shelf-life
Spent reagent disposal considerations	Toxicity or biohazard, if applicable
Operator training availability; technical support availability	

Source: Based on Flatland and Vap.[11]

laboratory is likely to be more exhaustive than for commercial assays. However, validation beyond verification of manufacturer's claims should be undertaken even for commercial assays if conditions of the laboratory's intended use differ from that validated by the manufacturer (e.g., different specimen type, different species, different reagent type, or other change). In human medicine, Clinical Laboratory Improvement Amendments (CLIA, the federal law governing performance of medical diagnostic laboratories) states in Section 493 that any laboratory modifying a Federal Drug Administration (FDA)-approved test system, developing a system not subject to FDA approval, or using a test system for which no manufacturer performance claims are available must evaluate, as applicable, accuracy, precision, analytical sensitivity, analytical specificity/interfering substances, reportable range, reference intervals, and "any other performance characteristic required for test performance."[1]

Quality Goals

Prior to beginning analytical performance verification or validation studies, the laboratory should set an analytical quality goal for the measurand in question. Although metrologists favor setting separate goals for imprecision and bias, medical laboratorians often think in terms of total measurement error (i.e., the combined effects of imprecision and bias upon a measured result).[49,48] Whether the total error model (favored by Westgard et al.) or uncertainty of measurement (a metrological model promoted in International Organization for Standardization (ISO) 15189[2]) is the better approach to understanding and assessing error in the clinical laboratory is under active debate[31,48,12] (see Chapter 138).

Historically, analytical quality goals have been derived from various sources, including regulatory requirements, expert consensus, biological variation data, "state of the art" (i.e., the highest level of analytical performance that is technically achievable), and patient outcome studies.[9,36] The American Society for Veterinary Clinical Pathology (ASVCP) endorses use of allowable total error (TE_a, an expert consensus-based goal) in two published guidelines,[14,28] and it is becoming more common for biological variation-based quality goals to be incorporated into veterinary assay validation and statistical quality control (QC).[21] In the US currently, veterinary diagnostic laboratories are not subject to regulatory oversight, and individual laboratories should choose quality goals defensible for their circumstances based on published recommendations, scientific evidence, finances, and logistics.

Validation Studies

Analytical properties defined in Table 139.1 are assessed using specially designed scientific studies. Analytical performance assessment typically begins during or immediately after installation of an analytical method in the laboratory. With more complex systems (e.g., a wet chemistry analyzer), at least some verification of manufacturer performance claims will likely be carried out by a field engineer installing the equipment. This should be documented in writing. Once a method is successfully installed, laboratory staff should engage in a familiarization period during which operators are trained to properly perform testing. The familiarization period typically includes learning the test principle and intended use; instrument operation, including specimen requirements, use of reagents, controls, and any calibrators; necessary chemical and/or biosafety precautions; reviewing manufacturer instructions; and writing standard operating procedures tailored to the laboratory.[17] Generating preliminary control data and quality control validation are also components of installing a new laboratory method.[42] Once operators are familiar with the test system and stable operation can be

documented via quality control procedures, verification of additional performance claims and further analytical performance validation can begin.

For any analytical performance validation, the laboratory must first choose whether to use commercial control material and/or patient specimens (e.g., pooled plasma). Advantages of commercial materials include that these are readily available, stable specimens with known target values. Disadvantages include that these may have a different matrix from veterinary patient specimens and may not be available at measurand concentrations of medical interest to veterinarians. Advantages of patient specimens are that they can provide a species-specific evaluation of assay performance and are hopefully available at concentrations of medical interest. Disadvantages include lack of specimen stability and, potentially, specimen availability. Analytical performance validation of assays involving unstable specimens (e.g., fresh whole blood) or labile measurands (e.g., blood gases, ammonium) may necessarily be limited by logistical concerns.

Imprecision

Precision is the closeness of agreement between independent measurement results obtained under specified conditions.[38] Imprecision (random error), the opposite of precision, is represented by standard deviation (SD), in measurand units or coefficient of variation (CV) in units of percent.[46] Observed SD and CV values can be compared to manufacturer performance claims and/or quality goals for imprecision, if available. SD and CV values can additionally be used in the calculation of TE_{obs} (see Table 139.1).

When reporting imprecision study results, it is important that the circumstances be clearly stated because measurement conditions will impact the results. Historically, experiments assessing imprecision have referred to calculation of "within-run" and "between-run" SD and CV.[17,46] Current Clinical and Laboratory Standards Institute (CLSI) guidelines in human diagnostic laboratory medicine recognize that more tightly controlled "repeatability" conditions (same operator, equipment, and laboratory) are expected to show greater precision than less tightly controlled "within-laboratory" conditions (different operators or equipment).[38,6]

Imprecision should be studied at measurand concentrations of medical interest (i.e., that reflect concentrations likely to occur in the anticipated patient population) and that span most or all of reportable value range for the instrument in question. Imprecision study designs can vary, depending upon the evaluator's needs or intended use of the imprecision data. In general, study designs targeted to instrument manufacturers and assay developers (who establish performance claims) are more complex than those aimed at diagnostic laboratories (who simply need to verify manufacturer claims).

A simple estimate of repeatability can be obtained by performing ≥20 replicate measurements of a specimen and calculating mean, SD, and CV of the resulting data.[17,46] There is precedent in the veterinary literature for crude precision assessment of in-clinic equipment using three to five replicate measurements.[34,35] CLSI guideline EP15 for human diagnostic laboratories recommends assessment of both "repeatability" (formerly known as within-run imprecision) and "within-laboratory" imprecision (formerly known as total imprecision). Repeatability assesses imprecision when all measurements are made under identical conditions. Within-laboratory imprecision employs less-rigid conditions (e.g., different operator and/or different runs) and a longer timeline (days), but still limits assessment to the same laboratory, equipment, and reagent lot.[6] Both repeatability and within-laboratory SD and CV can be calculated from data generated by measuring two concentrations of material in triplicate (in one run), once daily, for 5 days. The EP15 guideline provides formulae and a worksheet to facilitate calculations.[6]

When analyzing precision, it is important to look at average measurand concentration (i.e., mean of the dataset) in addition to SD and CV. Dispersion of precision study data (i.e., SD or CV) can be constant throughout the range of measured values or vary with measurand concentration; this relationship is sometimes referred to as an assay's precision profile.[26] Since CV is SD expressed as a percentage of the mean, if SD is constant throughout a range of measured values (i.e., independent of concentration), CV will vary inversely with measurand concentration. If SD varies with measurand concentration, then CV will be more constant through the range of measured values. An assay's precision profile can help determine whether more than one quality goal is needed to monitor performance at different measurand concentrations.[26] The precision profile also impacts choice of regression model during method comparison data analysis. When SD is constant throughout the range of measured values, unweighted regression models may be used; when SD varies with measurand concentration, weighted regression procedures are more appropriate.[26]

Bias

Bias of an assay or instrument is assessed relative to a target that is chosen to represent the true measurand concentration, which, in reality, is unknowable. Observed bias can be compared to a quality goal for bias, if available, or used in calculation of TE_{obs} (see Table 139.1).

The target in bias assessment can be a peer group mean from external quality assessment (EQA) program data, results from another analytical method, or can be the known, manufacturer-reported results for an assayed control material or certified reference material.[10] In veterinary laboratory medicine, it may not be possible to obtain species-specific commercial materials for use in bias assessment, and bias is often studied using a combination of commercial (often human-derived) assayed control materials and species-specific method comparison data.[8,15,34,35] It is important that method comparison studies involve adequate specimens ($n \geq 40$) that are independent and have concentrations spanning most or all of the reportable ranges of the methods involved.[18]

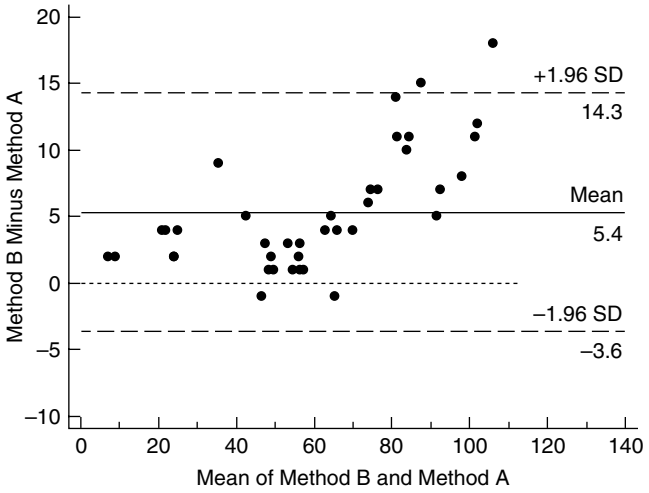

FIGURE 139.1 Bland–Altman difference plot for two fictitious instruments, Method A (reference method) and Method B (method undergoing performance assessment). The difference between the methods is plotted on the *y*-axis, and the mean of both methods is plotted on the *x*-axis. The small-dashed line parallel to the *x*-axis corresponds to zero (no difference between methods). The solid line parallel to the *x*-axis is the mean difference (5.4 units), and the larger dashed lines represent ±1.96 standard deviations around the mean difference (from −3.6 to 14.3 units). Virtually all differences are greater than zero, indicating constant systematic error (results of Method B are numerically greater than those from Method A throughout the range of measured values). Proportional bias is evident from the upward trend in the data points (as measurand concentration increases, differences become numerically larger).

Bias (systematic error) is divided into constant and proportional bias, each of which can be assessed individually. Method comparison statistical analysis includes descriptive statistics for each method's data set, difference plot analysis, and regression analysis. Difference plots (Figure 139.1) are used for graphical assessment of data and may be interpreted using either Bland–Altman limits of agreement (defined as ±1.96 SD from the mean difference) or limits based on the combined imprecision of both methods.[3,18,17] Regression analysis provides statistical evidence of constant bias if the 95% confidence interval for the y-intercept does not include the value zero and statistical evidence of proportional bias if the 95% confidence interval for the slope does not include the value 1. The regression model should be chosen based on the range, correlation coefficient, and precision profile of the data sets.[18,26] Passing–Bablok and Deming regression models are often used, as assumptions for least squares regression may not be met by clinical laboratory methods.[26]

Linearity and Reportable Range

An assay's reportable range is determined by the manufacturer and should reflect the concentration range within which measured values meet declared quality goals for imprecision and bias. The upper limit is often identical to an upper linearity limit. The lower limit may correspond to the lower linearity limit or may be based on another quantity such as a detection limit.[26] Verification of linear range is important if the laboratory uses two-point calibration, during which an instrument's calibration is assessed based on two measurand concentrations (high and low) only.[43]

Verification of linear range can be assessed using serial dilutions of a concentrated patient specimen or specimen pool; use of at least four concentrations is recommended to establish linear range; calibration verification can be done using as little as two concentrations.[43] A suitable diluent (physiologic saline, zero calibrator) should be used, and the anticipated concentrations of each dilution should be calculated using the dilution factors.[17] Measured values are compared to expected values using scatter plots and linear regression.[17,43] A 95% confidence interval for the slope that includes the value 1.0 provides statistical evidence of linearity. Regression residuals can be used to guide analysis and provide additional evidence supporting linearity ("runs test").[26] In regression, a residual (calculated by statistical software) is the difference between an observed (measured) value and the corresponding value predicted by the regression model. Residuals can be plotted on a graph showing residuals on the *y*-axis and the observed value, or average of the observed and predicted values, on the *x*-axis. A line parallel to the *x*-axis is drawn at zero, and distribution of residuals around the zero line is evaluated. If data are linear, residuals should be randomly distributed around the zero line.[24] Nonlinearity is indicated by deviation of points away from zero (known as a "run," or sequence of points, above or below the zero line).[26]

Detection Limit

The detection limit is the smallest measurand concentration that an assay can distinguish from a blank specimen with a stated statistical probability.[17] Verification of a detection limit is most crucial for assays expected to measure low concentrations, such as hormone assays and drug tests. Various detection limits are defined, and two are presented here. Limit of blank (LoB) is the highest measurement result likely to be observed with a stated probability using a blank specimen. Limit of detection (LoD) is the smallest quantity of measurand that can be detected with a stated probability.[40]

To determine LoB, a suitable blank specimen (e.g., plasma, serum, or physiologic saline to determine LoB of a hematology instrument) is measured in replicate ($n \geq 20$ is suggested).[17,40] Data are used to calculate mean and SD. LoB is calculated using the formula in Table 139.1. The constant 1.65 is a Z factor for estimating LoB given a one-tailed distribution (positive direction) with 95% probability. LoD is determined via replicate measurements of both blank and spiked specimens; these should have a similar matrix. Data are used to calculate mean and SD of each specimen type, and LoD is calculated per the formula in Table 139.1.[40]

Recovery and Interference

Recovery and interference address analytical specificity. Recovery studies are used to estimate proportional systematic error, and interference studies are used to estimate proportional error induced by substances in the sample matrix other than the measurand of interest.[41] In a recovery study, paired specimen aliquots containing, respectively, added measurand or an equal volume of diluent (e.g., water, serum, plasma, physiologic saline, or calibration blank) are measured in duplicate. Recovery is calculated by averaging results for each duplicate pair and calculating the percent recovery (Table 139.1).

An interferent study follows the same design, except that interferent (known quantity of hemoglobin, bilirubin, lipid, or other substance of interest) is added to the spiked aliquot rather than measurand. The percent change in concentration as a result of interferent addition is calculated as presented in Table 139.1. Alternatively, concentration change can be expressed in measurand units as a mathematical difference between the spiked and diluted aliquots.[41] Interference may be positive (causing increased measurand concentration) or negative (causing decreased measurand concentration). More bias is expected with increased quantity of interferent. The mathematical relationship between interferent quantity and measured results may be linear or nonlinear. A graphical depiction of interference is called an interferograph, which depicts interferent concentration on the *x*-axis and percent change in measurand concentration following interferent addition on the *y*-axis.[16]

Judging Method Analytical Performance

Observed Total Error

Observed total error (TE_{obs}) combines observed bias and imprecision into one quantity calculated with a stated statistical probability (Table 139.1). TE_{obs} can be compared to a predetermined quality goal; such goals are often given in units of percent. If the value for TE_{obs} is numerically smaller than the quality goal, then the assay performs within acceptable limits. If the value for TE_{obs} is numerically larger than the quality goal, further refinement of the assay (e.g., instrument adjustments, operator training, reagent changes) is needed.[23] If improving assay performance is not possible, then the laboratory must decide whether an alternate assay is needed, or whether accepting the existing assay and a more lax quality goal is justifiable.[23]

Sigma Metric

Six sigma (σ) is a statistically based quality control system adopted from manufacturing. The sigma metric is a unitless indicator of assay performance. In clinical laboratory medicine, σ ranges from 0 to 6.[20] The metric is calculated as $\sigma = \frac{(TE_a - \%Bias)}{CV}$, where TE_a is allowable total error and %Bias and CV are calculated as presented in Table 139.1. Assays with $\sigma = 5$ or 6 are stable, high-performing methods with minimal analytical error. Assays with $\sigma \leq 3$ are considered poor performers.[20] Sigma-based assay selection, control rule selection, and quality control

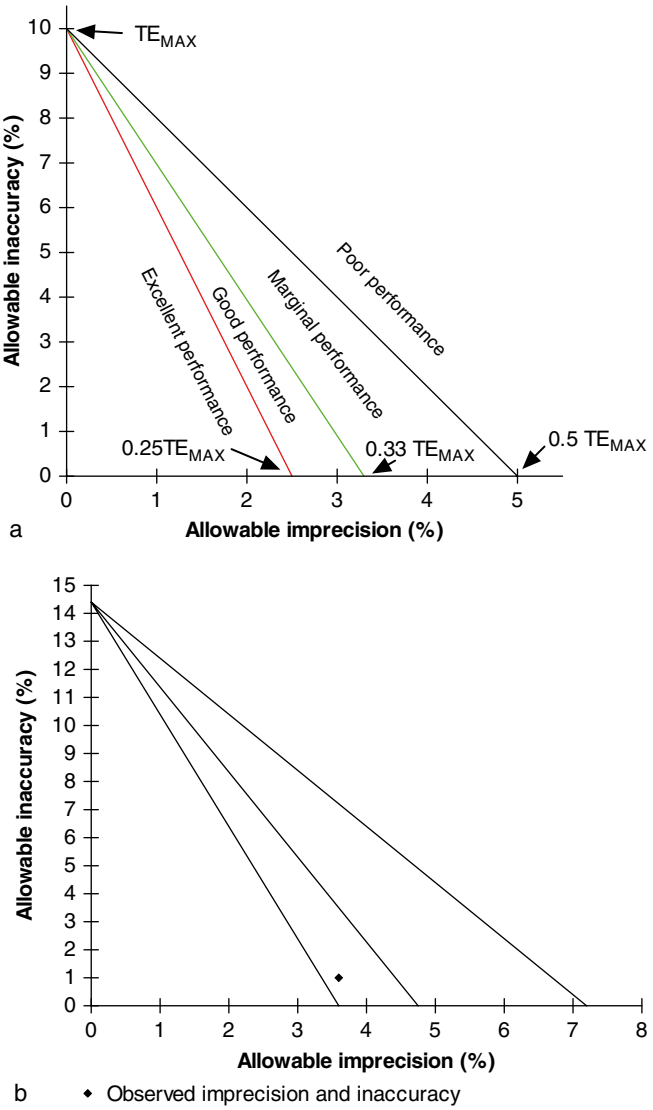

FIGURE 139.2 MEDx charts for assessing analytical performance. (a) MEDx chart for a test with a maximum allowable total analytical error (TE_{MAX}) of 10%. The lines represent different currently accepted total error criteria: line marked ($0.5 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = inaccuracy (bias) + 2SD; line marked ($0.33 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = inaccuracy (bias) + 3SD; line marked ($0.25 \cdot TE_{MAX}$) represents the total error criterion TE_{MAX} = inaccuracy (bias) + 4SD. TE_{MAX} can be calculated from biological variation data or be derived from another source (e.g., TE_a based on expert consensus, or a regulatory requirement). By plotting the observed inaccuracy and imprecision of a test into its MEDx chart, the analytical performance of the assay can be classified as poor, marginal, good, or excellent; (b) MEDx chart for total WBC count with TE_{MAX} 14.4%. Inaccuracy and imprecision were estimated for WBCs on an automated hematology analyzer as 1% and 3.6%, respectively, and using the MEDx chart, it is concluded that the test has good analytical performance.

are strongly advocated by Westgard QC, and multiple resources regarding six sigma implementation in the clinical laboratory are available via that organization.[47,49]

Method Decision Chart

The method decision (MEDx) chart (Figure 139.2) is a graphical tool designed to facilitate assessment of assay analytical performance in light of a quality goal. MEDx charts plot allowable bias and imprecision (in units of %) on the *y* and *x* axes, respectively. The *y*-axis is scaled to TE_a, and the *x*-axis scaled to half of the *y*-axis. Lines drawn from the maximum *y*-axis value to various points on the *x*-axis divide the chart into zones indicating excellent, good, marginal, and poor analytical performance. Lines demarcating these zones represent TE_a = %Bias + 2SD, %Bias + 3SD, and %Bias + 4SD. To use the chart, an "operating point" representing an assay's observed %Bias and CV (Table 139.1) are plotted on the chart. The zone in which the operating point falls indicates method performance.[44] MEDx charts are closely related to operating specifications (OPSpecs) charts, a graphical tool used for quality control validation that plots lines representing various control rules relative to the assay's operating point.[39]

DIAGNOSTIC PERFORMANCE VALIDATION

Once analytical performance of a test is deemed satisfactory for the intended purpose, evaluation of diagnostic performance can begin. In its simplest version, diagnostic test performance validation compares results from a test under evaluation, i.e., index test, to another test deemed the "gold standard" for disease diagnosis (known as single-test accuracy studies).[25] Importantly, both the index and gold-standard tests should be applied to the same study population suspected to have the target disease of interest on the basis of clinical signs which represent predetermined inclusion criteria. All study subjects should be tested using the gold-standard test, irrespective of their index test result; i.e., the two tests should be applied and interpreted independently.[25] The study population is subsequently divided into diseased and nondiseased individuals based on a negative gold-standard test result, and diagnostic accuracy of the index text is calculated.[25].

Diagnostic accuracy studies can be impacted by bias, and careful study design is crucial.[50] Study inclusion and exclusion criteria, stage and signs of disease, and the population studied must be carefully defined. Detailed data reporting that includes clear descriptions of the study design and results is necessary to help the reader understand context, since indices of test performance can vary with disease prevalence, disease severity, diagnostic setting, and other patient characteristics. Authors of diagnostic accuracy studies should follow STARD (Standards for the Reporting of Diagnostic Accuracy) guidelines and checklists for study design and data reporting.[4]

Sensitivity and Specificity

Diagnostic test performance data can be summarized in a two-by-two table as follows:

	Gold-standard test POSITIVE	**Gold-standard test NEGATIVE**	**Total**
Index test POSITIVE	True positives (TP)	False positives (FP)	TP + FP
Index test NEGATIVE	False negatives (FN)	True negatives (TN)	FN + TN
Total	TP + FN	FP + TN	TP + FN + FP + TN

Sensitivity (SN) is the probability of a positive test result in a diseased individual (sometimes referred to as true positive rate, although there is no time factor). Specificity (SP) is the probability of a negative test result in a nondiseased individual (true negative rate).[7] SN and SP are calculated from the table using these formulae and often expressed in units of percent:

$$SN = \frac{TP}{TP + FN}; SP = \frac{TN}{FP + TN}.$$

Ninety-five percent confidence intervals for SN and SP can be calculated using statistical procedures for binomial distribution.[25] Overall diagnostic accuracy of a test is defined as the proportion of correct classifications out of all classifications and is calculated as:

$$\text{Accuracy} = \frac{(TN + TP)}{TN + TP + FN + FP}.$$

SN and SP vary with the cutoff value used to define disease and have an inverse relationship; as SN increases for a given test, SP decreases, and vice versa. An inherent limitation of using a single decision threshold to determine diseased versus nondiseased status is that determination of disease presence or absence is dichotomous (binary) and interpretation of disease status does not factor in magnitude of the abnormal result.[13] Use of receiver operating characteristic (ROC) curve analysis to tailor cut-point selection for a given test and testing circumstances and the use of likelihood ratios (LRs) to estimate post-test probability of disease mitigate this limitation.[13]

Predictive Values

Positive predictive value (PPV) is the probability that an individual having the target disease will test positive. Negative predictive value (NPV) is the probability that an individual without the target disease will test negative.[7] PPV and NPV are impacted by SN and SP.

Importantly, PPV and NPV are also affected by the prior probability or prevalence of disease; PPV and NPV will vary as disease prevalence varies. Single NPV and PPV values calculated for a given prevalence, SN, and SP will not be uniformly applicable to all possible clinical situations.[7] PPV and NPV can be calculated from the two-by-two table provided in the earlier text if the study population's disease prevalence is the same as the animal population to which the test will be applied. In that case, PPV and NPV are calculated as:[17]

$$\text{PPV} = \frac{\text{TP}}{\text{TP} + \text{FP}}; \text{NPV} = \frac{\text{TN}}{\text{TN} + \text{FN}}.$$

Otherwise, PPV and NPV are calculated using the formulae:[7]

$$\text{PPV} = \frac{\text{SN} \times \text{prevalence}}{(\text{SN} \times \text{prevalence}) + \left[(1 - \text{SP}) \times (1 - \text{prevalence})\right]};$$

$$\text{NPV} = \frac{\text{SP} \times (1 - \text{prevalence})}{\left[\text{SP} \times (1 - \text{prevalence})\right] + \left[(1 - \text{SN}) \times \text{prevalence}\right]}.$$

PPV is greatest when prevalence is high; NPV is greatest when prevalence is low. Calculating PPV and NPV for a range of possible prevalences to facilitate clinical use of PV has been recommended.[7]

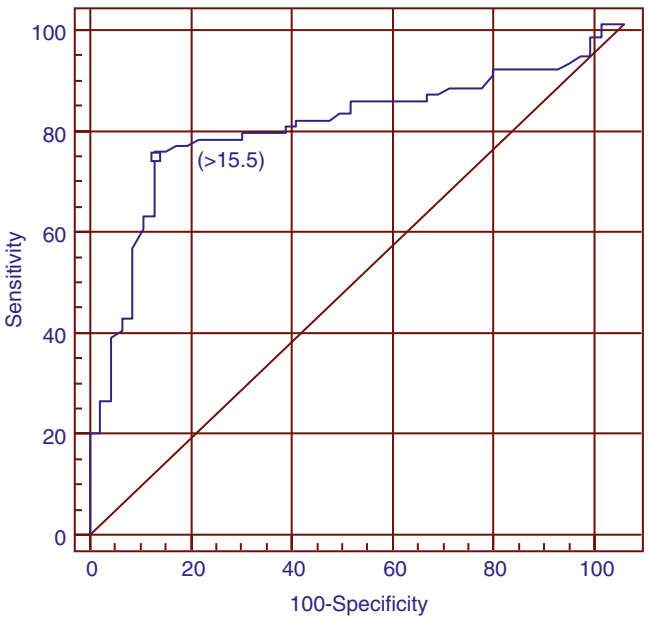

FIGURE 139.3 Receiver operating characteristic (ROC) curve. Tests with poor performance approach the diagonal line. Tests with good performance trend upward and leftward. The highest sensitivity and specificity are represented in the point at the upper left corner. The cutoff value that gives this point in this plot is 15.5. For screening diagnostics, sensitivity should be maximized. (**Sources:** Gardner and Greiner;[13] Linnet et al.[25])

Receiver Operating Characteristic Curves

ROC curves plot the true positive rate (SN) on the *y*-axis and the false positive rate (1-SP) on the *x*-axis.[13] The curve is constructed by plotting SN and (1-SP) pairs (operating points) for each possible cutoff value defining diseased and nondiseased for a given test (Figure 139.3).[13,25]

In general, the closer the plotted curve of SN and (1-SP) data pairs is to the upper left-hand corner of the graph, the better the test is at discriminating diseased and nondiseased individuals. This upper left corner represents the maximum combined SN and SP for that test.[13,25] The formal metric evaluated is area under the curve (AUC). AUC ranges from 0.5 (probability of a positive or negative test result equivalent to a coin toss) to 1 (perfect test performance, i.e., 100% SN and 100% SP).[13] ROC curves are commonly used to assess overall diagnostic accuracy of a given index test. They may also be used to refine decision thresholds for disease diagnosis and to compare accuracy of multiple tests used in the same clinical context[13] (see Chapter 140).

Likelihood Ratios

Positive or negative likelihood ratios, for dichotomous test results, reflect the probability of obtaining a positive or negative result in a diseased individual divided by the probability of obtaining a positive or negative result in a nondiseased individual. Mathematically, likelihood ratios represent slopes of the ROC curve and are calculated as:

$$\text{Positive LR} = \frac{\text{SN}}{(1 - \text{SP})}; \text{Negative LR} = \frac{(1 - \text{SN})}{\text{SP}}.$$

Positive LR (PLR) ranges from 1 to infinity; negative LR (NLR) ranges from 0 to 1.[13] For example, a PLR of 4.0 means that a positive test result is four times as likely to occur in a diseased versus a nondiseased individual. A LR of 1.0 means that a test result does not change the pretest probability of disease (i.e., it provides no useful information).[13] Guidelines for LR interpretation are that tests with satisfactory diagnostic performance should have a PLR of at least 2.0 and a NLR close to zero.[17]

Error Grids

An error grid is a graphical tool comparing the clinical impact of results from an index test (*y*-axis) to those from a comparative method (*x*-axis) using paired results from the same set of patient samples. The Parkes consensus error grid for evaluation of human glucometers is a common example.[32] CLSI guideline EP27 provides instructions for error grid construction and recommends $n \geq 100$ patient samples for error grid analysis.[29] As for method comparison studies assessing analytical performance, data used in error grid analysis should span a range of medically important concentrations and include data at or near commonly used medical decision thresholds. The error grid divides

paired test results into zones (labeled A, B, and C) predicting the likelihood of causing patient harm. Results falling into Zone A have minimal potential to cause patient harm, whereas results falling into Zone C are highly likely to cause patient harm. Zone B results represent moderate potential for patient harm.

The main challenge of error grid analysis is building the grid and establishing the zone boundaries, which are based on medical decision thresholds for the measurand (e.g., blood glucose), patient population (e.g., patients receiving insulin), and disease (e.g., Type 1 vs. Type 2 diabetes) in question.[32] Species is an additional consideration for veterinary measurands. To facilitate risk assessment and the setting of zone boundaries, medical decision thresholds must have clear clinical consequences (e.g., administer dextrose vs. administer insulin). Once constructed, an error grid can be used repeatedly to compare the clinical performance of two assays, assuming decision thresholds and their medical implications have not changed.[32] Error grid use is not common in veterinary method comparison studies, but has been reported with glucose and cortisol testing.[19,22]

INTRODUCTION

The diagnostic workup of veterinary patients is a decision-making process. Preliminary differential diagnoses are established based on a thorough history and physical examination. Subsequently, decisions that rule in or rule out the differential diagnoses are based on interpretation of laboratory tests including hematology and other clinical pathological data. For these decision-making processes to be consistent, established decision criteria are essential. These criteria may be in the form of decision limits or population-based and subject-based reference intervals (RIs). Optimally, these criteria are objectively tailored to the specific clinical situation as with decision limits or to the demographic or individuality of the specific patient as with various types of RIs. This is necessary to limit false decisions, decreasing the risk of false diagnoses. Creatinine is a perfect example of an analyte for which different types of decision criteria may be most relevant in specific clinical scenarios. Although population-based creatinine RIs are most frequently applied, breed-specific RIs are known to be more representative in certain breeds, such as greyhounds.[44] For monitoring renal function in an individual feline patient, subject-based RIs are more sensitive.[40] Finally, creatinine decision limits are used for staging renal failure in cats and dogs using the International Renal Interest Society guidelines.[23] Establishing any of these decision criteria requires an investment of time and effort and should be approached with an awareness of the objectives and procedures for determining each of these references. In addition, knowledge of biological variation is paramount for the exploration of reference values.

Decision limits categorize patients as "condition present" or "condition absent"; therefore, they are dependent on the clinical objective and only applicable for specific clinical situations.[36] Because decision limits are not relevant for every analyte or in every clinical situation, population-based RIs are more commonly used. Reference intervals describe the reference value distribution obtained from a reference sample group of healthy subjects representative of the patient population.[36] A measured value outside the RI is unlikely to

originate from a healthy subject and will thus signify a diseased patient. As such, population-based RIs are independent of the clinical objective and more globally applicable; however, they must be representative of the specific population for which they will be used.

A joint guideline from the Clinical and Laboratory Standards Institute (CLSI) and International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) "Defining, Establishing, and Verifying RIs in the Clinical Laboratory" was updated and released in 2008.[9] Working groups from the American Society for Veterinary Clinical Pathology (ASVCP) and the European College of Veterinary Clinical Pathology (ECVCP) published a similar joint guideline for veterinary species.[15] The guideline is a welcome opportunity to standardize how RIs are established and communicated in veterinary medicine and should be applied as widely as possible.

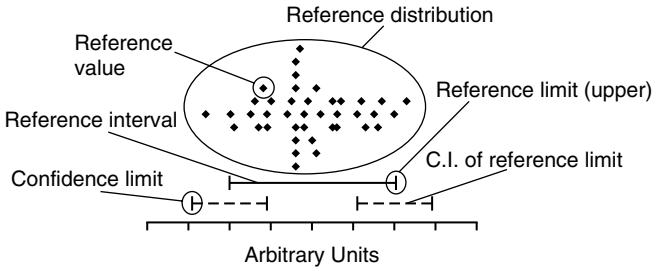

FIGURE 140.1 Nomenclature used in the establishment of RIs. A reference population (e.g., healthy dogs) is defined. Reference values (diamonds) are determined from a reference sample group. These values characterize the reference distribution from which reference limits are calculated that delineate the RI. Reference limits have a certain degree of variability that can be expressed by a confidence interval (CI), which is delineated by confidence limits. (**Sources:** CLSI[9] and Friedrichs et al.[15])

ESTABLISHMENT OF PROSPECTIVE REFERENCE INTERVALS

Several options exist for RI generation including de novo establishment (prospective), establishment using existing databases (retrospective), and transference from another source. Step-by-step guidelines for establishing de novo RIs for veterinary species and definitions of terms have been published by the ASVCP and closely align with the CLSI document revised in 2008 (Tables 140.1 and Figure 140.1).[9,15] A checklist of recommended elements for researchers, clinicians, authors, reviewers, and editors has been generated by the ASVCP Quality Assurance and Laboratory Standards Committee. The checklist is intended to aid in complete reporting of the process and results associated with RI development. Transparent reporting of the strengths and limitations of the RI enable the user to better interpret clinical data. The list is not intended to be used to bar manuscripts from publication by reviewers (Appendix 1). The benefits of available, less than ideal data should be weighed against the need for near-perfect data. Although the choice of statistical procedures stimulates much discussion, the number one priority in de novo RI establishment is to minimize unintended variability during reference subject selection and the collection and analysis of reference

TABLE 140.1 Outline of the protocol for obtaining reference values and establishing RIs.

1.	Establish a list of analytical interferences and sources of biological variability from the literature.
2.	Define the reference population, establish selection, exclusion, and partition criteria, and design a questionnaire to reveal these criteria in potential reference subjects.
3.	Create a consent form for participation in the RI study and have the owner of the reference subject complete the questionnaire and sign the consent form. Categorize the potential reference subjects as healthy based on history, physical examination, and clinical pathology data.
4.	Decide on the appropriate number of reference subjects with consideration of desired confidence limits and the homogeneity of the intended reference population.
5.	Select subjects (or data in retrospective studies) from the reference sample group based on the inclusion criteria and health assessments.
6.	Prepare the selected reference subjects for specimen collection consistent with the routine practice for that analyte. Collect and handle biological specimens in accordance with routine practices for patient specimens.
7.	Analyze specimens using well-defined methodology and consistent with routine practices for patients.
8.	Review the reference data for possible errors and prepare a histogram to visually evaluate the distribution of data.
9.	Inspect the reference data for possible outliers. Use statistical methods appropriate to data distribution to identify and eliminate verified outliers. Repeat this process until no outliers remain.
10.	Replot the reference data on a histogram and determine distribution, usually by a goodness-of-fit test. If data are not Gaussian, attempt transformation to a Gaussian distribution.
11.	Calculate the upper and lower reference limits, and the reference limit confidence intervals, using parametric, nonparametric, or robust methods depending on the distribution of reference data and size of the reference sample.
12.	If reference sample size is sufficient, determine need for partitioning if there is evidence of clinically important differences in the analyte across subgroups.
13.	Document the details of these procedures for future reference by clinicians and laboratorians, who may transfer the RI.

Sources: CLSI[9] and Friedrichs et al.[15]

samples. Identifying an adequate number of healthy reference subjects that are representative of the patient population and analyzing high-quality samples with well-controlled methods are significant achievements. Postsampling statistical procedures cannot correct for poor quality samples from unscreened reference subjects analyzed by methods that are unmonitored or unvalidated. If reference values are of high quality, the choice of statistical procedure is of little consequence providing rules based on data distribution are followed.

A well-conducted RI study should establish selection and exclusion criteria that define the reference population and document how health is determined. Exclusion criteria may include selected physiologic states (e.g., pregnancy) and extreme physiologic conditions (e.g., recent intense exercise). All subjects with evidence of disease should be excluded. When relevant physiologic information pertaining to the analyte of interest is available, identification of reference subjects preferably occurs by a direct a priori or prospective method, where criteria for selection, exclusion, and partitioning are decided before selection of reference subjects. When the effects of various partitioning factors (sex, age, reproductive status, etc.) are unknown, as may occur for a new analyte, a direct a posteriori or retrospective sampling method may be used in which selection, exclusion, and partitioning criteria are applied after the results are reviewed. To be representative of the laboratory's patient results and to model preanalytical variability, sample collection and handling should conform to the laboratory's established protocols.

Statistical analysis begins with graphic presentation of the reference values, most commonly as a frequency histogram. Gaussian and right-skewed distributions are most common. If the history and health of the population are well-documented, reference samples are of high quality and analytical methods are validated, the emphasis should be on retaining rather than deleting apparent outliers.[9] However, when health status is unavailable or is difficult to document, as occurs in free-ranging wildlife, outlier status should be objectively interrogated and any suspect values eliminated. Because additional outliers may be revealed upon elimination of far outliers, this process should be repeated in a population with unknown health status until all identified outliers are removed. Statistical procedures for outlier detection include distribution-dependent and distribution-independent methods and procedures that detect outliers at one or at both extremities.[21,25] For outlier procedures that are distribution-dependent, reference data must be Gaussian or transformed to Gaussian prior to application. Distribution-independent methods can be applied to data of any distribution.

Once outliers are addressed, the frequency histogram should be revised and data distribution verified as Gaussian or non-Gaussian, most commonly through a goodness-of-fit test. The Shapiro–Wilk is a powerful normality test for reference distributions, although the power for all such tests is low when sample sizes are small.[31,37] Whenever the reference value distribution is Gaussian or can be transformed to fit a Gaussian distribution, the RI can be determined by parametric methods.[9,12] Several transformation functions can be applied; however, the Box Cox procedure efficiently transforms many reference value distributions to normality.[18]

Alternatively, because assumptions of normality are easily violated,[31] the IFCC and ASVCP recommend nonparametric statistics whenever reference sample sizes of at least 120 are attained. The nonparametric method is a ranking method that commonly represents the central 95% of the healthy population and is determined as follows: n reference values are ranked and an interval is then delineated by ranks r_1 (2.5th) and r_2 (97.5th), with $r_1 = 0.025(n + 1)$ and $r_2 = 0.975(n + 1)$. In theory, a RI can be determined by nonparametric methods with as few as 39 samples; as this is the lowest value of n where r_1 and r_2 will reach integer values, namely, $r_1 = 1$ and $r_2 = 39$. However, at this power, no outlying values can be removed.[15]

An iterative (robust) method has been described that offers a relevant alternative to the nonparametric approach when $n < 120$. In short, it works by initially locating the median and spread of observations and then, through an iterative process, actual observations are down weighted according to their distance from the central tendency. For detailed instructions on computation, which can be performed in common spreadsheets, original literature can be consulted.[22] The robust method performs well with small sample sizes (n = 20–40), unintended inclusion of outliers, and without prior transformation in right-skewed distributions typical of reference data. All three methods (parametric, nonparametric, and robust) can be calculated, and the resulting RIs compared; if they are similar, the choice of method is inconsequential.[22] If they differ, the desired interval may depend on the analyte and the clinical question. Selection of the narrowest interval minimizes overlooking possible pathologic changes, but may increase the false positive rate.

Confidence intervals (CIs) of the upper and lower reference limits should be determined in order to reflect the precision of the limits. These confidence intervals will be narrower with larger reference sample sizes and with more homogeneous reference sample groups.[6] Confidence limits can be calculated using parametric, nonparametric, and bootstrap methods based on data distribution and the size of the sample.

The question of sample size pervades all RI discussions. A reference sample size of 120 is often touted as an "optimal" number, although n = 120 is better described as "sufficient," as this number permits the nonparametric calculation of the 2.5th and 97.5th percentile limits with nonparametric 90% CIs around these limits. Statistically speaking, the optimal reference sample size is a function of the reference value distribution and the desired tolerance and confidence of the RI.[41] The question of sample size differs whether one is determining RIs for homogeneous populations (e.g., dogs of the greyhound breed) or for heterogeneous populations (e.g., dogs of all breeds). The former requires fewer and the latter more reference subjects in order to be representative of the relevant patient population. In general, more is better. An example of misrepresentation of RIs due to small sample sizes is provided in the veterinary literature.[6]

ESTABLISHMENT OF INDIRECT REFERENCE INTERVALS BY DATA MINING

One solution to the frequent problem of small reference sample sizes is to harvest results from laboratory databases, a procedure called data mining.[27] In addition to very large sample sizes that permit creation of subgroup RIs specific to age and sex classes, advantages include harmonization to the laboratory's patient demographics, preanalytical procedures, and analytic methods and faster completion of the task with less inconvenience to subjects. The possibility of including results from unhealthy subjects can be minimized by using biological and statistical filters to exclude results likely originating from unhealthy individuals and by selecting databases comprised primarily of samples collected from patients during wellness checks, blood donor screenings, or preoperative assessments for elective surgeries. Several intriguing procedures are described for establishing indirect RIs from laboratory archives, some of which are available as open source software.[2,11,28]

TRANSFERENCE AND VERIFICATION OF REFERENCE INTERVALS

An alternative to establishing de novo RIs is transference and verification of a preexisting RI. Transference may occur when a newer model replaces an older analyzer or new methods or analyzers are introduced. The laboratory may choose to adopt RIs from the manufacturer or from another laboratory. When choosing a RI for transference, collection and processing protocols, analytical methodology, quality performance, and population demographics are important considerations. RI verification is more often successful when these factors are closely aligned between the donor and recipient laboratories.

A straightforward RI verification procedure compares 20 reference values, collected from the laboratory's healthy patient population, with the donor RI. Although previously described as a validation procedure, the term verification is preferred for the simplified process described here; validation implies a more comprehensive assessment.[9,35] Age and sex distribution of the sample group should mirror that of the laboratory's patient population. The donor RI is accepted if two or fewer reference values fall outside the donor RI and rejected if five or more fall outside the donor RI. If three or four fall outside the donor RI, the procedure can be repeated with an additional 20 reference values or the RI can be rejected. If verification again fails, then the donor RI is rejected (Figure 140.2a). Distribution of the 20 test samples within the donor RI should be considered. Values that are clustered toward the upper or lower limit or around the mean indicate that the donor RI is not entirely representative of the patient population and a de novo RI should be developed. When no verification samples from the receiving laboratory's patient population exceed transferred RI, the RI may be too wide. Although this scenario is not addressed in the CLSI guidelines, establishing de novo RI is advised. In an example of transference and verification of RIs from one coagulation analyzer to a different coagulation analyzer from the same manufacturer, rejection of the donor RI was correctly anticipated given the differences in preanalytical and analytical methods.[17] In another example using a larger sample group, 30 of 36 equine biochemical and hematologic RIs from a large reference laboratory were transferred and verified for Friesian horses, whereas six were not.[39] For these six analytes, de novo RIs were determined and reported.

An indirect or data-mining approach to verification has been described. This approach requires that the majority of samples in the laboratory's database be from healthy individuals so that the health-based distribution can clearly be identified.[35] The most useful parameter for bias assessment using this indirect approach is to compare the midpoint of the mined data (mean, median, or mode depending on data distribution) to the corresponding midpoint of the proposed RI.[26] The midpoint is resistant to results from unhealthy subjects and has less uncertainty. In addition, the expected flagging rate for the proposed RI, i.e., the rate of results above and below the respective reference limits, can serve as an indicator of comparability.[26] Laboratory RIs should be reverified, by direct or indirect methods, every 3–5 years as recommended in ASVCP guidelines.[15]

If the donor RI is rejected, any discrepancy may be due to systematic bias between methods, which can be quantified through a method comparison study (Figure 140.2b).[24] Although method comparison studies often include samples from unhealthy subjects whose values exceed the reference limits, this is discouraged when comparing methods for RI transference so as not to overestimate the strength of the correlation.[35] If systematic bias is identified and the *y*-intercept of the regression line is small compared to the RI, then both the upper and the lower donor reference limits can be transformed by the regression equation (Figure 140.2b). If the analyte has a narrow range of values, such as with electrolytes, the mean difference between methods may be sufficient to adjust the transferred reference limits. The transformed RI subsequently should be verified with samples from 20 healthy subjects as previously described (Figure 140.2c). If verification is unsuccessful, additional reference values must be obtained to establish the RI de novo.

REFERENCE INTERVALS FOR SUBGROUPS OR INDIVIDUALS

Subgroup Reference Intervals (Partitioning)

The suitability of a particular population for RI generation assumes homogeneity in that population. If homogeneity is violated in a clinically important manner, the subgroup (partition) should be identified and separate RIs created. Clusters of outlying values within healthy populations suggest heterogeneity due to breed, sex, age, or other characteristics and should prompt further investigation and documentation. Several examples of veterinary subgrouping exist, including measures of red blood cell mass in Friesian horses.[39] Most often, the discrepancy

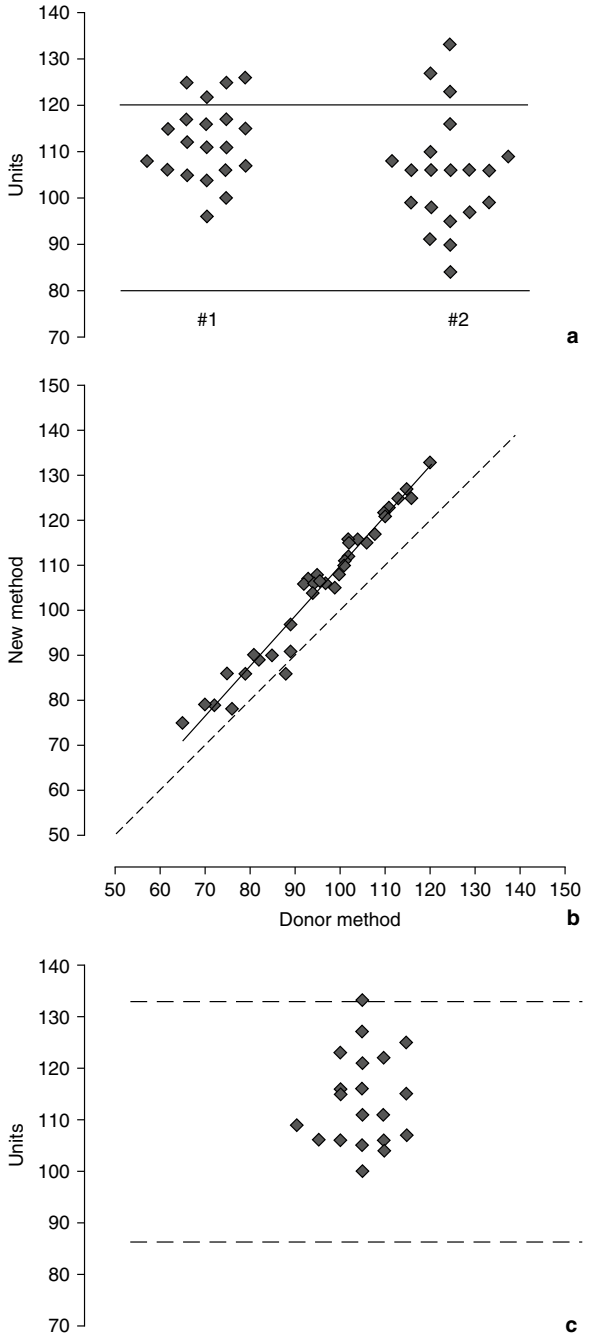

FIGURE 140.2 Transferred RIs (black lines) are verified by comparison of reference values from the laboratory's healthy patient population (diamonds, $n = 20$). If one or two values fall outside the RI, the donor RI is accepted. However, if three or four values fall outside (a, #1), the process must be repeated using the same acceptance criteria (a, #2). In this second assessment, three values fell outside the donor RI; therefore, the RI is rejected; (b) A method comparison study can determine the presence and magnitude of systematic bias, and if the *y*-intercept is small compared to the RI, the regression equation can be used to transform the donor reference limits to fit local methodology. In this case, the linear regression analysis result was $Y = 1.11X - 1.3$, $r^2 = 0.96$ with a *y*-intercept of 1.3 that is small compared to the donor RI of 80–120; the reference limits were transformed by the regression equation [1.11 × 80 – 1.3; 1.11 × 120 – 1.3] to the new interval of 87.5–140.9; (c) The transformed RI is then verified as described, in this case with success as fewer than two reference values fall outside. The dotted line in (b) represents the line of agreement between methods ($Y = X$).

is unidirectional; outlying observations are either systematically higher or lower than established limits. Therefore, the subgroup will have a statistically different mean or median than the general population. Differences in variation causing bidirectional discrepancy are infrequent and will not be described here.

The clinical significance of a subgroup discrepancy should be assessed before creating partitioned RIs. One criterion for partitioning RI is if the difference between subgroup means exceeds 25% of the combined RI width; a second criterion is if more than 4% of individuals in the subgroup fall outside the established RI.[20,30] Additional factors to consider include ease of identifying subgroup members, reference sample size for each subgroup, reference value distribution of both the subgroup and the combined group, and prevalence of subgroup members within the larger population. Reference interval partitioning is commonly based on phenotypically recognized subgroups, but may include genotype if this information is available and clinically relevant.

Subject-Based Reference Intervals

Biological variation describes the expected variation of a blood value across a group of individuals as well as the variation within an individual. Factors that affect biological variation include, but are not limited to, age, sex, breed, pregnancy, and production states as well as season and geographic location. The width of a population-based RI is mainly determined by the analyte's combined analytical, intraindividual (within-individual, CV_i) and interindividual (or within-group, CV_g) variation.[1,5,14] Analyte variability within an individual (CV_i) has a similar or narrower width than that within the group (CV_g). Validated biological variation data in veterinary species are expanding. Updated procedures and guidelines for generating and reporting biologic variation data can help standardize how biological variation is determined and communicated and should be applied as universally as possible.[1,5,14] A cross-disciplinary committee of professionals with expertise in this topic established the website, vetbiologicalvariation.org.[40]

An objective measure, for determining whether biological variability within an individual mirrors the variability within the group or whether it is narrower, is the index of individuality defined as the ratio CV_i/CV_g.[5] If CV_i is much smaller than CV_g, there is marked analyte individuality, indicating that a population-based RI would be insensitive in detecting pathological changes in an individual patient. The inverse of the index of individuality, CV_g/CV_i, is a more intuitive ratio in that an analyte with a low inverse ratio has low individuality and an analyte with a high inverse ratio has high individuality.[7] An index of individuality <0.6, or an inverse ratio >1.67, is generally accepted as a criterion for defining high individuality. In contrast, an index of individuality of >1.4, or an inverse ratio of <0.7, indicates low individuality. The prevailing clinical decision may influence the appropriate decision criterion when an index falls between these or, alternatively, analyte individuality can be increased by partitioning the RI into subgroups.[7] In theory, when an inverse ratio is high,

subject-based references are optimal for detecting pathologic changes in an individual, and when the inverse ratio is low, population-based RI suffice for clinical decision-making. In practice, clinical decisions are made using the available RI, and information on biological variability and analyte individuality are used to determine the sensitivity of that RI. When insufficient numbers of individuals are available to create a representative population-based RI, such as occurs with zoological or endangered species, subject-based references may be a suitable alternative.

For a subject-based approach, data on biological and analytical variability are used to determine a homeostatic set point for an individual patient, and a reference change value (RCV) is calculated that signifies a clinically significant difference in a single blood result or between serial blood results for that patient.[5,7] The homeostatic set point is an individual's average measurable quantity of an analyte that is maintained by dynamic physiologic control during health; CV_i represents variation around this set point, and CV_g represents variation between homeostatic set points across individuals. The RCV is defined as the amount of change needed between two results from the same individual to be considered different within a stated probability, taking into account analytical error (CV_a) and expected variation within an individual (CV_i).[5,7]

Several prerequisites central to the generation of population-based references are equally important for establishing subject-based references. These include meticulous control of preanalytical variation, selection of healthy reference subjects, identification and removal of outliers, and utilization of statistical models relevant to data distribution.[5] Minimizing analytical variability (CV_a) is of even greater importance for biological variation studies; therefore, when possible, samples should be analyzed in duplicate within one analyzer run.[5,14] Review of published biological variation parameters in animals reveals differences for the same analyte across studies, documenting the need for a universal and rigorous approach.[40]

DECISION LIMITS (THRESHOLDS)

Unlike RIs that are descriptive of the distribution of blood values in healthy subjects, a decision limit is a predetermined test threshold that distinguishes between two subgroups of a target population.[15,36] Decision limits have several purposes, including distinguishing a particular condition in patients presenting with analogous signs of disease, defining a critical value (flag) for clinical action, establishing prognosis by staging or grading, or assessing disease risk at a population level. Examples of these include a decision limit for pancreatic lipase immunoreactivity for the diagnosis of pancreatitis in dogs presenting with acute abdomen,[42] an empirical critical value for neutropenia to suspend chemotherapeutic drug administration,[32] a mitotic index that predicts a high-grade mast cell tumor,[29] and nonesterified fatty acid concentrations for herd-level risk of periparturient disease.[33]

The clinical scenario and the disease spectrum within the target population are integral components to the contextual selection and use of a decision limit. Establishing the clinical usefulness of a test decision limit, however, requires not only selecting a limit and determining diagnostic accuracy of the test but also exploring diagnostic efficacy.[8] The latter is a property not of the test, but of the circumstances in which the decision limit is applied. Relevant factors include the prevalence or probability of disease, possible clinical outcomes and their relative values, risks to patients of incorrect information, and costs and benefits of various treatment options. Guidelines for designing and interpreting prospective studies to establish decision limits and to assess diagnostic accuracy are addressed by CLSI and the ASVCP and are summarized in the following text.[8,15]

The process begins with defining the clinical question and the target population to which the decision limit will apply.[10] In addition, the assay's role in decision-making for the relevant condition should clearly be stated. A new test may be investigated for triage, replacement, or as an add-on to existing tests for the same condition.[10] The target population must be well defined with regard to the nature, duration, and severity of the condition as well as to age-range, sex, and other relevant findings using inclusion and exclusion criteria. As for RI determination, study subjects should be representative of the target population and selected prospectively to include statistically relevant numbers of both condition-positive and condition-negative individuals to avoid selection bias.

Test subjects should include individuals with the disease of interest, with look-a-like diseases, and with conditions that might otherwise be difficult to categorize in order to represent the condition's spectrum encountered in clinical practice; i.e., not restricted to healthy subjects or subjects with clinically apparent disease. As an example, the sample group selected to assess the discriminatory ability of natriuretic peptide assays for cardiac disease included dogs presenting with respiratory signs that had either primary cardiac disease, with and without heart failure, or primary respiratory disease.[4] Selecting subjects without knowledge of test results also minimizes selection bias that can affect the choice of a decision limit and estimates of diagnostic accuracy. Having an equal number of subjects in each category minimizes the uncertainty of diagnostic accuracy estimates, but is not always possible.[8]

The true clinical status of the subjects should be established by accepted and unbiased diagnostic criteria, independent of the test under investigation or a chemically related analyte. For tests evaluating disease severity or prognosis, standardized staging, grading, or scoring schemes and common outcome assessments should be used. Tests with subjective assessments should be determined by consensus.[8] Verification or definitive diagnosis may require long-term follow-up

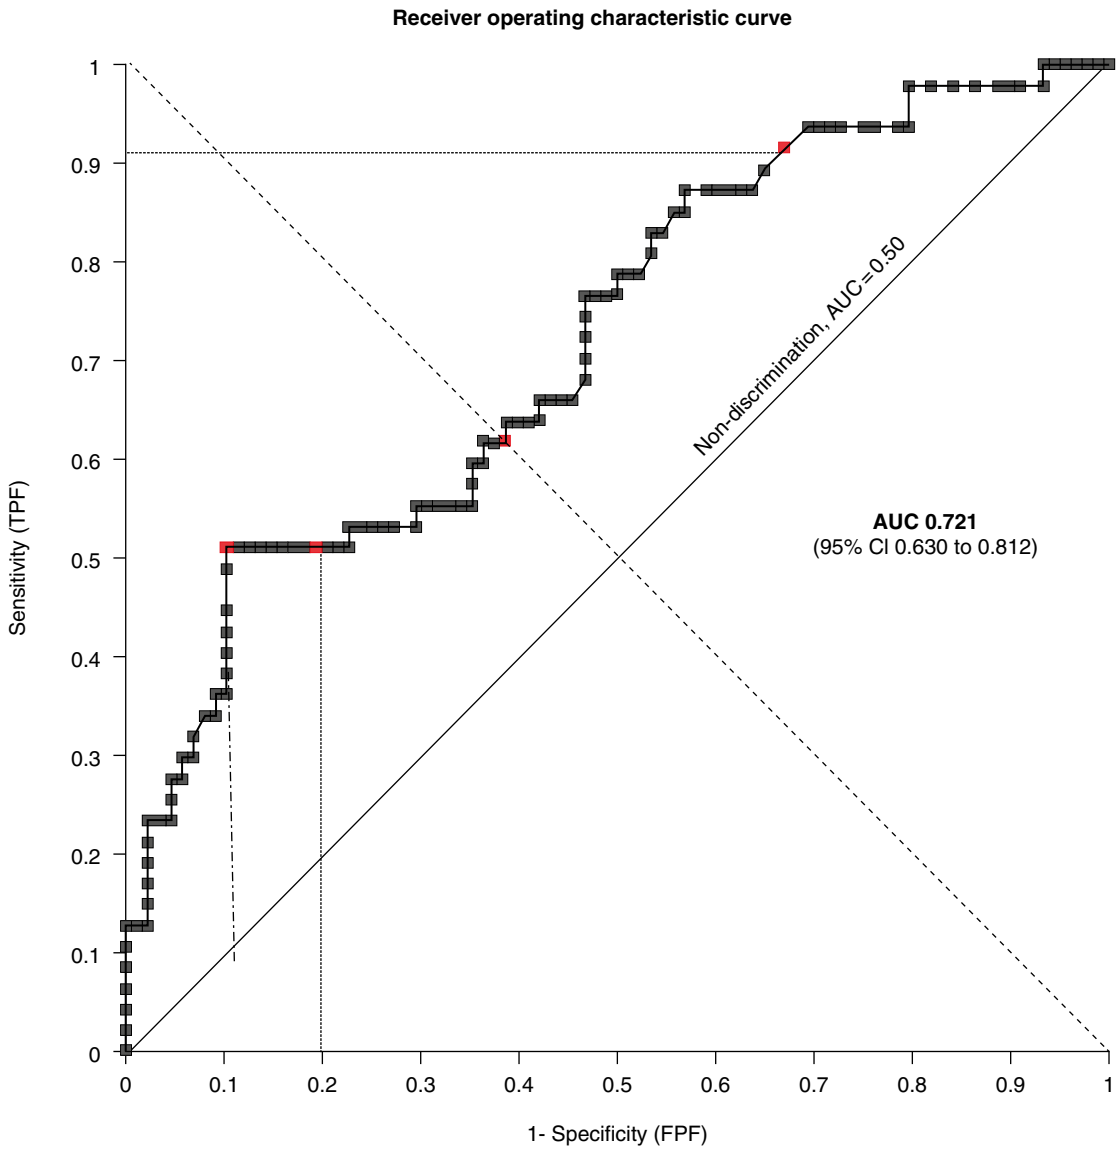
including documented response to treatment or disease progression or histopathologic evaluation through biopsy or necropsy. This can minimize censoring of difficult to categorize subjects or subjects with indeterminate test results and maintain adequate sample size.

Testing should occur across the anticipated spectrum of disease for which the test is intended and at the same time that comparative testing is performed. If multiple tests are being compared, all tests should be performed on the same sample, at the same time, and in all subjects. If sample stability permits, batch analysis minimizes between-run analytical variation. Protocols for categorizing unexpected or indeterminate test results should be established in advance.[10] Excluding subjects with such results leads to bias favoring test performance. Sample collection should comply with protocols for patient preparation and sample handling for the analyte.

Analytical requirements for accuracy and precision are equally applicable to decision limits and RIs. A major challenge for universal application of a decision limit is ensuring precision and minimizing bias across laboratories. A major prerequisite to cross-laboratory precision is calibration material traceability to recognized standards, such as the CRM 470 standard for human serum proteins established by the IFCC.[3] However, such programs are rare, if not absent, in veterinary clinical laboratory medicine. As such, decision limits in veterinary medicine are most often derived for assays that are performed at a central laboratory or by the same methodology at multiple laboratories. It is important to remember that decision limits, like RIs, are determined in a defined population and may not perform equally in populations with demographic and pathophysiologic differences. Creation of universal calibration standards for acute phase proteins in veterinary species is under discussion by the International Society of Animal Clinical Pathology.[13]

Receiver operating characteristic (ROC) curves are integral to assessment of diagnostic assays.[8] Applications of ROC curves include establishing decision limits, determining whether a test performs better than chance, assessing diagnostic accuracy, and evaluating whether two tests for the same process have equivalent diagnostic potential.[8] To prevent overestimation of diagnostic performance, separate studies for selecting decision limits and establishing diagnostic accuracy should be performed. More detailed descriptions of ROC curve construction and interpretation can be found in published resources.[8,16,19]

Selection of a decision limit to distinguish between condition-positive and condition-negative status entails a trade-off between sensitivity and specificity. The purpose of the test in any specific clinical scenario dictates whether a decision limit with high sensitivity (rule in), high specificity (rule out), or balanced test performance is desired. The ROC curve graphically represents the entire theoretical range of diagnostic test performance for the selected subject group at multiple decision limits. The true positive fraction (sensitivity) is plotted on the *y*-axis, and the false positive fraction (1-specificity) is plotted on the *x*-axis with perfect test performance located in the upper left corner.[19] Because sensitivity and 1-specificity are independently plotted, the ROC curve is independent of disease prevalence.



Using a ROC curve, the decision limit can be selected in several ways (Figure 140.3). One is to select a balanced decision limit where sensitivity equals specificity. This point is located where a line drawn from the lower right to the upper left corner intersects the test curve. A second method maximizes the summation of sensitivity and specificity (highest test accuracy), which occurs at the point of maximal vertical distance of a line drawn from the nondiscrimination line to the test curve. This method also maximizes the Youden's index.[43] A third method selects a decision limit based on a desired sensitivity or specificity based on the test's purpose. For example, if a highly sensitive decision limit for sodium:potassium ratio (NA:K) is desired to screen patients for hypoadrenocorticism, then a decision limit of <27 should be selected in order to capture all such patients for subsequent adrenocorticotropic hormone stimulation testing. On the other hand, if a more specific decision limit is desired, then a Na:K of <15 can be chosen.[38] As this example demonstrates, multiple decision limits can be selected for the same subject cohort by modifying the clinical question.

Selecting a decision limit by these methods does not account for factors contributing to diagnostic efficacy as previously described. To address this limitation, some authors suggest using a test index called, "number needed to misdiagnose."[19] This index is the number of cases correctly diagnosed before a single incorrect diagnosis is made. The closer the test is to the gold standard, the higher the index. Although mathematically complicated, the equation can be adapted to account for pretest probability and the cost of true positive and false positive test results.

The area under the curve (AUC) on a ROC plot is an estimate of a test's discriminatory ability (diagnostic accuracy) as well as representative of the average sensitivity over all specificities, and, conversely, the average specificity over all sensitivities.[8] Although theoretically starting at zero (100% misclassification), the applied accuracy interval is from 0.5 (nondiscrimination) to 1.0 (perfect accuracy). Ninety-five percent CIs should be reported with the AUC; if the CI includes 0.5, then the test may provide no useful information. The AUC also can be used to statistically compare the accuracy of different tests; in general, the higher the AUC, the more discriminatory the test.

PRESENTATION OF REFERENCE INTERVALS AND DECISION LIMITS

Reference intervals typically are printed on laboratory reports along with patient results. This only should be done when the provided RIs are applicable to the patient demographic. In addition, identification of results that fall above and below the RI often is denoted. Subgroup RIs should thoroughly be described and

Test >	(Sensitivity)		(Specificity)	FP proportion	FN proportion	Youden's index
242	0.915	0.915	0.330	0.670	0.085	0.244
368		0.617	0.614	0.386	0.383	0.231
524		0.511	0.795	0.205	0.489	0.306
571		0.511	0.898	0.102	0.489	0.408

FIGURE 140.3 Decision limits that satisfy specific clinical purposes can be selected from a ROC curve. The following decision limits are displayed in red and defined from left to right as: (1) A decision limit of >571 units maximizes the sum of sensitivity and specificity (maximum Youden's index), and is located on the curve at the maximal vertical distance from the line of nondiscrimination. This is also the closest point of the curve to the upper left corner of the graph. (2) Optimization at a chosen specificity of approximately 80% (approximately 20% FPF) yields a decision limit of >524 units. (3) The decision limit of >368 units, at which sensitivity and specificity are equivalent, is located at the intersection of the curve with a line drawn from the lower right to the upper left corner (dashed line) of the graph. (4) Optimization at a chosen sensitivity of approximately 90% yields a decision limit of >242 units. The AUC is an overall measure of a test's discriminatory ability (diagnostic accuracy). Created with Analyse-it® version 5.10.8 and a series of 138 test results from 47 condition-positive and 88 condition-negative dogs. AUC: area under the curve. CI: confidence intervals. FPF: false positive fraction. TPF: true positive fraction.

communicated to users. Reference intervals that represent a proportion of reference values other than the typical 95% coverage also should be prominently displayed.[9] If decision limits are available for certain analytes, these should be reported separately and not admixed with RIs. If multiple decision limits are utilized for different clinical situations, a brief summary of recommendations as well as the source of the limits should be included in the report. Additional details of the RI or decision limit study, such as the inclusion and exclusion criteria and the number of subjects, should be provided upon request in a written or an electronic report. The ASVCP RI guidelines provide a comprehensive list of information that should be included in summary documents and in publications of RI.[15] A more recently generated checklist is also available for authors and reviewers (Appendix 1). A recent study reports compliance for each of 35 such items in RI publications from nondomestic species.[34] A checklist of information for inclusion in reports of diagnostic accuracy studies is addressed in the updated Standards for Reporting of Diagnostic Accuracy Studies (STARD) guidelines.[10]

Author Checklist for Manuscripts Reporting Reference Intervals

Reference Interval Checklist prepared by QALS Committee, April 2020[a]

METHODS

1.a) Reference population – inclusion and exclusion criteria ☐ Yes ☐ No 1.1, 1.2

1.b) Population geographic location ☐ Yes ☐ No 1.1

1.c) Partitioning factors, if applicable ☐ Yes ☐ No 1.2, Section 12

2.a) Sample size; number of reference individuals ☐ Yes ☐ No 1.2.3

2.b) Justification of sample size ☐ Yes ☐ No Section 1.2

3.a) Animal acquisition ☐ Yes ☐ No 5.1

3.b) Animal source ☐ Yes ☐ No 1.2.2–1.2.4

3.c) IACUC approval (or equivalent) ☐ Yes ☐ No

4.a) Laboratory specimen collection protocols ☐ Yes ☐ No Section 5

4.b) Lab specimen handling procedures ☐ Yes ☐ No Section 5

4.c) Analytical methods ☐ Yes ☐ No Sections 6 and 7*

5.a) Data inspection and outlier tests (Tukey's, Dixon), eg, histograms, box plots ☐ Yes ☐ No Section 8

5.b) Handling outlier values (strategy used to review and decide if values are removed). For wildlife especially, outlier detection should be repeated until outliers are identified and considered for removal. ☐ Yes ☐ No Section 9

5.c) State the threshold for interpreting the *P*-value of the test for normal distribution. For each measurand, provide the *P*-value of the normality test and conclusion about the distribution (Gaussian or Non-Gaussian) ☐ Yes ☐ No Section 10**

6.a) Reference intervals or limits ☐ Yes ☐ No Section 11***

6.b) Confidence intervals around the upper and lower reference limits; include the formula/method used (e.g., parametric, robust) ☐ Yes ☐ No Section 11

6.c) If partitioning included, report the steps (5.a -6.b) for each subgroup ☐ Yes ☐ No Section 12

6.d) Confirm steps 5.a – 6.b were recalculated for all measurands after outliers removed from original population data ☐ Yes ☐ No

6.e) Statement confirming methods follow ASVCP guidelines ☐ Yes ☐ No

RESULTS

7.a) Report the study period, including animal recruitment ☐ Yes ☐ No

7.b) Final number of reference individuals, after outlier removal ☐ Yes ☐ No

7.c) Number of samples excluded for technical issues or outliers ☐ Yes ☐ No

7.d) Clinical and demographic characteristics of reference population ☐ Yes ☐ No

7.e) Distribution results: normality test used, p-value, threshold used for interpretation of p-value, and conclusion about distribution (Gaussian or Non-Gaussian) ☐ Yes ☐ No**

7.f) Computational method (e.g., parametric, robust) and reference intervals for each measurand (the method is based on sample size) ☐ Yes ☐ No

7.g) Confidence intervals (CI) around the lower and upper limits of the reference interval, or the reason why the CI could not be reported ☐ Yes ☐ No****

7.h) Statistical differences, or other means used for partitioning ☐ Yes ☐ No

7.i) Reference intervals for partitioned groups ☐ Yes ☐ No

7.j) For low sample number groups, report descriptive statistics only ☐ Yes ☐ No

7.k) N<10, present all data ☐ Yes ☐ No

DISCUSSION

8.a) Limitations for reference intervals/limits/values ☐ Yes ☐ No

8.b) Unique value of the reference intervals, e.g., for unusual species or unique disease challenge ☐ Yes ☐ No

8.c) Practical application of the reference intervals, and where additional data are needed ☐ Yes ☐ No

REFERENCES

9.a) Citations for reference interval guidelines or review articles ☐ Yes ☐ No

9.b) Citations for methodology validation in the studied species, if applicable ☐ Yes ☐ No

[a]https://cdn.ymaws.com/www.asvcp.org/resource/resmgr/qals/reference-interval-checklist.pdf, accessed September 2021

*If analyses performed by author(s), include a statement about the analyst(s) proficiency, and quality control/quality assurance procedures to ensure the instruments were performing properly at the time of the study. If analyses performed by a reference laboratory, an attempt should be made to obtain QA/QC information.

**Normality, or distribution, tests are designed for large populations. Smaller population sizes are often obtained in veterinary medicine and it has been demonstrated that a threshold p-value of 0.3, instead of 0.05, more accurately characterizes the results (e.g., Shapiro-Wilks, D'Agostino-Pearson, etc.). If the tests' p-value <0.3, the measurand would be judged as having a Non-Gaussian distribution.

***The ASVCP Quality Assurance and Laboratory Standards committee developed and Excel template to create a reference interval reporting table (https://www.asvcp.org/page/QALS_Guidelines, accessed September 2021). Formats are provided to report hematology and chemistry reference intervals (where $n \geq 20$) or descriptive statistics ($n < 20$).

****Comparing the width of the confidence intervals (CI) around the lower and upper reference interval (RI) with the width of the RI × 0.2 may aid in evaluating the level of precision; when the CI width > 0.2 RI width, then collecting additional reference samples may be warranted.[34]

Acronyms and Abbreviations

BM, bone marrow; BSA, bovine serum albumin; CD, cluster of differentiation; CD71, transferrin receptor; CD45, leukocyte common antigen; CLL, chronic lymphocytic leukemia; $DiOC_6$, dihexyloxacarbocyanine; EDTA, ethylenediaminetetraacetic acid; FACS, fluorescence-activated cell sorting; FITC, fluorescein isothiocyanate; FL, fluorescence; FSC, forward scatter; MDS, myelodysplastic syndrome; MGG, May–Grünwald–Giemsa stain; M:E ratio, myeloid:erythroid ratio; nm, nanometer; LDS, laser dye styryl; PBS, phosphate-buffered saline; PE, phycoerythrin; SSC, side scatter.

BONE MARROW COLLECTION IN DOGS AND CATS

Indications and Contraindications

Bone marrow (BM) examination is indicated to investigate hematopoietic disease and blood smear abnormalities. Bone marrow collection should be performed in animals with suspected lymphoproliferative or myeloproliferative disease and neoplasia, myelodysplastic syndrome (MDS), staging of diagnosed lymphoma, histiocytic neoplasia, multiple myeloma, metastatic carcinoma (especially mammary carcinoma), and other sarcoma. Unexplained hypercalcemia, hyperproteinemia (gammopathy), and fever of unknown origin also may raise the suspicion of paraneoplastic syndrome and warrant BM evaluation. Diagnostic workup of unexplained, persistent cytopenias including nonregenerative anemia, neutropenia especially in the absence of left shift and toxic change, as well as bicytopenia or pancytopenia requires assessment of production. Abnormal peripheral blood cell populations, such as blasts, rubricytes in the absence of regeneration, and atypical morphology of WBCs, RBCs, or platelets, also necessitate BM evaluation.

Contraindications for BM aspiration include severe coagulopathies. Thrombocytopenia, however, is not a contraindication for BM collection because significant

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

hemorrhage is rarely a problem. The risk of BM infection is negligible.[22] The most important contraindication, however, is performing a BM aspirate that is unnecessary.[8]

Collection of a Bone Marrow Aspirate versus Core Biopsy

The advantage of aspiration is that single cells are evenly spread on a slide enabling excellent cell morphology evaluation and lineage identification.[23] During BM aspiration and smear preparation, BM tissue architecture is somewhat disrupted. Tissue architecture is maintained by core biopsy allowing the proportions and location of hematopoietic cell populations and stromal cells to be evaluated.

Indications for BM core biopsy include:[23] (1) a BM aspiration which is repeatedly not successful (punctio sicca); (2) nondiagnostic BM cytology (e.g., BM aplasia or hypoplasia); (3) focal abnormalities (e.g., myelofibrosis, granulomatous inflammation, multiple myeloma, BM necrosis, metastatic carcinoma); (4) metastatic neoplasia. Some clinicians routinely collect both samples because the need for BM core biopsy frequently cannot be predicted at the time of BM aspiration.

Techniques and Locations of Bone Marrow Collection

Common collection sites in dogs and cats include the anterior greater tubercle of the humerus and the iliac crest (Figure 141.1). In toy breeds and cats with a small iliac crest, the femoral trochanteric fossa can be used. Use of the sternum risks penetrating the thoracic cavity and injuring intrathoracic organs and should only be used as a last resort or during necropsy. Bone marrow aspiration and core biopsies are painful and heavy sedation with analgesia or general anesthesia is typically used.

The sedated or anesthetized dog is positioned in lateral recumbency. The skin over the collection site is shaved and aseptically prepared. Approximately 1–2 mL of a 2% lidocaine solution is used for local anesthesia of all tissue layers, especially the well-innervated periosteum. A stab incision with an 11-scalpel blade may be made to decrease skin contamination and interference during needle rotation. A 13–19 gauge × 2.5 cm Klima-Rosegger, Rosenthal, or Illinois sternal needle with an interlocking stylet is used for BM aspiration with smaller sizes used in cats and larger sizes in most dogs.[4] The flat portion of the humeral greater tubercle or iliac wing is palpated. The needle is inserted with slow rotating movements either at a 90° angle (perpendicular) to the humerus or at a 45° angle, parallel to the long axis of the ilium. After removal of the stylet, a 6–12 mL syringe typically containing EDTA is attached to the needle.

The syringe can be prepared using a 5–10% EDTA anticoagulant solution, created by mixing 0.5 mL of sterile saline into a 7 mL EDTA tube.[5] This solution is drawn into the collection syringe, and some EDTA may be expelled dependent upon the animal's size and expected BM yield. Anticoagulant choice should be based on planned diagnostic protocol. Heparin is the anticoagulant of choice for some flow cytometric protocols. However, heparin anticoagulated marrow should not be used for microscopic cytologic examination, as it causes significant staining and morphologic artifacts.

Marrow is aspirated into the syringe by applying quick negative pressure until about approximately 1 mL or more of marrow is collected (dependent upon the size of the animal). The syringe contents are expelled into a Petri dish and should contain a mixture of blood, floating fat globules, and granular white-gray BM particles (Figure 141.2).

A microhematocrit tube or thin glass pipette is used to pick up several BM particles and only a small amount of blood, thereby concentrating the marrow particles (Figure 141.3). This material is transferred to a glass slide and spread using a gentle squash smear technique.[4]

FIGURE 141.1 Demonstration of iliac crest site for BM collection in a dog.

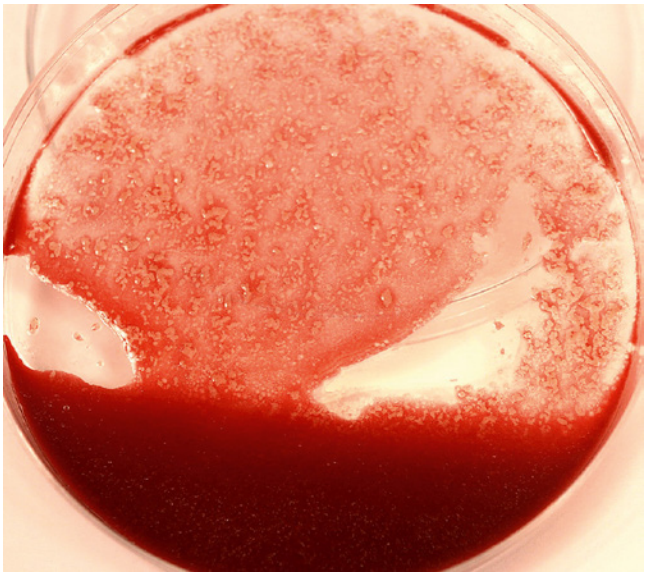

FIGURE 141.2 Bone marrow aspirate biopsy material expelled into a Petri dish displays numerous glistening fatty particles which can be collected by microhematocrit tube or pipette. (Source: Photo courtesy of University of Florida Clinical Pathology Collection.)

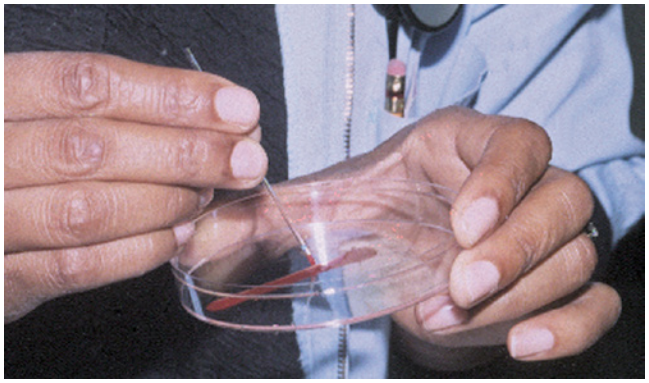

FIGURE 141.3 Particle collection. Particles are picked up using a microhematocrit tube to be expelled onto a glass slide. A squash preparation is then made from the droplet. (Source: Photo courtesy of Rose Raskin, University of Florida.)

At least six to eight quality BM smears should be prepared which can then be used for special stains as needed for neoplastic diagnosis. After BM collection, gauze is applied with firm pressure to the aspiration site for a few minutes to stop any bleeding.

Core biopsy specimens may be taken at 1 cm or more distant to the previous needle placement or at an alternate site for better representation of the patient's bone marrow tissue. Core biopsies should not be performed in close proximity to the aspirate site, as artifactual hypocellularity of the core sample may be induced. The core biopsy is performed with an 11–13 gauge Jamshidi needle, a cylindrical needle with a tapered distal end and beveled cutting tip. Once the Jamshidi needle is seated into the cortical bone, the stylet is removed; then the needle advanced by rotation as far as possible. The needle may be withdrawn slightly and then readvanced at a slightly different angle, or the needle can be rotated/stirred to break off the sample and ensure it remains in the needle core. Once the needle is withdrawn, the stylet is introduced into the needle in a retrograde fashion, so the core sample can be gently collected and transferred to a tissue cassette. Rolling the core sample on a glass slide prior to placement in formalin can provide additional cytologic samples. The core is placed in neutral, buffered 10% formalin for a minimum of 2 hours. The core sample should ideally be at least 1 cm long and contain 10 trabeculae microscopically.[4] The fixed marrow core must be decalcified prior to histologic processing. The core may be transferred to 70% ethanol for transport, which has the benefit of decreasing potential toxicity and formalin fumes.

BONE MARROW COLLECTION IN HORSES

The sternum is the most commonly used site for BM collection in adult horses, with the rib at the costochondral junction also possible.[29,31] In foals, the iliac wing is also a possibility and precludes penetration of the chest and pericardium. The sternum is not covered by significant muscle mass and the cortical bone is relatively thin. Disadvantages include an awkward angle for the procedure in the standing, sedated horse and proximity to the heart, though at some distance from the sternum in the adult horse. The tuber coxae are only used for obtaining marrow in foals and young horses, as thick cortices can make access difficult.[29] The rib contains active marrow throughout life and is an easy site to reach, but has several disadvantages including thick cortices which can be difficult to penetrate in adult horses. The rounded rib surface can make it difficult to seat the needle in the bone and increases the risk of slipping off the rib and puncturing the pleural cavity, potentially resulting in pneumothorax.

BM aspiration and core biopsies are performed in standing, sedated patients. The skin over the site should be clipped and aseptically prepared. All tissue layers, including the periosteum, are anesthetized with a 2% lidocaine solution. A 15 gauge × 5 cm Jamshidi BM biopsy needle (also called a Janus® needle) is preferred for marrow aspiration. A stab incision is made in the skin and the needle is inserted until it reaches the bone. The bone is penetrated using a slow rotational movement until the needle is firmly seated in the bone. For the sternebrae, the needle is then advanced 1–2 cm further into the marrow cavity. If the iliac wings are used, a technique similar to that described for the dog can be used. BM aspiration and sample preparation are similar to that described for the dog and cat with size appropriate instrumentation. An 11 gauge × 10 cm Jamshidi biopsy needle is used to obtain core biopsy specimens with similar sampling and preparation as described for the dog and cat.

BONE MARROW COLLECTION IN RUMINANTS

Bone Marrow Collection in Cattle

Bone marrow aspiration smears and core biopsy specimens from adult cattle have been obtained from the sternum (preferred) and the rib using a Turkel® trephine needle (Trephine Instruments Inc., USA).[14,36] Advantages of the sites are similar for that described in the horse. The iliac crest is unsatisfactory because of bovine pelvic anatomy. The adjustable depth control of the Turkel trephine needle helps prevent penetration of the pleural cavity, but does not eliminate the risk.

Cattle should be sedated before BM aspiration. Intravenous xylazine provides adequate sedation. A 15 gauge × 5 cm Jamshidi BM biopsy needle may be used for marrow aspiration and an 11 gauge × 10 cm Jamshidi biopsy needle can be used to obtain core specimens. The aspiration site is the 3rd or 4th sternebra. This site can be located by counting the ribs starting with the last one; however, the location on the sternum coincides with an imaginary line joining the olecranon. With the ox in a standing position, a small area over the sternum is shaved and aseptically prepared, and all layers of tissue, including the periosteum, are anesthetized with a 2% lidocaine solution. A stab incision is made in the skin and the Jamshidi needle is inserted (with stylet in place) until it reaches the bone. The bone is penetrated using a slow rotational movement until the needle is firmly seated in the bone. The

needle should be advanced approximately 1–1.5 cm. One can frequently sense when the needle enters the marrow cavity because of a sudden reduction in resistance.

In calves, the proximal humerus is an excellent site for marrow collection. Calves can be restrained in lateral recumbency and the method described for dogs and cats can be followed. A 15 gauge × 5 cm Jamshidi or Illinois sternal biopsy needle with the needle guard removed can be used for aspiration biopsy and an 11 gauge × 10 cm Jamshidi needle can be used for core biopsies.

Bone Marrow Collection in Sheep

The sternum is the preferred site for BM collection in sheep.[9] Sheep are restrained in a sitting position by an assistant who holds a foreleg in each hand. The 3rd or 4th sternebra is located by following the rib to its articulation. The site is aseptically prepared and anesthetized as described for cattle. A 15 gauge × 5 cm Jamshidi or Illinois sternal biopsy needle with the needle guard removed can be used for aspiration. For BM aspiration, the depth of penetration from the skin surface varies between 2.5 and 3.0 cm and bone penetration is approximately at 0.5 cm. An 11 gauge × 10 cm Jamshidi needle can be used for core biopsies.

Bone Marrow Collection in Llamas and Camels

The sternum is the preferred site for bone marrow collection in llamas.[1] Bone marrow collection has been described from the dorsal rib of dromedary camels.[25] Adult llamas and camels are sedated with intravenous xylazine and can be standing, placed in a chute, or in left lateral recumbency. Generally, a good marrow sample from camelids may be obtained from the midline of the sternum at the level of the elbow's caudal aspect when positioned naturally.[17,18,20] In llamas, the 3rd or 4th sternebra is located by following the rib to its articulation. In dromedary camels, a site over the 5th through 8th dorsal rib was aseptically prepared and anesthetized as described for cattle. The site is aseptically prepared, anesthetized with 2% lidocaine, and an 11–16-gauge bone marrow biopsy needle is used to obtain samples. Bone marrow samples are most frequently aspirated into EDTA, but may be collected with no anticoagulant if bone marrow smears are prepared immediately. Slides are air-dried and stained with appropriate stains.

BONE MARROW COLLECTION AND PROCESSING IN LABORATORY ANIMALS

In recent years, toxicological clinical pathology generally uses flow cytometric analysis for quantitative BM evaluation, and cytologic preparations to assess morphologic changes and abnormalities in maturation or proliferation. Quantitative BM evaluation includes total nucleated cell counts, differential cell counts, and a myeloid:erythroid (M:E) ratio. Flow cytometry counts more than 10,000 cells, thus providing a much faster and accurate measurement of cell populations than microscopic assessment.

Sampling Procedures

Following humane euthanasia of small rodents (mouse and hamster), dislocate the hind limb from the pelvis, strip away the muscle, and cut the femur at the edges of the stifle and coxofemoral joints (Figure 141.4). Split the femoral cylinder open lengthwise with a scalpel or small electrical saw, use a small brush dipped in hypotonic fetal bovine serum (two parts serum:one part distilled water), brush cells out of the femur and onto a glass slide, air-dry slides, and stain them with a Romanowsky stain.[19,30]

Bone marrow collection from rats and chinchillas does not have to be terminal, but should be done under general anesthesia. Marrow can be collected from the iliac crest, trochanteric fossa of the proximal femur, or tibial crest. The sternum may be used; however, accidental perforation of the chest is possible. The periosteal bone and skin are blocked with 2% lidocaine and a stab incision is made through skin. An 18–20 gauge, 1 inch biopsy needle is rotated through the periosteum into the bone marrow cavity similarly to that described for the dog. Marrow is then aspirated by applying negative pressure with a 3 cc syringe, with a similar volume to marrow ratio as that in the dog. The sample is smeared or brushed onto a slide and stained as mentioned in the earlier text.[2,31]

Terminal collection in the dog and cynomolgus monkey may use the fifth rib which is removed at necropsy and trimmed of muscular tissue. A 1 cm piece of rib is cut from the distal end articulating above the costal cartilage (Figure 141.5). The BM tissue is flushed, approximately five times, with 2 mL phosphate-buffered saline (PBS) containing 50% fetal bovine serum using a needle and syringe (Figure 141.6). The BM cell suspension is

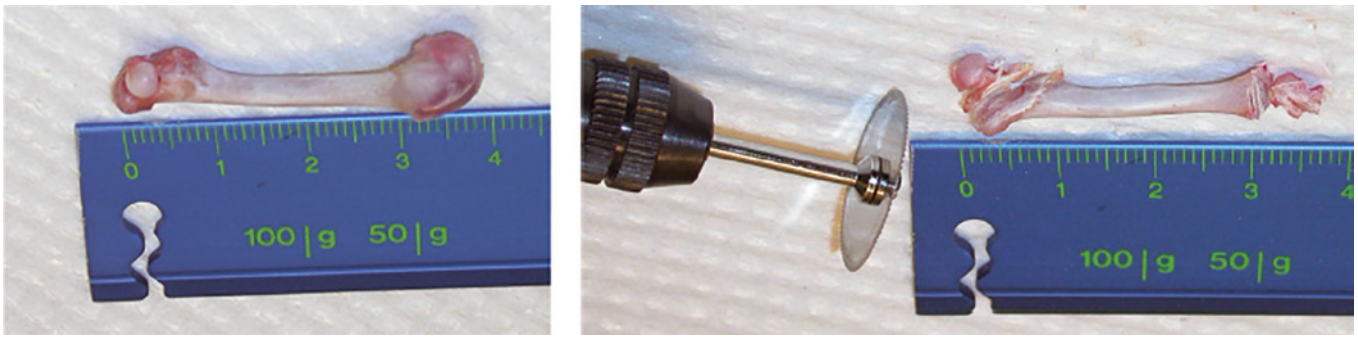

FIGURE 141.4 BM sampling procedure from the femur in rodents.

FIGURE 141.6 The flushing of BM from the piece of rib (dog and monkey) or from the femur of rodents.

washed and resuspended in cold PBS containing 0.5% bovine serum albumin (BSA). The nucleated cell count is determined using a hematology analyzer and the cell concentration is adjusted to 10^7 cells/mL (Figures 141.5 and 141.6).

Flow Cytometry Staining Techniques

Saad et al. described a method for rat BM differential cell counts using a combination of two monoclonal antibodies for the differential expression of leukocyte common antigen (CD45) and transferrin receptor (CD71).[30] This was coupled with the side scatter for cellular complexity and nucleic acid staining using LDS-751 (Thermo Fisher Scientific, Carlsbad, CA, USA) for separation of nucleated cells from mature red blood cells (Figure 141.7). A similar approach can also be used for monkey and mouse BM analysis. Briefly, BM cells are labeled with fluorescein isothiocyanate (FITC)-conjugated anti-CD45 and phycoerythrin (PE)-conjugated anti-CD71 monoclonal antibodies. The tube is incubated in an ice bath in the dark for 20 minutes, then washed with PBS containing 0.5% BSA. The cell pellet is resuspended in 0.4 mL cell fixative (1% formaldehyde). Twenty µL of LDS-751 staining solution is added at least 20 minutes before sample analysis. The LDS-751 staining solution is prepared by diluting 20 µL stock solution (1 mg/mL methanol) with 3 mL PBS. Flow cytometric analysis is done using a 488 nm excitation wavelength from an argon-ion laser. Data can be collected from 10,000–20,000 cells from each sample in list mode to save forward scattered (FSC) values and side scatter (SSC) in a linear scale, and FL1 (green), FL2 (orange), and FL3 (red) in a logarithmic scale. A cytogram of CD45 versus SSC can be plotted for all LDS-751-positive cells (nucleated cells) on a cytogram of LDS 751 versus SSC. Standardized gates define the percentages of erythroid, lymphoid, and myeloid cells. Dog BM analysis is based on cellular complexity and CD45 expression in combination with LDS-751 staining (Figures 141.7 and 141.8).

Other flow cytometry approaches for BM analysis of laboratory animals are described in the literature. For rodents, Martin et al.[16] described a flow cytometric method based on membrane potential using 3,3′-dihexyloxacarbocyanine iodide ($DiOC_6$) staining (Figure 141.9). A combination of 2′,7′-dichlorofluorescein-diacetate staining (indirect myeloperoxidase staining) and monoclonal antibodies for lymphocyte subpopulations (OX-52 for T-lymphocyte and OX-4 for B-lymphocyte) was used by Criswell et al.[5] for the rat BM differential analysis (Figure 141.10). Flow cytometric methods using cellular

complexity and light scatter properties in combination with CD71 or CD45 expressions have been described for rat[23] and dog[26] BM evaluation. More recent work by Zhao et al.[41] described a method for rat BM analysis using the combination of CD3, CD45R, CD71, CD11b/c, and the DNA dye DRAQ5.

Materials for Push Smear Bone Marrow Cytological Preparation

Reagents for push/compression smear cytological preparation include: immunological grade bovine albumin, 22%, polymerized (Median Diagnostics), several pieces of 4 × 4 cm square parafilm, bone cutter for sampling of longitudinally sliced femur, scissors, paintbrush no. 0 or 1 regardless of species, and glass slides. The following procedure may be used:

1. Place a drop of bovine albumin on several pieces of parafilm square.
2. For rodent femur preparations, cut the femur lengthwise, using sharp tools.
3. Pick out as much BM as possible with the brush; place on parafilm next to the drop of bovine albumin fluid.
4. Dip brush in albumin fluid and mix into the BM to make a uniform solution.
5. Place a drop of BM suspension on four to five slides.
6. Place another slide gently on top of the slide containing the sample and spread slides apart.
7. Air dry.

Cytologic Cytospin Slides from Flow Cytometric Samples

For cytospin slides, take 100 µL of the BM suspension prepared for flow cytometry and add 400 µL PBS containing 0.5% BSA. From this diluted cell suspension, 100 µL is placed in the funnel of a cytocentrifuge. The specimen is centrifuged at 50 g for 3 minutes and the slide is removed and air dried.

Processing and Staining for Histologic Preparations

Histologic processing must create sections that are 4 µm or less, which is thinner than many tissues. Recommended stains include standard H&E, Giemsa (to improve assessment of the erythroid line and potential mast cells), and periodic acid–Schiff (to improve assessment of the granulocytic lines and other proteinaceous material). Rodent BM requires slightly longer staining time with Giemsa staining for the best differentiation between nucleated RBCs and lymphocytes. The Giemsa stain needs to be freshly prepared just before use and care should be taken to maintain a pH of 6.8 for the phosphate buffer. Optional stains include Prussian blue for the evaluation of iron stores, reticulin to assess reticulin fibrosis, and trichrome to assess collagen fibrosis. Increased trichrome staining, indicating type 1 collagen, in humans is associated with more severe disease and a poorer prognosis.[13]

SLIDE PREPARATION AND STAINING OF CLINICAL BONE MARROW SAMPLES

Slide Preparation

Several techniques for preparing BM smears in a clinical veterinary setting have been described. The most commonly used techniques are:

1. Preparation of a wedge-type smear (no anticoagulant needed).
2. Drop-squash or particle-squash preparations (require EDTA as anticoagulant).

For preparation of a wedge-type smear, several drops of the aspirated BM are ejected onto a microscope slide and a spreader slide is backed into the area containing concentrated BM particles and a wedge-type smear is prepared. Generally, up to 10–12 slides should be made.[23]

For the pull or squash preparation, concentrated BM particles from the hematocrit tube are placed on a slide and gently spread by a second longitudinally placed slide or coverslip.[24] The slide is subsequently tilted, so excess blood is drained away. EDTA-anticoagulated BM can be placed in a Petri dish for collection of BM particles. Marrow particles, seen as white to clear specks in the red marrow, can be picked up with a microhematocrit capillary tube using capillary action and are carefully transferred onto a second slide so that squash preparations can be made.[24]

Staining

After preparation, BM smears are quickly air-dried. Routine staining is performed with Romanowsky-type stains (May–Grünwald–Giemsa stain, Wright stain). It is important to remember that BM smears require a longer staining time because they are thicker and the material is often unevenly distributed. Aqueous Romanowsky stains like Diff-Quik®, however, are less reliable because they do not stain chromatin structure as clearly as methanolic Romanowsky stains like May–Grünwald–Giemsa or Wright. Additional stains may be needed so that unstained slides should be saved. Cytochemical staining methods are discussed in Chapter 144.

EVALUATION OF BONE MARROW SMEARS IN LABORATORY ANIMALS

Cytological examination of a bone marrow smear is not routinely recommended in laboratory animals, but rather considered on a case-by-case basis.[3,28]

Indications for bone marrow cytological examination include:

- Evaluation of early hematopoietic precursors (maturation and potential drug-induced changes of morphology).
- Unexplained increases or decreases of cell counts in the peripheral blood.
- Differentiation between lymphoid and erythroid cells.
- Changes in erythrocyte indices such as increased mean cell volume suggestive of dyserythropoiesis.
- Atypical leukocyte morphology in the peripheral blood.

Conditions in which bone marrow cytology may be not necessary include:

- Decreased bone marrow cellularity due to reduction of all hematopoietic cell lineages proportional with a degree of restricted food intake (especially in rats, to a lesser extent in dogs).
- Changes in peripheral lymphocyte count, as there is no correlation with bone marrow lymphopoiesis.
- Regenerative changes in bone marrow or peripheral blood.
- Dysfunction of platelets or granulocytes.

Evaluation is performed similarly to clinical samples; however, use of interpretative terms such as hypocellularity or hyperplasia is discouraged. Findings should be reported in relation to a control group and interpretation of treatment-related change is done using hematologic and histopathologic data.

EVALUATION OF BONE MARROW SMEARS IN PATIENTS

Unlike evaluation of BM in laboratory animals, clinical evaluation of BM is qualitative. Thus, only the proportions of cellular populations in relation to each other, their maturation, and cellular morphology are reported. A 200–500 cell differential may be performed in order to better define cell proportions. For interpretation of these cytological findings, clinical signs and hematological results of the patient must be considered, as they indicate the actual demand for RBCs, WBCs, and platelets in the blood. For instance, BM with normal cellularity and a M:E ratio within the reference interval would be considered normal for a nonanemic animal, but hyporegenerative for an animal with a severe anemia and no reticulocytosis.

Criteria to be evaluated in BM smears include: (1) estimation of cellularity; (2) assessment of megakaryopoiesis; (3) evaluation of BM iron (not in cats); (4) M:E ratio; (5) maturation of cellular lineages (megakaryopoiesis, erythropoiesis, granulopoiesis, lymphopoiesis); (6) presence of dysplastic changes; (7) evaluation of other cell types (plasma cells, mast cells, macrophages, osteoclasts, osteoblasts); and (8) evidence of neoplastic cells or parasites.

While cellularity, megakaryopoiesis, stainable BM iron, and the presence of atypical cell clusters are evaluated by assessing several BM particles at 100× magnification, M:E ratio, maturation, and cellular morphology are assessed at 500× to 1000× magnification. As in people, cellular lineages are evaluated quantitatively and qualitatively, i.e., their numbers are classified as decreased, normal, or increased.[15] Cellularity is estimated in BM spicules by comparing the proportion of cells to fat tissue (cell-to-fat ratio). Normal cellularity ranges between 25% and 75% cells[10,34] and is age-dependent. BM spicules of growing animals contain approximately 75% cells, those of adults contain 50%, and marrow spicules of older animals 25% cells. As recommended previously for people, cellularity is reported as acellular, decreased, normal, increased, and markedly increased.[15]

The number of hemosiderophages in BM spicules is indicative of the amount of stored BM iron. Stainable BM iron is increased in chronic inflammation and immune-mediated anemia; however, it is decreased in iron deficiency and in newborn or young animals.[35] However, hemosiderophages are unequally distributed and their number may be under or overestimated. In cats, BM iron is typically not readily apparent.

Megakaryopoiesis assessment can also be difficult due to uneven distribution throughout the marrow and should be evaluated on low power fields where platelet precursors can be easily identified. The megakaryocyte percentage is highly dependent on the smear preparation technique and quality of BM films.[24] Therefore, megakaryopoiesis is routinely only semi-quantitatively assessed. Generally, large BM spicules should contain three to seven megakaryocytes[34] and >70% of megakaryocytes are mature.[10] Promegakaryocyte percentage >50% suggests regeneration[35] or a maturation defect. Megakaryopoiesis quantification can be performed by counting the number of megakaryocytes in 70–100 low power fields (100× magnification) on three slides.[23,24] Mean counts of 2.76 megakaryocytes/low power field and 1.55 megakaryocytes/low power field were obtained in one study, using drop-squash and particle-squash preparations, respectively.[24] Counting megakaryocytes in 20–25 spicule-containing fields achieves an acceptable variance of 20%.[21]

Proportions and maturation of erythroid, myeloid, and lymphoid cellular lineages are examined at 500× to 1000× magnification. M:E ratio determination should be accomplished using a 500–1000 cell differential count. Because particles have a greater granulocyte percentage, 50% of cells should be classified from BM particles and 50% from the smear's interparticle regions.[35] A differential cell count is indicated to document slight to moderate increases in blast cell counts that may differentiate myelodysplastic or low-grade leukemic conditions from benign conditions. Alternatively, a subjective M:E ratio

can be estimated during cytologic BM smear evaluation.[35] The normal M:E ranges from approximately 0.7 to 2.5 in healthy dogs,[20] 1.2 to 2.2 in healthy cats, 0.9 to 3.8 in healthy horses, 0.3 to 1.9 in healthy cows, and 0.8 to 1.7 in healthy sheep.[12]

M:E ratio interpretation requires consideration of BM cellularity and cytopenias in the peripheral blood. A normal M:E in the context of a hypercellular marrow indicates an equal increase in both myelopoiesis and erythropoiesis, which may or may not be expected based on changes in the peripheral blood. An increased M:E may be due to either a decrease in erythropoiesis or an increase in granulopoiesis; whereas a decreased M:E suggests either a granulopoietic hypoplasia or an erythropoietic hyperplasia. A M:E index of >75:1 suggests pure red cell aplasia due to immune-mediated destruction of early erythroid precursor cells.[39] In contrast, pure white cell aplasia is rare.[40]

The maturity of cells in the erythroid and myeloid series should also be evaluated. Similar to human interpretation, maturation is assessed and reported as normal or abnormal and cellular morphology should be evaluated, commented on, and described if abnormal.[15] Normally, >85% of cells in the granulocytic (i.e., metamyelocyte, band, and segmented cells) and erythroid (i.e., rubricyte and metarubricyte) lineages should be in the mature nonproliferative pool. Immaturity in these lineages along with marked dysplasia are caused by leukemias or myelodysplastic syndromes. Immaturity and maturation arrest of cellular lineages accompanied with mild to moderate dysplasia might be due to an immune-mediated hemolytic anemia or neutropenia in which precursor cells are destroyed at a particular stage of maturation.

Small mature lymphocytes are normally <10% of cells in dogs.[8,10] Normal lymphocyte proportion can be higher in the cats, up to 16%[26] and rarely up to 28%.[7] Increased lymphopoiesis of up to 56% lymphocytes[37] can be observed in immune-mediated diseases and is generally accompanied by mild lymphocytosis in the peripheral blood ($<10^9$/L).[39] Differentiation from chronic lymphocytic leukemia (CLL) might be difficult in some cases. However, CLL results in a diffuse BM infiltration and a progressive moderate to severe lymphocytosis in the peripheral blood. Atypical lymphocytes with nucleoli, uniform indented nuclei, or azurophilic intracytoplasmic granules may be seen. CLL is characterized by a monomorphic cellular population, generally T-lymphocytes; while in reactive lymphocytosis, a mixed cellular population mainly comprised of B-lymphocytes is seen. Thus, immunophenotyping by flow cytometry may be helpful to differentiate neoplastic from reactive lymphocytosis[39] (see Chapters 64 and 69–72).

Plasma cells are present in low numbers (<5%).[8,10] Mildly to moderately increased plasma cell numbers indicate chronic inflammatory processes. Markedly increased number of plasma cells (>30%) or atypia including pale blue cytoplasm, fine chromatin pattern, or high numbers of flame cells, i.e., plasma cells with an eosinophilic cytoplasmic rim, suggest multiple myeloma. Definitive diagnosis includes presence of additional criteria such as monoclonal gammopathy, hypercalcemia, anemia, Bence Jones proteinuria, and/or osteolysis in long bones or vertebrae (see Chapter 70).

Low numbers of macrophages are normally found in the BM. Increased numbers of macrophages are observed in chronic infectious diseases, such as leishmaniasis, ehrlichiosis/anaplasmosis, or systemic mycosis. Macrophages with cytophagia indicate immune-mediated cell destruction. Increased macrophage proliferation (>3%)[38] with concurrent bi- or pancytopenia in the periphery are suggestive of hemophagocytic syndrome, aka hemophagocytic lymphohistiocytosis).[11] Hemophagocytic syndrome is a hyperinflammatory immunopathy which can be due to a primary neoplasia in the macrophage line or secondary to underlying disease including severe inflammation, infections such as ehrlichiosis, anaplasmosis, leishmaniasis, or a paraneoplastic syndrome. Macrophage proportions >30% and cellular atypia such as marked macrocytosis, macrokaryosis, and multinucleation are suggestive of histiocytic neoplasia[39] (see Chapters 18, 49, and 74).

Osteoblasts and osteoclasts are rarely found in the BM. They may be observed in young, growing animals. In adult animals, they are indicative of a disturbed calcium:phosphate ratio or neoplasia.

BM may be evaluated for staging of lymphoma or may reveal metastasis of other tumors. Neoplastic plasma cells, mast cells, or histiocytic cells may be observed. Uncommonly, nonhematopoietic tumor cells are found, such as metastatic carcinoma.[34]

USE OF HEMATOLOGY ANALYZERS FOR BONE MARROW ANALYSIS

Cytological examination of BM is time-consuming, labor-intensive, and requires a highly experienced examiner. Thus, hematology analyzers have been used in laboratory animals (dogs and rats)[6,27,32] and patients (dogs)[2,33] to perform a preliminary BM differential count, i.e., the classification of granulocytic and lymphoid/erythroid cells and determination of the M:E ratio. In patients, typical cytograms are indicative of some forms of leukemia. In the ADVIA 2120™ (Siemens), leukocytes are classified based on their peroxidase content and their cellular volume. Especially, the information about the cellular peroxidase concentration might be helpful to classify the origin of neoplastic cells (lymphoid versus myeloid/monocytic).

APC, allophycocyanin; CHCM, corpuscular hemoglobin concentration mean; CHr, reticulocyte cellular hemoglobin content; CV, coefficient of variation; MCVr, mean cell volume reticulocyte; MPV, mean platelet volume; PCT, plateletcrit; PLT-I, impedance platelet count; PLT-O, optical platelet count; FITC, fluorescein isothiocyanate; FMO, fluorescence minus one; FRET, fluorescence resonance energy transfer; FSC, forward scatter; IMHA, immune-mediated hemolytic anemia; MFI, median fluorescence intensity; PE, R-phycoerythrin; LED, light-emitting diode; PMT, photomultiplier tubes; RBC-optical, RBC optical count; RDW, red cell distribution width; RET-H*e*, reticulocyte hemoglobin equivalent; SSC, side scatter; V, volume.

Flow cytometry measures multiple parameters across a large number of cells. This has many valuable applications in clinical hematology, as diagnosis and prognostication of hematologic disorders frequently rely on determination of relative or absolute frequencies of specific cell types. When combined with ex vivo stimulation of cells, flow cytometry can detect functional hematologic disorders and provide experimental insights into the hematopoietic system. Modern flow cytometers achieve high resolution, allowing measurement of microparticle generation to be included in these functional assessments. Flow cytometry also has the potential to guide therapeutic decisions, e.g., by revealing personalized therapeutic targets or providing early detection of therapeutic failure.

As flow cytometry takes on an increasingly important role in veterinary hematology, this has been matched by a requirement for increasingly complex assays. Successful development of flow cytometry assays requires knowledge of flow cytometer mechanics and the properties of the various cellular markers available. Additionally, to ensure patient safety, it is necessary that assays are adequately validated and quality assurance procedures are in place to monitor long-term assay performance. Hematology instruments that utilize flow cytometry are discussed here, with information regarding manual methods and more general hematology quality assurance provided in Chapter 137.

INSTRUMENTATION AND BASIC PRINCIPLES OF LIGHT SCATTER AND FLUORESCENCE

Most flow cytometers use hydrodynamic focusing to force cells into single file as they flow past a focused laser. This is achieved by a combination of the instrument's fluidics and the flow cell. The sheath fluid (e.g., blood bank saline) and the sample are moved separately through the instrument toward the transparent quartz glass flow cell by air pressure, syringe, or peristaltic pump. The sample is then injected into the sheath fluid. The pressure of the sample fluid is higher than the sheath fluid, creating laminar flow in which the sheath fluid and sample move parallel to each other without mixing. This produces a central core stream of sample, surrounded by sheath fluid. If instrument settings are optimal, as the diameter of the flow cell narrows, the cells are organized into single file with each cell aligned in the center of the core stream. If this goal is achieved, illumination of each cell is consistent as it passes through one or more lasers focused in the center of the core stream.

The instrument optics includes lasers that illuminate cells, filters, and detectors that collect the resulting light scatter and fluorescent signals. Lasers emit light of a specific wavelength, and the number and wavelengths of the lasers available vary between flow cytometers. The site at which each laser is focused in the flow cell is referred to as the interrogation point. In colinear flow cytometers, multiple lasers are focused at the same interrogation point. Each laser in a parallel flow cytometer has a different interrogation point, so cells are illuminated on multiple occasions, and thus generate temporally separate signals for each laser that must be collated to link all the data generated by a single cell.[56]

When cells (or particles) move through the laser beam, they create light scatter. Low-angle or forward scatter (FSC) (i.e., 2°–20°) reflects cell size, although FSC is also influenced by other properties such as refractive index. Side scatter (SSC) refers to light that is deflected at high angles. This is influenced by the internal complexity of the cell (e.g., cytoplasmic granules) (Figure 142.1). Very small objects, such as circulating microparticles, are an exception to this general rule. For these particles, FSC or SSC may provide information about size, and the parameter that provides the best resolution varies between different flow cytometers (Figure 142.2).[67]

If specific targets on or within the cell have been stained with fluorescent labels, such as fluorochrome-conjugated antibodies, fluorescent signals are also emitted as cells move through a laser beam of the appropriate excitation wavelength. This excitation wavelength is absorbed by the fluorochrome and causes excitation of an electron. As the electron returns to its resting or ground state, it emits energy in the form of a light photon of lower energy and, therefore, longer wavelength than the excitation wavelength.

Fluorescent signals, FSC, and SSC are routed to detectors. Typically, this involves dichromatic mirrors that direct light to filters that restrict the wavelengths that reach each detector. Band-pass filters allow a narrow range of wavelengths to pass; short-pass filters allow only wavelengths of light below a certain threshold to pass, and long-pass filters allow only wavelengths above a certain threshold to pass. Filters can thus be constructed to allow only wavelengths that correspond to the peak emission wavelengths of specific fluorochromes to reach a particular detector. This combination of a filter and detector is often referred to as the channel for detection of certain fluorochrome (e.g., the fluorescein isothiocyanate (FITC) channel or green channel).

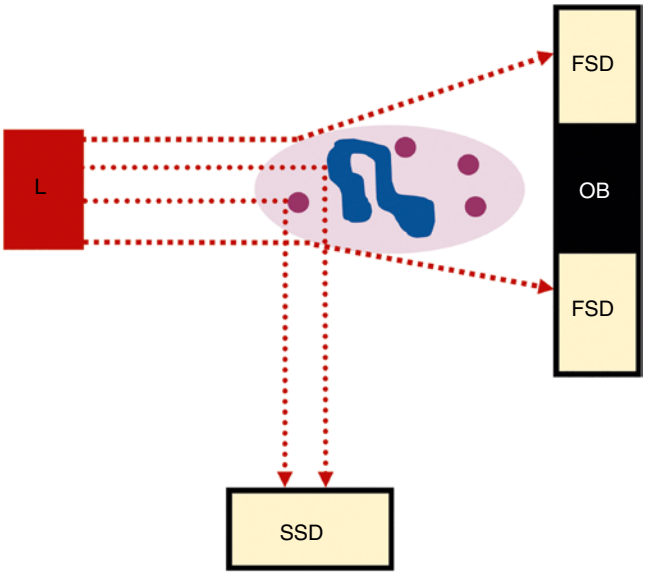

FIGURE 142.1 Cell size and complexity influence light scatter. When a laser (L) illuminates cells, this creates low-angle forward scatter, which reflects cell size. This light reaches the forward scatter detector (FSD), which incorporates an obscuration bar (OB) that blocks light coming directly from the laser source without deflection. Features of the cell, such as granules or membrane irregularities, create high-angle side scatter and these photons reach the side scatter detector (SSD), providing a measure of complexity.

Detectors convert light photons to electrons. There are several types of detector, but photomultiplier tubes (PMT) and photodiodes are used most commonly.[78] Photodiodes are light-sensitive semiconductors that are typically reserved for FSC, because they do not produce internal amplification of the signal and so can only be used for brighter signals.[78] Avalanche photodiodes are used in some newer flow cytometers and have a higher quantum efficiency in the infrared range than PMTs, used to detect fluorescence and side scatter in most instruments.[81]

Within the PMT vacuum tube, received light photons hit a photocathode. This results in emission of electrons, which in turn hit a series of dynodes that each emit increasing numbers of electrons. This creates a greatly amplified electric current by the time the photoanode of the PMT is reached. This electric current passes to a transimpedance amplifier, where it is converted to a voltage pulse, which is proportional to the photon signal originally received by the detector.[78] This pulse is further processed with subtraction of nonspecific noise by the baseline restorer and, in some cases, by an additional programable amplification step.[78]

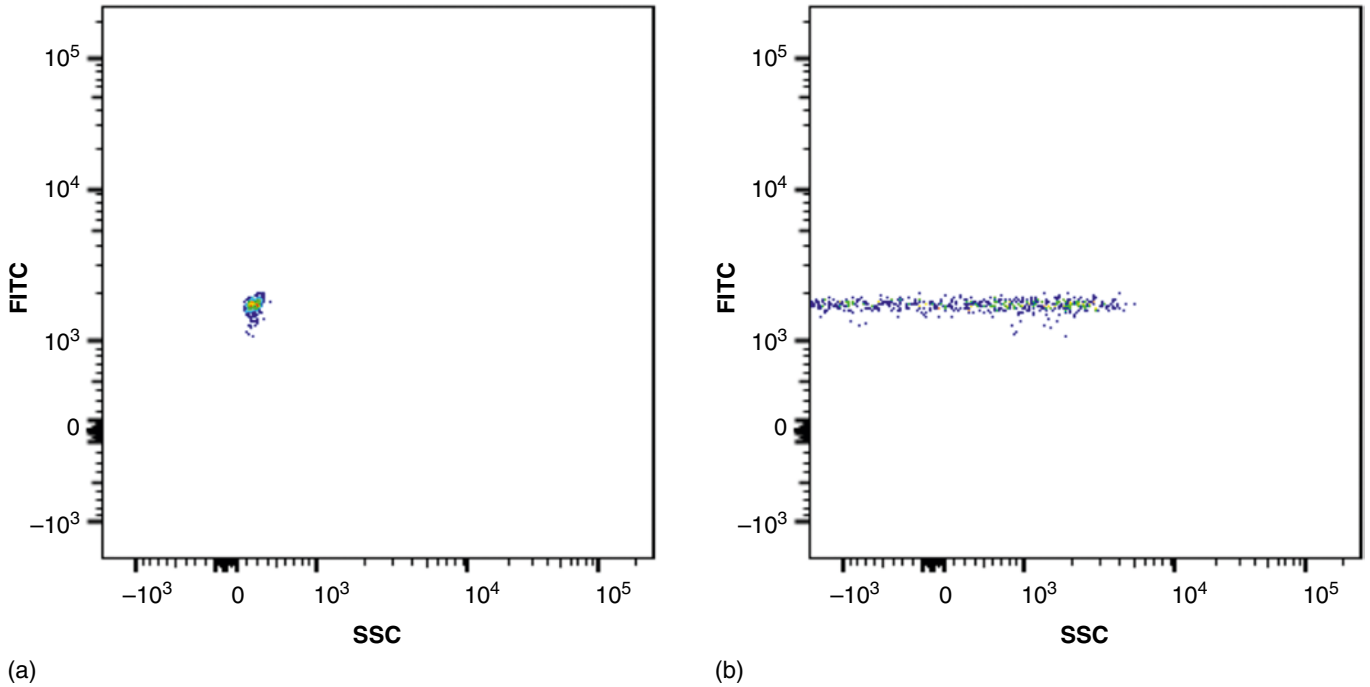

FIGURE 142.2 Side scatter provides better resolution than forward scatter for small particles on some instruments. Polystyrene sizing beads of 0.5 μM diameter were analyzed using a Fortessa X-20 (BD Biosciences). (a) When side scatter is plotted against fluorescence, a tight population is produced, reflecting the uniform diameter and fluorescence of the beads; (b) By contrast, forward scatter is highly variable, producing a dispersed population which does not accurately represent the size characteristics of the beads.

The combination of fluidics, optics, and electronics means that each time a cell passes through the laser interrogation point and generates photon signals, multiple voltage pulses are generated that reflect its FSC, SSC, and fluorescence. The peak of each pulse, referred to as the pulse height, reflects the maximum photon signal received from the cell by the relevant detector.[56] This maximum emission generally occurs when the cell is maximally illuminated in the center of the laser interrogation point.[56] The pulse area is a measure of the total amount of light emitted or scattered by the cell.[27,56] The pulse width reflects the duration of the pulse[56] and thus is influenced by the size of the cell.

For analysis, these continuous data are converted into more manageable discrete digital data by grouping similar values into categories, termed bins. The more bins used, the better the ability to distinguish differences in the signals generated by different cells (i.e., the better the resolution). These binned data are provided to the end user as a flow cytometry standard (FCS) file, which can be analyzed using flow cytometry software. Flow cytometry data analysis typically involves setting gates that group cells or particles based on FSC, SSC, and/or fluorescence properties. Populations can be compared using the percentage of cells classified as positive for a marker or combination of markers, or their median fluorescence intensity (MFI) for markers of interest.

Principles of Cell Sorting

Commonly available flow cytometers fulfill the requirements for many clinical and experimental hematology applications. There are more specialized flow cytometers available, including imaging flow cytometers (which allow concurrent microscopic imaging of individual cells) and cell sorters. Flow cytometric cell sorters typically use electrostatic focusing to separate and collect cells with specified flow cytometry characteristics for use in downstream applications, such as culture or further experimental analysis.

In most sorters, this is achieved by breaking the flow stream up into a series of single-cell droplets generated after cells pass through the laser interrogation point.[3] The time between a cell passing through the laser and being released in a droplet (termed the drop delay) should be constant.[3] This ensures that, when pulses detected by the electronics classify a cell as meeting the user's requirements, an electric pulse is applied to the droplet containing the same cell as it breaks off from the flow stream. This creates an electronic charge on the droplet, and as it subsequently moves through a strong electric field, it is deflected into a collection tube. Droplets that contain cells that do not meet the user's specifications are not charged and so move through the electric field without deflection into a centrally located waste channel. The success of cell sorting depends on correctly linking flow cytometry findings of one cell to a droplet containing the same cell, and consistently generating droplets that contain only single cells.[3] The conditions needed to achieve this are beyond the scope of this chapter, but references with more detail are provided.[3,15]

SAMPLE PREPARATION AND PROCESSING

The aim of processing flow cytometry samples is to achieve a single-cell suspension labeled for the markers of interest. General suggestions for achieving this are

discussed here, but specific samples and markers will have their own individual requirements. Detailed review of relevant literature before designing a protocol avoids producing inaccurate results due to preanalytical errors. For example, review of published guidelines regarding centrifugation conditions for microparticle studies is invaluable for investigators measuring microparticle concentrations for the first time.[38-40] Similarly, performing optimization experiments to confirm that a protocol consistently and efficiently generates reliable results before analyzing clinical or experimental samples can ensure high-quality data and allows removal or refinement of protocol steps to avoid wasting time or resources.

Preferred material varies with specimen and assay type. For immunophenotyping of peripheral blood and bone marrow aspirates, samples anticoagulated with EDTA are frequently used. This has the advantage that cellular morphology is well-preserved allowing concurrent cytologic assessment.[30] Flow cytometric evaluation of platelets can be performed on whole blood, platelet-rich plasma, or preparations that have been further purified (e.g., by gel filtration), with sodium citrate commonly used as the anticoagulant for functional assays. Platelet-rich plasma is collected by slow, room temperature centrifugation (e.g., 170 g for 10 minutes with no brake).[2] For veterinary patients where acceptable venipuncture volume may be limited, this slow centrifugation results in a low volume of platelet-rich plasma that is challenging to separate from blood. Mixing blood in a 1:1 or 1:2 ratio with a buffer such as buffered saline-glucose-citrate increases fluid volume, and platelet concentration is typically adequate for functional assays or further purification.[2]

Delay between sample processing and analysis leads to increased dead and dying cells. Nonviable cells display nonspecific antibody binding and altered marker expression,[31,80] release DNA that increases cell clumping,[3] and generate debris.[3,17] Delay in analysis may also alter responsiveness in functional assays,[10] alter autologous antibody binding in immunological assays,[43] and result in greater in vitro generation of microparticles.[39] For immunophenotyping of unfixed specimens, storage of up to 24–48 hours is typically considered acceptable. However, the maximum delay varies with sample type and marker of interest. For example, immediate analysis has been recommended for high-grade lymphomas, while blood for B-cell clonality screening may tolerate longer storage.[30] Heparinized whole blood from healthy dogs stored for 12–16 hours did not significantly alter expression of lymphocyte markers CD3, CD4, CD8, and CD21.[18] Immunophenotyping after 24 hours storage also did not alter clinical interpretation for six canine lymph node aspirates (three normal, three with lymphoma) stored in a buffer containing fetal bovine serum and EDTA.[22]

Addition of autologous serum, protein supplementation (e.g., fetal bovine serum or bovine serum albumin), or use of tissue-culture-specialized flow transport media may help preserve viability during transport and storage.[30] Potential undesirable effects of such agents should be considered; e.g., avoiding media that contains phenol red is recommended due to its contribution to background fluorescence.[30] Cell fixation at collection may prolong sample stability.[71] However, the reported success of immediately postcollection fixation protocols varies, and there are also marker-specific effects of fixation.[71] Frozen, cryopreserved peripheral blood mononuclear cells can also be used for flow cytometry, but cryopreservation may influence findings for some cell types.[6] Users should survey the literature and where necessary perform validation studies to determine the effects of storage and transport, particularly for functional assays and microparticle quantification. Even small details can have a major impact on such studies; e.g., microparticle quantification samples must be transported upright with minimal agitation until centrifugation to avoid in vitro microparticle generation.[39]

Many flow cytometry protocols involve keeping cells on ice during transport and processing. This may increase viability and reduce changes such as internalization of surface receptors and bound antibodies. However, this should be confirmed for the cell type and assay performed, as in some cases cooling cells may be unnecessary or undesirable.[30] Notably, cooling of platelets is generally avoided, as it can induce activation.[47]

Cells are usually washed and stained in a buffer that contains a source of protein (e.g., bovine serum albumin), which promotes viability and helps to block nonspecific antibody binding. The metabolic inhibitor, sodium azide, is commonly incorporated into buffers to prevent bacterial contamination and inhibit capping and internalization or loss of cross-linked antibody–antigen complexes. However, addition of sodium azide can reduce cell viability and negatively affect staining for some markers.[95]

Buffer formulation can be adjusted to reduce cell clumping. Large cell clumps can clog the flow cytometer, and smaller aggregates could generate data that reflects multiple rather than individual cells. Clumping can be reduced by use of calcium- and magnesium-free buffers, addition of EDTA, and if dead cells are in large numbers, DNase. Mesh filters can also be used before analysis to remove larger clumps.[3] Buffers can also be a source of debris, which is problematic when trying to separate small particles such as platelets or microparticles from background noise.[17] Filtering of buffers immediately before use is recommended for these samples.[17] Specific additives are required for some functional assays. For example, in plasma-based platelet activation assays, Gly-Pro-Arg-Pro amide is added to inhibit fibrin polymerization.[47]

For WBC flow cytometry, RBCs are usually removed during processing.[84] This removes a source of nonspecific binding and autofluorescence and ensures that events collected are relevant to the experimental or clinical question. Density gradients or RBC lysis by ammonium chloride or commercial lysing agents are described. Lysis has been recommended for immunophenotyping due to concerns about selective WBC loss with density

gradients.[84] The processing stage during which lysis is performed is variable, with some protocols requiring bulk RBC lysis as an initial step and others including a lysis step for each individual tube after staining.[84] Guidelines regarding timing of lysis steps for specific applications are available.[84] For example, stain–lyse–wash protocols are suggested as providing the best signal discrimination, but are recommended against when cell loss must be minimized.[84]

Cells are labeled by incubation with antibodies or other markers (e.g., nucleic acid dyes). This can be performed in tubes or a 96-well plate. Cell number added to each tube or well should be consistent, with a target of 10^6 cells per tube commonly suggested.[80] If labeling of intracellular markers is performed, fixation and permeabilization are necessary.[84] Fixation before or after staining can also be performed when staining surface markers, allowing greater flexibility in the timing of analysis, and reducing biosafety concerns.[30,84] However, fixation can alter staining properties and surface marker display, and should therefore be validated.[30,84] Fixation is also unsuitable if viable cells are required for downstream applications, e.g., culture of sorted cells.

Direct staining, in which the sample is incubated with primary antibodies conjugated to fluorochromes, is common. Two-step or indirect staining can also be performed by incubating cells with a primary antibody that is either unlabeled or tagged with biotin. Then, a secondary antibody that binds the primary antibody and is tagged with a fluorochrome; or for biotin-tagged primary antibodies, a fluorochrome bound to streptavidin. To avoid quenching of the fluorochromes, incubations are performed in the dark. This is particularly important for more unstable dyes, such as some tandem dyes.

Protocols often include multiple wash steps both before and after staining. However, washing is best minimized or avoided in some settings. This includes low cellularity samples and microparticle assays, as cells or microparticles will be lost during washing.[30] Platelets aggregate upon centrifugation, and washing therefore requires addition of inhibitors (e.g., prostaglandin I2). If washing is not performed, unbound antibody can be quenched by adding large volumes of buffer or fixative.[63]

Manually setting up flow cytometry assays carries a risk of technical error, particularly when large numbers of antibodies are added to a single tube, or large numbers of tubes with different combinations of antibodies are required. Use of commercial antibody cocktails reduces the risk of errors in antibody addition, but unfortunately these are currently not widely available for veterinary applications.[30] Users can make and store their own antibody cocktails; but it is important to confirm that this does not compromise assay performance due to aggregation or differences in storage requirements for different components of the cocktail.[30] Even if long-term storage of antibody cocktails is not possible, assay setups that combine larger volumes of antibody into a master-mix that is split between multiple tubes are preferable to repeatedly adding small volumes of antibody to different tubes, as this reduces pipetting error and risk of cross-contamination of antibodies. There is a move toward automating the staining process, which not only reduces the risk of error but increases traceability and has the potential to increase throughput.[26]

CHOICE OF ANTIBODY AND FLUOROCHROME

Antibody Selection

The ideal antibody for flow cytometry binds the target of interest with high-affinity and minimal off-target binding. When sourcing commercial antibodies, two basic considerations help with initial selection. First, purchase an antibody sold commercially as suitable for flow cytometry. Flow cytometry requires antibodies to bind epitopes in their native or near-native conformation rather than the denatured proteins typically used in western blotting. Flow cytometry may use different fixation techniques than immunohistochemistry and often omits antigen-retrieval steps. Therefore, an antibody that performs well in other techniques may not be suitable for flow cytometry. Second, source an antibody sold as cross-reactive with the species of interest, including for proteins that are generally well-conserved between species, as the epitope against which an antibody was raised may be outside evolutionary well-conserved regions.

Even when using an antibody sold as suitable for the application and species, investigators or laboratories should verify performance. There is variability between manufacturers in the assiduousness of antibody performance testing and differences in performance of antibodies sold by different manufacturers as reactive against the same target. Performance may also vary with different protocols and conjugates.[34] Investigator-performed validation often relies on obtaining expected staining patterns in cells known to be positive and negative for the marker of interest.[62] While suggestive of antibody binding to the target of interest, this does not directly confirm that the antibody is bound to the marker of interest. Furthermore, this approach may not be adequate to confirm acceptable performance in all samples. For example, staining may follow the expected pattern in cells from a healthy individual, but differences in the ratios of the protein of interest versus other antigens may result in off-target binding in some patient samples.[89] For clinical samples, correlation of flow cytometry results with cytology, histology, and clinical characteristics can help confirm performance.[62]

Use of alternative techniques, such as microscopy or western blotting, may provide additional evidence that the antibody is specific for the antigen of interest. These techniques have the advantage that they are widely available; but, as already discussed, antibodies may perform differently in different assays. More rigorous approaches to antibody validation have been recommended, but may be challenging to employ in a clinical setting.[89] These include genetic strategies in which expression of the protein of interest is eliminated; orthogonal strategies that compare results to an antibody-independent method,

such as mass spectrometry, and use of tagged proteins or independent antibodies binding the same antigen at a different epitope.[89] In addition to validation at initial purchase, it is important to confirm stable performance at each lot change.[23] When developing new multiantibody panels, confirming performance is similar using the antibody alone and in combination with other antibodies is necessary due to the possibility of steric hindrances and other interferences.[23]

To achieve good antibody performance, the staining protocol must be optimized. Undesirable binding may arise because an antibody recognizes multiple similar epitopes or recognizes an epitope shared by multiple antigens (i.e., specific but unwanted epitope recognition).[29] Alternatively, undesirable binding can be the result of nonspecific, weak electrostatic interactions or binding of the Fc portion of the antibody to Fc receptors on antigen-presenting cells.[29] Weak, nonspecific interactions can be minimized by antibody titration.[29] Several protocols are available. One of the simplest optimization techniques is to stain the same cell population with increasingly dilute antibody solutions. Then, calculate the ratio of median fluorescent intensity for the positive and negative cells.[13] The highest ratio provides the best balance between specific staining and background noise.[13] As discussed, dead and dying cells can be a significant source of nonspecific binding. Use of viability stains to identify and exclude dead cells from analysis helps to avoid misinterpretation of dead cells as cells with aberrant marker expression.[37] Fc blocking reagents can overcome nonspecific binding by Fc receptors, but endogenous plasma immunoglobulins perform the same function and render Fc blocking unnecessary for most blood-based assays.[37]

Fluorochrome Selection

There are several considerations when choosing fluorochromes. The laser must be capable of exciting the fluorochrome at the appropriate wavelength, and the filter must be able to detect the emitted wavelength. The next consideration is the extent to which each potential fluorochrome will distinguish positive versus negative cells for the marker of interest. This is influenced by several factors, including fluorochrome brightness, marker expression, and spectral overlap.[29]

Spectral overlap occurs when light emitted by multiple fluorochromes reaches the same detector.[29] To demonstrate this, consider selecting a second fluorochrome to use in a two-color flow cytometry experiment with a FITC-labeled antibody and a flow cytometer with 530/30, 585/40, and 675/25 filters. FITC has a 525nm emission peak, meaning it is most likely to emit photons of 525 nm, which can be detected using a 530/30 band-pass filter. However, FITC also emits lesser numbers of photons at longer wavelengths that could be detected by other filters. The probability of FITC emitting photons in the range detected using a 585/40 nm band-pass filter is greater than for those detected by a 675/25 filter. In other words, the FITC signal will spill over or bleed into the 585/40 filter. Selecting allophycocyanin (APC), which has an emission peak of 660 nm, as the second fluorochrome would therefore be preferable to R-phycoerythrin (PE), with its emission peak of 578 nm.

Compensation is a mathematical process which corrects for dye signal spill over into another detector, allowing combinations of fluorochromes with some spectral overlap (Figure 142.3).[49] However, while compensation brings the average fluorescence for the spillover channel to zero, it does not remove measurement

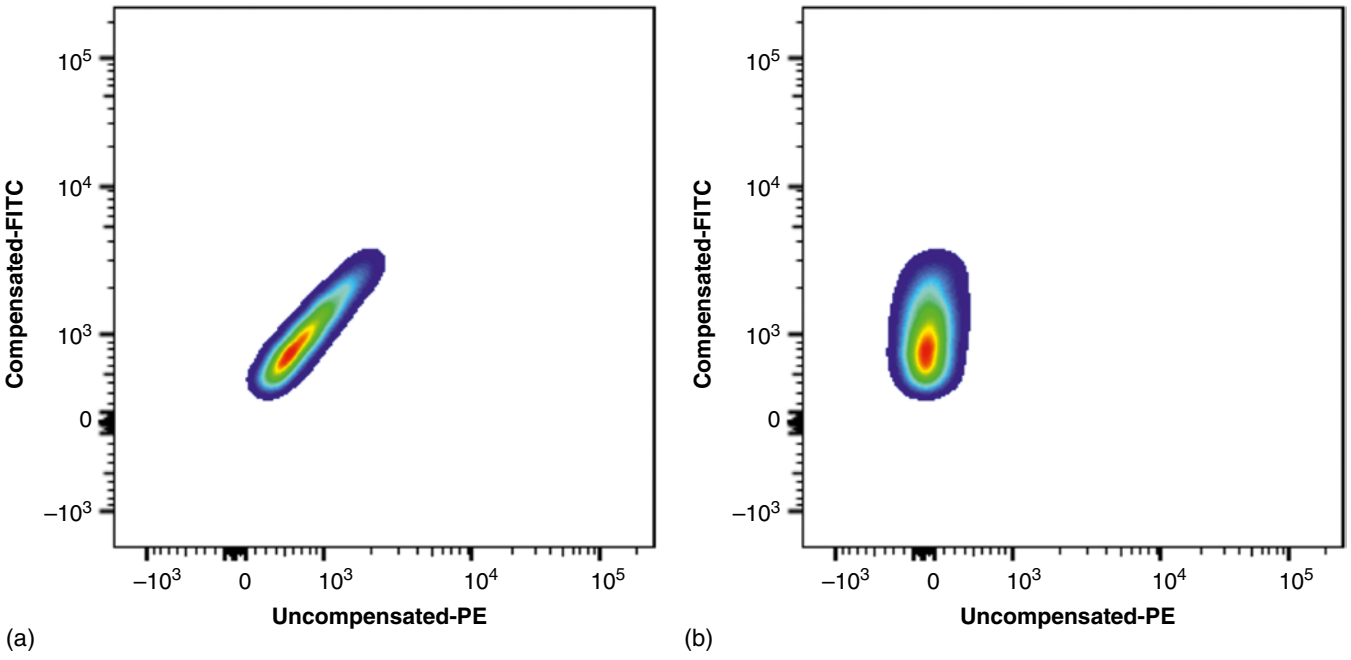

FIGURE 142.3 Compensation is a mathematical operation that corrects for spectral overlap between fluorochromes. Cells are shown stained with FITC alone. (a) Before compensation, there is spillover of the FITC signal into the PE detector; (b) Compensation corrects this spillover and brings the median fluorescence intensity for PE to zero.

error.[49] This creates data spreading, which reduces the ability to distinguish dim events from background noise in the compensated channel.[49] Therefore, combining fluorochromes to minimize spectral overlap improves sensitivity for markers expressed at low concentrations.[29] This can be challenging when constructing large multicolor panels, but semiconductor quantum dots can improve fluorochrome separation.[11] These manufactured nanocrystals have narrow emission spectra, so multiple quantum dots can be combined with minimal spectral overlap.[11] Additionally, quantum dots can be excited by a wide range of wavelengths, allowing multiple quantum dots to be interrogated using a single laser.[11]

Tandem dyes are another example of manufactured dyes that expand the number of fluorochromes that can be combined in a multicolor panel. These are covalently bound pairs of fluorochromes that display fluorescence resonance energy transfer (FRET). When excited by an appropriate wavelength, the donor fluorochrome transfers energy to the acceptor fluorochrome, resulting in emission of light. This can create an increased difference between excitation and emission wavelength, termed the Stokes shift. For example, PE has an excitation peak of 496 nm and an emission peak of 578 nm, but in the tandem dye PE-Cy7, the emission peak is shifted to 785 nm. Tandem dyes, therefore, facilitate construction of multicolor panels in which the same laser is used to excite multiple fluorochromes without excessive emission spectral overlap.

There are specific considerations when using tandem dyes. The efficiency of FRET is influenced by the ratio of donor to acceptor molecules, which may vary between lots.[58] FRET efficiency is also reduced if there is degradation of the tandem dye. This may occur during storage, particularly if conditions are not ideal (e.g., exposure to light, freezing),[58] or during incubation with cells.[42] If the donor fluorochrome emits energy without excitation of the acceptor, this could create misleading results. Consider an experiment using both PE- and PE-Cy7-conjugated antibodies. Unrecognized degradation of the PE-Cy7 fluorochrome would lead to cells binding this antibody being misclassified as positive for the marker detected by the PE-conjugated antibody.[49] Additionally, if the PE and PE-Cy7 antibodies are bound in close proximity to the same cell, FRET may occur between the two conjugates, resulting in quenching of the PE signal by its interaction with PE-Cy7.[58]

When deciding which fluorochrome to use for each marker of interest, the marker expression must be considered. Markers expressed at low concentration should be labeled using the brightest fluorochromes for adequate sensitivity.[49,58] Brightness depends on the specific fluorochrome's signal strength and the instrument's efficiency of detection. However, brightness is also influenced by the nonspecific signal generated by negative cells. This background noise is the result of both sample (e.g., autofluorescence) and instrument (e.g., electronic noise) properties.[58] The instrument-specific stain index provides a measure of brightness[49]:

(Median positive – median negative)/2*SD negative.

For detection of low-expression markers in multicolor panels, it is also necessary to consider the impact of other fluorochromes.[57] Sensitivity is reduced if the detector for a low-expression marker is also receiving signals from other fluorochromes.[57] This is influenced by instrument features (e.g., alignment, filters) and can be quantified by construction of a spillover spreading matrix.[57] The details of this technique for panel optimization are beyond the scope of this chapter, but are found in the reference provided.[57]

Non-Antibody-Based Probes

There are a number of non-antibody-based fluorescent probes. These include dyes used to distinguish live and dead cells (e.g., nucleic acid dyes, amine dyes, and vital dyes), nucleic acid probes to assess gene expression and phosphatidylserine-binding molecules for detection of platelet activation and apoptotic cells (e.g., lactadherin, annexin V). An advantage for veterinary studies is that these probes are generally not species-specific. However, users must be familiar with the properties of the specific probe. For example, annexin V binding to phosphatidylserine requires continuous exposure to calcium.

COMPENSATION AND GATING CONTROLS

Inclusion of controls is vital to ensure appropriate compensation and gating. Gating is the process of selecting cells of interest and relies on gating controls which allow the user to set boundaries that define cells as positive or negative for a specific marker.

Unstained Cells

An unstained, but otherwise identically processed sample allows autofluorescence assessment. In single-color experiments, unstained samples can often be used to define positive versus negative cell populations (i.e., as a gating control). However, when two or more fluorochromes are combined, an unstained control is not a suitable gating control because it will not reflect the background introduced by other fluorochromes.

Single-Stained Controls

For experiments using more than one fluorochrome, compensation controls are required.[50] These are stained with a single fluorochrome to allow quantification of the spillover signal from this fluorochrome into the detectors used for other markers.[50] To allow calculation of compensation, both a positive and a negative population must be present. In most situations, either cells or compensation beads can be used.[50]

Compensation beads can be purchased from numerous manufacturers and are typically a mix of polystyrene microspheres that capture antibodies (producing the positive population) and uncoated beads that do not (producing

the negative population). An advantage of compensation beads is that they can generate bright signals for fluorochromes that would produce only dim signals for cells which have rare- or low-expression markers.[50] Furthermore, beads consistently produce a clear separation between the positive and negative population. However, beads cannot usually be used for non-antibody-conjugated fluorochromes (e.g., nucleic acid dyes) and may not be suitable when autofluorescence is prominent (e.g., due to use of a violet laser or cell properties).[30]

Regardless of whether cells or beads are used, compensation controls should be handled identically to test samples to ensure any effects of the protocol (e.g., fixation, permeabilization) on the fluorochrome are taken into account.[50] It is also important that both the positive and negative populations should have similar autofluorescence (e.g., beads cannot be used as the negative control for cells or vice versa).[30]

Fluorescence Minus One (FMO) Controls

Fluorescence minus one (FMO) controls are prepared by staining cells with all but one of the antibodies used in a panel.[29] These controls allow the background signal generated by autofluorescence, spectral overlap, and data spreading revealed by compensation to be defined.[29] FMO controls are therefore required for multicolor studies, as unstained or single-stained controls would not reveal the full extent of spectral overlap and data spreading.[29] FMO controls are useful to define negative and positive gates, but FMO gates do not include the contribution from nonspecific binding of the omitted antibody.[50] Therefore, antibody titration and blocking steps must be optimized when using this approach.

Isotype Controls

Isotype controls are antibodies of the same class which are conjugated to the same fluorochrome as the assay antibody, but they do not recognize any antigens present in the sample.[29] In theory, isotype controls allow determination of nonspecific binding.[29] In practice, their use has fallen out of favor, with many authors advising against isotype controls for quantitative flow cytometry experiments detecting cell surface markers.[29,80] This reflects the difficulty in manufacturing an isotype control that perfectly matches the nonspecific binding characteristics of the assay antibody. For example, more cells may stain with an isotype control than a test antibody.[29] For immunophenotyping, gating based on naturally occurring negative populations within the sample has been proposed as an alternative to isotype controls.[80]

Other Controls

A number of other controls can be used for gating including gating controls that exploit marker-binding properties. For example, in platelet studies using annexin V to label exposed phosphatidylserine, a calcium-free buffer can be used as a gating control. As discussed in the earlier text, annexin V requires continuous exposure to calcium in order to maintain binding to phosphatidylserine. Any fluorescence of the calcium-free control therefore represents nonspecific binding, providing a threshold to distinguish positive versus negative populations. Cells known to be negative for the marker of interest can also provide an internal, negative control for gating.[29] However, nonspecific binding and autofluorescence can vary between different cells types.[29] Consequently, the internal negative population must be the same cell type as the positive population.[29] Differently treated cells can also provide biological gating controls.[50] For example, unstimulated cells could be used to define the negative population for a marker that is upregulated upon stimulation.[50] When determining if biological controls are suitable for gating, it is important to consider if experimental conditions may alter cellular properties, such as autofluorescence or nonspecific binding. There are also nonbiological controls that are useful in specific experiments, such as the sizing beads used for setting microparticle gates.[12]

Samples split into multiple aliquots and analyzed on multiple occasions can determine if assay performance is consistent over time.[50] For immunophenotyping, these often take the form of frozen cryopreserved peripheral blood mononuclear cells.[50] Such controls both monitor the consistency of analyzer performance and allow error detection in assay setup.

SAMPLE ANALYSIS

Instrument Setup

Several settings need to be defined by the user for experimental analysis. These include the number of events collected per tube or well. The more events collected, the greater the statistical power of the data analysis, but also the longer the acquisition time and the greater the risk of tubes running dry and air being introduced into the fluidics. For many analyzers, the default is to collect 10,000 events in a gate defined by the user, but this must be considerably increased for analysis of rare events.

Only events that reflect cells (or particles) of interest contribute to the statistical power of the analysis. To keep data file sizes manageable, the user can exclude events generated by cellular debris or electronic noise by defining the minimum signal that triggers data collection and storage, termed the threshold. Events below the threshold are ignored. The threshold should be set conservatively to ensure that useful data are not lost.[78] Typically, FSC is used to define the threshold, as in most instances both cells positive and negative for fluorescence are of interest.[97] Exceptions include DNA measurement of the cell cycle, or detection of very small objects such as bacteria. Sizing beads are commonly used for setting the threshold in microparticle studies.

Many flow cytometers require the user to adjust the PMT voltages to ensure that photon signal amplification received is optimal. The higher the voltages applied to

the PMT dynodes, the greater the number of electrons released and, thus, the greater the current generated in response to the photon signal received.[96] Therefore, if the PMT voltage is too low, cells generating dimmer signals will be missed. Whereas if the voltage is too high, excessive background noise will be generated. One commonly used approach to determine a baseline appropriate voltage is to assay a calibration bead that produces dim fluorescence (e.g., the peak 2 bead of the SPHERO Rainbow Calibration Particles) at progressively increasing voltages.[50] The coefficient of variation (CV) for the beads' fluorescence decreases as the voltages increase, reflecting improved signal to noise ratio.[50] Eventually, a plateau is reached beyond which increasing the voltage further does not improve the signal generated for the dim bead.[50] The voltage at which the plateau is reached provides an indication of the optimal voltage for that PMT on that instrument with the current optical configuration, but may change if alterations are made to lasers, filters, etc.[50] This baseline is a useful starting point for adjusting voltages for individual experiments.[50] If bright events for a fully stained sample containing cells that reflect the full range of expected fluorescence for the experiment are off scale, the PMT voltage can be reduced.[50] If cells, known to be negative events, are producing strong fluorescence signals, this is likely due to nonspecific staining (e.g., due to failure to adequately titrate antibodies), rather than voltage setup.[50]

The flow rate can also be adjusted. A slow sample flow rate increases data collection time, but improves hydrodynamic focusing, creating a narrow core stream.[98] This reduces coincident events, when two cells or particles pass through the laser interrogation point simultaneously. At slow flow rates, cells also move consistently through the center of the laser interrogation point, producing more constant illumination than at higher flow rates. This means slower flow rates produce better data resolution, which is particularly important when analyzing rare events and small particles. Flow rate should be kept constant throughout analysis, as gates set for data acquired at one flow rate may not be suitable for data acquired at another.

Data Collection and Analysis

Flow cytometry studies generally involve collection of FSC, SSC, and fluorescence data. This can be in the form of pulse height, pulse area, and/or pulse width. Pulse area (which depends on pulse height and width) is most commonly used for displaying and gating cells, but can be problematic for platelets and small particles. If the laser beam's diameter is similar to that of the cell or particle, pulse width is linearly related to particle diameter for most parameters.[27] This is not the case if the cell or particle of interest is smaller than the diameter of the laser beam, and so pulse height provides better resolution of particles and platelets than pulse area.[40]

Coincident events can be generated when two individual cells pass through the laser beam simultaneously, or when aggregates (often referred to as doublets) form between two or more cells. Signals from these pairs of cells cannot be separated by the electronics. If they are not recognized as an artifact, results may be misleading.[36] Coincident events and doublets have similar pulse height to individual cells, but take longer to pass through the laser, increasing pulse width and area. This means that when FSC or SSC area or width is plotted against height, doublets and coincident events lie away from the linear distribution of the main population of individual cells. Linear distribution assessment cannot be used for small particles, as the relationship between particle diameter and pulse width is not linear. Instead, coincident and swarm events are identified by a lack of linearity when samples are diluted.[35] Use of light scatter properties for doublet identification may also be unsuitable if these properties are altered by experimental conditions.[9]

Automated flow cytometry data analysis is an area of active research.[74] Currently, most flow cytometry analyses rely on manual gating.[74] This is usually performed on data displayed as one-parameter histograms or two-parameter plots. Most commercial flow cytometry software also allow construction of more complex data displays of three or more markers, but these are challenging to use for manual gating.

Gating often follows a hierarchal or sequential approach, in which a subpopulation of cells is selected by an initial gate, and then broken down into smaller subpopulations by subsequent gates. This is referred to as parent–child gating, as the later "child" gate contains only cells from the earlier "parent" gate. Combination Boolean gating can identify complex subpopulations, using AND, NOT, and OR gates.[97] Back gating can be used to verify that placement of earlier gates has not led to loss of cells of interest.[97] This is particularly useful if population characteristics change due to experimental conditions. For example, a platelet gate set based on resting platelets may exclude a significant proportion of stimulated platelets, and if this is not recognized, display of activation markers may be underestimated.

Flow cytometry results can often be reported as the percentage of cells positive for a particular marker or combination of markers. Absolute concentrations, rather than percentages, are reported by flow-cytometry-based hematology instruments and in a number of other flow cytometry applications including microparticle quantification, CD34+ enumeration, and WBC contamination assessment in leukoreduced blood products. For volumetric flow cytometers, the sample volume is recorded and subpopulation concentrations can be calculated directly.[21] In other systems, concentrations can be calculated based on counting beads added at a known concentration to each flow cytometry sample[66] or derived from CBC data and flow cytometry percentages collected concurrently.[14,21]

For markers that show a staining continuum rather than discrete positive and negative populations, it may be necessary to report staining intensity. This can involve broad categories such as dim versus bright, as is frequently reported for immunophenotyping markers whose staining intensity has prognostic significance.[14] The European Canine Lymphoma Consensus Network

has recommended that where possible this classification expression should be based on comparing the staining intensity of neoplastic cells to that of the nearest normal hemic population.[14] When more subtle changes in marker expression have clinical or experimental consequences, MFI or indices derived from MFI comparisons (e.g., ZAP-70 expression index for human chronic lymphocytic leukemia) between cell populations may be reported quantitatively.[53] MFI is sensitive to small changes in sample processing and instrument performance, and therefore close attention to quality control is particularly important.[53]

QUALITY ASSURANCE

Flow cytometry shares many general quality control requirements with other assays (see Chapter 137). These include the need for staff training and competency assessment, standard operating procedures for sample handling and processing, instrument maintenance, reagent quality assessment (e.g., verifying lot-to-lot performance),[23] appropriate control selection, reporting, and quality control procedures. To ensure ongoing adequate performance, the laboratory must implement a quality control protocol incorporating both statistical and nonstatistical components.[80]

Flow cytometry also has specific requirements related to instrument quality control. During the initial setup phase and after maintenance or alterations to configuration, extensive instrument validation is required.[80] These validation procedures are typically performed by a manufacturer's representative and are not discussed here, but references are provided for readers requiring more detailed information.[64,80,96] Proficiency testing is desirable for clinical assays, but can be challenging for flow cytometry assays that use unfixed cells.[70] Frozen, cryopreserved peripheral blood mononuclear cells or stabilized samples[70] may provide suitable alternatives to fresh specimens for proficiency testing (see Chapter 138). Flow cytometers and hematology instruments incorporating flow cytometry require regular cleaning to maintain resolution, and thus tight CV for quality control and sample particles or cells.[84] Statistical quality control requirements vary between instruments and applications. For research flow cytometers, there are numerous software and quality control material options, which often involve manufacturer-specific indices and protocols. These generally include PMT standardization, checks on optical alignment, laser power and fluidics, assessment of sensitivity and linearity, and compensation checks.

A brightly fluorescent commercial quality control bead can be used to monitor PMTs. Either the voltage required to obtain a specific MFI or the MFI achieved for a set voltage can be measured for each PMT. MFI or voltage can be compared to predefined targets and plotted against time in a Levey–Jennings plot for early detection of performance shifts.[61,64] At the time of writing, veterinary guidelines that define acceptable performance are not available, but published targets include a <5% change in voltage to achieve a MFI located between the 10th and 90th percentiles of at least 20 replicates[64] or ≤15% change in MFI for a specific voltage.[33] Failure to achieve a target may be due to faulty PMT, loss of laser power, a dirty filter, or improper optical alignment.[33,64]

Optical alignment refers to the focusing of lasers on the core stream center, the detectors, and filters which may scatter light.[74] This can be assessed using alignment particles, which have very uniform size and fluorescence, and therefore a small CV when analyzed on a correctly aligned flow cytometer.[74] Adjusting alignment to maximize peak height and minimize CV allows the user to set-up flow cytometers that require daily alignment (e.g., most cell sorters), while monitoring shifts in CV for standardized beads alerts users to problems in instruments with fixed alignment.[64,74]

Linearity is necessary for correct compensation, and is commonly assessed using combinations of multiple quality control beads of known, differing intensities.[74,84] Fluorescence sensitivity is the ability of the flow cytometer to resolve dim particles from background noise or unstained particles.[74] This can be assessed directly using a combination of unstained and dimly stained particles.[74,84] Alternatively, detector performance can be summarized using mathematically derived Q and B statistics based on light-emitting diodes (LEDs) or fluorescent particles.[74] Q is the number of photoelectrons generated in the detector per fluorochrome molecule, and B is the number of fluorochromes that would produce the amount of background light detected.[28]

APPLICATIONS IN VETERINARY CLINICAL LABORATORIES

Hematology Instruments

Counting blood cells automatically began in the 1930s with a photoelectric method using dark-field optics. In the 1950s and 1960s, electrical impedance technology was developed, which exploits the poor electrical conductivity of cells. In impedance instruments, cells are suspended in an electrolyte solution and pass through a small aperture between two electrodes, creating changes in conductance that are proportional to cell size. By comparing the voltage peak created by each cell to voltage threshold established for particles of known size, cells could be classified by cell type and indices such as mean cell volume (MCV). Alternatively, cells can be identified using floating thresholds, where a valley is identified between two distributions in order to identify the threshold which best distinguishes different cell types in the individual sample.

In the mid-1970s, the Ortho Diagnostics Systems entered the multiparameter hematology instrument market and launched a cell-counting instrument which was based on laser light scatter and utilized the concept of hydrodynamic focusing. Numerous hematology instruments are now available which incorporate flow

cytometry, either as the sole means of analysis or in combination with impedance technology. These include reference laboratory analyzers (e.g., ADVIA 120 and ADVIA 2120i, Siemens Medical Solutions; Sysmex XN-V series, Sysmex Corporation) and benchtop instruments suitable for in-clinic use (e.g., ProCyte Dx manufactured by Sysmex and distributed by Idexx; Element HT5, Heska Corporation). The American Society for Veterinary Clinical Pathology has released quality assurance guidelines for point-of-care testing, which include specific recommendations for statistical and nonstatistical quality control of benchtop hematology instruments.[19] Flow cytometry can enumerate RBCs, WBCs, and platelets in peripheral blood, and provide descriptive indices. Some instruments can also provide valuable information for other samples, including bone marrow, body cavity effusions, and cerebrospinal fluid.

RBC Measurands

ADVIA hematology instruments rely exclusively on light scatter for measurement of RBC count and MCV. To ensure light scatter reliably reflects cell volume rather than cell shape, cells are converted to spheres by treatment with sodium dodecyl sulfate and fixed with glutaraldehyde.[32] FSC (2°–3°) generated by these sphered cells is proportional to cell volume (V) and SSC (5°–15°) to hemoglobin concentration (HG).[32] These are displayed to the user as individual histograms and as a RBC V/HG cytogram, in which the FSC for each RBC is plotted on the *y*-axis and SSC on the *x*-axis (Figure 142.4).[32] This plot allows rapid recognition of shifts away from a normocytic, normochromic RBC population, such as microcytic hypochromic RBCs in iron deficiency, or abnormal subpopulations including RBC aggregates in an agglutinating sample.[32] Several indices are calculated from the light scatter measurements, including MCV, red cell distribution width (RDW), and corpuscular hemoglobin concentration mean (CHCM). ADVIA systems also provide a colorimetric HG measurement after lysing RBCs, from which mean corpuscular hemoglobin concentration (MCHC) is calculated.[8] Discrepancy between MCHC and CHCM can provide insights into potential interferences. For example, MCHC but not CHCM will be falsely increased by lipemia, severe hemolysis, or Heinz bodies.

The Sysmex XT-2000iV combines flow cytometric and impedance technology and thus provides both an optical (RBC-O) and impedance (RBC) RBC concentration.[59] Comparison of these two measures can identify inaccuracies in quantification, as has been described for a dog with a discrepancy between RBC-O and RBC because leukemic cells or cell fragments falsely elevated RBC-O.[59]

Reticulocyte Measurands

Flow cytometry detects both cell volume and RNA content. The latter can be measured using fluorescent stains (e.g., polymethine), optical light scatter, or absorption created by dyes such as new methylene blue. Flow cytometry offers considerable advantages over manual reticulocyte counts, notably increased precision. Manual canine reticulocyte counts performed by a single technician are reported to have a CV of 19–23%[1] as compared to 1–6.1% for automated reticulocyte counts reported by the Sysmex XT-2000iV.[8] However, automated reticulocyte counts are susceptible to interferences including false increases due to Howell–Jolly bodies, neoplastic WBC fragments,[59] or intra-RBC parasites such as *Babesia* spp.[65] There are also species-specific considerations, as illustrated by the good correlation between manual counts of feline aggregate reticulocytes and automated reticulocyte counts by the Sysmex XT-2000iV.[44] It is also necessary to use instrument-appropriate reference intervals and criteria for defining anemia as regenerative, because automated counts are typically higher than manual counts in normal animals.[54] Further information on manual reticulocyte counts is provided in Chapter 137.

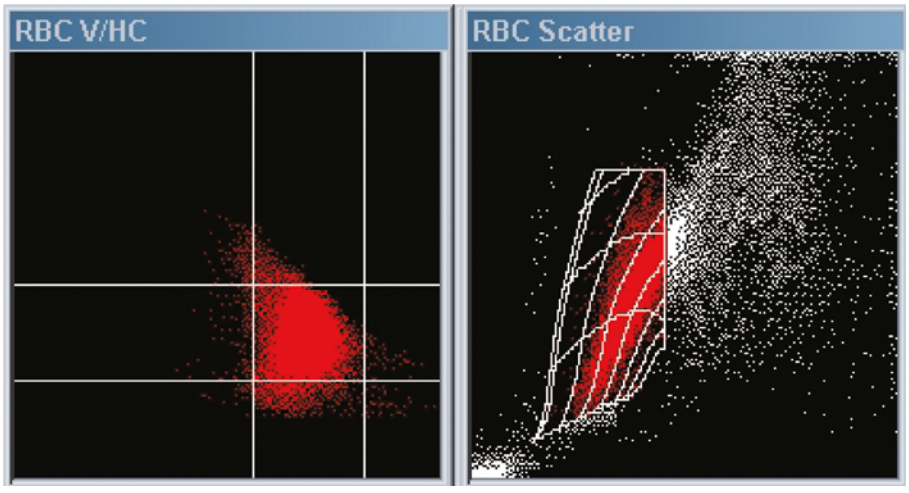

FIGURE 142.4 Red blood cell scatter cytogram and corresponding RBC V/HG cytogram of a normal dog. The RBC scatter cytogram displays high-angle light scatter (5°–15°) on the *x*-axis and low-angle light scatter (2°–3°) on the *y*-axis. The RBC V/HG cytogram displays hemoglobin concentration on the *x*-axis and RBC volume on the *y*-axis.

Flow cytometry can provide further characterization of reticulocytes including reticulocyte volume and hemoglobin concentration, such as the mean cell volume reticulocyte (MCVr), reticulocyte cellular hemoglobin content (CHr), and corpuscular hemoglobin concentration mean reticulocyte (CHCMr) reported by ADVIA analyzers or the reticulocyte hemoglobin equivalent (RET-H*e*) provided by the ProCyte.[20,73] Reduced CHr has been reported in dogs with absolute iron deficiency, but similar reductions occur in other conditions, including inflammatory disease and portosystemic shunts.[51,69,73,79]

WBC parameters

The ADVIA hematology systems use two methods for flow cytometric WBC assessment, the peroxidase channel and the basophil or lobularity channel.[7] Both the peroxidase and basophil channel provide a total WBC count, with the basophil channel usually reported. The instrument will flag discrepancies between the two counts, providing internal quality control. For the peroxidase channel, WBCs are treated with 4-chloro-1-naphthol, which is converted to a dark precipitate by those cells with endogenous peroxidase activity.[72] Cells are gated based on FSC (i.e., size) and peroxidase-staining intensity, producing a five-part differential consisting of neutrophils, eosinophils, lymphocytes, monocytes, and large unstained cells (Figure 142.5).[7,54,82] Feline eosinophils lack peroxidase activity, and are instead identified by light-scatter and oxazine-750 staining in the reticulocyte channel.[7,54] The instrument provides a PEROX cytogram with FSC on the *y*-axis and peroxidase staining on the *x*-axis.[82] This allows the user to screen for inaccuracies in the WBC differential, such as reduced peroxidase activity in immature neutrophils resulting in merging of the neutrophil population into the monocyte gate when a left shift is present.[82]

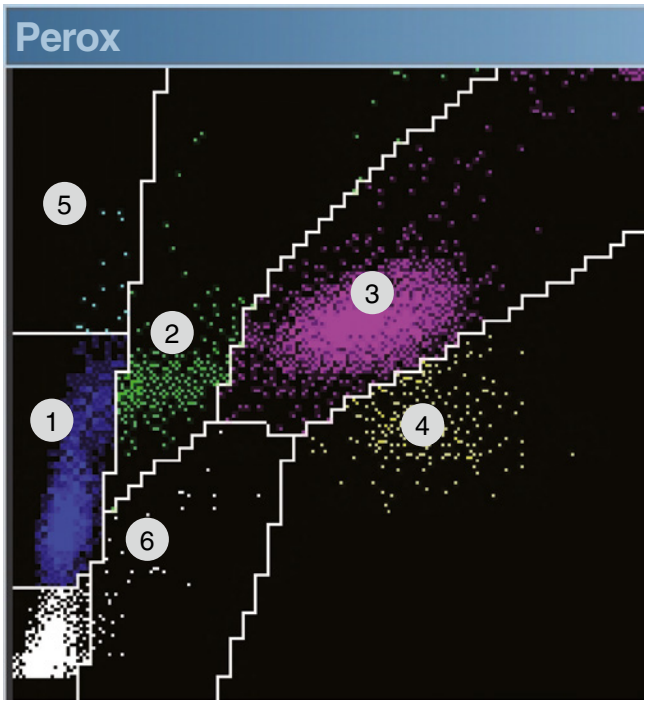

FIGURE 142.5 Peroxidase (PEROX) cytogram of a healthy dog. Cells are gated using light absorption, proportional to peroxidase staining, on the *x*-axis and cell size on the *y*-axis. Gate 1: lymphocytes; gate 2: monocytes; gate 3: neutrophils; gate 4: eosinophils; gate 5: large unstained cells; gate 6: platelet clumps.

In the basophil/lobularity channel, WBCs are lysed and the cytoplasm removed by treatment with phthalic acid and surfactant.[82] The bare nuclei are then gated on FSC (i.e., size) and SSC (i.e., nuclear density/lobularity), allowing cells to be classified as mononuclear (i.e., lymphocytes, monocytes), polymorphonuclear (i.e., neutrophils, eosinophils), or lysis-resistant.[82] In rabbits and humans, basophils are lysis-resistant, allowing differentiation of basophils from other WBCs by the ADVIA systems.[46] Canine and feline basophils are lysed, resulting in unreliable basophil counts in these species.[46] The ADVIA systems provide a BASO cytogram with FSC on the *y*-axis and SSC on the *x*-axis, and the predrawn gates allow the user to rapidly identify changes that may have clinical significance. Examples include increased lysis-resistant cells in leukemia, a lack of separation between mononuclear and polymorphonuclear populations, or shortening of the polymorphonuclear population, consistent with a left shift.[82]

The Sysmex XT-2000iV also identifies basophils by lysis resistance, as displayed on the WBC/BASO channel cytogram, with the same limitations as the ADVIA 120/2120 in veterinary species.[45] The Sysmex XT-2000iV's second WBC channel separates WBCs into neutrophils, lymphocytes, monocytes, and eosinophils based on SSC (i.e., complexity) and staining with polymethine, which binds nucleic acids and cytoplasmic organelles (Figure 142.6).[45] The ProCyte DX is a benchtop instrument that also provides a WBC differential based on SSC and fluorescent measurement of nucleic acid content.[45] Both instruments provide error flags and the Sysmex XT-2000iV will block reporting of the differential cell count if cell populations are not clearly separated. However, visual inspection of the provided scattergram appears more sensitive to potential errors.[45,87] For example, in a study analyzing 106 feline blood samples analyzed on the ProCyte DX, 14 samples had overlapping neutrophil and lymphocyte populations resulting in lymphocyte concentration overestimation and underestimation of neutrophil counts, but only nine samples were flagged by the instrument.[87] Using this methodology, lack of separation of neutrophils and lymphocytes is common in samples with a left shift and toxic change, due to increased RNA content in neutrophils.[87]

Platelet Measurands

In-clinic instruments generally rely on impedance for platelet counts and assessment of platelet indices, such as mean platelet volume (MPV). The Sysmex XT-2000iV generates both impedance (PLT-I) and optical platelet counts (PLT-O), and the agreement between these two

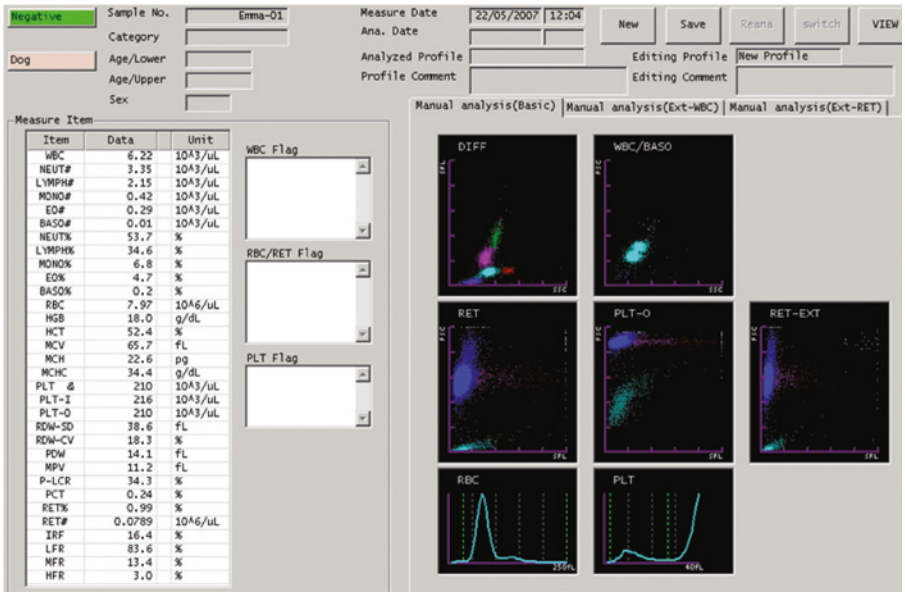

FIGURE 142.6 Routinely available data reported by the Sysmex XT-2000iV (canine sample). On the left, numerical data; and on the right, the graphical report including plots of the WBC SSC (i.e., complexity) against side fluorescence (DIFF) and FSC against side fluorescence for reticulocytes (RETIC) and platelets (PLT-O).

indices is a useful indicator of potential interferences.[77] For the Sysmex XT-2000iV, optical characterization of platelets relies on FSC to measure size, and fluorescent measurement of RNA content.[85] These data are displayed as a cytogram with FSC on the *y*-axis and fluorescence on the *x*-axis.[85] RNA measurement allows user-specified gates to be constructed for identification of immature platelets with increased RNA content, termed reticulated platelets.[60] The Sysmex XT-2000iV can provide optical platelet indices including MPV and the calculated value, plateletcrit (PCT),[60,77] but does not consistently report these; e.g., if the impedance platelet histogram is flagged as abnormal.[77,86] A potential source of confusion when reviewing the veterinary literature is the use of "plateletcrit" to both describe the calculated value from optical systems and the direct measurement by quantitative buffy coat analyzers.[86,88]

The ADVIA hematology analyzers use flow cytometry alone for determining platelet count.[8] Data collection and reporting are similar to RBCs, with a number of graphical displays generated from light scatter by sphered platelets. This includes individual histograms and the PLT scatter plot, in which SSC is plotted on the *x*-axis and FSC on the *y*-axis.

Provision of scatter plots or cytograms by both instruments allows the user to rapidly identify abnormities such as large platelets or potential interferences such as RBC ghosts.[85] The ADVIA systems report several optical platelet measurements, including MPV and the calculated PCT. Evidence regarding the clinical utility of platelet indices in veterinary species is limited, but the PCT (determined by an ADVIA 120) increases above a predefined threshold earlier than platelet count in dogs recovering from immune-mediated thrombocytopenia.[75] This suggests PCT may be valuable for monitoring platelets in patients with increased MPV.[75] The ADVIA 2120 has been reported to underestimate PCT of healthy Cavalier King Charles Spaniels compared to a quantitative buffy coat analyzer, particularly those with the most severe breed-associated macrothrombocytopenia.[88] This, at least in part, likely reflects exclusion of large platelets from the platelet gate by the ADVIA 2120 and other instruments.[88]

Immunophenotyping

Immunophenotyping is the process of identifying cells based on antigen display. In veterinary medicine, immunophenotyping is most commonly applied to the classification of lymphoproliferative or myeloproliferative disorders based on lineage-specific markers (see Chapters 63 and 64). These classifications provide prognostic information[4,16,76,94] and have the potential to guide therapy, e.g., by distinguishing mediastinal lymphoma from lymphocyte-rich thymoma.[41] Immunophenotyping can also be used to evaluate lymphocyte alterations in primary or acquired immune deficiencies, such as X-linked severe combined immunodeficiency[25] or feline immunodeficiency virus,[52] and immune-mediated diseases such as immune-mediated hemolytic anemia (IMHA)[83] (see Chapters 35–38). Immunophenotyping also has applications in transfusion medicine, such as detection of platelet surface antigens.[48]

Functional Assays

Flow cytometry is used in a number of WBC and platelet functional assays (see Chapters 78 and 79). One major advantage of flow cytometry in platelet functional assessment is the concurrent assessment of platelet activation, using markers such as phosphatidylserine

exteriorization or P-selectin expression and microparticle release in response to stimuli. This allows recognition of subtle platelet function defects, such as reduced microparticle release in canine Scott syndrome.[10]

Investigation of Immune-Mediated Disease

Flow cytometry can be used to detect increased antibody binding to RBCs, neutrophils, or platelets (see Chapters 35–38 and 80). Increased antibody binding may be consistent with primary or secondary immune-mediated disease, but sensitivity and specificity of each assay and the effect of time delay between sample collection and analysis should be considered.[93] Initial studies suggested that detection of RBC-bound immunoglobulins by flow cytometry had a high sensitivity for IMHA in dogs and horses. When sick animals were included as controls, there was a lower specificity than direct Coombs testing.[68,92] In two larger studies, 18 of 54 dogs[24] and 5 of 22 dogs[55] with clinical findings consistent with IMHA were negative for RBC-bound antibodies, suggesting diagnostic sensitivity may be lower than initial estimates when in routine use. Publications regarding detection of neutrophil-bound IgG describe only a small number of cases, but do suggest that this may be helpful in diagnosis of immune-mediated neutropenia.[90,91] Direct assays for detection of platelet-surface-associated IgG are reported to be 30–77% sensitive for primary immune-mediated thrombocytopenia in dogs[5,93] with a specificity of 76%.[5]

CONCLUSION

High-quality flow cytometry data require stringent quality assessment with attention to assay validation as well as instrument monitoring and maintenance. When quality assurance is in place, flow cytometry has the potential to improve diagnosis and treatment of clinical patients, as well as provide experimental insights that will lead to improvements in future care.

CHAPTER 143

Testing for Immune-Mediated Hematologic Disease

K. JANE WARDROP, MELINDA J. WILKERSON, and CINZIA MASTRORILLI

Coombs Test
  Methodology
  Diagnostic Significance
  Alternate Technologies for Antiglobulin Tests
Antineutrophil Antibody Tests
Antiplatelet Antibody Tests
Antinuclear Antibody Test
Investigation of Drug-Induced Autoantibodies
  Method of Antibody Detection
  Drug-Induced Hematologic Disease in Veterinary Medicine

Acronyms and Abbreviations

ANAs, antinuclear antibodies; DAT, direct antiglobulin test; dsDNA, double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; FITC, fluorescein isothiocyanate; FSC, forward scatter; hnRNPs, heterogeneous nuclear ribonucleoproteins; IAT, indirect antiglobulin test; ID, immunodiffusion; IIF, indirect immunofluorescence; IMHA, immune-mediated hemolytic anemia; IMN, immune-mediated neutropenia; IMT, immune-mediated thrombocytopenia; ITP, immune thrombocytopenia; Jo-1, histidyl tRNA, synthetase; LE, lupus erythematosus cell; LIA, line immunoassay; MCTD, mixed connective tissue diseases; PBS, phosphate-buffered saline; PCNA, proliferating cell nuclear antigen; PM–Scl, polymyositis–scleroderma antigen; PSAIg, platelet-surface-associated immunoglobulins; RBC, red blood cell; RBMX, RNA-binding motif protein, X chromosome; RNP, ribonucleoproteins; ROC, receiver operating characteristic; Scl-70, topoisomerase I antigen; SLE, systemic lupus erythematosus; Sm, Smith antigen; SS-A/Ro, Sjögren's-syndrome-related antigen A; SS-B/La, Sjögren's-syndrome-related antigen B; SSC, side scatter.

Immune-mediated hematologic diseases such as immune-mediated hemolytic anemia (IMHA), immune-mediated thrombocytopenia (IMT), immune-mediated neutropenia (IMN), and disorders such as lupus erythematosus have been previously described in veterinary medicine (see Chapters 35–37, 43, 52, and 80). Testing typically involves detection of antibody directed against cellular antigens. This chapter will describe specific tests available for the diseases mentioned in the preceding text.

COOMBS TEST

The Coombs test, also known as the antiglobulin test, is used to detect antibody and complement on the surface of RBCs in IMHA diagnosis. Antibodies directed against the RBC surface cause premature RBC destruction. These are often incomplete antibodies that sensitize or coat RBC, but fail to agglutinate them without addition of potentiators to alter the RBC zeta potential or without the addition of antiglobulin reagent. Most incomplete antibodies are IgG and are thus detected by anti-IgG serum, as contained in antiglobulin reagent. IgM antibodies also can be incomplete. These incomplete antibodies produce antibody-dependent complement activation; thus, antiglobulin reagents are also designed to react with complement components on the RBC surface, with the main components detected being C4 and C3. Polyspecific reagents for veterinary use typically

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.

contain anti-IgG, anti-IgM, and anti-C3. Monospecific reagents are also available.

Methodology

Two forms of the Coombs test are used in veterinary medicine: the direct antiglobulin test (DAT) and the indirect antiglobulin test (IAT). The DAT, that detects immunoglobulin and/or complement bound directly to RBC, is used to evaluate IMHA patients (see Table 143.1). In this procedure, the addition of antiglobulin reagent to RBC with bound immunoglobulin or complement causes agglutination. The IAT detects unbound antibodies against RBCs in the patient's serum, and is used in crossmatching or antibody screening. The antiglobulin test can also be performed using microdilution (microtiter) plates, immunochromatography strips, gel columns, and capillary tubes.[70] Microdilution plates allow for a greater number of antiglobulin reagent dilutions and use smaller volumes of reagent and RBC per well. The use of multiple dilutions increases test sensitivity.[10]

A comparison of four different direct Coombs test methods in anemic and nonanemic dogs showed comparable and consistent results, even after storage of chilled blood samples for 1 week.[10] Using polyclonal antiglobulins, the immunochromatographic strip, capillary, and gel microcolumn methods were compared to a standard microtiter DAT. Transfusion did not cause false DAT+ results, and dogs treated with immunosuppressive drugs still remained DAT-positive for days to weeks.

Diagnostic Significance

The Coombs test is most commonly used in IMHA diagnosis in veterinary medicine. The antiglobulin test, as an aid in IMHA diagnosis in dogs, was first described by Miller et al. in 1954.[48] Direct antiglobulin test positive hemolytic anemia was first described in cats in 1973 by Scott et al.[60] Several studies which used the antiglobulin test to detect IMHA in horses have been described.[43,47]

Sensitivity of the DAT in IMHA detection can be variable, with sensitivity as low as 48% reported in dogs.[32] However, the test remains a useful diagnostic tool, especially when combined with clinical signs of hemolytic anemia, spherocytosis, and persistent autoagglutination. False negative test results may be caused by incomplete RBC washing, insufficient RBC-bound antibody, elution of Ig or C3, or prozone effect.[52,71]

Interestingly, false positive results in the absence of IMHA can also occur. Dogs with infections, inflammatory disorders, and myeloproliferative and lymphoproliferative diseases have been reported to have a high incidence of C3b bound to RBC.[62] Hemolytic disease in these dogs was minimal or absent. A positive DAT needs to be interpreted with caution with concurrent conditions. In another study, 16 of 20 anemic cats were DAT-positive. Eleven of the 16 were feline leukemia virus (FeLV)-positive, and the remaining five positive cats had inflammatory disease or hemoplasmosis. The prevalence of positive antiglobulin tests in 89 healthy cats was recently documented.[1] A direct, microtitration antiglobulin test at 37, 23, and 4 °C was used. At 37 °C, only four cats were positive at a low dilution (1:2), and two cats were transiently positive at a high dilution (≥1:2048). At 4 °C, 91% of the cats had invalid results, and agglutination was present in the negative control well. Optimization and validation of the DAT to minimize analytical error are required prior to use in IMHA diagnosis.

Alternate Technologies for Antiglobulin Tests

Most of the alternate DAT technology has been designed to either increase test sensitivity or decrease the subjectivity associated with agglutination assessment. Enzyme-linked antiglobulin tests appear to enhance sensitivity, but are difficult to perform and decrease the diagnostic specificity for IMHA.[4,33] Flow cytometry has been shown to be a sensitive diagnostic technique for IMHA in dogs and horses, with some decrease in specificity.[56,75] Flow cytometry has been used to determine RBC-bound immunoglobulin isotypes in dogs with IMHA. Results suggest that IMHA dogs with two or more immunoglobulin isotypes have a more severe degree of anemia, spherocytosis, and autoagglutination.[29] The test necessitates a flow cytometer in the laboratory (see Chapter 142).

TABLE 143.1 Direct antiglobulin test (DAT) tube technique.

1.	Place one to two drops of a 2–5% RBC suspension in a 10 or 12 × 75 mm test tube.
2.	Wash three to four times with normal saline or with phosphate-buffered saline (PBS). Thoroughly decant the last wash residual in order to avoid dilution or neutralization of the antiglobulin reagent.
3.	Immediately add antiglobulin reagent in amounts and as diluted per manufacturer's guidelines. Standard dilutions for canine antiglobulin are 1:2, 1:4, and 1:8. Prepare a negative control tube by adding saline instead of reagent to a tube.
4.	Incubate tubes according to manufacturer's directions.
5.	Centrifuge, gently dislodge RBC button, and record agglutination reactions observed as the cells come off the button. If no agglutination is apparent, a small amount of the tube contents can be placed on a slide and examined microscopically.
6.	If available, add IgG-sensitized RBCs (known as "check" cells) to nonreactive (unagglutinated) tests. Centrifuge and examine for agglutination.
7.	If a positive DAT is obtained, monospecific reagents (if available for the species) can be used to determine whether immunoglobulin or complement (or both) are present. Freshly washed cells must be used for this step.

ANTINEUTROPHIL ANTIBODY TESTS

IMN has been described in dogs, cats, and horses.[9,17,46,79] The disease is frequently diagnosed by exclusion of other diseases known to cause neutropenia, supportive bone marrow findings, and by response to corticosteroids. Direct diagnosis involves detection of antineutrophil antibody; however, antineutrophil antibody tests are not widely available. Previous techniques for detection have included leukoagglutination,[69,79] indirect immunofluorescence of bone marrow aspirates,[46] and flow cytometry.[31,73] An indirect leukoagglutination test used to determine antineutrophil antibodies in two dogs demonstrated that serum from the patients but not from a control dog caused agglutination of the patient's neutrophils following incubation with Coombs reagent.[46] A leukoagglutination method described failed to identify any antineutrophil antibody in 55 feline neutropenic patients.[13] An indirect flow cytometry assay and leukoagglutination testing were used to detect IMN in a 3-day-old foal with neonatal isoerythrolysis.[79]

Direct and indirect flow cytometry are described as the most sensitive tests for antineutrophil antibodies. Canine patient serum was incubated with paraformaldehyde-fixed neutrophils and subsequently incubated with fluorescein-conjugated rabbit anti-dog IgG.[73] Indirect flow cytometry demonstrated antibody in five of six dogs with a clinical diagnosis of IMN and lack of antibody detection in six of six dogs with neutropenia associated with other diseases.[72]

ANTIPLATELET ANTIBODY TESTS

Immune-mediated thrombocytopenia has been described in dogs[40], horses,[45] and rarely in cats.[34] To be consistent with the International Working Group recommendations for standardization of terminology and a recent veterinary review, IMT is now referred to as immune thrombocytopenia (ITP).[37,58] ITP may be primary (idiopathic), or secondary to primarily tick-borne infectious agents, neoplasia, or drug administration.[40] In dogs with primary ITP, the platelet-reactive antibodies are of an IgG class directed against platelet surface glycoprotein GPIb or GPIIb and/or GPIIIa (CD41/CD61).[41,42,61] In secondary ITP, platelet destruction can be caused by immune-complex binding to platelet Fc receptors, exposure of new antigens after membrane damage, nonspecific adsorption of foreign antigens (i.e., drugs), or newly generated antigens produced during the course of infectious or neoplastic diseases.[40] Methods to detect platelet antibodies in ITP patients include the direct immunofluorescent test for megakaryocytes; however, it requires a bone marrow aspirate and has variable sensitivity.[40] Bone marrow evaluation has merit in these cases for increased megakaryocytopoiesis has been reported in dogs with ITP that also have platelet-bound antibodies.[18]

Indirect methods to detect serum antibodies that have binding specificities for platelets (platelet-bindable antibodies) and direct methods to detect platelet-surface antibody (platelet-surface-associated immunoglobulins (PSAIg)) include enzyme-linked immunosorbent, immunoradiometric, and immunofluorescent (microscopy or flow cytometry) labeling techniques.[35,61,77] Indirect assays to detect antiplatelet antibodies in canine serum are not often performed because levels of circulating platelet-bindable antibodies are typically low resulting in low diagnostic sensitivity.[35,42]

Direct assays using flow cytometry to detect PSAIg are currently the most common methods for dog, horse, and cat blood samples.[18,34,45,77] Direct immunofluorescent assays for ITP have high diagnostic sensitivity (90–95%) and low diagnostic specificity.[42] Although direct PSAIg flow cytometry assays are common in human medicine, finding veterinary diagnostic laboratories that perform this assay is difficult. One of the first direct flow cytometry assays for PSAIg detection in veterinary species used a monoclonal antibody specific for canine IgG.[38] More information about this diagnostic assay is available at http://www.ksvdl.org/laboratories/clinical-immunology/#platlet. Recent modified assays use polyclonal antibodies to canine immunoglobulins[3] (Figure 143.1). In one report, often platelets with PSAIgG are smaller in size based on forward scatter (FSC).[77] Furthermore, dogs considered to have primary immune-mediated thrombocytopenia have significantly lower platelet concentrations and low mean platelet volumes than dogs with thrombocytopenia due to other diseases.[3] It is not known whether the formation of smaller platelets is a consequence of activation and microparticle formation during the assay or an in vivo phenomenon. There is recent interest in studying platelet microparticles as risk factors for prothrombotic conditions in patients with ITP or other diseases.[15] Not all laboratories use CD61 to identify platelets. CD61 expression can be greatly reduced in patients with ITP,[3,78] which may indicate CD61 modulation in these patients.

Direct labeling techniques identify the presence of surface-associated immunoglobulins, but do not identify autoantibodies specific to platelet glycoproteins. Diagnostic sensitivity and specificity of any method for PSAIg detection should reflect its ability to detect immunoglobulins on the platelet surface in patients with ITP.[30,59] Enhanced diagnostic sensitivity for primary ITP diagnosis in dogs can be achieved when results of direct/indirect IgG and IgM flow cytometry assays were combined with increased reticulated platelet results.[3] However, this combination decreased diagnostic specificity.[3] Use of a receiver operating characteristic (ROC) curve to optimize sensitivity and specificity is needed (see Chapters 80 and 140). Primary ITP diagnosis, in both human and veterinary medicine, is often based on clinical impression, exclusion of known causes of thrombocytopenia, and response to treatment.[30,61,67] For this reason, the American Society of Hematology defined PSAIg detection inappropriate and unnecessary in primary ITP patients.[23,30] Nonetheless, the PSAIg assay could be useful as a screening test for primary ITP due to its high sensitivity.[30,68] A negative result in a patient not treated with glucocorticoids rules out an immune-mediated mechanism of the

(a), (b), and (c) represent dot plots of cells from platelet-rich plasma (PRP). (a) Scatter plot of the complexity (SSC-A) and size (FSC-A) of platelets (green), and contaminating RBCs (red). Two distinct populations of platelets of different sizes are noted; (b) Size versus fluorescent plot of PRP incubated with an isotype control antibody (FITC-labeled mouse IgG); (c) Size versus fluorescence plot of PRP incubated with a monoclonal antibody specific to canine IgG. (d), (e), and (f) represent histograms of the gated platelet population. (d) Unlabeled platelets; (e) Platelets incubated with isotype control in which vertical line is placed where <1% of the cells are positive to the right; (f) Platelets binding to anti-canine IgG are shifted to the right of the vertical line (15% of the gated platelet population). (**Source:** Kansas State University, Clinical Immunology Diagnostic Laboratory.)

platelet destruction; whereas, positive results must be confirmed by more specific assays, such as the monoclonal antibody-specific immunomobilization of platelet antigen assay, only available in human medicine.[8,55,68] Other testing including the measurement of thrombopoietin levels or evaluation of the function of regulatory T and B cells have been pursued in human medicine, but are not available as diagnostic tests in animals.[37]

A major disadvantage of PSAIg assays is poor sample stability that can lead to false positive results.[76,77] Platelets can be activated by improper blood collection, poor sample handling (i.e., unnecessary agitation of the tube), low storage temperature, prolonged time to sample preparation (storage time), and centrifugation steps, with subsequent exposure of IgG, typically contained within the alpha granules, on the platelet surface.[14,39,51,76] Platelet shape changes can be evaluated by flow cytometry as an indicator of activation. When activated, the platelet population (FSC versus side scatter (SSC) plots) spreads from the normal, well-defined oval shape to an elongated and narrower scatter plot (Figure 143.2).[51]

Flow cytometry methods using whole blood samples have been proposed as alternative methods to minimize in vitro platelet activation that occurs during the preparation of platelet-rich plasma.[65] However, prolonged contact with leukocytes before platelet separation can trigger platelet activation.[67] Because the principal sources of platelet activation occur in a preanalytical phase, strict preanalytical quality control is required. Positive results must be interpreted with caution in the context of clinical and supporting laboratory findings.

ANTINUCLEAR ANTIBODY TEST

Antinuclear antibodies (ANAs) are a heterogeneous population of antibodies reacting against self nuclear components.[36,74] ANAs do not appear to play a prominent role in the pathogenesis of disease, but their identification is used as one of several clinical and laboratory criteria for diagnosis and monitoring of autoimmune disorders in both human and veterinary medicine[6,7,36] (see Chapter 52).

The indirect immunofluorescence ANA (IIF-ANA) test is considered the gold standard screening test for detection of circulating ANAs in both human and veterinary medicine, and it is often referred to as the "ANA-test."[7,28,36] Briefly, serial serum dilutions are applied to a commercially available glass slide, which contains nuclear-rich tissue substrates fixed in separate wells. Typically, substrates are composed of either rat liver sections or human monolayer epithelial cells (e.g., Hep-2, HeLa, Vero,

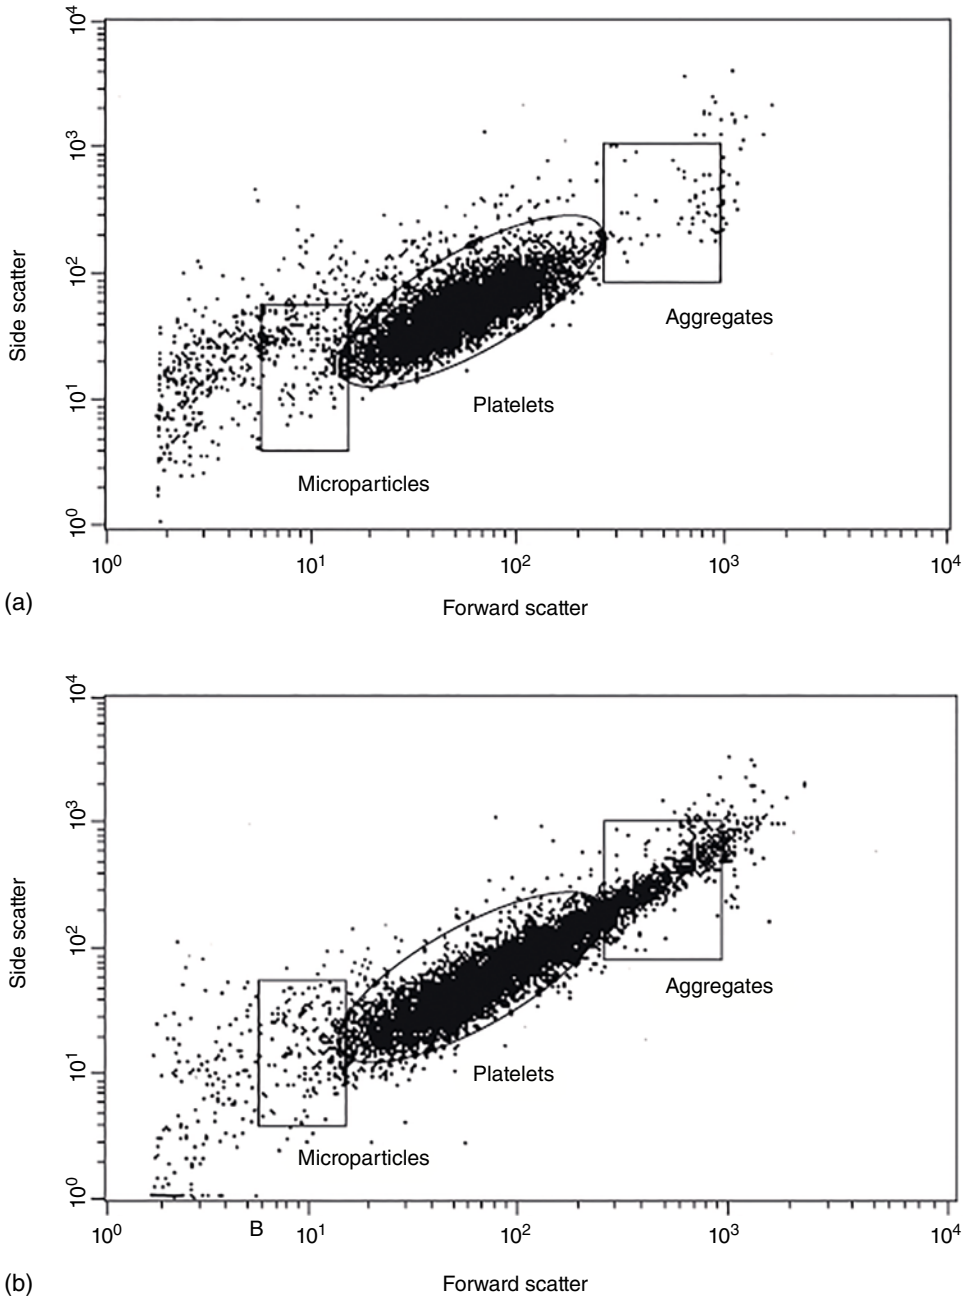

FIGURE 143.2 Forward-angle versus side-angle light scatter plots. (a) The scatter of nonactivated platelets is a characteristic well-defined oval shape; (b) Platelets activated with 20 ng/mL phorbol myristate acetate. The platelet population spreads to form an elongated and narrower scatter plot. Platelet fragments (microparticles) and platelet aggregates are produced upon activation and are discernible as two distinct populations with a lower and higher forward scatter, respectively. (**Source:** Moritz et al.[51])

Hep-2000).[26,28,5-7] After a 30-minute incubation, the slide is rinsed with phosphate-buffered saline (PBS) and secondary anti-species-specific antibody, typically conjugated with fluorescein isothiocyanate (FITC), is applied to the wells. After a 30-minute incubation, the slide is washed with PBS to remove unbound antibody, and analyzed using fluorescence microscopy. Positive and negative controls for veterinary species are usually not commercially available; serum aliquots from patients that previously tested negative and positive are typically stored by laboratories for this purpose. A negative ANA reaction is identified by a lack of fluorescence in the substrate, which may appear reddish-orange because of the counterstain. Samples are considered positive when a clearly discernible fluorescent pattern in the nucleus is present.[28,36,54]

In human medicine, the pattern of nuclear fluorescence in the IIF-ANA test suggests the specific antibody type. Speckled staining is the most frequently identified pattern in humans, but is not specific for a particular autoimmune disease. The speckled pattern

is seen when antibodies to non-DNA components, collectively called extractable nuclear antigens, are present. These include ribonucleoproteins (RNP), topoisomerase I antigen (Scl-70), Smith antigen (Sm), and Sjögren's-syndrome-related antigens A and B (SS-A/Ro, SS-B/La), which are associated with mixed connective tissue diseases and systemic lupus erythematosus (SLE), scleroderma and SLE, and Sjögren's syndrome sicca complex and SLE, respectively. A homogeneous or peripheral nuclear staining usually indicates the presence of antibodies directed against chromatin constituents, such as double-stranded DNA (dsDNA) or histones. In people, the presence of these autoantibodies is characteristic of SLE or drug-induced lupus. Centromere and nucleolar staining are more often associated with scleroderma, polymyositis, and other connective tissue diseases.[7,36]

Because the IIF-ANA test has low specificity, positive human samples are often further analyzed for the identification of the specific autoreactive antibodies, which can be linked more directly to determined autoimmune disorders.[36] Specific ANAs can be identified with ELISA, immunoblot, human protein arrays, immunodiffusion (ID), and radioimmunoassay using either purified extracts or recombinant antigens.[5,6,36,74] In some human medical laboratories, a panel for the simultaneous detection of a variety of specific ANAs has replaced the IIF-ANA test.[5] The application of ANAs in veterinary medicine is mostly restricted to the use of the IIF-ANA test as an aid in SLE diagnosis.[7,28] Historically, the lupus erythematosus cell test (LE test) was used to diagnose this disorder, but is uncommonly used due to a high incidence of false-negative and false-positive results (see Chapter 52). SLE is rarely reported in cats and horses, and lack of comparative data makes the IIF-ANA titer interpretation difficult.[22,26,66] Antinuclear antibody titers in cats diagnosed with SLE are usually low (below 1:40) and overlap with the titers of healthy subjects. Furthermore, titers as high as 1:100 can transiently be found in both FeLV- and feline infectious peritonitis (FIP)-positive cats.[26,66]

In dogs, a positive IIF-ANA titer is expected in 97–100% of SLE cases, but the sensitivity of immunofluorescence varies between laboratories and substrate employed.[11,26] Antinuclear antibodies can also be produced in many inflammatory and infectious diseases, and a positive immunofluorescence result must be interpreted in the context of clinical signs and laboratory data.[28,64] Therefore, a positive IIF-ANA test is listed in the revised American Rheumatism Association diagnostic criteria for people adapted for dogs, but should not be considered the sole criterion for canine SLE diagnosis.[12,28]

Positive IIF-ANAs have been described in dogs with non-autoimmune disorders such as atopic dermatitis, onychodystrophy, and black hair follicular dysplasia, and in subjects seropositive for *Bartonella vinsonii* subsp. *berkhoffii*, *Ehrlichia canis*, or *Leishmania infantum*.[24,26,53,64] Dogs with nonprimary immune-mediated disorders tend to have low positive titers (91% ≤ 1:256), but positive titers up to 1:4000 occasionally can occur.[11,24,28,50,64]

By contrast, higher immunofluorescence titers were found to be clearly correlated with signs of autoimmune diseases (1:100 on Hep-2)[28] and titers ≥1:640 were considered to be a good predictor of immune-mediated diseases in dogs.[63] Positive titers can also be found in healthy dogs, especially when cryopreserved sections of rodent liver are employed.[26,28] The appropriate threshold titer of positivity must be determined in each laboratory based on a control population and substrate type. In general, high titer cutoffs (e.g., 1:100) are required with rat liver substrates to decrease the false-positive rate.[28] Hansson et al. found the Hep-2 substrate to be superior to rat liver sections not only for its high specificity (no false positives at 1:25 dilution in 100 healthy dogs), but also because it provides an easier and more consistent pattern discernment.[28]

Using Hep-2 slides, two major patterns are recognizable in dogs: the homogeneous pattern, characterized by an intense fluorescence staining of the chromosomal area in mitotic cells; and the more commonly occurring speckled pattern, chromosome-negative (Figure 143.3).[7,28] An association between homogeneous immunofluorescence pattern and SLE has been reported to occur in dogs, but the speckled immunofluorescence pattern does not appear to be associated with a specific canine autoimmune disease, as observed in people.[7,27]

The identification of specific ANAs is not routinely done in veterinary medicine.[7] In dogs, specific ANAs have been analyzed by using double immunodiffusion technique of Ouchterlony, ELISA, human protein arrays, and line immunoassay (LIA), which is a type of immunoblot that uses recombinant, synthetic, or natural antigens attached in separate lines on a strip.[6,7,36,74] Anti-dsDNA antibodies can be confirmed with the *Crithidia luciliae* indirect immunofluorescence test.[7]

Some ANAs have been identified in both human and canine patients, such as antibodies directed against histones, RNP A, RNP C, RNP-70K, Sm, SS-B, SS-A (both Ro-60 and Ro-52), Scl-70, polymyositis–scleroderma antigen (PM–Scl), histidyl tRNA, synthetase (Jo-1), and proliferating cell nuclear antigen (PCNA).[7,11,49] Other autoantigens, such as the anti-type 1 (anti heterogeneous nuclear ribonucleoproteins (hnRNPs) G, encoded by the gene RBMX) and anti-type 2, are confined to dogs and are not detected by tests for human ANAs.[7,27,49,74]

The significance of most of these canine autoantibodies is still unclear. Previous literature reports that in dogs with SLE, ANAs are rarely directed against dsDNA, but are mostly against nuclear proteins such as histones and RNP.[11,27,49,54,74] In a subsequent study, antibodies against dsDNA were found in a quarter of IIF-ANA-positive dogs with unknown clinical diagnosis, while antibodies against histones were found less often.[7] In previous studies, an association between immunofluorescence patterns observed using the IIF-ANA test and specific ANAs was not identified, even though reacting bands were exclusively found in speckled patterns.[27,74] More recently, the homogenous pattern has been most frequently associated with anti-dsDNA and antinucleosome

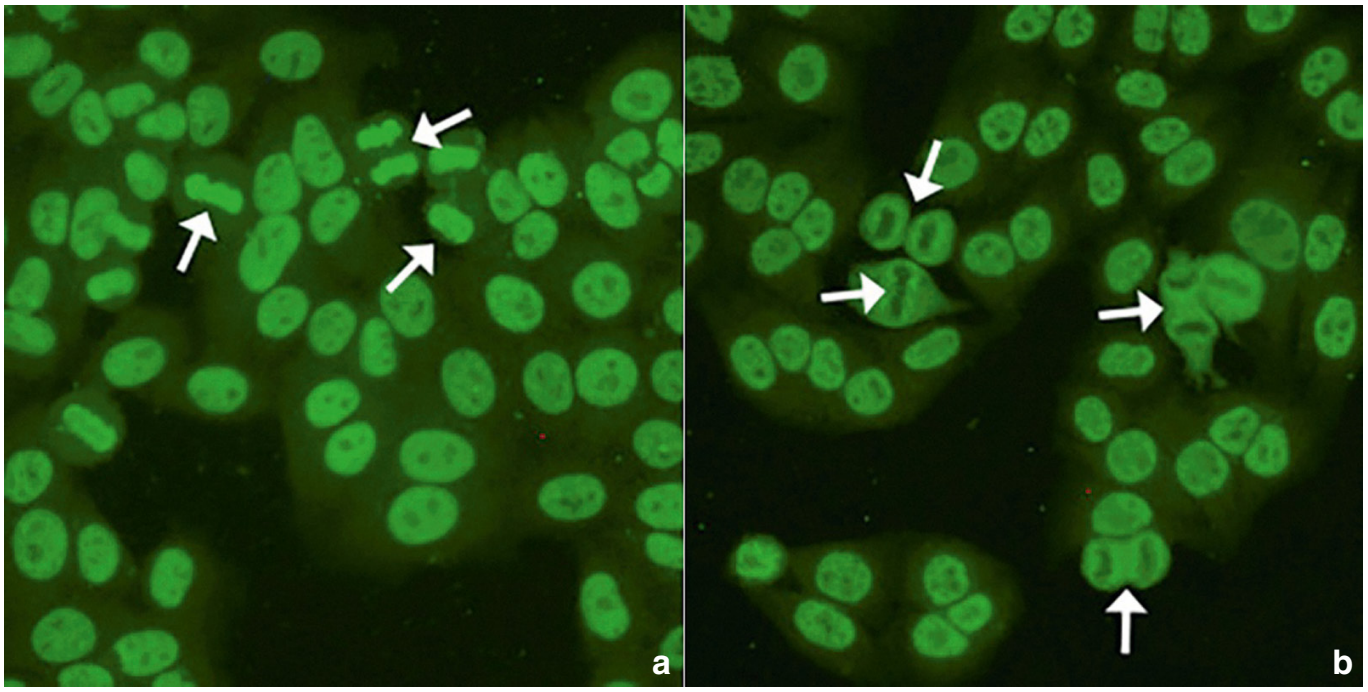

FIGURE 143.3 Antinuclear antibody patterns of canine sera showing ANA positivity in the indirect immunofluorescence test (IIF-ANA) using human Hep-2 cells as substrate. Canine serum samples reacted with FITC-conjugated anti-canine IgG to produce (a) homogeneous pattern. Arrows are pointing at the fluorescent chromosomal regions in mitotic cells; (b) Speckled pattern. Arrows are pointing at the negative staining of the chromosomal regions in fluorescent mitotic cells. (Source: Reproduced from Bremer HD et al.[7], Elsevier Publishing.)

antibodies, while dogs with the speckled pattern have high concentrations of anti-RNP and/or anti-Sm antibodies.[7]

The discrepancies between studies are most likely due to different detection methods, the lack of well-defined diagnostic criteria for the different canine autoimmune diseases, and differences in inclusion criteria for investigated populations.[7,27]

INVESTIGATION OF DRUG-INDUCED AUTOANTIBODIES

Drugs can induce the formation of antibodies, either against the drug itself, against intrinsic cellular antigens modified by the drug, or both (see Chapters 13 and 15). This has been most frequently described in humans with drug-induced IMHA.[2,20,21] Drug-dependent antibodies require that the drug be present. Drug-independent antibodies react similarly to true autoantibodies (i.e., no drug is needed to demonstrate the presence of antibody). Drugs can bind loosely or firmly to cell membranes and antibodies may be made to (1) the drug itself, necessitating drug binding for in vitro detection; (2) cell membrane components; or (3) part drug, part membrane components, producing an in vitro reaction typical of an immune complex mechanism.

Method of Antibody Detection

Drug-induced anti-RBC antibodies in humans are usually associated with a positive DAT. Further investigation of suspected hemolysis due to drug-dependent antibodies requires special methods,[19] e.g., drug-treated RBCs are prepared for detection of antibodies to penicillin. Washed, packed, group O RBCs are incubated with penicillin dissolved in buffer. The cells are then washed and a PBS cell suspension is prepared. These cells are mixed with patient serum, incubated, centrifuged, and examined for hemolysis or agglutination. Antibody-free serum and serum containing known antibody are used as negative and positive controls, respectively. The cells are also tested by an indirect antiglobulin technique. For demonstration of immune-complex formation involving drugs, the patient serum is incubated with a suspension of the drug in question. The mixture is then added to enzyme-treated group O RBCs, incubated, centrifuged, and examined as described for the drug-coated cells. Controls are used as indicated in the earlier text. Drug-independent antibodies react similarly to most IMHA cases, with a positive DAT test result.

Diagnosis of drug-induced immune-mediated granulocytopenia or thrombocytopenia is generally considered when there is a temporal association of the drug and the cytopenia, rather than by actual antibody detection in the presence of drug. An exception would be

heparin-induced thrombocytopenia, a condition described in human patients receiving unfractionated or low-molecular-weight heparin. Immunogenic complexes formed by heparin and platelet factor 4 cause antibody formation, and these anti-heparin/PF4 antibodies can be detected with commercially available immunoassays.[1,25]

Drug-Induced Hematologic Disease in Veterinary Medicine

Drug-induced immune hematologic disease has been poorly documented in veterinary medicine, though pancytopenia has been associated with penicillin and potentiated sulfonamide administration in horses.[16,44] Most reports show a temporal association of a drug with hematologic disease, but no actual testing for drug-associated antibody. The Coombs test was positive in horses with penicillin-induced hematolytic anemia, and their sera produced agglutination of penicillin-coated RBCs. In one horse, antipenicillin antibody titers decreased progressively throughout the observation period.[57]

Acronyms and Abbreviations

AGE, agarose gel electrophoresis; AGP, α-1-acid glycoprotein; ALP, alkaline phosphatase; APP, acute-phase proteins; APR, acute-phase response; ASVCP, American Society for Veterinary Clinical Pathology; CAE, cellulose acetate electrophoresis; CZE, capillary zone electrophoresis; CK, creatine kinase; CRP, c-reactive protein; CV, coefficient of variation; EDTA, ethylenediaminetetraacetic acid; EPH, electrophoresis; ELISA, enzyme-linked immunosorbent assay; Hp, haptoglobin; HRE, high-resolution electrophoresis; LDH, lactate dehydrogenase; pigMAP, porcine major acute-phase protein; PON-1, paraoxonase-1; RBP, retinol-binding protein; RID, radial immunodiffusion; SAA, serum amyloid A; SDS, sodium dodecyl sulfate; SPE, serum protein electrophoresis; TIBC, total iron-binding capacity; TRF, transferrin; TTR, transthyretin.

GENERAL PRINCIPLES OF ELECTROPHORESIS

Electrophoresis (EPH) separates molecules such as nucleic acids, proteins, lipids, and carbohydrates in an aqueous solution based on their physical and chemical properties, such as size, weight, electrical charge, and shape, using an electric field that induces migration of charged molecules toward an electrode. The main components of an electrophoretic apparatus include: two metal electrodes of opposite charge (anode or positive electrode, cathode or negative electrode), connected by a conductive buffered electrolyte solution, and a power supply. The alkaline buffered electrolyte solution (pH 8.4–8.8) induces most of the proteins to be negatively charged; thus, the proteins migrate toward the positively charged anode. Electrophoretic conditions are characterized by electrical parameters (i.e., current, voltage, amperage, temperature) and factors related to buffers and support media, such as ionic strength, pH, viscosity, pore size, etc. Electrophoresis equipment must provide constant voltage, amperage, and temperature to minimize the variability of migration; thereby, optimizing

result reproducibility. For example, high temperatures may alter the migration rate, possibly resulting in distorted bands and, consequently, peaks. Dissipation of heat generated by electrical resistance can be a major problem, especially in older units.

ELECTROPHORETIC METHODS IN VETERINARY MEDICINE

In veterinary clinical practice, EPH techniques are mainly used to evaluate the protein profile of body fluids, by separating proteins in fractions based on mobility, e.g., serum protein electrophoresis (SPE) or separating unique proteins based on their molecular weight, e.g., urine electrophoresis. Additional techniques used in research settings may have application to clinical settings in the near future.

Zone Electrophoresis

The sample is placed in a narrow zone or band in the stabilizing medium at a suitable distance from each electrode. Molecules are fixed in lanes on a stabilizing medium or support (paper, cellulose acetate, agarose, or polyacrylamide gel) to avoid random dispersion into solution, such that migration fractionates the sample revealing reproducible banding patterns.

Separated bands may be stained with Ponceau red, Amidoschwarz acid violet, Coomassie blue, etc., and measured by densitometry.[12] A densitometer is a spectrophotometer that measures light, aka optical density, transmitted through a semitransparent material, e.g., the electrophoretic gel or support medium. It creates an electrophoretogram, which is a diagram or graph of peaks of different height and width directly corresponding to the fractionated protein bands' optical density and width. Area under each peak is expressed as a percentage which represents each fraction's relative proportion. Percentage values are then converted to absolute values by multiplying by the total serum or plasma protein concentration, likely measured by the biuret method, though measurement by other methods is possible. The electrophoretogram data should be digitally stored, printed, and interpreted with an appropriate data acquisition system.

Historically, cellulose acetate has been used as a solid support medium to separate proteins based on their isoelectric point (pI). Briefly, serum samples are placed on the cellulose acetate strip and into an alkaline buffer, usually a barbital buffer. Once the electric field is applied at a constant voltage, proteins with a pI higher than the buffer pH (e.g., albumin and most of the globulins), being negatively charged, migrate toward the anode. Gamma-globulins, which have a pI lower than the buffer pH, migrate very slowly and essentially do not move. Compared to paper, which was previously used as an EPH support, cellulose acetate has a lower adsorption capacity and generates sharper electrophoretic bands. Cellulose acetate electrophoresis (CAE) usually generates five to six electrophoretic peaks, namely, albumin, α-1-globulin, α-2-globulin, β-globulin (in some species further divided in β-1- and β-2-globulin), and γ-globulin from most animals' serum. While inexpensive, CAE can be time-consuming and high-resolution separation comparable to current techniques is not possible.[16]

Agarose Gel Electrophoresis

Thin-layer agarose gel EPH has replaced CAE in most veterinary diagnostic laboratories due to clearer separation of protein fractions and sharper peaks. Agarose gel electrophoresis (AGE) and CAE share the same principle, but precasted, 0.5–1% agarose gels are used in an almost fully automated procedure. After the densitometric analysis, software evaluates the peaks automatically generating relative values. The number of EPH fractions is usually comparable to that obtained with the most advanced CAE equipment, but better differentiation between α-1- and α-2-globulins and between β-1- and β-2-globulins is observed.[2] Agarose gels with variable pore sizes are available, which can be used to separate other molecules useful in diagnostic veterinary medicine, such as urine proteins, lipoproteins, nucleic acids, and isoenzymes.

Sodium dodecyl sulfate (SDS) is an anionic detergent, meaning that its molecules have a net negative charge. Above 1 mM SDS concentration, most proteins are denatured by negative charges on the SDS molecule and, concurrently, are strongly attracted to the anode. Adding SDS to agarose gel electrophoresis (SDS-AGE) or polyacrylamide gel electrophoresis (SDS-PAGE) separates proteins mainly by molecular mass instead of charge. SDS-AGE may be used clinically for proteinuria characterization. SDS-PAGE provides increased resolution, but is time- and labor-consuming for routine applications, and is therefore used for research purposes.[12]

Capillary Zone Electrophoresis

Compared to the previously described techniques, the principle of molecular separation used in capillary zone electrophoresis (CZE) is quite different. Separation of peptides, proteins, nucleic acids, and other compounds occurs in a free solution by the simultaneous and opposite effect of an electrical field and electroendosmotic forces that develop inside a small capillary tube, usually a narrow-bore fused silica capillary tube. A strong, alkaline (pH = 10) borate buffer is typically used which results in most proteins being negatively charged. The applied potential electrical difference between the two ends of the capillary tube creates the electrophoretic force. It attracts the positively charged molecules toward the cathode and the negatively charged molecules toward the anode. Concurrently, the internal surface of the capillary tube is negatively charged. The positively charged cations close to the capillary wall are attracted to the negatively charged cathode, dragging the buffer solution in the same direction. This electroendosmotic

flow exceeds the force of the electrical field, leading to a net cathodal migration of the protein fractions (Figure 144.1). The migration of negatively charged proteins (e.g., albumin), which are electrically attracted to the anode, is slowed in correlation with their charge:mass ratio.[3]

CZE, a high-resolution electrophoretic technique, fractionates serum proteins in more than six peaks in most species. This modified technique has a high capillary surface to volume ratio, which efficiently dissipates excessive heat generated when a high voltage of about 10,000 V is applied, thus decreasing the Joule effect. Usually, equipment for CZE is more expensive than the older techniques, but a significantly faster throughput of 4–6 minutes versus 1 hour, small sample volumes, and the ability to process one sample at a time with complete automation result in significant cost savings.[28] Moreover, CZE does not require densitometric analysis, since a UV detector that measures 200–220 nm absorbance quantifies separated proteins. Therefore, there is also no need for special stains, reducing toxic waste and cost.

Immunoelectrophoresis

Immunoelectrophoresis combines electrophoresis and immunodiffusion. After electrophoretic separation, monoclonal or polyclonal antibodies are applied which bind a specific protein or set of proteins. This technique was first used to identify individual proteins migrating in the different globulin fractions.[1] Identification of immunoglobulin monoclonal components found in multiple myeloma is currently a commonly utilized diagnostic application.

There are several available immunoelectrophoretic techniques, which are uncommonly used for diagnostic purposes.[24] In the Grabar/Williams method (or immunofixation), after standard AGE, antibodies are added to a trough cut in the agar. Individual proteins bound to the added antibodies will diffuse toward one another and precipitin arcs will form. The immunosubtraction method may be used with capillary equipment. Immunoglobulins (usually identified by monoclonal peaks) are removed from the serum sample using antibody-coated beads specific for the target immunoglobulin. Then, CZE is repeated on the absorbed serum. If the coupled antibody removed the target protein, treated samples will show subtraction (i.e., the monoclonal peak will disappear). The limitation of immunoelectrophoresis in veterinary medicine is the relative lack of cross-reacting and validated antibodies for domestic animals at this time.[28]

Isoenzyme Electrophoresis

The total serum activity of clinically relevant enzymes, e.g., creatine kinase (CK), lactate dehydrogenase (LDH), and alkaline phosphatase (ALP), is the sum of different isoenzymes originating in different tissues. Specifically, there are three predominant CK isoenzymes deriving from skeletal muscle (CK-MM), heart (CK-MB), and brain (CK-BB), five LDH isoenzymes with different tissue specificity (LDH-1 to LDH-5), and at least three ALP isoenzymes including hepatic (L-ALP), bone (B-ALP), and intestinal (I-ALP). Isoenzyme electrophoresis identifies the isoenzyme(s) contributing to the total increased serum enzyme activity which can provide information regarding the underlying tissue-specific pathogenesis of disease (e.g., increased CK-MB in myocardial disease in certain mammals).[30]

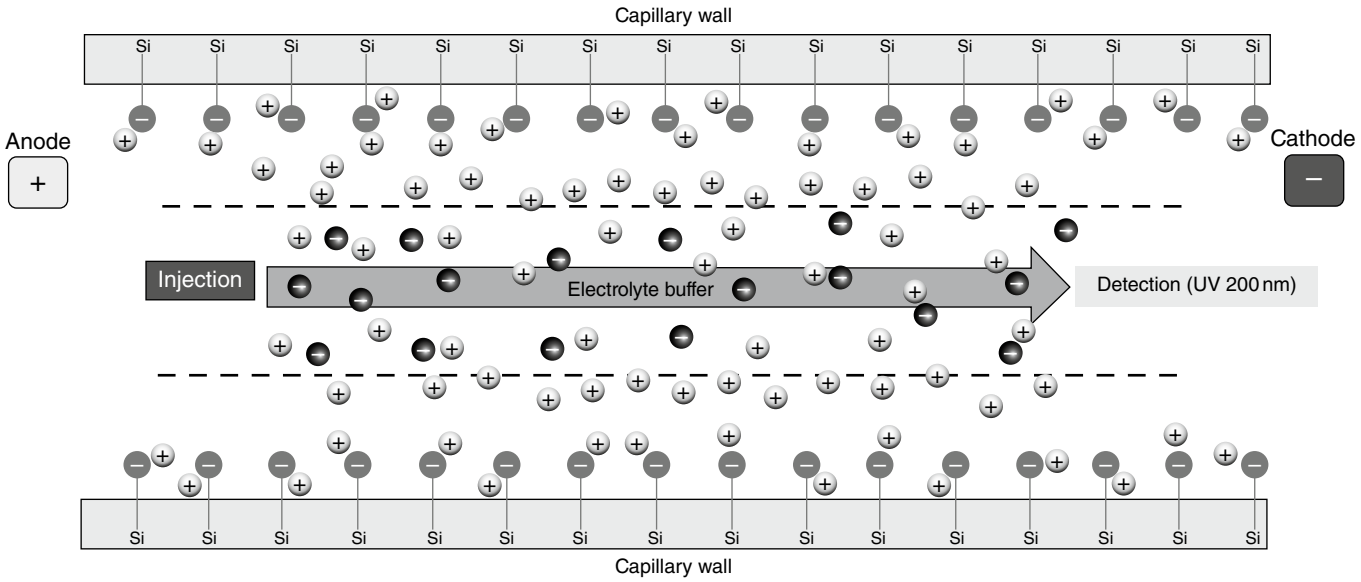

FIGURE 144.1 Capillary zone electrophoresis. The negatively charged silica surface of the capillary wall (Si) attracts positive ions from the buffer. An electrical double layer at the capillary wall–buffer interface is created, resulting in a net electroosmotic flow of the buffer toward the cathode. Protein migration velocity depends on the charge: negatively charged molecules will move more slowly than positively charged molecules.

ACUTE-PHASE PROTEIN DETECTION

The acute-phase proteins (APP) change their basal blood concentration during innate, acute inflammatory responses. The classic APP proteins and APP pattern vary between species and not all APPs have clinical relevance, especially across species (Table 144.1).[10,29,31] Several validation studies have expanded the use of APP in veterinary laboratories.[7,22,25,33,35] The following proteins represent the most common APPs used as diagnostic markers in domestic animals (Table 144.2).

Fibrinogen (Factor Ia)

Fibrinogen concentration measurement requires citrated plasma, as serum does not contain coagulation factors. It is mainly used in equids and cattle and is found in the beta region of the electrophoretogram. Heat precipitation is the simplest method to estimate fibrinogen concentration, but is not specific for fibrinogen. As fibrinogen concentration is second only to albumin, the heat precipitation method does approximate fibrinogen concentration. Briefly, the difference in total protein concentration, measured by refractometer, is calculated between two plasma samples, one at room temperature and one heated to 56–58 °C. However, this method is not sensitive enough to detect hypofibrinogenemia.[36] The Clauss modified thrombin clotting time evaluates the conversion of fibrinogen to fibrin and is measured in time to clot, not in concentration. A fibrinogen dysfunction or lower fibrinogen concentration results in a prolonged time to clot formation. Immunotesting is the most accurate assay to quantify fibrinogen if species-specific antibodies are available (see Chapter 88).

TABLE 144.1 Acute-phase proteins (APPs) in common domestic animals.

Species	Positive APPs	Negative APPs
	Major and moderate APPs	
Dog	CRP*; SAA; Fib; Hp	Alb; TRF; TTR; RBP; PON-1
Cat	SAA*; AGP; Hp	Alb; TRF; TTR; RBP; PON-1
Horse	SAA*; Fib; Hp	Alb; TRF; TTR; RBP; PON-1
Ruminants	Hp*; SAA	Alb; TRF; TTR; RBP; PON-1
Pigs	Hp; SAA; pigMAP*	Alb; TRF; TTR; RBP;
Birds	TRF*; Hp; AGP; SAA; Fib	Alb

AGP = α-1-acid glycoprotein; Alb = albumin; CRP = C-reactive protein; Fib = fibrinogen; Hp = haptoglobin; pigMAP = porcine major acute-phase protein; PON-1 = paraoxonase-1; RBP = retinol-binding protein; SAA = serum amyloid A; TRF = transferrin; TTR= transthyretin.
* Characteristic APP for the species.

Serum Amyloid A

Serum amyloid A (SAA) is typically used to investigate inflammation in horses and cats, whereas its inconsistent increase during acute-phase response (APR) in dogs has limited the use of SAA as a marker in this species.[10,29] All analytical methods for SAA quantification that are commercially available and validated for use in veterinary species are antibody-based, including ELISA, turbidimetric immunoassay (TIA), and latex agglutination turbidimetric (LAT) immunoassay.[7,25] Most of these assays are designed for human SAA identification, using both monoclonal or polyclonal antibodies. However, several studies have validated ELISA, TIA, and LAT immunoassays in a variety of animal species, including cats, horses, dogs, and exotic species as well.[7,8,18] Many assays have been adapted for automated clinical chemistry analyzers, resulting in decreased time and cost and, therefore, in increased use in veterinary diagnostic laboratories. Recently, a monoclonal immunoturbidimetric SAA assay with an extremely broad working range has been validated for use in horses.[23]

C-Reactive Protein

C-reactive protein (CRP) is a major APP in dogs and people, and a minor APP in horses and pigs; whereas in cats and cattle, there is no evidence of a significant CRP concentration increase during inflammation.[10,31] For this reason, validation studies to transfer CRP assays used in human medicine were completed, mainly for use in canine species.[22,25,29]

Similar to other APPs, immunoassays such as ELISA, immunoturbidimetry, slide/capillary reversed passive latex agglutination tests, and time-resolved immunofluorometric assay (TR-IFMA) are used to measure CRP concentration in body fluids. The lack of cross-reactivity using human-based assays hampered the extensive use of CRP, but in recent years the identification of both cross-reacting antihuman polyclonal antibodies and canine-specific methods suitable for automation have enabled the clinical use of CRP in dogs.[22,32] A modified immunoturbidimetry assay for measurement of low or ultralow concentration CRP, referred to as high-sensitivity CRP (hsCRP) assay, has been validated using canine serum.[21]

α-1-Acid Glycoprotein

Unlike SAA and CRP measurement, a validated automated immunoassay for α-1-acid glycoprotein (AGP) detection in domestic species is still not available at this time. Species-specific antibodies are employed for AGP measurement in dogs, cattle, and cats, in which AGP reacts as a major APP. The radial immunodiffusion (RID) technique is the only validated method in veterinary medicine and is manually performed. RID is time-consuming and has increased imprecision in comparison to automated analyses.[28] A higher individual and analytical coefficient of variation was detected for AGP measurement with RID compared to other APPs in

TABLE 144.2 Main serum proteins of domestic animals and related peaks.

Electrophoretic zone	Proteins	Function
Prealbumin (some reptiles and birds)	Transthyretin	Hormones and vitamin transport
Albumin	Albumin (rare bisalbuminemia)	General transport, oncotic pressure maintenance
	Need to	
	Triglycerides	*Lipemic samples*
α-1-globulins	α-1-antitrypsin	Trypsin inhibitor
	α-1-acid glycoprotein	Acute-phase protein
	α-1-antichymotrypsin	Chymotrypsin inhibitor
	α-1-fetoprotein	Unknown
	α-1-lipoprotein	High-density lipoprotein
	Transthyretin (most mammals)	Hormones and vitamin transport
	Triglycerides	*Lipemic samples*
α-2-globulins	α-2-macroglobulin	Protease inhibitor
	Haptoglobin	Acute-phase protein
	Ceruloplasmin	Acute-phase protein
	Fibronectin	Wound healing
	Pre-β-lipoprotein	Very-low-density lipoproteins
	Retinol-binding protein	Binds vitamin A
	Vitamin D-binding protein	Binds vitamin D
β-1-globulins	Transferrin	Binds iron
	β-lipoprotein	Low-density lipoprotein

γ-globulins	Immunoglobulin M	Immunity
	Immunoglobulin G	Immunity
	C-reactive protein	Acute-phase protein

Sources: Eckersall[12]; Harr[17]; Keren.[24]

dogs.[26] Immunoturbidimetry for feline and canine AGP measurement has been developed and validated on a research basis, but commercially available kits are still not accessible.[2]

Haptoglobin

Haptoglobin is used to monitor the APR mainly in ruminants, where its basal level is considerably lower than in inflammatory conditions.[9] Haptoglobin measurement may be performed using spectrophotometry, either automated or using multiwell ELISA plates, or by immunoassays. The first documented veterinary method employs detection of hemoglobin's peroxidase activity in the hemoglobin–haptoglobin complex and has been validated in a variety of domestic and wild ruminants.[11] Major limitations of this assay are significant interference with hemolysis such that hemolyzed samples should not be analyzed and a short shelf-life of reagents. Immunoreactive methods are typically minimally affected by hemolysis and use antisera against haptoglobin to produce a precipitated product that is measured by RID, nephelometry, or turbidimetry. However, antibodies against human haptoglobin used in commercially available kits may have decreased cross-reactivity in some animal species. Antibody lots must therefore be validated in each species to be investigated in the laboratory. In cows, a novel automated species-specific immunoturbidimetric assay has acceptable intra- and inter-assay coefficient of variation (CV)s, accuracy, and limit of quantification. Immunoassay using species-specific monoclonal antibodies has enhanced the specificity and sensitivity of haptoglobin detection in hemolyzed specimens.[4]

Negative Acute-Phase Proteins

Proteins that decrease in concentration during inflammation are defined as negative acute-phase proteins.[12] Albumin and transferrin (TRF) are considered major negative APPs in many species (except birds)[34] and can be measured by spectrophotometry on wet chemistry analyzers. Specifically, bromocresol green is commonly used for albumin measurement in animals, although this nonspecific dye-binding technique has low analytical sensitivity and specificity. The EPH absolute value has superior accuracy, and immunonephelometry is still considered to be the gold standard.[37]

Serum transferrin is measured as total iron-binding capacity (TIBC) by spectrophotometry using the saturation/precipitation method (see Chapter 27). Briefly, a known amount of excess oxidized, ferric ion (Fe^{3+}) is added to the sample to saturate all available transferrin sites and unbound Fe^{3+} is precipitated with magnesium carbonate. The amount of remaining iron bound to transferrin is then determined. The difference between the unsaturated iron-binding capacity (UIBC) and the initial amount of ferric iron is the TIBC. Lipemia and the presence of free iron in serum (e.g., during hemolysis and iron overload) may increase TIBC value. The accuracy of TIBC measurement as an index of iron deficiency is limited by the individual diurnal variation in plasma iron concentration.[19]

There are numerous other minor negative APPs including retinol-binding protein (RBP) and transthyretin (TTR), but assays for their measurement in domestic species have gained interest for research purposes only. Recently, paraoxonase-1 (PON-1), a high-density lipoprotein (HDL)-bound enzyme produced by the liver and involved in antioxidant processes, has been proposed as a negative APP based on its decreased activity during inflammation in people and animal species.[33,35] Spectrophotometry can be used to measure PON-1 activity and its ability to hydrolyze different substrates, most commonly paraoxon, phenyl acetate, 5-thiobutil butyrolactone, and 4-nitrophenyl acetate. The presence of several substrates, possible gene polymorphisms, and lack of control sera are current limitations when using PON-1 in clinical settings.[5]

QUALITY ASSURANCE FOR ELECTROPHORESIS AND ACUTE-PHASE PROTEIN DETECTION

Specific quality assurance (QA) guidelines for protein electrophoresis and acute-phase protein detection in veterinary laboratories are not available in the literature at this time. However, general recommendations about the preanalytical phase, method validation, reporting, reference intervals, etc., are defined in the American Society for Veterinary Clinical Pathology (ASVCP) Quality Control Guidelines and may also be applied to the methods described in this chapter.[14,15,39]

Preanalytical Phase

Selection of Suitable Specimens

Electrophoresis with AGE, CAE, and CZE is commonly performed on serum or plasma samples, but any body fluids containing an adequate protein concentration may be analyzed. Most EPH assays require small sample volumes (10–100 μL) allowing protein quantitation in small, volume-restricted animals. Conventional EPH techniques, such as AGE and CZE, have an analytical sensitivity of 0.25–0.50 g/L and bands of <1 g/L are visible but cannot be accurately quantified.[38] Specimens containing very low protein concentrations are therefore not suitable for EPH techniques used in clinical settings and require higher resolution techniques. Other biological fluids such as effusion, synovial fluid, and milk may have a sufficient protein content for accurate quantitation. Other interfering factors in these specimens may affect the analytical accuracy and specificity. Milk, some effusions, and synovial fluid may require hyaluronidase (or similar enzyme) addition to reduce the fluid viscosity. Low-protein fluids, e.g., urine and cerebrospinal fluid, may produce undetectable bands unless more sensitive techniques are employed (e.g., SDS-AGE/SDS-PAGE).[20]

APP measurement in veterinary medicine has been successfully performed in numerous body fluids, including milk, urine, synovial fluid, effusion, cerebrospinal fluid, and saliva. Saliva represents an optimal specimen when a noninvasive sampling approach is required. Method-specific reference intervals or decision thresholds must be established in the different fluids prior to clinical use, and after the analytical method has been analytically validated in that species.[6,14]

Interfering Substances

Fibrinogen in plasma samples migrates in the beta–gamma region and may interfere with EPH interpretation using AGE and CZE.[13] EDTA or heparinized plasma should be avoided if fibrinogen will interfere with needed diagnostic circulating protein evaluation in mammals. Plasma EPH is standardly used in avian and reptile species due to irreversible gelling of a percentage of serum samples.[27] Several methods to remove fibrinogen from plasma have been proposed, including ethanol precipitation and reptilase treatments.[13] Hemoglobin from hemolytic serum samples results in a pointed beta-1 peak; whereas high triglyceride levels may cause increased "albumin" and α-globulin bands. Bilirubin in icteric samples does not modify electropherograms using AGE, but increased albumin bandwidth due to increased bilirubin concentration has been reported using CZE.[3] In humans, intravenously administered iodinated, radio-opaque agents and antibiotics have been reported to generate abnormal spikes in albumin, α-1-, and β-globulin fractions using CZE.[3]

Lipemia, hemolysis, and icterus are not reported to affect immunoturbidimetric assays for CRP, SAA, and haptoglobin measurement.[4,22] Haptoglobin measurement by detection of peroxidase activity and colorimetric assays is decreased by free hemoglobin in hemolyzed samples, whereas lipemia and hyperbilirubinemia have no effect on Hp concentration.[11]

ANALYTICAL PERFORMANCE

A laboratory QA program should verify analytical precision and accuracy of all method components, including preanalytical and postanalytical factors, instruments, and reagents. Instruments must maintain constant temperature, voltage, and amperage to ensure result reproducibility. If instrument parameters are not constant, the laboratory should contact the manufacturer for repair or replacement of the instrument. Buffer pH must also be constant and, if stored, should be regularly checked with a quantitative pH meter. In contrast to human medicine, where specific standards and control materials are provided for this purpose, the peculiarity of electrophoretograms in different species may require the use of species-specific standards to assess EPH instruments' analytical performance. Nevertheless, a human-based QC material can be used as the standard which should be run as one lane on all gels to confirm that the equipment is performing within specifications. A species-specific control sample may be included with each run, to be used for statistical QC protocols.[28]

The inter- and intra-assay imprecision (coefficient of variation) of SPE reported in veterinary species of <3% for albumin and γ-globulin concentrations and <10% for the less represented fractions (e.g., α-1-globulins) are acceptable for diagnostic use. CZE is more reproducible (has a lower CV) than CAE and AGE.[16] Stored, frozen, patient samples may be used in repeatability experiments to verify that the assay's imprecision is acceptable. Accuracy assessment, without available species-specific standards of known concentration, may be achieved by serial dilution of normal and abnormal sera from species investigated by the laboratory. Dilutional effects must be considered for very low concentration serum proteins.[38]

Densitometry tracings should be evaluated to ensure that gates are correctly placed in protein troughs by the instrument's software. Protein fractions should be quantified in g/L after transformation of percentages using quantitative total protein concentration (using the biuret method as the established gold standard). As possible differences related to equipment settings and method may occur, laboratories should establish their own reference intervals.[15]

Multilevel standards for calibration and other QA are available for APP measurement.[25] Species-dependent, validated reagents should be employed, if available, to optimize results. The large variability in published reference intervals across veterinary laboratories requires establishment of internal reference intervals. Reference intervals reported in the literature should not be used by the laboratory or clinician, as their use may result in misdiagnosis. The known large variability in APP measurement begs for harmonization across laboratories.[25]

ELECTROPHORETOGRAM INTERPRETATION AND REPORTING

SPE identifies five to seven fractions, depending on the method. From the anodal to cathodal end, the peak order is albumin, α-globulin, β-globulin, and γ-globulin. Conventionally, the point halfway between the beginning and end of the curve corresponds to the limit between α-2- and β-globulins. The point halfway between the start of β-globulins and the curve's end is defined as the start of the γ-globulin region. This may be modified in pathologic electrophoretograms. Except for albumin, each peak represents numerous different proteins that can be further identified by other techniques. The precise composition of each peak is known in humans and one could speculate that the human data may be similar to many animal species, though likely not exact (Table 144.2).

SPE interpretation must be based on visual inspection of the electrophoretogram, the protein fraction absolute values, and possibly the gel banding pattern, especially to detect QA issues. The use of relative values (%) must be avoided, as it may lead to misdiagnoses.

Normal Electrophoretic Patterns in Domestic Animals

Albumin is the predominant fraction found in normal electrophoretograms. The number of globulin fractions varies with the species and method used, but should be standardized for the different species in the laboratory's clientele. Both α- and β-globulin regions may be subdivided into α-1- and α-2- or β-1- and β-2-globulins, respectively. This latter separation is less evident in ruminants and not possible when using plasma. In healthy dogs and cats, a further subfractioning of γ-globulins may be warranted. In most nonmammalian species, a band more anodal than albumin is often observed and therefore referred to as prealbumin.[27] This band has been shown to represent transthyretin as well as other possible α-globulins and is due to the varying migration of albumin in these species.[17] Examples of normal electropherograms are found in Figure 144.2.

Pathologic Electrophoretic Patterns

SPE has low diagnostic specificity for individual diseases. Therefore, confirmatory tests are required post hoc. Common electrophoretic abnormalities observed in diseased, domestic animals are provided (Table 144.3 and Figure 144.3).

FIGURE 144.2 Electrophoretograms from healthy animals. (a) Horse (AGE); (b) Cow (AGE); (c) Dog (AGE); (d) Cat (AGE); (e) Goat (AGE); (f) Rabbit (AGE); (g) Parrot (CZE); (h) Lion (AGE). From left to the right, peaks correspond to albumin, α-1-globulins, α-2-globulins, β-1-globulins, β-2-globulins, γ-globulins.

TABLE 144.3 Electrophoretic patterns and associated pathological conditions.

Electrophoretic pattern	Pathological condition
Increased α-1- and α-2-globulins, decreased albumin and transferrin	Acute inflammation
Increased α-2-, β-2-, and γ-globulins (C3 band)	Subacute inflammation
Increased α-1- and α-2-globulins, and polyclonal γ-globulin increase	Chronic inflammation, infectious diseases (e.g., feline infectious peritonitis; leishmaniasis in dogs)
Very low albumin, transferrin, and γ-globulin with increased α-2- and β-1-globulins	Nephrotic syndrome
Decreased albumin and total proteins with a polyclonal increase in γ-globulins ± β–γ bridging	Liver disease/cirrhosis
Decreased total protein, albumin, and γ-globulin	Mild protein loss
Polyclonal increase in γ-globulins with oligoclonal banding	Chronic infections, autoimmune diseases, lymphoproliferative processes
Hypogammaglobulinemia	Immune deficiency
Monoclonal gammopathy	Lymphoproliferative process involving B cells and plasma cells
Biclonal gammopathy	Possible presence of two clones of monoclonal immunoglobulins (neoplastic)
Oligoclonal gammopathy	Ehrlichiosis in dogs

Inflammation

APPs migrate in the α-1-, α-2-, or β-2-fractions (Table 144.2) and acute inflammation may produce a spike in these regions. Haptoglobin contributes to a significantly increased α-2-globulin concentration, especially in ruminants, due to its higher concentration compared to other characteristic APPs in many species. In chronic inflammation, albumin concentration may decrease and a polyclonal or apparent monoclonal gammopathy may appear.

Polyclonal Gammopathy

The γ-region is predominantly composed of IgG-type immunoglobulins. Polyclonal gammopathies are indicated by a broadly increased γ-band that may be caused by any sterile or septic inflammatory process including autoimmune disease, but are commonly caused by infectious disease (e.g., canine leishmaniasis, feline infectious peritonitis). A subfractioning of γ-globulins may be warranted in diseases causing hypergammaglobulinemia. A sharper, monoclonal-appearing peak may be observed in some infections (e.g., canine ehrlichiosis), referred as oligoclonal gammopathy. This must be differentiated from true monoclonal gammopathy.

Monoclonal Gammopathy

Monoclonal gammopathies are characterized by a homogenous formation of paraproteins that present as a sharp, well-defined single peak. By definition, the peak should have the same width or be narrower than the albumin peak. Despite the name, monoclonal components may also be observed in the β-fraction and, rarely, in the α-2-fraction.[28] Differential diagnosis for this appearance includes multiple myeloma, extramedullary plasma cell neoplasia, Mott cell neoplasia, other B cell lymphoma, and ehrlichiosis.

Nephrotic Syndrome

The relative changes in protein proportions found in nephrotic syndrome are the perfect example of why only absolute protein concentrations should be used. Urinary loss of albumin and small proteins results in hypoalbuminemia and proportional shift in the A:G ratio. Larger proteins migrating in the α-2- and β-regions (e.g., α-2-macroglobulin, lipoproteins, and many others) remain in circulation and their relative proportion (%) increases, generating apparent spikes on the electrophoretogram. Hypoalbuminemia should be noted and validated reference intervals for absolute protein concentrations then used to assess for abnormality in other banding regions to prevent incorrect interpretation.[28]

β-γ Bridging

A lack of demarcation between β-2- and γ-fraction, results from increased concentrations of IgA, IgM, and/or IgG and is usually associated with severe infections. In the presence of severe hypoalbuminemia, it is also the hallmark of chronic liver failure/cirrhosis due to hepatitis.[28]

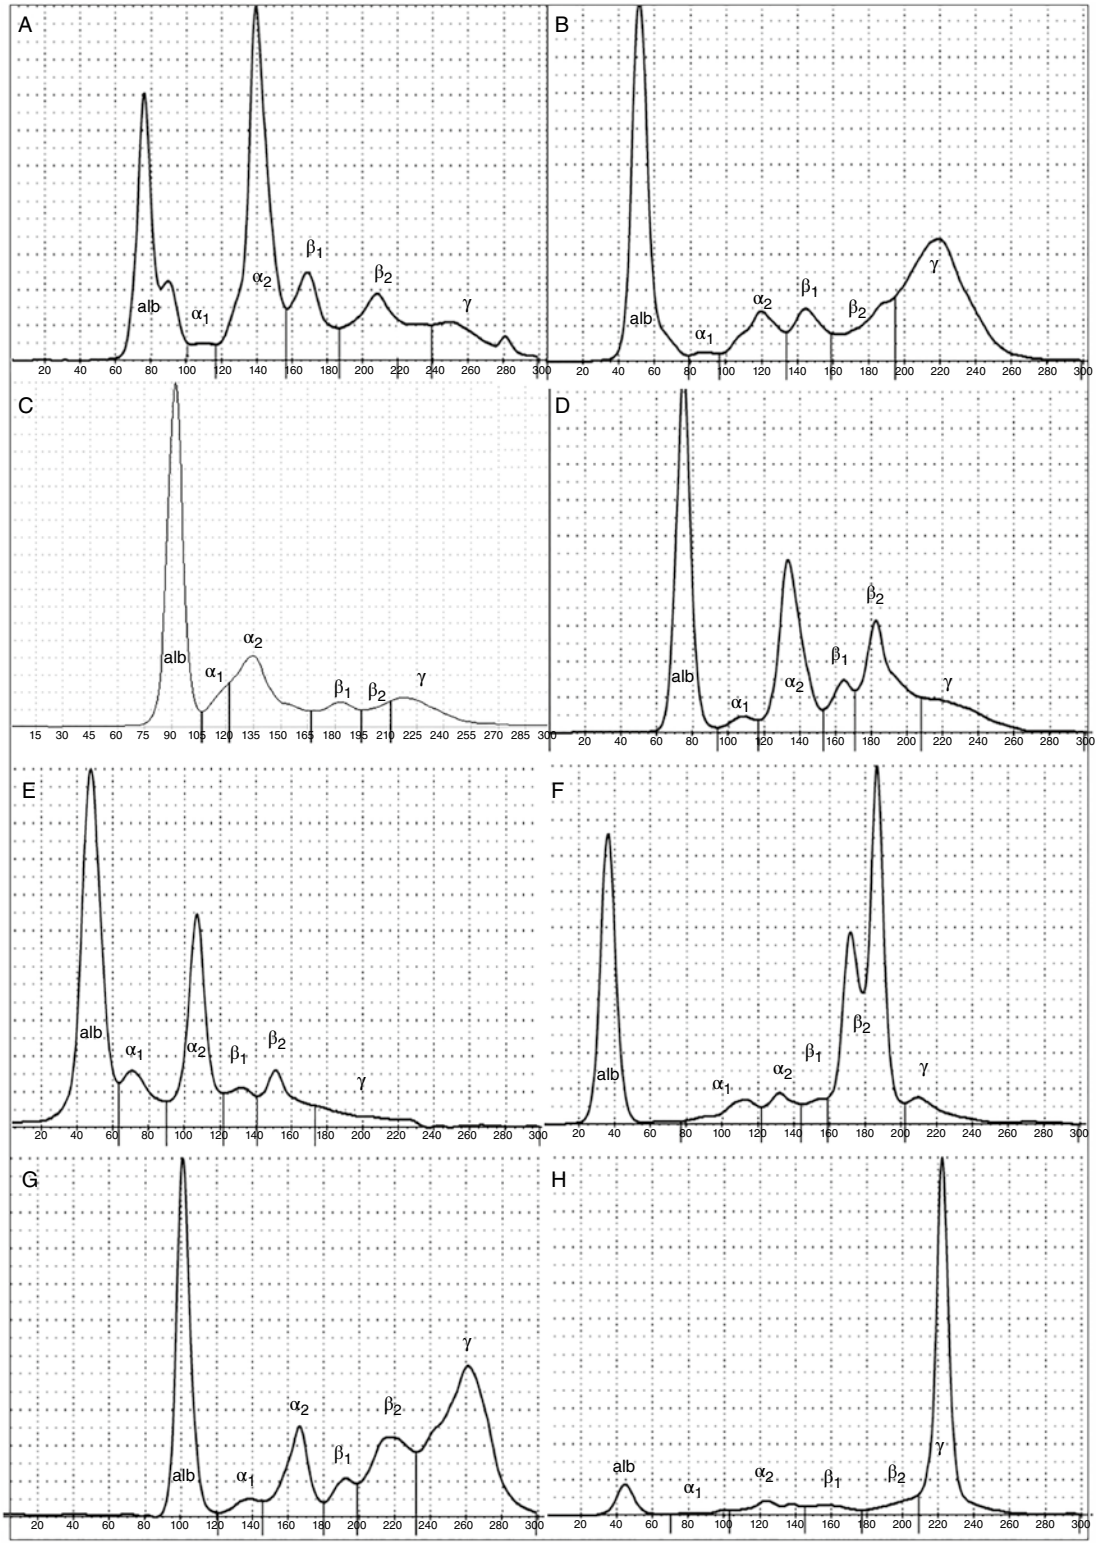

FIGURE 144.3 Electrophoretograms from diseased animals. (a) Horse with nephrotic syndrome (AGE), known absolute protein concentrations are required for interpretation of the graph; (b) Horse with chronic hepatitis (AGE) representing a polyclonal gammopathy; (c) Cow with acute inflammation (AGE), the increased α2 globulin concentration is likely Hp; (d) Dog with proteinuria (AGE), known absolute protein concentrations are required for interpretation of the graph; (e) Python with anorexia (AGE) with increased α2 globulin concentration which could be due to oviparity or acute phase proteins; (f) Cat with a plasma cell tumor (AGE) representing a possibly biclonal gammopathy; (g) Dog with leishmaniasis (AGE) representing a polyclonal gammopathy; (h) Cat with multiple myeloma (AGE) representing a monoclonal gammopathy. From left to the right, peaks correspond to albumin, α-1-globulins, α-2-globulins, β-1-globulins, β-2-globulins, and γ-globulins.

Acronyms and Abbreviations

CT, cycle threshold; dNTP, deoxyribonucleotide triphosphate; DNA, deoxyribonucleic acid; EDTA, ethylenediaminetetraacetic acid; FFPE, formalin-fixed paraffin-embedded; ISH, in situ hybridization; mRNA, messenger ribonucleic acid; PCR, polymerase chain reaction; qPCR, quantitative polymerase chain reaction; RCA, rolling circle amplification; RNA, ribonucleic acid; RT-PCR, reverse transcription polymerase chain reaction.

The development and advances in molecular diagnostic techniques have rapidly accelerated the discovery, detection, and characterization of infectious agents in the last 35 years. Since the inception of PCR technology in the early 1980s,[17,19] the field of molecular diagnostics has evolved rapidly while the costs and time associated with running such tests have decreased dramatically. Projects that may have originally constituted doctoral dissertations can now be completed in short order by relative neophytes in the laboratory.

As molecular diagnostics will routinely guide the diagnosis and treatment of disease in animals, it is imperative that clinicians and pathologists understand the basic tenets of PCR and common variations of the technique. This chapter will provide an overview on the basics of PCR and advanced molecular diagnostics to serve as a primer appropriate for veterinary clinicians.

SAMPLING AND PREANALYTICAL CONSIDERATIONS

The most sensitive and specific diagnostic assays are still unable to compensate for poor sample collection and storage. As such, consideration should always be given to the ideal sample for testing, the appropriate materials needed for collection and submission, storage conditions before and during transit, and transit time. It is always recommended to refer to the diagnostic laboratory performing the testing for any specific sample recommendations. Certain laboratories may recommend the use of one swab type over another. Some laboratories may also recommend the use of nucleic acid extenders, such as RNAlater®, for certain assays, while others may wish to avoid the material. In general, maintaining samples frozen or on ice will not adversely affect nucleic acid extraction. However, allowing samples to warm to ambient or higher temperatures for extended periods of time may result in nucleic acid degradation. This is particularly true if RNA targets are desired, as RNAses are ubiquitous and will rapidly cleave RNA into small fragments that may decrease assay diagnostic sensitivity.

Preserved samples can pose unique challenges for molecular testing. In general, samples preserved fresh in ethanol will serve as an excellent source of nucleic acid. The same is not usually true for samples preserved in formalin. Formalin chemically cross-links proteins and nucleic acids by two distinct and extremely effective methods.[18] Cross-linking results in substantial DNA fragmentation, and the longer a sample is maintained in formalin, the more dramatic the effect can be. Formalin

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

can also directly modify nucleic acids.[28] Formalin storage of samples for ≥72 hours will greatly reduce detection of PCR amplicons of 300–350 nucleotides or more. While such samples can still be useful for real-time PCR, their utility for end-point PCR is limited. However, molecular assays can be designed with formalin-fixed paraffin-embedded (FFPE) tissues in mind to maximize the diagnostic potential for some agents. Another processing technique that can have negative effects on downstream nucleic acid analysis is acid decalcification, as may be routinely performed on samples containing mineral or bone. If decalcification is required, chelating agents, such as EDTA, should be used. For blood samples, lithium heparin can have significant inhibitory downstream effects in molecular testing, and other common anticoagulants, such as EDTA, are recommended.[24] Unstained blood smears and cytologic impressions can also be a viable source of nucleic acids for molecular testing, depending on the desired testing.[3]

The last major preanalytical consideration, if applicable, is the selection of an appropriate diagnostic laboratory. There are many veterinary molecular diagnostic laboratories in both the academic and private sectors. Not all are created equal or have the same commitment to quality assurance and quality control. It is important to confirm that the laboratory you are utilizing runs appropriate controls, sequences samples for confirmation when appropriate, and can provide interpretation of results in complex cases. Moreover, not all tests will have the same sensitivity and specificity, and when dealing with veterinary species, it is always important to verify the test has been validated in the host in question. Establishing a professional relationship with the laboratories that you utilize for testing will go a long way in meaningful discourse on the findings and limitations in test results.

NUCLEIC ACID EXTRACTION

The extraction of nucleic acids from samples has been greatly facilitated by the ready availability of a variety of commercial extraction kits. Kits for manual and automated extractions of DNA, RNA, or both DNA and RNA, are available for a variety of input material, including blood, swabs, fresh tissues, FFPE tissues, fecal material, tissue culture cells, and other organic material. While extraction biology can vary widely, column-based extraction methods are the most commonly available.[23] Briefly, in column-based extractions, samples are lysed, nucleic acids are bound to packed silica columns, washed with various (often proprietary) formulations of salts and detergents, and then eluted in water or dilution buffer. Depending on the nature of the column, the extractions can be optimized for the concentration of RNA or DNA. Other critical steps of the extraction process, particularly of tissue samples, include lysis and digestion; these are usually achieved by some combination of mechanical homogenization and enzymatic digestion. For certain tissues very rich in nucleic acids (such as a liver and spleen), care should be taken to limit the size of the tissue sample extracted so as to not overwhelm the column with nucleic acid. The addition of additional enzymes, such as lyticase, can also facilitate the extraction of infectious agents with a cell wall, such as fungi.[10] Following nucleic acid extraction, the quantity and quality of extracted nucleic acids should be quantified spectroscopically or fluoroscopically. Extracts from samples containing non-host organic material (such as feces or environmental samples) may have carryover of PCR inhibitors that can interfere with downstream PCR, and in certain samples dilution of eluted nucleic acids is important to decrease this potential inhibition.[21] Lastly, it is always recommended to perform an extraction negative control concurrent to sample extractions. Extraction negative controls should be tested alongside extracted samples to rule out contamination during the extraction process.

TENETS OF PCR

While numerous variations of PCR exist, the central tenets of the technique are the same. PCR is cyclical and exponential amplification of nucleic acids by the action of thermostable DNA polymerases. These polymerases engage short oligonucleotides (primers) bound to complementary sequence in single-stranded DNA. With this cyclical amplification, target sequences present at incredibly low levels can be amplified to a point where they can be detected visually by gel electrophoresis and can be sequenced for analysis.

The required components of a typical PCR include the following: (1) DNA-dependent DNA polymerase; (2) a forward (sense) primer; (3) a reverse (antisense) primer; (4) deoxyribonucleotide triphosphate (dNTPs); (5) buffer for optimal polymerase activity; (6) template nucleic acids. The DNA-dependent DNA polymerases utilized in PCR were originally discovered in bacteria evolved to live at very high temperatures (geothermal vents and springs). Taq polymerase was originally isolated from the bacterium *Thermus aquaticus*.[5] Pfu DNA polymerase, a high-fidelity polymerase with proofreading activity also commonly used in PCR, was isolated from *Pyrococcus furiosus*.[15] The thermostable nature of these polymerases is essential to resist denaturation at the high temperatures necessary to promote the separation of double-stranded DNA into single strands. While the components necessary for PCR can be purchased separately, commercial master mixes containing all necessary elements other than primers and template DNA are commonly available.

Primers are the most important component of PCR in conferring assay sensitivity and specificity. Primer design, while greatly assisted by the availability of commercial software, is a process that combines science, art, and luck. There are many factors to consider in primer design, including but not limited to length, guanine and cytosine (GC) content, and secondary structure potential.[6] Degenerate primers can be designed

to decrease the specificity of a PCR. This can be incredibly useful if designing an assay to detect multiple strain or species variants of a nucleic acid target. In degenerate primers, at select positions multiple, mixed bases (such as an adenine [A] or a guanine [G]) are present in the primer mixture. While the decrease in specificity resultant of such degeneracies can increase the diversity of preferred targets for PCR, it can also increase the amplification of unwanted, nontarget sequences.[13]

Appropriate controls are necessary for accurate interpretation of PCR results. Assay positive controls as well as both assay and extraction negative controls are all worthwhile running for each batch of samples tested. Sources for potential positive controls include previously confirmed positive extractions, gel-extracted amplified nucleic acids from a prior assay, or commercially synthesized artificial controls (oligomers, gBlocks®, or plasmids). There are multiple benefits of using artificial controls, including the introduction of unique novel sequence that can be screened for to rule out laboratory sample contamination and accurate assessment of copy number for control curves.

End-Point PCR

End-point (also referred to as conventional, consensus, or qualitative) PCR can amplify short fragments of nucleic acids from a DNA template (Figure 145.1a,b). The components of an end-point PCR reaction are exactly as described in the earlier text, and include polymerase, primers, dNTPs, and template DNA. A typical end-point PCR cycle consists of the following stages: (1) Initial denaturation (94–96 °C); (2) 30–45 sequential cycles of (a) denaturation (94–96 °C), (b) annealing (variable), and (c) elongation (72 °C); (3) Terminal elongation (72 °C); (4) Holding (4–12 °C). The denaturation stages promote the dissociation of double-stranded DNA into single strands. The annealing stage is the period when the primers bind to the template DNA. A variety of temperatures can be used for this step. A general rule of thumb when establishing a new assay is to use an annealing temperature 5 °C lower than the lowest melting temperature (T_m) of the two primers. However, there is a lot of flexibility with this temperature, and it is an important variable to alter in assay optimization. Unique techniques varying annealing temperatures with cycle, such as touchdown PCR which utilizes annealing temperatures higher than calculated primer melting temperatures, can sometimes be useful in increasing assay specificity and sensitivity.[11] The elongation phase allows for template transcription from the bound primer, and occurs at the optimal temperature for polymerase activity. Amplicons are visualized by gel electrophoresis, and additional testing, such as sequencing, is required to confirm specific amplification.

Nested and Heminested PCR

A variation on end-point PCR that can increase assay sensitivity and/or specificity is the addition of a second round of PCR amplification using unique primers complementary to sequence internal to the primers used in the initial round of PCR (Figure 145.1b). In a fully nested PCR assay, both the forward and reverse primer sequences are unique and complementary to sequence internal to the round one primers. In a heminested assay, one unique primer with complementary sequence internal to either the round one forward or reverse primer is coupled with the converse round one primer. One or more primers may be degenerate to decrease specificity. In both instances, the input template DNA for the round two reaction is a small aliquot of the round one reaction. The products require visualization by gel electrophoresis for confirmation of appropriate amplification.

Reverse Transcription (RT)-PCR

For RNA targets, such as the genomes of RNA viruses or mRNA, RNA must first be transcribed to DNA before it can be amplified by PCR. This initial reverse transcription is achieved by another enzyme, reverse transcriptase. The reverse transcriptase of Moloney murine leukemia virus (MMLV) is commonly utilized for this, and there are many commercially available kits that include MMLV RT as part of an RT-PCR master mix.[8] Reverse transcription of the input RNA can be achieved utilizing either target-specific reverse primers, random oligonucleotide hexamers, or, for the case of mRNA, by an oligomer of poly-deoxythymidine that binds to the polyadenylated tail.[2] The reverse transcription step is performed prior to the initial denaturation step of PCR, as the high temperature step will denature the thermolabile RT. The sample can then proceed on with either end-point PCR or real-time PCR.

Real-Time (Quantitative) PCR

In contrast to end-point PCR, which requires gel electrophoresis following the PCR assay to assess for the presence of amplified nucleic acids, real-time PCR monitors for PCR amplification at the end of each PCR cycle via fluorescence.[1] Though not uniformly the case, real-time PCR assays are often more sensitive than end-point assays. Amplicon target sizes are also generally much shorter and often in the range of 100–200 nucleotides. The components of a real-time PCR are similar to an end-point assay in that there is still a requirement for a forward and reverse primer, DNA polymerase, and input template DNA (Figure 145.1c,d). The fundamental difference is the addition of a fluorescent signal as well as a passive reference dye. The type of fluorescent signal depends on the type of real-time PCR assay, which will be discussed in more detail in the following text. The PCR cycle stages are altered slightly and consist of (1) initial denaturation (94–96 °C); and (2) 30–45 sequential cycles of (a) denaturation (94–96 °C) followed by (b) annealing/elongation (generally 55–60 °C).

Dye-based real-time PCR relies on the properties of a group of dyes, such as SYBR green, that emit a fluorescent signal only when incorporated into double-stranded

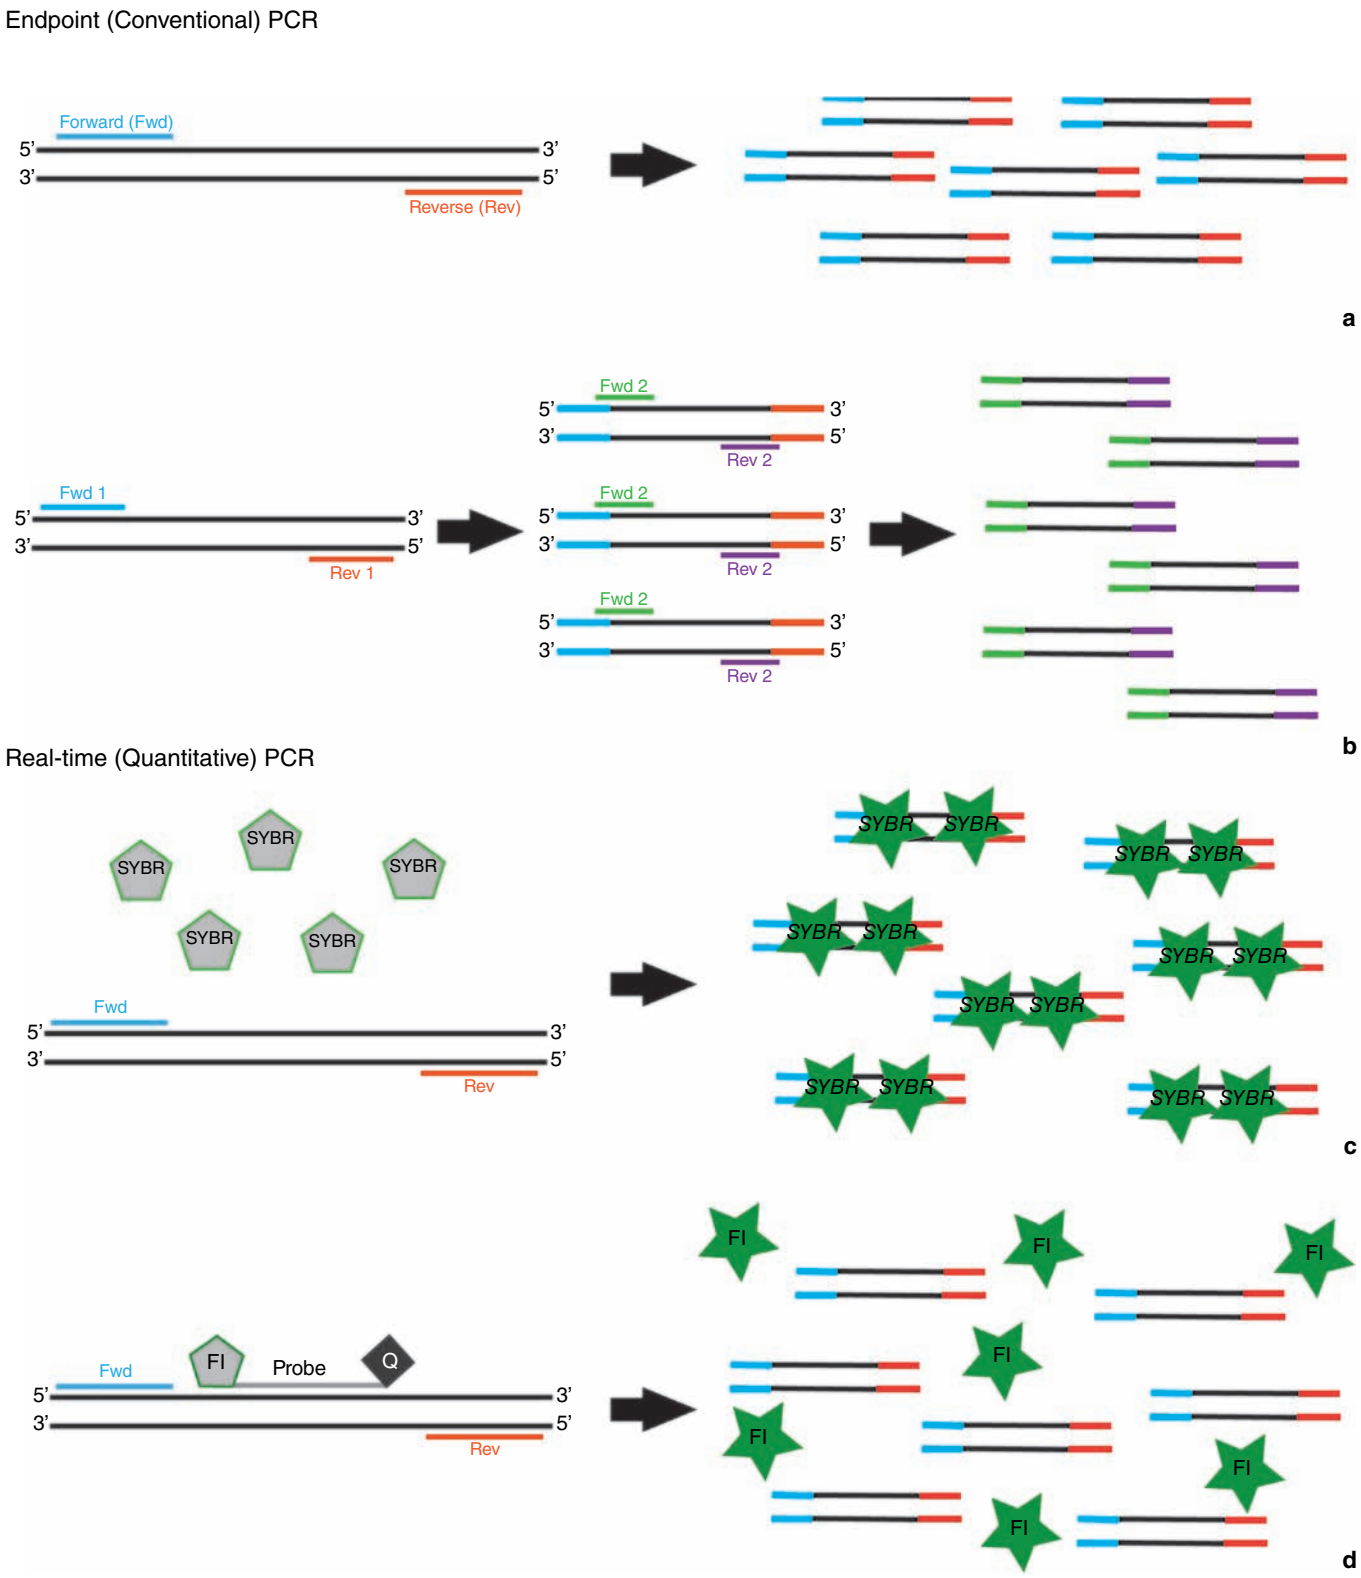

FIGURE 145.1 Schematic comparison of commonly used types of PCR. (a) and (b) End-point (conventional) PCR assays result in the exponential amplification of nucleic acid targets that must be visualized by gel electrophoresis. (a) In standard end-point PCR, a single pair of complementary oligonucleotides (primers) in a forward (sense) and reverse (antisense) orientation is utilized to amplify a known target; (b) In nested end-point PCR, a first round reaction is run using one pair of primers, and additional primers located internal to the round 1 primers are then utilized in an additional round of PCR to further amplify a known product. This technique can be used to both increase assay sensitivity and specificity. (c) and (d) Real-time (quantitative) PCR assays also result in exponential amplification of target nucleic acids, but the amplification is measured by changes in fluorescence over time. (c) In dye-based real-time PCR, the intercalation of dyes (SYBR) into double-stranded DNA results in the production of a fluorescent signal; (d) In probe-based real-time PCR, the liberation of a fluorophore (Fl) from a complementary probe and associated quencher molecule (Q) as a result of polymerase exonuclease activity results in the production of a fluorescent signal that increases with each round of PCR amplification in positive samples.

DNA.[29] At the end of each PCR cycle in a dye-based real-time PCR, the amount of incorporated dye is measured as a fluorescent signal. In a positive sample, the fluorescent signal will increase exponentially with each cycle due to an increase in the number of double-stranded DNA resultant from the PCR (Figure 145.1c). One major drawback of this style of real-time PCR is that the dye incorporation is nonspecific; if there is nontarget amplification, it will still be read as a positive signal. While techniques such as melt curve analysis can help differentiate true positives from false positives, it adds an additional step and can still complicate result interpretation.[25] The technique also has limited utility for the simultaneous detection of multiple target sequences.[9]

The advent of probe-based (also referred to as TaqMan or hydrolysis probe) PCR revolutionized real-time PCR.[12] In contrast to SYBR green real-time PCR, the fluorophore is attached to an oligonucleotide sequence complementary to the target DNA (Figure 145.1d). This probe also contains a quencher molecule that absorbs the energy emitted from the fluorophore. During transcription of the target DNA the bound probe is fragmented, liberating the fluorophore from the activity of the quencher molecule which allows for emission of the fluorescent signal. As in dye-based techniques, the fluorescent signal is measured at the end of each round of amplification. Not only does the addition of specific complementary probes increase the specificity of the assays, the availability of multiple fluorophore/quencher combinations with unique absorption/emission spectra allows for the detection of multiple target sequences in a single assay (multiplex real-time PCR).[27]

In both dye- and probe-based real-time PCR assays, positive samples exhibit a characteristic amplification curve, which will cross a baseline cycle threshold (C_t) value. The C_t value is inversely proportional to the amount of target nucleic acid in the initial sample. In other words, the more target nucleic acid, the earlier the amount of detected fluorescence will be higher than the threshold, and therefore the lower the C_t value. Positive samples may just be reported as positive, or may include a C_t value or count number. Count numbers are inferred from standard curves of known concentrations. Samples that do not cross the baseline threshold, cross the threshold beyond a certain cutoff (usually around 39–40 cycles), or exhibit atypical amplification curves are reported as negative or undetermined. Samples are often run in duplicate or triplicate to increase detection of weak positives.

Rolling Circle Amplification

Rolling circle amplification (RCA) is a technique useful for circular nucleic acid targets, including some viruses and plasmid DNA.[16,21] Unlike the previously described PCR techniques, the process is isothermal and does not require cyclical stages of heating and cooling. The polymerases utilized for rolling circle amplification do not have to be heat stable, and the most commonly used polymerase is phi29 from a bacteriophage. RCA does not require any predetermined sequence knowledge, and can be a great tool for viral discovery. However, the technique can be laborious and requires a substantial amount of processing and sequencing.

SEQUENCING MODALITIES

Sequence determination of PCR products (sequencing) is most commonly achieved by classical Sanger sequencing, a method developed by Sanger and Coulson in 1975.[20] At its core, Sanger sequencing is similar to PCR in that it requires template DNA, primers, and a DNA polymerase. Where it differs is that a subset of dNTPs are modified (dideoxynucleoside triphosphate; ddNTP) and fluorescently labeled. The amplification reaction is terminated when the polymerase incorporates a fluorescently labeled ddNTP into the strand. The fluorescent signal is detected and reported in a chromatogram.[7] Analysis of the chromatogram allows for determination of the input sequence. Sanger sequencing is widely commercially available, and single reactions can be run for just a few dollars. Sanger sequencing reactions are limited by length (500–700 bases) and the inability to differentiate mixed input sequences for which the initiation primer will bind.

Technological advances and decreased costs associated with next-generation nucleic acid sequencing have facilitated significant advances in science. The dramatic and rapid decrease in the cost of these techniques has made previously financially unfeasible testing modalities viable in the diagnostic and research setting. In next-generation sequencing modalities, including Illumina, PacBio, and pyrosequencing, no a priori knowledge of the sequence is required, and immense amounts of sequence data can be generated from mixed templates.[22] This is particularly powerful for metagenomic analyses. One of the challenges with these methods is the cost, which, while dramatically reduced in the past few years, can still be prohibitive for some. Another is the amount of bioinformatic analysis that can be required for interpretation of derived sequences. Despite the limitations, it is an exciting time for molecular diagnostics and pathogen discovery with the availability of these techniques.

IN SITU HYBRIDIZATION

In situ hybridization (ISH) is a powerful tool that can colocalize the presence or expression of nucleic acids to a certain cell type or within a lesion. Recent procedural and technologic advances have dramatically improved the sensitivity and specificity of the technique.[4,26] ISH works well on both cytologic and formalin-fixed paraffin-embedded preparations, and can be analyzed colorimetrically or fluoroscopically. Potential targets include both host mRNA and pathogen nucleic acids, with the technique being particularly powerful in placing novel pathogens within a putative lesion.[14]

Knowledge of target sequence and, ideally, the host genome are all that is required. Both a negative control probe and a positive host housekeeping gene control probe are important for accurate interpretation of results in most cases. The assay can also be complexed with immunohistochemistry to allow for concurrent detection of protein and nucleic acids.

Acronyms and Abbreviations

For a glossary of relevant genetic terms, please see Table 146.1.

cDNA, complementary DNA;CNVs, copy number variations; DNA, deoxyribonucleic acid; GWAS, genome-wide association studies; IL-2RG, interleukin-2 receptor subunit gamma; Indels, insertion/deletion polymorphisms; NGS, next-generation sequencing; PCR, polymerase chain reaction; PRKDC, protein kinase, DNA-activated, catalytic subunit; RAG1, recombination activating gene 1; RNA, ribonucleic acid; RNAseq, RNA sequencing; SNPs, single-nucleotide polymorphisms; WES, whole-exome sequencing; WGS, whole-genome sequencing.

DEFINITIONS OF INHERITED CONDITIONS

Genetic information is inherited from parents to offspring. Typically, this information provides instructions to produce proteins that determine chemical and physical traits, including hematologic diseases. Genes that code genetic information are packed in paternal and maternal chromosome pairs in each cell's nucleus. Chromosomes are filament-like structures that contain tightly coiled DNA and histone proteins. The DNA sequence provides the blueprint for protein synthesis, and sequence alterations are called mutations. DNA mutations can be inherited from a parent, in which case they are found in all cells of an offspring. Other DNA mutations acquired during an individual's lifetime are called somatic mutations, and may affect only certain cells and underlie cancers. According to the central dogma of biology, the DNA template is transcribed into a RNA template and then the RNA template is translated into a protein product.

Genotype Versus Phenotype

The genetic basis for hematologic disease is determined by the inheritance of genes containing specific DNA mutations. The phenotypic expression of these genes, through synthesis of specific proteins, often includes interaction with environmental signals that trigger activation of typical molecular pathways. An individual's genotype is the complete set of genes, inherited from both parents. The individual's phenotype is all of its identifiable characteristics, which are influenced by its genotype, environmental factors, and interactions between the two.

Congenital Conditions, Phenocopies, and Epigenetics

Disease phenotypes present at birth are termed congenital. These conditions can be inherited, or the result of environmental factors such as toxins, nutritional imbalances, or infections during gestation. Conditions that cause later onset of disease can also be inherited or acquired. Some inherited diseases are manifested under certain conditions. For example, inherited coagulation factor deficiencies (e.g., hemophilia A or B) lead to excessive bleeding post trauma or surgery. However, rodenticide poisoning can lead to acquired coagulation factor deficiencies with similar symptoms of excessive bleeding. Phenocopy describes conditions caused by environmental influences that mimic known inherited diseases.[29,93]. Alterations to gene activity in absence of changes in DNA sequence are termed epigenetic.[93] Any interference to the path from transcription to a physiologically functional protein is considered an epigenetic factor. Epigenetic modifications can be transmitted to offspring (inherited), or they can be reversed during reproduction.

Penetrance and Variable Expressivity

Penetrance is the proportion of individuals with a mutation that have phenotypic characteristics of a trait, or symptoms of an inherited disorder.[93] If <100% of individuals with a mutation exhibit the disorder, the penetrance is reduced or incomplete. When an inherited disorder is experienced in a wide range of severity, age of onset, or progression of disease, it is variably expressed.

Modes of Inheritance

The pattern in which a genetic trait or disorder is inherited is termed the mode of inheritance. Modes of inheritance for single-gene disorders are categorized based on a dominant or recessive pattern and chromosomal locations (i.e., autosomal, X-linked, or mitochondrial). Autosomal disorders typically cause equal numbers of affected males and females. When a mutation in a single allele is sufficient to cause a phenotype, it fits an autosomal dominant inheritance pattern. In autosomal recessive inheritance, mutations in both parental alleles are required to cause a phenotype. X-linked inheritance refers to disease causing mutations located on the X-chromosome. Larger proportions of affected males are observed because males have a single X chromosome. While females may be affected, they tend to be silent carriers that transmit the disorder.

Non-Mendelian disorders include mitochondrial inheritance, and complex or multifactorial inheritance. In mitochondrial inheritance, a mutation in the mitochondrial DNA, which is maternally transmitted, causes the disorder. Males and females are equally affected. Disorders with complex inheritance are caused by variations in multiple genes and their interactions with environmental factors. Susceptible individuals who exhibit the phenotype have sufficient numbers of certain genetic variations and are exposed to environmental factors that interact with their genetic variations, acting as triggers.

The mode of inheritance helps determine the risk of disease occurrence in related individuals and allows one to predict the disease state of progeny. Genetic selection against single-gene disorders using DNA screening tests in breeding animals is relatively straightforward. However, addressing complex conditions requires careful consideration of multiple genetic variants; sometimes with opposing effects on disease phenotype.[38] DNA mutations are found in every individual and inherited conditions affect both pure-bred and mixed-breed animals.[35] Typically, the frequency of animals affected by a recessive disorder is lower within mixed-breed population, but when considering an individual animal, inherited conditions should be listed as differential diagnoses regardless of breed status.[135]

GENETIC ANALYSIS

See Chapter 59 for cytogenetics review. DNA variations commonly used in genetic analyses include:

Single-nucleotide polymorphisms (SNPs) are substitutions of one nucleotide by another. SNPs are the most abundant form of genetic variation, found on average every 1000 bases in the dog genome.[81] SNPs may represent benign polymorphisms or mutations. Typically, polymorphic SNPs are found in noncoding sequence (i.e., introns) at a frequency of 1% or higher within a population. SNPs in coding DNA regions (i.e., exonic) may act as point mutations and alter protein structure or function; e.g., prekallikrein deficiency in Shih Tzu dogs caused by a single base substitution in exon 8 of the KLKB1 gene,[99] and factor VII deficiency in multiple breeds caused by a base substitution in exon 5 of factor VII.

Insertion/deletion polymorphisms (indels) are gains or losses of one or more nucleotides. Indels are less common than SNPs, found on average every 2400 bases; still they comprise a large proportion of DNA sequence variation. Exonic indels may cause frameshift mutations that can result in a premature stop codon; e.g., in dachshunds, a one-base deletion in exon 4 of the enzyme palmitoyl protein thioesterase 1 (PPT1). The frameshift

leads to a premature stop codon that causes neuronal ceroid lipofuscinosis-1.[7] An insertion in exon 7 of the factor XI gene causes factor XI deficiency in Kerry blue terriers.[114]

Copy number variations (CNVs) are genomic differences in copy number of DNA segments that range between hundreds to millions of bases. CNVs in mammalian genomes are common in gene families related to cell signaling and adhesion, olfactory receptors, sensory perception, immunity, and reproduction.[44] A duplication of 12.3 kilobases was recently discovered within the von Willebrand factor (VWF) gene in pigs affected by von Willebrand disease type III.[78]

Genetic analysis methods include:

Genome-wide association studies (GWAS) represent a powerful tool for investigating the genomic architecture of inherited traits. GWAS compare the frequencies of DNA variants between cohorts of cases (i.e., individuals affected by an inherited condition) and controls. GWAS typically utilize a hundred thousand to a million common DNA variants such as SNPs evenly spaced across the entire genome. Subsequent statistical analyses determine the likelihood of a variant to be associated with a disease. GWAS are hypothesis-free and do not require knowledge about mode of inheritance or pedigree information. With the complete sequencing of the entire genomes from most domestic species, high resolution SNP arrays were developed, which enable successful GWAS. In dogs, extensive linkage disequilibrium due to intense selection for breed-specific traits allows for remarkably effective mapping of loci for inherited traits by GWAS. Examples for successful GWAS include the discovery of a causative point mutation in ATP13A2 for neuronal ceroid lipofuscinosis in Tibetan terriers,[128] and mutations in CUBN that cause cobalamin malabsorption in beagles, border collies, and mixed-breed dogs.[36]

Whole-genome sequencing (WGS) is another method in which the order of DNA nucleotides in the individual's entire genome is determined. Next-generation sequencing (NGS), or high-throughput sequencing, describes several different modern sequencing technologies that offer much quicker and cheaper DNA and RNA sequencing compared to Sanger sequencing.[132] In general, the sequencing process involves the preparation of a library of short DNA fragments through either enzymatic or sonication techniques. These short DNA strands are then ligated to generic adapters in vitro. PCR amplification is performed using either emulsion PCR in oil–water emulsion micelles or bridge PCR on a solid surface coated with complementary primers. Subsequent amplicon sequencing is performed by pyrosequencing, sequencing by ligation, or sequencing by synthesis. The large number of short reads generated from this process must then be aligned against a reference sequence. A plethora of software have been developed not only to align the reads, but to also determine where deviations from a reference sequence exist.[91] These advanced techniques facilitate progress in the molecular study of genetic diseases, and allow breakthroughs in genomics; e.g., identification of a mutation in CLN8 that caused neuronal ceroid lipofuscinosis in a mixed-breed dog,[55] and a FAS-ligand variant associated with autoimmune lymphoproliferative syndrome in cats.[1]

In whole-exome sequencing (WES), all protein coding exons within an individual genome are sequenced. Next-generation sequencing can be used to determine this subset of DNA nucleotides called the exome, which is estimated to be only approximately 2% of an entire mammalian genome. Exome sequencing is proposed to be an efficient method to identify novel candidate mutations that cause inherited conditions, because most known disease-causing mutations occur in exons.[34]

Gene Expression

Over- and underexpressed genes in affected individuals compared to those in unaffected individuals can provide useful information to assist studies of simple as well as complex traits. Profiling of alternatively expressed transcripts can highlight a molecular pathway at play, identify biomarkers, or characterize response to therapy. Reliable evaluation of regulation of gene expressions is required for our understanding of the connection between genotype and phenotype. Technologies such as DNA microarray were developed in order to provide this type of expression analysis. Sample preparation begins with isolation of total RNA followed by reverse transcription to generate complementary DNA (cDNA). The sample cDNA sequences serve as nucleic acid probes that are covalently bound to glass slides. Known target sequences that are fluorescently labeled are hybridized to the probes and scanned.

Scanned images are converted to signal intensities and the data are processed using application-specific software. Software packages allow statistical analysis of the null hypothesis that a gene is not differentially expressed between two disease states. The sensitivity of microarrays enables a reliable detection of a twofold change in gene expression.

Microarrays can detect single-nucleotide polymorphisms, exon junctions, and gene rearrangements, but are limited to the transcripts bound to the array slides. Microarrays are only as good as the bioinformatic data available for the model organism's genome and transcriptome, and need to be updated to contain the most up to date sequence information.[112]

Gene expression profiling by microarray technologies has been successfully applied to study the transcriptional changes that occur in diseased versus normal tissues, such as heart, vessels, and blood cells in different cardiovascular disorders.[51]

Next-generation sequencing can also be used to sequence the complete expressed transcripts, or transcriptome, from cells or tissues; an approach called RNA sequencing or RNAseq.[112] RNAseq is independent of existing genome sequence data and has the capacity to sequence tissue-specific and novel transcripts. RNAseq can quantify transcript expression levels, predict exon–intron boundaries, and identify alternatively spliced

isoforms. RNAseq advantages over microarray gene expression platforms include higher resolution, detection of rare low-abundance transcripts, and polymorphism identification (i.e., SNPs) within transcripts.[112] Microarrays typically have a lower cost, have simpler computational analyses, and require less storage space for data.[112]

Genetic Testing

Screening for a genetic disorder is indicated when there is familial disease presentation, young age of onset, or when routine CBC, biochemistry, or urinalysis suggest known inherited disorders.[77] In dogs, genetic disorders should not be ruled out without further testing in pure and mixed-breed patients alike.[135] Screening of asymptomatic breeding animals is commonly requested prior to their use, as many breeders are aware of the availability of DNA tests, and strive to utilize them to apply selection against known inherited disorders.

ONLINE SOURCES OF AVAILABLE DNA TESTS

Orthopedic Foundation for Animals: https://www.ofa.org/diseases/dna-tested-diseases/all-dna-tests
University of Pennsylvania Inherited Disorder Test Search: https://www.vet.upenn.edu/research/academic-departments/clinical-sciences-advanced-medicine/research-labs-centers/penngen/penngen-tests

Phenotype Testing

Phenotype testing determines the individual's phenotype for a trait, and does not give information about the genotype; i.e., what an animal is capable of passing on to its offspring. The methods depend on the analyte tested, not the genetic or nongenetic origin, and frequently include antibody-based testing, though numerous modalities are possible. Serum cobalamin measurement by competitive protein-binding assay is used to diagnose cobalamin deficiency, regardless of the etiology.

Genotype (DNA) Testing

Genetic or DNA testing identifies disease-causing mutations in genes. Genetic test results can confirm or rule out a suspected genetic condition and establish an individual's carrier status. A list of DNA tests available for dogs, cats, horses, livestock other than horses, and miscellaneous species at the time of writing this chapter is provided in Tables 146.2–146.7. It is noted that new DNA tests are constantly becoming available and readers are advised to remain updated by using online resources or by direct contact with testing laboratories. DNA tests have several advantages compared to phenotype tests. DNA can be collected from any cell other than RBCs in mammals. Noninvasive tools such as buccal or saliva swabs are used frequently and hair follicles or whole blood are sampling options. DNA can also be extracted from semen, urine, and feces. DNA samples from any aged patient can be tested; e.g., newly born animals, prior to clinical symptoms, and before an animal is sold. DNA from dead animals can also be tested, as long as an appropriate sample (e.g., frozen semen) that was collected while the animal was alive exists. DNA is very stable and there are no special shipping requirements, unlike other bioproducts such as RNA. RNA is extremely unstable; special conditions and stabilizing solutions are required in order to preserve RNA for diagnostic purposes.

Mutation Tests

DNA mutations have been identified for numerous monogenic disorders (Tables 146.2–146.7). DNA mutation tests for companion animals are being offered by a large number of commercial molecular genetic laboratories. DNA mutation tests are laboratory assays that need to be validated; however, validation is not commonly documented for DNA tests of veterinary species. Different laboratories use different assays that employ different primers sets, DNA concentrations, and number of PCR cycles, to name a few. Variations in assay false-positive and false-negative rates need to be taken into account when interpreting test results. Another important consideration for ordering and interpreting DNA mutation tests is that they are mutation-specific and breed-specific. Consequently, only the animals within breeds where the same exact mutation was identified are expected to have it. An absence of the tested mutation in all other breeds does not imply inherited disease-free status. For example, severe combined immunodeficiency is an autosomal recessive disorder in Parson Russell terriers, caused by a PRKDC gene mutation; however, in basset hounds and cardigan Welsh corgis, it is an X-linked disorder caused by several different mutations in interleukin-2 receptor subunit gamma (IL-2RG). Another dog breed with autosomal recessive severe combined immunodeficiency and yet another different gene mutation is Frisian water dog with a RAG1 mutation (Table 146.2). Unfortunately, some of the commercial DNA testing laboratories report DNA test results as "the animal is free of DNA mutations." This outcome merely reflects the limits of our current knowledge of DNA mutations. A more comprehensive statement should be "free of known mutations that are included in the assay." Results from 1000 human genomes revealed that people carry an average of 250–300 recessive mutations, and at least 50 mutations previously associated with inherited disorders.[37] It is reasonable to expect that the average dog will carry a similar burden

of disease-associated variants, many of which are not currently being interrogated by existing DNA tests.

When the exact mutation is unknown, DNA variations that segregate together with a presumed causative locus can be evaluated. These DNA variations, called associated markers, can be SNPs, indels, or CNVs. These marker tests may be inaccurate, since the mutant gene itself cannot be directly tested. It is important to consider this when prioritizing diagnostic procedures, and when reaching clinical decisions.

Odds Ratio Versus Genetic Risk Complex diseases are caused by a combination of DNA variations and environmental factors. For complex disease, a number of genetic mutations typically contribute to the risk for showing disease symptoms. The degree of contribution varies between different genes, gene combinations, and particular mutations. Some changes have large and some have small effects. The number and combination of changes in an animal's genome determine its overall risk of disease. Relative or genetic risk represents the proportion of individuals with DNA mutations that will suffer an associated inherited disorder in the future. An odds ratio represents the proportion of affected animals in which associated DNA mutations were detected. These terms are frequently used interchangeably; and odds ratios are often interpreted as if they were equal to relative risks. This ignores the actual meaning of a ratio of odds. It is common in the literature to describe an odds ratio of "2" as a "twofold risk" of developing disease. This inaccuracy is often misleading because the odds ratio tends to overestimate the relative risk.[122] Case-control studies are limited by design to odds ratio calculation because of their retrospective nature.

DNA Test Utility for Veterinarians

The clinical utility of a genetic test refers to the impact of the testing information on clinical care. Clinical utility depends on the availability of effective tools to treat or reduce clinical symptoms in the patient. The presence of a known disease-causing mutation in sick patients can assist in prognosis and anticipation of further symptoms or complications. Mutation identification also enables genetic counseling for animal breeders and farmers. An animal that carries a disease-causing mutation can be bred to an individual that does not carry the same mutation. Expecting breeding animals to be clear of all deleterious alleles is unrealistic, and it may negatively impact breed diversity.

The clinical validity of a genetic test (i.e., the ability of a genetic test to predict a disease phenotype) depends on the phenotype's penetrance and expressivity (Table 146.1). However, when no mutations are identified, it does not eliminate the possibility of an inherited condition. A negative result may mean that a genetic alteration still exists but cannot be identified with current available knowledge or technologies.

TABLE 146.1 Glossary of relevant genetic terms.

Term	Description
The central dogma of biology	Gene expression entails RNA transcription from a DNA template followed by messenger RNA (mRNA) translation into proteins
Genotype	The genetic makeup of an individual
Phenotype	The physical and biochemical manifestation of the genotype in an individual
Mutation	A change in the DNA sequence; a mutation may be beneficial, neutral, or harmful
Penetrance	The frequency of phenotypic characteristics caused by the genotype
Variable expressivity	The range of phenotypic manifestations (age of onset, severity, different signs and symptoms) caused by a specific genotype
Autosomal chromosomes	Species-specific number of paired sets other than the sex chromosomes
Sex chromosomes	The X and Y chromosomes that determine the individual's sex
Allele	One of two parental genes, arise by mutation, found at a certain location on a chromosome
Homozygous	The two alleles have the same DNA sequence (i.e., a mutation)
Heterozygous	The two alleles have different DNA sequence (i.e., a mutation is found only on one of the two alleles)
Congenital	A condition present at birth
Epigenetic	Altered protein activity without a change in the DNA sequence
Phenocopy	Conditions caused by environmental influences that mimic known inherited diseases

Source: Based on Morris-Rosendahl.[93]

Information needed to interpret and utilize DNA tests includes the following. The testing laboratory should provide clear and easy-to-follow information regarding the disease, mode of inheritance, gene mutation(s), and specific breeds that can benefit from testing. Peer-reviewed documentation is preferable. Information about the penetrance and expressivity of the tested mutation should also be available. For clinical cases, it is important to consider genetic variability (e.g., different genes or different mutations within a single gene) and phenocopies. For screening of breeding animals, knowledge of the current mutation's frequency within the breed is imperative.

TABLE 146.2 Inherited hematologic disorders in dogs.

Dog breed	Disorder	Inheritance	DNA test
greater Swiss mountain dog	Bleeding diathesis due to a P2RY12 mutation[19]	Heterozygous and homozygous dogs may bleed	Yes
Irish setter, red and white setter, mixed breed	Canine leukocyte adhesion deficiency due to an ITGB2 mutation (CLAD I) [121]	Autosomal recessive	Yes
German shepherd dog, mixed breed	Canine leukocyte adhesion deficiency due to a FERMT3 (kindlin-3) mutation (CLAD III) [61]	Autosomal recessive	Yes
Australian shepherd, giant schnauzer	°Cobalamin malabsorption due to AMN mutations[69]	Autosomal recessive	Yes
beagle, border collie, mixed breed	°Cobalamin malabsorption due to CUBN mutations[69]	Autosomal recessive	Yes
collie: rough, smooth; mixed breed,	Cyclic neutropenia due to an AP3B1 mutation[59]	Autosomal recessive	Yes
chow chow, golden retriever, Labrador retriever, mixed breed	Elliptocytosis due to a SPTB mutation[115]	Autosomal dominant	Yes
German hunting terrier	Exercise-induced metabolic myopathy due to a ACADVL mutation[80]	Autosomal dominant	Yes
Airedle terrier, Alaskan klee kai, beagle, Finnish hound, giant schnauzer, mixed breed, Scottish deerhound, Welsh springer spaniel	Factor VII deficiency due to a FVII mutation[67]	Autosomal recessive	Yes
Belgian Malinois, boxer, German shepherd dog, Havanese, mixed breed, Old English sheepdog	°Factor VIII deficiency due to FVIII mutations; hemophilia A[25]	X-linked recessive	Yes
Airedale terrier, German wirehaired pointer, Lhasa apso, Rhodesian ridgeback	°Factor IX deficiency due to FIX mutations; hemophilia B[54]	X-linked recessive	Yes
American cocker spaniel, Chihuahua, Jack Russell terrier	Factor X deficiency[96]	Presumed autosomal dominant	No
English springer spaniel, great Pyrenees, Kerry blue terrier	Factor XI Deficiency due to a FXI mutation[114]	Presumed autosomal dominant	Kerry Blue Terrier only
basenji, Irish wolfhound	Fanconi syndrome due to a FAN1 mutation[16,39]	Autosomal recessive	Basenji only
English springer spaniel	Fucosidosis due to a FUCA1 mutation[98]	Autosomal recessive	Yes
Alaskan husky, beagle, English springer spaniel, Portuguese water dog, Shiba Inu, Siberian husky	°Gangliosidosis (GM1) due to GLB1 mutations[74]	Autosomal recessive	Yes
Japanese chin, mixed breed	Gangliosidosis, (GM2, type I; B variant) due to a HEXA mutation[105]	Autosomal recessive	Yes
poodle (toy)	°Gangliosidosis, (GM2, type II; Sandhoff variant) due to HEXB mutations[105]	Autosomal recessive	Yes
bluetick hound, Cairn terrier, Dalmatian, Irish setter, kelpie, mixed breed, West Highland white terrier	°Globoid cell leukodystrophy (Krabbe disease) due to GALC mutations[53]	Autosomal recessive	Yes
Maltese	Glycogen storage disease Ia due to a G6PC mutation[71]	Autosomal recessive	Yes
Finnish Lapphund, Lapponian herder, Swedish Lapphund	Glycogen storage disease II due to a GAA mutation[105]	Autosomal recessive	Yes
curly-coated retriever	Glycogen storage disease IIIa due to an AGL mutation[130]	Autosomal recessive	Yes

TABLE 146.2 (Continued)

Dog breed	Disorder	Inheritance	DNA test
American foxhound, beagle, mixed breed	Hypocatalasia (or acatalasemia) due to a CAT mutation[94]	Presumed autosomal recessive	Yes
Cairn terrier, Cavalier King Charles spaniel, Norfolk terrier	Macrothrombocytopenia due to TUBB1 mutation[31]	Autosomal recessive	Yes
Akita	Macrothrombocytopenia[56]	Unknown	No
pug	May–Hegglin anomaly due to a MYH9 mutation[40]	Presumed autosomal dominant	Yes
Plott hound	Mucopolysaccharidosis I due to an IDUA mutation[89]	Autosomal recessive	Yes
Labrador retriever	Mucopolysaccharidosis II; unknown gene mutation[127]	X-linked	No
dachshund, New Zealand huntaway	°Mucopolysaccharidosis IIIA due to SGSH mutations[131]	Autosomal recessive	Yes
Chesapeake bay retriever, Great Dane, miniature pinscher, poodle (miniature, toy), schnauzer (miniature), Welsh corgi	°Mucopolysaccharidosis VI due to ARSB mutations[125]	Autosomal recessive	Yes
Brazilian terrier, German shepherd dog, mixed breed[¶]	°Mucopolysaccharidosis VII due to GUSB mutations[62]	Autosomal recessive	Yes
poodle	Niemann–Pick disease, type A; unknown gene mutation[21]	Unknown	No
boxer	Niemann–Pick disease, type C1; unknown gene mutation[76]	Unknown	No
cane corso, dachshund	°Neuronal ceroid lipofuscinosis-1 due to PPT1 mutations[72]	Autosomal recessive	Dachshund only
dachshund	Neuronal ceroid lipofuscinosis-2 due to a TPP1 mutation[7]	Autosomal recessive	Yes
American Staffordshire terrier, bull terrier, mixed breed	Neuronal ceroid lipofuscinosis-4A due to an ARSG mutation[2]	Autosomal recessive	Yes
Australian cattle dog, border collie, mixed breed	Neuronal ceroid lipofuscinosis-5 due to a mutation in CLN5[88]	Autosomal recessive	Yes
Chinese crested, chihuahua	Neuronal ceroid lipofuscinosis-7 due to a MFSD8 mutation[6]	Autosomal recessive	Yes
Alpine dachsbracke, Australian cattle dog, Australian shepherd, English setter, mixed breed[$], saluki	°Neuronal ceroid lipofuscinosis-8 due to mutations in CLN8[55]	Autosomal recessive	Yes
American bulldog, mixed breed	Neuronal ceroid lipofuscinosis-10 due to a CTSD mutation[8]	Autosomal recessive	Yes
Tibetan terrier	Neuronal ceroid lipofuscinosis-12 due to an ATP13A2 mutation[128]	Autosomal recessive	Yes
Australian shepherd, Australian cattle dog, basenji, border collie, Boston terrier, cocker spaniel, Coonhound, Danish/Swedish farmdog, foxhound, German shepherd dog, mixed breed, Samoyed	Pelger–Huët anomaly; unknown gene mutation[120]	Autosomal dominant	No
American cocker spaniel, English cocker spaniel, English springer spaniel, German spaniel (wachtelhund), mixed breed, whippet	°Phosphofructokinase (PFK) deficiency due to PFKM mutations; glycogen storage disease VII[64]	Autosomal recessive	Yes, excluding German Spaniel
Mixed breed, shih tzu	Prekallikrein deficiency due to a KLKB1 mutation[99]	Autosomal recessive	Yes

(*Continued*)

TABLE 146.2 (Continued)

Dog breed	Disorder	Inheritance	DNA test
Clumber spaniel, Sussex spaniel	Pyruvate dehydrogenase deficiency due to a PDP1 mutation[22]	Autosomal recessive	Yes
basenji, beagle, Cairn terrier, Labrador retriever, mixed breed[£], pug, West Highland white terrier	°Pyruvate kinase deficiency due to PKLR mutations[52]	Autosomal recessive	Yes
German shepherd dog	Scott Syndrome: Platelet dysfunction due to a TMEM16F (ano6) mutation[20]	Autosomal recessive	Yes
Parson Russell terrier	Severe combined immunodeficiency due to a PRKDC mutation[10]	Autosomal recessive	Yes
Frisian water dog	Severe combined immunodeficiency due to a RAG1 mutation[100]	Autosomal recessive	Yes
basset hound, Welsh corgi (Cardigan)	°Severe combined immunodeficiency due to IL2RG mutations[100]	X-linked	Yes
golden retriever	Spectrin deficiency; unknown gene mutation[111]	Autosomal dominant	No
great Pyrenees, mixed breed, otterhound, Scottish deerhound	°Thrombasthenia type I (Glanzmann) due to ITGA2B mutations[17]	Autosomal recessive	Yes
basset hound, Eskimo spitz, Landseer, mixed breed[€]	°Thrombopathia due to RASGRP1 (CalDAG-GEFI) mutations[18]	Autosomal recessive	Yes
border collie, mixed breed	Trapped neutrophil syndrome due to a VPS13B mutation[92]	Autosomal recessive	Yes
barbet, Bernese mountain dog, coton de Tulear,	von Willebrand disease I due to a VWF mutation	Presumed autosomal dominant	Yes
Dobermann pinscher, Drentsche patrijshond, Dutch partridge dog, Dutch shepherd, French water dog, Havanese, German pinscher, Irish red and white setter,			
Irish setter, Kerry blue terrier,			
kromfohrländer,			
Manchester terrier (regular, toy), mixed breed, papillon, phalène, poodle (standard, miniature, toy),			
Welsh corgi, stabyhoun, West Highland white terrier			
Chinese crested dog, German shorthaired pointer, German wirehaired pointer	°von Willebrand disease II due to VWF mutations[73]	Autosomal recessive	Yes
Dutch kooiker, mixed breed[¥], Shetland sheepdog, Scottish terrier	°von Willebrand disease III due to VWF mutations[104]	Autosomal recessive	Yes

° Multiple breed-specific mutations identified.
Mutations identified within mixed breed dogs:
^ Cairn terrier and West Highland White terrier mutation.
ꟻ German Shepherd dog mutation.
$ Australian Shepherd mutation.
£ Beagle and West Highland White terrier mutations.
€ Basset Hound and Eskimo Spitz mutations.
¥ Shetland Sheepdog mutation.

TABLE 146.3 Inherited hematologic disorders in cats.

Cat breed	Disorder	Inheritance	DNA test
Domestic cat, Ragdoll	Blood group antigen AB due to CMAH mutations[15]	Autosomal	Yes
Persian cat	Chédiak–Higashi syndrome; unknown gene mutation[30]	Presumed autosomal recessive	No
Domestic cat	Dihydropyrimidinase deficiency due to a DPYS mutation[24]	Presumed autosomal recessive	Yes
British shorthair, domestic cat	Factor IX deficiency due to FIX mutations; hemophilia B[50]	X-linked	No
Domestic cat	Factors IX and XII, combined deficiency; unknown gene mutation[33]	Unknown	No
Domestic cat	Factor X deficiency; unknown gene mutation[49]	Unknown	No
Domestic cat	Factor XI deficiency; unknown gene mutation[118]	Unknown	No
Domestic cat	Factor XII deficiency due to FXII mutations[11,86]	Autosomal recessive	No
Domestic cat	Feline leukocyte adhesion deficiency due to ITGB2 mutation (FLAD I)[9]	Autosomal recessive	Yes
Domestic cat, Korat, Siamese	Gangliosidosis (GM1) due to a GLB1 mutation[84]	Autosomal recessive	Yes
Domestic cat, Korat, Siamese	Gangliosidosis (GM2) due to a GM2A mutation[85]	Autosomal recessive	Yes
Burmese, domestic cat, Japanese domestic cat, Korat	Gangliosidosis (GM2, type II; Sandhoff variant) due to HEXB mutations[68]	Autosomal recessive	Yes
Domestic cat	Globoid cell leukodystrophy (Krabbe disease); unknown gene mutation[110]	Unknown	No
Norwegian Forest cat	Glycogen storage disease IV due to a GBE1 mutation[43]	Autosomal Recessive	Yes
Domestic cat	Hyperlipoproteinaemia due to a LPL mutation[48]	Autosomal recessive	Yes
Domestic cat	Hypothyroidism due to a TPO mutation[45]	Autosomal recessive	Yes
British shorthair	Lymphoproliferative syndrome, autoimmune (ALPS) due to a FASLG mutation[1]	Autosomal recessive	Yes
Domestic cat, Persian	Mannosidosis-alpha, due to a MAN2B1 mutation[12]	Autosomal recessive	Yes
Domestic cat	Mucolipidosis II due to a GNPTAB mutation[46]	Autosomal recessive	No
Domestic cat	Mucopolysaccharidosis I due to an IDUA mutation[57]	Autosomal recessive	Yes
Birman, domestic cat, Ragdoll, Siamese	Mucopolysaccharidosis VI due to ARSB mutations[83]	Autosomal recessive	Yes
Domestic cat	Mucopolysaccharidosis VII due to GUSB mutations[124]	Autosomal recessive	Yes
Domestic cat	Niemann–Pick disease (C1) due to mutations in NPC1[87]	Autosomal recessive	No
Domestic cat	Niemann–Pick disease (C2) due to a mutation in NPC2[133]	Autosomal recessive	No
Domestic cat, Siamese	Porphyria, acute intermittent (AIP) due to mutations in HMBS[27]	Autosomal dominant and recessive	Yes
Domestic cat	Porphyria, congenital erythropoietic (CEP) due to UROS mutations[28]	Autosomal recessive	Yes
Abyssinian, Bengal, domestic cat, Egyptian Mau, LaPerm, Maine Coon, Norwegian Forest, Savannah, Siberian, Singapura, Somali	Pyruvate kinase deficiency due to a PKLR mutation[52]	Autosomal recessive	Yes
Himalayan	von Willebrand disease III; unknown mutation[42]	Autosomal	No

TABLE 146.4 Inherited hematologic disorders in horses.

Horse breed	Disorder	Inheritance	DNA test
American Quarter Horse, Arabian, Standardbred, Tennessee Walking Horse, Thoroughbred	Factor VIII deficiency; hemophilia A[97]	X-linked	No
Dales pony, Fell pony, Gypsy horse	Foal immunodeficiency syndrome due to a SLC5A3 mutation[41]	Autosomal recessive	Yes
American Saddlebred	Glucose-6-phosphate dehydrogenase deficiency[113]	Unknown	No
American Quarter Horse, American Paint Horse	Glycogen storage disease IV due to a GBE1 mutation[126]	Autosomal	Yes
Austrian, Icelandic, Peruvian Paso	Neuronal ceroid lipofuscinoses; unknown gene mutation[119]	Unknown	No
Arabian	Pelger–Huët anomaly; unknown gene mutation[47]	Unknown	No
Arabian, Caspian horse	Severe combined immunodeficiency due to a PRKDC mutation [108]	Autosomal recessive	Yes
American Quarter Horse, Oldenburg, Peruvian Paso, Thoroughbred, Warmblood	Thrombasthenia type I (Glanzmann) due to ITGA2B mutations [26]	Autosomal recessive	Yes
American Quarter Horse, Thoroughbred	von Willebrand disease; unknown gene mutation[103]	Unknown	No

TABLE 146.5 Inherited hematologic disorders in livestock.

Breed	Disorder	Inheritance	DNA test
Cattle			
Blonde d'Aquitaine, Limousin	Bovine erythropoietic protoporphyria due to a FECH mutation[65]	Autosomal recessive	Yes
Fleckvieh, Holstein Friesian, Jersey	Bovine leukocyte adhesion deficiency due to an ITGB2 mutation (BLAD I)[109]	Autosomal recessive	Yes
Japanese Black	Chédiak–Higashi syndrome due to a LYST mutation[75]	Autosomal recessive	Yes
Japanese Brown	Factor VIII deficiency due to a FVIII mutation; hemophilia A[70]	X-linked	Yes
Holstein, Japanese Black, Sahiwal	°Factor XI deficiency due to FXI mutations[90]	Autosomal recessive	Yes
German Fleckvieh, Swiss Braunvieh	Fanconi syndrome due to a SLC2A2 mutation[66]	Autosomal recessive	Yes
Brahman, Droughtmaster, Shorthorn	°Glycogen storage disease II due to GAA mutations[32]	Autosomal recessive	Yes
Angus, Brangus, Galloway, Murray Grey	Mannosidosis-alpha, due to MAN2B1 mutations[116]	Autosomal recessive	Yes
Devon	Neuronal ceroid lipofuscinosis-5 due to a CLN5 mutation[60]	Autosomal recessive	Yes
Hereford	Niemann–Pick disease type A; unknown gene mutation[106]	Unknown	No
Japanese Black	Spherocytosis (BAND3 deficiency) due to a SLC4A1 mutation[63]	Autosomal dominant	Yes
Fleckvieh-Simmental	Thrombopathia due to a RASGRP2 (CalDAG-GEFI) mutation[18]	Autosomal recessive	?

TABLE 146.5 (Continued)

Breed	Disorder	Inheritance	DNA test
Sheep			
Swiss Alpine	Factor VIII deficiency due to a FVIII mutation; hemophilia A[101]	X-linked	No
Romney Marsh	Gangliosidosis (GM1) due a GLB1 mutation[3]	Autosomal Recessive	No
British Jacob sheep	Gangliosidosis (GM2, type I; B variant) due to a HEXA mutation[117]	Autosomal Recessive	Yes
Southdown	Gaucher disease, type I due to a GBA mutation[134]	Autosomal Recessive	No
Polled Dorset	Globoid cell leukodystrophy (Krabbe disease); unknown gene mutation[102]	Presumed autosomal recessive	No
German Blackface	Porphyria cutanea tarda due to a UROD mutation[95]	Autosomal Recessive	No
Goats			
Nubian	Mannosidosis-alpha, due to MAN2B1 mutations[79]	Autosomal recessive	No
Nubian	Mucopolysaccharidosis IIID due to a GNS mutation[23]	Autosomal recessive	Yes
Pigs			
All pigs	Blood group ABO due to a GGTA1 mutation[129]	Autosomal Recessive	Yes
Norwegian Yorkshire	Porcine dense deposit disease; hereditary factor H deficiency[58]	Autosomal Recessive	No
Yorkshire	Severe combined immunodeficiency due to DCLRE1C mutations[123]	Autosomal Recessive	Yes
Mixed breed	von Willebrand disease III due to VWF mutations[78]	Autosomal Recessive	?

° Multiple breed-specific mutations identified.

TABLE 146.6 Inherited hematologic disorders in miscellaneous species.

Miscellaneous species	Disorder	Inheritance	DNA test
American mink	Chédiak–Higashi syndrome[4]	Autosomal recessive	No
Guinea pig	Mannosidosis-alpha due to a MAN2B1 mutation[13]	Autosomal recessive	No
Rhesus monkey	Globoid cell leukodystrophy (Krabbe disease) due to a GALC mutation[82]	Autosomal recessive	No
Emu	Gangliosidosis (GM1); unknown gene mutation[14]	Unknown	No
Emu	Mucopolysaccharidosis IIIB due to a NAGLU mutation[5]	Autosomal recessive	Yes

TABLE 146.7 Inherited hematologic disorders in birds.

Avian species	Disorder	Inheritance	DNA test
Emu	Gangliosidosis (GM1); unknown gene mutation[14]	Unknown	No
Emu	Mucopolysaccharidosis IIIB due to a NAGLU mutation[5]	Autosomal recessive	Yes

SECTION 10 GLOSSARY

The following definitions and formulas are provided to ensure that the terms used subsequently are understood by all readers.

Bias: Systematic difference between a measured value and a value representing true analyte concentration or activity. Bias can be due to analytical error within the test system or reflect disagreement between a test system and a comparative method due to inherent methodologic and/or operational differences. Bias can be calculated from method comparison, quality control (QC), or proficiency testing data. See systematic error.

Biological variation: Variation in blood values between individuals and groups of the same species.

Control limits: Numerical limits calculated using a control rule and used during statistical QC to interpret control data and define unacceptable results (probable analytical error).

Control rule: Mathematical rule used in statistical QC to calculate control limits. Westgard defined a logical sequence of multiple control rules known as "Westgard rules" that can be applied for generic statistical QC. Individual control rule(s) for a given method can also be selected during a process of QC validation.

Decision limits: A predetermined test threshold that distinguishes between condition-present and condition-absent subgroups of a target population. Analyte concentration or activity at which medical interpretation and patient care will be impacted.

External quality assessment (EQA): An interlaboratory comparison program in which specimen aliquots are periodically measured by participants, who receive a report from the program provider comparing their results to those from a peer group using statistical analysis or comparing their results to a known target using statistical quality control tools. Often used synonymously with proficiency testing (PT).

Imprecision: Variability of data from a set of replicate measurements expressed as standard deviation (SD) or coefficient of variation (CV).

Peer group: Participants using the same method and/or instrument in an interlaboratory comparison.

Probability of error detection (P_{ed}): Probability that control data will be rejected (deemed unacceptable) when analytical error is correctly identified. Ideally, P_{ed} should be 100%; in clinical laboratory practice, $P_{ed} \geq 90\%$ is considered adequate.

Probability of false rejection (P_{fr}): Probability that control data will be rejected (deemed unacceptable) when no analytical error is present. Ideally, P_{fr} should be 0.00; in clinical laboratory practice, $P_{fr} < 0.05$ is considered adequate.

Proficiency testing (PT): An interlaboratory comparison program in which specimen aliquots are periodically measured by participants, who receive a report from the program provider comparing their results to those from a peer group using statistical analysis or comparing their results to a known target using statistical quality control tools. Often used synonymously with external quality assurance.

Quality control (QC): Laboratory procedures ensuring that accurate patient results are released; includes statistical and nonstatistical procedures.

QC material (QCM): Assayed or unassayed test material having known stability and used for statistical QC of laboratory testing. Data resulting from QCM measurement are known as control data.

QC validation: The process of tailoring statistical QC to a given analytical method, measurand, and quality goal.

Random error: Synonymous with imprecision.

Repeat patient testing (RPT): A statistical QC method using patient results obtained from repeated patient sample testing.

Reference interval: The interval between, and including, two reference limits. The reference interval is designated as the interval of values from the lower reference limit to the upper reference limit. In some cases, only one reference limit is important, usually the upper limit and the corresponding reference interval are zero.

Reference limit: A value derived from the reference distribution.

Reference value: The value (test result) obtained from a reference individual (e.g., calcium result from the blood sample of a study participant).

Statistical QC: Application of statistical principles, control rules, and control limits to control data in order to detect analytical error. Control data are most commonly derived from repeated measurement of stable QCM over time in internal or external quality assessment. The principle underlying statistical QC is that, in a stable test system, control data over time should approximate a Gaussian distribution.

Schalm's Veterinary Hematology, Seventh Edition. Edited by Marjory B. Brooks, Kendal E. Harr, Davis M. Seelig, K. Jane Wardrop, and Douglas J. Weiss.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.

Systematic error: Dysfunction of a test system causing disagreement between a measured result and some representation of true measurand concentration/activity; mathematically, systematic error is represented by difference and occurs in one direction (positive or negative). Systematic error can be constant over a range of concentrations/activities or can change as concentration/activity changes proportionally. See bias.

Total error (TE): The sum of random and systematic error.

Total error allowable (TE_a): An analytical quality requirement specifying the amount of total error that is acceptable, as it will not change clinical decisions.

Total error observed (TE_{obs}): The sum of random and systematic error of an analyte as measured by a given method or instrument. TE_{obs} is unique to an individual instrument/method and may vary across analyte range, by species, and over time.

BASIC CALCULATIONS

$$\text{Mean} = \frac{x_1 + x_2 + x_3 + \ldots + x_n}{n}.$$

$$\text{Standard deviation}(\text{SD}) = \sqrt{\frac{\Sigma(x_i - \bar{x})^2}{(n-1)}}.$$

$$\text{Coefficient of variation}(\text{CV}) = \frac{\text{SD}}{\text{Mean}} \times 100.$$

$$\text{Bias in}\% = \frac{\text{Mean}_{\text{target}} - \text{Mean}_{\text{measured}}}{\text{Mean}_{\text{target}}} \times 100.$$

Total error observed (TE_{obs}) = 2 × CV + Bias (%) or
2 × SD + Bias (unit).
