About the cover

From left: Nala was rescued by Ross University veterinary students in 2016 on the island of St. Kitts, where she was found covered with ticks and ill with ehrlichiosis. Nala adopted Dr. Clarissa Freemyer and now lives in Raleigh, North Carolina. **Middle top:** Bone marrow aspirate from a cat with systemic histoplasmosis. Macrophages have phagocytized numerous *Histoplasma* organisms. **Middle middle:** Cerobrospinal fluid from a dog with Large Granular Lymphocyte lymphoma. Note the azurophilic granules in the large lymphoid cells. **Middle bottom:** A Hyacinth Macaw photographed by Dr. Robin W. Allison in the wilds of the Pantanal, Brazil- the world's largest tropical wetland. **Right:** Imprint of an ulcerative lesion on a cat's paw showing numerous *Cryptococcus* organism. This was Mary Anna Thrall's first attempt at taking a cytologic sample, and the inspiration for her to become a clinical pathologist (circa 1974, new methylene blue stain).

VetBooks.ir

Dr. Mary Anna Thrall dedicates the third edition of this book to her veterinary students, interns, residents, graduate students, and other trainees at Colorado State University and Ross University School of Veterinary Medicine who have made the profession of veterinary medicine and the specialty of clinical pathology extremely rewarding and enjoyable for many years. I also dedicate this edition to my adult children Joseph Bammer, Dr. Anna Freemyer-Brown, Sarah Freemyer, and Dr. Clarissa Freemyer, all of whom are happy, wonderful, and productive people who excelled in spite of my somewhat neglectful parenting.

Dr. Glade Weiser dedicates this edition to Dr. Gary Kociba for his mentorship and willingness to risk hiring a faculty member as an untrained clinical pathologist coming out of internal medicine. Soon after, Drs. Bob Hall and Don Meuten joined the section as trainees. Truth be known the three of us jointly contributed to each other's training. In addition, I treasure the numerous mentorship and working relationships over the years with faculty, staff, and colleagues at the University of California Davis, the Ohio State University, Colorado State University, Coulter Electronics Inc., Heska Corporation, and the American College of Veterinary Pathologists. Lastly, working with many clinical pathologists in training over the years was a most rewarding renewable source of inspiration.

Dr. Robin W. Allison dedicates this edition to Dr. Mary Anna Thrall, who was my inspiration to become a clinical pathologist somewhat late in life. As a veterinary technician in mixed animal practice taking continuing education classes at Colorado State University, I marveled at her knowledge of cytology and vowed to "become her." I may not have entirely succeeded, but not for lack of trying. I will always treasure the wonderful relationships with so many talented clinical pathologists I've become friends with over the years. Additionally, this edition is dedicated to the trainees and veterinary students that made sure I never stopped learning by asking great questions; you are the future of clinical pathology.

As someone trained in clinical pathology but having a career in clinical exotic animal medicine, Dr. Terry W. Campbell dedicates this edition to his animal patients who have been the fountainhead of his education. It has been a joyfully inspirational experience working with clinical pathologists at Kansas State University and Colorado State University and exploring the world of comparative clinical pathology throughout the many years.

Preface

On behalf of the contributing authors and Wiley-Blackwell, we are pleased to introduce the Third Edition of *Veterinary Hematology and Clinical Chemistry*, now titled *Veterinary Hematology, Clinical Chemistry, and Cytology*. Our goal is to provide an image-rich, readable resource addressing routine laboratory diagnostics in veterinary practice. The theme of the presentation is applied clinical pathology for veterinary students and veterinary health professional teams in the practice setting. We aimed to maintain our intended target audience and original organizational structure. We believe that the addition of cytology to the textbook makes it a complete and valuable reference for anyone interested in clinical pathology.

Audience

A continuing trend in frontline veterinary medicine is the movement of laboratory diagnostics into the veterinary facility. Evolving technological advancements in point-of-care diagnostic capability drive this trend, which increases the need for education in veterinary clinical pathology. Although this book was written primarily for veterinary students and practitioners, it has applications for a broader audience, serving as a useful adjunct for the educational and reference needs of a variety of other users. The following audiences may benefit from this resource:

- Students in professional veterinary medical education programs.
- Health professional teams in veterinary care facilities.
- Clinical pathologists and clinical pathologists in training.
- Product development groups using veterinary clinical pathology.

Organization

Veterinary Hematology, Clinical Chemistry and Cytology is organized into seven sections, arranged as follows:

I: Presents principles of laboratory technology and test procedures used in veterinary laboratories to generate laboratory results. It also presents perspectives on how laboratory data interpretation is used in diagnosis and overall clinical case management.

II: Presents hematology and hemopathology of common domestic species. This includes all aspects of the hemogram or complete blood count, bone marrow, hemostasis, and transfusion medicine.

III: Presents hematology of common nondomestic species encountered in veterinary practice.

IV: Presents clinical chemistry of common domestic species and is organized primarily by organ system.

V: Presents clinical chemistry of common nondomestic species.

VI: Presents cytology of common domestic species and includes cytology of inflammation, neoplasia, skin and subcutaneous tissue, body cavity effusions, joint fluid, internal organs, and lymph nodes.

VII: Provides a compilation of clinical cases. Each case includes a signalment, brief history, and pertinent physical examination findings. Then, relevant laboratory data are presented in tables followed by a narrative interpretation of the data.

Comments, Revisions, and Addition Highlights

Development of data interpretation skills by veterinary students, clinical pathologists in training, and practitioners continues to be the primary focus in this edition. While rules for interpreting diagnostic tests assume homogeneity of pathophysiologic responses, we realize that not all of our animal friends have "read the book," although most do, as seen in Figure P.1.

Revisions of chapters have been made throughout where needed. Chapters that have been extensively revised are the following:

- Glade Weiser updates Chapter 2 to include a section on cytology, with details on fluid and tissue sample collection, preparation, staining, and approach to specimen examination.

VetBooks.ir

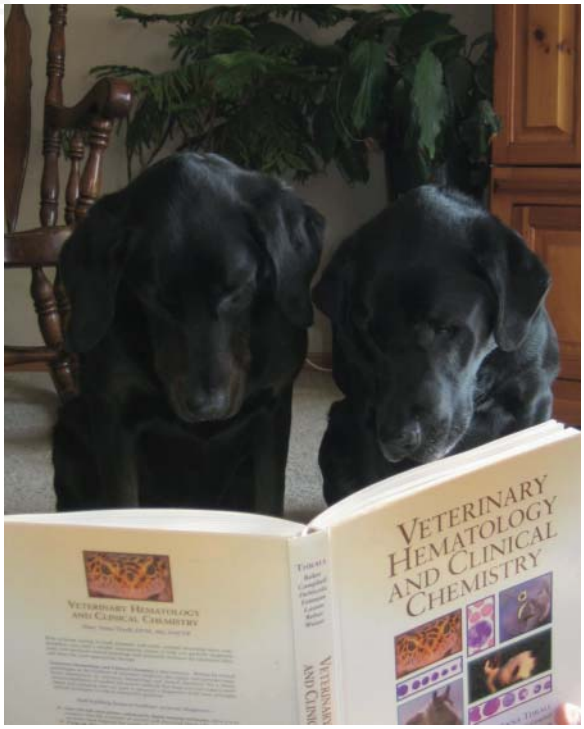

Figure P.1 Dogs caught "reading the book" in an attempt to make their disease responses predictable. Not all will read the book. Source: Courtesy of Dr. Sara Hill.

• Jim Meinkoth, Oklahoma State University, provides a complete revision of the chapter on diagnosis of hemostasis disorders.
• Karl E. Jandrey, University of California, who is board certified in veterinary emergency and critical care, provides new information from a criticalist viewpoint as a coauthor of the chapter on blood transfusion and cross-matching.
• Saundra Sample, University of Missouri, is a new coauthor of two chapters on laboratory evaluation of the kidney and laboratory evaluation of the thyroid, adrenal, and pituitary glands.

Additions include the following: Sreekumari Rajeev, who is board certified in both anatomic pathology and microbiology and is a professor of infectious disease at the University of Tennessee, provides a new chapter on laboratory diagnosis of infectious disease, which discusses a logical approach to the use of modern tools that are available to diagnose infectious disease, a topic of increasing importance particularly as it relates to zoonotic diseases.

Another very important addition is a new cytology section, with seven new chapters. Contributors of new chapters include the following:
• Robin W. Allison from Oklahoma State University is the author of two of the new chapters, one on inflammation and infectious agents and one on body cavity effusions.
• Jim Meinkoth, co-author of *Diagnostic Cytology and Hematology of the Dog and Cat,* 3rd edition, is the author of a chapter on cytology of joint fluid.
• Donald Meuten, who is board certified in both clinical and anatomical pathology, and the editor of the 5th edition of *Tumors in Domestic Animals*, brings years of experience and expertise to the chapters discussing cytology of neoplasia, skin masses, and lymph nodes.
• Kristina Meichner, who is board certified in both clinical pathology and internal medicine (oncology), brings her expertise in cytology and oncology to three of the new chapters.
• Mary Anna Thrall is the coauthor of three of the new chapters on cytology, including cytology of abdominal organs, and cytology of lymph nodes.
• Andrea Bohn is the coauthor of two of the new chapters, cytology of abdominal organs and cytology of lymph nodes.

The clinical case presentations in what is now Section VII, edited by Dr. Alex Mau, are intended to provide readers "practice" to develop interpretive skills by seeing examples of how data are interpreted into pathologic processes and how pathologic processes may culminate in a diagnostic scenario, not unlike reading and solving a mystery in a novel. The original cases are retained because their classical usefulness does not change. Forty-three new cases have been added to this edition by several contributors, to whom we are grateful for sharing.

It is our wish that readers not only learn principles and skills from this work but also enjoy interacting with it. As veterinarians and specialists in bioanalytical pathology, we share our passion for the art and science of laboratory diagnostics applied to animal health.

Respectfully submitted,

Glade Weiser
Mary Anna Thrall
Robin W. Allison
Terry W. Campbell

About the Companion Website

This book is accompanied by a website containing:

I

General Principles of Laboratory Testing and Diagnosis

VetBooks.ir

1 Laboratory Technology for Veterinary Medicine

Glade Weiser
Loveland, CO, USA

This chapter presents an overview of the laboratory technology used to generate data for hematology and clinical biochemistry. For the procedures and technologies likely to be employed within veterinary hospitals, general instructions and descriptions provide a review of the principles previously learned in laboratory courses. This, in conjunction with the instructions accompanying different devices and consumables, should enable users to reproduce the procedures to a satisfactory performance standard. For technologies more likely to be used only in large commercial or research laboratories, the overview provides familiarity with the basic measuring principles.

Hematologic techniques

Basic techniques applicable for any veterinary hospital

The procedures outlined here are most appropriate for the in-house veterinary laboratory in most practice settings. These procedures, with the exception of a cell-counting hematology system, require minimal investment in instrumentation and technical training. These basic hematologic procedures include:

- Blood mixing – for all hematologic measurements.
- Packed cell volume or hematocrit by centrifugation.
- Plasma protein estimation by refractometry.
- Cell-counting instrumentation.
- Microscopic differential leukocyte count and assessment of blood film pathology.

Blood mixing

The blood sample is assumed to have been freshly and properly collected into an ethylenediaminetetraacetic acid (EDTA) tube (as described in Chapter 2). When performing any hematologic procedure, it is important that the blood is thoroughly mixed. Cellular components may settle rapidly while the tube sits on a counter or in a tube rack (Figure 1.1).

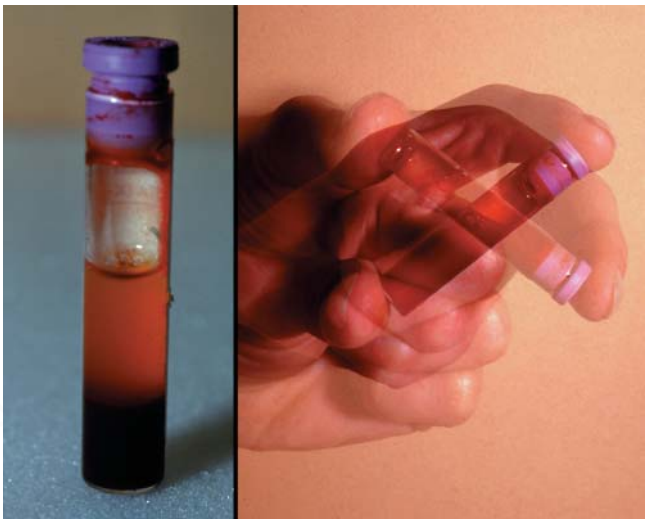

Figure 1.1 Left. Gravity sedimentation of whole blood. Right. A gentle, repetitive, back-and-forth tube inversion technique used to manually mix blood before removing aliquots for hematologic procedures.

As a result, failure to mix the sample before removing an aliquot for hematologic measurement may result in a serious error. Mixing can be performed by manually tipping the tube back and forth a minimum of 10–15 times (Figure 1.1). Alternatively, the tube may be placed on a rotating wheel or tilting rack designed specifically to mix blood (Figure 1.2).

Packed cell volume

The packed cell volume value is the percentage of whole blood composed of erythrocytes. It is measured in a column of blood after centrifugation that results in maximal packing of the erythrocytes. Tools for performing the packed cell volume include 75 × 1.5 mm tubes (i.e., microhematocrit tubes), tube sealant, a microhematocrit centrifuge, and a tube-reading device.

The procedure is performed using the following steps. First, the microhematocrit tube is filled via capillary action

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Companion website: www.wiley.com/go/thrall/veterinary

Figure 1.2 Representative mechanical blood-mixing table. The surface holds several tubes on a ribbed rubber surface and tilts back and forth at the rate of 20–30 oscillations per minute.

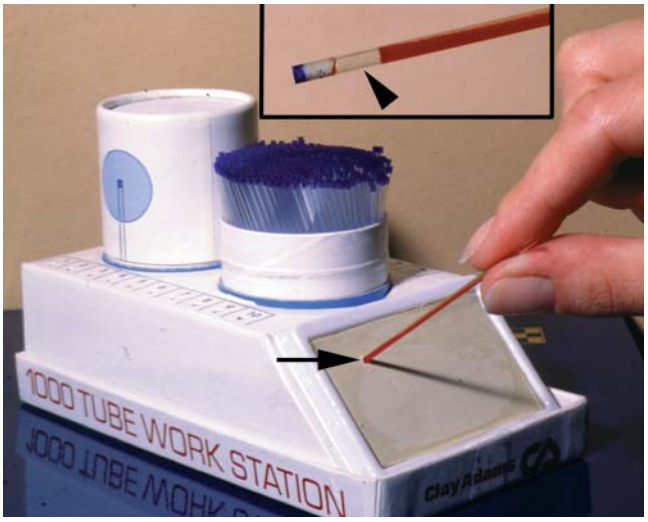

Figure 1.4 A microhematocrit tube is sealed by pressing two to three times into the clay sealant (arrow). Note that a small amount of air trapped between the blood and white clay is not a problem (arrowhead in the inset).

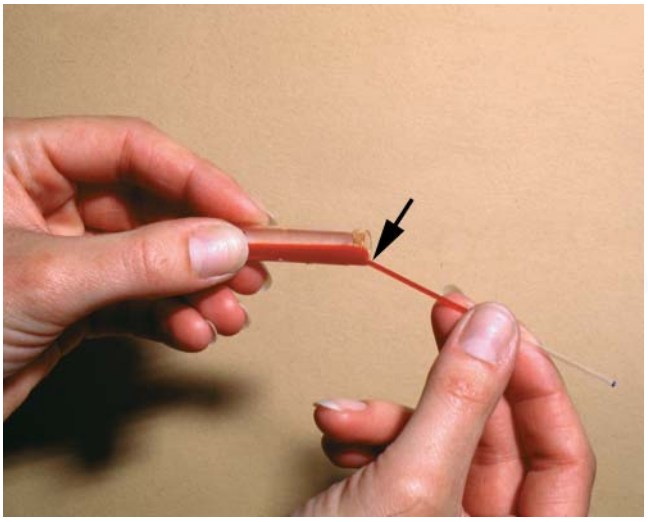

Figure 1.3 Proper technique for filling a microhematocrit tube. The tube should be positioned horizontally or tilted slightly downward to facilitate filling by capillary action. Capillary action is established by touching the upper end of the tube to the blood (arrow).

Figure 1.5 Representative microhematocrit centrifuge. The head and motor are designed to spin the tubes at very high speeds to achieve maximal erythrocyte packing.

by holding it horizontally or slightly downward and then touching the upper end to the blood of the opened EDTA tube (Figure 1.3).

Next, allow the tube to fill to approximately 70–90% of its length. Hold the tube horizontally to prevent blood from dripping out of the tube, and seal one end by pressing the tube into the tube sealant once or twice (Figure 1.4). Note that air may be present between the sealant and the blood (Figure 1.4). This is not a problem, however, because the trapped air is removed during centrifugation.

The tube is then loaded into the microhematocrit centrifuge according to the manufacturer's instructions (Figures 1.5 and 1.6). The microhematocrit centrifuge is designed to spin the lightweight tube at very high speeds to generate sufficient centrifugal force to completely pack the red cells within 2–3 minutes. With such centrifugal force, most (or all) of the plasma is removed from the layers of packed cells.

Three distinct layers may be observed in the tube after removal from the centrifuge: the plasma column at the top, the packed erythrocytes at the bottom, and a small, middle white band known as the buffy coat (Figure 1.7). The buffy coat consists of nucleated cells (predominantly leukocytes) and platelets, and it may be discolored red when the nucleated erythrocyte concentration is prominently

Figure 1.6 Placement of microhematocrit tubes on a microhematocrit centrifuge head. Note the proper orientation of two microhematocrit tubes, with the clay-sealed end positioned at the outer ring of the centrifuge head (double arrow).

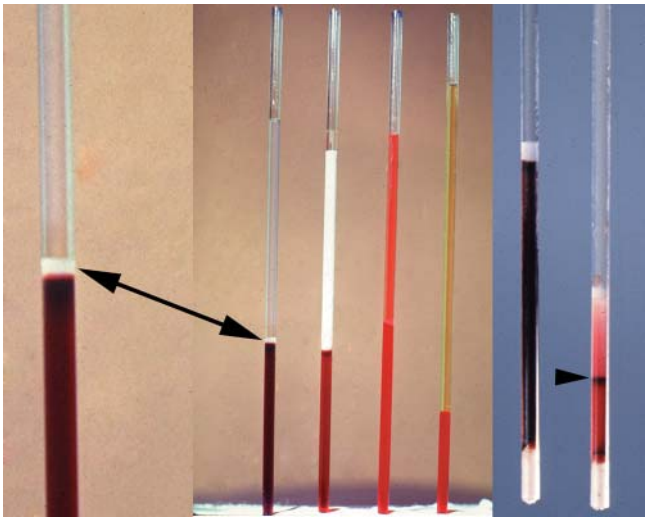

Figure 1.7 Normal and abnormal spun microhematocrit tubes (four tubes in middle panel). The tube on the left is normal. Note the packed erythrocytes at the bottom, plasma layer at the top, and buffy coat in the middle (arrow; enlarged at left). The second tube illustrates lipemia, the third hemolysis, and the fourth icterus. Note also that the hematocrit is considerably decreased in the fourth tube. Two additional tubes illustrate buffy-coat abnormalities (enlarged at right). The first of these tubes has an increased buffy coat that correlates with an increased leukocyte concentration. The second (right) is from a sheep with leukemia and has a dramatically increased buffy coat. The leukocyte concentration was greater than 400,000 cells/μL. There is also severe anemia. With such major abnormalities in cell concentration, separation of erythrocytes and leukocytes is not complete, and division may be blurred. What is interpreted as being the "top" of the erythrocyte column is indicated by the arrowhead. The red discoloration of the buffy coat may be caused by a prominent increase in nucleated erythrocytes.

increased. Observations of any abnormalities in the plasma column above the red cells should be recorded. Common abnormalities such as icterus, lipemia, and hemolysis are shown in Figure 1.7. Icterus is excessively yellow pigmentation of the plasma column that suggests hyperbilirubinemia; the magnitude of this hyperbilirubinemia should be confirmed by a biochemical determination of serum bilirubin concentration (see Chapter 27). The observation of an icteric coloration to the plasma is diagnostically useful in small animals. It is not reliable in large animal species, however, because their serum usually has a yellow coloration from the normal carotene pigments associated with their herbivorous diet. Lipemia is a white, opaque coloration of the plasma column because of the presence of chylomicrons. Lipemia most commonly is associated with the postprandial collection of blood, but it also may be associated with disorders involving lipid metabolism (see Chapter 32). Hemolysis is a red discoloration of the plasma column, which usually results from artifactual lysis of red cells induced during the collection of blood. A small quantity of lysed erythrocytes is sufficient to impart visual hemolysis. Therefore, if the hematocrit is normal, one may assume it is an artifact. Less commonly, causes of anemia that result in intravascular hemolysis give rise to observable hemolysis in the plasma fraction, which also is known as hemoglobinemia (see Chapter 9). This will typically also be associated with hemoglobinuria.

The packed cell volume is measured on a reading device, such as a microhematocrit card reader (Figure 1.8). The procedure is performed by positioning the erythrocyte–clay interface on the 0 line and the top of the plasma column on the 100 line. The position of the top of the erythrocyte column is then read on the scale as the packed cell volume.

Plasma proteins by refractometry

After measurement and observation of the microhematocrit tube, the plasma column may be used to estimate the plasma protein concentration on the refractometer (Figure 1.9). This instrument may be used to estimate the concentration of any solute in fluid according to the principle that the solute refracts (or bends) light passing through the fluid to a degree that is proportional to the solute concentration. The principle or property being measured is the refractive index relative to distilled water. The scale for a particular solute can be developed from refractive index measurements calibrated to solutions with known solute concentrations. In clinical diagnostics, refractometry is used to estimate the plasma protein concentration and urine specific gravity.

Plasma protein is measured using the plasma column in the microhematocrit tube. The tube is broken above the buffy-coat layer (Figure 1.10), and the portion of the tube containing the plasma is used to load the refractometer (Figure 1.11). The instrument then is held so that an ambient light source can pass through the prism wetted with

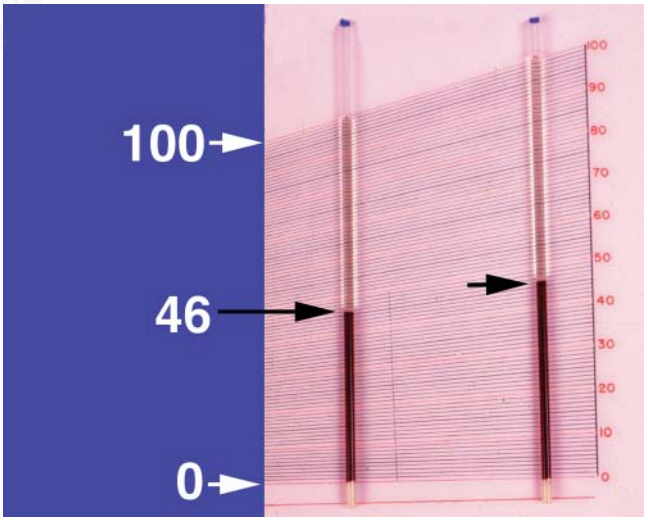

Figure 1.8 Determination of packed cell volume on a microhematocrit tube card reader using two tubes of blood from the same patient sample. Note that the scale allows the tube to be read over a considerable range of filling levels. The steps are to line up the erythrocyte–clay interface with the 0 line, line up the top of the plasma column with the 100 line, and then read the top of the erythrocyte column on the scale. The positions of these steps are indicated by the arrows. Note in this example that the packed cell volume is 46%.

Figure 1.9 Refractometers. The lower refractometer is more rugged, because it is encased in rubber. It is known as a veterinary refractometer, and it has a canine and feline urine specific gravity scale that calibrates for minor differences between species during this determination.

plasma, and the light refraction is read on a scale through an eyepiece (Figure 1.12).

The protein measurement is regarded as being an estimate based on calibration, assuming that other solutes in the serum are present in normal concentrations. The measurement may be influenced by alterations in other solutes. Most notably, lipemia may artificially increase the protein

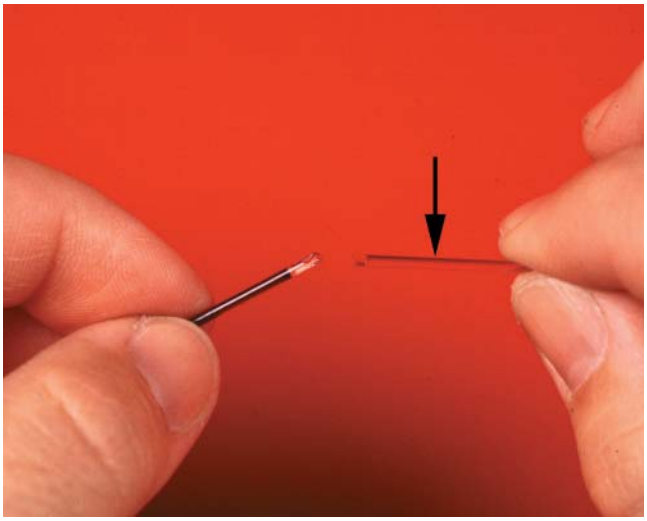

Figure 1.10 Preparation of the microhematocrit tube for measuring plasma protein concentration. The tube is broken just above the buffy coat to yield a column of plasma (arrow).

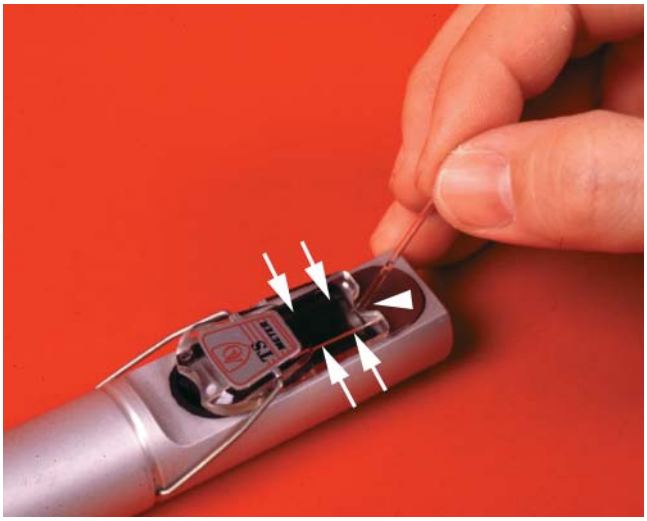

Figure 1.11 Loading plasma from the microhematocrit tube to the refractometer. To wick plasma onto the refractometer, capillary action is established by touching the end of the plasma tube at the notch of the prism cover (arrowhead). Flow should establish a thin layer of plasma under the plastic cover to fill the area delineated by arrows. After reading, the plastic cover is flipped back and wiped clean with a laboratory tissue.

estimate by as much as 2 g/dL. Other alterations of solutes such as urea and glucose influence the protein estimate to a much lesser, and usually negligible, degree.

Determination of total leukocyte concentration

Two general approaches are available to determine the leukocyte concentration. Historically, cell concentrations were measured manually using a blood dilution placed onto a hemocytometer and counted while observing by

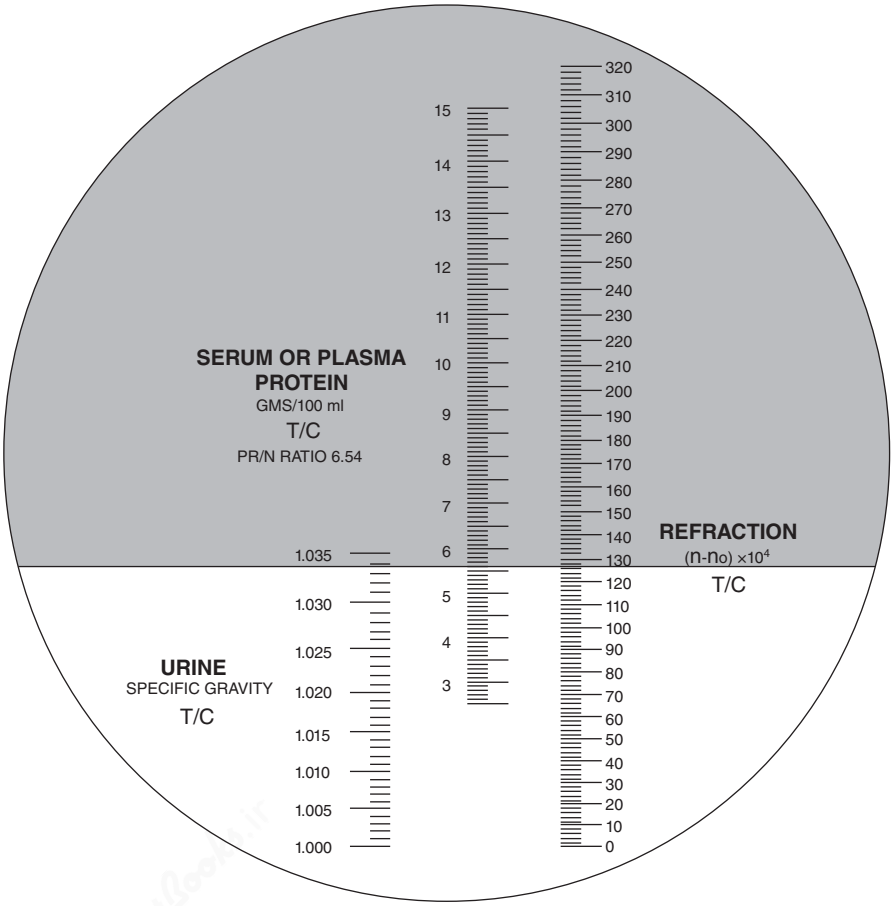

Figure 1.12 Representative refractometer scale as seen through the eyepiece. Light refraction creates a shadow–bright area interface that is read on the appropriate scale.

microscopy. This procedure, and associated consumables, is regarded as obsolete for the veterinary practice setting. This procedure has been replaced by automated hematology cell-counting systems or alternatively expanded buffy-coat analysis technology in which cellular estimates are made from layers in a specialized hematocrit tube. The total leukocyte count is the concentration of nucleated cells, because the techniques detect all the nuclei in solutions from which erythrocytes have been removed by lysis or centrifugation. Therefore, nucleated erythrocytes typically are included in this count. In most cases the concentration of NRBC is negligible, but on rare occasion they may make up an appreciable fraction of the total nucleated cell concentration.

A variety of electronic cell counters operate by enumerating nuclear particles in an isotonic dilution in which a detergent is used to lyse the erythrocytes. These systems must be engineered for animal blood, however, to generate accurate measurements of cell concentrations. There are also continued advances in these hematology systems for performing leukocyte differentiation. Three-, four-, and five-part differential systems exist. The differential capability works best with normal blood, but there are individual exceptions. All systems may produce questionable results when there is leukocyte pathology, and none properly detect abnormalities such as left shift, toxic change, and cell types outside the routine five normal cell types (see below). (For principles of hematology system operation, see the discussion of advanced hematologic procedures later in this chapter.) The quantitative buffy-coat analysis system (Idexx Autoread™, Idexx Laboratories) estimates the leukocyte concentration by measurement of the buffy-coat layer in a specialized microhematocrit tube, in which a float is present to expand the buffy-coat region for optical scanning.

In isolation, the total leukocyte count is not particularly useful for interpretive purposes; this measurement is used to determine the concentration of various leukocyte types that make up the differential count. The concentration of individual leukocyte types is the most useful value for the interpretation of disease processes. This information is determined by evaluating the stained blood film. Because of the limitations in automated leukocyte differentiation described above, it is important to utilize blood film examination in conjunction with automated hematology systems when blood is abnormal. This is essential not only for leukocyte characterization but also for evaluation of erythrocytes in cases of anemia and platelets when the instrument produces a decreased platelet concentration value. See further detail in the next section.

Microscopic differential count and assessment of morphology

The microscopic differential count and blood film examination is not necessarily required for all complete blood count (CBC) samples. Many samples can be classified as normal when analyzed by modern hematology instruments, especially when the CBC is part of a wellness examination. When all the data are normal, it is very unlikely to find additional useful information from the blood film examination. The need for blood film examination may be determined by examination of the instrumentation data output. The examples of data abnormalities that should prompt blood film evaluation include anemia, any data abnormality in the automated total leukocyte count or automated differential, and any concern about platelet concentration. Almost all automated instrument measurements are highly reliable on well-maintained systems. The measurement most likely to have inaccuracies is the automated differential count. This is because these systems are less likely to recognize and/or properly classify all of the nucleated cell types that do not belong in normal blood. Examples include nucleated erythrocytes, immature and blast forms of any cell lineage, and left shifted neutrophils. Therefore, it is important to perform a microscopic differential whenever the total leukocyte concentration is abnormal and/or when the distribution of cells determined by the instrument differential is abnormal. The next most likely problem is instrument counting of platelets. This is because platelet microclots are common in animal blood samples, especially from cats. The hematology instrument system will not count platelets in microclots. The blood film is helpful for identifying platelet microclots, qualitatively assessing their impact on an instrument platelet measurement value that is abnormally decreased. The examination procedures are described below.

Preparation of blood films and initial approach to blood film examination is detailed in Chapter 2, under "Collection, Preparation, and Examination Techniques for Clinical Microscopy Samples." Using the blood film monolayer area (aka counting area), the microscope should be adjusted to 100× objective oil immersion or high magnification observation for these procedures. The observer will then perform a systematic evaluation of the three major cell lines. This includes a differential count for leukocytes with notation about any abnormal cells, evaluation of erythrocyte morphology, and evaluation of platelets.

Within the counting area, the observer will move across fields and obtain the differential leukocyte count by classifying a minimum of 100 consecutively encountered cells. Cells are classified into a minimum of five to six categories, with the presence of abnormal cells being recorded into a category of "other." The specification of "other" is described or defined for the sample being examined. The common six categories of normal cells – neutrophil, band neutrophil, lymphocyte, monocyte, eosinophil, and basophil – are shown in Figure 1.13. (See Chapter 11 for additional visual details regarding leukocyte identification that may be helpful in differential counts.)

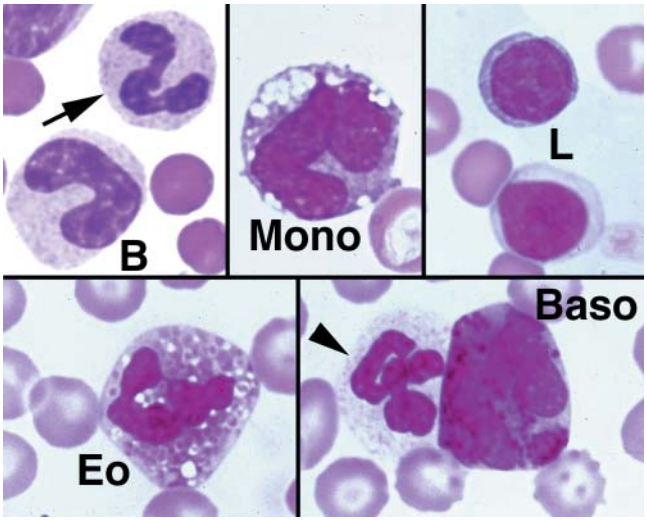

Figure 1.13 Basic leukocytes encountered in the differential count. Upper left. Neutrophils. Note the segmented neutrophil (arrow) and the constrictions in the nuclear contour. The band neutrophil (B) has smooth, parallel nuclear contours. Upper middle. Monocyte (Mono). The nucleus may have any shape, from round to bean-shaped to ameboid and band-shaped, as in this example. The cytoplasm is blue-gray and may variably contain vacuoles. Upper right. Two lymphocytes (L). Lower left. An eosinophil (Eo). Note that granules stain similar to the surrounding erythrocytes. Occasionally, granules may wash out in the staining procedure, leaving vacuoles. Lower right. Basophil (Baso) with dark granules that stain similar to nuclear chromatin. Note the adjacent neutrophil (arrowhead) and that neutrophils may have small, poorly staining granules that are much smaller than those of eosinophils or basophils.

The result of counting 100 cells is that the number of each leukocyte type is a fraction of 100, or a percentage of the leukocyte population. Once cells are categorized into percentages, they must be converted to absolute numbers for interpretation purposes. This is done by multiplying the total leukocyte concentration by the percentage of each leukocyte type, which yields the absolute number or concentration of each leukocyte in the blood sample. The following example illustrates the conversion of percentages to absolute numbers: (See Example 1.1, next page)

Any abnormalities in leukocyte morphology also should be noted. Important morphologic abnormalities are detailed in Chapter 13.

Erythrocyte morphology is then systematically evaluated. The observer should note any important erythrocyte shape or color abnormalities; this is particularly important for evaluating anemias. (See Chapter 6 for a review of morphologic erythrocyte abnormalities.)

The presence of platelet adequacy may be interpreted from a properly prepared blood film. A minimum of 8–12 platelets per oil immersion high-power (1000×) field may

Example 1.1. Conversion of percentage counts to absolute concentrations

Total white-blood-cell count = 10,000/μL
Differential white-blood-cell count:

	Percentages	Absolute numbers/μL
Neutrophils	60%	(6000)
Lymphocytes	30%	(3000)
Monocytes	5%	(500)
Eosinophils	5%	(500)

be interpreted as adequate. The number seen may be considerably greater than described, however, because of the wide range of normal platelet concentrations. This number is only a guideline for most microscopes with a wide field of view. It should be adjusted downward when using a microscope with a narrow field of view and upward if using one with a superwide field of view. If the platelets appear to be decreased, a search for platelet clumps on a low-power setting at the feathered edge should be performed. The ability to look for platelet clumps is also important when a cell counter produces a decreased platelet concentration value; this is a frequent problem in cats. Morphology of platelets also may be noted. Platelets that approach the diameter of erythrocytes or larger are referred to as macroplatelets or giant platelets. In dogs, these suggest accelerated platelet regeneration, but this interpretation usually is not applied to macroplatelets in cats.

Advanced hematologic techniques

Historically, these capabilities were limited to central laboratories. Over the past 20 years, there has been rapid technological evolution resulting in reduced cost and complexity such that these capabilities are now available to the common veterinary facility. Currently, the predominant differences of the larger, more expensive systems used by commercial laboratories are higher throughput rate, automated tube handling, and more sophisticated differential counting technology. (See Chapter 2 for additional discussion of equipment and laboratories.) Hemograms performed on modern hematologic instrumentation provide the following additional measurements.

Items determined by spectrophotometry or calculation:

- Hemoglobin concentration of blood, g/dL.
- Mean cell hemoglobin content, pg.
- Mean cell hemoglobin concentration (MCHC), g/dL.

Items determined by cell (particle) counting and sizing:

- Erythrocyte concentration of blood, $\times 10^6$ cells/μL.
- Mean cell volume (MCV; the average size of erythrocytes), fl.
- Hematocrit (equivalent to the packed cell volume), %.
- Platelet concentration of blood, $\times 10^3$ cells/μL.
- Mean platelet volume (MPV), fl.
- Total and differential leukocyte concentrations, $\times 10^3$ cells/μL.
- Reticulocyte concentration, $\times 10^3$ cells/μL.

The method and applicability for each of these measurements are now described.

Items determined by spectrophotometry or calculation

Hemoglobin concentration

This measurement of the quantity of hemoglobin per unit volume, expressed as g/dL, is performed in conjunction with the total leukocyte count. Briefly, a blood sample is diluted, and a chemical agent is added to rapidly lyse cells, thereby liberating hemoglobin into the fluid phase. Nucleated cells remain present in the form of a nucleus with organelles collapsed around it. The absorbance of light at a specific wavelength then may be measured by spectrophotometry in a small flow cell known as a hemoglobinometer. The absorbance of light is proportional to the concentration of hemoglobin. The system is calibrated with material of known hemoglobin concentration using reference techniques.

Interpretation of the hemoglobin concentration is the same as that of the packed cell volume, or hematocrit. It is an index of the red cell mass per unit volume of blood in the patient. Because it is roughly equivalent to the packed cell volume, however, it is not particularly useful for clinical interpretations. Most clinicians are more familiar or experienced with interpreting packed cell volumes. The hemoglobin value is always proportional to hematocrit and is a separate, independent measurement. Therefore, the hemoglobin value may serve as a quality-control adjunct for laboratory personnel when used to calculate the MCHC.

Mean cell hemoglobin

The mean cell hemoglobin is calculated from the hemoglobin concentration and erythrocyte concentration. It is regarded as being redundant to other measurements and, therefore, is not useful.

Mean cell hemoglobin concentration

The MCHC is calculated from the hemoglobin concentration and the hematocrit. It provides an index for the quantity of hemoglobin (HGB) relative to the volume of packed erythrocytes (expressed as g/dL):

$$\frac{\text{HGB (g/dL)}}{\text{PCV (\%)}} \times 100 = \text{MCHC (g/dL)}$$

where PCV is the packed cell volume. An example calculation is

$$\frac{10\ \text{g/dL}}{30\%} \times 100 = 33.3\ \text{g/dL}$$

A universal relationship among mammalian species, other than the camel family, is that the hemoglobin value normally is approximately one-third of the hematocrit value. Thus, from the relationship described, the MCHC for all mammalian species ranges from approximately 33–38 g/dL. Because members of the camel family (camel, llama, alpaca, vicuna) have relatively more hemoglobin within their cells, their MCHCs are expected to range from 41 to 45 g/dL.

The MCHC is not particularly useful for clinical interpretations; however, it is useful to laboratorians for monitoring instrument performance. The rationale is that the hematocrit and hemoglobin are determined on different blood aliquots, which are diluted in two different subsystems of the instrument. A malfunction in either of these subsystems may result in a mismatch between the hemoglobin and the packed cell volume, which is reflected by a deviation from the reference interval. In addition, some abnormalities of blood can result in an artifactually increased MCHC, and these can include any factor that causes a false increase in the spectrophotometric determination of hemoglobin relative to the hematocrit. Severe hemolysis in the sample is a common cause of an increased MCHC. Alternatively, common examples of increased turbidity that interfere with light transmittance are lipemia and a very large number of Heinz bodies (see Chapter 9) in cats. Erythrocyte agglutination, as may occur in immune-mediated hemolytic anemia, may result in a false-high MCHC. In this situation, the hemoglobin measurement is accurate, but the hematocrit is falsely low because the agglutinated erythrocytes are out of the system's measuring range and are therefore not counted or sized in derivation of hematocrit.

Two erythrocyte responses related to anemia may be associated with a slightly decreased MCHC. The first is marked regenerative anemia. Reticulocytes or polychromatophilic cells are still synthesizing hemoglobin and, therefore, have not yet attained the cellular hemoglobin concentration of a mature erythrocyte. A very high fraction of reticulocytes is required, however – such as greater than 20% – to develop a detectable decrease in MCHC. The second is severe iron deficiency, in which cells have a reduction in hemoglobin content because they are smaller (i.e., microcytic) but also may have a minor reduction in cellular hemoglobin concentration. There are no causes of a dramatically decreased MCHC (<28 g/dL) other than an analytic instrument error.

Items determined by cell (particle) counting and sizing

Cell-counting and sizing technologies

A brief overview of cell-counting and sizing technology common to all of these measurements is appropriate. One of two technologies is used by most hematology instrument systems.

The first is light-scatter measurement of cells passing through a light source. Cells are passed through a flow cell that is intersected by a focused laser beam. The physical properties of the cell scatter light to different degrees and at different angles relative to the light source. Cell passages eliciting scatter events may be counted to derive the cell concentration. The degree of scatter in the direction of the light beam, which is known as forward-angle scatter, is proportional to the size of the cell. In addition, measurement of light scattered to different angles may be correlated with cellular properties, which leads to the ability to differentiate nucleated cell types.

The second is more common and incorporated into a wider range of instrument designs and may also be used as a second measuring principle in light-scatter systems. This is electronic cell counting, which is also known as impedance technology or Coulter technology (after the original inventor). It is based on the principle that cells are suspended in an electrolyte medium, such as saline, that is a good conductor of electricity. The suspended cells, however, are relatively poor conductors of electricity. Thus, these cells impede the ability of the medium to conduct current in a sensing zone known as an aperture. By simultaneously passing current and cells through a small space or aperture, deflections in current can be measured (Figure 1.14). In addition, the size of the cell is proportional to the resultant deflection in current. This volumetric size discrimination may be used to measure the size distribution of erythrocytes, to discriminate platelets from erythrocytes, and to partially differentiate leukocytes. Cells within a given population are counted and assigned to a size distribution by particle-size-analyzer circuitry (Figure 1.15). The particle-size analyzer assigns each cell to a size scale that is divided into a large number of discrete size "bins" of equal size. The size scale is calibrated with particles of known size. By rapidly accumulating several thousand cells, a frequency distribution of the sizes of the cell population may be constructed (Figure 1.16).

The size distribution curve is most useful for the evaluation of erythrocytes in the laboratory. It also may be used to derive leukocyte differential and platelet information.

The following measurements derive from the described cell-counting and sizing technology. Because of the considerable differences in erythrocyte and platelet sizes between species, instrument systems require careful design and/or adjustment to accurately obtain the various measurements. For example, instruments manufactured for the analysis of human blood do not perform accurately for most animal species without modification.

Erythrocyte concentration

The erythrocyte concentration is measured directly by counting the erythrocyte particles in an isotonic dilution of blood.

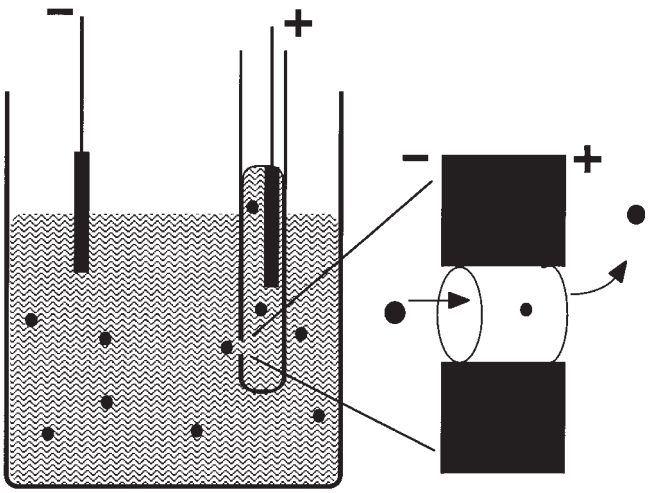

Figure 1.14 Principle of electronic impedance cell counting. Left. Overview of the fluidic chamber. Cells (dots) are diluted in an isotonic fluid (wavy lines). Two electrodes (+ and –) are separated by a glass tube containing a small opening or aperture. Electric current is conducted by the isotonic fluid across the electrodes via the aperture. Vacuum is applied to move the fluid and cells through the aperture. Right. Magnified, diagrammatic view of the aperture. Cells flow through the aperture (arrows). The aperture is a cylindric shape with a volume called the sensing zone. While occupying space within the aperture, cells transiently impede the flow of current. Cell passages are counted as deflections in the current voltage. In addition, the magnitude of voltage deflection is proportional to the volume of the cell.

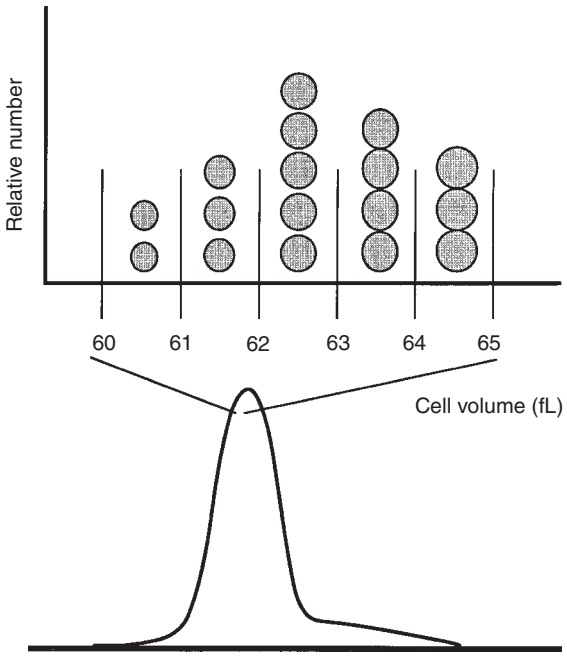

Figure 1.15 Cell volumes assigned to size bins. In the case of erythrocytes, a cell volume scale of approximately 30–250 fl is divided into a large number of discrete size bins (e.g., 60–61 fl, 61–62 fl). As the cells are counted, they are assigned to size bins (circles). Accumulation of many cells allows the construction of a size distribution histogram on the cell-volume scale (curve tracing at bottom). The drawing of bins at the top would represent a small area of the total curve.

This value is not useful for purposes of clinical interpretation. It generally parallels the packed cell volume and hemoglobin concentration, but the packed cell volume is the preferred value for the interpretation of erythrocyte mass. The erythrocyte concentration is used by the instrument to calculate the packed cell volume (described later).

Mean cell volume, erythrocyte histogram, and red cell distribution width

As the erythrocytes are counted, their size distribution is simultaneously constructed (Figure 1.16), and from this size distribution, the MCV is easily calculated. The red cell distribution width (RDW) is a mathematic index describing the relative width of the size distribution curve. It is the standard deviation of most of the erythrocytes divided by the MCV. The tails of the erythrocyte distribution usually are excluded from this mathematic treatment.

These values are useful for the evaluation of anemia. Iron deficiency results in the production of microcytic erythrocytes, and accelerated erythrocyte regeneration results in the production of macrocytic erythrocytes. Early in these responses, a widening of the erythrocyte size distribution and RDW value may be observed (Figure 1.16). As a larger proportion of these cells accumulate during the response, the curve shifts in the respective direction, and eventually, the MCV may fall out of the reference interval. The RDW

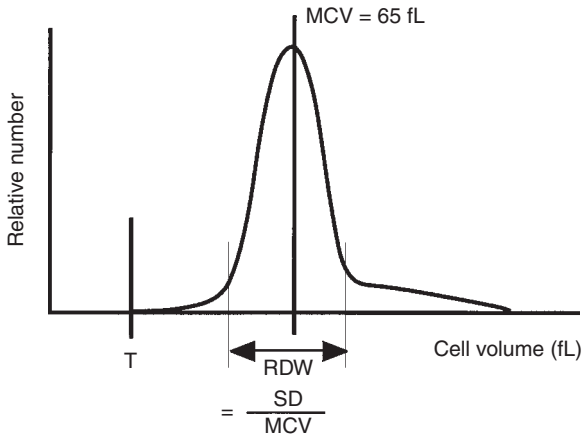

Figure 1.16 Histogram of erythrocyte size distribution. The *x* axis is the cell volume, and the *y* axis is the relative number of cells at each volume. Only cells above a specified volume or threshold are included in the analysis; this is indicated by the vertical bar (T). The mean cell volume (MCV) is indicated by the large vertical bar. The RDW (red-cell distribution width) value, an index of volume heterogeneity, is the standard deviation (SD) divided by the MCV, with the SD being that of the volumes of erythrocytes within the region indicated by the fine lines marked by the double arrow.

is more useful in the laboratory, in conjunction with the examination of blood films, whereas the laboratorian and the clinician both may interpret the MCV. Examples of interspecies variation and representative reference intervals for MCV are

Humans	80–100 fl
Dogs	60–72 fl
Cats, horses, and cows	39–50 fl
Sheep	25–35 fl
Llama	21–29 fl
Goat	15–25 fl

For additional detail on microcytic and macrocytic anemias and other breed-specific information regarding erythrocyte size, see Chapter 7.

Hematocrit

One of the advantages of hematology instrumentation is that the hematocrit may be determined by calculation, thereby avoiding the need for microhematocrit centrifugation. The instrument calculates hematocrit (HCT) using the erythrocyte concentration (RBC) and the MCV:

$$(\text{MCV} \times 10^{-15}\ \text{L}) \times (\text{RBC} \times 10^{12}\ \text{L}) = \text{HCT}$$

Or, simplified:

$$\frac{\text{MCV} \times \text{RBC}}{10} = \text{HCT}$$

Thus, for example:

$$\frac{\text{MCV } 70\ \text{fL} \times 7.00\ \ \text{RBC}}{10} = \text{HCT } 49\%$$

Platelet concentration

Platelets may be counted simultaneously with erythrocytes. Because platelets are considerably smaller than erythrocytes, however, they are analyzed in a separate area of the particle-size-analyzer scale. Most species have little or no overlap between platelet and erythrocyte volume, thereby making such analysis both simple and accurate. Cats are an exception, in that their platelets are approximately twice the volume of those in other domestic species. In addition, macroplatelet production is a frequent response during most hematologic disturbances in cats. This response is not specific for any specific disease pattern, but it results in considerable overlap between erythrocyte and platelet size distributions, thus making determination of accurate counts difficult. Therefore, feline platelet counts should be regarded as being estimates only. Because large platelets tend to get counted as erythrocytes, the platelet concentration frequently may be artifactually low. Microclots are also a common contributor to some fraction of platelets not being counted. In general, if the platelet concentration falls in the reference interval, it may be regarded as being adequate. If the platelet concentration is decreased, however, the blood film should be examined by a laboratorian as described above to confirm this finding.

White blood cell and differential leukocyte concentrations

To analyze leukocytes, a lytic agent is first added to a dilution of blood. This agent rapidly lyses or dissolves cytoplasmic membranes, thereby making the erythrocytes and platelets "invisible" to the detection technologies. Only nuclear particles of nucleated cells remain, around which is found a "collapse" or condensation of cytoskeletal elements and any attached organelles. These particles are measured by one of the detection technologies previously described to obtain the total leukocyte concentration. Using specially formulated lytic reagents, the degree of collapse may be controlled to different degrees in different leukocyte types. The result is a differential size that can be measured by a particle-size analyzer or light-scatter technology. Automated differential leukocyte counting is not as perfected in domestic animals as in humans; however, the procedure is reasonably accurate for normal blood and, therefore, is very useful in situations such as safety assessment trials, in which most (or all) of the blood samples to be analyzed are normal. When blood is abnormal, however, the frequency of analytic error in the differential count increases considerably. Analytic errors are handled by using the blood film for comparison and the visual differential count whenever an instrument analytic error is either present or suspected. It is essential to monitor instrument performance by visual inspection of the histogram or cytogram display for each sample to know when analytic failure occurs. It is very difficult, if not impossible, to determine this simply by monitoring numeric data from the instrument. Therefore, use of this technology requires considerable training and expertise by the operator to monitor the instrument performance and appropriately intervene with visual inspection of the blood film.

Summary of blood analysis by automated or semiautomated instrumentation

The flow of dilutions, analysis, and calculations within an automated hematology instrument is summarized in Figure 1.17. This flow has two main pathways. In one, an isotonic dilution of blood is made for erythrocyte and platelet analysis. In the other, a dilution is made, into which a lytic agent is added; in this pathway, leukocytes and hemoglobin are measured.

Reticulocyte concentration

Reticulocyte enumeration

The reticulocyte concentration is very useful in the evaluation of anemias. The rate of release of reticulocytes from the

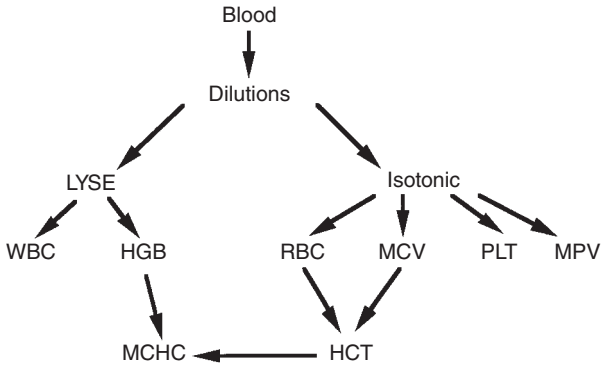

Figure 1.17 Summary of blood analysis pathways in an automated instrument. Two major dilutions are made (see text). In the left pathway, a lytic agent is added, and leukocytes are counted and the hemoglobin concentration measured. In the right pathway, erythrocytes and platelets are counted and sized. From the direct measurements, the hematocrit is calculated. A cross-check between the two pathways is provided by calculation of the mean cell hemoglobin concentration (MCHC).

bone marrow is the best assessment regarding the function of the erythroid component of bone marrow. (See Chapters 7–9 for a more detailed discussion of the anemias.)

The basis for the reticulocyte count involves the events in the maturation of erythroid cells. The developing erythroid cell is heavily involved in aerobic metabolism and protein (i.e., hemoglobin) synthesis. As it nears the final stages of maturity, the nucleus undergoes degeneration and is extruded from the cell, and the organelles supporting the synthetic and metabolic events are removed. After denucleation of the metarubricyte, the remaining erythrocyte undergoes its final maturation, which involves the loss of ribosomes and mitochondria during a period of 1–2 days. To enumerate reticulocytes, a stain is applied to erythrocytes, thereby causing aggregation of these residual organelles. This results in visible, clumped granular material that can be seen microscopically (Figure 1.18). The aggregation is referred to as reticulum, hence the name reticulocyte. Reticulocytes are equivalent to the polychromatophilic cells observed on the Wright-stained blood films (Figure 1.18). Evaluation of polychromatophilic cells on the Wright-stained blood film can provide an assessment of the bone marrow response to anemia. The appearance of these cells, however, is more subjective, and they are more difficult to quantitate than counting the corresponding cells on the reticulocyte stain.

Stains that can be used are new methylene blue (liquid) and brilliant cresyl blue, which is available in disposable tubes that facilitate the procedure (Figure 1.19). First, several drops of blood are added to the stain in a tube. The tube then is mixed and incubated for 10 minutes. From this mixture, a conventional blood film is made and air-dried. A total of 1000 erythrocytes are counted and categorized as either reticulocytes or normal cells. From this, the percentage

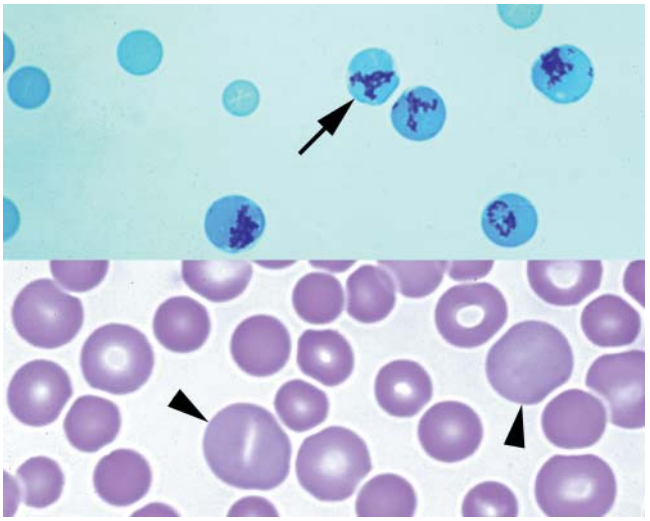

Figure 1.18 Reticulocytes. Top. Representative reticulocyte (arrow) using new methylene blue stain. Note the dark-staining, aggregated organelles in several reticulocytes. Bottom. Blood film stained with Wright-Giemsa stain. Polychromatophilic cells (arrowheads) are roughly equivalent to reticulocytes on the counterpart stain.

Figure 1.19 Examples of reticulocyte stains. Left. New methylene blue in a liquid dropper bottle. Right. Commercial preparation of brilliant cresyl blue. The stain is coated on the bottom of disposable tubes.

of reticulocytes is derived. Interpretation of the percentage reticulocytes is somewhat misleading, however, because it does not account for the degree of anemia. Thus, for purposes of interpretation, the absolute reticulocyte concentration should be calculated by multiplying the erythrocyte concentration (RBC) by the percentage of erythrocytes that are reticulocytes:

$$\text{RBC}/\mu\text{L} \times \% \text{ Reticulocyte} = \text{Reticulocytes}/\mu\text{L}$$

Some instrument systems are also capable of reticulocyte enumeration. The method involves staining erythrocytes with a fluorescent dye that binds to residual RNA in the reticulocyte that is not present in the mature erythrocyte. RNA content, proportional to fluorochrome per cell, is measured and gated to differentiate reticulocytes from mature erythrocytes and other nonerythroid cell types. The percent and absolute values are presented as described above.

Interpretation of the Reticulocyte Concentration

The reticulocyte concentration is most useful in dogs and cats, and it also has some application in cows. It is not used in horses, however. Reticulocyte maturation is confined to the marrow space in the horse, and reticulocytes almost never are released into their circulation. Reticulocyte concentration guidelines for domestic mammals are the concentrations to be expected when the hematocrit is normal:

Dogs and cats	0–60,000 cells/μL
Cows	0 cells/μL
Horses	Do not release reticulocytes

When anemia is present, a greater degree of release from the marrow is to be expected if the marrow can respond to the anemia. This gives rise to the following guidelines for the interpretation of reticulocyte concentrations with respect to the type of anemia present:

Nonregenerative anemia to very poor regeneration	0–10,000 cells/μL
Nonregenerative to poorly regenerative anemia	10,000–60,000 cells/μL
Regenerative anemia with mild to moderate output	60,000–200,000 cells/μL
Maximal regeneration	200,000–500,000 cells/μL

Reticulocyte maturation

In dogs, reticulocyte maturation occurs in 24–48 hours. Maturation involves a continuum of progressive loss of the visible organelles (Figure 1.20).

Cats are unique in that more than one kind of reticulocyte may be present. These reticulocytes are of the aggregate and the punctate forms (Figure 1.21). The aggregate reticulocyte has a clumped reticulum that appears to be identical to that of other species. In the punctate reticulocyte, discrete dots are seen without any clumping; other species do not have this reticulocyte counterpart. Only aggregate reticulocytes appear to be polychromatophilic with Wright stain. Punctate reticulocytes are indistinguishable from normal, mature erythrocytes with Wright stain.

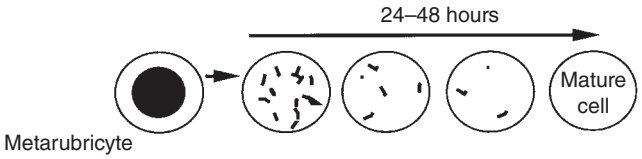

Figure 1.20 Sequential erythroid maturation as related to the reticulocyte stain and interpreted in dogs. The metarubricyte denucleates on leaving the reticulocyte. Reticulum is progressively lost during a 24–48-hour period, resulting in a mature erythrocyte.

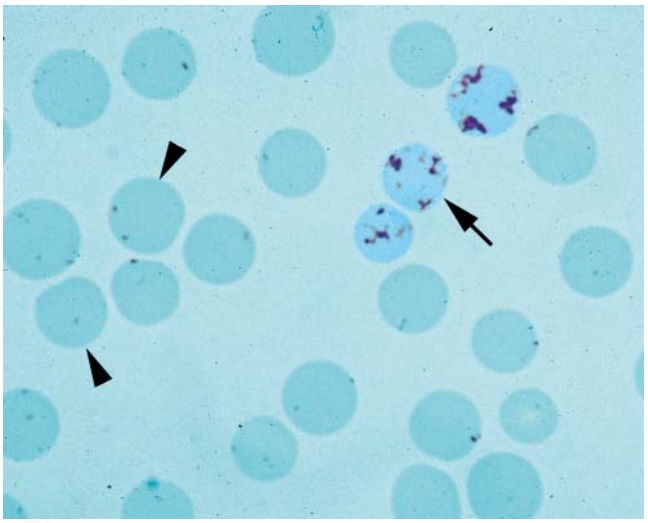

Figure 1.21 Feline reticulocyte morphology with new methylene blue stain. Three aggregate reticulocytes are in the field; note the representative one (arrow). The remainder of the cells are punctate reticulocytes; note the representative cells (arrowheads).

Reticulocyte maturation in cats also may be viewed as a continuum (Figure 1.22). Aggregate reticulocytes mature to the punctate form in approximately 12 hours; the punctate cells may continue to mature for another 10–12 days. Because of the short maturation time of aggregate reticulocytes, these cells are the best indicator of active marrow release. Therefore, only aggregate cells are counted in cats, and interpretive guidelines apply to this cell type only. Experience is required to exclude punctate cells when performing the reticulocyte count.

Organization of the complete blood count (hemogram)

It is useful to summarize the described basic and advanced determinations in a way that shows the organization of how they are performed and interpreted. This provides a mental framework for simplifying the complexity of this information into an everyday, intuitive tool: the hemogram. The techniques for generating data may be organized conceptually as

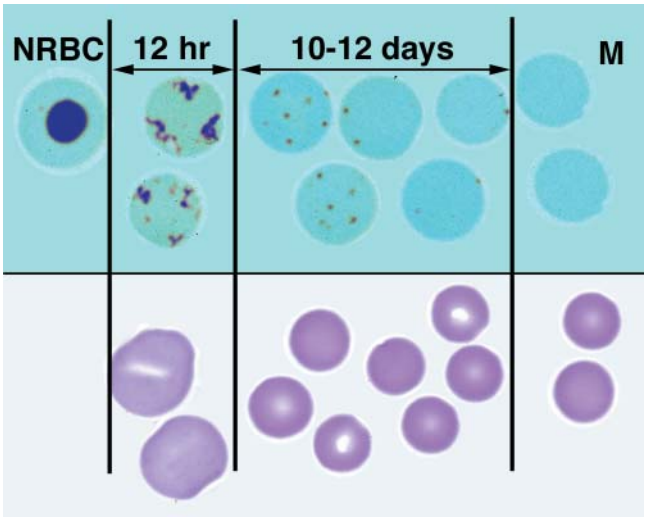

Figure 1.22 Feline reticulocyte maturation, progressing from left to right. Top. Cells stained with new methylene blue. After denucleation of the metarubricyte (NRBC), an aggregate reticulocyte is formed. This cell matures to the punctate form in approximately 12 hours. The punctate forms continue to mature by slow loss of punctate granules during a 10–12-day period. Mature cells (M) on the right have no granularity. Bottom. Corresponding cells stained with Wright-Giemsa stain. Note that polychromatophilic cells correspond to aggregate reticulocytes. Punctate and mature cells are indistinguishable with Wright-Giemsa stain.

direct measurements, microscopic procedures, and calculations. The CBC may include:

Direct measurements:

- Packed cell volume (by microhematocrit centrifugation).
- Hemoglobin concentration.
- Red cell concentration (RBC).
- Mean cell volume (MCV).
- White cell concentration.
- Plasma proteins (by refractometer).
- Platelet concentration.
- Mean platelet volume (MPV).

Microscopic procedures:

- Differential white cell count.
- Red cell morphology.
- Platelet morphology and assessment of adequacy.
- Microscopic reticulocyte enumeration in patients with anemia.

Calculations:

- Hematocrit, when instrument derived.
- Erythrocyte indices (e.g., MCHC, MCH, and RDW).
- Absolute white blood cell differential values.
- Absolute reticulocyte count.

These determinations are organized into a report form that aids the clinician in efficiently interpreting the information. The best way for this information to be organized is into banks of data that relate to the three major cell lines (i.e., erythrocytes, leukocytes, and platelets). For each cell line, all pieces of relevant information are organized in one place on the form.

Laboratory tests useful in the diagnosis of immune-mediated hemolytic anemia

Coombs or antiglobulin test

The Coombs or antiglobulin test is used as an aid in establishing the diagnosis of immune-mediated hemolytic anemia by detecting species-specific immunoglobulin that is adsorbed or attached to the surface of erythrocytes. The test uses the Coombs reagent, which is a polyclonal serum (usually prepared in rabbits) to the immunoglobulins of the species of interest. Some reagent manufacturers claim their reagent also detects complement. The procedure involves washing the erythrocytes in saline to remove plasma proteins and immunoglobulin that may be nonspecifically associated with erythrocytes. An aliquot of washed cells then is incubated with the Coombs serum. If appreciable patient immunoglobulin is attached to the erythrocytes, the Coombs serum induces erythrocyte agglutination. By means of two binding sites per molecule, the Coombs reagent immunoglobulin binds the patient immunoglobulin attached to the erythrocytes. The two binding sites result in progressive bridging of erythrocytes, which is visualized as agglutination. The absence of agglutination is interpreted as being a negative result, whereas the presence of agglutination is interpreted as being a positive result. Appropriate controls are performed as well.

False-negative reactions are a common problem with the Coombs test, likely because of the elution of pathologically adsorbed immunoglobulin or immune complexes during washing of the erythrocytes in preparation for the test. The best evidence for this is that prominent autoagglutination may disappear with washing. Autoagglutination, if confirmed microscopically, may be interpreted as being equivalent to a positive Coombs test. False-positive reactions also may occur, but are less well documented because the test is typically only performed when one suspects the disease.

Saline fragility test

Resistance of patient erythrocytes to hemolysis is measured in decreasing concentrations of saline. This test is not commonly used because of its complexity and labor intensity. It remains a useful diagnostic aid, however, in occasional cases of immune-mediated hemolytic anemia in which other hallmark pieces of information are not clearly interpretable. An equal aliquot of erythrocytes is added to a series of tubes containing decreasing concentrations of saline. After incubation, the tubes undergo centrifugation, and the hemoglobin concentration then is measured on the supernatant. A tube with distilled water serves as an index for 100% hemolysis. A plot of the percentage hemolysis and the concentration of saline facilitates interpretation, as shown in Figure 1.23.

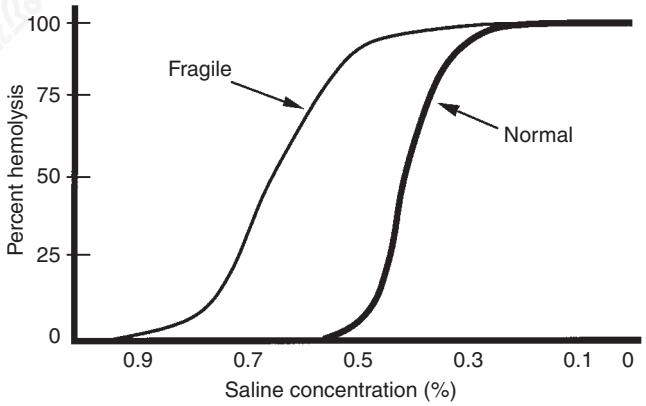

Figure 1.23 Erythrocyte fragility curve. Percentage hemolysis is plotted against decreasing saline concentration. Note the normal curve (arrow marked Normal). Increased erythrocyte fragility is recognized by a shift of the curve to the left (arrow marked Fragile).

These tests must not be used or interpreted in isolation. They are to be used in conjunction with analysis of other hematologic data and morphologic evaluation of the blood film by the laboratorian. Because of the frequency of false-negative and -positive results with the Coombs test, interpreting the results of this test in the light of the other available hematologic information is important. (See Chapter 9 for a detailed discussion of the strategy for diagnosing immune-mediated hemolytic anemia.)

Chemistry techniques

A wide variety of techniques, which have been incorporated into many different instrument designs, are used in veterinary clinical chemistry. No attempt is made here to discuss all of these techniques and instruments, but the basic information on a variety of chemistry techniques used in analyzing samples from animals is provided. A complete understanding of these techniques is not necessary for veterinarians who send clinical chemistry samples to a reference laboratory; however, an increasing number of chemistry instruments are being marketed to veterinarians for in-practice use. Therefore, an understanding of how these instruments work is important for understanding the advantages and disadvantages of the various instruments, the laboratory techniques necessary for their use, the problems that might arise during their use, and the basic principles underlying their variations in design.

The chemistry techniques discussed in this chapter and the substances that may be measured with them are listed in Table 1.1. Absorbance or reflectance photometry is used to measure most of the substances in clinical chemistry profiles. Fluorometry also is used to measure certain analytes in some clinical chemistry analyzers. Blood pH, partial pressures of carbon dioxide and oxygen, and concentrations of electrolytes such as sodium, potassium, and chloride most commonly are measured by electrochemical methods. Atomic absorption spectrophotometers are not commonly used in clinical chemistry laboratories; rather, they are more common in laboratories testing for elements considered nutrients and/or toxicants. Osmometers are common in clinical chemistry laboratories and are used to measure blood and urine osmolality or osmolarity. Protein electrophoresis is used to measure concentrations of the various protein fractions comprising the total serum protein, especially in samples with either decreased or increased protein concentrations. Light-scatter techniques that quantitate

Table 1.1 Techniques in veterinary clinical chemistry and substances measured with those techniques.

Technique	Substances measured
Photometry	
Absorbance photometry	Glucose, BUN, creatine, calcium, phosphorus, magnesium, protein, albumin, bilirubin, bile acids, ammonia, cholesterol, bicarbonate, total CO_2, enzymes
Reflectance photometry	Similar to those measured by absorbance photometry
Atomic absorption spectrophotometry	Many elements including nutrients and toxicants (e.g., calcium,[a] magnesium,[a] lead, arsenic)
Fluorometry	Glucose, bilirubin, bile acids, calcium, magnesium, enzymes, antithrombin III, heparin, plasminogen, hormones, drugs
Light-scatter techniques	
Turbidimetry	Immunoglobulins, antigen–antibody complexes, other large proteins, drugs
Nephalometry	Immunoglobulins, antigen–antibody complexes, other large proteins, drugs
Electrochemical methods	
Potentiometry	Blood pH, PCO_2, sodium,[b] potassium,[b] chloride[b]
Amperometry	PO_2
Coulometry and conductometry[c]	BUN
Osmometry	Osmolality or osmolarity
Protein electrophoresis	Albumin, α-globulin, β-globulin, γ-globulin

BUN, blood urea nitrogen.
[a]May be used to measure the concentration of these substances in solid tissues that have been ashed or digested. Absorbance photometry is more commonly used to measure concentrations of these substances in serum or plasma.
[b]Electrodes used to measure concentrations of these electrolytes are called ion-selective electrodes.
[c]Conductometry also is used to perform cell counts in some hematology analyzers.

turbidity are used less commonly to measure the concentrations of substances such as large protein molecules.

Photometry

Photometry is a general term used to describe an analytical chemistry technique in which the concentrations of substances and the activities of enzymes are determined by measuring the intensity of light passing through or emitted from a test chamber. This test chamber contains the substance to be detected and, in most cases, reagents intended to react with that substance to produce a color reaction. Strictly speaking, the term spectrophotometry should be applied when the instrument being used has the ability to produce light of a variety of wavelengths through some type of light-fractionating device, such as filters, prisms, or diffraction gratings.

Absorbance spectrophotometry

Absorbance spectrophotometry is an analytic technique in which concentrations of substances are determined by directing a beam of light through a solution containing the substance to be detected (or a product of that substance) and then measuring the amount of light that either of these absorb. The principles described here are incorporated into automated and semiautomated processes on today's chemistry analyzers. Automation, from sample and reagent addition management to calculation of test results to generation of a patient diagnostic report, is made possible by computer control and information processing integral to these systems.

To understand absorbance spectrophotometry, some basic knowledge regarding light is necessary. Typically, light is classified by its wavelength, which is measured in nanometers (nm). Light with the shortest wavelengths (<380 nm) is termed ultraviolet (UV) light (Table 1.2). Light in the visible spectrum has wavelengths of 380–750 nm. Light with the longest wavelengths (>750–2000 nm) is termed infrared (IR) light. The energy of light is inversely proportional to its wavelength; therefore, UV light has the highest energy and IR light the lowest.

Table 1.2 Wavelengths resulting in ultraviolet light, various colors of visible light, and infrared light.

Wavelength (nm)	Color
<380	None (ultraviolet)
380–440	Violet
440–500	Blue
500–580	Green
580–600	Yellow
600–620	Orange
620–750	Red
750–2000	None (infrared)

The visible spectrum includes a variety of wavelengths that represent the colors with which we are familiar. It is important to remember that color results from the transmittance or reflectance of light. In other words, a green object is that color because it reflects the green area of the visible spectrum and has absorbed the other wavelengths of light in that spectrum. Likewise, a green solution is green because it allows light in the green area of the visible spectrum to be transmitted through it and has absorbed the visible light of other wavelengths. These same principles also apply to light outside the visible spectrum. Different substances absorb and reflect different wavelengths in a pattern that is typical for that substance. The pattern in which a substance absorbs light at various wavelengths is known as its absorption spectrum, and each substance has its own unique absorption spectrum.

A basic absorbance spectrophotometer is diagrammed in Figure 1.24. Various sources of light can be used, with the choice being based on the portion of the spectrum desired plus issues such as longevity of the bulb and the basic instrument design. In the application of absorbance spectrophotometry for measuring the concentration of a substance, a wavelength of light that is absorbed by that substance (or by a product of that substance) is used. This wavelength is determined by examining the absorption spectrum of the substance of interest. Usually, the wavelength chosen is the one at which the maximum absorbance occurs. Occasionally, however, some other wavelength may be chosen to avoid interference with substances such as hemoglobin and bilirubin, which may be present in serum samples secondary to hemolysis (*in vitro* or *in vivo*) or disease leading to high bilirubin concentration. Hemoglobin and bilirubin have their own absorption spectrums, and methods attempt to avoid using the wavelengths that these substances strongly absorb.

A monochromator is an optical device between the light source and the measuring cuvette. It will narrow the spectrum of light that passes to and through the cuvette. Monochromators can be filters, prisms, or diffraction gratings. When attempting to produce light of a specific wavelength, the actual range of wavelengths produced by a monochromator is called the spectral bandwidth. Each type of monochromator can produce rays of light at certain spectral bandwidths. Monochromators capable of producing light of a narrow spectral bandwidth have more spectral purity. The importance of spectral purity varies with the type of spectrophotometry, however, and with the substance being analyzed. Filters may be a thin layer of colored glass that transmits light at wavelengths corresponding to the filter's color, or they may be more complex structures, with a layer of dielectric material sandwiched between two pieces of glass coated with a thin layer of silver. The latter type of

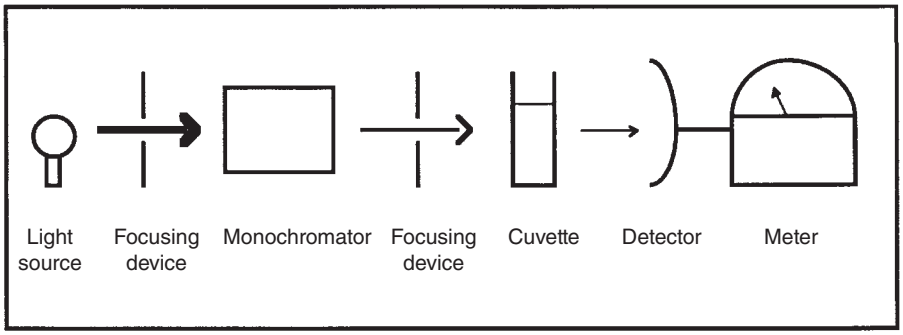

Figure 1.24 Components of a simple absorbance spectrophotometer. Arrows represent light.

filter transmits light at wavelengths equal to or at multiples of the thickness of the dielectric layer. In some cases, multiple filters may be placed in series to produce light of greater spectral purity. Prisms separate the wavelengths of white light by refracting this light. As light passes through a prism, shorter wavelengths are bent more than longer wavelengths, thus separating them. The desired wavelength then can be selected from this spectrum for transmission. Diffraction gratings are a metal or glass plate covered with a layer of metal alloy into which multiple parallel grooves have been etched. When the grating is illuminated, each groove separates the light into a spectrum, and light of specific wavelengths is produced as wavelengths that are in phase are reinforced and those that are not in phase are canceled.

The focusing devices usually are lenses or slits that are inserted before and/or after the monochromator. This placement varies with the instrument. Focusing devices are used to narrow the light beam, to produce parallel light rays, and/or to regulate the intensity of the light reaching the photodetector. In some modern instruments, application of fiber optics has eliminated some of the lens and slits used for narrowing and directing the light beams.

Cuvettes are also known as absorption cells. They have constant dimensions for a given instrument, and they can be made of various materials (e.g., glass, quartz, or plastic) and be of various shapes (e.g., round, square, or rectangular). The materials or shapes used depend on the instrument design and on the portion of the light spectrum being used. During analysis, a solution containing the absorbing substance is placed in the cuvette, and the light rays that have been produced pass through the cuvette walls and the solution. If the correct wavelength has been chosen, the substance absorbs this light in direct proportion to its concentration. In addition to the absorbing substance, the cuvette walls and the solution in which the substance is suspended also absorb small amounts of light. It is, therefore, necessary to "zero" spectrophotometers in order to eliminate the effect of these other factors, and this typically is accomplished by taking an absorbance reading on a cuvette containing only the solution in which the substance is suspended (i.e., the solution contains none of the absorbing substance). The absorbance reading of the instrument typically is set to zero while reading the absorbance of this "blank." Some spectrophotometers are designed to read the absorbance of the test solution and the blank solution simultaneously, which requires splitting the light beam and then shining each beam through either the test or the blank cuvette.

Photodetectors collect the light that has passed through the cuvette (i.e., the light that has not been absorbed). Several different technologies can be used in photodetectors. Factors such as cost, sensitivity, speed of response to changes in light intensity, propensity to fatigue (i.e., decreased response over time despite constant light intensity), and heat sensitivity help to determine which technology is used in a given application. Regardless of the type of photodetector, the underlying mechanism involves the production of electrons and, therefore, an electrical current in response to light striking the detector. This electrical current then is transmitted to a readout device or meter.

Readout devices or meters measure the electrical current produced by the photodetector. This current can be read out directly, but more commonly, this information is converted to a readout that gives either the absorbance or the actual concentration of the substance being measured. This conversion usually requires some type of microprocessor, which can store and use calibration information (discussed later) and also automatically adjust for the reading of the blank sample. The actual readout might be presented as some type of digital display, but it more commonly is printed.

Modern readout devices also incorporate recorders for obtaining multiple absorbance readings on the same sample over time. This is most useful in kinetic assays. In such assays, a reaction is allowed to occur over a period of time, and the production or disappearance of the absorbing substance is evaluated at multiple time points by measuring the absorbance of light normally absorbed by that substance. The change in absorbance over the time period is proportional to the activity of an enzyme or to the concentration of a substance, depending on which is being assayed. Such an assay obviously requires a device that can record and use data produced over time.

In addition to the basic instrumentation of absorbance spectrophotometry, the basic physical chemistry principles used in obtaining measurements via this technology also should be understood. When a light beam of a certain wavelength is projected through a solution containing a substance that absorbs light at that wavelength, the light is absorbed in direct proportion to the concentration of that substance. The intensity of the light leaving the solution, therefore, is less than the intensity of the light entering the solution. If these two intensities are known, the percentage transmittance of light (%T) can be calculated. For instance, if the intensity of light entering the cuvette is designated as I_1 and the intensity of light leaving the cuvette as I_2, then %T is calculated as

$$\%T = \frac{I_2}{I_1}$$

The intensity of light entering the cuvette is measured by projecting light of the appropriate wavelength through a cuvette containing the solution in which the substance to be measured is suspended. In this case, however, the solution contains none of the substance. Therefore, %T is set at 100% for this "blank" solution. The solution containing the substance to be measured is then placed in a similar cuvette, and the light is intensity measured, after which the %T can be assessed.

In the described situation, transmittance varies inversely and logarithmically with the concentration of the substance being measured. If %T versus the concentration of such a substance is plotted, a curved line results (Figure 1.25). Light that is not transmitted is absorbed; therefore, transmittance and absorbance are inversely related, as described by the formula

$$\text{Absorbance} = 2 - \log \%T$$

Because of this relationship, absorbance of light increases linearly with increasing concentration of the substance being measured (Figure 1.25). This linear relationship between absorbance and concentration makes it more convenient to deal with absorbance than with transmittance during spectrophotometric analysis. Modern spectrophotometers measure transmittance but then convert transmittance to absorbance. In addition, microprocessors in most spectrophotometers convert absorbance results to concentrations or activities and then report these in a final diagnostic test result format.

The concentration of a substance can be calculated from the absorbance by use of Beer's law:

$$A = abc$$

where A is the absorbance measured, a is the molar absorptivity (also known as the proportionality constant), b is the light path in centimeters (the diameter or width of the cuvette through which the light passes), and c is the concentration of the substance in question. The concentration (c) then can be calculated as

$$\text{Concentration} = \frac{A}{ab}$$

For Beer's law to apply, a linear relationship must exist between concentration and absorbance. In some cases, this might be true only up to certain concentrations or absorbance levels. To assure that Beer's law applies to a given assay, calibration solutions (also known as calibrators), which contain known concentrations of the substance to be measured, are used. The ranges of concentrations used as calibrators should include those that might be measured in samples from patients. Absorbance results for each calibrator are plotted against the concentrations of these calibrators to establish a calibration curve. Ideally, this curve is a straight line rather than an actual curve, showing that a linear relationship exists between absorbance and concentration (Figure 1.26). In most applications, one or more calibrators are included with each series of sample measurements. It is

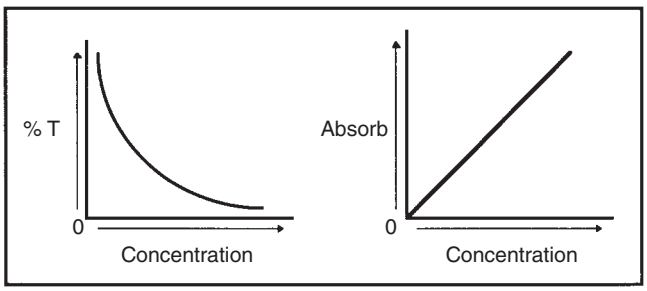

Figure 1.25 The relationships between percentage transmittance (%T), absorbance (Absorb), and concentration of a substance being measured. Note that as the concentration increases, %T decreases logarithmically or nonlinearly and absorbance increases linearly.

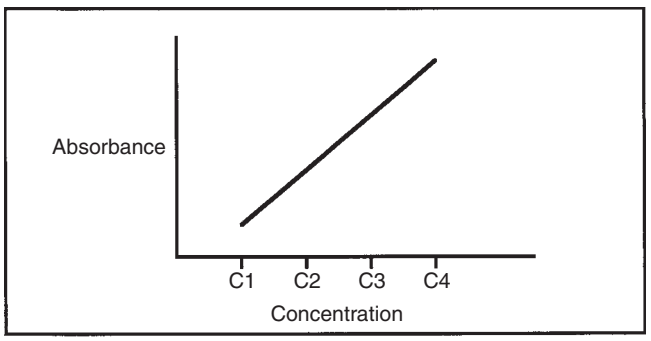

Figure 1.26 Use of calibrators to establish a calibration curve. In this case, four calibrators (C1, C2, C3, C4) were used. Note the linear relationship between concentration of the substance being measured and resulting absorbance.

best, however, to reestablish the calibration curve at frequent intervals (at least daily), because many slight day-to-day changes in the conditions of the test can affect this curve. These changes (e.g., light intensity, temperature, condition of reagents) can occur even in situations when instruments and reagents have been designed to minimize such variation. If a linear relationship does exist between the concentrations of the calibrators and the resulting absorbances, the solutions are said to obey Beer's law, and the calibrators can be used to establish a calibration constant (K):

$$K = \frac{\text{Concentration of the calibration solution}}{\text{Absorbance of the calibration solution}}$$

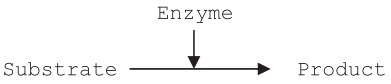
If K is known, then the concentration of an unknown solution can be calculated as

$$\text{Concentration of unknown} = (\text{Absorbance of unknown}) \times K$$

Microprocessors in instruments can plot absorbance results from calibrators, assure that a linear relationship exists, and calculate the calibration constant. These results are stored, and the concentrations of unknowns are calculated by measuring their absorbances and calibration constant.

A linear relationship between concentration and absorbance over the possible range of unknown concentrations is highly desirable, but a nonlinear calibration curve also can be used to derive unknown concentrations. In such a case, enough calibrators must be used to define the shape of the calibration curve, and as with a linear calibration curve, the range of calibrator concentrations should include the possible range of concentrations that might be found in samples from patients.

In absorbance spectrophotometry, two types of assay methods – endpoint or kinetic – may be used. In both types, the same principles of spectrophotometry described earlier apply. Endpoint assays usually are applied when measuring the concentration of some preexisting substance in serum or plasma. In such an assay, reagent(s) is added to a quantity of serum, and a chemical reaction occurs. The product resulting from this reaction then is measured by spectrophotometry. In other words, the solution in which the reaction has occurred is placed in a cuvette (or the reaction itself might have occurred in the cuvette), a light beam of a wavelength absorbed by the product is projected through a cuvette, and the absorbance is measured. By using a calibration curve and/or a calibration constant, the concentration of the substance being measured then is calculated. An example of an endpoint assay is a method for measuring the concentration of serum calcium:

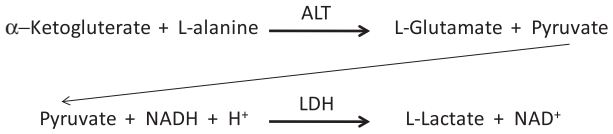


$$\text{calcium} + \text{o-cresolphthalein complexone} \rightarrow \text{calcium–cresolphthalein complexone}$$

In this assay, the substance of interest (i.e., calcium) is complexed with cresolphthalein complex one, which has a purple color and absorbs light at a wavelength of 570 nm. This reaction is allowed to occur long enough to allow nearly all of the calcium in the sample to be complexed. More calcium–cresolphthalein complex one results in more light being absorbed and a higher concentration of calcium reported by the instrument. After the absorbance is determined, it is compared with the absorbance of a calibration solution, and the absorbance of the unknown then is calculated as

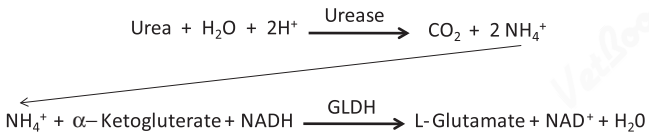
$$\text{Concentration of the unknown} = \text{Absorbance of the unknown} \times \frac{\text{Concentration of the calibration solution}}{\text{Absorbance of the calibration solution}}$$

Note that the second portion of this formula is the calibration constant (K).



Kinetic assays typically have been used to measure enzyme activities but also have been adapted to measure the concentrations of many analytes in blood. Typically, enzyme concentrations are not measured directly in clinical chemistry. Rather, the amount of enzyme in the serum usually is gauged indirectly, by the activity of that enzyme. Enzymes are proteins that catalyze (i.e., speed-up) chemical reactions, with the result that substrate is converted to product more quickly:

To measure an enzyme's activity, the rate at which it converts a substrate to a product must be assessed. The more quickly conversion occurs, the higher the enzyme activity is assumed to be. To measure the rate of conversion from substrate to product, the rate at which the product is being produced must be assessed, and this requires multiple measurements of the product concentration over time. Because this type of assay is a dynamic process, it is termed a kinetic assay. In a kinetic assay of enzyme activity, a solution containing the substrate of the enzyme of interest is added to the sample serum in a cuvette that already is in a spectrophotometer. When enzyme in this serum begins to convert substrate to product, absorbance is measured periodically by the same methods and using the same principles of spectrophotometry described previously (i.e., using a light beam of a wavelength absorbed by the product). In this process, the conversion rate of substrate to product is monitored. This rate can be converted to enzyme activity by using a formula involving the rate of absorbance change and several constants related to the absorptivity of the product as well as



to test characteristics such as sample volume, total sample volume, and light path.

An example of a kinetic enzyme assay is an assay of alanine aminotransferase (ALT) activity:

where LDH is lactate dehydrogenase. In this assay, NADH is converted to NAD^+ at a rate proportional to the activity of ALT in the sample. The NADH absorbs light at 340 nm, and its rate of disappearance is measured by periodically assessing the absorbance of the reaction mixture. The rate of absorbance change in this mixture can be converted to units of ALT activity.

As previously noted, kinetic assays also are used for measuring the concentrations of preexisting substances in the blood. In these assays, the rate of appearance or disappearance of an absorbing substance is monitored by periodically measuring the absorbance of the reaction mixture. An example of a kinetic assay for measuring the concentration of a preexisting substance is an assay of the blood urea nitrogen (BUN) concentration, which uses the chemical reaction

where GLDH is glutamate dehydrogenase. In this reaction, the disappearance rate of NADH is monitored by periodically assessing the absorbance of the reaction mixture at a wavelength of 340 nm. The disappearance rate is proportional to the urea nitrogen concentration in the serum being tested. The BUN concentration is calculated by relating the rate of change in the absorbance of the sample with that of a calibrator.

Enzyme activity also can be measured by endpoint methods, which involve mixing serum with reagent containing substrate for the enzyme and then allowing the conversion of substrate to product to proceed for a specific period of time. At the end of that period, the concentration of substrate or product is measured. The more substrate used or product produced during the time period, the higher the enzyme activity is assumed to be.

Reflectance photometry

The principle of reflectance photometry is used in a few large, automated clinical chemistry analyzers and in several of the smaller clinical chemistry analyzers designed for in-practice use. Most of these instruments use "dry chemistry" systems, in which the fluid to be analyzed is placed on a carrier that contains the reagents for the assay. This carrier can take different forms, including a dry fiber pad or a multilayer of film. After the sample is applied, the chemical reaction occurs in this carrier, and a product is formed in a concentration proportional to that of the substance being measured. The carrier then is illuminated with diffused light, and the intensity of the light reflected from the carrier is measured and compared with that of either the original illuminating light or the intensity of light reflected off a reference surface. Reflectance photometry, therefore, is analogous to absorbance photometry in that the chemical reaction occurring in the carrier results in a product that absorbs a portion of the illuminating light. The remaining light is reflected, analogous to transmittance in absorbance spectrophotometry, to a photodetector that measures its intensity. The intensity of the reflected light is not related linearly to the concentration of the substance being produced. As a result, formulas are required to convert the reflectance results to concentrations. These formulas vary with the type of instrument being used.

Atomic absorption spectrophotometry

Atomic absorption spectrophotometry (AA) is used for measuring the concentrations of many elements. Advantages of AA include its superior sensitivity (i.e., it can detect smaller concentrations) and its ability to measure the concentrations of various elements. AA is typically limited to toxicology laboratories for clinical purposes. Applications include measurement of concentrations of elements such as lead, copper, and selenium in fluids or tissues. As the name implies, AA involves measuring absorption of energy by atoms. This technique involves heating a sample in a flame that is hot enough to cause the element in question to dissociate from its chemical bonds and form neutral atoms – but not hot enough to cause large numbers of electrons to jump to the excited state. These atoms then are in a low-energy (i.e., ground) state and can absorb light of a narrow wavelength that is specific for that element. If a light of this wavelength is projected through the flame, the amount of light absorbed is proportional to the concentration of the element in the sample. Measurement of the amount of light absorbed, therefore, allows the concentration of that element in the sample to be calculated. Focusing devices, photodetectors, meters, and readout devices serve the same purposes in AA as in other types of spectrophotometry.

Fluorometry

Fluorometric techniques can be used in a wide variety of applications, ranging from measurement of the concentrations of substances to assessment of the numbers and other characteristics of larger particles, including cells. This section discusses use of these techniques in measuring concentrations of various substances in body fluids.

Among the substances that can be measured by these techniques are some that commonly are measured in clinical chemistry analysis (e.g., bilirubin, bile acids, glucose, calcium, magnesium, and various enzymes), substances related to coagulation (e.g., antithrombin III, heparin, and plasminogen), drugs, and hormones. Some of these substances are fluorescent; in other cases, measurement of these substances is possible by linking other fluorescent substances to the analyte of interest, either directly or indirectly, as the result of a series of chemical reactions.

The basic principle underlying use of fluorometry is that certain substances, when exposed to light of the proper wavelength, will fluoresce. Fluorescence results when a substance absorbs light at one wavelength and then emits light at a longer (i.e., lower energy) wavelength. The ability to fluoresce varies with a compound's chemical structure; therefore, not all compounds can be readily measured by fluorometry.

The basic design of a fluorometer is shown in Figure 1.27. A variety of light sources, including various types of bulbs and lasers, can be used. Most fluorescent compounds absorb light at 300–550 nm; therefore, light sources must produce light at these wavelengths. The primary monochromator isolates light at the proper wavelength to produce fluorescence in the substance being analyzed. Each compound can best be caused to fluoresce at specific wavelengths, and these wavelengths are known as the apparent excitation spectrum of the compound. Of these wavelengths, a narrow band at which peak fluorescence is caused usually is chosen to be isolated by the primary monochromator and, from there, transmitted to the cuvette. When light strikes the solution in the cuvette, it produces fluorescence in the substance being measured. The detector of this fluorescent energy usually is placed at a 90° angle from the projected (i.e., the exciting) light beam. This placement means that light from the exciting light beam continues straight through the cuvette and does not need to be dealt with by the secondary monochromator or the detector. Because fluorescent energy is projected in all directions, this energy can be measured at 90° without measuring the energy from the exciting light beam. Some fluorometers incorporated into absorbance spectrophotometers measure fluorescence directly in the path of exciting light (i.e., an end-on design), because this is the typical light path for absorbance spectrophotometers. In such cases, mechanisms must be incorporated to exclude excitation light that has passed through the cuvette.

The secondary monochromator excludes light from sources other than the fluorescence itself and allows only a narrow band of wavelengths to pass to the photodetector. Just as each fluorescent compound has an apparent excitation spectrum of light in which optimum fluorescence occurs, each compound also has an emission spectrum, which is the spectrum of wavelengths in which most of the emitted fluorescent energy from that compound is found. To develop a fluorescent assay, the emission spectrum of the compound of interest must be determined. Then, the narrow band of wavelengths in which maximum emission occurs is isolated by the secondary monochromator. Light passing from the monochromator is collected by a photodetector, measured, and processed in a manner similar to that described for spectrophotometry. Various lenses, slits, and, in some cases, polarizing devices are included in fluorometers

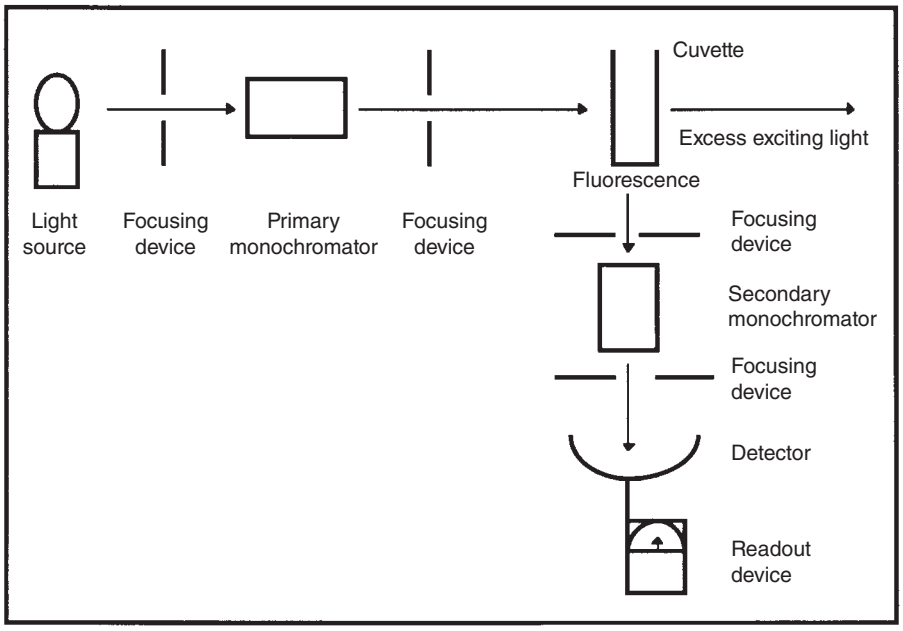


Figure 1.27 The basic design of a fluorometer. Arrows represent light.

to help direct and/or polarize light as well as to reduce stray light in the system.

A wide variety of fluorometer designs are available. Strictly speaking, fluorometers are instruments that can produce light at only a few wavelengths, because their primary monochromator is a filter. Many instruments that use fluorometry have primary monochromators that are diffraction gratings or prisms. These instruments can produce a spectrum of excitation wavelengths and are known as spectrofluorometers. Some fluorometers are designed to compensate for variations in the intensity of the light source and, therefore, decrease the frequency with which calibration is required. Fluorometers also might use a pulsed light source and measure fluorescence only during those periods of time when the source is off. This technique, which is known as time-resolved fluorometry, eliminates the effects of light scatter.

Interference by other molecules is a potential problem when biologic fluids are being analyzed by fluorometry. Some of these molecules fluoresce (e.g., bilirubin and some proteins), whereas others scatter light (e.g., proteins and lipids). When developing assays on biologic fluids, adjustments must be made to minimize the effects of these molecules.

Although the mechanism of measuring concentrations is different, the basic procedure for performing fluorometry is similar to that for absorbance spectrophotometry. Calibrators are used to establish a calibration curve, and blanks are used to negate any effects other than those attributable to the substance of interest. At low concentrations of fluorescing substances (e.g., resulting in an absorbance of <2% of the exciting light), a direct, linear relationship usually exists between fluorescence and concentration. If the concentration of the fluorescing substance is high (e.g., >2% of the exciting light is absorbed), the relationship between fluorescence and concentration might be nonlinear.

Light-scatter techniques

Light-scatter techniques can be used to measure the concentrations of larger molecules in fluids. When light is projected through solutions containing large molecules such as immunoglobulins and other large proteins, antigen–antibody complexes, and some drugs, these molecules cause light to scatter in all directions. These techniques, therefore, are potentially useful in measuring the concentrations of these substances. With light scattering, the wavelength of the light being scattered is the same as that of the light being projected into the solution. By assessing the degree of light scattering, the concentration of the substance of interest can be measured. Two techniques, turbidimetry and nephelometry, use the principles of light scattering to make such measurements.

In turbidimetry, the decreased intensity of a light beam passing through a turbid solution is measured. The intensity of light decreases, because a portion of it has been scattered by the large molecules of interest. A basic turbidimeter is diagrammed in Figure 1.28. In a turbidimeter, light rays are projected through a cuvette containing the analyte in solution, and the intensity of light leaving the solution (i.e., the transmitted light) is measured in a straight line from the transmitted light. The decrease in transmitted light intensity is proportional to the concentration of the analyte. A turbidimeter, therefore, is similar in principle to an absorbance spectrophotometer.

In nephelometry, a beam of light also is projected through a solution containing the analyte, but the photodetector is placed at a 90° angle to the cuvette (Figure 1.29). In addition, scattered rather than transmitted light is measured. The intensity of the scattered light is proportional to the concentration of the analyte. Nephelometry, therefore, is analogous to fluorometry in terms of configuration of the light path. If a solution is not visibly turbid, nephelometry is a somewhat better technique than turbidimetry.

A direct relationship exists between the concentrations of light-scattering molecules and the degree of light scattering. A direct relationship also exists between the sizes of the light-scattering molecules and the degree of light scattering. When developing light-scatter techniques, the size of the particles being measured must be considered, because larger particles (e.g., immunoglobulin M, chylomicrons,

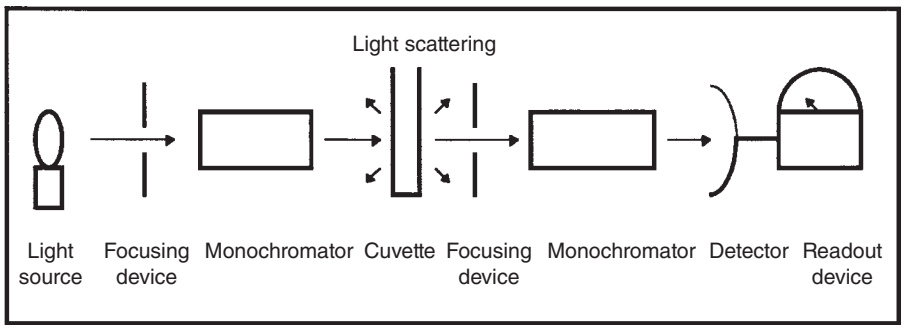

Figure 1.28 A basic turbidimeter. Arrows represent light.

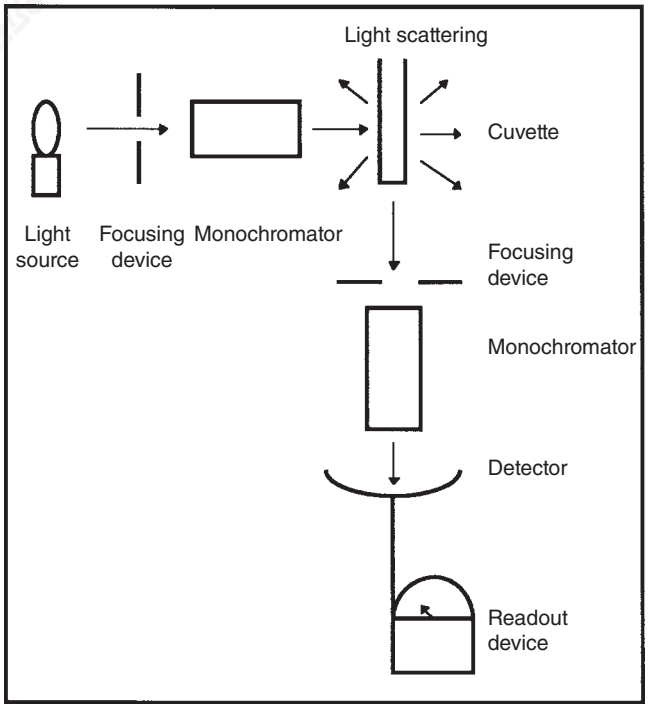

Figure 1.29 A basic nephalometer. Arrows represent light.

and antigen–antibody complexes) cause an asymmetric distribution of scattered light. In some cases, the position of the photodetector must be altered to adjust for this. Large molecules or particles other than those of interest can interfere with light-scatter techniques as well.

With light-scatter techniques, the analytic procedures are similar to those of absorbance spectrophotometry. Calibrators are used to establish a calibration curve, and blanks are used to negate the effects of reagents and other light-scattering molecules.

Electrochemical techniques

A variety of electrochemical techniques are used in clinical chemistry and most often are applied in measurements of electrolytes and acid-base status. This includes electrolytes such as sodium (Na^+), potassium (K^+), chloride (Cl^-), ionized calcium (Ca^{+2}), pH (H^+), and partial pressures of oxygen (pO_2) and carbon dioxide (pCO_2) in whole blood. These techniques also can be used to measure other substances if the chemical reactions used in the assay system result in production or consumption of an ion. For example, such reactions exist for determination of glucose, urea, and creatinine concentrations. Basic electrochemical techniques and examples of some of their applications are described in this section. Electrochemical methods are applied through a wide variety of electrode and instrument configurations. In recent years, several electrochemical systems have had complexity, cost, and applications reduced to practice in point-of-care formats. These systems have rendered blood gas, electrolyte, and selected chemistry capability both affordable and practical in the typical veterinary facility. Some of these devices utilize microfabricated disposable cartridges in which these measurements are made on whole blood. Other systems use small volumes of blood injected into a port leading to sample flow-through fluidics within the analyzer. Regardless of design, these instrument systems typically combine potentiometry, amperometry, and conductometry to provide acid-base and electrolyte panels, as described below.

Potentiometry

Potentiometry is commonly used for measurement of pH (i.e., hydrogen ion concentration), partial pressures of carbon dioxide and oxygen, and concentrations of electrolytes in whole blood or serum. In potentiometry, the electrical potential between two electrodes is measured, thereby giving a value that can be used to calculate the concentrations of various electrolytes.

Potentiometry involves the development and measurement of the potential difference between two electrodes. This technique is used to measure electrolyte concentrations using ion-selective membrane electrodes, also known as ion-specific electrodes (ISEs). The technique is used to measure ion concentrations in whole blood, plasma, serum, and occasionally other body fluids. The ISE is the variable electrode sensor immersed in the sample of measurement interest; see Figure 1.30. The ISE has a barrier or membrane that isolates the internal electrode from the body fluid. Only the specific ion being measured is allowed to cross or interact

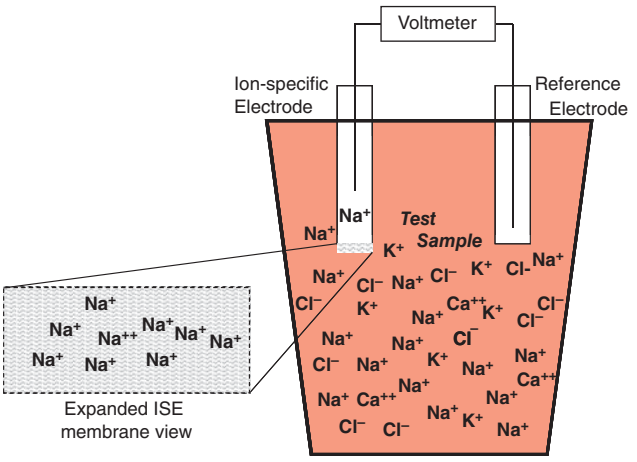

Figure 1.30 Schematic drawing of an ion-selective electrode (ISE) for potentiometric measurement; see text for further explanation. There is a reference electrode, chemically saturated to have fixed potential. The test sample contains differing concentrations of various ions. The ISE selectively allows movement of the ion of interest (e.g., Na^+) into or across the membrane, resulting in a potential difference between the two electrodes (expanded view). The potential difference is proportional to the concentration of specific analyte being measured.

with the barrier, leading to accumulation of charge on the internal electrode. At equilibrium, the potential in the ISE will vary depending on the concentration of ionic interaction with the sample. The second electrode is a reference electrode that has constant, fixed potential. The basic principle is that contact of the ion-selective membrane with the body fluid results in ion-selective passage or interaction with the ISE membrane leading to development of a potential difference from a reference electrode. A sensitive voltmeter is used to measure the potential difference when the ISE has come to equilibrium with the sample. The potential difference that develops is due to the activity of the ion being measured. The potential difference is used to calculate the concentration of ion in the sample. The ISE system is calibrated with solution containing known concentration of the ion of interest.

ISEs are the core technology in most or all modern blood gas and electrolyte analyzers, including those recommended for in-clinic applications. The design and materials used to manufacture these electrodes vary considerably. An important component of each electrode is a membrane that is selective for the ion that the electrode measures. The membrane may be composed of thin glass specially formulated to allow diffusion of a specific ion; glass is used in ISEs for pH and Na^+ measurement. A second type of membrane involves a water insoluble ion exchange chemistry coupled with a barrier membrane matrix. This type of electrode may be used to measure K^+, NH_4^+, and Ca^{2+}. There are also solid-state electrodes consisting of a single crystal of some ion-selective material or salt imbedded in an inert matrix membrane. This type of electrode is typically used to measure chloride (Cl^-).

The partial pressure of carbon dioxide (PCO_2) in the blood also is measured by potentiometry. This method is used in blood-gas analyzers. Whereas CO_2 is not an ion, the CO_2 electrode is designed to produce an ion in proportion to the PCO_2 in the blood. The design of such an electrode is shown in Figure 1.31 as a modified pH electrode. In this electrode, a chamber containing sodium bicarbonate solution is separated from the blood sample by a thin membrane. The CO_2 diffuses through the membrane into the sodium bicarbonate solution, and the following chemical reaction occurs:

$$CO_2 + H_2O \rightarrow H_2CO_3$$

$$H_2CO_3 \rightarrow H^+ + HCO_3^-$$

The amount of CO_2 that diffuses through the membrane affects the H^+ concentration in the sodium bicarbonate solution in direct proportion to the PCO_2. The remainder of this electrode is a pH electrode that senses the change in H^+ concentration of the sodium bicarbonate solution. These changes alter the electrical potential of this electrode, and the instrument then calculates the PCO_2 from these changes.

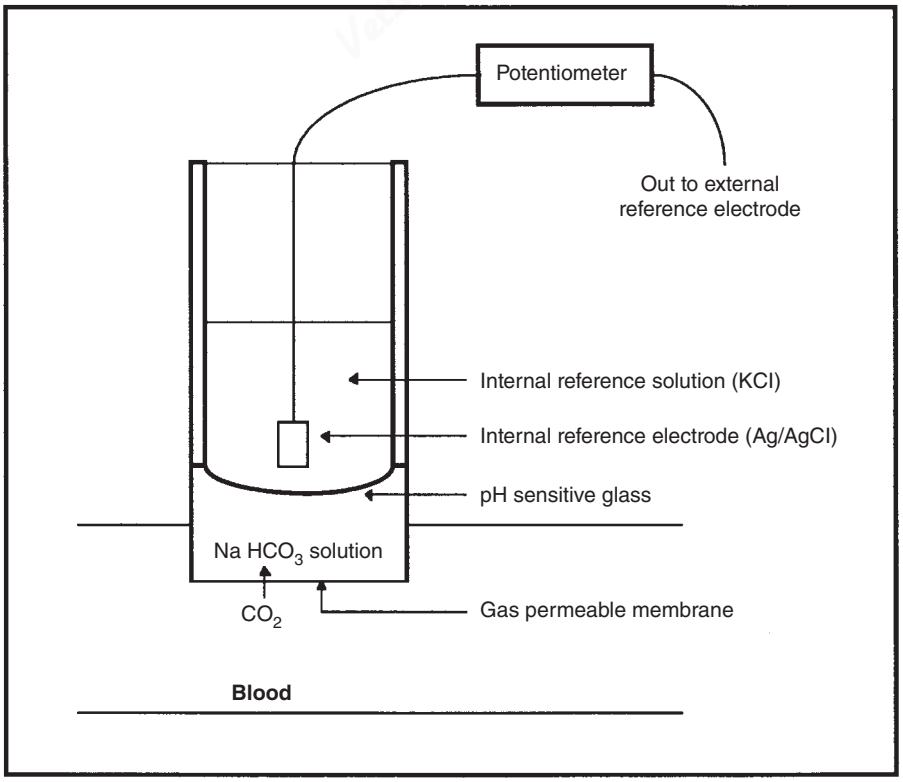

Figure 1.31 An electrode designed to measure the partial pressure of carbon dioxide in the blood.

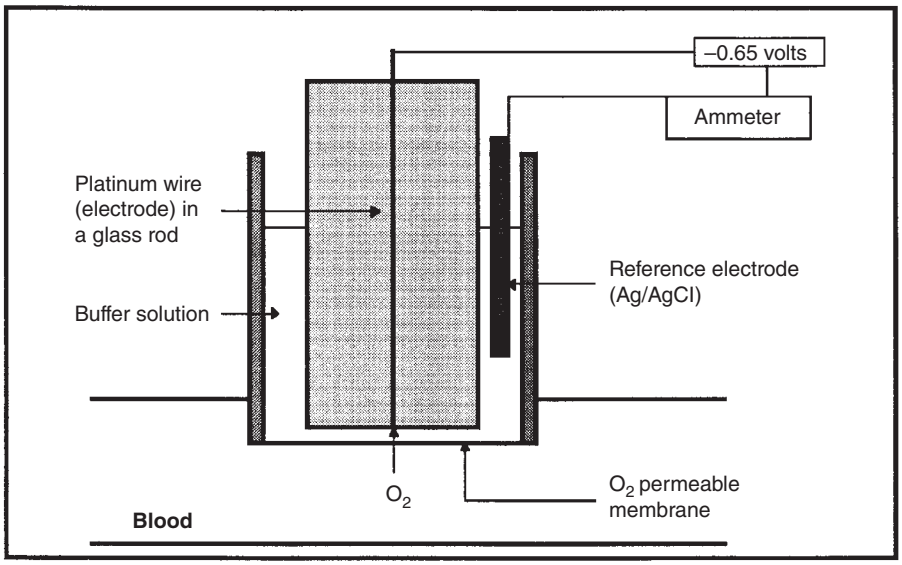

Figure 1.32 An electrochemical cell designed to measure the partial pressure of oxygen in the blood.

Amperometry

Amperometry is a technique that measures the electrical current passing between two electrodes in a chemical cell while a constant voltage is applied. This differentiates the technique from potentiometry, in which no electrical current flows and no voltage is applied. The most common application of amperometry in clinical chemistry is electrochemical measurement of the partial pressure of oxygen (PO_2) in blood.

The technique is most easily understood by considering how this electrochemical cell operates. A typical PO_2 electrode is diagrammed in Figure 1.32. An electrical potential of −0.65 V is applied to this electrode, and almost no current passes through this electrode if no oxygen is present. When this electrode is submersed in blood, O_2 from the blood diffuses through the O_2-permeable membrane and comes into contact with the tip of the platinum electrode. The O_2 then is reduced by the reaction:

$$O_2 + 2H_2O + 4 \text{ electrons} \rightarrow 4\ OH^-$$

This process consumes electrons and, therefore, produces an electrical current under these conditions. An ammeter is used to measure this current as amperage. The amount of current produced is proportional to the PO_2 of the blood. Calibration solutions are used to relate the amperage to the PO_2 of the unknown.

Coulometry and conductometry

Coulometry and conductometry are two other electrochemical methods that occasionally are used to measure the concentrations of substances. Coulometry involves measurement of the amount of electrical energy passing between two electrodes in an electrochemical cell. This electrical current is produced by chemical reactions occurring at the surfaces of each of two electrodes, resulting in the loss or gain of electrons by these electrodes. The amount of electrical current produced is directly proportional to the concentration of the substance being measured. This substance is consumed in an electron-using or electron-producing process. Unlike potentiometry, the actual current rather than the potential between two electrodes is measured, and unlike amperometry, no outside voltage is applied to the system. This method has been applied to the measurement of serum chloride concentrations.

Conductometry involves measurement of a fluid's ability to conduct an electrical current between two electrodes when a voltage is applied to the sample in the system. This property, which is known as electrolytic conductance, occurs via movement of ions in the fluid. The conductivity of an aqueous fluid depends on the concentration and ionic strength of the electrolytes in that fluid: the higher the electrolyte concentration, the higher the conductivity. Conductometry can be used to measure the production of ions by chemical reactions. Therefore, it is possible to measure the concentration of a substance in a fluid if it is used in a chemical reaction producing ions in numbers proportional to the substance of interest. The increased conductivity resulting from the production of these ions would then be proportional to the original concentration of the substance being measured. It is also possible to measure hematocrit by conductometry on some clinical systems. The plasma fraction readily conducts current while cellular mass acts as an insulator, impeding current. As the hematocrit increases, the ability of the sample to conduct current decreases. This measurement can be calibrated. The calculation factors in

electrolyte concentrations simultaneously measured in the same sample.

Osmometry

Osmometry involves measurement of the concentrations of particles in a fluid. The clinical significance of these concentrations, which are reported as osmolality (particles per kilogram of solvent [osmol/kg]) or osmolarity (particles per liter of solvent [osmol/L]), is discussed in Chapter 25. To understand osmometry, the changes that occur in a solution when concentrations of particles (i.e., solute) dissolved in a fluid (i.e., solvent) increase must be understood. These changes, which are known as colligative properties, are increased osmotic pressure, decreased vapor pressure, increased boiling point (because of decreased vapor pressure), and decreased freezing point. Any of these colligative properties could be used to measure osmolality or osmolarity. Among those properties that actually are used to make these measurements are freezing-point depression and decreased vapor pressure.

The freezing-point depression technique is the most commonly used. As the name implies, this type of osmometer measures the freezing point of a solution through a number of steps involving freezing, thawing, and freezing again. This process is monitored by a thermistor, which measures temperature, and it determines the freezing point by determining the temperature at equilibrium between freezing and thawing. The osmolality or osmolarity of the fluid then is determined by comparing this temperature with those of various calibration fluids with known osmolality or osmolarity.

Vapor pressure osmometers are less commonly used. These instruments measure the osmolality or osmolarity of a fluid by determining the dew point (i.e., the temperature at the point of equilibrium between vaporization and condensation) of that fluid. The dew point is a gauge of vapor pressure: the higher the osmolality or osmolarity of a fluid, the lower its dew point. In general, vapor pressure osmometers are not considered to be as precise as freezing-point osmometers. In addition, volatile substances such as ethanol are not detected by vapor pressure osmometers, whereas they are detected by the freezing-point depression technique.

Protein electrophoresis

Electrophoresis is an analytic technique based on the movement of charged particles through a solution under the influence of an electrical field. In clinical chemistry, electrophoretic techniques most commonly are used to separate and analyze serum proteins. When serum is placed on or in a supporting substance that allows migration of these proteins and can carry an electrical charge, these proteins move through this material just as other charged particles do. The movement of proteins through such a substance depends on the net charge on the protein molecule, the size and shape of the protein molecule, the strength of the electrical field applied, the type of supporting medium, and the temperature. In a given electrophoresis application, the latter three items are held constant. Therefore, the migration of protein molecules depends on the net charge and on the size and shape of the molecules. As a result, different serum proteins migrate at different rates and, possibly, in different directions in the supporting substance.

A simple electrophoresis chamber is demonstrated in Figure 1.33. Small amounts of serum are placed in specific areas on the surface of the supporting substance or in small depressions cut at one end. Supporting substances commonly used include agarose gel and cellulose acetate. Starch gel is less commonly used in clinical applications. Polyacrylamide gel also can be used for protein electrophoresis and separates more serum protein fractions than the other supporting substances. Polyacrylamide electrophoresis does produce interesting information, but the clinical applications of this information in veterinary medicine are not understood. The common supporting substances usually are in the form of a sheet, and they either have buffer incorporated into them when they are produced or are soaked in buffer before use. The buffer determines the pH at which the

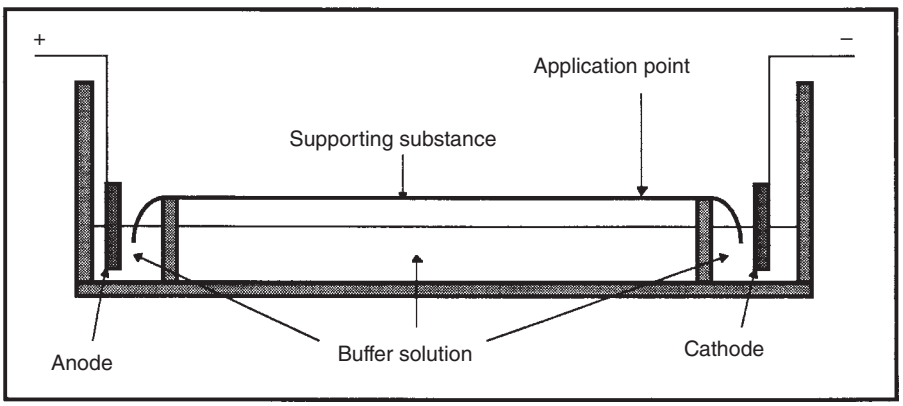

Figure 1.33 A simple electrophoresis chamber.

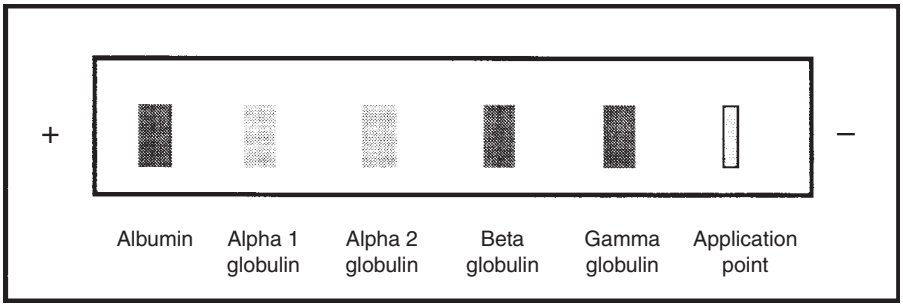

Figure 1.34 Typical electrophoretic separation of serum proteins in a sheet of supporting substance. The type and number of fractions actually separated depends on the type of electrophoresis application and on the species from which the serum was sampled.

process occurs, and the pH determines the type of charge as well as the net charge on each type of protein molecule. Both ends of the supporting substance are in contact with buffer solution in an adjacent well. These buffer solutions are not in contact with each other, however, or with the buffer solution in the center well. The electrical current is applied to the system by electrodes placed into each of these wells. A negatively charged cathode is placed in the well at one end, and a positively charged anode is placed in the well at the other end. The serum sample typically is applied at the end near the cathode, because most proteins are negatively charged and migrate toward the anode. When an electrical current is applied to this system, proteins migrate toward either the anode or the cathode, depending on whether they are negatively charged (i.e., toward the anode) or positively charged (i.e., toward the cathode). As noted, the rate of this migration depends on both the net charge of the molecule and its size and shape, and because these vary with the different types of proteins, different proteins migrate at different rates. If this migration is allowed to occur for a fixed period of time, various protein fractions are isolated along a straight line in the supporting substance.

A typical distribution of serum protein fractions in a sheet of supporting substance after electrophoretic separation is shown in Figure 1.34. Albumin is the smallest of the serum proteins and has the highest net negative charge relative to its size. Albumin, therefore, migrates faster than the other proteins, and it advances further toward the anode during the time allowed for separation. The globulins are larger than albumin and therefore do not migrate as far toward the anode. The relative migration distances of the globulins depend on the relationship of their size to their net negative charge. The gamma globulins have the smallest net negative charge relative to their size and, therefore, migrate the shortest distance toward the anode. In some techniques, the application point actually might lie in the gamma-globulin region, with some gamma globulins migrating to the cathode side of this point. The number of fractions separated depends on the electrophoretic technique used and the species being analyzed. (These separations are discussed in more detail in Chapter 30.)

Once electrophoretic separation is completed, the protein fractions usually are identified and quantified. Staining these fractions aids in this process. Various types of dye that stain protein can be used, including amido black, bromphenol blue, Coomassie brilliant blue, nigrosin, and ponceaus. After staining, it is possible, with experience, to visually identify the various protein fractions based on their order of migration. Visual examination also sometimes reveals apparently increased quantities of some protein fractions. This quantitation is more easily accomplished using a densitometer to scan the protein pattern and calculate the percentages and absolute quantities of protein in each fraction. A densitometer measures the amount of protein in each fraction by projecting light through these fractions as these are mechanically passed over the light source. A photodetector determines the width and density of each fraction. Results are reported as a densitometer scan, which more commonly is known as an electrophoretic pattern or electrophoretogram, as shown in Figure 1.35 and as both a percentage and an absolute value for each protein fraction. The absolute value for each fraction is calculated by the microprocessor in the instrument using the total protein concentration,

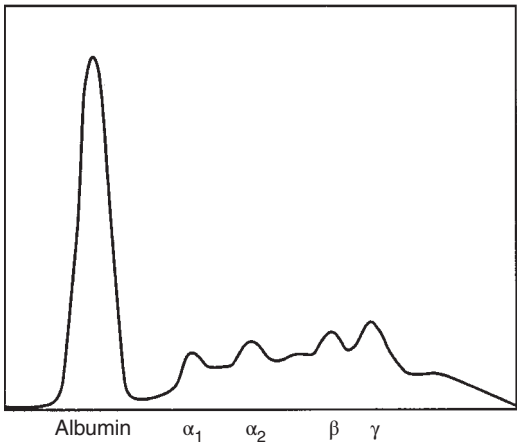

Figure 1.35 A densitometer scan (electrophoretic scan) of a serum protein electrophoresis separation.

which is entered by the operator, and the percentage of each fraction as determined by the densitometer:

$$\text{Absolute quantity of each fraction} = \frac{\text{Percentage of each fraction} \times \text{Total serum protein}}{100}$$

Most densitometers automatically identify each fraction as well as the boundaries between these fractions. The operator can and should change these in some cases.

Once the absolute quantities in the various fractions are determined, they can be compared with known reference intervals for that species, and any abnormalities can be identified. Use of such data in clinical chemistry of proteins is discussed in Chapter 30.

CHAPTER 2

2 Sample Collection and Processing, Preparations for Clinical Microscopy, and Analysis of Laboratory Service Options

Glade Weiser
Loveland, CO, USA

In the previous chapter, laboratory technology was reviewed. To take advantage of this technology and its medical diagnostic capability, however, samples for the respective procedures must be properly collected and prepared. In particular, the use of clinical microscopy for blood and cytology has steadily grown over the last 30 years. Proper technique for preparing material for microscopic examination would benefit considerably from improvement and is an emphasis in this chapter.

The veterinarian must make laboratory diagnostics choices from a vast array of in-clinic and centralized service options. Although there is continual growth and improvement in in-clinic diagnostic instrumentation, this capability is not for all facilities. The choices may be influenced by several factors. The important factors include the type of practice (e.g., general, outpatient clinic, emergency facility, specialty referral center), geographic location, expertise of paraprofessional employees, and practice style of the individuals involved. This chapter presents rules for proper sample processing and guidelines for selecting laboratory diagnostics options.

Blood sample collection and processing

Regardless of the technique or laboratory used for any diagnostic test, obtaining reliable results starts with proper collection and handling of the sample. Sample collection, processing, testing, and interpretation all must be properly performed as a complete, sequential chain of events for a diagnostic result to have its intended value. For example, even the most reliable test, performed in the most reliable facility and interpreted by the most skilled diagnostician, cannot overcome the error introduced by an inappropriate technique used in sample collection or handling. This section provides guidelines for sample collection and handling that will ensure the initial sequence of events are properly performed.

Containers for sample collection

A variety of commercially available tubes are used for blood collection. These tubes contain the appropriate anticoagulant for the various diagnostic procedures and a vacuum for drawing in the appropriate volume of blood. These tubes are commonly known as vacutainer tubes (after the trademark of Becton Dickinson). The following commonly used vacuum tubes are described in the approximate order of their frequency of use. Tubes are commonly referred to by their stopper color, which is used to identify the type of anticoagulation system the tube contains (Figure 2.1).

Red-top or serum collection tube

The red-top or serum collection tube contains no anticoagulant. Blood that is placed in this tube is expected to clot so that serum may be harvested. This tube is used to collect serum for common biochemical determinations, such as those tests used in creating biochemical profiles.

Lavender-top tube

The lavender-top tube contains the anticoagulant ethylenediaminetetraacetic acid (EDTA) salt. This tube is used to collect blood for hematologic determinations. The EDTA anticoagulant results in the most consistent preservation of cell volume and morphologic features on stained films. The liquid tripotassium (K3) salt has the most commonly used form of EDTA. A newer formulation is dipotassium (K2) salt that is spray dried into plastic tubes. The tubes are larger and have a recommended visual fill line. Either of these formulations is preferred for use in preservation of cell volumes as measured on automated hematology analyzers. The plastic K2 tubes may be more forgiving of underfilling. It is anticipated that plastic K2 tubes may eventually make

the K3 liquid in glass tubes obsolete. Powdered forms are not recommended because of slower, inconsistent mixing with blood that is added to the tube.

Green-top or heparin tube

The green-top tube contains lithium heparin. This anticoagulant is used for certain special biochemistry tests, particularly those that require a whole-blood aliquot for determination and that might be influenced by the presence of other chemical anticoagulation systems.

Some in-house systems also recommend use of lithium heparin for all common clinical chemistry determinations. The advantage is that time is not required for clotting to completion to yield serum. The plasma may be separated immediately for testing, and results for most analytes are equivalent for serum and plasma. There are two exceptions. Total protein will be slightly higher for plasma because it includes fibrinogen. Potassium averages about 0.5 mmol/L higher for serum because of platelet release during clotting.

Lithium heparin is also used for electrochemical determinations. A common sample handling error is overheparinization inherent in manual addition of heparin to collection syringes. The various heparin salts will cause errors to most electrochemical measurements including blood gases, electrolytes, and hematocrit by conductometry. Various in-house electrochemical acid-base and electrolyte analyzers are now available. It is highly recommended that special collection syringes containing "balanced" or "saturated" heparin be used. These are manufactured to contain the minimal amount of heparin. Heparin has the ability to weakly bind calcium and cause false-low ionized calcium measurement. Balanced heparin is a formulation that has the binding sites saturated with calcium so that binding in the patient sample does not occur. Use of these syringes will minimize sample handling errors for electrochemical measurements.

Blue-top or citrate tube

The blue-top tube contains sodium citrate. It is used for coagulation biochemistry determinations.

Sure-Sep tube

The Sure-Sep tube is a variation of the red-top tube containing no anticoagulant. The stopper is red with black mottling. The tube contains a gel that separates packed cell fractions from serum when it undergoes centrifugation. It is convenient for use in situations when centrifugation at the site of collection and transport to the laboratory without

the transfer of serum to a separate tube are desirable. The gel physically separates cells from the serum fluid, thus preventing analyte metabolism from occurring at the cell/fluid interface.

Gray-top or fluoride tube

The gray-top tube contains sodium fluoride. Fluoride is not an anticoagulant, however. Rather, it inhibits enzymes in the glycolytic pathway and prevents erythrocytes from metabolizing glucose while whole blood is transported to the laboratory. It is not commonly used.

Microtainers

Very small volume tubes are available for special applications such as very small laboratory animals. These may range from 0.25 to 1 mL. These should be avoided in general veterinary practice because of sample handling error potential. For example, it is very difficult to achieve proper mixing of blood in a 0.5 mL EDTA tube because of surface tension within a very small tube.

Tips for filling vacuum tubes

A few simple habits must be developed for appropriately filling tubes:

1. The ratio of blood to anticoagulant volume is important for hematology and blood coagulation biochemistry tests; therefore, a tube with anticoagulant should be filled to the volume specified for that tube. The amount of vacuum in the tube facilitates this, but the user should watch to ensure that this consistently occurs.

2. Recommendations for the tube filling order after venipuncture vary. Animal applications are different from the human setting because of differences in collection. When collecting blood for several diagnostic procedures, fill the tube(s) containing anticoagulant first and the tube containing no anticoagulant last. The most commonly used combination of tubes is an EDTA and clot/serum tube. The EDTA tube should be filled first so that platelet aggregation and clot formation is minimized. This is unimportant in the tube without anticoagulant because the blood is expected to clot in that tube. This deviates from the recommendation for humans. When filling the EDTA tube first, there is potential to contaminate the blood remaining in the syringe with EDTA. This can severely alter chemistry measurements such as calcium and potassium. Therefore, it is critical when filling an EDTA tube to avoid backflow of blood from the tube to the needle or connected syringe.

3. Vacuum tubes should be filled using minimal positive force, because forceful passage of blood through the needle may cause hemolysis, which in turn may cause an error in the biochemical measurements. Smaller-gauge needles are more likely to cause hemolysis. In particular, use of a 25-G needle, advocated by some, should be avoided because of inherent slow draw and hemolysis in tube transfer. An 18- to 20-G needle is best for most collection procedures.

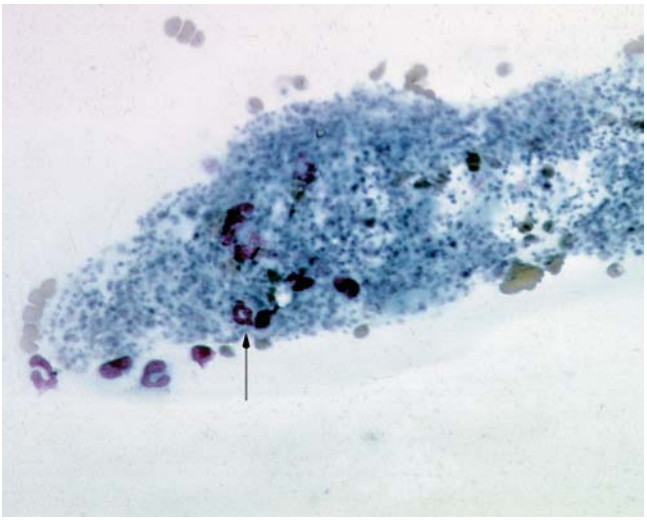

Figure 2.2 Platelet aggregation observed on a stained blood film. Tissue contamination may result in microclots that consist of hundreds of platelets, which falsely decrease the platelet concentration. Microclots also may trap leukocytes. Note the representative leukocyte (arrow); low magnification.

4. Clean venipunctures with no tissue contamination are important. Tissue contamination may result in unwanted platelet aggregation and clotting in samples collected using anticoagulants (Figure 2.2). As a result, select venipuncture sites (e.g., the jugular vein) that likely will yield the appropriate volume of blood needed for the diagnostic tests being ordered for a given patient.

5. Select a venipuncture site that will yield the desired amount of blood easily. This means being able to draw the blood with little or no collapse of the vein so that blood may be transferred to the anticoagulant tubes as rapidly as possible. Recommended venipuncture sites for diagnostic screening procedures such as a hemogram and biochemical profile include the jugular vein for small dogs, cats, horses, and cows; and the cephalic or jugular vein in medium to large dogs. These procedures generally require 4–12 mL of blood depending on the laboratory and the complexity of the screening procedures.

General sample handling procedures

Hematologic procedures

Blood collected for a complete blood count (CBC) should be analyzed within 1 hour or be prepared in the proper way for analysis at a later time. If the blood is not analyzed within one hour, a blood film should be prepared (see below) and the tube refrigerated. Morphologic features of cells may deteriorate rapidly on storage of blood in an EDTA tube; an air-dried blood film preserves the morphology of such cells for later examination. Refrigeration of the blood tube also helps to preserve the cell components that are measured by automated cell-counting systems. For example, cell swelling that could produce artifactual increases in mean cell volume

(MCV) and hematocrit will occur, as blood is stored in a tube at room or higher temperature. For some analytical systems with differential capability, it is recommended by the laboratory that blood be held at room temperature. Blood should never be frozen, however, because this will result in lysis of the cells. In addition, blood films should not be refrigerated, because water condensation on the glass may damage the cellular morphology.

For hematologic measurements, the EDTA tube should be filled to the specified volume, and tissue contamination during venipuncture should be avoided. Underfilling the EDTA tube results in excess EDTA, which osmotically shrinks erythrocytes. In turn, this results in falsely decreased packed cell volume and calculated MCV when the microhematocrit procedure is used.

Clinical biochemistry procedures

Blood collected in the red-top tube is allowed to clot for 15–30 minutes and then centrifuged to separate the cellular components from the resultant serum. The fluid phase of the blood should be separated from the cellular elements, because cells metabolize certain chemical components in the serum. The most notable example is glucose. If left in contact with cellular elements, glucose is metabolized at a rate of approximately 10% per hour. After centrifugation, serum is harvested by a transfer pipette to a second tube or is dispensed directly to devices for biochemical determinations (Figure 2.3). Harvested serum should be analyzed quickly; otherwise, it can be refrigerated for as long as 24–48 hours. If serum is to be held for longer than 24–48 hours, it should be frozen, and serum that is to be held frozen indefinitely (e.g., for archival purposes) should be stored at −70 °C. Most chemical constituents are stable under these conditions. If serum is frozen and then thawed for analysis, the thawed aliquot should be thoroughly mixed before testing.

Serum enzymes require separate consideration regarding storage. A general rule is that for best reliability, serum enzyme activities should be determined within 24 hours of collection. Long-term archival storage of samples for determination of serum enzyme activity is not advised. Data on the exact stability of serum enzyme activity under various storage conditions are difficult to interpret. Knowledge regarding this subject has not been updated in any systematic way in recent years, and historical data were not collected in any consistent manner. Thus, our current understanding of enzyme stability during storage may be summarized as follows: Commonly measured enzymes, including alanine aminotransferase (ALT), aspartate aminotransferase, and alkaline phosphatase, and amylase activities are satisfactorily stable (>70% activity) when stored at 4 °C. Freezing, however, may result in considerably accelerated loss of ALT activity. Creatine kinase activity should be measured as soon as possible, because considerable activity is lost after 24 hours regardless of the storage conditions.

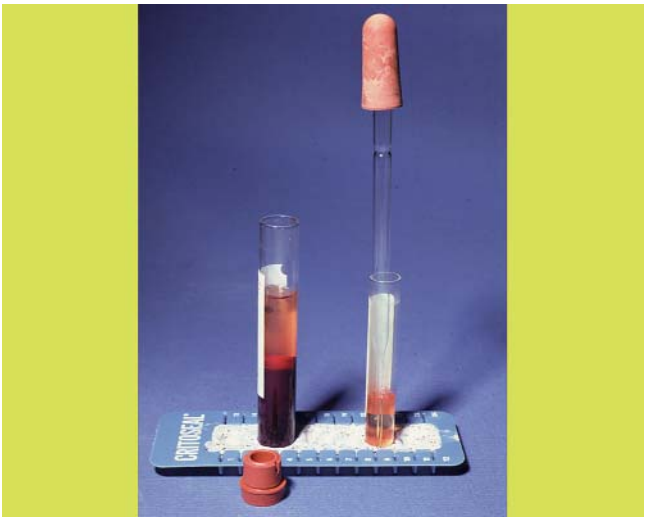

Figure 2.3 Serum preparation for biochemical tests. The tube on the left was allowed to clot and then centrifuged to pack the cells below the serum layer. A transfer pipette is used to transfer serum from the centrifuged sample to the tube on the right.

Special procedures

Special laboratory diagnostic procedures are usually performed by centralized or commercial laboratories because of the complexity or specialized instrumentation involved. These procedures are performed less frequently, and they are more dependent on unique requirements of the technology employed by the laboratory undertaking the procedure. For example, endocrine assays may vary in measuring principle and reagents used, resulting in considerable sample handling and results interpretation differences. As a result, the laboratory protocol for special procedures should be rigorously followed rather than committing these requirements to memory.

Collection, preparation, and examination techniques for clinical microscopy samples

The purpose of this section is to provide guidance on slide preparation for hematologic and cytologic samples. Sample handling techniques that limit interpretability will also be illustrated.

Ability to maximize blood and cytology sample microscopic diagnostic yield involves considerable skill and experience. One skill is pattern recognition. Pattern recognition in microscopy is the ability to (i) identify features such as cellularity, individual cellular detail, and any organization present between cells, and (ii) interpret the integrated findings into a pattern consistent with a specific diagnostic interpretation. See Chapter 3 for discussion about perspective on pattern recognition skill. Another, perhaps

more important skill involves a sequence of collection and processing procedures. These sample handling procedures include ability to properly collect, prepare, stain, and utilize a microscope to extract diagnostic information from slides. A defect in any of these sample handling procedures may introduce compromising artifacts and/or render the cytology nondiagnostic.

Hematology – blood films

Collection

Blood collection in an EDTA tube for the CBC or hemogram is described above. It is important that a "clean stick" occur to collect blood for hematology. This means insertion of the needle directly into the sampling vein before aspiration of sample to avoid any tissue contamination. Tissue contamination during venipuncture results in platelet aggregation (Figure 2.2). Platelet aggregation artifactually decreases the platelet concentration measurement determined by cell-counting systems and may contribute to fluidic obstruction in hematology instruments. The blood film may be made immediately following venipuncture by transfer of blood directly from the needle to the slide(s) but is most often made from a small aliquot removed from the EDTA tube.

Blood film preparation

The stained blood film is an essential tool for determining the concentrations of individual leukocyte types (i.e., differential count) and for evaluating important pathologic abnormalities involving leukocytes, erythrocytes, and platelets. Successful derivation of information from the blood film requires a proper technique, which both creates a monolayer of individually dispersed cells and a minimal disturbance of relative cell distributions that reflect the cell concentrations in mixed blood. A poorly prepared film presents confusing artifacts and may result in cell distributions on the slide that lead to serious errors in the differential count. Preparation of a good-quality blood film requires mastery of a specific technique (Figures 2.4–2.6). The most common procedure is known as the wedge or push technique and uses two glass microscope slides. A drop of blood is placed near one end of the first slide supported on the counter. The second slide is placed on the first in a way that forms a "wedge" consisting of a 30–45° angle in front of the drop of blood. The second slide, which is known as the pusher slide, then is backed into the drop of blood and advanced forward to the end. This should be accomplished in one rapid motion that involves a flip of the wrist holding the pusher slide. Downward pressure on the pusher slide should be minimal.

Learning this technique in the presence of someone experienced with making good films is helpful, and considerable practice is advised. A common poor technique is to push the pusher slide too slowly, thereby creating a film that is too thin. This results in very poor distribution of leukocytes at the end of the film and artifacts in the evaluation of erythrocytes.

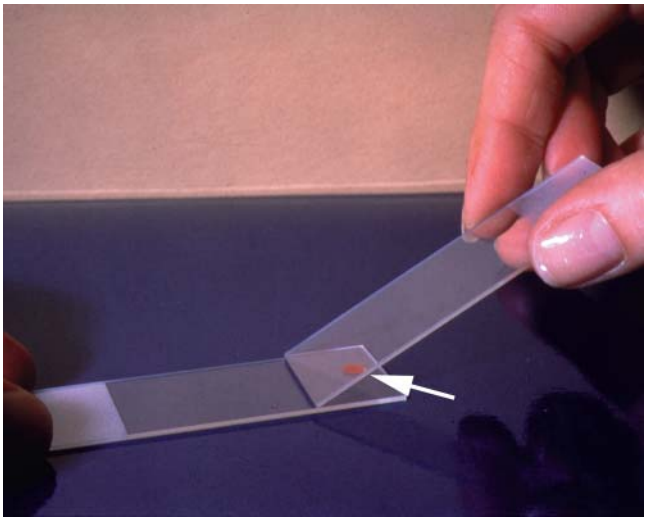

Figure 2.4 Blood film preparation. The blood slide is held on a firm surface, and a drop of blood is placed near the end (arrow). The pusher slide then is placed on the blood slide in front of the drop of blood to form an angle of approximately 30°.

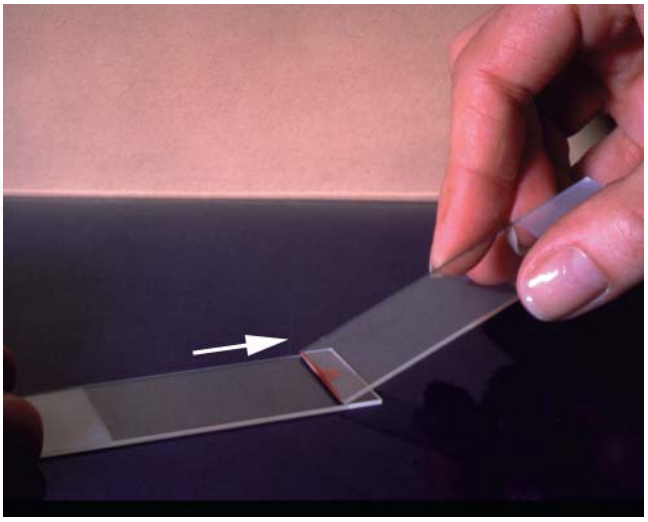

Figure 2.5 Blood film preparation. The pusher slide is backed into the drop of blood with a directional movement (arrow).

In blood with reduced viscosity, such as that from patients with severe anemia, increasing the angle to avoid a slide that is too thin is useful.

Diagnostic cytology – fluid and tissue samples

Collection

Tissue aspirates

Required materials used for aspiration are typically a 5–12 mL syringe and a needle ranging from 18 to 20-G having adequate length for the site being sampled. Very small needle diameter such as a 25-G is discouraged. For superficial tissue aspirates such as lymph nodes and cutaneous or

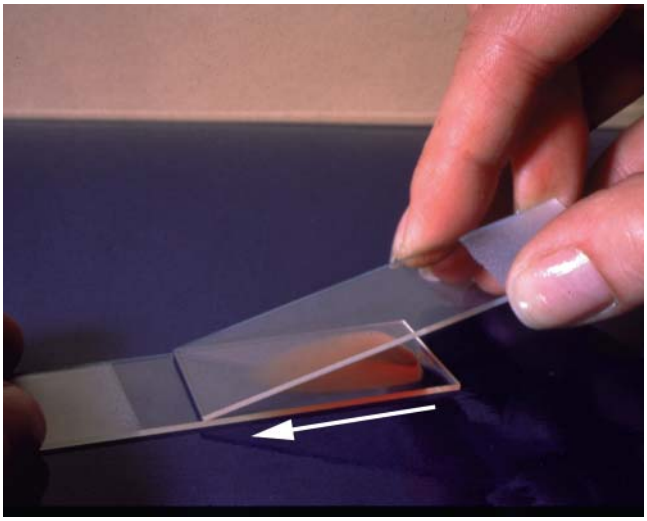

Figure 2.6 Blood film preparation. The pusher slide is pushed forward with a rapid directional movement (arrow). It is important that the movements shown in Figures 2.4–2.6 are a single, rapid procedure involving a flip of the wrist. Considerable practice is required to develop this skill. The result should be a uniform film of blood that gets progressively thinner (see Figure 2.16).

subcutaneous lesions, the mass or area of interest should be moderately isolated by digital manipulation. This will facilitate needle insertion and associated potential movement of the mass away from the insertion force. For body cavity organ or mass lesions physical isolation is not feasible, and the aspiration may typically be ultrasound guided.

There are varying techniques promoted for the physical process of aspiration. The technique recommended here is to apply aspiration negative pressure with the syringe as soon as the needle is placed in the desired location. Aspiration negative pressure may be progressively increased until one to two drops of material appear in the hub of the syringe. If blood is initially obtained, negative pressure should immediately be released. Additional aspiration is likely to yield only a blood sample. Slides should be made of this initial sample to determine if diagnostic tissue cells other than blood are present. If no material is obtained in this initial attempt, the needle may be redirected in adjacent tissue in the area of interest followed by another attempt at aspiration.

Once the sample is aspirated, slides should be made as soon as possible to avoid possible sample clotting. Material is transferred from the syringe and needle directly to slides using the preparation procedure described below.

Body cavity fluid aspirates

Examples of commonly sampled fluids are abdominal, thoracic, synovial, cerebrospinal fluid (CSF), and large abnormal encapsulated tissue fluid spaces. Cavity fluid aspiration is intuitive once the needle is placed in the fluid-containing space. Typically, only a few milliliters of fluid are needed for analysis and cytology. The aspirated fluid is transferred to an appropriately sized EDTA tube to prevent clotting. Aliquots of fluid are then available for various analysis procedures and for preparation of air-dried slides. Additional fluid should also be placed in a red-top tube if there is possibly a reason for biochemical analysis procedures.

Bone marrow aspirates

Marrow samples are unique in that cortical bone must be accessed and penetrated with a special needle to prevent plugging while accessing the marrow space. The sites that most commonly are used for bone marrow aspiration in dogs are the proximal end of the femur at the trochanteric fossa, the iliac crest, and the proximal humerus (Figure 2.7). The trochanteric fossa and humerus are the preferred sites in cats, and the ilium, ribs, or sternum usually are aspirated in horses, cattle, and camelids. If general anesthesia or sedation is not used, a local anesthetic is indicated. Both the subcutis and periosteum should be infiltrated with anesthetic. Bone marrow biopsy needles (16–22-G) are commercially available (Figures 2.7 and 2.8); conventional hypodermic needles without stylets tend to plug with bone and are not suitable. After surgical preparation of the skin, the needle is introduced. In thick-skinned animals, the skin may be incised to facilitate introduction of the needle. Once the needle is against cortical bone, it should be rotated until firmly seated in the bone and then advanced a few more millimeters, all while keeping pressure on the stylet to prevent any backward movement and subsequent bone plugging (Figure 2.8). The stylet then is removed, the syringe attached, and negative pressure applied, but only until marrow becomes visible in the syringe barrel. Aspiration of a larger volume results in contamination of marrow

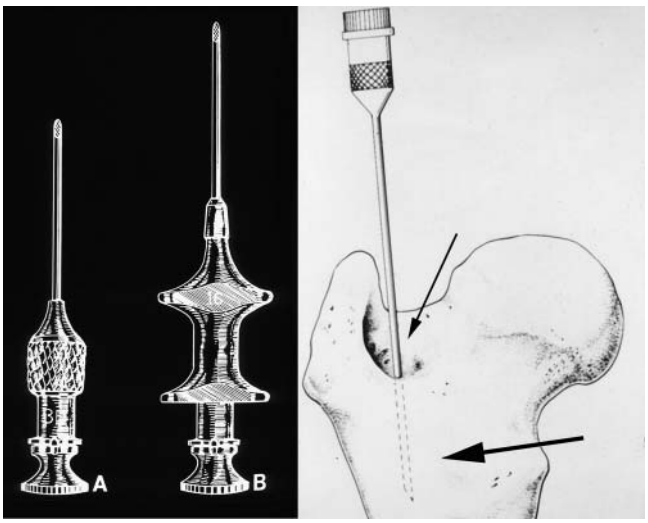

Figure 2.7 Left. Examples of commercially available bone marrow needles with stylets. Right. Correct placement of bone marrow needle in the trochanteric fossa.

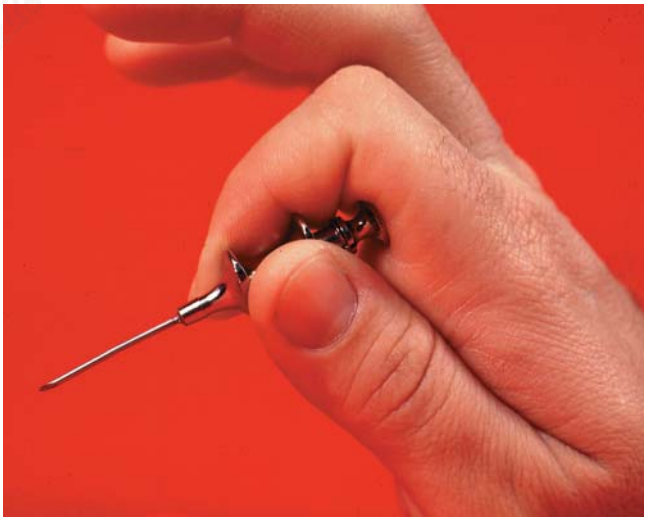

Figure 2.8 The bone marrow needle must be held with pressure against the stylet to keep the stylet in place within the needle, thus preventing bone plugs.

with blood. Once the marrow is collected, it should be placed in an EDTA (disodium ethylenediaminetetraacetate) tube, or slides made very quickly, because clotted samples are nondiagnostic. Alternatively, two or three drops of 10% EDTA solution can be placed in the syringe before aspiration. Pull films are prepared as indicated below by the pull film technique described under slide preparation.

If marrow elements cannot be obtained by aspiration even though multiple sites may be attempted, a core biopsy is indicated. Core biopsies are collected using a Jamshidi marrow biopsy needle. An infant- or pediatric-sized needle should be used for small animals. After collection, the core of marrow can be gently rolled onto the surface of a glass slide for cytologic evaluation before placing the core in formalin solution for fixation.

Tissue imprint

Imprint cytology has become relatively uncommon. However, some may use it occasionally for samples of tissue taken during exploratory surgery or in the postmortem examination setting. The key to making a monolayer imprint is to utilize a small amount of tissue and minimize the tissue fluid present. If a large tissue mass is excised, a small (less than 1 cm square) area should be cleanly cut for imprinting. The imprint surface should then be gently blotted on a paper towel or other absorbent surface to remove excess surface tissue fluid. The blotted surface is then gently touched to the glass slide in several places. Avoid "painting" the slide with the tissue or moving it laterally while touching down to the glass. If the imprints look wet and dry slowly, blot again and repeat the procedure.

Imprints are also occasionally made of ulcerated dermal lesions. The same principles apply, although trimming of the tissue is not done. The lesion should be gently cleaned of contaminant debris as much as practical and then blotted as above before making an imprint to the glass slide.

Slide preparation of fluid and tissue aspirate samples, including bone marrow

Perspective

An observed obstacle to diagnostic yield is the fraction of cytologic preparations with varying degrees of less than desirable quality, from compromised by excess artifact to being uninterpretable. A large part of success in pattern recognition is ability to navigate various artifacts. Artifacts are present on well-prepared cytologic samples, but they dramatically increase in suboptimally prepared samples. Additional artifacts or complications in the general practice setting can be related to inadequate stain maintenance and a maladjusted microscope. Experience at pathology laboratories indicates that cytologic slide preparation is the major weak link in all of the steps leading to the procedure's ability to provide useful diagnostic information. The fraction of uninterpretable or compromised samples is surprising.

The objective of preparing diagnostic samples of tissue or fluid aspirates is to create a monolayer of cellular material from the sample. This is more difficult to achieve for cytology than for making blood films because of the variation in viscosity and texture across various sample types. Body cavity fluid samples tend to be the least viscous, usually much less than blood. Tissue aspirates are much more variable and may have small particulate tissue aggregates.

Body cavity fluid samples may be directly used to make slides when there is adequate cell concentration. An adequate cellularity guideline is greater than 10,000/μL. With lower cell concentrations, such as occurs in transudates and CSF, it is desirable to concentrate an aliquot of sample for slide preparation. This may be done by sample centrifugation, removing most of the supernatent, mixing the pellet with residual supernatent, and then making slides as described below. Central laboratories may use a cytocentrifuge designed to make concentrated slide preparations. This is typically required for CSF samples.

Recommended technique

The recommended technique involves use of as little fluid material as possible to allow spreading of material into a reasonable monolayer between two glass slides. In the laboratory, this is often called the "pull film" technique. The described steps are as follows:

- Pull films are made using a pair of slides. Multiple pairs may be prepared. (See Figure 2.9.)
- Using the syringe, transfer a small amount of material to one end of the first slide. This is typically one drop.
  - In the case of a body cavity fluid, the transfer may be made with a small laboratory pipette.

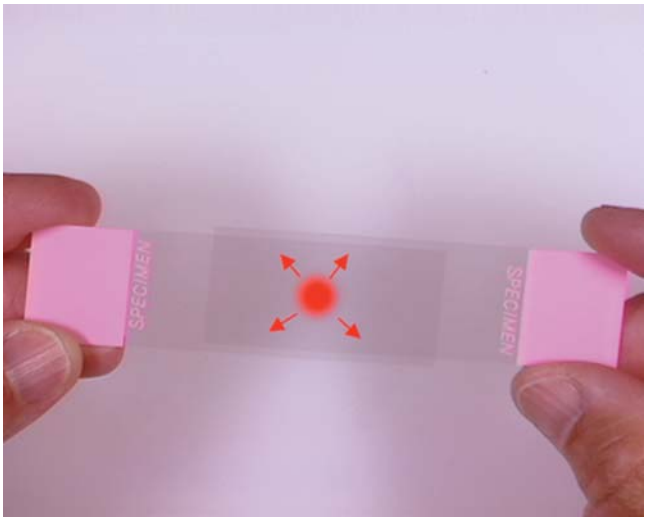

Figure 2.9 Two-slide technique for preparing pull films for cytology samples. The drop of material is allowed to spread slightly before pulling the two glass slides apart parallel from one another.

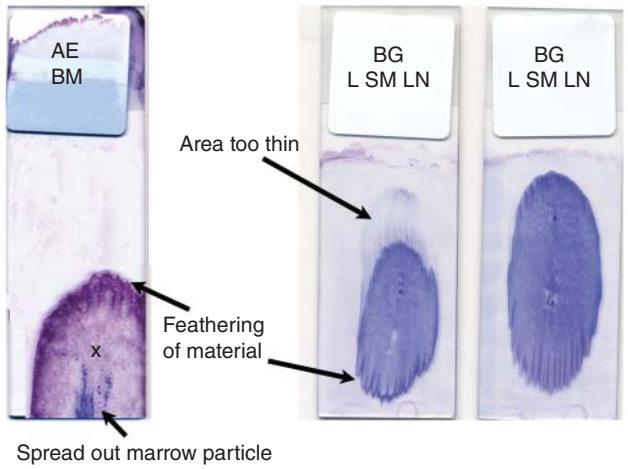

Figure 2.10 Examples of recommended "pull film" technique. The stained slide on the left is from a bone marrow sample. The "x," near the end of the glass slide, indicates the approximate location of the drop placed for spreading between two slides. The violet area indicates an area of marrow particle cellularity that is spread out. The two stained slides on the right are from a lymph node aspirate. Note that the droplet of material was placed more in the center of the first slide. This results in spreading over a larger area. An area indicated as too thin will consist of mostly broken cells. Both samples have feathering of material at the end or edge of material spreading. This indicates a desirable degree of spreading occurred and that good monolayers of intact cells will be present.

- In the case of a tissue aspirate, material may be transferred from the syringe or syringe and needle directly to slides.
- If a very small amount of tissue aspirate is obtained, it may be sprayed onto the same area and followed by the next step.
- Bone marrow aspirate is often placed in an EDTA tube. Material is transferred from the tube to the slide using an appropriate applicator such as a microhematocrit tube.

• Position the second slide to overlap the first, with the amount of overlap being about equal. Then, place the second slide onto the first and watch the material spread between the slides.
• As soon as the spreading slows, pull the two slides apart, making sure the slides remain parallel to each other.
• The result should show some feathering of the edges of the spreading (Figure 2.10). If the material covers all of the area of the slide overlap, too much fluid or material has been applied. Make another attempt with less material.
• If there is considerable friction in pulling the slides apart, then the material has spread too far. This will result in more broken cells due to shearing force on the glass.
• Air-dry the slides as rapidly as convenient and label them appropriately.

Sample slides are then ready for staining to confirm that cells other than blood are present. (See "Perspective on Use of Cytopathology" in Chapter 3.) Slides sent to a commercial laboratory should be labeled and placed in a suitable holder. Ideally some unstained slides are included. A plastic slotted slide holder is recommended. Cardboard slide holders are satisfactory but are associated with smashed slides more frequently. To avoid damaging water condensation on slides, do not refrigerate the slides or holder containing slides.

Examples of compromised to uninterpretable cytologic slide preparation

Examples of slide preparations that limit the diagnostic usefulness of cytology are illustrated here. Pathologists in the receiving laboratory setting commonly encounter these examples.

Slides that are too thick

There are a few techniques that result in thickness that prevents visualization of cells at worst and evaluation of cellular detail at best. A rule is: if one cannot see through material on the slide with the naked eye, it will be too thick to visualize cells with the microscope.

Too much material placed on slide. This is the most common cause of nondiagnostic slide preparations. This is usually seen with tissue aspirates having appreciable tissue fluid volume and bone marrow aspirates. Figure 2.11 shows example slides. So much material was applied that there is no area on the slide for spreading into a monolayer to occur. The result is a very thick background and complete lack of individual cellular detail. This is due to severe rounding up of cells and/or cells being superimposed in multiple layers, especially when there is background blood. On preparations like these, the thickness obscures light transmittance much more than on the thick part of a blood film.

Spray droplet and splatter techniques. Figure 2.12. This happens when the syringe is used to spray material onto the

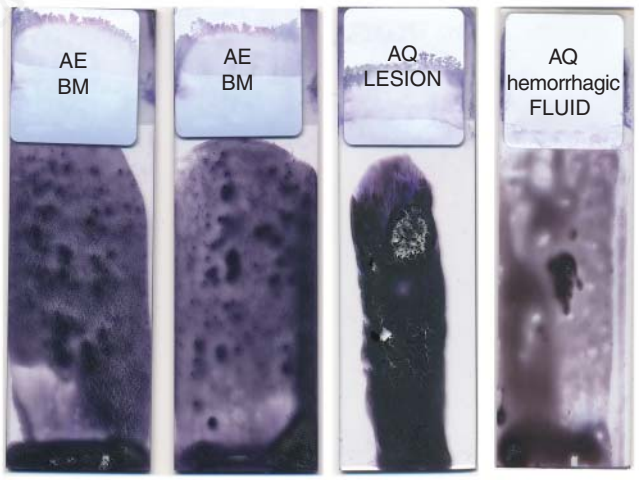

Figure 2.11 Three examples of very thick sample preparations. The two slides on the left are from bone marrow. The other two are bloody tissue aspirates. The problem is that too much material was placed on the slides. This prevents ability to spread material into a monolayer. Grossly, light transmittance is very poor. The result is inability to identify cells in almost all areas and marked rounding up of cells obscuring individual cell detail in the less thick areas. Samples such as these are usually not diagnostic.

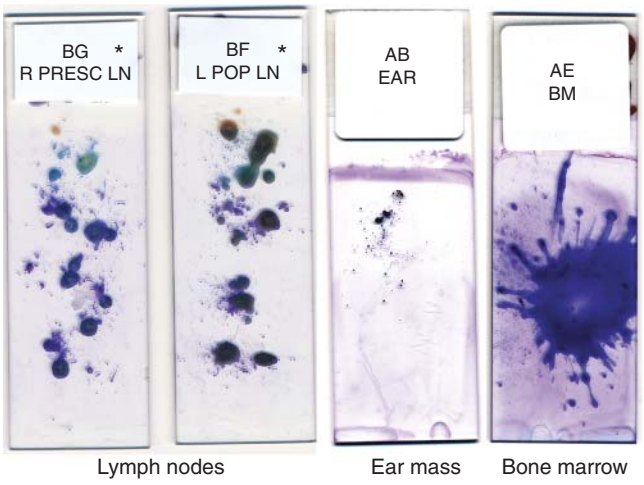

Figure 2.12 Examples of droplet, spray droplet, and splatter techniques. Note that in all of these slides there was no attempt to spread the applied material. Even the smallest droplets will be dark with thick background and very rounded up cells. How the bone marrow slide was prepared is beyond imagination.

slide, with no attempt to spread the material between two slides. This may happen when a very small amount of material is present, perhaps only in the needle hub. Alternatively, volume is present but there is no attempt to spread the material into a monolayer. The result is a background multiple cell layers thick and inability to visualize cellular detail.

Miscellaneous techniques. The "pull apart" technique is illustrated in Figure 2.13a. The technique involves placing a

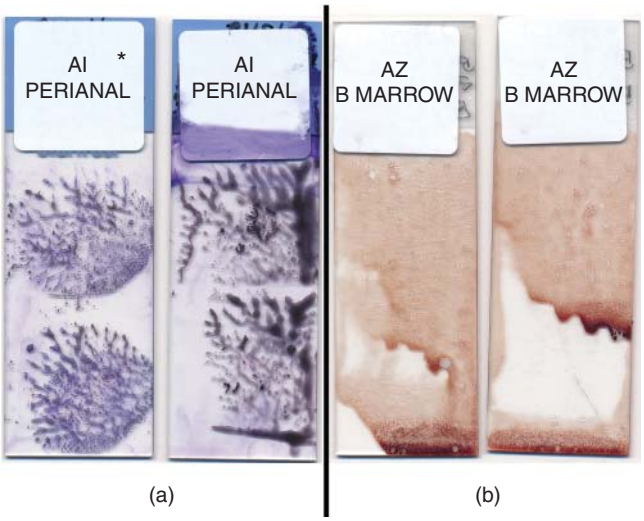

Figure 2.13 Two stained slides marked (a) are made by the pull-apart technique giving the characteristic arboreal appearance. Much of the material is too thick for evaluation. The observer must carefully navigate to find suitable monolayer material. The two unstained slides (b) are made from a bone marrow sample. Too much material was placed on the slides and then allowed to flow by gravity. Particles, indicated by the fatty droplet areas, are present. However, most of the material will be too thick for proper evaluation of individual cellular detail.

drop (usually large) of material between two slides and then pulling the slides apart perpendicular to each other. There is some spreading between the slides, but there is minimal filming into a monolayer. The result is a characteristic pattern of suction created by perpendicular slide separation. The appearance is like an image of tree branches. There will likely be areas thin enough for evaluation. However, this increases the skill required to navigate the slide to avoid the thicker material and concentrate on areas of better cellular detail. A bone marrow technique is shown in Figure 2.13b. A relatively large sample volume is loaded at one end of the slide. The slides are then positioned upright to allow the sample to flow down the slide by gravity. The objective is to not disrupt marrow particles of architecture as they separate from the fluid. Cellularity of particles may be evaluated this way on low power, but the sample is too thick for proper evaluation of individual cellular detail.

Procedures that may rupture more cells than desirable

Broken cells are present on almost all cytology preparations, but some techniques result in an undesirable fraction of broken cells making interpretation more challenging.

The painting technique. Some have an artistic urge to paint the sample onto the slide, as shown in Figure 2.14. The result will likely be a combination of thin areas in which most or all of the cells are broken. There may also be thick areas that are not spread properly. There will likely be interpretable areas, but navigation around the artifacts makes interpretation more challenging.

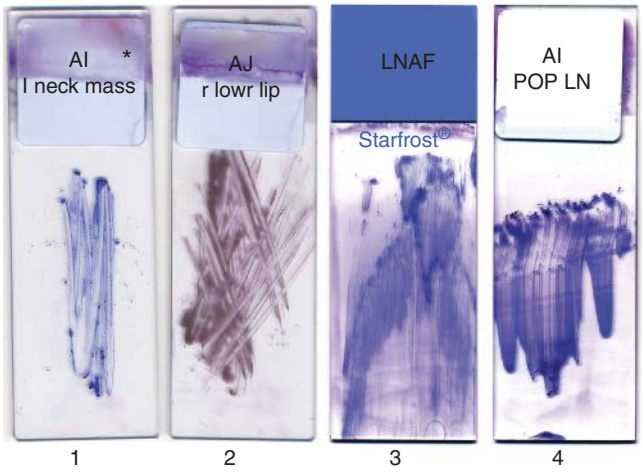

Figure 2.14 Stained slides marked 1 and 2 are examples of painting the cytology material on the slide. Stained slides marked 3 and 4 are examples of shearing the material on glass, as indicated by the long shear line pattern in the material. Both sample types will have many broken cells in the thin areas and variable areas of thickness.

The shearing technique. This involves spreading the material over a long distance of glass, creating a glacier effect. As the material gets thin there is a shearing force that ruptures the cells. This is seen grossly by long linear streaking of the material as seen in Figure 2.14. There may be interpretable areas, but navigation around the artifacts makes interpretation more challenging.

Staining, use of microscope, and examination of blood and cytology samples

Staining

After preparation, the blood film is usually stained within minutes. However, it may be stained within hours to days if it is being sent to a diagnostic laboratory. The staining system used for microscopic evaluation of cellular elements is the Wright stain, or a Wright stain modified by the addition of Giemsa. This is a relatively complex procedure that requires care and maintenance, thus often being limited to larger laboratory facilities. Quick-stain procedures that mimic the classical Wright stain are available, however, and for convenience, these are the most commonly used stains in the veterinary practice setting. The best-known stain kit is Diff-Quick (various online suppliers). Quick stains may result in nuclear over-staining and smudging of chromatin detail, but they provide sufficient quality for differential leukocyte counting and screening for morphologic abnormalities. Experience indicates that quick stains may suffer from inadequate maintenance in the veterinary practice setting. In particular, the basophilic dyes can be depleted as use of the stain progresses over time. This is seen as an insidious loss of nuclear staining and paleness of other basophilic organelles. It is important to regularly change the stain containers to prevent dye depletion. Examples of manual to automated staining systems are shown in Figure 2.15.

Figure 2.15 Blood film and cytology staining apparatus. Top. Manual staining jars containing Diff-Quick stain. Slides are manually moved from one jar to the next according to the manufacturer's instructions. Bottom. An automated stainer used for higher-throughput situations. Note the mechanical arm that moves a rack of slides (not shown) through the sequence of staining procedure baths (arrow). The stainer may be programmed to control the timing in each bath. Most such machines provide the ability to stain as many as 20–25 slides per cycle.

Use of the microscope

The microscope should be of good quality and optimally adjusted to minimize optically induced artifact on air-dried blood and cytology preparations. The good-quality microscope ideally has bright halogen or LED illumination at high magnifications, a flat field (plan) high-power objective, wide field of view optics, and an adjustable substage condenser. Oil immersion is typically required for cytology and hematology. Even with a quality microscope, a common problem is condenser maladjustment, especially when there are multiple users. When wet mounts are examined, it is necessary to dial the condenser's iris diaphragm down to increase contrast. An alternative to diaphragm adjustment is to lower the condenser. Either of these adjustments are a problem for the next user looking at an air-dried cytology of blood film sample. The increased contrast of a maladjusted condenser will obscure fine cellular detail important to pattern recognition in cytology. The user must be aware of the problem and adept at adjusting the condenser back to Kohler illumination. Kohler illumination involves raising the condenser to a proper height under the stage and ensuring the iris is opened. This adjustment optimizes optical performance by creating a light beam of relatively parallel rays passing through the specimen. Another more desirable solution is to employ two microscopes. One of lesser

quality is sufficient for wet mount preparations (e.g., fecal floatation, urine sediment, and skin scraping preparations). The second-quality microscope maintained by routine maintenance and proper condenser adjustment for Kohler illumination is reserved for air-dried preparations. The Kohler illumination adjustment procedure may be found in the microscope's documentation. The procedure may also be found in online tutorials such as https://www.microscopyu.com/tutorials/kohler or https://www.olympus-lifescience.com/en/microscope-resource/primer/anatomy/kohler.

Examination of blood films

Once stained, the anatomy of a blood film must be known to properly orient the slide for microscopic viewing (Figure 2.16). The largest part of the film is the thick area or body, in which cells are superimposed and leukocytes are rounded up, thereby making microscopic evaluation of all components difficult. The feathered edge occurs at the end of the film. Artifacts in this area include broken leukocytes and the inability to evaluate the erythrocyte morphology. The counting area is a small area between the thick portion and the feathered edge, and it consists of the best monolayer of cells in which microscopy is optimal. Leukocytes are flattened out so that the internal detail is most evident.

The amount of interpretive disease relevance that can be gained from examination of the blood film is proportional to the expertise available for the examination. Success in dealing with all components of such examination depends on the quality of film making, stain maintenance, ability to look in the correct place, ability to differentiate preparation artifacts from morphologic abnormalities, and experience with interpretive blood film pathology. To the extent that the user cannot make these distinctions, abnormal blood films should be referred to a specialist for examination and/or second opinion. This is especially important when the numerical data indicate a major hematologic abnormality such as anemia, abnormal leukocyte concentrations, or suspected thrombocytopenia.

It is important to examine the gross appearance of blood films as a correlate to artifact recognition. Improper preparation can be recognized, thereby alerting the observer to artifacts that can be avoided and preventing any associated, errant interpretations. Common abnormalities that may be recognized grossly are presented in Figure 2.17. The most common and important abnormality is a slide that is too thin, which can be recognized by streaks progressing toward the feathered edge. This results in a leukocyte distribution that presents major errors in the differential count. In addition,

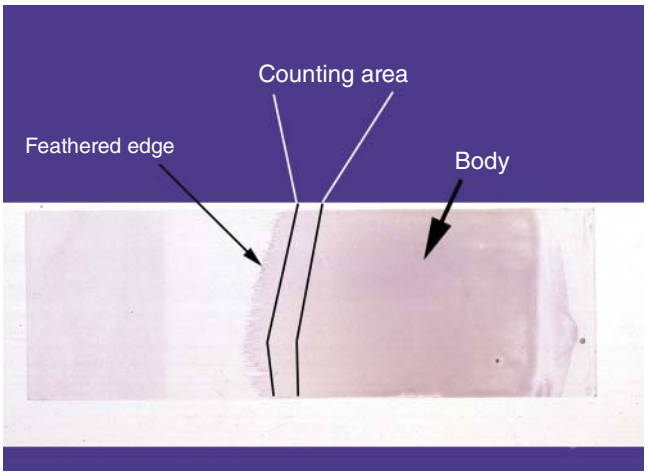

Figure 2.16 Anatomy of a stained blood film. Note the feathered edge (thin arrow) and the thick area or body of the slide (thick arrow). The counting area containing a monolayer of cells is present in a relatively small area, which is delineated approximately by the lines across the slide. This gross examination of the slide is very helpful in orienting the observer before placing the slide on the microscope stage. This facilitates alignment of the optics over the proper area of the slide, making it easier and faster to perform low-magnification observations and to find the counting area.

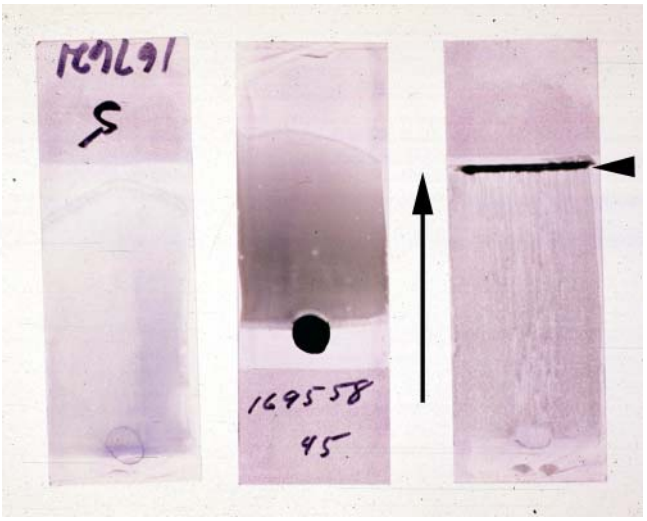

Figure 2.17 Gross appearance of blood films. All three of these films are oriented the same way. The drop of blood was placed near the bottom of the picture, and the film was made by pushing in the direction of the arrow. The middle film has a normal appearance and intensity of color. The appearance is homogeneous but gets progressively thinner as one approaches the feathered edge. The film on the left is very pale; this is the appearance when severe anemia is present. With severe anemia, blood viscosity is reduced, resulting in a much thinner film. The film on the right is made improperly and does not yield accurate information. The pusher slide was pushed too slowly, making a thin film with streaks. Note the streaking and irregularity over most of the slide. Blood was still present at the end of the slide as well, resulting in a line of densely concentrated cells (arrowhead). It is not possible to find a good monolayer for evaluation of erythrocyte morphology on this slide. In addition, the leukocytes are disproportionately concentrated at the end of the slide, which ordinarily has a feathered edge. Performing a differential count will be difficult in this case – and likely not accurate. A thin slide as a result of pushing too slowly is the most common problem in technique found at veterinary facilities.

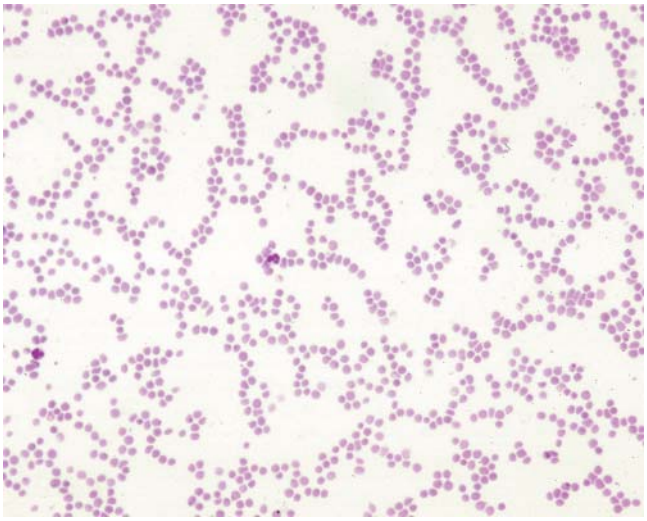

Figure 2.18 Low-magnification appearance of the feathered edge. Note the reticulated pattern of erythrocyte distribution. Artifactual loss of central pallor makes evaluation of erythrocyte morphology difficult, and false interpretation of pathologic abnormalities is likely to occur in this area.

there is not an area adequate for the evaluation of erythrocyte abnormalities.

The observer should locate the counting area using the 10× objective. The feathered edge is recognized by a loss of erythrocyte central pallor and a reticulated pattern of erythrocyte distribution on the film (Figure 2.18). Quick, low-power examination of the feathered edge is useful for the detection and identification of abnormalities such as microfilaria, platelet clumps, and unusual large cells that are preferentially deposited here (Figure 2.19). The thick area is

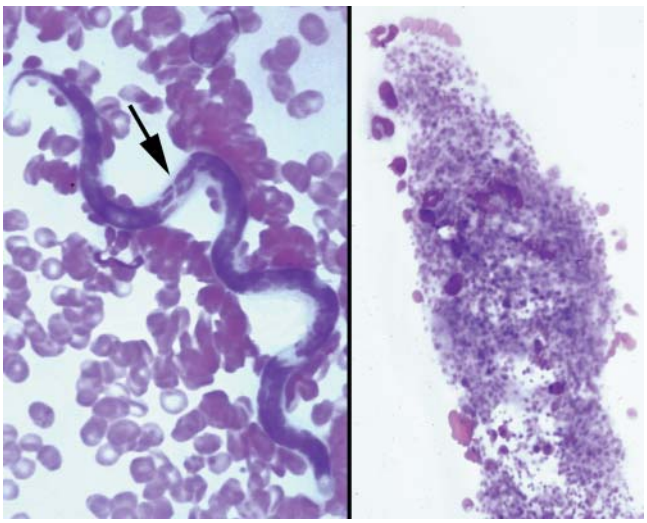

Figure 2.19 Large items pushed to the feathered edge. Left. Microfilaria (arrow) in an animal with heartworm disease. Right. A large clump of platelets with trapped leukocytes. Several hundred platelets are contained in this microclot.

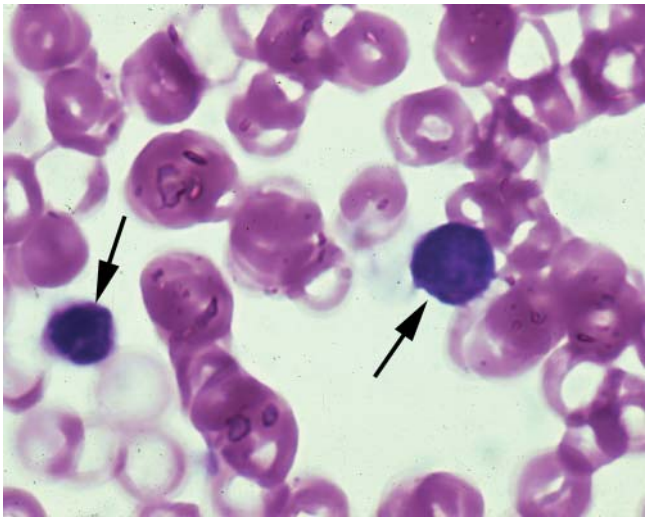

Figure 2.20 High-magnification appearance of cells in the thick area or body of slide. Note the superimposition of erythrocytes, thus making evaluation of erythrocyte morphology difficult. In addition, specifically identifying leukocytes (arrows) is difficult to impossible. In this area, leukocytes are spherical or rounded up rather than flattened. It is not possible to see intracellular detail or even the delineation between the cytoplasm and the nucleus. This makes cell identification very difficult, especially in cytology samples.

recognized by a progressive superimposition of erythrocytes as the observer moves further into the thick area of the slide. In very thick areas, the evaluation of cells is severely compromised (Figure 2.20). The counting area is recognized by a monolayer of evenly dispersed cells (Figures 2.21 and 2.22).

Once the counting area is located, the experienced observer can estimate the leukocyte concentration on a well-prepared blood film. This is useful as a gross quality-control measure, and it is recommended that the observer gain experience at this by repetitive comparison of leukocyte density on well-prepared blood films with total leukocyte counts from a cell counter. The low-power appearances of a leukocyte count in the normal range, marked leukopenia, marked leukocytosis, and high magnification leukocyte detail are shown in Figures 2.23–2.25, respectively.

Once these assessments are completed in the counting area, the microscope should be set to 100× for oil immersion, high-magnification observation. The observer will then perform a systematic evaluation of the three major cell lines. This includes a differential count for leukocytes with notation about any abnormal cells, evaluation of erythrocyte morphology, and evaluation of platelets. These procedures are defined in detail in Chapter 1.

Examination of cytology slides

Tissue aspirates including bone marrow

As indicated above, blood film evaluation involves seeking a specific area of the slide. The area is specified by the best probability of finding a monolayer of cells. Within that

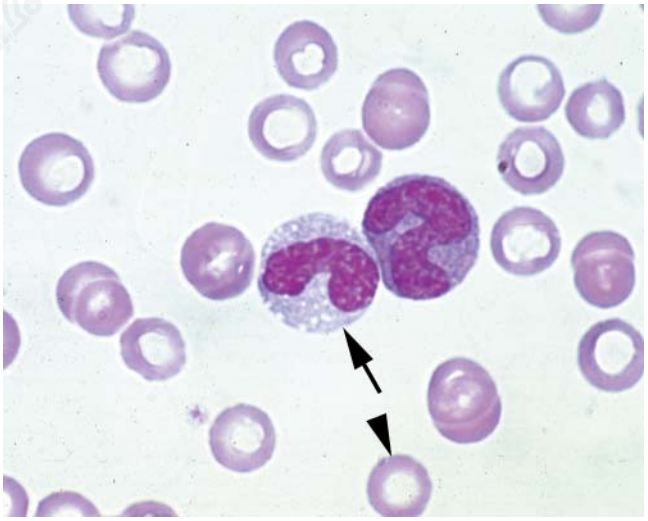

Figure 2.21 High-magnification appearance of cells in the counting area or monolayer. Note the minimal superimposition of erythrocytes, which facilitates evaluation of erythrocyte morphology (arrowhead). Leukocytes (arrow) are flattened on the slide, which makes it possible to see details of the cytoplasm and nucleus. Note that the nuclear borders are sharply delineated from the surrounding cytoplasm.

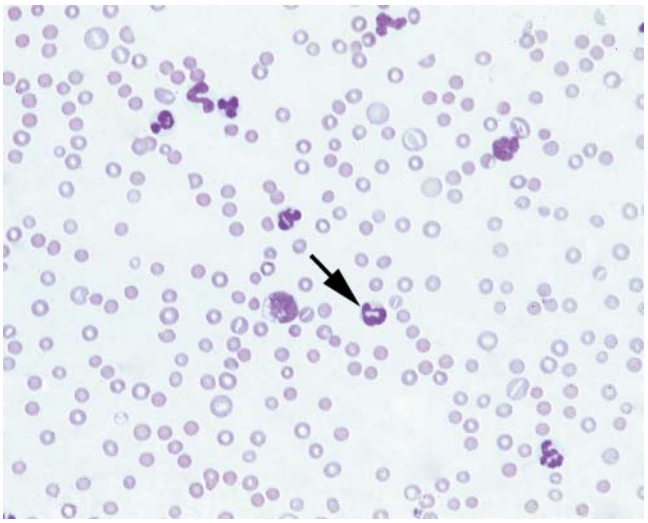

Figure 2.22 Low-magnification appearance of the counting area. Note the evenly dispersed cells and the ability to visualize the erythrocyte central pallor. The density of leukocytes (arrow) is that expected with a leukocyte concentration in the normal range.

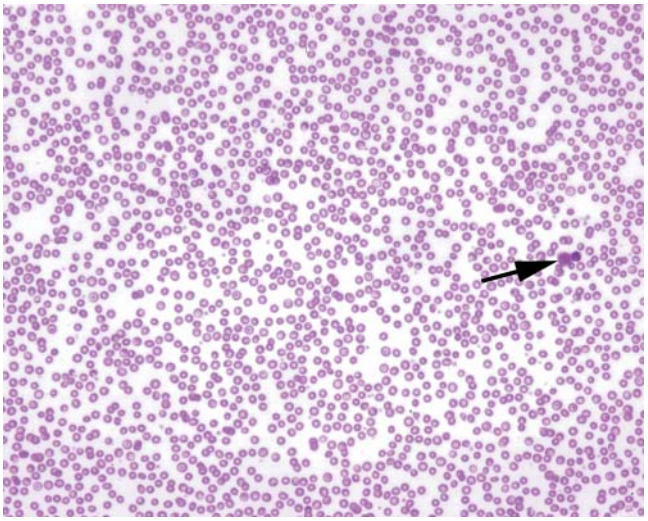

Figure 2.23 Low-magnification appearance of the counting area with a marked decrease in the leukocyte concentration. A rare leukocyte per field is present (arrow).

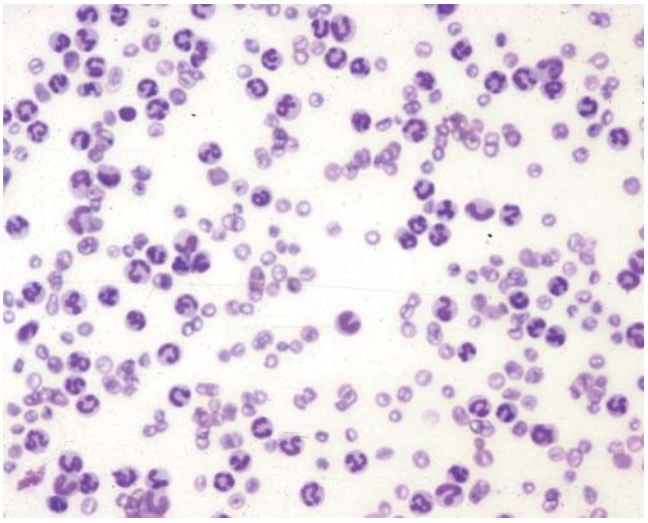

Figure 2.24 Low-magnification appearance of the counting area with a marked increase in leukocyte concentration. The density of leukocytes is considerably greater than that seen in Figure 2.22.

area, the sample is homogeneous in that cells are somewhat evenly dispersed per unit area because of sample mixing. In contrast, evaluation of cytology slides is very different. This is because the sample is likely very heterogenous in terms of distribution of elements on the slide(s). The findings that will be of interest may be completely unpredictable in terms of location on the slide. There is little to no fluid phase in which the cellular elements may be evenly mixed. The approach required is somewhat like a search and rescue mission. The procedure starts with using low power. For most, this is the 10× objective. Some will use the 4× objective, particularly on samples with low cellularity. Low power is used to scan the slide area primarily for cellular areas and secondarily to navigate to avoid areas of broken cells (thin areas) and areas of rounded up cells (thick areas). See Figure 2.20 for an example of rounded up cells in blood. Once a sense of the best areas of the slide is obtained, high magnification is used to evaluate individual cellular detail and make searches for other relevant findings. The presence of organisms is an example of an additional relevant finding in a lesion

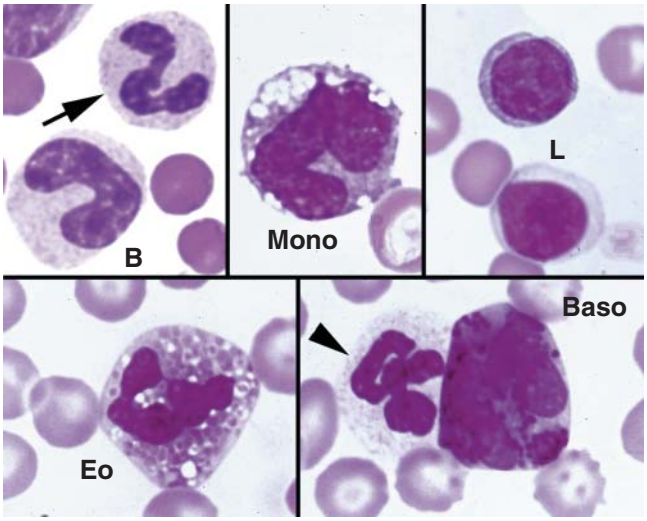

Figure 2.25 Basic leukocytes encountered in the differential count. Upper left. Neutrophils. Note the segmented neutrophil (arrow) and the constrictions in the nuclear contour. The band neutrophil (B) has smooth, parallel nuclear contours. Upper middle. Monocyte (Mono). The nucleus may have any shape, from round to bean-shaped to ameboid and band-shaped, as in this example. The cytoplasm is blue-gray and may variably contain vacuoles. Upper right. Two lymphocytes (L). Lower left. An eosinophil (Eo). Note that granules stain similar to the surrounding erythrocytes. Occasionally, granules may wash out in the staining procedure, leaving vacuoles. Lower right. Basophil (Baso) with dark granules that stain similar to nuclear chromatin. Note the adjacent neutrophil (arrowhead) and that neutrophils may have small, poorly staining granules that are much smaller than those of eosinophils or basophils.

characterized as inflammatory based on the cellular pattern present. In straightforward diagnoses, this scanning process is completed rapidly by examination of multiple fields. This is because the low-power findings appear consistent across multiple examined areas. In more complicated cases, the process of going back and forth between low and high magnification is used to assess many different areas, and sometimes multiple slides. During this process, experience is required to not be misled by confusing artifacts.

During the examination process, a cumulative description of the findings is made mentally or on paper. The findings become the basis of the diagnostic report and will support the concluding interpretation or diagnosis. Additional factors specific to examination of bone marrow aspirates are detailed in Chapter 15.

Body cavity fluids

Fluid samples are more like blood in that the distribution of elements on the slide is more homogeneous. This is because the cell population is usually evenly mixed and suspended in the background fluid. Therefore, the approach is similar to the above but can be limited to evaluation of less area. The recommended approach is to seek an area in which the cells are least rounded up. Then, use high magnification for identification of cell types present and evaluation of any morphologic abnormalities. Often, a differential count is performed to accompany a cell concentration measurement.

Analysis of diagnostic service implementation options

The veterinary facility has several options for obtaining laboratory diagnostic data. These may be generally considered as falling into three categories:

1. In-house (performed on the premises).
2. Commercial veterinary laboratory.
3. Human laboratory or community hospital.

Several factors should be considered when formulating a strategy for using one (or more) of these options. The veterinary facility should self-assess the following:

1. Type of practice (e.g., general practice, outpatient clinic, emergency facility, specialty referral center).
2. Geographic location (proximity to reliable service options).
3. Practice style of the individuals involved.
4. Willingness to implement and evaluate quality-assurance programs.
5. Willingness to invest the time to evaluate and troubleshoot diagnostics systems that have varying degrees of complexity.
6. Willingness to invest in a good microscope and training of personnel regarding basic clinical microscopy.
7. Desired turnaround times.
8. Ability to invest in instrumentation and training for the operators.

Advantages and disadvantages of in-house laboratory testing

It is known that approximately 85% of veterinary facilities utilize instrumentation for hematology and clinical chemistry to some degree. The available instrumentation has been rapidly evolving to increase sophistication and capability that approaches that of the central laboratory [1]. Modern information management allows integration of diagnostic system results into client reports as well as the electronic medical record.

Advantages of in-house laboratory testing include rapid turnaround time and control over when testing is performed relative to when samples are collected in a particular practice setting. In-house testing may also have economic advantages in certain situations.

Disadvantages of in-house laboratory testing include the issue of technical operator expertise for basic laboratory technology, which may not be available or affordable in many veterinary facilities. Attention to detail and quality assurance also must be managed by someone on site,

and the investment in instrumentation is required. In addition, access to a clinical pathologist to help with the characterization of abnormal screening tests, particularly blood film analysis for hematology, must be cultivated, and arrangements for specialized testing to supplement in-clinic diagnostic tests must be procured.

Advantages and disadvantages of commercial veterinary laboratories

The major advantages of commercial veterinary laboratories are the cost leveraging of automated instrumentation and centralized testing volume, a complete menu of testing services, professional oversight of technical performance, and pathology support. Because the automated instrumentation is dedicated to animal-specific diagnostics, it is usually already adapted for the proper analysis of animal samples. Quality-control programs are usually implemented as well, but these may be variable.

The major disadvantages of commercial veterinary laboratories include relatively fixed turnaround times, which are dictated by local sample transportation logistics. In addition, sample transportation is a major part of the cost of the service.

Advantages and disadvantages of human laboratory facilities

The advantage of human laboratory facilities is that they may be the only available option in less populated areas. The disadvantages, however, are considerable. The instrumentation, particularly for hematology, is usually not modified for animal-specific diagnostics, and knowledge about the consequences is often lacking. Animal-specific pathology support is usually nonexistent or minimal. The technologists do not have training in veterinary hematology, and nobody on site can provide that training. In addition, turnaround times for animal testing may not receive the appropriate priority relative to the primary purpose of the laboratory.

Factors to consider when committing to in-house testing

Investment in instrumentation

Acquiring diagnostic capability in chemistry and hematology requires an investment of approximately $10,000–$25,000 – or more. The cost of instrumentation has somewhat stabilized in this range, but the technical capability for this investment continues to improve. For example, advanced diagnostic capability in hematology that cost in excess of $80,000 during the 1980s now has greater capability and can be obtained for $10,000–$15,000. The useful technical life span of most instrumentation should be viewed as being from 5 to 7 years. Lease plans may facilitate the acquisition of instrumentation in ways that involve planned replacement at 3–7-year intervals. Such plans may involve both the system and consumables. These plans generally pay for themselves during use by their flow of diagnostics revenue generation per month.

Commitment to personnel

Commitment to personnel requires hiring – and retaining – a technologist who is capable of reliable performance in diagnostics. Essential elements include an understanding of the basic laboratory technology, an ability to perform these procedures, a willingness to implement quality control, and a mindset that allows the technologist to seek consultation when he or she is confronted with uncertainty.

Commitment to quality assurance

A commitment to quality assurance involves a willingness to invest in periodic training regarding diagnostic technology for the personnel who perform these procedures as well as in the oversight of a regular quality assurance program [2]. The latter involves regular monitoring of instrumentation accuracy and precision using commercial control materials with known target values. This may cost from $100 to $300 per month for materials.

Establishing a pathology consultation relationship

A working relationship with a veterinary clinical pathologist to provide help with data interpretations and morphologic assessments in difficult cases, as well as microscopy support, is highly desirable. A relationship with an anatomic pathologist is also required for interpretations of surgical biopsy specimens.

The business plan

Veterinarians who are considering in-house testing must have a mindset that allows them to use diagnostics liberally as part of their practice style. Instrument salespersons may make a compelling case for how one or two CBCs per day will pay for the cost of an instrument system. The same occurs for chemistry as well. First and foremost, these schemes are profitable for the seller, but this may or may not be true for the buyer. One should not make this investment without first analyzing the costs of various alternatives, such as the use of external laboratories. Veterinarians who perform only occasional diagnostic workups likely are better off using an external laboratory. Alternatively, diagnostics may be viewed as a source of revenue if the practice style calls for a combination of frequent diagnostic workups, preanesthetic testing, and wellness testing programs. Thus, a business plan should be created that projects the number of diagnostic tests to be performed across the practice caseload. Multiplying these numbers by the projected internal charge for laboratory tests will yield the gross revenue of

the proposed in-house testing effort. Recommended target values are the charges for similar tests imposed by a veterinary commercial laboratory in the region. The projected gross revenue then should be compared with the projected costs, including instrumentation amortization, consumable supplies, personnel, training, quality assurance, and time for supervision.

For chemistry, one must recognize that most of the currently available systems are not economically favorable for performing complete biochemical profiles in-house. For example, the cost of consumables per test with an in-house system may easily exceed $1–$3 per test. This cost can be higher with plans that consolidate instrument placement with a consumable use plan. By comparison, a complete biochemical profile may be obtained from a commercial laboratory for approximately $16–$20. With these circumstances, one is paying a premium for the convenience of in-house profile results, often while the client waits. In-house chemistry is more economically favorable for monitoring single tests or mini-panels after a diagnosis and treatment plan have been implemented.

Factors to consider when selecting external laboratory services

Instrument adaptation

Instrumentation must be suitably adjusted for animal blood testing. This is particularly important regarding hematologic analyses. Such adaptation is most likely to occur in veterinary commercial laboratories, and it is much less likely to be found in human hospital laboratories that analyze animal samples as a secondary priority.

Sample pickup service

Many veterinary laboratories offer once or twice daily sample pickup service to facilitate the shortest possible time from sample collection to the return of results. The tradeoff is that courier services represent a considerable fraction of the cost of the laboratory service. Human laboratory facilities usually rely on users to transport samples to the facility.

Appropriate turnaround time

In general, the rate-limiting step is transporting the sample to the laboratory. The trend toward consolidation of laboratory services, however, often results in very large transportation distances, thus extending the turnaround time. Once a sample arrives at the laboratory, most facilities perform the analyses as rapidly as possible and then electronically report the results. Laboratories that prioritize animal samples behind a busy human diagnostics schedule may not provide convenient timing for the delivery of results.

Species-specific ability

The laboratory should have the ability to recognize and interpret species-specific morphologic and pathologic abnormalities. In addition, the laboratory should be able to provide knowledgeable evaluation of abnormalities in data and morphology on blood films and cytology.

Consultation

The veterinary user must be able to consult with laboratory staff and pathologists regarding abnormal or unusual data generated by the laboratory. This may involve a combination of telephone and email.

Decision process

The analysis of one's diagnostic options may be summarized as follows: The decision process for implementing diagnostic support is complex, and this complexity is enhanced by rapidly changing technologies and services. It is advisable to run some experiments to facilitate this analysis. To maintain flexibility when uncertainty exists, it is advisable to avoid entering long-term purchase or service agreements.

CHAPTER 3

3 Perspectives in Laboratory Data Interpretation and Disease Diagnosis

Glade Weiser[1] and Robin W. Allison[2]

[1]Loveland, CO, USA
[2]Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

The ability to interpret laboratory data is based on knowledge regarding the normal physiologic mechanisms underlying each laboratory test and recognition of the effects of diseases on these normal physiologic mechanisms and, therefore, on the test results themselves. With these perspectives, one can assess possible explanations for an alteration in a laboratory test result, and one can sort through these possibilities to identify the most likely explanations. If performed properly, laboratory testing and interpretation of laboratory data can provide significant insights regarding diseases and respective therapeutic options. Most chapters in this book discuss normal physiologic mechanisms and the effects of disease processes on these mechanisms as well as on laboratory test results; this chapter provides basic information that applies to the interpretation of all types of laboratory data.

Introduction

The typical laboratory diagnostic workup may consist of 30–50 different parameters or pieces of information. Laboratory reports could be more simplified. For example, about half of the values in a routine hematology report are either redundant calculations or are used solely for calculation of more important parameters. These unimportant values are not diagnostically useful and cause time-consuming clutter. However, both instrument manufacturers and laboratory service providers are reluctant to remove those parameters for fear of appearing to offer less information than competitors.

The busy clinician is faced with distilling this complex body of information into a summary that, when combined with other historical and physical findings, may diagnose health or potential disease. The veterinary clinician in training often learns this process by trial and error. The purpose here is to provide some basic background and perspective to facilitate that process. This includes an understanding of reference intervals, sensitivity/specificity of laboratory tests, knowledge of factors that may introduce errors in laboratory results, the role of laboratory quality control, and a discussion of how to develop a skilled approach to interpreting laboratory data.

Reference interval background

To recognize laboratory results as being abnormal, the values expected to be obtained from healthy animals must be known. These normal values are correctly termed reference intervals; although they may also be referred to as reference ranges, this is technically incorrect since the term "range" refers to a single number describing the difference between two values. A reference interval is typically defined as values encompassing the median 95% of a tested population of apparently healthy animals. Inherent in this definition is that 2.5% of the healthy population will have values outside either side of the median 95%, suggesting they are abnormal.

When interpreting patient data, the first interpretive step is to sort data into normal and abnormal values. Flagging each abnormal value on the laboratory report form often starts this process. Information systems can do this by comparing the value against the defined reference interval. However, determination of abnormal is not as simple as it may seem for a couple of reasons. First, reference intervals are usually based on limited population testing and do not account for variation within subpopulations defined by age, sex, breed, or other factors. Second, one must think probabilistically about values that are near the reference limit. An abnormal flag does not necessarily mean the value is abnormal for that animal.

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Different statistical methods can be used to establish reference intervals, but all of them begin with the sampling of animals from an apparently healthy population. In most cases, healthy animals are those that have no apparent illness and have no detectable abnormality in cursory examination. Reference intervals must be established for each species being tested, but such intervals would ideally also be established for subdivisions within that species when some characteristic of a subgroup results in significantly different reference intervals compared with those for the species as a whole. These subdivisions might occur on the basis of age, breed, gender, pregnancy status, or type of husbandry. Because establishing reference intervals is an expensive, time-consuming task, intervals for such subdivisions are usually not established, and veterinarians generally use a single reference interval for all animals of a given species. When this is the case, it is important to consider variations in those test results that could relate to the previously mentioned characteristics (e.g., age, breed, gender) and to consider these characteristics when evaluating the possible causes of values falling outside the reference interval (especially mildly abnormal values). For example, the hematocrit (HCT) reference interval for dogs is usually regarded to be approximately 36–55%. However, it is known that some small breeds, notably the poodle, typically have HCT values in the 50s. A poodle dog with an HCT of 42 may be anemic. Another example is the serum enzyme alkaline phosphatase (ALP). Because bone remodeling is a potential source for this enzyme, serum ALP activity is considerably greater in young growing animals than in adults of the same species. Many such interpretive nuances are developed from experience. Refinement of population subset reference intervals may someday be performed in veterinary medicine, but this will require compilation of a huge database.

Adequate numbers of normal animals must be sampled to develop intervals that are valid for healthy animals from the defined population. In general, the more animals that are sampled, the more likely the reference intervals will truly reflect the range of values to be expected from healthy animals. Sampling large numbers of animals to make the results most reflective of the healthy population is desirable, but practical constraints (e.g., availability of apparently healthy animals, costs of obtaining samples and of performing large numbers of tests) dictate limits on the number of animals that can actually be tested. For best reliability, at least 120 samples should be analyzed when establishing reference intervals. The minimum number of samples to establish a crude reference interval is generally considered to be 40.

Several statistical methods exist for establishing reference intervals. The method of using mean ±2 SD was historically used to define the median 95% of the tested population, but this is only valid if the test results have a normal or Gaussian distribution (Figure 3.1a). This approach is flawed if the test results are not normally distributed (Figure 3.1b).

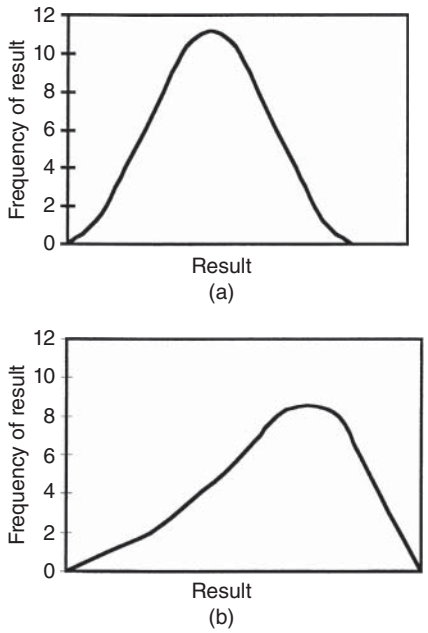

Figure 3.1 Two distributions of values resulting from sampling a large number of apparently healthy animals. (a) Plotted by their frequency of occurrence, these values form a symmetric, bell-shaped curve. This is known as a normal or Gaussian distribution. (b) Plotted by their frequency of occurrence, these values form an asymmetric distribution that is skewed toward the higher values. This is not a normal distribution (a non-Gaussian distribution).

It is now thought that most laboratory test data are not normally distributed. A simple solution is to derive reference intervals using a nonparametric technique. With nonparametric methods, all of the test values are rank ordered, any outliers are removed, and then the middle 95% of test results define the reference interval. As an example, for a population of 120 rank-ordered results, the lowest 3 and highest 3 ($2.5\% \times 120 = 3$) are removed, and the remaining results define the median 95% of the population. A few values from the apparently healthy sample population might be markedly higher or lower than most of the other values. These extreme values are known as outliers and are likely indicative of occult disease. If outliers are included in the sampled values when the intervals are calculated, they will widen the reference intervals, thus making the test less sensitive for the detection of unhealthy animals. One relatively simple rule of thumb for defining an outlier is to calculate the difference between the highest (or lowest) value and the second-highest (or lowest) value. If this difference exceeds one-third of the range of all values, then consider the highest (or lowest) value to be an outlier, and eliminate it when calculating the reference intervals. Once this value has been eliminated, the same test can be applied to the next highest (or lowest) value. For example, Figure 3.2 presents the blood glucose values obtained from a population of 120 apparently healthy animals plotted in

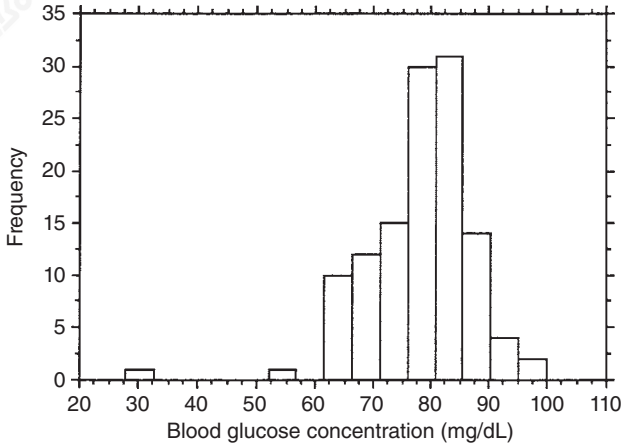

Figure 3.2 Blood glucose values obtained from a population of 120 apparently healthy animals and plotted in a frequency distribution histogram. Frequency represents the total number of samples with that blood glucose concentration.

a frequency distribution histogram. One value (30 mg/dl) is obviously much lower than the others. The difference between this value and the next lowest value is 25 mg/dl, and the range of all values is 70 mg/dl (100–30 mg/dl). Because 25 mg/dl is greater than one-third of the range of all values (70 ÷ 3 = 23.3), the lowest value (30 mg/dl) is eliminated as an outlier. If this value is eliminated, the difference between the remaining lowest value (55 mg/dl) and the next lowest value is then 10 mg/dl. This is less than one-third of the range of all remaining values (45 ÷ 3 = 15) and, therefore, should not be eliminated as an outlier.

An example of establishing a reference interval by the rank order nonparametric method is presented in Table 3.1, which uses the data as presented in Figure 3.2. As noted earlier, one value (30 mg/dl) has been eliminated as an outlier; therefore, the range of the remaining 119 values is 55–100 mg/dl. Identifying and eliminating those values in the lowest 2.5% and in the highest 2.5% then determines the central 95% of these ranked values.

The statistical method just described is applicable when the sampled population includes 40 or more animals. If fewer than 40 animals are sampled, the lower and upper 2.5% of values cannot be reliably determined. In such a case, the reference interval is considered to be the observed range of values that remains after the outliers have been eliminated. Such a reference interval is less reliable than those determined from a larger population.

Limiting reference intervals to 95% rather than 100% of values obtained from healthy animals is an attempt to maximize detection of diseased animals. As defined by reference intervals, approximately 5% of healthy animals will have values considered to be abnormal for any given test.

Table 3.1 An example of nonparametric determination of a reference interval.*

Lowest 10 values and their ranks										
Value	30	55	65	65	65	65	65	65	65	65
Rank	1	2	3	4	5	6	7	8	9	10
Highest 10 values and their ranks										
Value	90	90	90	90	95	95	95	95	100	100
Rank	110	111	112	113	114	115	116	117	118	119
Highest value of the lower 2.5% = 0.025 × (number of values + 1)										
Highest value of the lower 2.5% = 0.025 × (119 + 1) = **3**										
Lowest value of the upper 2.5% = 0.975 × (number of values + 1)										
Lowest value of the upper 2.5% = 0.975 × (119 + 1) = **117**										
Lower values eliminated from reference interval										
Value	30	55	65							
Rank	1	2	3							
Upper values eliminated from reference interval										
Value	95	100	100							
Rank	117	118	119							
Resulting reference interval = 65–95										

[a] Blood glucose concentrations were obtained from 120 apparently healthy animals, and one of these values was eliminated as an outlier (see Figure 3.2). The method involves ranking values from lowest to highest, calculation of ranks representing the highest rank of the lower 2.5% of values and the lowest rank of the upper 2.5% of values, and eliminating values corresponding to these ranks as well as values corresponding to lower and higher ranks, respectively. The remaining values are the central 95% and are used as the reference interval.

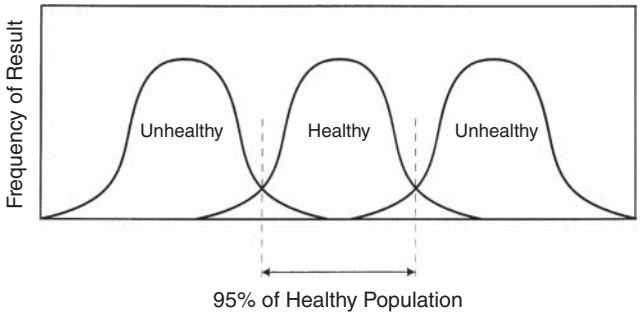

Figure 3.3 The overlap of laboratory values that can be expected from healthy and unhealthy populations (populations with diseases that cause either decreases or increases in the values for a given test). Note that defining the reference interval at 95% of the healthy population excludes the values from some healthy animals, but it also excludes the values from most unhealthy ones (i.e., it allows one to recognize these animals as being potentially unhealthy). If the reference interval were broadened to include more of the potential values from healthy animals, it would also recognize more values from unhealthy animals as being normal (i.e., the unhealthy animal might not be detected). Using a reference interval based on 95% of the healthy population is a compromise that increases the sensitivity of the test for recognizing unhealthy animals while causing only a few healthy animals to be recognized as being potentially unhealthy.

By extension, if many tests are performed on an individual animal (as is common in biochemical profiles), the likelihood of that individual having at least one abnormal test result increases dramatically. For example, in a 20-test biochemical profile, approximately 64% of healthy animals will have at least one abnormal value. It is also possible that animals with disease may have respective laboratory values just within the reference interval. One must recognize the reality that healthy and unhealthy animals overlap at each end of the reference interval (Figure 3.3). Thus, the concept of a black-and-white delineation between normal and abnormal does not exist. The clinician must learn to think probabilistically about laboratory data, particularly for values close to reference limits. Therefore, laboratory values that are close to the reference limits need to be more closely correlated with the patient history, clinical signs, or other laboratory data to assess the likelihood that they represent disease. Test results that are markedly above or below the reference limits, however, are more easily recognized as representing disease.

An adjunct to population reference intervals is the individual health database. Ideally, a laboratory value database is established for young adult companion animals or other animals of value. This data may serve to identify more precisely where that animal's values reside relative to the more broad range of the general species population. For example, a dog has an HCT value of 52% defined in its health database. If sometime later the HCT is measured at 39%, there is a high probability of an underlying disease resulting in anemia, even though the laboratory report may not flag the value as abnormal.

Sensitivity, specificity, and predictive values

When interpreting laboratory abnormalities, the concepts of sensitivity, specificity, and predictive values must be considered. Sensitivity is a measure of the frequency with which the test result will be positive or abnormal in animals with the respective disease process. The following formula is used to determine sensitivity:

$$\text{Sensitivity}(\%) = \frac{\text{TP}}{\text{TP} + \text{FN}} \times 100$$

where TP (true positive) is the total number of animals that tested positive and actually have the disease process, and FN (false negative) is the total number of animals that tested negative but actually have the disease. For instance, if the sensitivity of a test for a disease is 99%, then 99 of 100 animals with that disease will have a positive (i.e., abnormal) result. One percent of the animals with the disease will have a negative (i.e., normal) result; that is, 1% of the tests would have false-negative results. Specificity is a measure of the frequency with which the test result will be negative or normal in animals without the disease one wishes to detect. The following formula is used to determine specificity:

$$\text{Specificity}(\%) = \frac{\text{TN}}{\text{TN} + \text{FP}} \times 100$$

where TN (true negative) is the total number of animals that tested negative and actually do not have the disease, and FP (false positive) is the total number of animals that tested positive but actually do not have the disease. For instance, if the specificity of a test for a disease is 99%, then 99 of 100 nonaffected animals will have negative (i.e., normal) results. One percent of nonaffected animals will have a positive (i.e., abnormal) result; that is, 1% of the tests would have false-positive results.

Sensitivity and specificity are established by applying the test in question to animals with known disease status (i.e., animals known to have or not have the disease in question). Another diagnostic procedure, often termed the "gold standard," is used to establish which animals do or do not have the disease. This gold standard is often another laboratory test known to be reliable for detecting the disease. Sensitivity and specificity, therefore, do not apply directly to animals of unknown disease status, but they do provide information regarding the reliability of the test in question for detecting that disease.

In practice, one needs to know the reliability of a test for detecting a certain disease in animals with unknown disease status. In other words, how reliable is an abnormal or a normal test result for predicting whether the animal does or does not have the disease in question? In this situation, predictive values define the chances that abnormal or normal

test results are reliable indicators of disease status. Predictive values depend on the sensitivity and specificity of a test, but the prevalence or likelihood of the disease in the population being tested affects predictive values as well. Such prevalence or likelihood of disease is established before performing the test, based on the judgment of the veterinarian of the chance (expressed as a percentage) that the animal has the disease in question. This judgment can be based on several other observations, including patient history, clinical signs, other test results, and epidemiologic data. Both positive (i.e., abnormal) and negative (i.e., normal) test results have predictive values. The predictive value of a positive test (positive predictive value) is the probability that a positive (abnormal) test result truly indicates the animal has the disease:

$$\text{Positive Predictive Value} = \frac{\text{TP}}{\text{TP} + \text{FP}} \times 100$$

where TP is the total number of animals that tested positive and actually have the disease, and FP is the total number of animals that tested positive but actually do not have the disease. The higher the predictive value of a positive test, the more likely it is that an animal with a positive (i.e., abnormal) test result actually has the disease in question. Tests with high positive predictive values will produce few false-positive results; thus confidence is high in a positive test result.

The predictive value of a negative test (negative predictive value) is the probability that a negative (normal) test result truly indicates the animal does not have the disease:

$$\text{Negative Predictive value} = \frac{\text{TN}}{\text{TN} + \text{FN}} \times 100$$

where TN is the total number of animals that tested negative and actually do not have the disease, and FN is the total number of animals that tested negative but actually do have the disease. The higher the predictive value of a negative test, the more likely it is that an animal with a negative test result does not have the disease in question. Tests with high negative predictive values will produce few false-negative results; thus confidence is high in a negative test result. As stated previously, predictive values are determined from a combination of the sensitivity and specificity of the test and the veterinarian's pretest judgment regarding the likelihood of the disease in that animal. A rather complex formula to estimate predictive values based on these factors does exist, but the roles of sensitivity, specificity, and disease prevalence or likelihood in the interpretation of diagnostic test results can be understood without it. The roles of these three factors are best understood by considering a hypothetic situation in which an excellent diagnostic test is used to detect a specific disease. The heartworm antigen test is a good example of such a diagnostic for which there is abundant data. This test has a sensitivity of 99% (i.e., it will be positive or abnormal in 99 of 100 animals with the disease) and specificity of 99% (i.e., it will be negative or normal in 99 of 100 animals without the disease). This test has excellent performance when applied in areas with reasonable prevalence of heartworm infection. However, if this test is used for screening a population of animals in which you, as the veterinarian, judge there is a 1% chance of the disease being present, the following predictive values result:

$$\text{Predictive value of a positive test} = 50\%$$

$$\text{Predictive value of a negative test} = 100\%$$

In other words, a positive or abnormal test is correct 50% of the time and incorrect 50% of the time. This is equivalent in reliability to flipping a coin, and it might lead one to question the wisdom of performing such a test in a population with a low likelihood of disease. In this situation, however, a negative or normal test result is almost 100% reliable in ruling out the possibility that an animal has the disease (i.e., the predictive value of a negative test is approximately 100%). This combination of excellent test sensitivity and specificity with low prevalence or likelihood of disease is quite common when using serologic tests to screen for various infectious diseases.

Because most diagnostic tests have an inherent sensitivity and specificity, the most easily altered factor that affects the predictive value is the pretest likelihood of the disease. Veterinarians can use this to enhance the predictive values. For instance, in the previous example, a test with excellent sensitivity and specificity was used to screen for a disease in a population with a low prevalence of that disease. This resulted in a low positive predictive value. If, however, a veterinarian were presented with an animal that had a history, clinical signs, and other features suggesting that disease, such an animal would represent a different population, and the veterinarian would establish a different, higher pretest likelihood for that disease. In such a case, the veterinarian would, perhaps, be 75% certain that the animal had the disease in question. Therefore, the predictive value of a positive test result would be nearly 100%, and the predictive value of a negative test result would be approximately 97%. The test result in this scenario would, in fact, be very reliable for predicting the presence or absence of the disease in question.

In summary, the more likely that an animal has a certain disease before the test is performed, the more reliable a positive or abnormal test result suggesting the presence of that disease will be. The effects of the pretest likelihood of disease on the positive and negative predictive values of a test are demonstrated in Figures 3.4 and 3.5. In practice, most veterinarians incorporate this approach to diagnostic testing instinctively. If the test result is compatible with the disease the veterinarian suspected before conducting the test, this result is considered to be supportive evidence that the

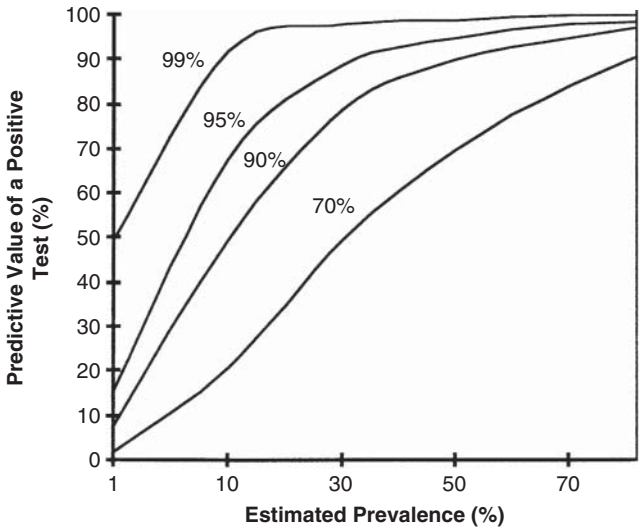

Figure 3.4 The effect of various pretest estimates of disease likelihood on the predictive value of a positive test. Each line represents a different level of sensitivity and specificity (99% = 99% sensitivity and specificity, 95% = 95% sensitivity and specificity, and so on). The predictive value of a positive test decreases as the pretest estimate of disease likelihood decreases.

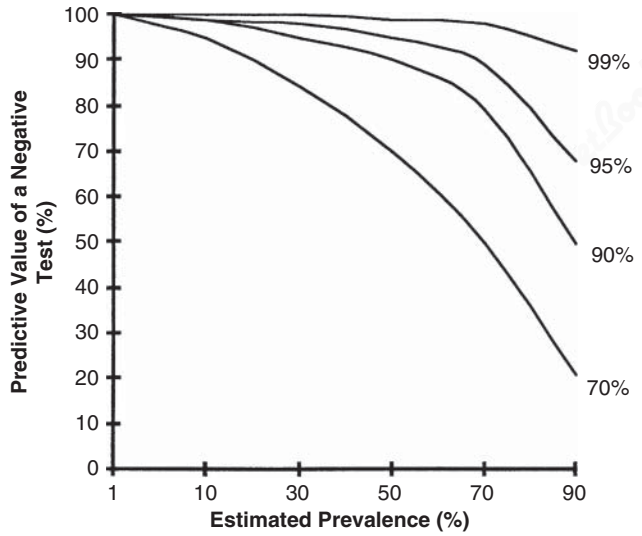

Figure 3.5 The effect of various pretest estimates of disease likelihood on the predictive value of a negative test. Each line represents a different level of sensitivity and specificity (99% = 99% sensitivity and specificity, 95% = 95% sensitivity and specificity, and so on). The predictive value of a negative test increases as the pretest estimate of disease likelihood decreases.

animal has the disease; if the result is not compatible with the suspected disease, the veterinarian does not completely rule out that disease but does begin to consider other options more seriously. Biochemical abnormalities that suggest a disease that was not strongly suspected before the profile was completed will occasionally be detected, and in this situation, these abnormalities are not as reliable in predicting that disease as they would be had the disease been previously suspected.

Most routine clinical pathology tests (i.e., hematology, biochemistry, and urinalysis) have sensitivities and specificities for detecting any given disease that are considerably less than the 99% in the previous example. This makes the pretest likelihood of disease an even more important factor in this type of testing. For instance, both the sensitivity and specificity of the pancreatic enzyme amylase for detecting pancreatitis are quite low. Serum amylase activity is routinely measured on some biochemical profiles. Thus, an increased serum amylase activity on a biochemical screen from a dog in which pancreatitis was not previously suspected would have a very low positive predictive value, because the sensitivity, specificity, and pretest likelihood of pancreatitis are all low. On the other hand, an increased serum amylase activity on a biochemical profile from a dog with clinical signs that suggest pancreatitis would have a much higher positive predictive value. This concept is important to remember whenever unexpected abnormalities are detected on any routine clinical pathology test.

Quality control

To obtain reliable laboratory test results, the quality of the results being produced must be monitored so that they are both accurate and precise. Accuracy is a gauge of how close the result is to the true value for that test, and precision is a gauge of how repeatable the result is when assaying the same sample. A single result might be accurate, for instance, but if a similar result cannot be obtained repeatedly using the same sample (i.e., if the test is not precise), then the results for that assay are not reliable. Conversely, one may obtain the same result repeatedly using the same sample, but if that result does not reflect the true value for the substance being measured (i.e., if the test is not accurate), then the results again are not reliable.

Reputable laboratories maintain quality-control programs to ensure the accuracy and precision of their results. This is accomplished by assaying control samples at previously determined intervals along with the samples from patients. These intervals might be daily or several times per day, depending on the workload of the laboratory. The control samples are similar to those from patients (e.g., blood or serum) and are usually obtained from a commercial source. Control samples can be categorized as either assayed (i.e., the probable accurate value for the test in that control sample has been previously determined) or unassayed (i.e., the probable accurate value for the test in that control sample has not been previously determined). If unassayed control

samples are obtained, the laboratory then establishes the probable accurate value for that sample using methods similar to those summarized earlier for determining reference intervals. Because establishing such probable accurate values is both time-consuming and expensive, most laboratories today use assayed control samples. Only assayed controls are suitable for in-clinic quality control.

During routine laboratory operation, the result from each control sample is compared with what is documented to be the accurate result for that sample. This tests the accuracy of the assay. In addition, results obtained from the control sample over time are analyzed to determine if the value obtained changes over time, thus establishing the precision of the test. Both accuracy and precision usually are assessed by graphing the values obtained from the control sample on a quality-control chart (Figure 3.6). Some instrumentation will have onboard software for automated analysis and management of quality-control data. If the results obtained from the control sample are outside the previously established acceptable range, which is also known as the control limit (usually ±2–3 SD from the mean), or if the results drift either up or down over time, then a problem with the analytic instrument, reagents, or operator may exist. Results obtained from patient samples during these "out-of-control" periods are rejected, and the analytic methods used are carefully reviewed to correct the problem.

Quality-control programs are common in large reference laboratories, but they are also important for in-clinic laboratories. Manufacturers may supply quality-control materials with laboratory instruments. These programs should be followed in detail to have some assurance that the results produced by the in-clinic laboratory are reliable.

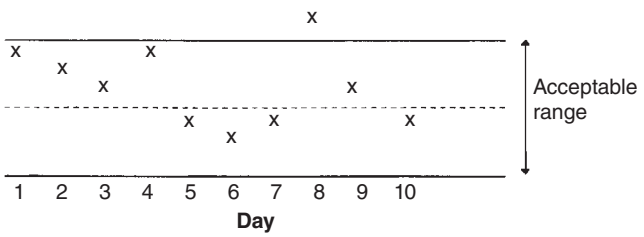

Figure 3.6 An example of a quality-control chart used to monitor the accuracy and precision of a laboratory test. To produce this chart, a control sample was analyzed each day along with the patient samples. Daily results from the control sample are plotted (X). The dashed line (- - -) represents the expected mean value for this sample. Solid lines (—) represent acceptable positive and negative variation from the mean value. Note that the result on Day 8 was outside the acceptable range of variation. This would trigger rejection of the results for the test on that day until completion of an assessment of the instrument, reagents, and operator to identify and correct the problem. The chart indicates problem resolution on Day 9 with acceptable control performance.

Common factors that introduce error in laboratory values

There are a number of factors that can cause laboratory test result errors that may affect interpretation of the patient status. These should be considered whenever a laboratory result(s) is either nonsensical or does not match the patient's condition. These factors can be classified as preanalytical, analytical, and postanalytical errors. Preanalytical errors are the most common and may be introduced by a number of problems related to sample collection and handling. Analytical errors occur at the level of the test methodology and may be due to either an interfering substance or phenomenon within the sample or a problem with the test method performance. The latter is now relatively rare and is typically recognized and prevented with a quality-control program. Postanalytical errors may be due to transcription or other errors related to report generation and distribution. Postanalytical errors are also relatively rare with the current use of automated laboratory information systems and report generation.

Sample handling errors

A number of preanalytical factors may result in laboratory test errors. Improper handling of samples is the most common cause of gross errors in laboratory test values. These are procedural errors that violate handling rules related to sample stability or other processing variables. Some common sample handling errors in veterinary facilities include:

- Sample labeling and transcription errors, leading to data assigned to the wrong patient.
- Use of wrong anticoagulant
- Inappropriate anticoagulant contamination of the sample.
- Improper ratio of anticoagulant to sample.
- Traumatic transfer of blood to tubes causing hemolysis (see below).
- Improper storage conditions during transportation to a laboratory.
- Improper sample storage conditions before analysis.
- Lack of or insufficient mixing of blood for hematology measurements.

There are specific sample handling procedures that must be followed to ensure sample quality, and these may vary depending upon the laboratory test being requested. Central laboratories provide these procedures for proper sample submission. Suppliers of in-clinic diagnostic instrumentation also provide these procedures. Failures related to these procedures occur because the person(s) involved are either not aware of them or are not paying attention to detail. It is the responsibility of the veterinary facility to ensure that the respective procedures be followed exactly to minimize associated errors in laboratory results. The various personnel in the

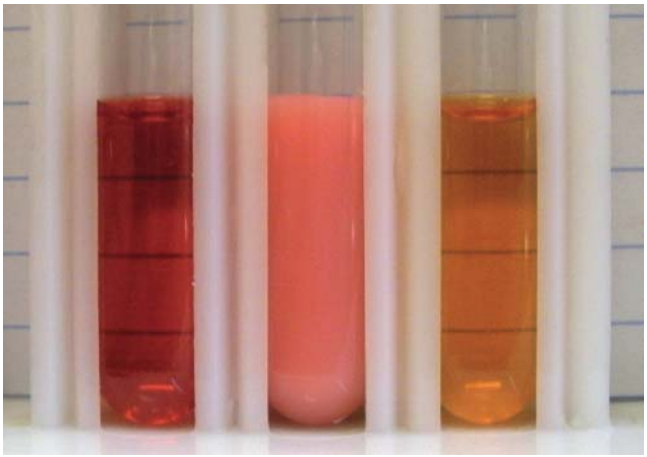

Figure 3.7 Hemolysis, lipemia, and hyperbilirubinemia (left to right) in serum samples. Lipemic serum here is tinged pink as a result of concurrent hemolysis; it may appear white to red-tinged.

veterinary facility often have limited training in laboratory technology. For this reason, it is recommended that facilities designate a lead person or key laboratory operator to educate others about and monitor laboratory-related procedures.

Interfering substances: lipemia, hemolysis, and hyperbilirubinemia

An interfering substance is a common source of analytical error that is present in the sample. Hemolysis, lipemia, and increased serum bilirubin (Figure 3.7) can potentially affect the results of biochemical assays. Hemolysis refers to the lysis of erythrocytes and liberation of hemoglobin and may occur either in the circulating blood (*in vivo*) or during or after blood collection (*in vitro*). Hemolysis in the sample is usually due to improper sample collection or handling. Hemolysis may interfere with assay results by color interference with spectrophotometric assays. Less commonly, hemolysis may cause a false increase in analyte being measured as a result of marked differential concentrations or enzyme activities between serum and erythrocytes. For instance, horses and cattle have high concentrations of potassium within erythrocytes, whereas dogs (with some exceptions) and cats do not. Therefore, marked hemolysis may result in a falsely increased serum potassium concentration in horses and cattle, but not in most dogs or in cats.

Lipemia causes visible turbidity of the serum, often making it opaque to transmitted light. It is expected to occur in small animals when they have not been fasted before blood collection. It may also occur in hyperlipidemic syndromes. This interference with light transmission can interfere with spectrophotometric assays, particularly in liquid or cuvette chemistry systems. It can also result in apparent dilution of normal substances (e.g., electrolytes) in the aqueous component of serum, resulting in falsely decreased concentrations (ion exclusion effect).

Increased serum bilirubin concentrations result in a serum with a darker-yellow color than normal for that species. This increased color can interfere with the results of spectrophotometric assays.

The potential alterations in biochemistry results caused by hemolysis, lipemia, and hyperbilirubinemia vary with the substance being assayed and with the method being used for the assay itself. Reference laboratories usually can provide specific information regarding the effects of hemolysis, lipemia, or hyperbilirubinemia on test results. Likewise, manufacturers may provide this information for in-house diagnostic laboratory instrumentation.

It is also conceivable that drugs and other chemicals may alter laboratory test reactions. Known interferents are typically outlined in reagent application sheets. This information is usually available from the laboratory or in the form of technical briefs from diagnostics suppliers.

Approach to interpreting laboratory data

Comments on general approach

It is important to appreciate that individual diagnostic test results are rarely interpretable into a clinical diagnosis. Abnormal test results typically indicate a relatively nonspecific pathologic process. Grouping of several abnormal results may improve the specificity of the process or processes. It is usually only after integration of history, physical findings, and other diagnostic procedures with laboratory data abnormalities that a more defined clinical diagnosis is achieved. Most laboratory abnormalities have multiple potential causes, and the history and physical examination results should be used to determine which of these potential causes is most likely. Using a combination of history, physical examination results, and the pattern of laboratory abnormalities, the veterinarian should attempt to summarize the likely operative pathologic processes present. This summary can often be translated into a working clinical diagnosis or diagnoses. Patterns of abnormal test results often suggest which tissue or organ systems are affected, which pathologic processes are occurring, or both. For example, a combination of an increased concentration of blood urea nitrogen (BUN; a test of kidney function) with a urine specific gravity indicative of inadequate urine concentration is very suggestive of renal failure, whereas an increased BUN with concentrated urine (high specific gravity) is more suggestive of conditions such as dehydration or shock.

Of course, not every abnormality will fit neatly into one disease process, nor will every laboratory profile result in a specific diagnosis. In some cases, more than one disease process may be occurring, thereby producing a confusing combination of abnormalities. These are considered difficult cases that may require analysis over time to unravel and

may benefit from consultation or second opinion interaction with associates.

Analysis of sequential changes in laboratory values over time is sometimes helpful in establishing a diagnosis and is important for monitoring progress of the disease or case management. For instance, periodic determinations of BUN in an animal with renal failure may indicate whether treatment to reestablish renal function is succeeding (i.e., BUN should be decreasing) or not. Negative findings in the form of normal test results also have value. These can rule out tentative differential diagnoses that were considered on the basis of history or physical examination findings.

Expectations and skilled diagnostics interpretation

Behind the scenes of the general approach described above, there are a number of nuances that may be described as expectations related to diagnostics. Sometimes clinicians are handicapped by unrealistic expectations for laboratory data. The discussion here is aimed at clarifying some of the more common expectations to aid the clinician-in-training to be more adept at data interpretation. Important considerations include the following:

- How measurement reproducibility affects data interpretation.
- Magnitude of change associated with disease(s).
- Relationships or interdependency between diagnostic tests.
- Reference intervals and the elusive determination of what is normal vs. abnormal.
- Laboratory test results that are inconsistent with preconceived notions.

Measurement reproducibility

This is discussed first because it influences other expectations and is important for interpretation of sequential laboratory data. A common misconception is that the numbers on a laboratory report are definitive numbers. The reality is that if an individual test is repeated multiple times on the same sample by the same method in the same laboratory, a range of results will be obtained. If results are produced by two different laboratory methods, even more variation may be encountered. Actual reproducibility will vary, but some guidelines for satisfactory analytical performance for a single method are:

- Most hematology results – ± 10% of value.
- Platelets – ± 20% of value.
- Most clinical chemistry results – ± 10% of value.
- Enzyme activities in clinical chemistry – ± 15% of value.

When comparing results between laboratories or methods, even greater variation should be expected.

A practical understanding of the expected reproducibility results in the following interpretive guidelines:

- Data must be interpreted with some latitude, especially when test results are near reference limits. This is discussed further under "Interpreting Normal Versus Abnormal."
- When two different laboratories or methods generate results for the same sample, relatively large differences in "numbers" may occur, but usually the interpretation of those numbers is the same. This often occurs when comparing in-house results with commercial laboratory results.
- When a new sample is analyzed to evaluate patient change, only relatively large change should be interpreted as conclusive change in the patient.

Magnitude of change associated with disease

Considerable experience is required to understand the relationship between the *magnitude* of a given laboratory test abnormality and the *severity* of the associated disease condition. It is not practical to communicate detailed guidelines for all laboratory tests in this chapter. Small numerical changes or abnormalities indicate important or severe disease for some laboratory tests. Examples might include pH, potassium (K^+), creatinine, calcium, phosphorus, albumin, and endocrine assays. For most other laboratory tests, it takes a considerably larger numerical change or abnormality to indicate important or severe disease. Examples include enzyme activities, BUN, glucose, and most hematologic measurements.

The desired interpretive experience comes from repeated analysis of clinical case material. A starting point for veterinarians-in-training includes case discussions in various classes. This is narrated to some degree in various chapters in this textbook, and case presentations at the end of this textbook provide some representative examples. This knowledge is then expanded upon with the clinical cases encountered during the first several years of practice.

Relationships between diagnostic tests

Laboratory tests are more meaningful when interpreted in groupings that are interrelated with respect to pathophysiology. For example, a moderately abnormal increased BUN interpreted in isolation may define the relatively nonspecific process of decreased glomerular filtration rate. However, when grouped with hematocrit, total protein, creatinine, phosphorus, and urinalysis findings, the integrated interpretation is likely to be much more specific as to the probable cause of decreased glomerular filtration rate. In addition, the other values may corroborate each other when there is a question about the validity of a given value. Ideally, laboratory reports are organized in a way to provide some initial grouping that facilitates this relationship in interpretation. This is often organized by organ system, realizing that some analytes may have secondary relationships with more than one organ system. However, chemistry, hematology, and urinalysis reports are almost always segregated. The user must learn how to cross-interpret sections of the report to

Table 3.2 Grouping of laboratory tests for interpretation. Hematology is interpreted separately, but abnormalities may be referable to chemical abnormalities in the groups below.

Kidney	Liver	Metabolic	Specialty
BUN	Bilirubin	Glucose	CK
Creatinine	ALT	Calcium	Amylase
Phosphorus	AST	Total protein	Lipase
Urinalysis:	ALP	Albumin	Endocrine tests
Specific gravity	GGT	Cholesterol	Immunoassays
Chemistry	Bile acids	Sodium	Other special tests
Microscopic		Chloride	
		Potassium	
		pH	
		HCO_3	
		pO_2 (arterial)	

BUN, blood urea nitrogen; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase; GGT, gamma glutamyltransferase; CK, creatine kinase.

achieve all of the useful groupings. Table 3.2 shows one method of grouping laboratory tests that achieves most of the primary relationships for integrated interpretation. This is a place to start, realizing that secondary relationships will become more apparent with experience.

Interpreting normal versus abnormal

As discussed in the section "Reference Interval Background," laboratory data is often not conclusively interpretable as normal or abnormal, particularly when values are near the limits of the reference interval. Laboratory reports may contain flags, usually H for high or L for low. This flagging conditions the user to think too strictly about normal versus abnormal. Clinicians should be encouraged to interpret borderline and mildly abnormal values more loosely, in a probabilistic manner. When a laboratory test result is suspiciously abnormal, look for corroboration in other findings. Also factor in possible age and known breed considerations for suspect values.

Laboratory test results that are inconsistent with preconceived notions

Occasionally the clinician is surprised by an unexpected lab test value that is moderately or markedly abnormal. A common first reaction is to not believe the result is possible. A more appropriate reaction is to reanalyze the clinical situation. One should look for other laboratory values or undetected clinical abnormalities that may corroborate the value(s) in question. The history and physical should be reevaluated for findings that may corroborate the abnormal value; additional questions may need to be asked of the owner. Next, the possibility of a sample or sample handling error should be considered. Last, if no corroboration or errors can be found, it may be appropriate to repeat the test in question.

Summary of interpretive considerations

When interpreting laboratory data in conjunction with all other clinical and physical findings, remain aware of the following interpretive factors. With practice, these become habit of the astute clinician:

- Interpret laboratory values in related groups, organized by organ system.
- Interpret laboratory values probabilistically for abnormality, particularly when values are borderline with respect to the reference interval limits.
- Develop a sense of the expected magnitude of change in a value that is associated with important disease.
- Consider that analytical reproducibility is such that only relatively large changes in sequential values are indicative of true change.
- When laboratory values initially do not seemingly fit the clinical condition(s), evaluate for corroborating laboratory and clinical data.
- Train staff to prevent improper sample handling and interfering substances that may lead to erroneous laboratory data. Consider these possibilities when laboratory data is seemingly nonsensical.

Perspective on use of cytopathology

Pattern recognition is often portrayed in classrooms and textbooks as "easy." This is done using optimally prepared samples and then selecting images that are most representative of a specific diagnosis or interpretation. It is not so easy given the complexity of diagnostic expectations in place today. As a result, maximizing diagnostic yield usually requires the experience of an accomplished clinical pathologist.

By way of historical background, the teaching of diagnostic cytology for use in the veterinary practice setting was started by limited application to superficial swellings or growth lesions. Cytology was largely a screening procedure to determine if the process was inflammatory or neoplastic. If inflammation such as an abscess was ruled out, biopsy with histology was utilized for diagnosis. Body cavity effusions were relatively easy to evaluate. The practice progressed to evaluation of superficial enlarged lymph nodes and round cell tumors. Histology was utilized if the aspirate findings were difficult to interpret. This limited spectrum of processes was taught in veterinary school as easy to do by the general practitioner.

The evolution of cytology over the last 30 years has resulted in a marked increase in interpretive complexity. Examples contributing to this outlook include:

- Lesions such as lymphadenopathy and other swellings are recognized and sampled earlier in the disease progression.

- The degree of variation in morphologic manifestations in common cytological lesions has grown with accumulated years of practice experience.
- Both earlier sampling and degree of variation in morphology have necessitated special staining or molecular procedures to clarify diagnosis.
- Almost all organs and internal growth abnormalities are now sampled.
- In the cultural shift to minimize invasive procedures, expectations are that cytology provide as much definitive information as possible.

These changes in the practice of cytopathology have made interpretive complexity a specialty considerably beyond the ability of the general practitioner. The specialty has grown to be the predominant activity of clinical pathologists certified by the American College of Veterinary Pathologists. However, this evolution has not sufficiently influenced how cytopathology is taught in veterinary schools. There is still a trend to teach that general practitioners can be proficient in cytopathology, utilizing the traditional textbook samples in teaching laboratories. Most graduates independently discover that submission of samples to a diagnostic laboratory is best practice for cytopathology. This realization is perhaps counter to what is learned in clinical pathology courses.

A perspective offered for veterinary education would be to change the emphasis in clinical microscopy education. Important emphases offered are:

- Examine example case material in the classroom and teaching laboratory (slides) with emphasis on types of disease processes in which cytology best contributes to case management. De-emphasize the expectation that general practitioners can master cytology without a special interest in developing the expertise.
- Most important is how to prepare slides with minimal artifact. See Chapter 2.
- Examine at least one slide to make sure cells other than blood are present. Avoid nondiagnostic sample submissions that are acellular.
- Visualize what pathologists do in clinical microscopy in order to optimize future interaction with pathologists on case material.
- Prepare a good history along with submission of unstained slides to a diagnostic laboratory with a veterinary clinical pathologist. Experience how clinical history, or lack of, influences interpretation of cytopathology.
- Understand the diagnostic capability differences between cytology and histopathology in case management. These are highlighted in Chapter 40.

Comments on some current trends

In recent years, there has been a marked increase in fine needle aspiration of abdominal organs. The cultural shift toward less invasive procedures has been a major driver. Advances in radiographic and ultrasonographic capabilities coupled with the trend to use cytologic sampling of overt and suspicious imaging abnormalities has moved to the forefront of practice and subordinated exploratory laparotomy and thoracotomy. This has been challenging for pathologists. This is because there may be a gap in clinician expectations for diagnostic yield of body cavity organ cytology and what is feasibly deliverable. Certain practices that are now very common have questionable return on investment. Some of the more common samples received by laboratories are splenic and liver aspirates. Some examples of cytologic procedures that would benefit by qualification include the following.

Liver aspirates. The history accompanying many liver aspirate samples is limited to "increased liver enzymes." Without extensive further study, we propose this clinical finding in isolation is not an indication for liver aspiration. Almost always the cytologic findings are not specific and shed no light on why there are increased liver enzymes. Our experience is that liver aspirates are most helpful in documentation of either hepatic infiltrative disease or the suspicion that a mass is tissue that does not belong in normal liver. These examinations are prompted by other collective clinical findings suggestive of infiltrative disease or a definitive mass. Increased liver enzymes may be associated with those other more compelling clinical findings indicating cytologic sampling.

Splenic aspirates. The best part about retirement is no more splenic aspirates. Aspirates are often performed with the history that a nodule or suspicious echogenicity pattern was found on a routine abdominal ultrasound examination. Most adult to aged dogs may have incidental splenic nodular hyperplasia. These almost always yield cytologic findings consistent with nodular hyperplasia, or extramedullary hematopoisis, or no abnormalities because the sample consists of only blood. The above should not be an indication for splenic aspirate unless there is other clinical suspicion of more important splenic involvement of an infiltrative disease.

Another misconception is that splenic aspirates will confirm diagnosis of splenic hemangiosarcoma. The typical hemangiosarcoma is composed of mostly vascular sinus space. Aspiration yields only blood. It is uncommon for the aspirate to yield confirmatory sarcoma cells. The diagnosis is often suggested based mostly on signalment, presence of a splenic mass, history of hemoabdomen, and possibly the presence of a rare mesenchymal cell. All findings other than the rare cell make the diagnosis more likely.

In summary, the best indication for splenic aspirate is the presence of generalized splenomegaly in conjunction with suspicion of infiltrative disease such as lymphoma, myeloproliferative disease, mastocytosis, or malignant histiocytosis.

Diagnosis of specific organ neoplasia. Textbooks specializing in cytology may show cytologic examples of specific organ neoplasia. An example might be pancreatic carcinoma. This

may lead the clinician to believe that aspiration of a mass in the region of the pancreas can yield a specific diagnosis of pancreatic carcinoma. However, at best the cytology showed features of neoplasia. The textbook discussion indicates the lesion was confirmed by architecture seen by histopathology. The location is the better suggestion of pancreatic specificity than the cytologic findings. For most organ neoplasms, cytology suggests the presence of neoplasia based on general features of neoplasia. Then, location, location, location is often highly utilized in cytologic interpretation to suggest tissue of origin specificity. See Chapter 40 for additional perspective.

CHAPTER 4

4 Immunodiagnostics: Current Use and Future Trends in Veterinary Medicine

Wayne A. Jensen
Colorado State University, Fort Collins, CO, USA

Introduction

Immunodiagnostics are tests that use antibody–antigen binding to generate a measurable result that assists in the diagnosis of disease. As such, immunodiagnostics are also "immunoassays" (although the reverse is not always true). Antibodies are plasma glycoproteins, called gamma globulins or immunoglobulins (Ig), generated in response to exposure of the immune system to an antigen. Simply defined, an antigen is any substance that stimulates the immune system to produce antibodies. Antigens are usually proteins or polysaccharides. Immunodiagnostics were initially used in the diagnosis of infectious diseases, either indirectly by detection of antibody or directly by detection of antigen. Detection of antibody indicates previous exposure and not necessarily the active presence of the antigen.

Immunodiagnostics take advantage of the specific binding of an antibody to its antigen. An epitope is the portion of an antigen bound by an antibody. Binding between an antibody and its epitope is dependent on noncovalent interactions including ionic interactions, hydrogen bonds, and hydrophobic interactions. The strength of the interaction between a single antigen-binding site on the antibody and its epitope is called its affinity. Most antigens (e.g., viral capsid proteins) have multiple epitopes. Epitopes to which the greatest amount of antibody is produced are called immunodominant epitopes.

Immunodiagnostics are capable of detecting the presence (qualitative tests) or amount (quantitative tests) of an analyte (either antibody or antigen) present in the sample at concentrations below what can be accurately determined by other routine testing methodologies. Detection is usually accomplished by "labeling" either antigen or antibody and then using the labeled reagent to probe samples for the presence of antibody or antigen, respectively. Common labels used in immunoassays include enzymes (e.g., horseradish peroxidase, alkaline phosphatase, glucose oxidase, luciferase), fluorochromes (e.g., fluorescein, phycoerythrin), radioisotopes (e.g., I-125), or microparticles (e.g., colloidal gold, latex beads). For quantitative results, the signal measured from the sample is compared to the signal obtained from standards containing known concentrations of the analyte.

In addition to detection of antibodies or antigens associated with infectious disease, immunodiagnostic tests are also used for measurement of many other analytes including drugs, hormones, tumor markers, and markers of cardiac injury. In the case of drugs and hormones, the analytes measured are frequently haptens. A hapten can only elicit production of antibodies when combined with an antigenic carrier molecule. However, once formed, haptens can react with antibodies in the absence of association with the carrier.

Antibody structure

Antibodies or immunoglobulins are proteins produced by differentiated B lymphocytes. There are five classes of antibodies, namely, immunoglobulin A (IgA), immunoglobulin D (IgD), immunoglobulin E (IgE), immunoglobulin G (IgG), and immunoglobulin M (IgM). Each antibody consists of four polypeptides – two heavy chains and two light chains held together by interchain disulfide bonds to form a "Y"-shaped molecule (Figure 4.1). The IgD, IgE, and IgG antibody classes are found as a single structural unit, whereas IgA antibodies may contain either one or two units, and IgM antibodies consist of five disulfide-linked units (Figure 4.2).

Intrachain disulfide bonds support structural "domains" of approximately 110 amino acid residues in length each. Heavy chains are composed of either three (IgA, IgD, IgE) or four (IgE, IgM) constant domains and a single amino-terminal variable domain. The constant domains of the heavy chain define the class of each antibody and are responsible for the biological activity of the antibody. Light chains are composed

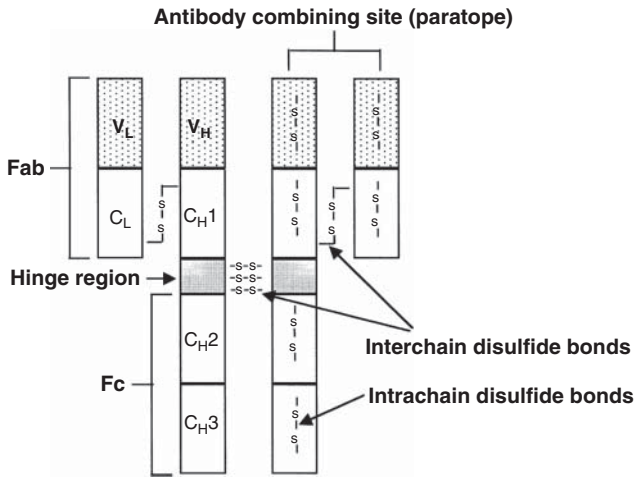

Figure 4.1 Schematic of an antibody molecule illustrating the heavy (H) and light (L) chains held together by interchain disulfide bonds. Intrachain disulfide bonds create structural "domains," each approximately 110 amino acid residues in length. The variable (V) domains of the heavy and light chains form the antigen binding site. The constant (C) domains define the class of the heavy (A, D, E, G, and M) and light (kappa or lambda) chains. Fab fragments contain the entire light chain and the variable and amino-terminal most constant domain of the heavy chain. Fc fragments contain the remaining constant domains of the heavy chain.

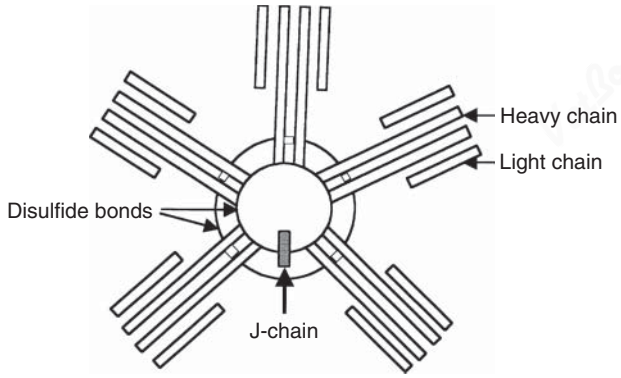

Figure 4.2 Schematic of IgM illustrating its pentameric structure, interchain disulfide bonds, and the J-chain.

of a single constant domain and a single amino-terminal variable domain. The constant domain of the light chain defines the type of light chain as either kappa or lambda. The combined variable regions of the heavy and light chains form the antigen binding site and are responsible for the specificity of antibody–antigen interaction. The presence of two heavy and two light chains results in two antigen binding sites for each antibody molecule (Figure 4.1).

Historically, proteolytic enzymes (proteases) have been used to cleave antibody molecules into functional fragments. Antibody molecules are cleaved into three fragments by limited digestion with the protease papain. Two of the fragments are identical and represent the two "arms" of the "Y." These fragments contain the antigen-binding activity and are termed Fab fragments (Fragment antigen binding). Fab fragments contain a complete light chain and the variable and amino-terminal most constant domain of the heavy chain (Figure 4.1).

The third fragment obtained from digestion with papain contains the remaining constant domains of the heavy chains and does not bind antigen. This fragment is referred to as the Fc fragment (Figure 4.1) because it was found to be readily "crystallizable." The Fc fragment is the part of the antibody molecule that interacts with effector molecules and cells. An example of this is the interaction of IgE with the FcERI receptor on mast cells. Relative to immunodiagnostics, Fc fragments are used to raise species- and class-specific antibodies for the detection of antibody responses to many infectious diseases. For example, anti-cat IgM and anti-cat IgG are used to differentially detect an IgM versus IgG immune response, respectively, which has been reported to be useful in the diagnosis of acute *Toxoplasma gondii* infection in clinically ill cats [1].

Another protease, pepsin, cleaves on the carboxy-terminal side of the disulfide bonds, generating a fragment, referred to as the $F(ab')_2$ fragment, that contains both "arms" of the "Y" (Figure 4.1). Pepsin cleaves the remaining portion of the heavy chain into several smaller fragments. Because the $F(ab')_2$ fragment contains both antigen-binding sites, it has the same antigen–cross-linking capabilities as the original antibody molecule. $F(ab')_2$ fragments are occasionally used in diagnostic assays because they maintain the specificity of the original antibody but lack the Fc fragment, which is sometimes associated with nonspecific binding.

Generation of antibodies used in immunoassays

Immunodiagnostics use antibodies to detect both antigens (e.g., proteins from infectious agents) and antibodies generated in response to foreign proteins. Antibodies used as reagents in immunodiagnostic tests can be either polyclonal or monoclonal. Antibodies are named by the species from which they were obtained and the antigen to which they were produced. For example, rabbit anti-canine γ chain is rabbit antibody specific for γ chain of dog IgG. Unless otherwise specified, antibodies are assumed to be polyclonal.

Polyclonal antibodies

Polyclonal antibodies are generated via hyperimmunization of an animal (e.g., rabbit, sheep, goat) with the antigen of interest. The animal's immune response to the antigen produces antiserum, a heterogeneous mixture of antibodies. Polyclonal antibodies therefore represent a mixture of antibodies derived from many different B lymphocyte clones, each with a unique B cell receptor and each capable

of binding the antigen. As a result, within each pool of polyclonal antibodies will be antibodies that bind to the numerous epitopes present on the antigen. Some of these antibodies will bind to their respective epitope with high affinity and some will have lower affinities.

Monoclonal antibodies

In 1975, Georges Köhler and César Milstein [2] demonstrated that fusion of antibody-producing B cells with myeloma cells that had lost their ability to secrete antibodies resulted in an immortal cell line or "hybridoma" that secreted a single monospecific antibody. In the fused hybridoma cell, the B cell supplies the ability to secrete a specific antibody, and the myeloma cell gives it immortality. The generation and use of monoclonal antibodies has been an important tool in research and medicine (in 1984, Köhler and Milstein received the Nobel Prize in Physiology or Medicine for their discovery of monoclonal antibodies).

Monoclonal antibodies are typically made using polyethylene glycol to fuse myeloma cells with spleen cells from a mouse that has been immunized with the antigen of interest. The success rate of fusion is low, so a selective medium is used that only allows the growth of hybridoma cells. After fusion, the mixture of cells is diluted and aliquoted into 96-well microtiter plates so that only approximately one-third of the wells will contain cells. This increases the chance that each resultant "clone" of cells was generated from a single parent cell.

Cell culture supernatants are then tested for the presence of antibody with the ability to bind to the antigen of interest (usually the same antigen that was used for immunization of the B cell donor mouse). Immunodiagnostic assays used for the screening process are typically high-throughput assays (e.g., ELISA or immunodot blot) to allow for the screening of hundreds of hybridoma clones. The subcloning process is repeated at least three times to ensure that the final clone was generated from a single parent cell. The most productive and stable clone (some hybridomas lose the ability to produce antibody over time) is then grown in culture medium to a high volume for large-scale production of monoclonal antibody.

Immunoassay formats

Immunoassays can be either competitive or noncompetitive. In competitive immunoassays, the analyte (antigen or antibody) in the sample competes with labeled antigen or antibody, and the signal generated is inversely proportional to the concentration of analyte in the sample (Figures 4.3 and 4.4). In noncompetitive immunoassays, the amount of analyte (antigen or antibody) in the sample is directly proportional to the signal generated (Figure 4.5).

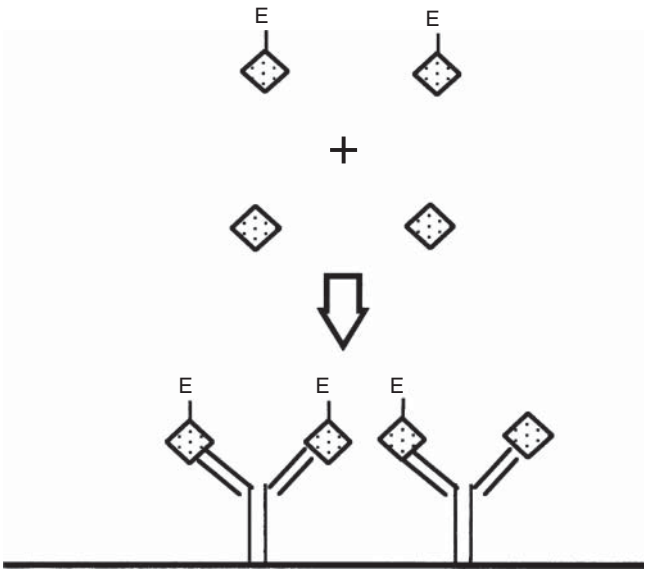

Figure 4.3 Illustration of a competitive immunoassay for the detection of antigen. In this example, antigen in the patient's sample competes with enzyme-labeled antigen for antibody bound to a solid phase. After a wash step to remove unbound enzyme-labeled antigen, addition of chromogenic substrate results in a color change that is inversely proportional to the quantity of antigen in the patient's sample.

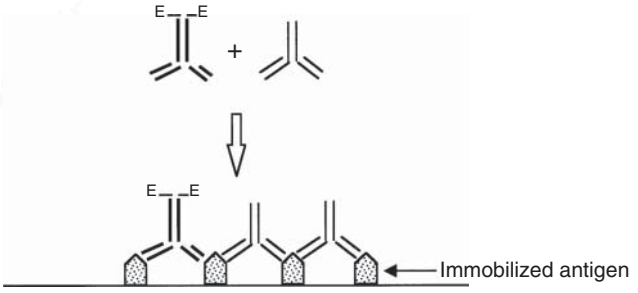

Figure 4.4 Illustration of a competitive immunoassay for the detection of antibody. In this example, antibody in the patient's sample competes with enzyme-labeled antibody for antigen bound to a solid phase. After a wash step to remove unbound enzyme-labeled antibody, addition of chromogenic substrate results in a color change that is inversely proportional to the quantity of antibody in the patient's sample.

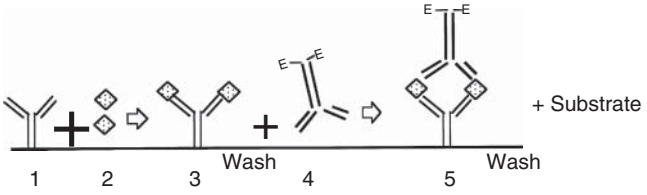

Figure 4.5 Illustration of a noncompetitive immunoassay for the detection of antigen. In this example, antigen in the sample is captured by antibody bound to a solid phase. After a wash step, enzyme-labeled antigen-specific antibody binds to the captured antigen. After another wash to remove unbound enzyme-labeled antibody, addition of chromogenic substrate results in a color change that is proportional to the quantity of antigen in the patient's sample.

Immunodiagnostic assays can also be either homogeneous or heterogeneous. Homogeneous immunoassays are performed simply by mixing the sample with reagents and measuring the signal generated (or a decrease in signal for competitive immunoassays) by the reaction chemistry that results from antigen–antibody binding. As such, homogeneous immunoassays do not require the separation of bound antigen–antibody from free antigen (or antibody). For this reason, homogeneous immunoassays tend to be easier and faster to perform; however, they are generally less sensitive. An example of a homogeneous immunoassay is the detection of antigen–antibody complex formation by measuring the resultant decrease in light transmission through the sample (turbidimetry); see Chapter 2.

Newer homogeneous immunoassay technologies utilize enzyme donor and enzyme acceptor pairs that readily associate to generate active enzyme. In these assays, antibody binding to an antigenic epitope or hapten incorporated into either the enzyme donor or acceptor subunit blocks the association (and, therefore, activity) of the enzyme. Analyte present in the sample binds the antibody and prevents it from binding to the enzyme subunit, thereby allowing the formation of active enzyme. As such, these assays are considered to be competitive immunoassays because the analyte–antibody binding reaction competes with the binding of antibody to the hapten-conjugated enzyme. Another example of a newer competitive homogeneous immunoassay technology utilizes fluorescence energy transfer where a "fluorescer" is conjugated to the hapten and the "quencher" is conjugated to the antibody. In the absence of analyte in the sample, the quencher-conjugated antibody binds the hapten-conjugated fluorescer and extinguishes the signal. In the presence of analyte in the sample, a portion of the quencher-conjugated antibodies bind the analyte and are therefore no longer available to bind the hapten-conjugated fluorescer and quench the fluorescence signal.

Unlike homogeneous immunoassays, heterogeneous immunoassays require the separation of antigen–antibody complexes from unbound antigen (or antibody) because the label is not affected by the antigen–antibody binding event. Using enzyme immunoassays (EIAs) as an example, unbound enzyme-conjugated reagent must be physically removed from bound enzyme-conjugated reagent prior to the addition of the enzyme substrate. This removal step is usually accomplished by "washing." Another characteristic of heterogeneous immunoassays is the requirement for unconjugated reagent to be fixed to a solid phase (Figures 4.3–4.5) to allow for removal of unbound enzyme-conjugated reagent without removal of the bound enzyme-conjugated reagent. Examples of solid phases commonly used in immunoassays include microtiter wells, nitrocellulose, and latex or magnetic beads.

Similar to homogeneous immunoassays, heterogeneous immunoassays can also be formatted as either competitive or noncompetitive assays. With competitive assay formats, the presence of analyte in the sample decreases the amount of signal generated. Common competitive immunoassay formats include:

1. Antigen in the sample competing with free labeled antigen for a limited quantity of bound unlabeled antibody (Figure 4.3).

2. Antigen in the sample competing with bound unlabeled antigen for a limited quantity of free labeled antibody.

In both of these formats, the binding of antigen in the sample to antibody (either bound or free) blocks binding of the labeled reagent to the solid phase and thus allows the removal of the labeled reagent in the subsequent wash step. Sensitivity can be improved in the first competitive immunoassay format by adding the sample to the bound unlabeled antibody prior to addition of the labeled antigen. Similarly, sensitivity can be improved in the second competitive assay format by adding the sample to the free labeled antibody prior to incubation with the bound unlabeled antigen.

In contrast to competitive immunoassays, noncompetitive immunoassays rely on direct measurement of antibody binding sites occupied by analyte. Another difference between competitive and noncompetitive immunoassays is in the relative concentration of reagents. As mentioned previously, competitive assays require limiting the quantities of antigen, antibody, or both. In contrast, reagents are applied in excess for noncompetitive heterogeneous immunoassays to maximize sensitivity.

A common noncompetitive heterogeneous immunoassay format for antigen is the capture or sandwich immunoassay (Figure 4.5). In this format, bound antibody (either polyclonal or monoclonal) specific for the antigen of interest is incubated with sample, washed, then incubated with another labeled antibody (either polyclonal or monoclonal) specific for the antigen of interest. Antigen present in the sample is "captured" (i.e. sandwiched) between the bound antibody and the labeled antibody with the amount of signal generated dependent on the amount of antigen in the sample. Examples of an antigen capture immunoassay frequently utilized in veterinary clinics are heartworm antigen tests manufactured by Heska (Solo Step® CH), IDEXX Laboratories (SNAP® RT and 4Dx), Zoetis (Vetscan® and Witness®), and others [3]. Noncompetitive immunoassay formats for the detection of antibody frequently use bound antigen to "capture" specific antibody and anti-Fc labeled antibodies for detection of captured antibody.

Factors influencing immunoassay design

Considerations in the selection of an immunoassay format include analyte characteristics and concentration, desired

endpoint (qualitative or quantitative), and the environment in which the test will be used.

Analyte characteristics and concentration

Small nonprotein analytes and haptens (e.g., thyroxine) are not readily detected in noncompetitive immunoassays due to the inability to "sandwich" the analyte because of a lack of a sufficient number of binding sites (epitopes). These analytes are best measured in heterogeneous competitive immunoassay or homogeneous immunoassay formats. Homogeneous immunoassay formats are most appropriate for antigens or haptens whose concentrations are relatively high (nmol/L) (e.g., total serum thyroxine), whereas heterogeneous competitive immunoassay formats are capable of detection limits in the picomolar range (e.g., free serum thyroxine). Noncompetitive heterogeneous assays in which reagents are applied in excess are capable of detection limits approaching 1 fmol/L [4].

Desired endpoint

All immunoassay formats can be used to report a qualitative result simply by identifying an assay "cutoff" (usually arbitrarily determined as three standard deviations above the mean of the negative controls) and reporting results as either positive or negative. Visual read test results are usually qualitative, but some test formats allow for semiquantitative results without the need for instrumentation by comparing the intensity of the signal generated from the patient's sample to an internal reference (e.g., IDEXX SNAP tests for equine IgG, canine and feline pancreatic lipase, and feline pro-brain natriuetic peptide) [5]. Most immunoassay formats can also be used to report quantitative results as long as the signal recognition technology is capable of detecting differences in signal magnitudes. Quantitative results usually require the use of calibrators containing known concentrations of analyte to establish a standard curve from which the sample analyte concentration is determined.

Environment

The environment in which the immunoassay is performed has important implications for format selection. As discussed previously, homogeneous immunoassays tend to be easier to perform because there are no washing steps involved. For this reason, homogeneous immunoassay formats are well suited for automation on high-throughput clinical analyzers. Due to the requirement for washing between reagents, heterogeneous immunoassays tend to require greater technical skill of the operator. Quantitative immunoassays (both homogeneous and heterogeneous) have historically required sophisticated equipment (e.g., spectrophotometer, spectrofluorometer, luminometer) for detection and quantitation of generated signals and are, therefore, usually performed in centralized laboratories.

Simple-to-use qualitative heterogeneous immunoassays have been available for use in veterinary practice for many years. These single-use, "in-clinic" tests (sometimes referred to as "point-of-care tests" or POCTs) either have built-in wash buffer that is manually activated (e.g., IDEXX SNAP), require the addition of wash buffer after application of sample (e.g., Zoetis VetScan and Witness), or do not require wash buffer (Heska Solo Step). The IDEXX SNAP tests are sandwich ELISA formatted tests for the detection of either antigen or antibody. The Zoetis VetScan and Witness tests and the Heska Solo Step test are lateral flow immunoassays (LFIAs). LFIAs are sandwich immunoassays that do not use enzyme/substrate for signal amplification but rather use antibody (or antigen) conjugated to particles (sometimes referred to as microspheres or beads) made of latex, gold, carbon, or metal for detection of antigen–antibody binding (Figure 4.6).

In LFIAs, the microsphere-labeled reagent (e.g., antibody) reacts with the analyte (e.g., antigen) as the sample wicks through the pads and membranes making up the test strip. As the mixture migrates through the "test window," antigen–antibody–microsphere complexes are captured at a "test" line by immobilized antibody (either antibody specific for the antigen of interest or an anti-Fc antibody). Excess and antigen-free complexes (e.g., in the case of a negative sample) continue migrating beyond the test line. Both the ELISA and LFIA in-clinic tests have built-in procedural controls. These are not true "positive" controls but rather

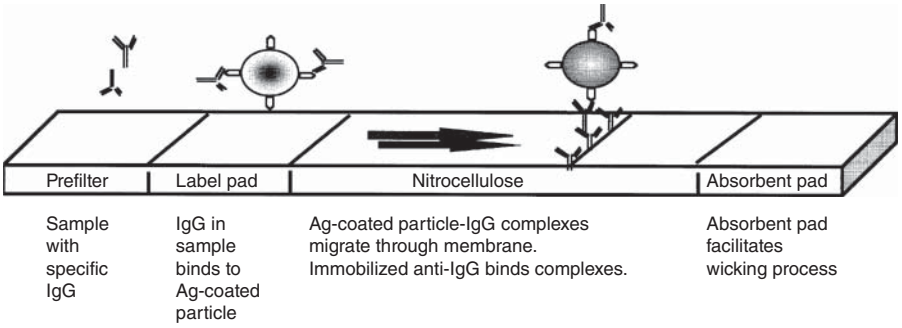

Figure 4.6 Illustration of a lateral flow immunoassay (not drawn to scale).

ensure that the enzyme was active and the sample flowed correctly for ELISA and LFIA tests, respectively.

Factors influencing immunoassay performance

As discussed earlier, immunoassay format can impact performance. In addition, both the reagents and samples used in immunoassays play a fundamental role in the quality of results provided.

Reagent considerations

Immunoassays for the detection of allergen-specific IgE serve as an example of the impact reagents can have on immunoassay performance. The ideal immunoassay would use high-affinity antibodies that are minimally cross-reactive. The specificity of early immunoassays for the detection of allergen-specific IgE was questioned due to the potential cross-reactivity of polyclonal anti-IgE antibodies with IgG [6, 7]. Allergen-specific IgG is found in sera from both atopic and nonatopic animals. Therefore, any cross-reactivity of the anti-IgE antibodies will decrease immunoassay specificity. For this reason, specific monoclonal anti-IgE antibodies and Fc epsilon receptor have been used as IgE detection reagents in allergen-specific IgE immunoassays [6, 8].

In addition to cross-reactivity of antibody, antigen cross-reactivity can also impact immunoassay specificity. In allergen-specific IgE immunoassays, it was found that taxonomically unrelated allergens contained cross-reacting carbohydrate epitopes. Specific IgE binding to these cross-reacting carbohydrate epitopes results in false positives relative to intradermal skin test results or immunoassay results using deglycosylated allergens [9, 10]. Importantly, cross-reacting carbohydrate epitopes are also found on horseradish peroxidase, an enzyme frequently used as a label in immunoassays. Under these conditions, non-IgE antibody (e.g., IgG) can simultaneously bind the carbohydrate epitopes found on both the allergen and horseradish peroxidase, generating a false-positive result for allergen-specific IgE [9, 11, 12]. For this reason, many allergen-specific IgE immunoassays now use alkaline phosphatase as the reporter enzyme rather than horseradish peroxidase [13].

Sample considerations

Relative concentrations of analyte in the sample can impact the quality of immunoassay results. In homogeneous immunoassays that measure antigen–antibody complex formation, excess antigen can saturate antibody binding sites and thereby prevent complex formation. The interference of excess analyte, resulting in a lower-than-actual measurement of analyte concentration, is referred to as the prozone effect or prozone phenomenon. Similarly, in immunoassays measuring a specific antibody class, excess antibody of a different class can bind the antigen and prevent binding by the antibody class of interest. Examples include interference due to excess IgG in allergen-specific IgE immunoassays resulting in an underestimation of IgE concentration (in atopic animals, the amount of IgG is frequently in great excess relative to the amount of IgE) [14].

Interference in immunoassays can also be caused by the presence of endogenous immunoglobulins that bind to antibodies from other species (heterophilic antibodies). Because mouse antibodies are frequently used as reagents for immunoassays, the detection of interference due to heterophilic antibodies specific for mouse immunoglobulin is not uncommon [15, 16]. In people these antibodies are termed human anti-mouse antibodies (HAMA), and they are thought to originate from either environmental exposure to mice or medical agents containing antibodies derived from mice [15]. Heterophilic antibodies have also been reported in dogs and cats [17, 18]. Heterophilic dog anti-mouse antibodies cause occasional false-positive results in some in-clinic heartworm antigen capture assays. In heartworm antigen tests, false positives can be differentiated from true positives by denaturing the antibodies (using heat or acid treatment of the sample) prior to performing the immunoassay (fortunately, heartworm antigen survives these denaturation processes). For this reason, it is important to verify positive heartworm antigen test results obtained from nondenatured samples prior to treatment for heartworms. Last, the presence of excess quantities of antigen-specific immunoglobulins in the sample can block capture immunoassays, resulting in false-negative results. The presence of blocking antibody is one cause of occasional false-negative heartworm antigen test results in *Dirofilaria immitis* microfilaria-positive dogs and cats [19, 20]. Similar to false-positive results, false-negative heartworm test results due to blocking antibody can be differentiated from true negatives by heat or acid treatment of the sample prior to performing the immunoassay.

Future trends for use of immunodiagnostics in veterinary medicine

In addition to development of new immunodiagnostic tests for both infectious and metabolic diseases of animals, future immunodiagnostics technology will provide quantitative immunoassays in the in-clinic environment. These instruments will be smaller and less expensive than the current quantitative instruments found in central immunodiagnostic laboratories. Benefits will include improved patient care due to the decreased time to obtain results, lower costs, and alleviation of concerns with shipping of samples to outside laboratories.

The first quantitative in-clinic immunoassay for thyroxine designed for use in veterinary medicine was developed using an EIA format in a single-use cartridge with results measured by a benchtop reader. Initial studies indicated that reproducibility and correlation with the reference standard laboratory-based test were inadequate [21]. However, more recent comparisons demonstrated acceptable reproducibility and better correlation of in-clinic and laboratory-based thyroxine immunoassays [22, 23]. Quantitative immunoassays for bile acids and cortisol using an EIA-based cartridge and reader system are also available. Studies indicate that there is very good agreement between the in-clinic and laboratory-based assays for bile acids and less so for the in-clinic and laboratory-based assays for cortisol [24, 25].

Quantitative immunoassay formats that do not use enzyme-dependent signal amplification would have the advantage of not requiring special handling (e.g., refrigeration) to prevent deterioration of the enzyme and substrate. However, current non-EIA-based qualitative tests (e.g., LFIAs) lack sufficient sensitivity for routine use in quantitative tests [26, 27].

Efforts are under way to develop quantitative immunoassays that retain the simplicity of non-EIA-based qualitative tests (e.g., LFIAs) with improved sensitivity. Following are examples of quantitative immunoassay technologies based on single-use cassettes that have potential for in-clinic use in veterinary medicine.

1. LFIAs that use a fluorescent dye instead of immunogold particles or latex beads result in 100–1000-fold increase in sensitivity [27–29]. Use of an LED light source and a CCD-camera-based instrument with densitometric analysis software would allow quantitation of the signal.

2. The Rapid Analyte Measurement Platform (RAMP™) produced by Response Biomedical Corporation (Vancouver, BC, Canada) uses fluorescent-dyed latex particles in an LFIA cassette. Antibody-conjugated latex particles bind to the analyte and are captured at the test line. Unbound antibody-conjugated latex particles are captured at the control line and serve as an internal calibrator. Fluorescence measured at the test and control lines is converted into a ratio that allows for correction of test-to-test variation. The RAMP immunoassay system has been shown to provide results comparable to a central laboratory immunoassay platform [30].

3. Magnetic particles have also been incorporated into LFIAs to increase sensitivity and provide quantitative results [31–33]. To function in LFIAs, the particles must be superparamagnetic, becoming magnetic only when placed in a strong magnetic field. Under these conditions, the magnitude of the change in the magnetic field is directly proportional to the amount of magnetic particles captured at the test line, which is proportional to the analyte quantity in the initial sample. Magnetic-particle-based immunoassays have a distinct advantage in that the signal is very stable over time.

4. The use of piezofilm in quantitative immunoassays was initially described in 2008 [34]. Piezofilm is a polymer film with piezoelectric properties that generates an electric charge when the film is exposed to heat or mechanical strain. In piezofilm-based immunoassays, capture antibody is attached to the surface of the film, and the detection antibody is conjugated to carbon colloids that absorb light. In the presence of antigen, the capture antibody–antigen-detection antibody complex is localized on the surface of the piezofilm. Upon stimulation with light, the generated heat is transferred to the piezofilm, eliciting an electric charge. An advantage of this technology is the lack of necessity for removal of the unbound carbon-conjugated antibody because heat generated by unbound conjugates is dissipated into the assay medium. The piezofilm immunoassay technology was developed as a point-of-care system by Vivacta Ltd. [34], acquired by Novartis in 2012 and then recently sold to Psyros Diagnostics.

Laboratory Diagnosis of Infectious Diseases of Animals

Sreekumari Rajeev
The University of Tennessee, Knoxville, TN, USA

The laboratory confirmation of infectious diseases complements veterinarians' clinical judgment through accurate identification of an etiologic agent. This improves patient care by enhancing the ability to implement appropriate treatment and preventive measures. To undertake an effective approach to diagnose infectious diseases, a veterinary practitioner must have basic knowledge of infectious agents observed in clinical syndromes. Regular submission of clinical specimens for diagnostic workup will advance a veterinarian's knowledge and interpretation skills, and in due course, the diagnostic process will become less cumbersome and more cost-effective. Veterinary practitioners must acquire adequate skills in pursuing a presumptive diagnostic strategy and reaching a differential diagnosis of clinical conditions based on history, symptoms, and direct examination of clinical samples. To improve efficiency, it is imperative that veterinary practitioners exercise evidence-based medicine and appraise the necessity of pursuing laboratory diagnosis of clinical cases they come across. During the diagnostic process, if laboratory confirmation is pursued, selection of appropriate sample type, sample collection and transport methods, diagnostic tests, and a laboratory that can offer these services are necessary. Preparation of a complete submission form, including all relevant patient information, is required to obtain meaningful test results. Finally, knowledge and experience in the interpretation of results and awareness of inherent issues associated with individual diagnostic tests are also needed.

Laboratory diagnosis of infectious diseases in animals is achieved mainly by two approaches: (i) the detection of the infecting agent or its components, and/or (ii) the detection of the host immune response to the infecting agents. The method of choice will be largely determined by the nature of infecting agents, the disease suspected, the stage of infection, the species of animals affected, and the availability of diagnostic tests. Although the use of diagnostic tests is not always required to establish the cause of an infectious disease, it is beneficial to attain a conceptual understanding of the usefulness of diagnostic tests and will prospectively help the practitioner save time and resources. The emergence, occurrence, and transmission of infectious diseases are dynamic processes. Evidence-based medicine can be better practiced by using the data obtained from routine diagnostic testing and developing diagnostic algorithms based on clinicians' experience in the geographic area of their practice. When interpreting diagnostic test results, consideration must also be given to sensitivity, specificity, and predictive values of the diagnostic tests used.

The processes involved in the diagnosis of an infectious disease can be categorized into three stages: preanalytic stage, analytic stage, and postanalytic stage, and each of these stages will ultimately support the accurate diagnosis of infectious diseases and optimal patient care [1]. The preanalytic stage involves steps taken by the veterinarian and the testing laboratory for specimen collection, transport and storage, and any other processing that occurs before the testing process happens. During the analytic stage, laboratory testing is done and procedures performed provide results. Laboratories must have strict quality-control and quality-assurance procedures in place to comply with testing protocols and reduce errors in testing. The postanalytic stage includes the final result preparation, entry of the data, reporting, and to some extent laboratory interpretation of results. All of these stages are prone to human error and may affect patient management. When an infectious disease process is suspected, a veterinarian must evaluate all of the possibilities of selecting a cost-effective and expedient diagnostic approach. To achieve this, a practitioner should not hesitate to consult with a pathologist and a clinical microbiologist. This chapter provides an overview of the general approaches used in the laboratory diagnosis of infectious diseases in animals.

Sample collection and shipping

Specimens suitable for diagnostic workup must be collected from the site of infection with minimal contamination, as soon as possible after the onset of disease, and before the initiation of therapy. Good specimen collection includes procedures in place to avoid introduction of contaminant bacteria from the surrounding skin or mucous membranes. To achieve this, disinfection or collection using specialized devices must be used as indicated for various body sites. Disinfection of the sample collection site using 70% ethyl alcohol, tincture of iodine, or chlorhexidine is recommended. Swabs are appropriate and commonly used collection devices; however, when a larger volume of a sample is necessary or when multiple diagnostic methods are to be applied, tissue affected or tissue aspirates may be submitted in lieu of a swab. There are many commercially available transport media to ensure the integrity of the specimen during transportation to the diagnostic laboratory. A variety of transport media are available and discussed at this manufacturer-sponsored site: www.bd.com/ds/productCenter/CT-Systems.asp. Appropriate sample storage is also critical in maintaining the integrity of the infectious agents in question. If delivered within 24–48 hours and collected in appropriate transport media, refrigeration is not generally required but advised to protect the sample in the event of any unforeseen delays in shipping.

Transportation of biological samples

Veterinary clinics and diagnostic laboratories must be vigilant in preventing exposure of individuals to zoonotic infectious agents. Leak-proof containers placed in a secure outer packaging are recommended for routine transportation of biological materials. Federal regulations apply to the transport of potentially infectious biological material, and veterinary staff must be familiar with packaging and transport requirements including preparation of shipping documents and potential changes to these guidelines.

Direct examination of clinical specimens

Macroscopic and microscopic examination of the clinical specimens may offer valuable clues about the ongoing infectious processes. For example, an abnormal macroscopic appearance of a clinical sample such as cloudiness in a urine sample, joint fluid, or cerebrospinal fluid (CSF) may indicate a possible inflammatory and a likely infectious process. Gross examination for the presence of external parasites such as ticks may direct the clinician to choose appropriate diagnostic tests targeting vector-borne diseases, especially in cases of diseases manifesting with broad clinical signs. Direct detection and identification of an infectious agent benefits improved patient care through the timely and appropriate choice of therapy before confirmation by downstream diagnostic procedures. Examination of unstained wet mounts is a simple but useful technique where a clinician examines a specimen directly placed on a glass slide under a coverslip by light microscopic examination. For example, detection of yeast cells with a halo representing the mucopolysaccharide capsule of *Cryptococcus neoformans* in an India ink stained wet mount preparation from the cerebrospinal fluid of cats with neurological signs or smears from skin lesions is diagnostic for *Cryptococcus* infection (Figure 5.1A). Use of 5% Lugol's iodine added as a nonspecific contrast dye to a fresh unpreserved fecal specimen enhances the detection of parasitic eggs and larvae parasitic cysts (Figure 5.1B). Examination of KOH-treated hair specimens for the diagnosis of dermatophyte infection is another useful technique.

Microscopic examination of stained clinical specimens provides useful information on the likelihood of an infection, likely pathogens, and predominant organisms if present. Immediate information on the number, morphologic characteristics of the microorganisms, and the host cellular response may provide useful information to the nature of infectious disease process. For example, observation of bacteria, fungal structures (hyphae, yeasts, and spores), and viral inclusions may render an immediate presumptive diagnosis and helps in making rational choices for therapy. Romanowsky staining methods used in cytology, such as Giemsa and Wright stains and their modification, quick stains such as Diff-Quik, are simple staining procedures and often may also have value in detecting infectious agents (Figure 5.2).

These stains are very helpful in demonstrating pathogenic yeasts (*Blastomyces, Cryptococcus, Histoplasma, Sporothrix schenkii*) and protozoan parasites (*Leishmania* and *Trypanosoma*) and occasionally inclusions resulting from viral infections caused by certain viruses, *Chlamydia*, and *Anaplasma*. Advanced and more specific techniques such as direct fluorescent antibody (DFA) staining are also available for a few agents. The need for a specific fluorescent

tagged antibody and a fluorescent microscope precludes its application at point-of-care facilities. This technique is effective when organism-specific antibodies are used to stain morphologically distinct organisms such as *Leptospira* (Figure 5.3).

Detection of antigens and microbial toxins through immunological techniques such as ELISA, agglutination tests, and precipitation tests is used for the detection of some pathogens; however, when interpreting the results, consideration must be given to published or manufacturer-supplied test parameters such as sensitivity, specificity, and predictive values of individual tests used.

Diagnostic approaches for bacterial infections

Direct microscopic examination

The presence of bacterial pathogens and any associated inflammatory components can be visualized by direct microscopic examination of stained smears. Gram, Wright, Giemsa, Diff-Quik, and acid-fast stains are used for the detection of bacterial pathogens from clinical specimens. Gram staining will allow the observer to differentiate between Gram-positive and Gram-negative bacteria; nevertheless, recognition of the host cell response is not optimal by this method (Figure 5.4).

Gram staining is a moderate to highly complex procedure, and the observer should have optimal training in differentiating bacterial pathogens and artifacts. The staining performance and interpretation can be challenging due to the complexity of the methodology, which is often underappreciated. Training and experience in interpretation are needed to achieve proficiency in this technique. An experienced microbiologist's skills are superior to veterinary clinical staff, and it is advisable that a veterinary practice seeks help from laboratories that routinely perform Gram staining. Size, shape, and Gram staining reactions of microorganisms may change in different environments as clinical samples are far more diverse than the material cultured in the laboratory and described in textbooks. The sensitivity of detection of bacteria by direct microscopy is low, and at least 10^4 bacteria must be present per milliliter of the sample to be visualized

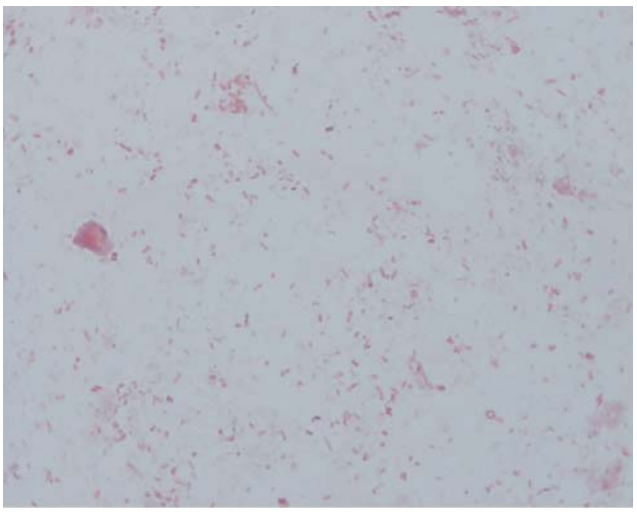

Figure 5.4 Gram stain of a canine ear swab. Mixed population of Gram-positive and Gram-negative bacteria are present.

by examination under a 100× oil immersion objective. Another drawback is that samples such as blood and CSF often yield the suboptimal sensitivity, resulting in false negatives. Direct smears routinely performed and examined in the diagnostic laboratory are quality-control indicators of outcomes of collection, transport, and downstream culture procedures.

Culture and isolation

Culture and isolation of bacterial pathogens followed by their identification is a relatively easy, sensitive, and specific method routinely used for reaching an etiological diagnosis of bacterial diseases. Isolation of a microbial pathogen supports its further characterization through genotypic and phenotypic analysis and antimicrobial susceptibility testing (AST) and can facilitate further epidemiologic studies. There are different types of culture methods, and the appropriate method or a combination of methods must be chosen based on pathogens in question. For example, fecal samples contain a variety of bacteria that are deemed as normal flora, and requesting a selective enrichment culture is necessary to improve the sensitivity of recovery of enteric pathogens *Salmonella, Listeria,* and *Escherichia coli*. Consultation with a clinical microbiologist is paramount in these situations for proper sample collection and selection of the appropriate culture method. General guidelines for microbiology test selection are given in Table 5.1.

Aerobic culture

Aerobic culture is routinely requested for fast-growing bacterial organisms that have aerobic or facultative anaerobic metabolism. This culture method utilizes a combination of nonselective media (Trypticase soy agar with sheep blood) and selective media that can recover Gram-negative organisms (MacConkey agar) and Gram-positive organisms (phenylethyl alcohol agar). Diagnostic laboratories are increasingly using chromogenic agars, which allow faster, selective, and presumptive detection of specific bacterial pathogens. Figure 5.5 shows microbial growth in various types of media used in a microbiology laboratory.

Table 5.1 General guidelines for microbiology test selection.

Clinical samples	Tests
Skin and superficial lesions	Aerobic culture
Wounds and abscesses	Aerobic culture, anaerobic culture, fungal culture
Tracheal and bronchial washes	Aerobic culture/anaerobic, fungal cultures
Eye, ear	Aerobic culture
Body fluids (pleural, peritoneal, joint spinal)	Aerobic culture and anaerobic culture
Milk	Aerobic culture
Blood	Aerobic culture, anaerobic culture
Feces	Aerobic, anaerobic, *Salmonella* culture

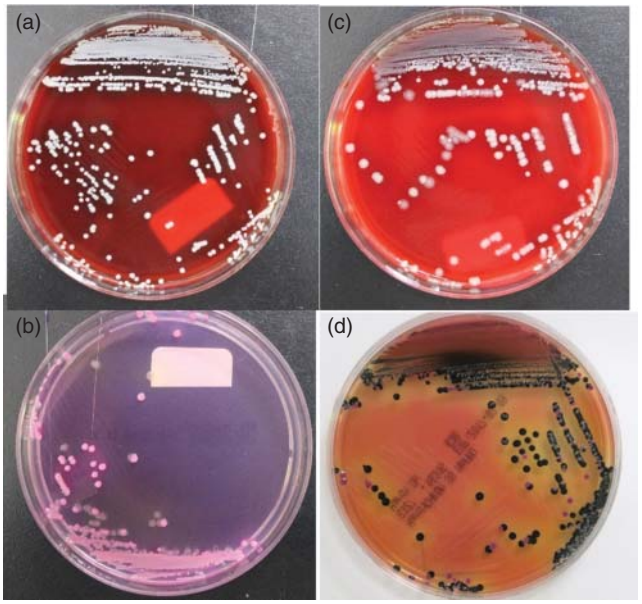

Figure 5.5 Primary culture media used for the growth of bacteria in aerobic cultures. (a) Trypticase soy agar with sheep blood allows the growth of a wide variety of bacteria. (b) MacConkey agar allows the growth of Gram-negative bacteria and can differentiate between a lactose positive and a lactose negative organism. (c) Phenylethyl alcohol agar allows the growth of Gram-positive bacteria. (d) Chromogenic agar specific for *Salmonella* allows the differentiation of *Salmonella* from other members of Enterobacteriaceae.

Routine aerobic culture procedures take approximately 24–72 hours to complete. The isolation of fastidious bacteria may have additional nutrient requirements (e.g., *Mycobacteria*), and the recovery of these may take longer and need special media or culture procedures. Fastidious *Mycobacteria,* including *M. bovis* and *M. avium* subsp. *paratuberculosis,* are routinely cultured in automated and continuously monitored culture systems, of which many are commercially available. The samples with positive signals from the machine must be confirmed by a combination of staining and polymerase chain reaction (PCR).

Anaerobic bacterial culture

Anaerobic bacterial infections are not uncommon in clinical conditions such as pneumonia, pleuritis, peritonitis, wounds, and abscesses. When mixed infections with aerobic and anaerobic bacteria are suspected, an anaerobic culture must be pursued along with routine aerobic cultures. Anaerobic bacteria do not tolerate atmospheric oxygen, and an anaerobic transport medium must be used for shipping. As anaerobic commensal bacteria are present in the mucous

Table 5.2 List of common anaerobic bacterial agents and choice of diagnostic tests.

Organism	Disease and species affected	Tests of choice
Clostridium perfringens	Wound infections, enteric infections, enterotoxaemia	Enterotoxin ELISA, PCR, anaerobic culture
Clostridium difficile	Enteric infections	Toxin ELISA, PCR, anaerobic culture
Clostridium chauvoei, *Clostridium novyi*, *Clostridium septicum*	Myositis in food animals (malignant edema, blackleg, gas gangrene)[a]	Direct fluorescent antibody staining
Fusobacterium sp., *Bacteroides* sp., *Dichelobacter* sp., *Prevotella* sp., *Porphyromonas* sp.	Abscess, various soft-tissue and bone infections, diarrhea	Anaerobic culture, PCR

[a]Anaerobic culture is often unrewarding in these cases.

membranes of animals, extreme care must be taken to avoid contamination. Culture may not be the appropriate method for some anaerobic agents. Table 5.2 lists common anaerobic bacterial agents and common choices of diagnostic tests.

Limitations of routine culture

Understanding the limitations of routine aerobic cultures and requesting special culture protocols or other suitable diagnostic procedures are required when infections with *Salmonella, Listeria, Mycoplasma, Brucella, Chlamydia,* and *Leptospira* are suspected. In *Salmonella* enteric infections, a selective enrichment culture is more sensitive in isolating *Salmonella* from other enteric bacteria than routine cultures. *Listeria* is a fastidious bacteria, and an enrichment culture is needed for the isolation of the bacteria from suspected neurologic cases from ruminants. *Mycoplasma* and some *Brucella* species need specific growth factors and incubation conditions. *Rickettsia* and *Chlamydia* will not grow in *in vitro* culture media, and cumbersome cell cultures are needed to cultivate them. Therefore, the choice of diagnostic test is critical in obtaining accurate and timely results. Similarly, attempts to culture for disease diagnosis can be barely rewarding in the decision-making process for some fastidious bacteria. For example, *Leptospira* culture needs prolonged incubation and special media, and alternative procedures such as serology, DFA test, or PCR or a combination of these tests will provide timely results. Interpretation of results should also account for differentiating normal flora from potential pathogens because many body sites harbor microbial flora. Correlation of the results with clinical signs and the presence of quantity and the type of organisms can assist the practitioner in the decision-making process. A heavy growth of a pure culture of a bacteria is indicative of infection, while multiple types of organisms (three or more types) isolated from a single sample in the absence of the growth of an obligate or primary pathogenic bacteria should be interpreted as contamination. When a negative result is obtained in the presence of obvious clinical signs or in a nonresolving illness, factors such as special bacterial growth requirements, prior treatment, sample collection and transport methods, and information from direct staining must be considered, and the process must be reevaluated.

Antimicrobial susceptibility testing

Antimicrobial therapy plays a vital role in controlling infections. AST routinely performed in conjunction with a bacterial culture determines whether a bacteria is susceptible to a particular antimicrobial agent; use this information for selecting an antimicrobial agent for treatment. A disk diffusion test (Kirby–Bauer test) and broth dilution test are commonly available; the broth dilution test is quantitative and provides the minimum inhibitory concentration (MIC) of an antimicrobial agent. MIC is the minimum concentration of the drug required to inhibit bacterial growth, and the availability of these data improves the selection of antimicrobial agents and dosage to optimize a favorable treatment outcome. In addition to the MIC value, several factors including pharmacokinetics, pharmacodynamics, and concerns of resistance emergence have to be considered while choosing the antimicrobial agents. Routine AST may also allow the building of an antibiogram to guide veterinarians in selecting the empiric therapy for future patients and will also help to monitor the evolution of drug resistance. Practitioners' awareness of the intrinsic resistance observed in certain bacterial pathogens will avoid inappropriate and ineffective therapies. A typical example is the use of aminoglycosides in treating anaerobic infections.

Diagnostic approaches for fungal infections

Fungi are eukaryotic organisms with complex and diverse morphological structures and as such, precise identification of a fungal species can be challenging. Only a limited number of fungi are known pathogens that can cause disease in a healthy animal, yet a large number of them are emerging as opportunistic and invasive infections in animals and humans. Frequent antimicrobial use and alterations in normal flora may predispose the colonization of fungi such as *Candida* in the skin and mucous membranes and may lead to clinical disease. Proper collection, handling, and transport of samples are required, as in the case of bacterial infections. Transportation and storage of clinical materials at room

temperature are recommended because some of the fungal agents such as dermatophytes are known to be sensitive to cold temperatures. Direct microscopic examination of clinical samples used in conjunction with culturing is a routine option for the diagnosis of fungal infections. By microscopic examination of these smears, arthrospores of dermatophytes can be observed within the hair shaft (endothrix) and outside of the hair shaft (ectothrix). Geographic location and travel history are important components of a diagnostic investigation because some fungal pathogens are endemic to certain geographic locations; *Coccidiodomyces* in the southwestern states of the United States and *Cryptococcus gattii* in the northwestern United States and western Canada are a few examples. The presence and characteristics of certain fungal organisms such as size, morphological features, and cellular location in clinical specimens may offer diagnostic clues.

Fungal culture and isolation are done using a specialized media (Sabouraud's dextrose agar) and low incubation temperature (29 °C), and so a specific laboratory request is necessary. Because prolonged incubation facilitates the growth of contaminant bacteria and saprophytic fungus, the addition of antibiotics or inhibitory chemical agents such as chlorhexidine in the media is necessary to isolate fungal organisms. Dermatophyte test media (DTM) is widely used by veterinary practitioners at the point of care for the diagnosis of ringworm infection. If dermatophytes are present, the media will change color due to the change in pH. However, color change itself should not be considered as diagnostic for dermatophytes, as other saprophytic fungal contaminants can cause a similar change in pH. Microscopic examination and identification of unique fungal species-specific structures such as hyphae, macroconidia, and microconidia must be performed for definitive identification.

Interpretation of fungal culture results must be pursued with caution because some body sites, especially the nasal cavity, skin, and mucous membranes, can easily be contaminated with fast-growing saprophytic fungal spores. Correlation of culture results with cytological and histopathologic evidence of fungal structures along with compatible host inflammatory response is required to make a confirmatory diagnosis. A negative result should also be interpreted with caution because some fungal agents may not grow in a routine fungal culture media.

Antifungal susceptibility tests

Antifungal susceptibility tests are not widely available, and service from reference laboratories must be sought for pursuing this. Choice of antifungal agents and the availability of AST interpretive criteria are limited. An accredited laboratory following Clinical and Laboratory Standards Institute (CLSI) or European Committee on Antimicrobial Susceptibility Testing (EUCAST) guidelines must be selected to assure appropriate quality control and quality assurance of testing.

Fungal antigen detection

Antigen detection methods are available for some systemic and invasive infections (galactomannan detection for *Aspergillus*). Antigen detection for dimorphic fungal infections (*Blastomyces, Coccidioides, Cryptococcus,* and *Histoplasma*) and a few others are available through commercial laboratories (MiraVista Diagnostics, Indianapolis, IN). A serum-based β-d-glucan assay is also available for the presumptive diagnosis of invasive fungal infections for which there is difficulty in obtaining clinical samples.

Diagnostic approaches for viral infections

Accurate and timely diagnosis of viral diseases in animals allows applicable clinical management, determination of prognosis, and prevention of transmission by enhancing biosecurity protocols and strategic use of vaccination protocols and management practices. In addition, an accurate diagnosis of a viral infection avoids unnecessary use of antibiotics and thereby minimizes the potential emergence of antimicrobial resistance. Viral diagnostics are challenging because virus growth requires sophisticated cell culture systems that are available only in reference diagnostic laboratories. Direct detection of viral pathogens includes detection of inclusion bodies by light microscopy in cytology and histopathology specimens, observing viral particles by electron microscopy, or by the detection of the agent or its components using immunological methods such as DFA test. The rapidity of these tests is useful for early diagnosis. Conventional techniques routinely used for the diagnosis of viral infections are time-consuming and often not practical for patient management. Developments in technology including the generation of specific monoclonal antibodies and improvements in enzyme immunoassays, shell vial cultures for virus isolations, and nucleic acid amplification methods have tremendously improved the timely detection of viral pathogens. Preanalytical steps, including specimen selection, collection transport, and processing methods, are as important as the selection of laboratory tests. Understanding of the viral pathogenesis and target organs affected is essential for the selection of clinical specimens for testing. Sample collection devices also have a significant effect on detection. For example, wooden shaft swabs may contain toxic compounds such as formaldehyde and are not suitable for virus isolation procedures. Calcium alginate-aluminum shaft swabs may also have inhibitory effects on PCR.

Rapid point-of-care tests

A variety of rapid point-of-care tests targeting viral antigens are available for detection in clinical specimens. In these tests, antibodies targeting specific viral antigens are either immobilized on a membrane or coated on plastic wells, and the viral antigens can be detected by various detection

systems. These tests are fast and easy to use in clinics. Immunoassays for viral antigen detection are commercially available for the diagnosis of a few viral infections (canine parvovirus, feline leukemia virus) and can be performed at the point of care. Specific attention should be given to the manufacturer's guidelines for proper running and interpretation.

Direct fluorescent antibody testing

DFA testing is a common method for detecting viral infection. When infecting cells, the virus localizes either within the cytoplasm or the nucleus depending on the type of virus and can be detected by use of FITC labeled, virus-specific polyclonal or monoclonal antibodies and observation through a fluorescent microscope.

Electron microscopy

Electron microscopy allows visualization of viral particles in clinical specimens with a highly specialized microscope that uses electron beams for detection. Electron microscopy is useful in diagnosing enteric viral infections such as parvovirus, coronavirus, and rotavirus infections. There are two types of electron microscopes, a transmission electron microscope and a scanning electron microscope; the former is the most often used for the diagnosis of infectious diseases. Negative staining using phosphotungstic acid is used for the detection of viral particles in clinical specimens. Specific morphology observed in these preparations allows the diagnostician to identify viruses to the genus level (Figure 5.6A,B). When inclusion bodies are suspected in lesions observed in H&E stained tissue histopathology preparations, a transmission electron microscope can reveal viral particles (Figure 5.6C,D).

Electron microscopy is especially useful in diagnosing emerging infectious diseases and unusual infections where etiology is completely unknown. Once the general morphologic characteristics of the virus are known, confirmation can be done by virus isolation, PCR, and sequencing. Electron microscopy offers excellent specificity due to the characteristic morphology of virus families but low sensitivity as a

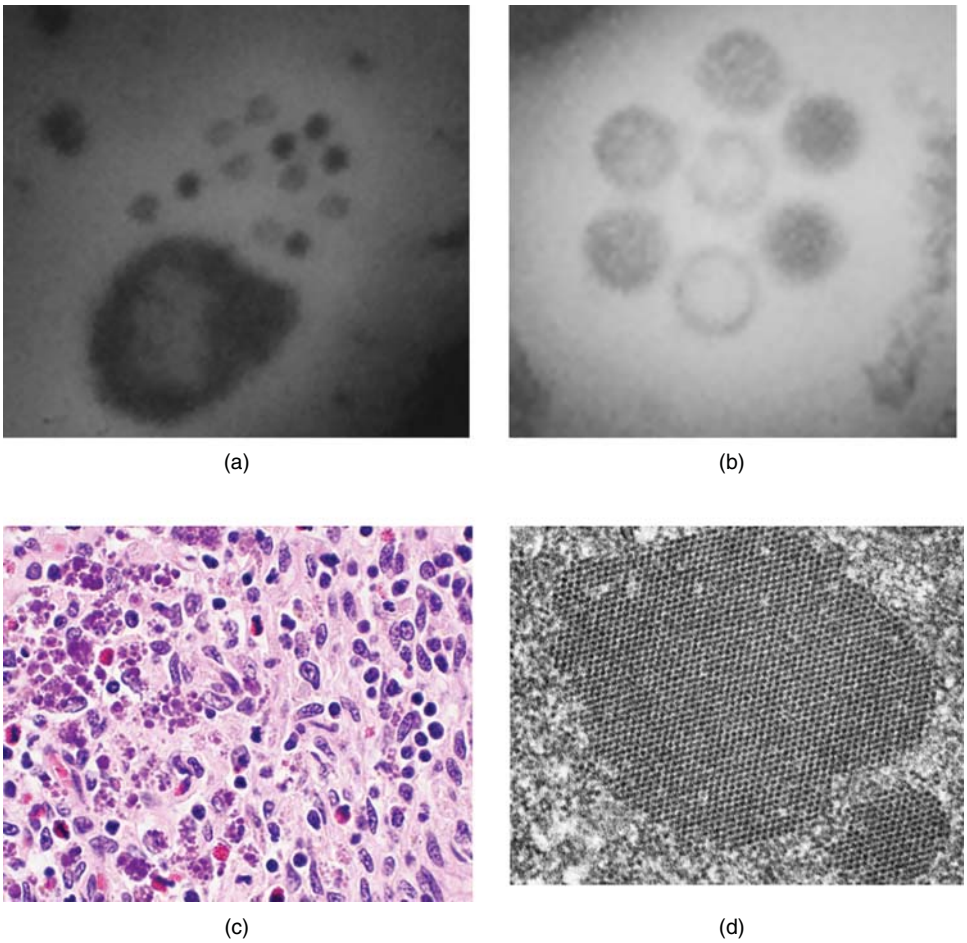

Figure 5.6 Electron microscopy is a valuable tool for the diagnosis of viral infections. A: Transmission electron microscopy (TEM) image of a negative stained feces containing parvovirus. B: TEM image of a negative stained feces containing rotavirus. C: H&E stained image of a lymph node containing circovirus inclusion bodies. D: TEM micrograph of the above section showing paracrystalline array of circovirus.

large number of viral particles are needed for visualization under the electron microscope. This technique is also useful for screening cell cultures when there are no detectable cytopathic effects (CPEs) as a result of virus growth

Virus isolation

Virus isolation in cell cultures, the gold standard test for the confirmation of viral infection, is a laborious process and requires growth of virus from clinical specimens in permissible cell lines. Processing of clinical specimens involves homogenization of samples in the cell culture media, removal of contaminant bacteria by filtration, and addition of antibiotics before inoculation. The growth of virus is detected by the presence of characteristic changes in the infected cells called CPEs. This is followed by confirmation using fluorescent antibody staining, PCR, or electron microscopy. Animal inoculations and isolation in embryonated chicken eggs are needed for growing a few viruses. The advantage of this technique is that a viable virus isolate, when obtained through cell culture or animal/egg inoculation, will allow further characterization of its properties, including virulence and antigenic variations, which can lead to development of vaccines, diagnostics, and antiviral drugs. Virus isolations are expensive, time-consuming, and need facilities for maintaining cell culture. This technique is not desirable for making quick and timely clinical decisions, and recently has increasingly been replaced by molecular techniques.

Antibody detection

Detection of antiviral antibodies is a widely used and reliable practice for the diagnosis of viral infections. The collection of serum is an easy, noninvasive procedure. Viral agents may not be present in the body during the entire duration of infection, but exposure to the virus can be confirmed by the presence of serum antibodies. Tests commonly used include virus neutralization (VN), agar gel immunodiffusion (AGID), hemagglutination inhibition (HI) assay, immunofluorescence assay (IFA), Western blots, complement fixation tests, and enzyme-linked immunosorbent assay (ELISA).

Virus neutralization

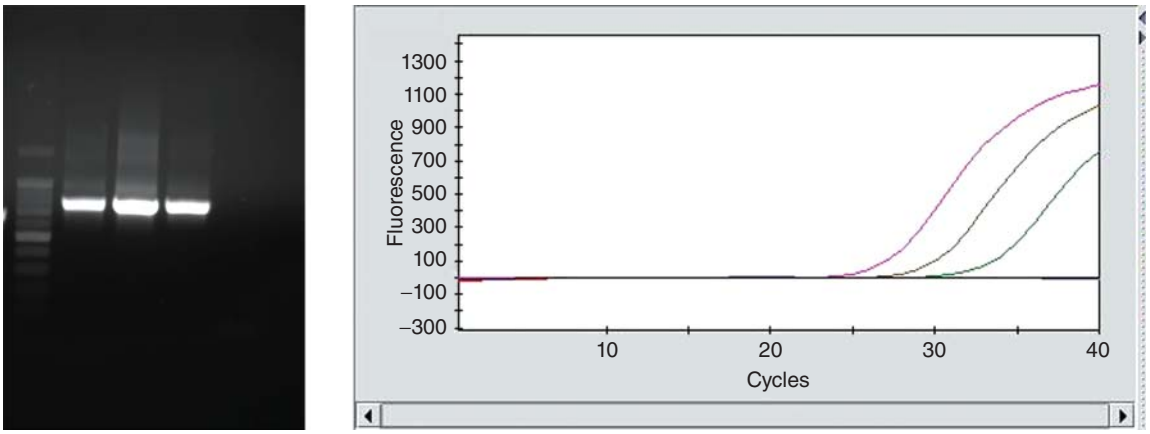
VN is a highly sensitive and specific detection procedure where virus neutralizing antibodies prevent the growth of the virus in cell culture. The antibody present in the serum can be quantitated, and the highest dilution of the serum that inhibits the neutralization is recorded as the antibody titer. Another variation of this test is the plaque reduction neutralization test (PRNT), which is used for plaque-forming viruses such as arboviruses. Paired serum antibody titer determination is often needed for confirmation of an active infection vs. exposure or a vaccine response. A paired serum testing of the acute and convalescent serum samples and the observation of a fourfold increase in antibody titer should confirm an active infection. This is achieved by testing a serum sample collected from an acutely ill animal and a sample collected after 2–4 weeks (convalescent serum sample) side by side. VN or PRNT assays are not widely available as these methods are laborious, time-consuming, and expensive. They also require maintenance of cell cultures, preparation and storage of titered virus stocks, trained personnel, and stringent quality-control measures.

ELISAs

One of the most common commercially available serology tests is ELISAs. These tests use plastic wells coated with viral antigens, and when the test serum is added, antiviral antibodies, if present in the test sera, will bind to the antigen. A secondary species-specific antibody conjugated with an enzyme such as horseradish peroxidase will allow the detection of the antibodies. Differentiation of antibody class IgM or IgG can facilitate the diagnosis of recent antibodies from ongoing infections or exposure. Interpretation of serology results can be complex and confounding. The nature of the disease, the pathogen, and the test parameters influence the outcome. A single positive or negative result is informative for only a few infectious diseases. For example, for diseases caused by retroviruses such as equine infectious anemia in horses, a single antibody positive test (a widely used AGID, or Coggins, test) can confirm infection. It is important to understand that in a patient with an infection, false-negative test results could still be observed in the early stage of an infection. Serology tests are beneficial in herd situations, where seronegative status provides a reasonable evidence of the absence of infection in a population.

Diagnostic approaches for parasitic infections

"Parasite" is a broad term and refers here mainly to eukaryotic organisms belonging to protozoa (single cell) and metazoa (arthropods and helminths, including nematodes, trematodes, and cestodes). Unlike bacterial and viral infections, historical diagnosis of parasitic infections was by identification of organisms using morphological criteria utilizing gross or light microscopical examination. Recently, many of these techniques have been replaced by molecular methods (PCR and sequencing) and antigen detection through immunoassays. Commercial and in-house kits for antibody detection are also increasingly available.



The most common specimen submitted for parasitology examination is the fecal sample for the detection of ova and parasites. Preservation of stool (5–10% formalin) is often practiced to retain the morphology of certain protozoan parasites and to prevent continued development of helminth eggs and larvae if there is a delay in transport of materials. Three common methods available are direct wet

mount, concentration, and permanently stained smears. Fresh feces is required for direct wet mounts to identify motile trophozoites. Wet mounts are not attempted in preserved specimens. The concentration of fecal samples using flotation or sedimentation is commonly used, and the concentrated samples are examined under the light microscope. Both surface film and the sediment must be examined in order to detect some of the heavy helminth and operculated eggs. Samples should be collected in clean screw cap and wide mouth containers without any water or urine contamination because the presence of urine will destroy the motile organisms. Permanently stained smears can be used for the detection of intestinal protozoa, and two common methods used are Gomori tissue trichrome–Wheatley modification and iron hematoxylin stains. These stains can be used for the confirmation of structures observed in wet smears (> than 300 fields must be examined).

Molecular methods

The golden era of molecular diagnostics originated after Dr. Kary Mullis's 1983 Nobel Prize–winning invention, the PCR, and has undergone remarkable advancements since then. In the diagnosis of infectious diseases, PCR applies to the amplification of pathogen-specific target nucleic acids, DNA or RNA using specific enzymes called DNA polymerases. For the detection of RNA as in RNA viruses, an additional step of conversion of RNA to DNA (reverse transcription) is carried out using an enzyme called reverse transcriptase. Primers specific to the target DNA fragment are designed for specific amplification of the pathogens. Automated machines called thermocyclers are used in the amplification of the nucleic acid. PCR allows sensitive and specific detection of pathogen-specific nucleic acid in a shorter turnaround time compared to conventional bacterial cultures or virus isolation. Challenges include false-positive reactions due the extremely sensitive nature of the assay, often arising due to contamination. False-negative results occur as a result of the inherent inhibition of the PCR assays due to the presence of PCR inhibitors in the sample and the quantity of DNA below the detection threshold. Interpreting the PCR results in the relevant clinical context may overcome some of these challenges. Depending upon the nature of agents sought, DNA, RNA, or total nucleic acid can be extracted using appropriate in-house techniques or commercially available nucleic acid extraction kits. In a conventional PCR, the amplified DNA fragment is detected using agarose gel electrophoresis and then visualized under ultraviolet (UV) light (Figure 5.7a). In a real-time PCR, DNA binding fluorescence dyes such as SYBR green or a DNA probe labeled with a fluorescent dye are used. The amplification of DNA is measured and observed real time using computer software (Figure 5.7b).

The real-time PCR assay can also be modified to quantify the pathogen load in a clinical sample. There are many design variations of PCRs; however, discussion of them is not within the scope of this chapter. One should discuss the advantages and disadvantages of these techniques with the laboratory provider. Recent advances such as the development of reagents with superior amplification efficiency, discriminatory target development to improve specificity, automated high-throughput platforms, the ability to multiplex and detect multiple pathogens at the same time, and a high potential for standardization have reduced the cost and improved the efficiency of PCR testing. PCR combined with sequencing of various targets as in multilocus sequence typing (MLST) allows the classification of strains and the detection of changes or mutation in virulence factors in

(a) (b)

Figure 5.7 (a) DNA is amplified by a conventional PCR using pathogen-specific primers and a validated thermocycling protocol. The amplified product is subjected to agar gel electrophoresis and visualized under the UV light. (b) For real-time PCR, fluorescent dye that binds to the amplified DNA or a hydrolysis probe is used for the detection of the product. The product can be quantified in relation to pathogen load using optimized and well-validated protocols.

microbial pathogens. A repertoire of PCR-based diagnostic tests are available for veterinary infectious disease diagnosis through state veterinary diagnostic laboratories or other commercial labs.

Next-generation sequencing

One of the latest technologies, next-generation sequencing (NGS), is increasingly becoming accessible for the diagnosis of infectious diseases [2]. Also referred to as "deep sequencing," "massively parallel sequencing," or "high-throughput sequencing," this procedure can be successfully implemented in clinical specimens where an infectious agent is suspected but cannot be detected by commonly available techniques. NGS is increasingly being used in human medicine and is especially beneficial in identifying novel and emerging pathogens.

Role of postmortem investigation in infectious disease diagnosis

Postmortem examination for understanding the cause of mortality is more commonly performed in veterinary medicine than in human medicine. The value of postmortem histopathology and microbiology is well recognized in the veterinary field in diagnosing infectious diseases during outbreaks of economically important diseases among food animal populations, uncovering emerging infectious diseases, and identifying those diseases for which the diagnosis might have been missed using other approaches. Accurate identification of infectious agents, tracking of antimicrobial resistance in organisms isolated, understanding the changes in pathogen virulence due to mutations, and epidemiological patterns of diseases will benefit future investigations. There is disagreement among clinicians about the value and usefulness of postmortem microbiology testing, as postmortem invasion and contamination can influence the interpretation of results. Correlation with patient history and the gross and microscopic findings is required for meaningful interpretation. Certain infectious diseases present with pathognomonic or characteristic lesions that can be used for the presumptive diagnosis and for the selection of follow-up tests. Storage of the carcass in a cooler and completion of the postmortem examination soon after death may reduce the postmortem overgrowth and increase the likelihood of accurately identifying the pathogens in question. Examination of the carcass soon after death is not practical in veterinary medicine due to the time taken for transport to reference veterinary diagnostic laboratories that are often not available closer to the patient location. Tissues with gross signs of infection must be collected carefully following sterile precautions using sterile equipment. Adequate size of tissue should be collected to allow proper searing to remove surface contaminants. Swabs are also acceptable for microbial culture; however, multiple swabs must be collected for multiple procedures. Fluids collected in nonleaking sterile screw-cap containers are preferable over those transported in syringes.

Role of biopsy and histopathology in infectious disease diagnosis

Routine biopsy and histopathology can provide strong evidence of the presence of an infectious agent, and associated inflammation that can help in the selection of downstream diagnostic tests required for confirmation. The knowledge of the presence and the location of bacterial organisms, their differential staining properties, and the nature of inflammation can help in the diagnostic process. Certain infectious diseases are easily diagnosed by histopathological evaluation of samples. The pathological changes in the tissue and the morphology of certain pathogens can definitively diagnose few infections. This is especially valuable for certain fungal infections where characteristic morphology of fungal organisms can be observed [1]. The typical examples include large spherules containing endospores in the tissue in *Coccidioides immitis* infection, broad-based budding yeasts in *Blastomyces dermatitidis* infections, and round to oval yeast cells surrounded by a large halo representative of a capsule in *C. neoformans* infections [1]. In addition, histopathology examination may reveal the evidence of coinfections that would have been missed by a single targeted microbiologic testing.

In viral infections, observation of inclusion bodies in the cytoplasm or nucleus, the formation of syncytia, and the nature of cellular infiltration can be significant findings. Characteristic intranuclear inclusion bodies in tissues of animals with herpesvirus infections, intracytoplasmic inclusion bodies in cases of canine distemper in dogs, and formation of a syncytium in respiratory syncytial virus infections in cattle can be diagnostic. Special staining of histopathology sections using Gram stains (Brown–Hopps or Brown and Brenn), acid-fast stains (Fite's acid-fast stain, Ziehl–Neelsen stain), Giemsa stains, and silver stains (Warthin–Starry stain, Grocott–Gomori's stain) is useful for the detection and differentiation of pathogens.

Immunohistochemistry techniques using pathogen-specific antibodies can reveal additional information that is not generally obtained by the examination of routine hematoxylin and eosin stained tissue sections (Figure 5.8) [3]. The examination of H&E stained specimens may be the best choice to diagnose conditions caused by those agents that may not grow in laboratory cultures. Examples include finding bacilli with haystack-like appearance in the hepatocytes in Tyzzer's disease caused by *Clostridium piliforme*, large sporangium containing spores in nasal polyps caused by *Rhinosporidium*

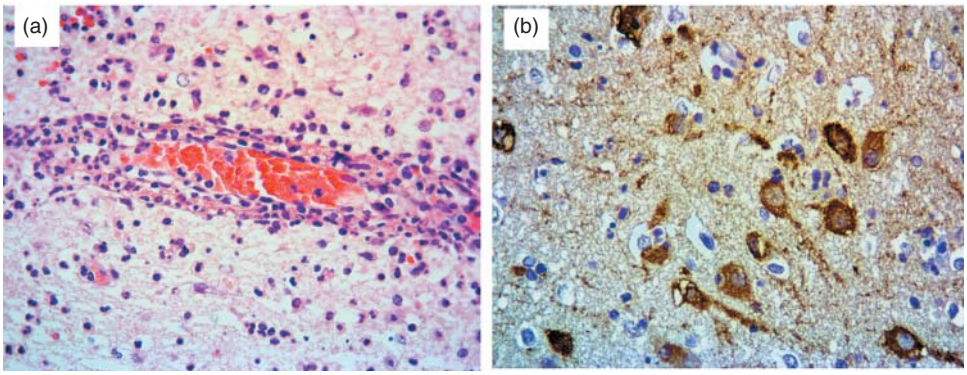


Figure 5.8 Perivascular cuffing is a feature of CNS infections. To identify the viral etiology an immunohistochemistry (IHC) was applied to detect eastern equine encephalitis (EEE) antigen in the brain. A: H&E stained brain section showing perivascular cuffing. B: IHC using anti-EEE antibodies was used to detect EEE antigen in the neuronal cytoplasm.

seeberi, and the presence of spiral bacteria in the intestinal epithelium in *Lawsonia intracellularis* infection.

Laboratory diagnosis of infections affecting various body systems

Certain infectious agents have predilections toward a particular body system, whereas some others may infect and alter multiple body systems. The outcome of infections depends on the pathogen, host, and conditions where infections were acquired. Opportunistic infections are on the rise in animals and humans due to changes in immunocompetency of the host and ecology. Diagnostic strategies for infectious diseases affecting various body systems are briefly discussed below. A list of selected pathogens, infectious diseases, the species of animals, and the recommended diagnostic tests are given in the Appendix 5.A.

Skin and soft-tissue infections

Skin, the major barrier in the body against microbial invasion, constantly interacts with the environment and is normally colonized with microbial organisms such as *Staphylococcus, Streptococcus,* and *Corynebacterium*. Infections of the skin and underlying tissues may have varying clinical presentations, and severity may range from superficial pyoderma to deep cellulitis and occasionally life-threatening conditions such as necrotizing fasciitis. *Staphylococcus, Streptococcus*, and rarely Gram-negative anaerobes are generally involved in these conditions. When deciding on the diagnostic approach, practitioners must be aware of those infectious and noninfectious systemic diseases that have cutaneous manifestations. For example, submitting a skin sample is required for diagnosing greasy pig disease caused by *Staphylococcus hyicus*, but submitting a skin sample for diamond skin disease, a systemic disease caused by *Erysipelothrix rhusiopathiae*, will result in false-negative results. Traumatic injuries to the skin and underlying tissue may allow invasion of anaerobic organisms leading to deep-seated infections resulting in an abscess, draining tracts, and myositis. In these situations, a delay in the identification of the cause and treatment lead to invasion of infection into deeper structures and blood and can be detrimental to the host. Cytological examination, skin biopsy, and bacterial and fungal culture are the common methods used for diagnosing skin infections. Samples must be collected after cleaning and debridement of the affected tissue. Because the majority of skin conditions are secondary to other predisposing factors such as allergy, ectoparasitism, and trauma, identifying and removing the predisposing factor and then addressing the infections will enhance the therapeutic success. A full-thickness biopsy is preferred over punch or wedge biopsy for histopathologic assessment of nonresolving skin lesions. Systemic viral infections including pox and vesicular diseases induce skin lesions. Many systemic infections caused by fungal organisms *B. dermatitidis*, *Histoplasma capsulatum*, *C. immitis*, and *C. neoformans* can have cutaneous manifestations. As skin may harbor normal flora, interpretation and differentiation of pathogens from colonizers is imperative to avoid initiating unnecessary antimicrobial therapy.

Gastrointestinal infections

A wide variety of microorganisms inhabit the gastrointestinal tract including aerobic, facultative anaerobic, and obligate anaerobic organisms, and the identity of many of them is unknown. The consortium of microorganisms termed as the intestinal "microbiome" is essential for the health and well-being of the host. Any imbalance in the composition of the microbiome may induce a disease state.

Oral cavity infections including gingivitis and periodontitis are common in dogs and cats, and the polymicrobial nature of these conditions can be confounding when trying to identify a precise etiology. Primary oral lesions occur with viral infections such as canine distemper virus, canine herpesvirus, feline calicivirus, and viral vesicular diseases

along with other systemic manifestations. The pursuit of diagnostic testing for pharyngitis and tonsillitis can be unrewarding due to the presence of a multitude of organisms in these locations unless a specific etiology is suspected (e.g., *Fusobacterium necrophorum* or *Histophilus somni* in calves causing necrotizing laryngitis). Low pH of the stomach inhibits the survival of many bacteria, but members of the species *Helicobacter* can colonize the stomach and cause ulcers and gastritis. Primary enteropathogenic organisms such as *E. coli*, *Salmonella*, *Clostridium perfringens, Clostridium difficile*, and *Campylobacter* spp. can be diagnosed by fecal cultures. Special selective enrichment cultures for these pathogens are often necessary to improve the detection sensitivity in the presence of normal microflora.

Detection of relevant toxins is more significant in cases of infections caused by *C. perfringens* and *C. difficile* because these organisms can be a part of the normal gastrointestinal flora. A freshly voided fecal specimen collected in sterile screw-cap containers and transported under refrigeration conditions is ideal for the recovery of enteric pathogens. A transport media such as Cary-Blair is recommended. If fresh feces is not available, a rectal swab may be collected after cleaning the anus with 70% alcohol. Multiple swabs must be collected for different tests such as culture, PCR, toxin testing, etc.

Respiratory tract infections

Primary viral and bacterial pathogens as well as commensal microbes present in the nasal cavity and oropharynx are capable of causing respiratory disease. Viral infections can destabilize the innate immune response mechanisms and make the host susceptible to secondary respiratory bacterial infections. In addition, several sporadically occurring systemic diseases such as anthrax, plague, and tularemia, though rare in animals, often have respiratory manifestations. Culture is one of the most common methods used for the diagnosis of respiratory tract bacterial infections. Interpretation of results can be perplexing due to the presence of normal microflora, which is abundant in the upper respiratory tract and nasal cavity. Therefore, the culture of nasal cavity, pharynx, and larynx is usually unrewarding, unless selected pathogens are sought. Infections of the lower respiratory tract, such as pneumonia and pyothorax, may induce systemic abnormalities; leukograms, blood gas analysis, and blood chemistry findings may provide further clues to the nature of the infectious process. Fecal testing is advised to rule out respiratory tract infections of parasitic origin. Imaging using radiography, ultrasonography, and endoscopic examination may also be pursued to obtain a better understanding of the location and severity of infections. Samples collected by fine-needle aspiration and properly collected transtracheal and bronchoalveolar lavage can be submitted for aerobic, anaerobic, or fungal cultures if indicated. Members of the genus *Mycoplasma* are involved in respiratory tract infections of many animal species and often occur as coinfection with other bacterial and viral agents; a mycoplasma culture or PCR must be requested. Direct staining (Gram's and acid-fast) will differentiate Gram-positive vs. Gram-negative bacteria and infections caused by organisms such as *Mycobacteria* and *Nocardia*.

Urogenital tract infections

The lower urogenital tract is normally colonized by bacteria. Bacterial infections of the urinary system affecting the urethra, bladder, ureters, and sometimes renal pelvis are common among companion animals. Asymptomatic colonization and bacteriuria may be observed in some animals. Gram-negative organisms *E. coli, Proteus, Klebsiella, Pseudomonas,* and *Enterobacter* and Gram-positive organisms *Staphylococcus, Streptococcus,* and *Enterococcus* are the most common isolates in canine urinary tract infections. Method of urine collection is a significant factor in interpreting urine culture results. Collection through cystocentesis is preferred over catheterization or midstream urine collection. Catheterization and midstream collection introduce commensal bacteria in the urine sample and are not preferable collection methods. A small volume of urine aseptically collected is useful for quantitative cultures. The culture results must be interpreted in conjunction with urine analysis results.

Infections of the reproductive tract may result in abortion or early embryonic death in pregnant animals. Fetal internal organs and stomach or abomasal fluid are ideal for testing if available. Fetal serum and paired serum samples (acute and convalescent) from the dam are also valuable resources for diagnostic testing.

Nervous system infections

Infectious diseases affecting the nervous system are often fatal, and the antemortem diagnoses can be challenging. Accurate and timely diagnosis is critical in therapy implementation. Developing a list of differential diagnoses through history and clinical examination, a complete blood count, serum biochemical profile, imaging, and serology in conjunction with CSF analysis imparts valuable information about the potential pathogen involved and will help the clinician in ruling in or out potential infectious agents. CSF analysis should be performed as quickly as possible after collection to avoid cell lysis. Refrigeration and the addition of bovine serum albumin or fetal calf serum to CSF can slow down the degeneration of the cells. Cloudiness due to increased cells, red discoloration due to either blood contamination or hemorrhage, and increased nucleated cell count in CSF (pleocytosis), and the presence of microbes may be observed in infections of the central nervous system (CNS).

Systemic infections

Systemic infections can be caused by a wide variety of infectious agents including bacterial, viral, fungal, and parasitic

organisms. Colonization of various body systems may occur depending on the portal of entry before dissemination of the agent or its toxins. In the case of tetanus or botulism, the systemic effects are due to the local infection and the production of toxins or ingestion of food contaminated with the toxin. A quick determination of the type of organism, potential entry and dissemination sites, and pathogenesis will result in a better prognosis. Although many infectious agents have a tissue tropism, almost all infectious agents can spread systemically in immunocompromised patients.

Conclusion

The basic approaches in the laboratory diagnosis of infections remain the same despite the changes in technology and the discovery of new and emerging infectious diseases. The diagnostic approach for each suspected infectious disease is dependent on availability of assays, assay performance, turnaround time, and the affordability of testing. Preanalytic steps strictly followed by the submitting clinician and the testing laboratory have a profound effect on the outcome. Infectious disease and clinical manifestations are a result of interactions between host, pathogen, and the environment, and each of these impact the nature of the disease and its manifestations. In view of all of the possibilities of infectious disease outcomes, including transient disease followed by recovery, subclinical or chronic disease and recovery, severe debilitating clinical disease, or persistent infections, a judicious yet pragmatic diagnostic approach and interpretation of the laboratory results are critical for management of the patient. Many pathogens can be seen as a part of normal flora, and an evaluation of the role of microbial agents or host response detected as a part of the disease process, although challenging, may be necessary for accurate interpretation.

5.A. List of Selected Pathogens/Major Infectious Diseases, Species of Animals, and the Recommended Diagnostic Tests

Steps involved in the laboratory diagnosis of infectious diseases:

1. Evaluate the objective of the diagnostic testing (patient management, herd screening, etc.).
2. Evaluate the benefits of the chosen testing process.
3. Identify a suitable laboratory and discuss the sample and test selection, transportation methods, turnaround time, cost, test parameters, and interpretation guidelines.
4. Collect and ship samples using proper guidelines for the sample and suspected infectious agent.
5. Interpret the test results and use the results based on the objective of the diagnostic testing process.

Bacterial pathogens

Organism: *Actinomyces* spp. (*A. viscosus, A. israelii, A. hordeovulneris*)
Diseases and species affected: Abscess, osteomyelitis, pleuritis, pyothorax, in dogs, cats, and other animals; pyogranulomatous osteomyelitis or lumpy jaw (caused by *A. bovis*) in cattle.
Preferred diagnostic tests: Aerobic and anaerobic cultures are required because there are aerobic and anaerobic members in this genus.
Comments: Opportunistic pathogens present in the mucosa; presence of sulfur granules in the lesion is suggestive of infection.

Organism: *Anaplasma* spp.
Diseases and species affected: *A. phagocytophilium* causes canine granulocytic anaplasmosis and infects neutrophils; *A. platys* causes canine cyclic thrombocytopenia and infects platelets; *A. marginale* causes tick fever in cattle and infects RBCs.
Preferred diagnostic tests: Complete blood count and visualization of the organisms in infected cells, serology, PCR.
Comments: Obligate intracellular pathogens, vector-borne infection.

Organism: *Bacillus* spp.
Diseases and species affected: *Bacillus anthracis* causes anthrax in domestic animals and human; *Bacillus cereus* and *Bacillus subtilis* are involved in wound infections, abortions, and food poisoning.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: *B. anthracis* can be presumptively diagnosed by detecting large rod-shaped bacteria with a capsule using the polychromatic methylene blue staining; anthrax is a reportable disease; zoonosis.

Organism: *Bartonella* spp.
Diseases and species affected: *Bartonella henslae* causes cat scratch fever in humans and a variety of nonspecific manifestations in cats, the reservoir host.
Preferred diagnostic tests: Peripheral blood smear evaluation, PCR, *Bartonella* culture, serology.
Comments: *Bartonella* spp. are host-adapted bacteria and are vector borne. They cause chronic and prolonged intraerythrocytic bacteremia; there are multiple species of *Bartonella* colonizing animals and their vectors.

Organism: *Bordetella bronchiseptica*
Diseases and species affected: Infectious tracheobronchitis in dogs and cats; atrophic rhinitis in swine.
Preferred diagnostic tests: Aerobic culture and PCR.
Comments: *B. bronchiseptica* is one of the pathogens involved in infectious respiratory disease complex in dogs.

Organism: *Borrelia* spp.
Diseases and species affected: There are many *Borrelia* species involved in Lyme disease and relapsing fevers in different host species.
Preferred diagnostic tests: Serology, PCR, *Borrelia* culture (rarely used).
Comments: Spirochete bacteria, vector-borne infection.

Organism: *Brachyspira hyodysentriae*
Diseases and species affected: Causes swine dysentery.
Preferred diagnostic tests: Anaerobic culture, PCR.
Comments: Spirochete bacteria.

Organism: *Brucella* spp.
Diseases and species affected: *Brucella abortus* (cattle), *Brucella melitensis* (sheep and goats), *Brucella suis* (pigs), *Brucella canis* (dogs) can cause reproductive tract and systemic diseases in various species of animals.
Preferred diagnostic tests: Serology, *Brucella* culture, PCR.
Comments: Reportable disease, zoonosis.

Organism: *Campylobacter* spp.
Diseases and species affected: *Campylobacter jejuni* is involved in enteric disease in animals. *C. fetus subsp. fetus* and *C. fetus subsp. venerealis* are involved in reproductive diseases in cattle, sheep, and goats.
Preferred diagnostic tests: Campylobacter culture, PCR.
Comments: *Campylobacter jejuni* is a major foodborne pathogen. They are microaerophilic and need specific specimen transport conditions.

Organism: *Chlamydia* spp.
Diseases and species affected: *C. abortus* causes ruminant abortion, *C. felis* causes pneumonia and conjunctivitis in cats, *C. psittaci* causes systemic disease in birds and is zoonotic.
Preferred diagnostic tests: Cytology (for the detection of inclusion bodies), PCR, isolations in cell culture.
Comments: Obligate intracellular bacteria, zoonosis.

Organism: *Clostridium* spp.
Diseases and species affected: *C. perfringens* and *C. difficile* are involved in enteric disease in animals. *C. chauvoei, C. novyi, C. septicum* cause myositis and systemic disease in food animals. *C. perfringens* is involved in enterotoxemia in animals. Several clostridial species are involved in abscess and wound infections. *C. tetani*, *C. botulinum* belong to a neurotoxic group.
Preferred diagnostic tests: Direct immunofluorescence testing, anaerobic culture, PCR, toxin screening.
Comments: The choice of diagnostic test is varied and depends on the condition of the animal species and infecting clostridial species.

Organism: *Corynebacterium* spp.
Diseases and species affected: *C. pseudotuberculosis* causes caseous lymphadenitis in sheep and goats, ulcerative lymphangitis in horses. *C. renale* group causes pyelonephritis in cattle. Numerous species can cause opportunistic infections.
Preferred diagnostic tests: Aerobic culture, PCR serology (synergetic hemolysin inhibition assay) to detect internal forms of disease.
Comments: Commensals in the skin and mucosa.

Organism: *Coxiella burnetii*
Diseases and species affected: Q fever, cattle, sheep, goats, dogs, cats.
Preferred diagnostic tests: PCR, serology, isolations in cell culture, serology using microimmunofluorescence tests (rarely performed).
Comments: Obligate intracellular bacteria, zoonosis.

Organism: *Dermatophilus congolensis*
Diseases and species affected: Skin infection in cattle, horses, and other mammals.
Preferred diagnostic tests: Cytology**,** aerobic culture, PCR.
Comments: Tram track-like appearance of bacteria in stained cytology preparations is diagnostic.
Organism: *Ehrlichia*
Diseases and species affected: *E. canis* causes canine monocytotropic ehrlichiosis, *E. ruminantium* causes heart water in ruminants.
Preferred diagnostic tests: Serology, PCR. *E. ruminantium* morula can be detected within the endothelial cells in stained brain squash preparations.
Comments: Obligate intracellular pathogen, vector-borne infection.

VetBooks.ir

Organism: *Escherichia coli*
Diseases and species affected: Enteric and systemic infections in all animals.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Pathogenicity varies with the virulence factors present. Presence or absence of a virulence factor can be screened through PCR.

Organism: *Francisella tularensis*
Diseases and species affected: Causes tularemia in dogs, cats, and other mammals.
Preferred diagnostic tests: Culture, PCR.
Comments: Tick-borne infection, zoonosis.

Organism: *Fusobacterium* spp.
Diseases and species affected: Causes abscess and wound infections in animals; *F. necrophorum* is involved in calf diphtheria, foot rot, and liver abscess in cattle.
Preferred diagnostic tests: Anaerobic culture, PCR.
Comments: Normal inhabitants of the mucosa.

Organism: *Helicobacter* spp.
Diseases and species affected: Multiple species of *Helicobacter* can cause gastric disease in animals. *H. hepaticus* and *H. bilis* are rodent pathogens.
Preferred diagnostic tests: PCR, *Helicobacter* culture.
Comments: *H. pylori* is involved in human gastric ulcers and neoplasms.

Organism: *Histophilus somni*
Diseases and species affected: Thromboembolic meningoencephalitis, pneumonia myocarditis, necrotic laryngitis in cattle.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Involved in shipping fever pneumonia complex in cattle.

Organism: *Leptospira* spp.
Diseases and species affected: multiple species/serovars cause systemic, renal, hepatic, and reproductive disease in animals.
Preferred diagnostic tests: Serology (microscopic agglutination test), PCR, direct fluorescent antibody staining.
Comments: Numerous serovars are maintained in kidneys of many mammalian hosts; zoonosis.

Organism: *Listeria monocytogenes*
Diseases and species affected: Febrile and systemic illness in monogastric animals, meningoencephalitis in ruminants.
Preferred diagnostic tests: *Listeria* enrichment culture, PCR.
Comments: Food safety pathogen; organism survives and grows under refrigeration conditions.

Organism: *Mannheimia hemolytica*
Diseases and species affected: Causes pneumonia in ruminants.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Involved in shipping fever pneumonia complex in cattle.

Organism: *Mycobacterium* spp.
Diseases and species affected: There are numerous pathogenic and saprophytic members in this group. *M. bovis* is a broad host range pathogen, causes tuberculosis in a variety of hosts. *M. avium subsp. paratuberculosis* causes chronic granulomatous enteritis (Johne's disease).
Preferred diagnostic tests: Test choice must be based on the suspected *Mycobacterium* spp.; for tuberculosis and paratuberculosis, specific cultures and PCRs are available; serology used for screening herds for paratuberculosis; mycobacterial culture or genus-specific PCR for other species; biopsy and acid-fast staining of the lesion.
Comments: Intradermal tests and interferon-gamma test available for screening herds for *M. bovis* infection.

Organism: *Mycoplasma* spp.
Diseases and species affected: Numerous species causing mainly respiratory diseases in animals and birds
Preferred diagnostic tests: *Mycoplasma* culture, PCR, serology.
Comments: Cell wall deficient bacteria.

Organism: *Nocardia* spp.
Diseases and species affected: Granulomatous inflammation of skin and internal organs, pleuritis, mastitis.
Preferred diagnostic tests: Biopsy and acid-fast staining, aerobic culture, PCR.
Comments: Sulfur granules may be present in the lesion, and the bacteria are partial acid-fast positive.

VetBooks.ir

Organism: *Pasteurella* spp.
Diseases and species affected: *Pasteurella multocida* causes hemorrhagic septicemia and pneumonia in cattle, pneumonia and atrophic rhinitis in pigs, and fowl cholera. Other *Pasteurella* species can cause respiratory infections and bite wound infections.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Opportunistic pathogens; *P. multocida* is a part of shipping fever pneumonia complex in cattle.

Organism: *Pseudomonas* spp.
Diseases and species affected: Multiple species involved in opportunistic infections of various body system. Major bacteria involved in canine otitis externa.
Preferred diagnostic tests: Aerobic culture.
Comments: Antibiotic resistance is common in this group.

Organism: *Rickettsia* spp.
Diseases and species affected: *R. rickettsia* causes Rocky Mountain spotted fever in dogs and cats.
Preferred diagnostic tests: Serology, PCR.
Comments: Vector-borne disease, infects endothelium, zoonosis.

Organism: *Rhodococcus equi*
Diseases and species affected: Causes foal pneumonia, ulcerative colitis, mesenteric lymphadenitis in horses.
Preferred diagnostic tests: Cytology of bronchoalveolar lavage fluid, aerobic culture, PCR.
Comments: Facultative intracellular bacteria.

Organism: *Staphylococcus* spp.
Diseases and species affected: Coagulase-positive species cause pyogenic infection of skin, bacteremia.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Commensals on the skin and mucous membranes, can infect multiple body systems.

Organism: *Streptococcus* spp.
Diseases and species affected: Many species cause pyogenic infection in a broad range of hosts; *S. equi subsp. equi* causes strangles in horses.
Preferred diagnostic tests: Aerobic culture, PCR.
Comments: Commensals of the mucous membranes, can infect multiple body systems.

Organism: *Salmonella* spp.
Diseases and species affected: Enteric and systemic infections in animals.
Preferred diagnostic tests: *Salmonella* culture, PCR.
Comments: There are host-adapted and host-specific (*S. gallinarum and S. pullorum*) species. A major food safety pathogen.

Organism: *Shigella* spp.
Diseases and species affected: Causes gastroenteritis in nonhuman primates.
Preferred diagnostic tests: *Shigella* culture, PCR.
Comments: Causes dysentery in humans.

Organism: *Trueperella pyogenes*
Diseases and species affected: *T. pyogenes* causes abscess in internal organs in cattle.
Preferred diagnostic tests: Aerobic culture and PCR.
Comments: A secondary invader in shipping fever pneumonia complex in cattle.

Organism: *Yersinia* spp.
Diseases and species affected: *Yersinia pestis* causes plague,
Y. enterocolitica and *Y. pseudotuberculosis* cause gastrointestinal infections.
Preferred diagnostic tests: *Yersinia* culture, PCR.
Comments: Plague is a vector-borne disease transmitted through rat fleas; zoonosis.

Vetbooks.ir

Fungus and fungus-like pathogens

Organism: *Aspergillus* spp.
Diseases and species affected: Rhinosinusitis, systemic infections in dogs and cats, abortion in cattle.
Preferred diagnostic tests: Cytology (presumptive), biopsy and histopathology, fungal culture, serology for antibody and antigen detection (galactomannan EIA, beta-D-glucan test).
Comments: *Aspergillus* spp. are saprophytic fungi ubiquitous in the environment. Disseminated aspergillosis occurs in dogs and cats.

Organism: *Blastomyces dermatitidis*
Diseases and species affected: *B. dermatitidis* causes systemic fungal infection with cutaneous manifestations (pyogranulomatous inflammation of skin and organs) in dogs, cats, horses, and humans.
Preferred diagnostic tests: Cytology, biopsy and histopathology, serology for antigen and antibody detection, fungal culture (not required).
Comments: Dimorphic fungus, environmental origin, large broad-based budding yeast in tissues, infections geographically restricted to Ohio and Mississippi River valley.

Organism: *Candida* spp.
Diseases and species affected: Local and systemic infections in animals, urinary tract infections in dogs and cats, thrush in birds.
Preferred diagnostic tests: Aerobic or fungal culture and PCR.
Comments: Commensals on the mucous membrane, antibiotic treatment predisposes animals to infection.

Organism: *Cryptococcus* spp.
Diseases and species affected: *Cryptococcus neoformans* and *C. gattii* cause chronic mycosis in dogs, cats, and rarely other animals. The most common systemic mycosis in cats.
Preferred diagnostic tests: Cytology, biopsy and histopathology, fungal culture, *Cryptococcus* latex agglutination test for antigen detection, PCR.
Comments: Environmental transmission; CNS infections are common in cats; a distinct mucopolysaccharide capsule that can be detected in wet smears stained with India ink.

Organism: *Coccidioides immitis*
Diseases and species affected: Pulmonary and disseminated coccidioidomycosis in animals.
Preferred diagnostic tests: Cytology, biopsy and histopathology, fungal culture, serology for antigen detection, PCR.
Comments: Dimorphic fungus, environmental transmission, geographically endemic in southwestern and western United States. Large spherules containing endospores can be detected in cytology or histopathology specimens.

Organism: Dermatophytes
Diseases and species affected: *Microsporum* and *Trichophyton* species cause ringworm in animals (dogs, cats, horses, cattle) and humans.
Preferred diagnostic tests: Direct examination for the detection of spores, dermatophyte culture, histopathology.
Comments: Zoonosis.

Organism: *Histoplasma capsulatum*
Diseases and species affected: Causes systemic fungal infection (pyogranulomatous inflammation of lungs and gastrointestinal tract and other organs) in dogs, cats, horses, and humans.
Preferred diagnostic tests: Cytology, biopsy and histopathology, serology, fungal culture (not required).
Comments: Dimorphic fungus, environmental transmission, small intracytoplasmic yeast cells in macrophages by cytology or histopathology.

Organism: *Malassezia* spp.
Diseases and species affected: Causes dermatitis, otitis externa in dogs.
Preferred diagnostic tests: Cytology, culture (fungal and aerobic).
Comments: Yeast cells with characteristic morphology can be observed in cytology; some species require special media to grow.

Organism: *Prototheca* spp.
Diseases and species affected: *P. wickerhamii* and *P. zopfii* cause cutaneous, gastrointestinal, CNS, eye, and rarely disseminated infections in dogs and cats and mastitis in cattle.
Preferred diagnostic tests: Cytology, biopsy and histopathology, aerobic and fungal culture, PCR.
Comments: A saprophytic achlorophyllus algae.

Organism: *Sporothix schenckii*
Diseases and species affected: Cutaneous, lymphocutaneous, and rarely systemic disease is seen in dogs and cats.
Preferred diagnostic tests: Cytology, biopsy and histopathology, fungal culture.
Comments: Dimorphic fungus, small cigar-shaped yeast cells are observed in direct smear examination.
Organism: Zygomycets
Diseases and species affected: This group of fungi (*Rhizopus, Absidia, Mucur, Conidiobolus, Basidiobolus*) can cause systemic and subcutaneous infection in dogs and cats and abortion in cattle.
Preferred diagnostic tests: Biopsy and histopathology, fungal culture.
Comments: Saprophytic fast-growing contaminant; careful interpretation of laboratory results is needed.

Vetbooks.ir

Viral pathogens

Organism: Adenoviridae
Diseases and species affected: Canine adenovirus 1 causes infectious canine hepatitis in young dogs, canine adenovirus 2 causes respiratory disease.
Preferred diagnostic tests: PCR, direct fluorescent antibody staining, virus isolation, serology (IgM detection), electron microscopy.
Comments: DNA virus; intranuclear inclusion bodies in affected cells can be detected on histopathology evaluation of lesions.

Organism: Arteriviridae
Diseases and species affected: Equine arteritis virus (EAV) infection in horses causes systemic disease, arteritis, and pneumonia(foals); porcine reproductive and respiratory syndrome (PRRS) virus causes reproductive and respiratory disease in swine.
Preferred diagnostic tests: RT-PCR, virus isolations, serology (virus neutralization assays, ELISA).
Comments: Enveloped RNA virus, may cause asymptomatic infections.

Organism: Bunyaviridae
Diseases and species affected: Akabane virus causes congenital disorders in animals, Rift Valley fever virus causes systemic disease and abortion in animals.
Preferred diagnostic tests: Serology, RT-PCR, virus isolation.
Comments: RNA virus, arbovirus (vector-borne virus).

Organism: Circoviridae
Diseases and species affected: Porcine circovirus 2 (PCV 2) is associated with postweaning multisystemic wasting syndrome in pigs; psittacine beak and feather disease virus causes a debilitating disease in psittacine birds; chicken anemia virus causes acute immunosuppressive disease in young chicken.
Preferred diagnostic tests: Histopathology, PCR.
Comments: Nonenveloped DNA virus, presence of intracytoplasmic botryoid inclusions in the lesions on histopathology.

Organism: Calciviridae
Diseases and species affected: Feline calicivirus is a major cause of feline respiratory disease; rabbit hemorrhagic disease virus causes hemorrhagic disease with high mortality in lagomorphs.
Preferred diagnostic tests: RT-PCR, direct immunofluorescence assay, virus isolation, electron microscopy.
Comments: Nonenveloped RNA virus.

Organism: Coronaviridae
Diseases and species affected: Transmissible gastroenteritis virus (TGEV) causes gastroenteritis in pigs; feline infectious peritonitis virus (FIPV) causes multisystemic disease in cats; avian infectious bronchitis virus causes tracheobronchitis in poultry.
Preferred diagnostic tests: FIPV, serology (antibody titers), histopathology, RT-PCR; TGEV direct immunofluorescence, antigen capture ELISA, RT-PCR.
Comments: Enveloped RNA virus; members of this family are many and can cause enteric and respiratory disease in animals.

Organism: Flaviviridae
Diseases and species affected: Bovine viral diarrhea virus (BVDV) causes a respiratory, gastrointestinal, and reproductive disease in cattle; border disease virus causes congenital defects in sheep; classical swine fever virus causes systemic disease in swine; West Nile virus (WNV) causes neurologic disease in animals and humans.
Preferred diagnostic tests: BVDV antigen capture ELISA and ear notch immunohistochemistry for the detection of persistently infected animals, serum neutralization assay, RT-PCR, ELISA for routine testing. WNV infection is diagnosed by IgM ELISA
RT-PCR, virus neutralization assay.
Comments: Many members are vector borne and zoonotic.

Organism: Herpesviridae
Diseases and species affected: Canine herpesvirus causes systemic disease in neonatal puppies with hemorrhage and necrosis of various organs, respiratory disease in adults. Bovine herpesvirus 1, equine herpesvirus 1, and porcine herpesvirus 1 can cause respiratory, reproductive, or neurologic disease in their hosts; alcelaphine herpesvirus causes malignant catarrhal fever.
Preferred diagnostic tests: PCR, direct fluorescent antibody staining, virus isolation, serology (IgM detection).
Comments: DNA virus, intranuclear inclusion bodies in affected cells can be detected on cytology or histopathology evaluation.

Organism: Orthomyxoviridae
Diseases and species affected: Influenza virus (equine influenza virus, swine influenza virus, avian influenza virus, and canine influenza virus) causes respiratory illness in the respective host species.
Preferred diagnostic tests: RT-PCR, virus isolation, serology (hemagglutination inhibition assay, ELISA, AGID).
Comments: Enveloped RNA virus, zoonosis.

Vetbooks.ir

Organism: Paramyxoviridae
Diseases and species affected: Parainfluenza virus in animals causes respiratory illness; avian paramyxovirus 1 (APMV1) causes Newcastle disease, a severe multisystemic including CNS disease in birds; canine distemper virus (CDV) causes multisystemic and neurologic disease in dogs.
Preferred diagnostic tests: APMV1-RT-PCR, serology (ELISA, hemagglutination inhibition); CDV-RT-PCR, direct fluorescent antibody staining, virus isolation, serology (IgM detection).
Comments: Enveloped RNA virus. There are several members in this group that cause respiratory and neurologic disease in animals. Intracytoplasmic and intranuclear inclusion bodies in affected cells can be detected on cytology or histopathology evaluation.

Organism: Papillomaviridae
Diseases and species affected: Causes papilloma in animal hosts (bovine papilloma, canine papilloma, equine papilloma).
Preferred diagnostic tests: PCR, electron microscopy.
Comments: Nonenveloped DNA virus. Papilloma virus causes preneoplastic and neoplastic conditions and is generally host specific.
Organism: Picornaviridae
Diseases and species affected: Foot and mouth disease virus (FMDV) causes a contagious vesicular disease, encephalomyocarditis virus cause encephalomyelitis and myocarditis in swine and elephants.
Preferred diagnostic tests: RT-PCR, virus isolation.
Comments: Nonenveloped RNA virus. There are several other members of the family causing respiratory and gastrointestinal diseases.

Organism: Polyomaviridae
Diseases and species affected: Avian polyomavirus causes budgerigar fledgling disease. Simian polyomavirus (SV40) causes CNS disorders in immunocompromised nonhuman primates.
Preferred diagnostic tests: PCR, electron microscopy.
Comments: Nonenveloped DNA virus. Large glassy, intranuclear inclusion bodies are typical in histopathology lesions.

Organism: Poxviridae
Diseases and species affected: Several species-specific pox viruses cause pox in animal species, general systemic disease, or local infections.
Preferred diagnostic tests: PCR, electron microscopy, virus isolation.
Comments: DNA virus enveloped, intracytoplasmic inclusions in affected epithelium.

Organism: Parvoviridae
Diseases and species affected: Canine parvovirus 2 generalized disease and enteritis in puppies; feline panleukopenia virus causes generalized illness and congenital lesions in cats. Porcine parvovirus causes reproductive disease and abortion in pigs.
Preferred diagnostic tests: PCR, electron microscopy, virus isolation, serology (hemagglutination inhibition assay).
Comments: Nonenveloped DNA virus, intranuclear inclusion bodies are typical in histopathology lesions.

Organism: Reoviridae
Diseases and species affected: Members of the orbivirus group, bluetongue virus (BTV), African horse sickness, and epizootic hemorrhagic disease virus can cause multisystemic disease in animals.
Preferred diagnostic tests: RT-PCR and serology (ELISA).
Comments: RNA virus, arbovirus (vector borne).

Organism: Rhabdoviridae
Diseases and species affected: Rabies virus cause rabies in animals and humans; bovine ephemeral fever virus causes febrile illness in cattle; vesicular stomatitis virus (VSV0) causes vesicular disease in cattle, pigs, and horses.
Preferred diagnostic tests: Postmortem diagnostics for rabies virus include histopathology, direct immunofluorescence, RT-PCR.
Comments: Enveloped RNA virus. VSV can be confused with foot and mouth disease so laboratory confirmation is essential.

Organism: Retroviridae
Diseases and species affected: Numerous species-specific (mammalian and avian) members. Feline leukemia virus (FeLV), feline immunodeficiency virus, bovine leukemia virus (BLV), caprine arthritis and encephalitis virus, visna-maedi virus.
Preferred diagnostic tests: Depending on the virus and the animal species affected, tests for antibody and antigen screening are available.
Comments: Retroviral genome integrates into the host genome.

Organism: Togaviridae
Diseases and species affected: Eastern equine encephalitis, Western equine encephalitis, Venezuelan equine encephalitis cause neurologic disease in equines, humans, and other animals.
Preferred diagnostic tests: RT-PCR, serology (IgM ELISA, serum virus neutralization, hemagglutination inhibition), virus isolation.
Comments: RNA virus, arbovirus (vector borne).

Vetbooks.ir

Parasitic infections

Organism: *Babesia* spp.
Diseases and species affected: Causes babesiosis characterized by hemolytic anemia in dogs, cattle, horses, and other mammals.
Preferred diagnostic tests: Blood smear examination, serology, PCR.
Comments: Protozoan parasite, vector borne, infects erythrocytes.

Organism: *Cytauxzoon felis*
Diseases and species affected: Cytauxzoonosis a nonspecific acute illness with broad manifestations in cats.
Preferred diagnostic tests: Peripheral blood smears, followed by PCR confirmation.
Comments: Protozoan parasite, vector borne (ingestion of infected ticks), infects erythrocytes and macrophages.

Organism: *Cryptosporidium* spp.
Diseases and species affected: *C. parvum* causes gastroenteric illness in a variety of animal species.
Preferred diagnostic tests: Acid-fast staining, fecal floatation, direct immunofluorescence assay, PCR.
Comments: Protozoan parasite, zoonosis.

Organism: *Hepatozoan* spp.
Diseases and species affected: *H. canis* and *H. americanum* cause asymptomatic to debilitating illness in dogs.
Preferred diagnostic tests: Peripheral blood smear evaluation, biopsy and histopathology of affected muscles, serology, PCR.
Comments: Protozoan parasite, vector borne, infects neutrophils and macrophages, myositis is a common lesion.

Organism: *Leishmania* spp.
Diseases and species affected: *L. infantum*, the main cause of canine and human leishmaniasis, causes cutaneous and visceral lesions (granulomatous inflammation) in dogs, humans, and other animals.
Preferred diagnostic tests: Cytology, biopsy and histopathology, serology, PCR.
Comments: Protozoan parasite, vector borne.

Organism: *Toxoplasma gondii*
Diseases and species affected: Multisystemic disease in animals; cats are reservoirs; abortion in sheep and pigs.
Preferred diagnostic tests: Serology (antibody detection), histopathology, PCR.
Comments: Zoonotic disease.

Organism: *Trypanosoma* spp.
Diseases and species affected: A variety of domestic and wild animals are affected. *T. cruzi* causes American trypanosomiasis (Chagas disease). *T. congolensis*, *T. vivax* cause African trypanosomiasis in domestic and wild animals.
Preferred diagnostic tests: Peripheral blood smear evaluation, serology, PCR.
Comments: Protozoan parasite, vector borne, zoonotic.

6 Erythrocyte Production, Function, and Morphology

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Erythrocyte production

Erythrocytes are primarily produced in the bone marrow (see Chapter 15) by a process called erythropoiesis, which is regulated by an oxygen-sensing mechanism. Erythropoietin, a cytokine produced in the kidney, is produced in response to low blood oxygen tension. Erythropoietin then binds to erythropoietin receptors on erythrocyte precursor cells; receptor activation then signals various pathways that allow the precursors to differentiate into mature erythrocytes (see Chapter 10). The maturation process includes cell divisions, decreased cell size, loss of organelles and, in mammals, loss of the nucleus, development of a membrane that is capable of moving through the microcirculation, and production and accumulation of hemoglobin for oxygen transport.

Erythrocyte function

The primary function of the erythrocyte is to transport hemoglobin, which carries oxygen from the lungs to the tissues to support oxidative metabolism. Hemoglobin is made of alpha- and beta-globin molecules associated with a heme molecule that contains an iron atom (Fe) in the reduced state. One coordination site on Fe binds reversibly with oxygen. A wide range of animals, vertebrate and invertebrate, use hemoglobins to transport oxygen. Comparative studies of hemoglobin are numerous, and differences exist between hemoglobins of mammalian species.

Erythrocyte morphology

The deformable, permeable membrane that encloses the red-cell components is made of lipids including phospholipids, cholesterol, and glycolipids, proteins, and carbohydrates. Alterations in the lipid or protein composition of the membrane may result in abnormal red-cell shapes. Membrane proteins form the cytoskeleton of the membrane and are attached to the cytoplasmic surface of the membrane. These proteins play key roles in maintaining both cell shape and integrity and have been named according to their relative location from the place of migration when solubilized and subjected to electrophoresis. Bands 1 and 2 (i.e., spectrin) and band 5 (i.e., actin), protein 4.1, paladin, and ankyrin are the major cytoskeletal proteins. The protein skeleton is coupled to the lipid membrane by ankyrin, which binds to band 3, and is strengthened by band 4.2. Proteins that are embedded in and span the lipid membrane are called integral proteins, and they play a role in tethering the protein skeleton to the lipid membrane. The anion bicarbonate/chloride exchanger band 3 is the most abundant protein in the erythrocyte membrane. It plays a role in gas exchange and maintaining erythrocyte hydration and also has a structural role by binding the lipid component of the membrane with ankyrin and protein band 4.2, 4.1, and other proteins. Even after shearing, the structure of the membrane can remain intact, resulting in erythrocyte fragments. Glycophorins are sialoglycoproteins that span the erythrocyte membrane and help prevent erythrocyte to erythrocyte and erythrocyte to endothelial cell association.

Normal erythrocyte morphology varies among different species (Figure 6.1). Mammalian erythrocytes are anucleate, unlike those of all other vertebrates, which have nuclei. Erythrocytes are round and somewhat biconcave in most mammalian species, except in members of the family Camellidae (e.g., llamas, camels, and alpacas), which have elliptical (oval) erythrocytes. The biconcavity causes stained red blood cells to appear to have a central, pale area, because the observer is looking through less hemoglobin in this area of the cell. This central pallor is most apparent in canine erythrocytes. Species with smaller erythrocytes, such as the cat, horse, cow, sheep, and goat, have less concavity and, thus, little to no central pallor. The biconcave disc shape is

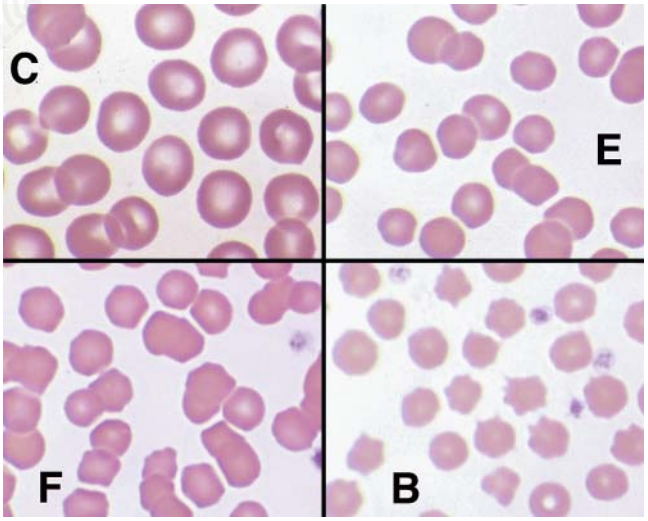

Figure 6.1 Normal canine (C), equine (E), feline (F), and bovine (B) erythrocytes. Note the larger size and marked central pallor of the canine erythrocytes compared to those of the other species. Wright stain.

efficient for oxygen exchange, and it allows the cell to be deformable as it moves through vasculature with a smaller diameter than that of the erythrocyte. Briefly, the significant differences between species are size, shape, amount of central pallor, tendency to form rouleaux, presence of basophilic stippling in regenerative response to anemia, and the presence of reticulocytes in response to anemia (Table 6.1).

Erythrocyte morphology often is an important aid in establishing a diagnosis regarding the cause of anemia, and it sometimes is helpful in establishing the diagnosis of other disorders as well. Critical to blood cell evaluation is adequate preparation of a blood film (see Chapter 1). The observer should examine the leukocyte counting area to evaluate erythrocyte morphology, because the red blood cells are neither too dense nor too flattened in this area. The interpretation of red-blood-cell morphology should be made in conjunction with other quantitative data from the complete blood count. For example, the degree of polychromasia in erythrocytes usually is more significant when the red-cell mass is decreased.

This chapter concentrates primarily on those morphologic characteristics that are most diagnostically useful. Morphology of erythrocytes is categorized here according to color, size, shape, structures in or on the erythrocytes, and the arrangement of cells on blood films.

Erythrocyte color

Polychromasia

Polychromatophilic cells are young erythrocytes that have been released early. Usually, they are large and more blue in color than mature erythrocytes (Figure 6.2). The blue color results from organelles (i.e., ribosomes, mitochondria) that are still present in the immature cells. The presence or absence of polychromatophilic erythrocytes is very important when determining the cause of anemia. If immature cells are released, the likely cause of the anemia is blood loss or blood destruction, with the bone marrow attempting to compensate by the early release of cells (see Chapter 9). If the anemia is caused by erythroid hypoplasia or aplasia within the marrow, then the level of polychromatophilic cells will not be increased (see Chapter 8). Horses are unique, however, in that they do not release significant numbers of polychromatophilic cells in the face of anemia.

The degree of polychromasia correlates well with the reticulocyte concentration, but it is more objective to quantify the regenerative response by counting reticulocytes (see Chapter 1). The reticulocyte is analogous to the polychromatophilic erythrocyte, but it is stained with a vital stain (e.g., new methylene blue or brilliant cresyl blue), which causes the ribosomes and other organelles to clump into visible granules (see Figure 1.18).

Hypochromasia

Hypochromic red blood cells are pale and have increased central pallor as a result of decreased hemoglobin concentration

Table 6.1 Significant differences in erythrocytes between species.

Species	Diameter (μm)	Rouleaux	Central pallor	Basophilic stippling	Reticulocytes (%)[a]	MCV (fl)
Dog	7.0	+	++++	–	1	60–72
Pig	6.0	++	±	–	1	50–68
Cat	5.8	++	+	±	0.5	39–50
Horse	7	++++	–	–	0[b]	36–52
Cow	5.5	–	+	+++	0	37–53
Sheep	4.5	±	+	+++	0	23–48
Goat	3.2	–	–	++	0	15–30

[a]With normal packed cell volume.
[b]Does not increase in response to anemia.

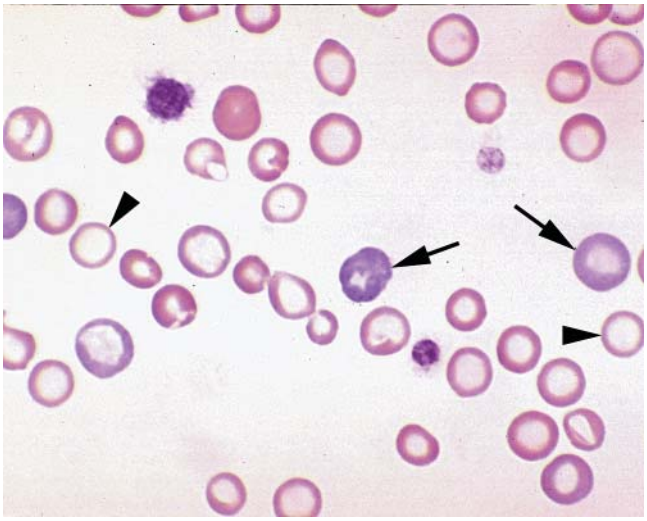

Figure 6.2 Blood film from a dog with iron-deficiency anemia. Note the lack of density of the blood film, suggesting marked anemia. Most of the erythrocytes are small and hypochromic (arrowheads). The anemia is regenerative, and numerous polychromatophilic erythrocytes are present (arrows). Wright stain.

from iron deficiency (Figure 6.2). Erythrocytes of iron-deficient dogs have more obvious hypochromasia than erythrocytes of other species with iron deficiency; erythrocytes of iron-deficient cats usually are not hypochromic. One needs to distinguish hypochromic cells from bowl-shaped (i.e., torocytes) or "punched-out" cells, which are insignificant (Figure 6.3). Bowl-shaped cells have a sharply defined, central clear area, and they also have a thicker rim of hemoglobin than is seen in true hypochromic cells. Immature polychromatophilic erythrocytes also may appear to be hypochromic, because their hemoglobin concentration is less than normal due to their increased volume. Although hyperchromic states do not exist, spherocytes appear to have increased color intensity because of their lack of concavity.

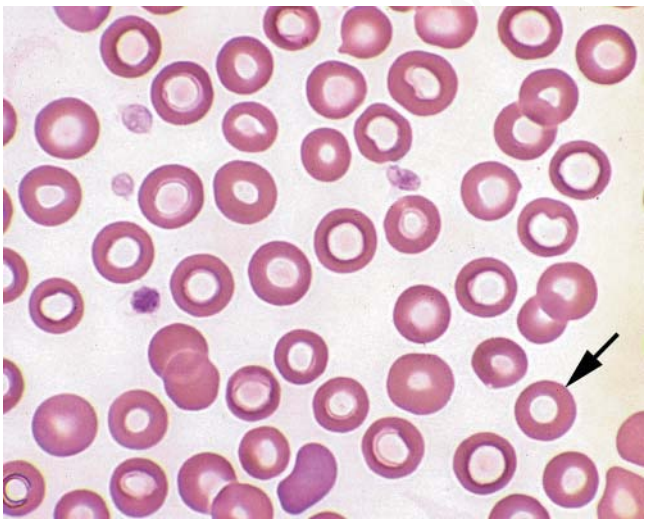

Figure 6.3 Blood film from a dog showing numerous torocytes ("punched-out" erythrocytes). Note the wide rim of hemoglobin and lack of hemoglobinization in the center of the cells (arrow). Torocytes can be mistaken for true hypochromasia. Wright stain.

Erythrocyte size

Variation in erythrocyte size is termed anisocytosis. This variation may result from the presence of large cells (i.e., macrocytes), small cells (i.e., microcytes), or both. In itself, the term does not provide any meaningful information. Red blood cells may appear to be small on the blood film because of decreased diameter, but the cell volume is the true measurement of red-cell size and is determined electronically (see Chapter 1). The best example of this is the spherocyte, which appears to be small because of its spheric shape and subsequent decreased diameter; however, the red-cell volume of spherocytes is almost always within the reference interval. Conversely, hypochromic microcytic iron-deficient red blood cells with an electronically determined decreased volume may have a normal diameter and, thus, not appear to be small on the blood film.

Microcytic erythrocytes

Cells must be markedly small before their decreased diameter can be visually detected (Figure 6.2). Mean corpuscular volume (MCV) is more valuable than blood film examination in assessing the true size of erythrocytes. Using automated cell-counting systems, a histogram or volume–distribution curve of the erythrocyte population can be generated. Mean cell volume is determined by analysis of the volume–distribution curve, and the hematocrit is then calculated by multiplying the MCV by the erythrocyte concentration (see Chapter 1). The most common cause of microcytosis is iron-deficiency anemia; a decreased MCV is the hallmark of such anemia. In some iron-deficient patients, the MCV may be normal even though the animal has a microcytic population of cells. In these cases, examination of the volume–distribution curve is helpful (see Chapter 1). The pathophysiology of the microcytosis is theorized to involve erythroid precursors continuing to divide until a near-normal complement of hemoglobin concentration is reached, resulting in small erythrocytes. Cells cannot obtain a normal hemoglobin concentration because iron is required to make hemoglobin. If the iron deficiency is severe, microcytosis and hypochromia may be observed on the blood film. In addition, membrane defects are present, which often lead to specific abnormalities in shape and fragmentation (discussed below).

Dogs and cats with portocaval shunts (portosystemic vascular anomalies) may have microcytosis that usually is related to abnormal iron metabolism. Many of these animals, especially cats, are not anemic; microcytosis without

anemia should trigger evaluation for a portosystemic shunt. Some breeds of dogs (e.g., Akitas and Shiba Inus) and cats (Abyssinian) may have smaller erythrocytes. Microcytosis, usually mild, can also be seen with other causes of iron-restricted hematopoiesis, such as anemia of inflammatory disease. Mild microcytosis has been reported in approximately 25% of cats with hyperthyroidism; the cause is unknown but may be due to iron-restricted hematopoiesis.

Excessive ethylenediaminetetraacetic acid (EDTA) in a blood sample can result in erythrocyte dehydration, shrinkage, and spurious microcytosis. Hyponatremia can also result in *in vitro* microcytosis with certain instruments as a result of erythrocyte shrinkage when put into the diluent; these erythrocytes had previously adjusted *in vivo* to being in a hyponatremic environment by increasing cytoplasmic water. Storing blood at room temperature for more than 24 hours before analysis may result in a falsely increased MCV, thus masking microcytosis caused by iron deficiency or portosystemic shunts.

Macrocytic erythrocytes

Macrocytic erythrocytes are large and have an increased MCV (see Figure 1.18, bottom). The most common cause of macrocytosis is increased numbers of immature erythrocytes that are polychromatophilic on Wright-stained blood films. Unlike other domestic species, horses release macrocytes that are not polychromatophilic. The associated increase in MCV usually is the only evidence of erythroid regeneration in horses. During regeneration, species other than dogs tend to produce regenerative macrocytes that are approximately twice the size of normal erythrocytes, resulting in a marked change in the MCV. Dogs, however, release macrocytes that usually are only slightly larger than normal erythrocytes. Macrocytosis without polychromasia or other evidence of an appropriate regenerative response is a common finding in anemic cats with myelodysplasia and myeloproliferative disease (see Chapter 16). This macrocytosis may be associated with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infection, and it also may be seen in FeLV-infected cats that are not anemic.

Other, more infrequent causes of macrocytosis include macrocytosis of miniature and toy poodles and hereditary stomatocytosis. Macrocytosis of miniature or toy poodles is rare, is thought to be hereditary, and is usually an incidental finding. Affected dogs are not anemic, but their erythrocyte count may be decreased. The MCV is usually 90–100 fL. Other findings include increased nucleated erythrocytes, increased Howell-Jolly bodies (often multiple), and hypersegmented neutrophils. Numerous abnormalities are seen in erythroid precursors on bone marrow film examination, including megaloblasts with nuclear and cytoplasmic asynchrony of maturation. The cause of the defect is unknown, and no clinical signs are associated with the disorder. Finally, stomatocytes in Alaskan malamutes and miniature schnauzers with hereditary stomatocytosis are macrocytic (discussed later).

Some anticonvulsant drugs, such as phenobarbital, phenytoin, and primidone, have been thought to induce macrocytosis, but macrocytosis was not experimentally reproduced in dogs receiving long-term anticonvulsant drugs. Vitamin B_{12} (i.e., cobalamin) and folate deficiency do not cause macrocytosis in domestic animals, but these deficiencies are a common cause of macrocytosis in humans. Giant schnauzers with hereditary cobalamin malabsorption are anemic, but this anemia is normocytic rather than macrocytic. Inherited cobalamin deficiency has also been reported in border collies and beagles and is commonly seen in animals with chronic enteropathies.

Spurious macrocytosis can be a result of erythrocyte swelling associated with storing blood at room temperature prior to analysis. Falsely increased MCV can also be seen in blood with agglutinated erythrocytes in patients with immune mediated hemolytic anemia when analyzed with an impedance-type analyzer, because agglutinated cells (doublets and triplets) may be recognized as one large cell. Agglutination can be recognized by examining the erythrocyte histogram. Hypernatremia results in erythrocytes being dehydrated *in vivo*, and with certain types of electronic cell counters, a spurious increase in MCV will be seen due to erythrocyte swelling *in vitro* after being placed in the diluent.

Erythrocyte shape

Abnormally shaped erythrocytes are termed poikilocytes. This terminology is not helpful, however, because it does not suggest a specific change in shape. Thus, no specific interpretation is possible. The most important shape changes include various types of spiculated erythrocytes, spherocytes, and eccentrocytes. Spiculated erythrocytes have one or more surface spicules and include echinocytes, acanthocytes, keratocytes, and schistocytes. One should be as specific as possible when describing shape changes, because certain types of abnormal red-cell shapes are associated with certain diseases. Less significant abnormally shaped red blood cells include leptocytes (i.e., folded or target cells), codocytes (i.e., target cells), dacryocytes (i.e., teardrop-shaped erythrocytes), and torocytes (i.e., bowl-shaped erythrocytes).

A few inherited abnormalities associated with red-cell shape change have been described in animals and include hereditary stomatocytosis in dogs, hereditary elliptocytosis resulting from band 4.1 deficiency in dogs reported in 1983, and more recently in a dog, elliptocytosis caused by a mutation in beta-spectrin was reported. Hereditary spherocytosis has been reported in Japanese black cattle resulting from band 3 deficiency and has also been reported in mice. Heriditary spherocytosis in people is usually a result of a spectrin defect. Hereditary spectrin deficiency has been reported in Dutch golden retrievers, and some of these dogs had spherocytosis and hemolytic anemia.

Most inherited abnormalities of red blood cell shape are associated with abnormalities of cytoskeletal protein, or plasma or red-cell membrane cholesterol or phospholipid concentration. Hereditary high potassium and reduced glutathione concentrations in erythrocytes of some dogs of certain Asian breeds (e.g., Akita, Shiba, and Jindo) lead to greater susceptibility to onion-induced oxidative damage.

Hemoglobinopathies have not yet been described in domestic animals, although they are reported frequently in humans. A relatively common hemoglobinopathy in humans is sickle cell anemia, which results from a single amino acid substitute in the adult beta-globin protein. Sickle cells (drepanocytes) from numerous deer species as well as some sheep and goat breeds have been reported, as shown in Figure 9.18. They were first described in 1840 and occur when the blood comes into contact with atmospheric oxygen or an alkaline pH. Most authors believe deer erythrocyte sickling is exclusively an *in vitro* shape change, and the sickling does not cause any pathologic traits.

Schistocytes and keratocytes

Erythrocyte fragments, also termed schistocytes, usually result from shearing of the red cell by intravascular trauma. This may be observed in animals with disseminated intravascular coagulopathy (DIC) as a result of erythrocytes being broken by fibrin strands, with vascular neoplasms (e.g., hemangiosarcoma), and with iron deficiency. Animals with DIC also may have a concurrent thrombocytopenia (Figure 6.4). When erythrocyte fragments are observed in blood films from dogs with hemangiosarcoma, acanthocytes usually are present as well. Fragmentation in iron-deficient erythrocytes apparently results from oxidative injury, leading to membrane lesions or increased susceptibility to intravascular trauma. Iron-deficient erythrocytes initially develop an apparent blister or vacuole, which is thought to represent an oxidative injury and in which inner membrane surfaces are cross-linked across the cell. Exclusion of hemoglobin may account for the colorless area. These lesions subsequently enlarge and break open to form cells with one or more spicules. When one spicule is present, these cells are commonly termed apple-stem cells; when two or more spicules are present, they are termed keratocytes (Figure 6.5). The projections from the keratocytes then fragment from the erythrocytes, thereby forming schistocytes.

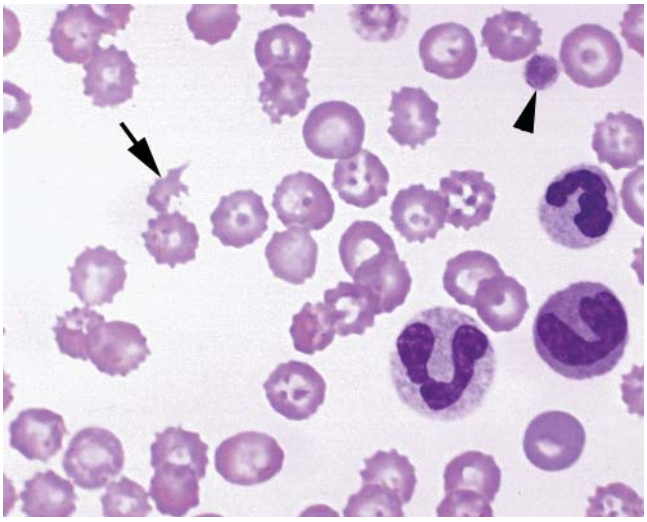

Figure 6.4 Blood film from a dog with splenic hemangiosarcoma and disseminated intravascular coagulopathy. Note the schistocyte (arrow) and single platelet in the field (arrowhead). Wright stain.

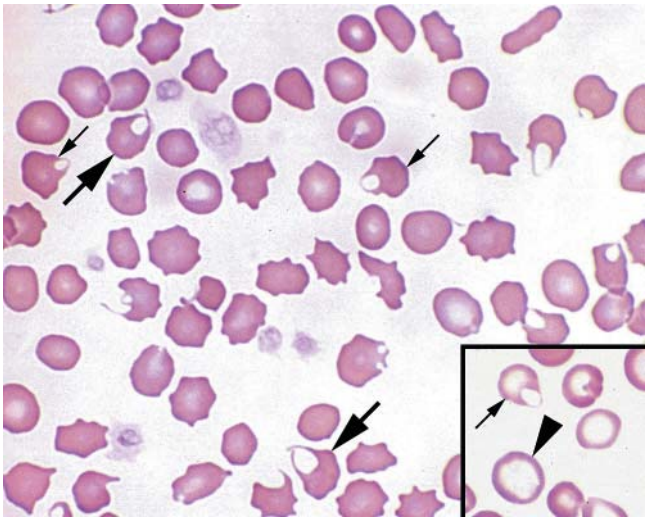

Figure 6.5 Blood film from a cat with iron-deficiency anemia. Note the erythrocyte membrane abnormalities. Lack of hypochromasia is typical for feline iron-deficient erythrocytes. Blister cells (small arrows) and keratocytes (large arrows) also are present. Inset. Blood film from an iron-deficient dog. Note the blister cell (small arrow) and hypochromic erythrocyte (arrowhead). Wright stain.

Acanthocytes

Acanthocytes, or spur cells, are irregular, spiculated erythrocytes with few, unevenly distributed surface projections of variable length and diameter (Figure 6.6). Acanthocytes occur through two mechanisms. They may result from changes in cholesterol or phospholipid concentrations in the red-cell membrane and commonly are seen on blood films from humans with altered lipid metabolism, such as may occur with liver disease; they are occasionally observed on blood films from dogs with liver disease. Acanthocytes, however, are commonly observed on blood films from cats with hepatic lipidosis. Approximately 25% of cats with hyperthryoidism were reported to have acanthocytes on the blood films.

They are also associated with mechanical injury such as may result from vascular trauma and are seen in approximately 25% of dogs with hemangiosarcoma. Although the

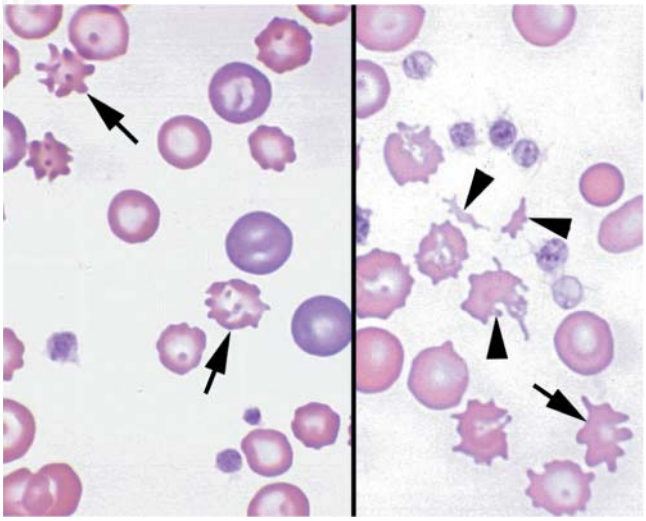

Figure 6.6 Blood film from an anemic dog with a ruptured hemangiosarcoma of the spleen. Left. Numerous acanthocytes are present (arrows). Note the large polychromatophilic cells in the same field, indicating that the anemia is regenerative. Right. Acanthocytes (arrow) and schistocytes (arrowheads) are typical findings in dogs with hemangiosarcoma. Wright stain.

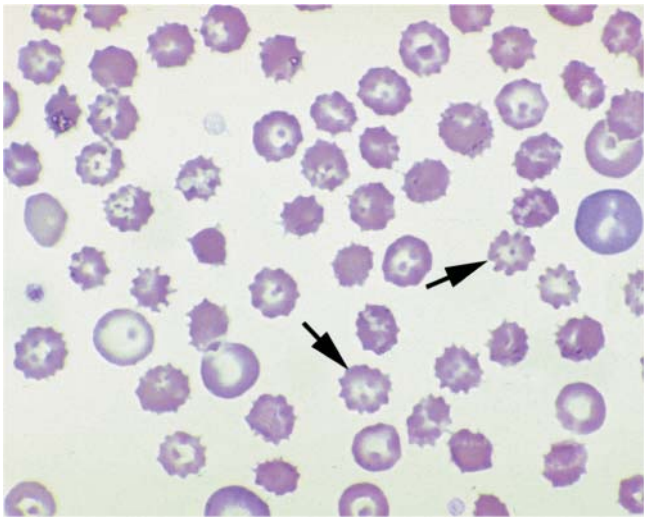

Figure 6.7 Blood film from a dog with lymphoma. Numerous echinocytes are present (arrows). Wright stain.

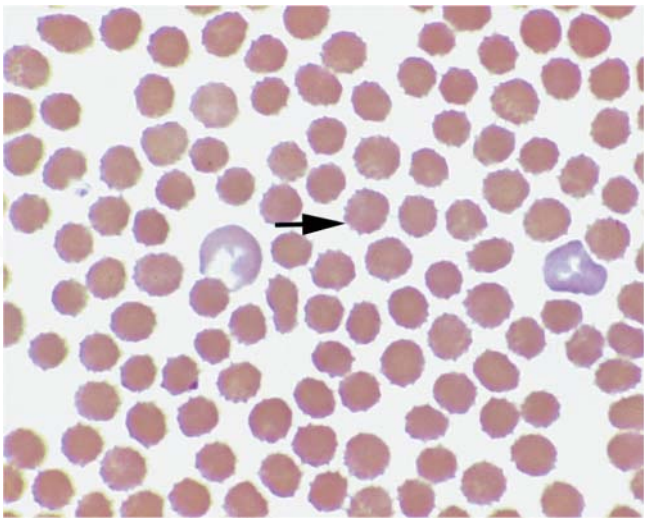

Figure 6.8 Blood film from a dog that was bitten by a rattlesnake approximately 24 hours previously. Almost all of the erythrocytes are echinospherocytes (arrow). Note that the polychromatophilic erythrocytes are not affected. Wright stain.

presence of acanthocytes in middle-aged to old large-breed dogs with a concurrent regenerative anemia may be suggestive of hemangiosarcoma, acanthocytes may also be observed in dogs with other types of neoplastic disease such as osteosarcoma and lymphoma, and they are also seen on blood films from dogs with non-neoplastic diseases including gastrointestinal, musculoskeletal, renal, immune-mediated disorders, DIC, and iron-deficiency anemia.

Echinocytes

Echinocytes (i.e., burr cells) are spiculated cells with numerous short, evenly spaced, blunt to sharp surface projections that are quite uniform in size and shape (Figure 6.7). Echinocyte formation can be an artifactual result (i.e., crenation) of a change in pH from slow drying of blood films, but it also has been associated with renal disease, lymphoma, snake envenomation, and chemotherapy in dogs and after exercise in horses. The echinocytes seen with snake envenomation are termed type 3 echinocytes, and they are quite characteristic, with numerous very fine spicules on all erythrocytes, except in cells that are polychromatophilic (Figure 6.8). In some instances of rattlesnake and bee envenomation, spheroechinocytes are formed. These erythrocytes appear to be spherocytes with fine spicules, usually present from 24 to 48 hours after envenomation, and are a reliable indication that envenomation has occurred.

Elliptocytes

Elliptocytes (ovalocytes) are elliptical or oval erythrocytes. Elliptocytosis is normal in members of the camel family, but in other mammals is either a hereditary (Figure 6.9) or acquired defect. Acquired elliptocytosis has been reported in dogs with myelofibrosis and myelodysplastic syndromes, in cats with portosystemic shunts and liver disease, and in cats that were given doxorubicin.

Spherocytes

Spherocytes are darkly staining erythrocytes that lack central pallor (Figure 6.10). They appear to be small, but their volume is normal. Spherocytes are not easily detected in species other than dogs because of the small size and lack of central pallor in the normal erythrocytes of most other domestic

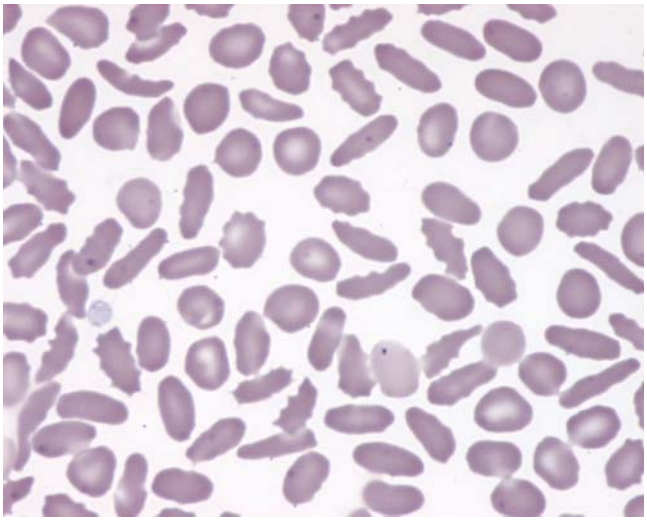

Figure 6.9 Blood film from a dog with elliptocytosis caused by a mutant beta-spectrin. Wright stain. Source: Courtesy of Drs. Melinda Wilkerson, Roberta Di Terlizzi, Steve Stockham, and Karen Dolce, Kansas State University.

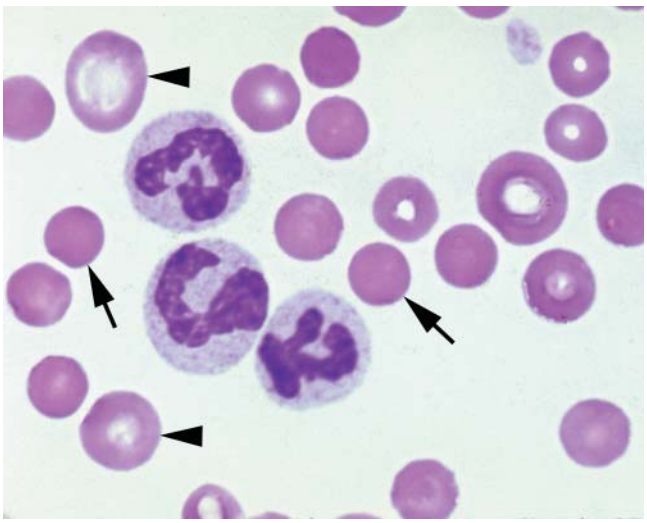

Figure 6.10 Blood film from dog with immune-mediated hemolytic anemia. Note the numerous spherocytes (arrows). The anemia is regenerative, as indicated by the polychromatophilic erythrocytes (arrowheads). Wright stain.

animals. Spherocytes have a reduced amount of membrane as a result of partial phagocytosis, which occurs because antibody or complement is on the surface of the erythrocyte. Spherocytes are very significant, in that their presence suggests immune-mediated hemolytic anemia (see Chapter 9). They also, however, may be seen after blood transfusion with mismatched blood.

Spherocyte formation has been reported in dogs with bee and snake envenomation and zinc toxicosis, and zinc toxicosis also may cause Heinz-body anemia. The mechanism of spherocyte formation with bee and snake envenomation

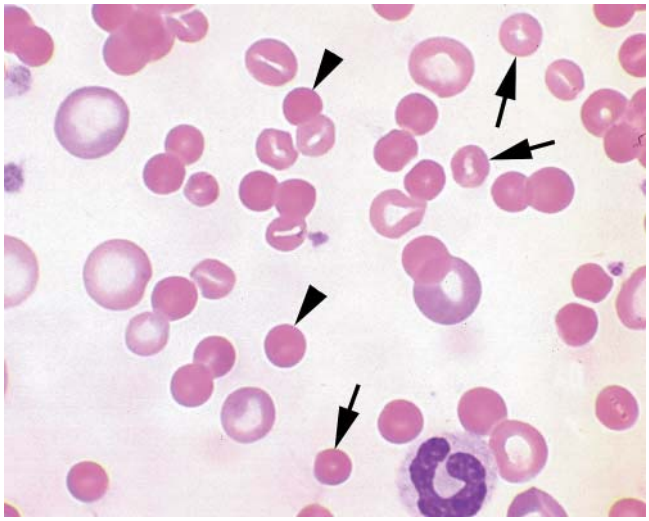

Figure 6.11 Blood film from a dog with immune-mediated hemolytic anemia. Many of the erythrocytes are spherocytes (arrowheads), and several incomplete spheres are present (arrows). Wright stain.

is a result of venom-containing enzymes and proteins. Melittin in bee venom induces pore formation in erythrocyte membranes, binds and stiffens spectrin, and stimulates phospholipase. Phospholipase A2 in bee and snake venom is an enzyme that alters phospholipid in the erythrocyte membrane.

Sometimes, a small amount of central pallor will remain in a spherocyte, and it then is termed an incomplete spherocyte (Figure 6.11). These spherocytes likely represent a continuum of membrane removal that finally results in a complete sphere.

Eccentrocytes

Features of eccentrocytes include shifting of hemoglobin toward one side of the cell, loss of normal central pallor, and a clear zone outlined by a membrane (Figure 6.12). They are associated with oxidative damage, especially in dogs that have ingested onions and other *Allium* family plants, and may be found in conjunction with Heinz bodies (discussed later). Eccentrocytosis and hemolytic anemia in horses have been associated with the ingestion of wilted red maple leaves and wilted leaves of trees of the *Pistacia* species. Animals with an inherited erythrocyte enzyme deficiency, glucose-6-phosphate dehydrogenase deficiency, may show increased susceptibility to oxidant-induced erythrocyte injury, resulting in eccentrocyte formation or increased incidence of Heinz bodies.

Leptocytes and codocytes

Leptocytes are erythrocytes that have undergone a surface-to-volume ratio change in which there is excess membrane relative to the internal contents, resulting in membrane folding and target-cell formation (Figure 6.13). They have

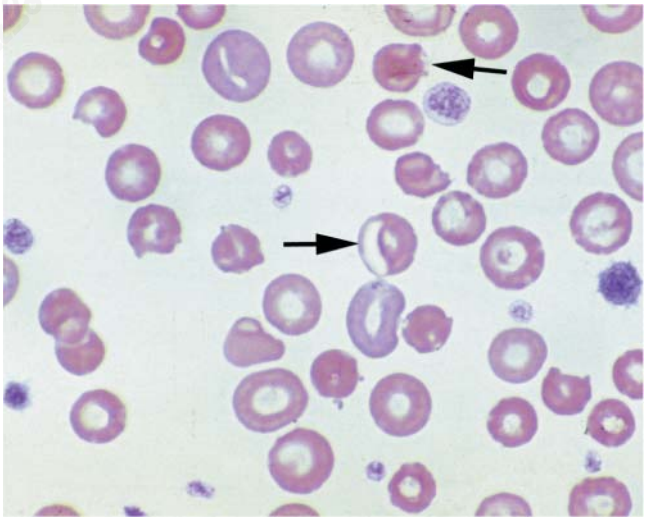

Figure 6.12 Blood film from a dog with Heinz-body anemia after ingestion of onions. Eccentrocytes are present (arrows). Wright stain.

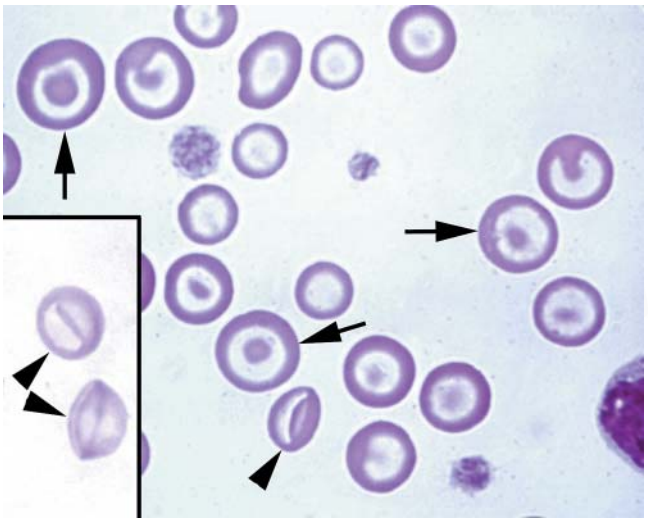

Figure 6.13 Blood film from a dog with numerous leptocytes. Note the numerous target cells (arrows) and folded cells (arrowheads). Wright stain.

little diagnostic significance, however, and may form *in vitro* secondary to contact with excess EDTA as a result of improperly filling the blood-collection tubes. Target cells also are referred to as codocytes and are thin, bowl-shaped erythrocytes with a dense, central area of hemoglobin that is separated from the peripheral hemoglobinized region by a pale zone. Target cells may be seen in dogs with increased serum cholesterol concentration, but they also are seen in a variety of other conditions and have little significance.

Stomatocytes

Stomatocytes are uniconcave erythrocytes with a mouth-like, clear area near the cell center (Figure 6.14). A few stomatocytes on the blood film usually are insignificant.

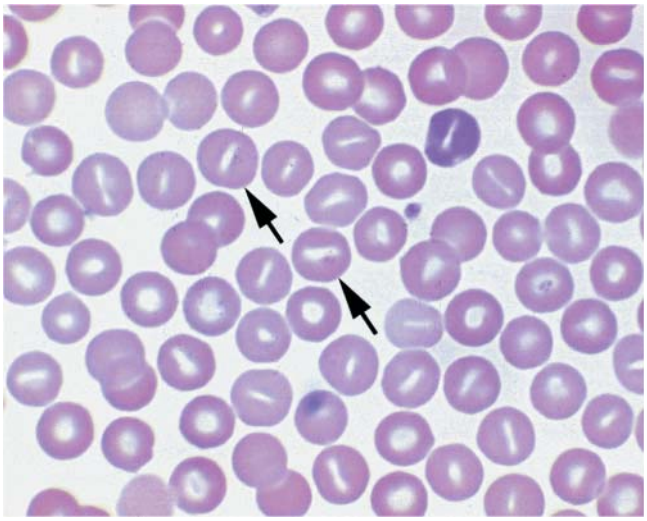

Figure 6.14 Blood film from a miniature schnauzer mix breed dog with hereditary spherocytosis. Note the numerous slit or mouth-shaped clear areas in the stomatocytes (arrows). Wright stain.

Hereditary stomatocytosis has been reported in several dog breeds, including Alaskan malamutes, miniature schnauzers, standard schnauzers, and the Drentse partrijshond. All of the disorders are inherited in an autosomal-recessive manner, but stomatocyte formation is caused by different defects in different breeds, involving either cell membranes or regulation of cell volume. Alaskan malamutes with hereditary stomatocytosis also have chondrodysplasia, and only a small percentage of the erythrocytes are stomatocytes. These stomatocytes are thought to form secondary to a membrane defect that allows increased sodium and water content of erythrocytes. Drentse partrijshond dogs with stomatocytosis also have hypertrophic gastritis, retarded growth, diarrhea, renal cysts, and polyneuropathy, and in this breed, the erythrocyte defect is thought to result from an abnormal concentration of phospholipids in the erythrocyte membrane. Miniature and standard schnauzers with stomatocytosis are asymptomatic; the cause of the erythrocyte defect in these breeds has not been described.

Structures in or on erythrocytes

Heinz bodies

Oxidative denaturation of hemoglobin results in Heinz body formation. Approximately 1–2% of erythrocytes from normal cats contain Heinz bodies, presumably because of an unusual propensity for hemoglobin denaturation due to feline hemoglobin molecules containing at least twice the number of reactive cysteine sulfhydryl groups as are in hemoglobin molecules of other species. Heinz bodies appear as small, eccentric, pale structures within the red cell, and they commonly seem to protrude slightly from the red-cell margin on Wright-stained blood films (Figure 6.14). Heinz bodies usually are 0.5–1.0 μm in diameter but may

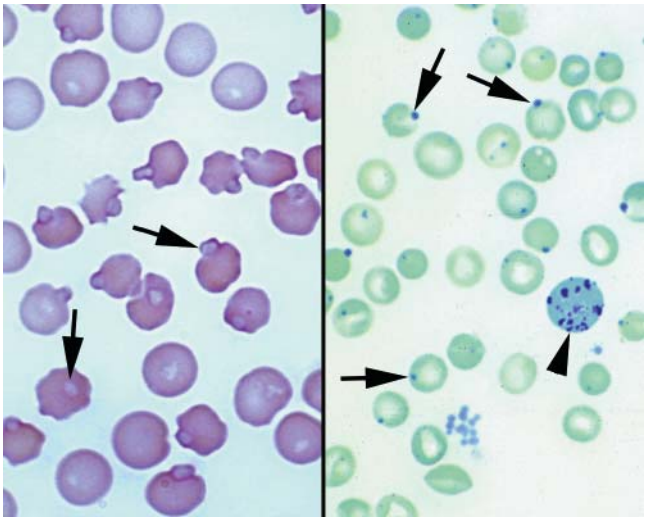

Figure 6.15 Blood films from a cat with acetaminophen toxicosis. Left. Heinz bodies appear as pale, light-blue structures (arrows). Wright stain. Right. Heinz bodies appear as blue structures (arrows). Note the reticulocyte (arrowhead). Brilliant cresyl blue stain.

be larger. They usually occur as single, large structures in feline erythrocytes, but in canine erythrocytes, they more commonly are small and multiple. Heinz bodies are difficult to see on Wright-stained blood films, particularly with canine erythrocytes, in which eccentrocyte formation may be more apparent. When stained with vital stains (e.g., new methylene blue or brilliant cresyl blue), Heinz bodies appear as blue structures (Figure 6.15). The presence of Heinz bodies reduces the deformability of the cell, making it more susceptible to both intravascular and extravascular hemolysis, and in some instances may change the antigenicity of the red cell membrane, resulting in immune mediated destruction. If large numbers of erythrocytes are affected, severe hemolytic anemia may result. Oxidative drugs and compounds known to induce Heinz-body formation include onions, garlic, leeks, chives, *Brassica* species of plants, wilted or dried leaves from red maple (*Acer rubrum*), benzocaine, zinc, copper, acetaminophen, propofol, phenazopyridine, phenothiazine, phenylhydrazine, naphthalene, vitamin K, methylene blue, propylene glycol, and skunk musk. Ill cats may develop a high concentration of Heinz bodies without being exposed to oxidant chemicals or drugs. The most common disorders associated with an increased concentration of Heinz bodies in cats are diabetes mellitus, lymphoma, and hyperthyroidism, but increased concentrations also may be seen in association with a wide variety of other diseases (see Chapter 9). The presence of Heinz bodies may result in falsely increased hemoglobin concentration readings, and subsequently an abnormally high mean corpuscular hemoglobin concentration (MCHC), as well as other spurious findings, such as leukocytosis and abnormal automated reticulocyte counts that have been observed with flow-based automated cell counters.

Basophilic stippling

In vivo aggregation of ribosomes into small basophilic granules is termed basophilic stippling (Figure 6.15). Normally, basophilic stippling is associated with immature erythrocytes in ruminants, and it may be seen to a lesser extent in cats and dogs with intensely regenerative anemia. Basophilic stippling not associated with severe anemia is suggestive of lead poisoning, but not all animals with lead poisoning have basophilic stippling. The enzyme pyrimidine 5′-nucleotidase, which is present in reticulocytes, normally catabolizes ribosomes; the activity of this enzyme is reduced in lead toxicosis and normally is low in ruminants.

Nucleated erythrocytes

Increased numbers of erythrocytes in which the nucleus remains (Figure 6.16) are associated with regenerative anemias and early release of these cells in response to hypoxia. Increased concentrations of nucleated erythrocytes also may be seen in animals with a nonfunctioning spleen and with increased levels of endogenous or exogenous corticosteroids. An increase in nucleated erythrocytes out of proportion to the degree of anemia frequently is associated with lead poisoning, but not all animals with lead poisoning have increased nucleated erythrocytes. In cats, the presence of nucleated erythrocytes in the absence of significant polychromasia is usually an indication of myelodysplasia or myeloproliferative disease.

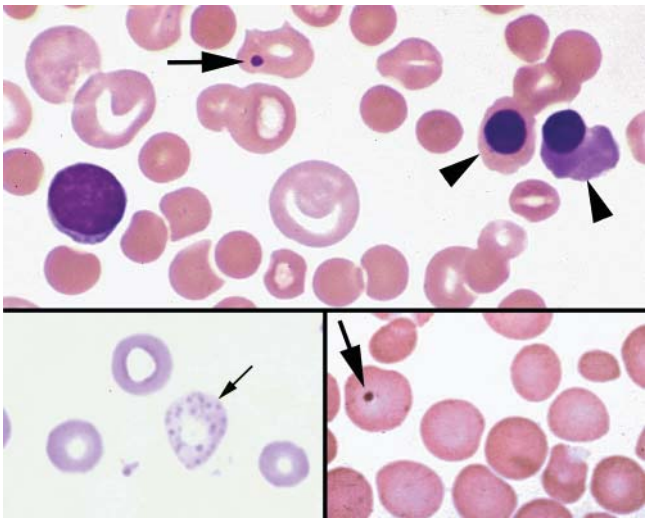

Figure 6.16 Top. Blood film from dog with immune-mediated hemolytic anemia. The anemia is very regenerative, and polychromatophilic erythrocytes, nucleated erythrocytes (arrowheads), and a Howell-Jolly body (arrow) are present. Note that the nucleated erythrocytes (metarubricytes) have variably colored cytoplasm. The one on the left has mature cytoplasm, whereas the one on the right has polychromatophilic cytoplasm. Lower right. A nuclear remnant, or Howell-Jolly body, is indicated by the arrow. Lower left. Basophilic stippling (small arrow) in a blood film from a dog with lead poisoning. Wright stain.

Howell-Jolly bodies

Nuclear remnants in erythrocytes are termed Howell-Jolly bodies. An increased concentration of Howell-Jolly bodies is associated with regenerative anemia, splenectomy, and suppressed splenic function. These bodies are small, round, dark-blue inclusions of variable size (Figure 6.16).

Siderotic granules

Siderotic granules are stainable iron granules within mitochondria and lysosomes. These siderotic inclusions are also referred to as Pappenheimer bodies, and their presence is thought to be associated with impaired heme synthesis. Erythrocytes containing these inclusions are termed siderocytes (Figure 6.17). Siderocytes in domestic animals are rare, but they have been associated with chloramphenicol therapy, myelodysplasia, and ineffective erythropoiesis of unknown cause.

Parasites

Erythrocyte parasites are discussed in more detail in Chapter 9. Spherocyte formation and agglutination may be observed on blood films from animals with erythrocyte parasites, because the organisms induce an immune-mediated anemia.

The primary parasitic disease of feline erythrocytes is infection with *Mycoplasma haemofelis* (Figure 6.18), which is a hemotropic mycoplasma organism that is the causative agent of feline infectious anemia. These organisms are attached to the external erythrocyte membrane and appear as rod-shaped organisms on the periphery of the erythrocyte or as a delicate, basophilic ring on the cell. A less common erythrocyte parasite in cats is the protozoan *Cytauxzoon felis*, which appears as a ring (diameter, 0.5–1.5 µm) and contains a small, basophilic nucleus (Figure 6.19).

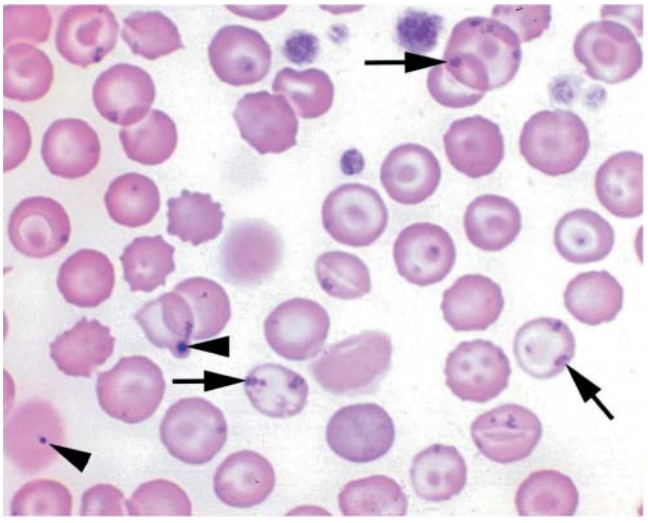

Figure 6.17 Blood film from a dog. Numerous erythrocytes (siderocytes) containing siderotic granules are present (arrows). Note the Howell-Jolly bodies (arrowheads). Wright stain.

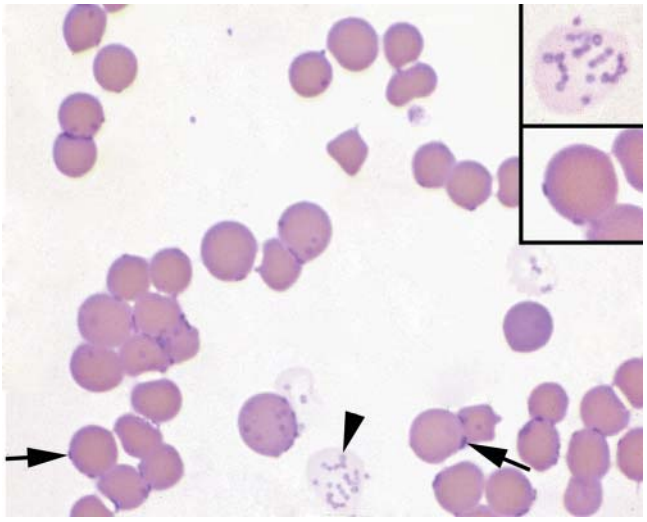

Figure 6.18 Blood film from an anemic cat. Note the numerous *Mycoplasma haemofelis* organisms. Some of these appear as small, ring-shaped organisms on the surface of a "ghost" erythrocyte that has lysed (arrowhead). Others appear as rod-shaped structures on the edge of erythrocytes (arrows). Insets. Higher magnification of both the ring and the rod-shaped forms. Wright stain.

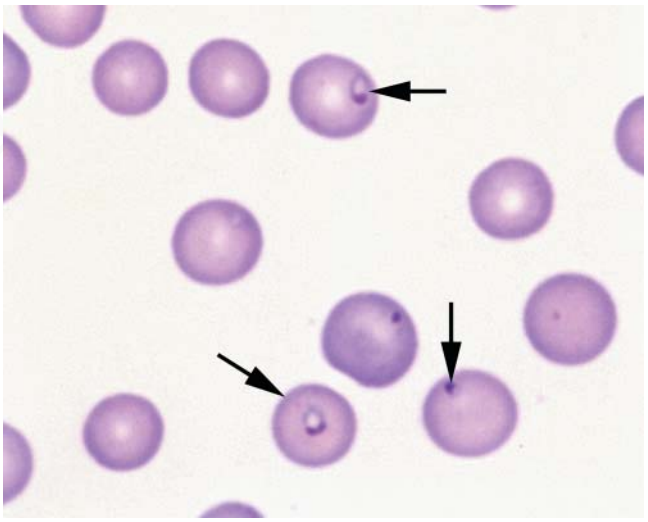

Figure 6.19 Blood film from a cat with *Cytauxzoon* organisms (arrows). Wright stain.

In dogs, erythrocyte parasites are rare in most parts of the United States. *Mycoplasma haemocanis* usually only occurs in dogs that have been splenectomized or that have nonfunctional spleens. The organisms appear as small dots that chain across the surface of the erythrocyte (Figure 6.20). *Babesia canis*, *Babesia vogeli*, and *Babesia gibsoni* are protozoal red-cell parasites in the dog that produce severe hemolytic anemia. Usually, *B. canis*, and *B. vogeli* appear as a

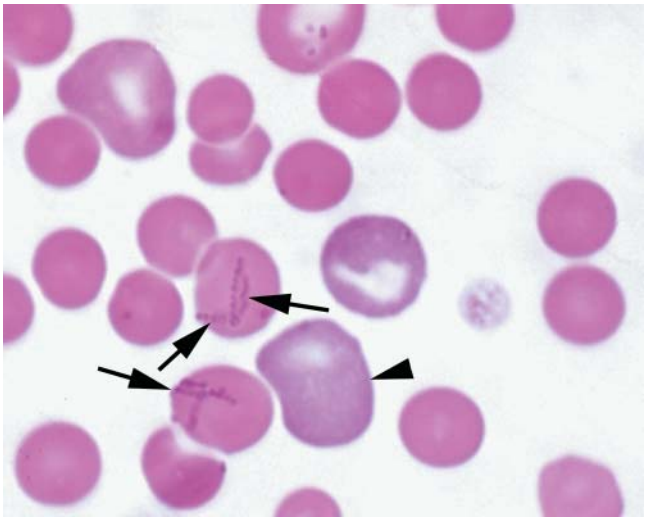

Figure 6.20 Blood film from a splenectomized dog with *Mycoplasma hemocanis*. Note the dot-like organisms that chain across the surface of the erythrocyte (arrows). The anemia is regenerative, as indicated by the polychromatophilic cell (arrowhead). Wright stain.

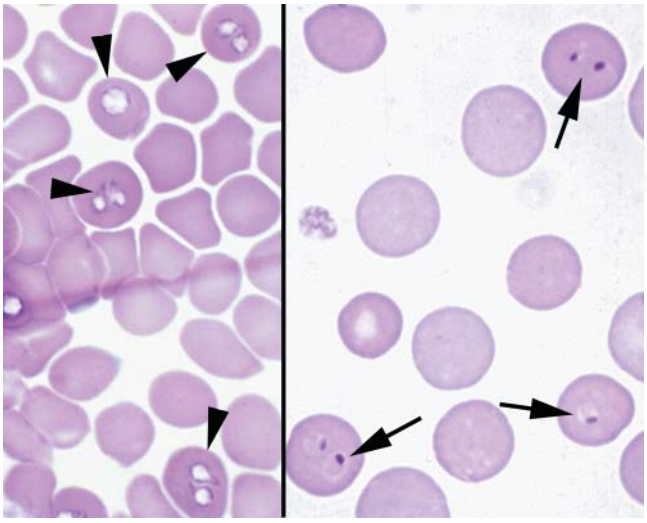

Figure 6.21 Blood film from dogs with babesiosis. Left. *Babesia canis* organisms appear as poorly staining, teardrop-shaped structures (arrowheads). Right. Blood film from a dog with *Babesia gibsoni* (arrows). Wright stain.

teardrop-shaped structure (Figure 6.20, left), but *B. gibsoni* is smaller and varies considerably in both size and shape (Figure 6.21, right). Other examples of erythrocyte parasites include, *Mycoplasma wenyoni* (Figure 6.22), and *Anaplasma* sp. (Figure 6.23).

Viral inclusions

Viral inclusions are occasionally seen in erythrocytes from dogs with distemper. Distemper inclusions, also sometimes referred to as Lentz bodies, are variable in size (~1.0–2.0 µm), number, and color (faint blue to magenta) and are more

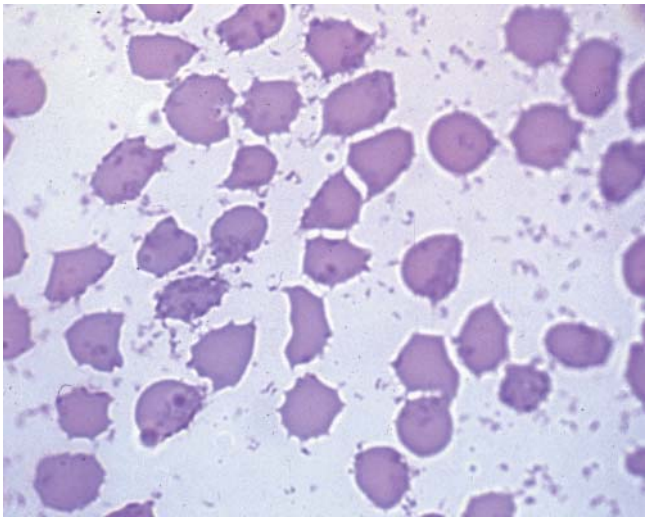

Figure 6.22 Blood film from a cow with *Mycoplasma wenyoni*. Note the many free organisms in the plasma. Wright stain.

frequently seen in polychromatophilic erythrocytes (Figure 6.24). Staining is typically more intense when using one of the quick Romanowsky stains.

Erythrocyte arrangement on blood films

Rouleaux formation

Rouleaux formation is the spontaneous association of erythrocytes in linear stacks, and its appearance is similar to a stack of coins (Figure 6.25). Marked rouleaux formation is normal in horses, a moderate amount is normal in cats, and a slight amount is normal in dogs. Rouleaux formation is enhanced, however, when the concentration of plasma proteins such as fibrinogen or immunoglobulins is increased.

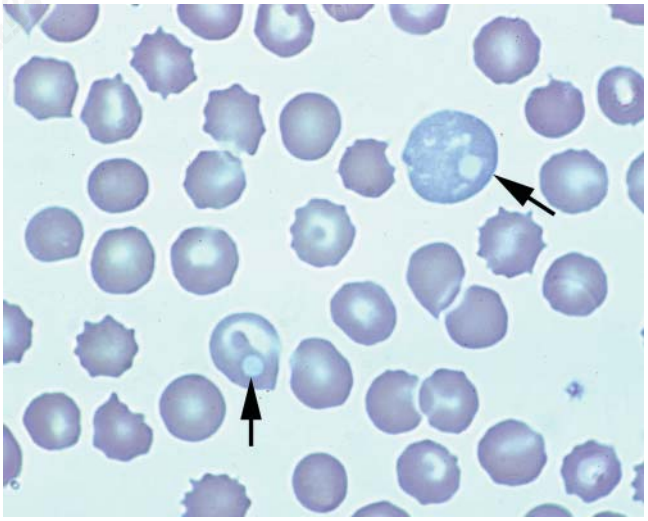

Figure 6.24 Blood film from a dog with distemper. Note the pale-blue viral inclusions of distemper with the erythrocytes (arrows). These inclusions may stain pale blue to dark magenta in color. Wright stain.

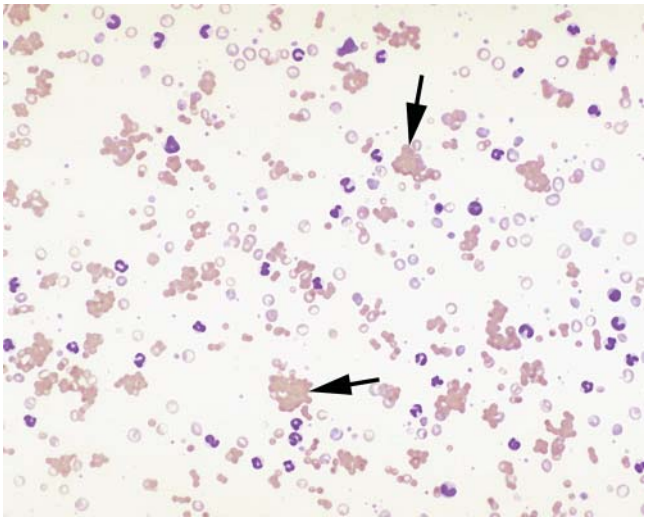

Figure 6.26 Blood film from an anemic dog with immune-mediated hemolytic anemia and marked agglutination. Note the large aggregates of spherocytes (arrows). Wright stain, low magnification.

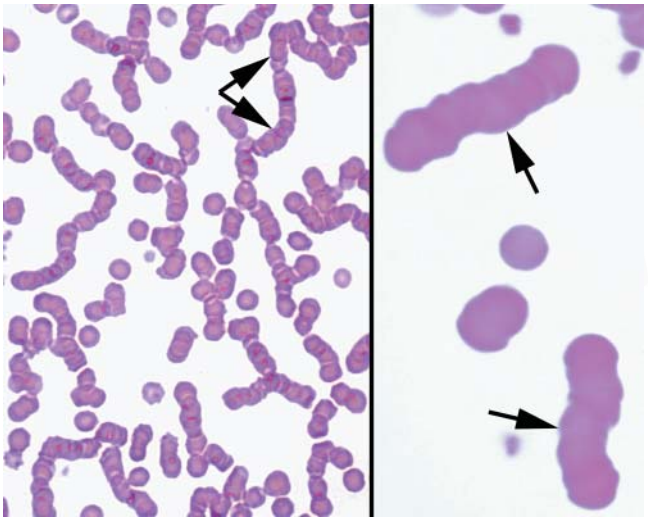

Figure 6.25 Blood film from a normal horse, illustrating rouleaux formation (arrows). Wright stain.

Increased rouleaux formation often is suggestive of a gammopathy; animals with multiple myeloma and canine ehrlichiosis almost always have increased rouleaux formation.

Agglutination

Agglutination of erythrocytes results in irregular, spheric clumps of cells because of antibody-related bridging (Figure 6.26). Agglutination is very suggestive of immune-mediated hemolytic anemia, but it also may be seen after a mismatched blood transfusion. To confirm that agglutination is present, mix several drops of isotonic saline with a drop of blood. This procedure is commonly referred to as a saline agglutination test. The recommended procedure of mixing one drop of saline with one drop of blood often results in false positives, especially if rouleaux is marked. Agglutination will persist in the presence of saline (Figure 6.26, left), whereas rouleaux formation will disperse. Agglutination may be so marked that it can be seen grossly on blood films and on the side of EDTA tubes (Figure 6.27, right). Agglutination may result in a falsely increased MCV and a falsely decreased red-blood-cell count, because agglutinated red cells (i.e., doublets and triplets) may be counted as large cells (see Chapter 1).

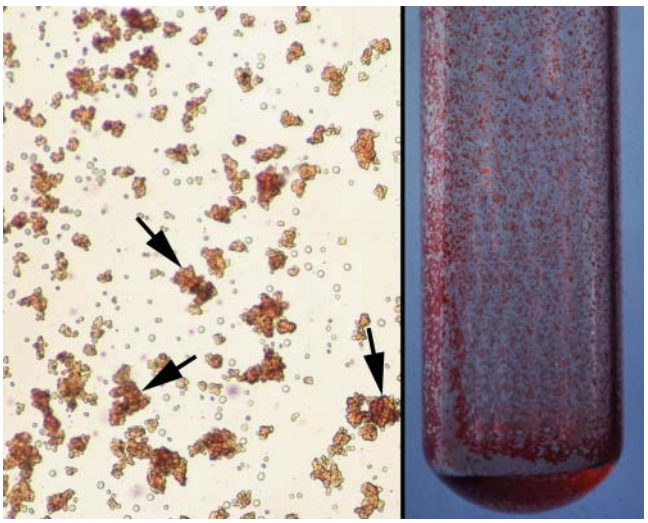

Figure 6.27 Blood from a dog with immune-mediated hemolytic anemia. Left. Blood has been mixed with isotonic saline, and agglutination persists (arrows). Right. Agglutination is so severe that it can be visualized grossly on the side of the EDTA blood-collection tube.

Erythroid dysplasia and neoplasia

Dysplasia and leukemia of red blood cells is covered in more detail in Chapter 16. Briefly, erythroid dysplasia, which is commonly seen in cats associated with FeLV, is characterized by a nonregenerative anemia in conjunction with macrocytosis and megaloblastic erythroid precursors, in which there is advanced cell hemoglobinization with incomplete nuclear maturation. Red-cell leukemia (M6) is relatively rare in dogs, but in cats, it usually is associated with FeLV. In these patients, an increased concentration of quite immature nucleated erythrocytes typically is present in the face of a severe, nonregenerative anemia (see Chapter 16).

CHAPTER 7

7 Classification of and Diagnostic Approach to Anemia

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Anemia is a decrease in the red blood cell (RBC) mass that results in decreased oxygenation of tissues. The RBC mass is determined by measuring the packed cell volume (PCV; i.e., hematocrit), the amount of hemoglobin in the blood, and the erythrocyte count (see Chapter 1). Of these three, PCV is used most commonly as the primary value for interpretation in North America, although when the hematocrit is calculated by automated cell counters, hemoglobin concentration is more accurate.

Anemia is a manifestation of an underlying disease that has produced increased erythrocyte destruction, increased erythrocyte loss through hemorrhage, decreased production of erythrocytes, or some combination of these events. Clinical signs usually relate to decreased oxygenation or associated compensatory mechanisms and may include pale mucous membranes, lethargy, reduced exercise tolerance, increased respiratory rate or dyspnea, increased heart rate, and murmurs caused by increased blood turbulence. Nonspecific clinical signs, such as weight loss, anorexia, fever, or lymphadenopathy, may be present if the animal has an underlying systemic illness. Specific clinical signs that are associated with blood destruction may include splenomegaly, icterus, and darkly pigmented urine resulting from hemoglobinuria or bilirubinuria.

The severity of clinical signs usually relates to the duration of onset, because animals with a slow onset, resulting from chronic blood loss or bone marrow dysfunction, usually compensate to some extent for the hypoxemia. Compensatory mechanisms include increased concentration of erythrocyte 2,3-diphosphoglycerate, which decreases the oxygen–hemoglobin affinity and, thus, enhances the delivery of oxygen to tissues, increases cardiac output, and aids in the redistribution of blood flow to vital organs. Death may occur in animals that experience severe acute blood loss or blood destruction. Appropriate therapy and prognosis is facilitated by determining whether the anemia is a result of erythrocyte destruction, blood loss, or lack of erythrocyte production, followed by establishing the diagnosis of the underlying disease. This chapter addresses the classification of and diagnostic approach to anemia.

Classification of anemia

Three general schemes are used to classify anemia: erythrocyte size and hemoglobin concentration, bone marrow response, and classification by pathophysiologic mechanism. The classification by erythrocyte size and bone marrow response are the most useful for clinical purposes, because they are tools that allow veterinarians to follow a mental pathway to a differential diagnosis. The pathophysiologic classification merely provides a conceptual framework for a diagnostic library of disorders that cause anemia.

Erythrocyte size and hemoglobin concentration

Traditionally, anemia has been classified by erythrocyte volume (i.e., mean cell volume [MCV]) and the amount of hemoglobin within erythrocytes (i.e., mean corpuscular hemoglobin concentration [MCHC]). An anemia is referred to as being microcytic when the erythrocytes are small, normocytic when they are of normal volume, and macrocytic when they are larger than the reference interval. Moreover, anemia is referred to as being hypochromic when the cells contain a less-than-normal hemoglobin concentration and as normochromic when they contain a normal hemoglobin concentration. Hyperchromic anemias do not occur, but the MCHC is falsely increased when the hemoglobin determination is falsely increased because of intravascular hemolysis, lipemia, or the presence of Heinz bodies. The MCHC is also falsely increased if the erythrocyte size falls below the threshold of RBC detection in the hematology analyzer. This will effectively reduce the hematocrit and increase the MCHC. Although spherocytes appear to be hyperchromic on blood films because of their shape, the hemoglobin concentration

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Companion website: www.wiley.com/go/thrall/veterinary

is normal in these erythrocytes. The MCHC, however, may be falsely increased in patients with immune-mediated hemolytic anemia because of intravascular hemolysis or agglutination, which causes errors in measurement of the RBC mass.

This classification system is useful, particularly as it relates to cell volume, in that microcytic anemias almost always result from iron deficiency. Other causes of microcytosis include hepatic portocaval vascular shunts in dogs and cats, some cases of anemia of inflammatory disease, and normal variations in certain breeds of dogs such as Akitas and Shiba Inus. A macrocytic anemia usually indicates that the marrow is functional and is releasing immature cells that are larger than normal in size. Macrocytosis without polychromasia or reticulocytosis should be evaluated further, because a regenerative response likely is not the cause in these patients. The MCV is of particular value in horses, because reticulocytes are almost never released into the circulation in significant numbers. Other causes of macrocytosis include feline leukemia virus, myelodysplasia, poodle macrocytosis, and hereditary stomatocytosis (see Chapter 6). Animals with a normocytic anemia usually have a nonregenerative or a preregenerative anemia. Preregenerative refers to anemia in animals with blood loss or blood destruction, but in which evidence of regeneration in the blood is not yet evident. Animals with a regenerative anemia, however, may have an MCV within the reference interval and, thus, be classified as having a normocytic anemia. The generated histogram or computer graphic is valuable in these patients, in that the subpopulation of macrocytic cells can be observed even though the MCV is normal (discussed later).

The MCHC is less useful in the classification of anemia, in that hypochromia usually is simply associated with an increased concentration of large, immature cells (i.e., regenerative anemia). Reticulocytes are still synthesizing hemoglobin; therefore, their hemoglobin concentration is less than that of mature erythrocytes. Occasionally, animals with iron deficiency may have a hypochromic as well as a microcytic anemia, but in most iron-deficient animals, the MCHC is within the reference interval.

Historically, MCV and MCHC were derived by calculations based on the PCV, hemoglobin concentration, and erythrocyte count. The MCV was calculated by dividing the PCV by the erythrocyte (RBC) count. For example, if the patient's PCV is 42% and its RBC count is 6.0×10^6, then the PCV divided by the RBC count is 70 fL (i.e., 42/6 = 7). In terms of mathematical logic, 1 µL = 10^9 fL, and 42% of 10^9 fL is 420,000,000 fL. Therefore, the MCV = 70 fL (i.e., 420,000,000 ÷ 6,000,000). The MCHC, which is the ratio of the weight of hemoglobin to the volume of erythrocytes in grams per deciliter, can be calculated by the following equation:

$$\text{MCHC(g/dL)} = \frac{\text{HGB}}{\text{HCT}} \times 100$$

For example, if the hemoglobin is 14 g/dL and the PCV is 42%, then the MCHC is 33.3 g/dL.

Electronic cell counters have made calculation of the MCV obsolete, because the cell volume can be measured electronically. Thus, the MCV and RBC are used to calculate the hematocrit (see Chapter 1). This technology has improved the usefulness of this classification of anemia, because subpopulations of microcytic or macrocytic erythrocytes can be observed in histograms or computer graphics, even when the MCV is within the reference interval (Figure 7.1). The RBC distribution width, which describes the width of the RBC size distribution, increases when subpopulations of either microcytic or macrocytic erythrocytes are present and often is increased before the MCV value falls out of the reference interval. The MCHC is still derived using the hemoglobin and PCV determinations; however, laser-detection technology using light scatter now allows for direct determination of the amount of hemoglobin within cells. Hemoglobin concentration using this type of technology is reported as corpuscular hemoglobin concentration mean (CHCM). Using this detection system, lipemia or hemolysis will not falsely increase the CHCM. Heinz bodies, however, may, because erythrocytes containing Heinz bodies are more optically dense. Electronic cell counters with flow cytometry capability calculate the indices of reticulocytes, which is very useful in detecting iron-deficiency anemia at an early stage (see Chapter 9).

Bone marrow response

Classification of anemia based on responsiveness of the bone marrow is very useful diagnostically. An anemia is classified as either regenerative or nonregenerative based on the number of immature erythrocytes that are circulating. Early release of immature erythrocytes is a normal marrow response to increased erythropoietin production, primarily by renal tissue, secondary to hypoxia. Increased numbers of immature erythrocytes are released into the circulation after blood loss or blood destruction, and they are indicative of a regenerative anemia. An increased concentration of immature erythrocytes usually is seen within 2–4 days after blood loss or destruction. A lack of circulating immature erythrocytes in the face of anemia indicates a nonregenerative anemia and should be considered as evidence of marrow dysfunction.

Immature erythrocytes observed using a Wright-stained blood film are polychromatophilic, and they have a blue-staining reticulum (i.e., reticulocyte) when new methylene blue or brilliant cresyl blue stains are used (see Chapters 1 and 6). In general, an anemia is considered to be regenerative if the reticulocyte concentration is greater than 60,000 cells/µL (see Chapter 1), or if there is increased polychromasia on the blood film. Reticulocytosis or increased polychromasia is a better indication of bone marrow responsiveness than is an increased MCV (see

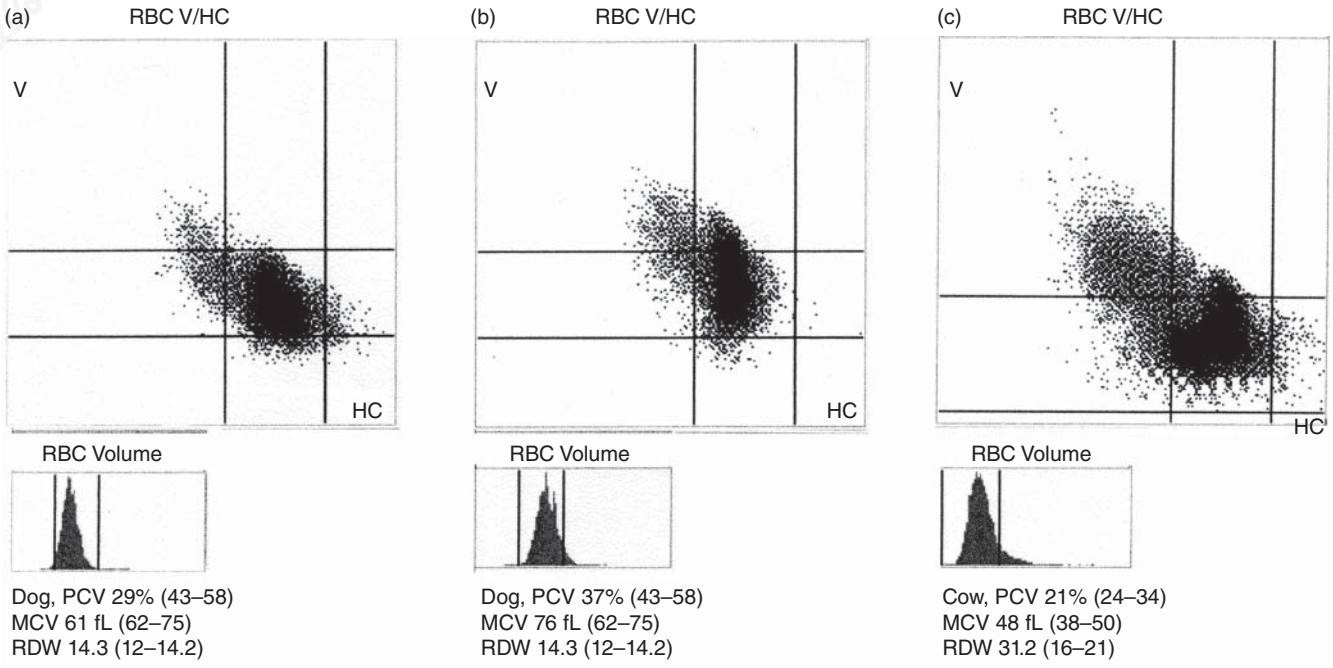

Figure 7.1 Red-blood-cell volume/hemoglobin concentration (RBC V/HC) cytograms and RBC volume histograms from six anemic animals generated by a Bayer Advia 120 (Bayer Corporation, Tarrytown, NY). On the RBC V/HC cytogram, hemoglobin (Hgb) concentration is plotted along the *x* (i.e., horizontal) axis, and cell volume is plotted along the *y* (i.e., vertical) axis. Each RBC is displayed based on volume and Hgb concentration, and normocytic normochromic cells are in the center box of each nine-box cytogram. Larger cells are displayed toward the top of the cytogram and hypochromic cells toward the left; thus, macrocytic hypochromic cells are displayed to the upper left of the cluster of normal erythrocytes. The RBC volume histogram represents the distribution of the RBCs by cell volume; normal samples have a bell-shaped curve. The mean corpuscular volume (MCV) and RBC distribution width (RDW) are determined from this histogram. The MCV is the mean of the RBC volume histogram, and the RDW is the coefficient of variation of the population. Each animal's species, packed cell volume (PCV), MCV, and RDW are provided beneath the RBC V/HC cytogram and RBC volume histogram. Reference intervals are in parentheses. (a) A 12-year-old mixed-breed dog with a mild anemia, mildly decreased MCV, and mildly increased RDW. The RBC V/HC cytogram shows that many of the erythrocytes are toward the bottom of the middle square, indicating they are microcytic. In addition, a population of hypochromic cells is present, some of which are normocytic and some of which are macrocytic. The RBC volume histogram is shifted toward the left, also indicating that many of the erythrocytes are slightly small. Iron-deficiency anemia was suspected in this patient and was confirmed by decreased serum iron concentration. The dog had a 3-month history of epistaxis associated with a nasal passage chondrosarcoma. (b) A 12-year-old miniature schnauzer with a very mild anemia, mildly increased MCV, and mildly increased RDW. The RBC V/HC cytogram shows a population of cells above the middle square that represents large cells. A population of macrocytic hypochromic cells is present as well. The RBC volume histogram is shifted slightly toward the right, and a population of macrocytic cells is evident. This is indicative of a regenerative anemia. (c) A 1-week-old anemic calf. Note the population of macrocytic hypochromic cells, even though the MCV is within the reference interval. The RDW is markedly increased. The reticulocyte count is 90,000 cells/μL (2%). The presence of macrocytic cells and reticulocytes indicates that the anemia is regenerative. The calf's umbilical stump had been bleeding since birth, and it also had blood in the feces for three days. The PCV on the previous day was 9%, and the calf received a blood transfusion at that time. Many of the normocytic cells probably are donor erythrocytes. The calf responded well to supportive therapy and 1 week later, the PCV was 27%. (d) A 13-year-old cat with a mildly decreased MCV. The RBC V/HC cytogram and RBC volume histogram are similar to those of the dog in panel a, suggesting iron-deficiency anemia. The cat had blood in the feces, as a result of intestinal (primarily colonic) lymphoma, for several weeks before this CBC was performed. The reticulocyte count is 108,000 cells/μL, indicating that the anemia is regenerative, but the immature erythrocytes are also small because of iron deficiency. (e) A 6-year-old cat with a slightly increased RDW. Note that most of the cells are macrocytic and hypochromic. The RBC volume histogram is shifted far toward the right because of numerous large erythrocytes, and the reticulocyte count is 233,260 cells/μL (10.7%), indicating a very regenerative anemia. The cat was Coombs positive, and a diagnosis of immune-mediated hemolytic anemia was made. No *Haemobartonella* organisms were observed on blood films taken during various days, but polymerase chain reaction for *Haemobartonella felis* was not performed. The cat was negative for feline leukemia virus. (f) A 12-year-old horse with a macrocytic anemia. Note the population of large cells, some of which are hypochromic. The RBC volume histogram is shifted toward the right, indicating a subpopulation of large cells. Reticulocytes are not released in horses, but the presence of macrocytic erythrocytes suggests that the anemia is regenerative. The horse was dehydrated, so it likely was more anemic than would be indicated by the PCV. Blood loss or blood destruction should be suspected in this case.

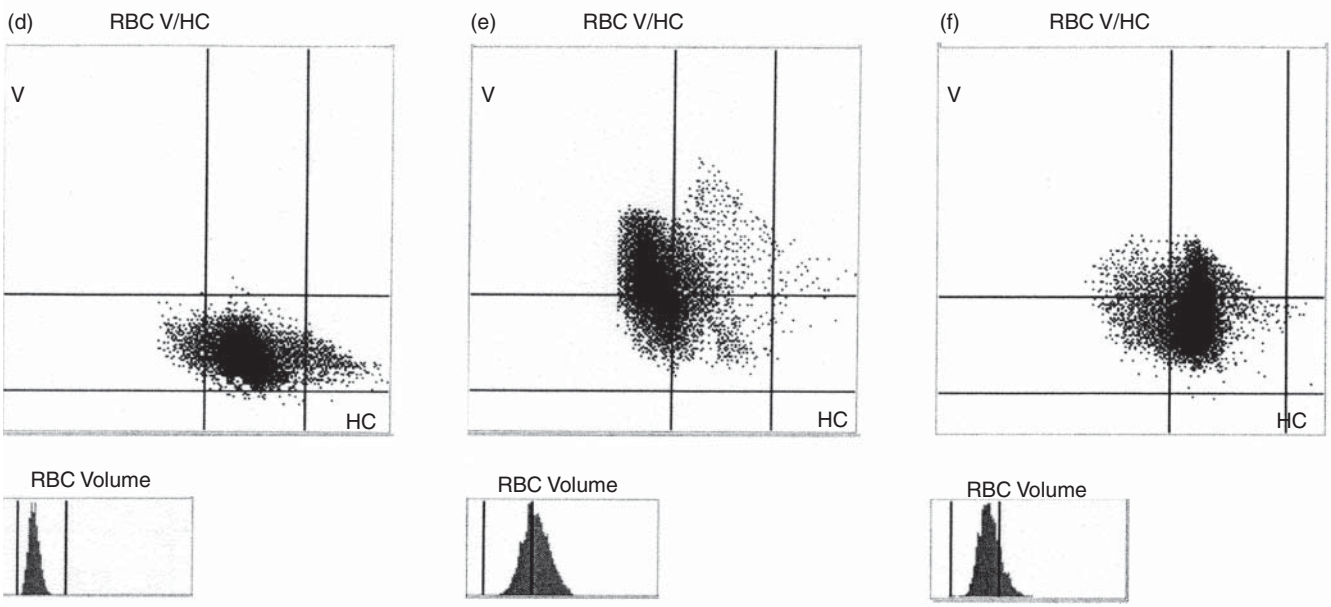

Figure 7.1 (*Continued*)

Chapter 6). Horses almost never release significant numbers of reticulocytes into the circulation.

Pathophysiologic classification

The pathophysiologic classification of anemia essentially is a categorization based on the underlying disorder. Nonregenerative anemia results from defective or decreased erythropoiesis (see Chapter 8). Decreased erythropoiesis usually is classified according to whether neutrophil and platelet production are also decreased (i.e., aplastic anemia) and whether RBC production is simply decreased (i.e., hypoplasia) or is completely absent (i.e., aplasia). Moreover, impaired erythrocyte production may be caused by an intrinsic (i.e., primary) marrow disorder, such as myelofibrosis, myelodysplasia, or myeloproliferative disorder, or it may be caused by an extrinsic (i.e., secondary) disorder. Secondary disorders include chronic renal disease; some endocrine disorders; inflammatory diseases; infectious agents, such as *Ehrlichia* sp., equine infectious anemia virus, and feline leukemia virus; immune-mediated destruction of erythrocyte precursors; and drug- or chemical-induced damage (see Chapter 15).

Regenerative anemia is caused by blood loss or erythrocyte destruction (see Chapter 9). Blood loss may be external or internal, and it may be acute or chronic. Causes of acute blood loss include trauma, bleeding lesions (e.g., tumors or large ulcers), and hemostatic disorders (e.g., thrombocytopenia or an inherited or acquired coagulopathy such as warfarin toxicosis or disseminated vascular coagulopathy). Common causes of chronic blood loss include bleeding lesions, particularly within the gastrointestinal tract, and gastrointestinal or external parasites. Erythrocyte destruction (i.e., hemolysis) may be either intravascular or extravascular, and it may result from intrinsic (i.e., primary) defects, such as hereditary membrane defects or enzyme deficiencies, or from extrinsic (i.e., secondary) causes, such as erythrocyte parasites or immune-mediated destruction. Intravascular hemolysis is the actual lysis of erythrocytes within the vascular system. Extravascular hemolysis occurs when abnormal erythrocytes are phagocytized by macrophages, usually within the spleen or liver. Common causes of erythrocyte destruction include immune-mediated mechanisms, erythrocyte parasites, and drugs and chemicals that produce oxidative damage, resulting in Heinz body formation. Less common causes of hemolysis include hypophosphatemia, water intoxication in young ruminants, bacteria (e.g., *Leptospira* and *Clostridium* sp.), heparin overdose, and hereditary erythrocyte enzyme deficiencies and membrane defects.

Diagnostic approach

When presented with an anemic patient, the ultimate goal is to establish a definitive diagnosis of the underlying disorder so that appropriate therapy can be initiated and a

prognosis established. Information can be obtained from the laboratory evaluation, the patient history, and the physical examination. The most clinically useful approach to anemia is based on the classification schemes involving a combination of bone marrow response and erythrocyte size.

Laboratory evaluation

The classification of an anemia based on erythrocyte size and marrow response (discussed earlier) is very important. Essential laboratory data include PCV, MCV, and reticulocyte count. Either blood loss or destruction will result in a regenerative anemia, and marrow dysfunction will result in a nonregenerative anemia. Furthermore, microcytosis usually is evidence of iron-deficiency anemia, and macrocytosis usually is evidence of regeneration. Additional information may be obtained from examination of the blood film; erythrocyte morphology may even reveal a definitive diagnosis (see Chapter 6).

Other laboratory procedures that may provide helpful information include plasma protein estimation by refractometry (see Chapter 1). Blood loss usually results not only in a loss of erythrocytes but also in a loss of other blood components, including protein. Thus, patients with blood loss may be hypoproteinemic. Other causes of hypoproteinemia, however, still must be considered (see Chapter 30). If blood is lost internally, such as within a body cavity, the protein usually is reabsorbed within hours.

Other components of the complete blood count (CBC) also may provide useful information. For example, if a patient is severely thrombocytopenic, anemia may be caused by blood loss secondary to impaired clot formation. On the other hand, if the leukocyte concentration, platelet concentration, and PCV are all decreased and the anemia is nonregenerative, then complete bone marrow failure is the likely cause of the anemia. An animal with a mild, nonregenerative anemia and increased immature neutrophils likely has an anemia of inflammatory disease (see Chapter 8).

Specific laboratory tests can be performed to help confirm or exclude a suspected diagnosis. If spherocytes are observed on the blood film of an anemic patient, then a Coombs test or a saline fragility test (see Chapter 1) can help to confirm immune-mediated hemolytic anemia. In patients with microcytic anemia, serum iron should be measured to determine if the microcytosis is caused by iron deficiency. In addition, the feces should be examined for blood, because chronic blood loss from the gastrointestinal tract is a common cause of iron-deficiency anemia (see Chapter 9). Anemic dogs, particularly those with a concurrent thrombocytopenia and hyperglobulinemia, should be tested for ehrlichiosis, and anemic cats should be tested for feline leukemia virus and feline immunodeficiency virus. Anemic horses should be tested for equine infectious anemia.

The biochemical profile also may provide essential information. Patients with mild to moderate, nonregenerative anemia may have disorders that are extrinsic to the marrow but that affect the marrow function. For example, animals with a nonregenerative anemia that are also azotemic because of kidney dysfunction likely have decreased erythropoietin production. All patients with an unexplained nonregenerative anemia should undergo bone marrow aspiration and examination (see Chapter 15).

Signalment and history

A complete and accurate patient history from the owner may provide valuable information. In some cases, the signalment is also helpful, because certain disorders are more common in certain breeds. For example, immune-mediated hemolytic anemia is relatively common in cocker spaniels. Acute blood loss results in acute onset of clinical signs, whereas both chronic blood loss and marrow dysfunction result in chronic onset of clinical signs. Therefore, determining if the onset of clinical signs was acute or chronic may be helpful. Asking the owner if other clinical signs are present may be useful as well. For example, a dog that is also experiencing polyuria and polydipsia may be anemic as a consequence of renal dysfunction. Alternatively, a dog that is experiencing periodic episodes of weakness may have recurring, intermittent, intra-abdominal hemorrhage secondary to a bleeding lesion (e.g., hemangiosarcoma). One should also determine any history of trauma or recent surgery and if the owner has observed any evidence of blood loss, such as hematuria or epistaxis. Melena, on the other hand, must be very severe to be obvious by visual examination of feces. Finally, one should inquire if the patient has had any possible exposure to plants, drugs, or chemicals that might induce blood destruction, marrow dysfunction, or gastrointestinal ulceration and associated blood loss.

Physical examination

A careful, routine physical examination may reveal additional information. For example, if bruising, petechiae, or ecchymoses are present in an anemic patient, the anemia may be secondary to decreased or dysfunctional platelets or to a coagulation disorder (see Chapter 17). If abdominal distension is present, intra-abdominal hemorrhage should be suspected, and an abdominal paracentesis and fluid evaluation should be performed. If the mucous membranes are icteric as well as pale, erythrocyte destruction should be suspected. If the mucous membranes are cyanotic or brown as well as pale, methemoglobinemia, which may accompany Heinz-body anemia, may be present.

Summary

In summary, the clinical signs, laboratory evaluation, signalment, history, and physical examination are all important in

establishing a diagnosis for the underlying cause of anemia. Chronic external blood loss usually results in iron-deficiency anemia, which can be diagnosed on the basis of decreased MCV and serum iron. Acute external blood loss usually can be diagnosed during the physical examination; however, internal blood loss may initially be difficult to differentiate from blood destruction. Significant internal blood loss usually occurs within a body cavity, so careful physical examination, body cavity aspiration, or other methods of visualization usually are diagnostic. Furthermore, many causes of blood destruction, such as immune-mediated destruction, Heinz bodies, or erythrocyte parasites, can be detected based on examination of blood films and erythrocyte morphology. Diagnostic procedures for specific causes of anemia are discussed in more detail in Chapters 8 and 9.

VetBooks.ir

8 Nonregenerative Anemia

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

CHAPTER 8

Anemia is classified as either regenerative or nonregenerative based on the number of circulating immature erythrocytes (polychromatophilic erythrocytes or reticulocytes). A lack of circulating immature erythrocytes indicates a nonregenerative anemia and provides evidence of marrow dysfunction. Most nonregenerative anemias are normocytic. Because the marrow takes approximately 2 days to respond to anemia (see "Reticulocyte Maturation," Chapter 1), patients with acute blood loss or blood destruction may appear to have a nonregenerative anemia, but it is actually preregenerative.

Nonregenerative anemia is further subclassified based on whether granulopoiesis (neutrophil production) and thrombopoiesis (platelet production) are also affected. Animals with nonregenerative anemia in conjunction with neutropenia and thrombocytopenia (pancytopenia) have either reversible or irreversible stem cell injury. Irreversible stem cell injuries are discussed in Chapter 15 and represent an intrinsic defect in proliferative behavior and/or regulation of stem cell entry into differentiated hematopoiesis. Some irreversible injuries may be induced by drugs, chemicals, viruses (e.g., feline leukemia virus [FeLV]), radiation, and immune-mediated stem cell injury, but the cause often is never discovered. Manifestations of stem cell injury range from dysplasia to lack of cell production (aplastic anemia) to uncontrolled neoplastic proliferation. Reversible stem cell injury is transient but also may be caused by drugs, chemicals, viruses, radiation, and immune-mediated destruction of stem cells. Reversible stem cell injury does not progress to neoplasia; however, both reversible and irreversible stem cell damage may be associated with myelofibrosis or myelonecrosis in response to the injury.

Pancytopenia also may result from myelophthisic disorders in which nonhematopoietic neoplasms, such as lymphoma and malignant histiocytosis, either metastasize to or originate in the marrow. In addition, pancytopenia may be seen with hemophagocytic syndrome, a rare condition that occurs secondary to infectious, neoplastic, or metabolic diseases and is characterized by the proliferation of benign histiocytic cells that phagocytize hematopoietic precursors.

Animals with nonregenerative anemia in conjunction with normal neutrophil and platelet concentrations may have an intrinsic marrow defect (pure red cell hypoplasia, aplasia, or apparent erythroid maturation defect), or they may have a disorder that is extrinsic to the bone marrow but results in defective or decreased erythropoiesis. Pure red cell aplasia also may be either reversible or irreversible, and it usually is immune mediated or caused by viral (FeLV) damage. Extrinsic causes of nonregenerative anemia include anemia of inflammatory disease, anemia of renal failure, anemias associated with endocrine disorders, and, rarely, nutritional deficiencies.

Aplastic anemia (aplastic pancytopenia)

Drugs, chemicals, toxins, and estrogen

Antineoplastic and immunosuppressive drugs, such as doxorubicin, cyclophosphamide, cytosine arabinoside, vincristine, hydroxyurea, and azathioprine, probably are the most commonly used agents that cause reversible stem cell damage in dogs. These drugs are used for brief periods of time, however, and usually result in a neutropenia and thrombocytopenia rather than a significant nonregenerative anemia. Drugs that have been associated with stem cell injury in animals include estrogen (dogs and ferrets), phenylbutazone (dogs and possibly horses), meclofenamic acid (dogs), griseofulvin (cats), phenobarbital (dogs and cats), phenytoin (dogs), colchicine (dogs), azidothymidine (a reverse transcriptase inhibitor; cats), chloramphenicol (dogs and cats), thiacetarsamide (dogs), and albendazole (a broad-spectrum anthelmintic; dogs and cats). Some drugs may induce stem cell destruction by immune-mediated mechanisms. In dogs, trimethoprim-sulfadiazine, cephalosporin, and phenobarbital have been associated with pancytopenia that may be immune-mediated. Drug-induced

immune-mediated stem cell injury usually responds to discontinuation of the drug. Idiopathic immune-mediated stem cell injury often responds to immunosuppressive therapy, but these injuries may take several weeks to respond and often require long-term treatment for resolution. Table 8.1 summarizes drugs and chemicals that may cause aplastic anemia in domestic animals.

Estrogen toxicosis may occur in bitches given exogenous estrogen for mismating, termination of pseudopregnancy, or urinary incontinence. Myelosuppression may result from the administration of excessive amounts of estrogen or from an idiosyncratic sensitivity to estrogen. Endogenous estrogen, resulting either from Sertoli cell tumors in male dogs or from cystic ovaries or granulosa cell tumors in female dogs, also may result in bone marrow suppression. Because ferrets are induced ovulators, marrow suppression from endogenous estrogen is a common – and potentially fatal – disorder in this species. The mechanism of estrogen toxicosis is unclear, but it is thought to result from the secretion (by thymic stromal cells) of an estrogen-induced substance that inhibits stem cells. Marrow suppression is preceded by an initial thrombocytosis and neutrophilia.

Aplastic anemia in cattle has been associated with grazing on bracken fern and ingestion of soybean meal contaminated with the solvent trichloroethylene. Benzene, a commonly used solvent, may cause aplastic anemia as well as leukemia. Mycotoxins have been associated with bone marrow suppression in horses and cattle, and experimental aflatoxin B_1 toxicity has been reported to cause aplastic anemia in pigs.

Infectious agents

FeLV can result in anemia by many mechanisms, one of which is induction of aplastic anemia. In addition, FeLV is associated with anemia that manifests as pure red cell aplasia or hypoplasia, myeloproliferative disorders (see Chapter 16), anemia of inflammatory disease, and hemolysis. Hemolytic anemias that may be associated with FeLV infection include Heinz-body anemia, immune-mediated hemolytic anemia, and feline infectious anemia (see Chapter 9). Before widespread use of the FeLV vaccine, approximately 70% of anemic cats were infected with FeLV. Anemia caused by FeLV often is macrocytic, or a subpopulation of the erythrocytes is macrocytic in the absence of reticulocytosis. This may be caused by prolonged dysplastic erythrocyte production resulting from FeLV-induced myelodysplasia (see Chapter 16).

Ehrlichia canis may result in pancytopenia by two mechanisms: immune-mediated destruction of circulating cells, or aplastic anemia (which also may be an immune-mediated mechanism). In addition, dogs with ehrlichiosis may present with only one decreased cell line (e.g., thrombocytopenia), may have a lymphocytosis, and commonly have hyperglobulinemia. The organism rarely is seen on blood films.

Equine infectious anemia virus (a lentivirus) causes anemia by a number of mechanisms, one of which is bone marrow suppression (possibly immune mediated). Parvovirus infection in dogs and cats causes acute bone marrow necrosis, but these animals usually recover or die before the anemia becomes significant.

Other infectious agents, such as systemic fungal or protozoal infections, have been reported to result in pancytopenia. The mechanism may be immune mediated.

Pure red cell aplasia/nonregenerative immune mediated anemia

Pure red cell aplasia is characterized by a markedly decreased concentration of erythroid precursors in the bone marrow in the face of normal granulopoiesis and thrombopoiesis, resulting in a severe nonregenerative anemia with normal neutrophil and platelet concentrations. Congenital pure red cell aplasia (Diamond-Blackfan anemia) is very rare in people, and has only been reported, but not proven, in one dog. Acquired pure red cell aplasia almost always is caused by immune-mediated destruction of erythroid precursors, and it often responds to immunosuppressive therapy. Spherocytes and agglutination are occasionally present, hemolysis is variable but is sometimes present, and

approximately half the affected dogs in some studies were Coombs' positive. Bone marrow examination usually reveals an apparent arrest at some stage of erythroid precursor maturation, ranging from the rubriblast to the metarubricyte stage. Phagocytosis of rubricytes or metarubricytes (rubriphagocytosis) is commonly seen in bone marrow aspirates, and some degree of myelofibrosis is seen in approximately half of affected dogs. Erythropoiesis is usually expanded (erythroid hyperplasia) up to the stage of the erythrocyte precursor that is being phagocytized. Occasionally, however, erythroid precursors are completely absent. Nonregenerative immune-mediated anemia is also referred to as precursor-targeted immune-mediated anemia (PIMA). While most affected dogs and cats respond to immunosuppressive therapy, the time from onset to a regenerative response (reticulocytosis) is usually several weeks, and may be months.

Some dogs and horses treated with recombinant human erythropoietin developed an immune response against the recombinant as well as endogenous erythropoietin, resulting in a reversible pure red cell aplasia. Recombinant, species-specific erythropoietin does not produce this syndrome. In one retrospective study, only 6% of dogs developed pure red cell aplasia associated with the administration of darbepoetin, a long-acting glycosolated synthetic recombinant human erythropoietin analog. Darbepoetin is thought to be less likely to produce pure red cell aplasia in dogs and cats than was epoetin, the first recombinant erythropoietin developed.

Finally, certain strains of FeLV virus (subgroup C) cause pure red cell aplasia.

Red cell hypoplasia

Nonregenerative anemia may result from abnormalities that are extrinsic to the marrow, including anemia of inflammatory disease, anemia of chronic renal failure, and anemia associated with endocrine disease, and rarely, anemia associated with nutritional deficiencies. Other laboratory findings such as an inflammatory leukogram, azotemia, other biochemical profile abnormalities or endocrine panel abnormalities usually are key to establishing the diagnosis of these types of anemias.

Anemia of inflammation

Anemia of inflammation (anemia of chronic disease) is probably the most common anemia in domestic animals, but it usually is mild and clinically insignificant. This type of anemia is associated with various types of inflammatory processes, including infections, trauma, kidney disease, neoplasia, heart failure, and obesity, and usually is mild to moderate, nonregenerative, and usually normocytic but occasionally microcytic. The pathogenesis of anemia of inflammatory disease is multifactorial, including changes in iron homeostasis, altered proliferation of erythroid progenitor cells and production of erythropoietin, and decreased RBC life span. Immune stimulation results in activation of T cells and monocytes that produce cytokines, such as interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), interleukin (IL)-1, IL-6, and IL-10 that affect iron metabolism. Lipopolysaccharide (LPS) and IL-6 induce hepatic production of hepcidin, which regulates iron homeostasis by repressing intestinal iron absorption as well as iron release from ferritin stores and by mediating other regulators of iron. Specifically, hepcidin inactivates ferroportin, which is responsible for transporting iron out of cells, and LPS can also downregulate divalent metal transporter 1 (DMT1) and ferroportin expression. These events result in inhibition of duodenal iron absorption and also decrease iron release from stores in macrophages and hepatocytes. Moreover, inflammatory cytokines up-regulate DMT1 expression on macrophages with a resultant increased uptake of iron into these cells. Additionally, IL-10 increases transferrin receptor expression, resulting in increased uptake of iron into cells, and TNF-α, IL-1, IL-6, and IL-10 also up-regulate ferritin expression, promoting intracellular storage and retention of iron. The combined effect of these changes is a relative iron deficiency in both the transport and functional pools, which limits availability of iron for erythropoiesis [see more on iron metabolism under "Chronic Blood Loss (Iron Deficiency Anemia)" in Chapter 9]. Independent of hepcidin and iron impairment of erythropoiesis, cytokines such as IL-1 and TNF also inhibit hypoxia-mediated stimulation of erythropoietin production in the kidney.

Laboratory findings include a decreased serum iron concentration, normal or decreased total iron-binding capacity (transferrin), normal or increased serum ferritin, and normal or increased stainable iron stores in the bone marrow. An inflammatory leukogram may be present as well. Occasionally animals with anemia of inflammation may have a microcytic anemia, and that along with the decreased serum iron concentration, makes anemia of inflammation sometimes difficult to distinguish from iron-deficiency anemia; in these cases, serum ferritin or bone marrow stainable iron (hemosiderin) may be helpful in differentiating the two disorders. However, transferrin is down-regulated with inflammation (a negative acute-phase protein), and ferritin is up-regulated with inflammation (a positive acute-phase protein), which may confound the differentiation. In humans with concurrent anemia of inflammation and iron deficiency anemia, the anemia is less microcytic and hypochromic than in patients with simple iron deficiency anemia, and this may be true in animals as well. Hepcidin measurement may become useful in distinguishing anemia of inflammation from iron deficiency anemia, since hepcidin is typically increased in patients with anemia of inflammation, and decreased in iron deficiency anemia. However, in humans

with renal disease, serum hepcidin is increased since it is eliminated through the kidney, rendering the test nondiagnostic for differentiating iron deficiency anemia from anemia of inflammation. In addition to iron metabolism parameters, other laboratory tests such as reticulocyte hemoglobin content and red cell distribution width (RDW) may be helpful in differentiating iron deficiency anemia and anemia of inflammation. Reticulocyte hemoglobin content has been shown to be decreased in dogs and cats with iron restricted hematopoiesis but has not yet proven to be very useful in differentiating true iron deficiency from functional iron deficiency such as is seen with anemia of inflammation and portosystemic shunts.

A decreased serum iron concentration presumably is advantageous to patients with inflammatory disease, because it reduces the availability of iron for bacterial growth. Treatment is aimed at alleviating the underlying disease. Parenteral iron supplementation may have some benefit, and treatment with recombinant erythropoietin may result in an increased hematocrit. Inhibitors of hepcidin and inflammatory modulators show promise for the future.

Anemia of chronic renal disease

Anemia associated with chronic renal disease usually is moderate to severe, nonregenerative, and normocytic. The severity of the anemia usually correlates with the severity of the renal failure as evidenced by the degree of azotemia. The primary cause for this anemia is lack of production of erythropoietin by the kidney, and treatment with recombinant canine erythropoietin or the more recently developed darbepoetin, a long-acting recombinant human erythropoietin analog, effectively increases the hematocrit in most dogs and cats. Other factors, such as increased bleeding tendencies, also may play a role in this type of anemia. Increases in serum parathyroid hormone and phosphorus concentrations and increased erythrocyte osmotic fragility have not been found to correlate significantly with the degree of anemia. Some patients with anemia of renal disease have concurrent anemia of inflammatory disease. Inflammation and oxidative stress are thought to play a role in the progression of chronic kidney disease, and increases in acute-phase proteins such as hepciden are associated with decreased serum iron, total iron binding capacity, and hematocrit in cats with chronic renal disease. It is likely that anemia of inflammatory disease, a functional iron deficiency, also plays a role in the development of anemia of chronic renal disease in dogs and cats, just as it does in humans.

Anemia associated with endocrine disease

Hypothyroid dogs almost always have a mild, nonregenerative, normocytic anemia, usually with a hematocrit of approximately 30%. This anemia responds to therapy for hypothyroidism and may simply be a manifestation of the lowered metabolic rate. Some dogs with hypoadrenocorticism, particularly those with glucocorticoid deficiency, have a mild, nonregenerative, normocytic anemia that often is masked by dehydration.

Anemia associated with nutritional deficiencies

Iron-deficiency anemia is the most common anemia associated with a nutritional deficiency, and while common in people, lack of nutritional iron is rarely seen in adult domestic animals. This type of anemia usually is regenerative until the late stages (unless complicated by anemia of inflammatory disease) and is discussed in Chapter 9. Other types of anemia related to nutritional deficiency are diagnosed very infrequently.

Cobalamin and folate are water soluble B vitamins that are cofactors of enzymes that are required for normal DNA synthesis, hematopoiesis, and neuron myelination. In humans, cobalamin and folate deficiencies result in nonregenerative macrocytic anemias as a result of defective DNA synthesis, ineffective hematopoiesis, and erythrocyte precursor maturation arrest. Macrocytosis is a result of asynchronous development of the erythrocyte cytoplasm and nucleus. Cobalamin deficiency is observed in dogs and cats as a result of a hereditary absence of intrinsic factor cobalamin receptors in ileal enterocytes, which is inherited as an autosomal recessive trait. This anemia is nonregenerative and usually normocytic, unlike the human counterpart, and has been reported in border collies, a beagle, giant schnauzers, and cats. Affected puppies fail to thrive. Other findings include neutropenia with hypersegmentation, anemia with anisocytosis and poikilocytosis, megaloblastic changes of the bone marrow, decreased serum cobalamin concentrations, methylmalonic aciduria, and homocystinemia. Parenteral, but not oral, cyanocobalamin administration eliminates all abnormalities except the decreased serum cobalamin concentration. Chinese Shar Peis have a high prevalence of cobalamin deficiency compared to other breeds and healthy Shar Peis may have subclinical cobalamin deficiency. The disorder is suspected to be hereditary; the hematologic findings have not been reported to date.

Hematologic findings in animals with acquired cobalamin deficiency as a result of gastrointestinal or pancreatic disease have not been well characterized, although some animals with acquired cobalamin deficiency have been reported to have a mild normocytic anemia. A recent retrospective study in dogs showed no association between cobalamin or folate deficiency and the nonregenerative macrocytic anemia that is seen in humans. Some cats with hyperthyroidism are hypocobalaminemic but not anemic. Cobalt deficiency in ruminants results in a normocytic, nonregenerative anemia and is caused by grazing on cobalt-deficient soil. Cobalt is required for synthesis of cobalamin by rumen bacteria.

9 Regenerative Anemia

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

The term "regenerative anemia" implies that the bone marrow is attempting to compensate for the anemia by increased erythrocyte production, as well as early release of immature red cells. This response is primarily due to increased erythropoietin production by hypoxia-sensing cells in the kidney (see discussions of erythrocyte production in Chapters 6 and 10). Indications that the anemia is regenerative are increased polychromasia on the Wright-stained blood film and increased reticulocyte concentration (other than in equine species, which do not release many immature erythrocytes). Mean cell volume (MCV) may be increased but is a less reliable indication of early release of cells than is the presence of reticulocytes or polychromasia. Regenerative anemia is caused by either blood loss or blood destruction or may be seen in the recovery phase of marrow dysfunction. Blood loss may be external or internal and may be acute or chronic. Causes of acute blood loss include trauma; bleeding lesions, such as tumors or large ulcers; and hemostatic disorders. Examples of hemostatic disorders include thrombocytopenia, inherited coagulopathies, and acquired coagulopathies, such as warfarin toxicosis or disseminated intravascular coagulopathy (DIC). Common causes of chronic blood loss include bleeding lesions, particularly within the gastrointestinal (GI) tract, and gastrointestinal or external parasites.

Blood destruction (hemolysis) may be either intravascular or extravascular and may be due to intrinsic (primary) defects, such as hereditary membrane defects or enzyme deficiencies, or extrinsic (secondary) causes, such as erythrocyte parasites or immune-mediated destruction. Intravascular hemolysis is the actual lysis of erythrocytes within the vascular system. Extravascular hemolysis occurs when abnormal erythrocytes are phagocytized by macrophages, usually within the spleen or liver. Common causes of erythrocyte destruction include immune-mediated mechanisms, erythrocyte parasites, and drugs and chemicals that produce oxidative damage resulting in Heinz body formation. Less common causes include hypophosphosphatemia, water intoxication in young ruminants, bacteria (*Leptospira*, *Clostridium*), heparin overdose, and hereditary erythrocyte enzyme deficiencies and membrane defects.

Blood loss

If blood is lost outside of the body, including loss into the GI tract, components of the blood such as iron and plasma protein are lost. On the other hand, if bleeding occurs within a body cavity, the protein is reabsorbed within hours, and most of the erythrocytes are reabsorbed by lymphatics within a few days. The remaining cells are lysed or phagocytized, and iron is reutilized.

Acute blood loss

If blood loss is acute, the packed cell volume (PCV) initially remains normal because both cells and plasma are lost. However, within a few hours both the PCV and plasma protein decrease as a result of dilution, as interstitial fluid is added to blood. By 72 hours post-bleed, polychromatophilic erythrocytes (reticulocytes) should begin to appear in blood, and their concentration usually peaks within approximately 1 week. Plasma protein should return to normal within about 1 week, unless blood loss is recurrent or ongoing. Examples of disorders causing acute blood loss include trauma and surgical procedures, coagulation disorders, thrombocytopenia, and bleeding tumors.

Thrombocytopenia may result in bleeding when the platelet concentration is less than 20,000–30,000 μL; however, in the author's experience, spontaneous bleeding does not usually occur until the platelet concentration is less than 5000 μL. Blood loss does not usually cause platelet concentrations to drop below 90,000 μL, although platelet function defects have been reported following acute blood loss. Electronic platelet cell count may be erroneously decreased due to platelet clumping but can then be estimated from the blood film (see Chapter 17). The combination of anemia,

Companion website: www.wiley.com/go/thrall/veterinary

reticulocytosis (or increased polychromasia), and hypoproteinemia is suggestive of blood loss, unless hypoproteinemia is coincidental to the blood loss. Causes of hypoproteinemia other than blood loss include decreased intake (malabsorption, maldigestion, starvation), decreased production (liver failure), or other types of protein loss (glomerulonephropathy, protein losing enteropathy).

Blood loss outside of the body is usually easy to diagnose, since the source of blood loss is apparent, unless it is being lost via the gastrointestinal tract. Blood loss within a body cavity is more difficult to diagnose, and thoracic or abdominal fluid evaluation may be necessary to confirm the diagnosis.

Erythrocyte morphology is usually normal with acute blood loss, with the exception of blood loss from hemangiosarcoma, one of the most common tumors of middle-aged to older dogs, especially large breeds such as German shepherds and golden retrievers. Hemangiosarcomas have been reported in cats but are rare. They are malignant vascular tumors typically found in the spleen, liver, and right atrium of the heart, and most have metastasized to the lungs or other organs by the time the diagnosis is made. Many dogs present due to acute signs associated with anemia as a result of rupture of the tumor, with blood loss into the abdominal cavity. Some affected dogs have a history of intermittent weakness, as a result of multiple events involving tumor rupturing and bleeding, followed by absorption of blood from the abdominal cavity.

Acanthocytes and schistocytes are seen in some dogs with hemangiosarcoma (Figure 9.1); these morphologic changes are helpful in making the diagnosis, although acanthocytes are seen in numerous disorders other than hemangiosarcoma (see Chapter 6). Acanthocytes may also be observed in blood aspirated from the abdominal cavity (Figure 9.2), although the diagnostic usefulness of this is controversial since erythrocyte shape abnormalities are commonly seen in body cavity effusions. Other common laboratory findings in dogs with hemangiosarcoma include reticulocytosis (increased polychromasia), transient hypoproteinemia, and thrombocytopenia, usually mild to moderate, as a result of localized microangiopathy within the tumor, or disseminated intravascular coagulation. Dogs with intra-abdominal bleeding hemangiosarcomas that are treated with surgical resection alone have a mean survival time of approximately 2–3 months, and dogs that are treated with a combination of surgical resection and chemotherapy have a mean survival time of approximately 4–10 months, depending on the protocol used.

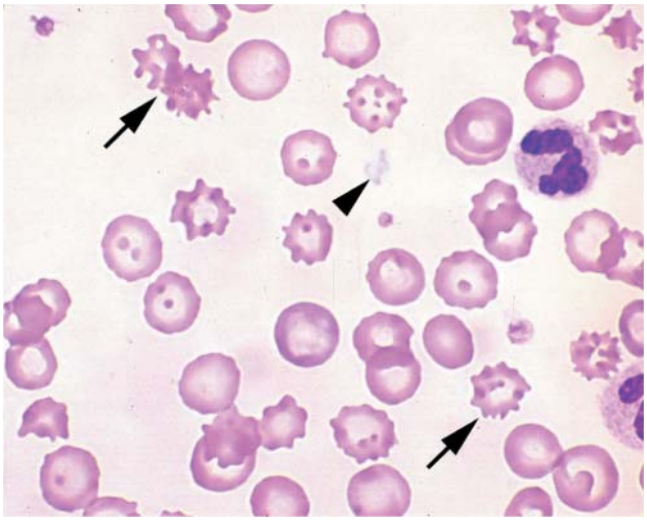

Figure 9.1 Blood film from a dog with hemangiosarcoma of the spleen. Note the acanthocytes (arrows) and schistocyte (arrowhead). Wright stain.

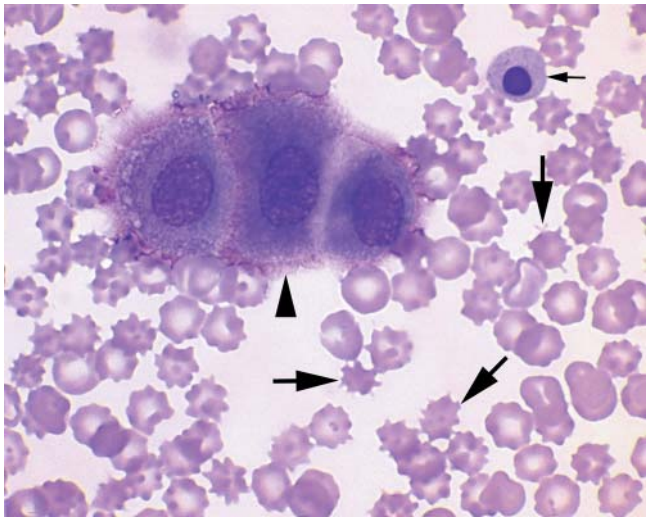

Figure 9.2 Abdominal fluid from a dog with ruptured splenic hemangiosarcoma and resultant hemoabdomen. Although morphology of erythrocytes is usually insignificant in body cavity effusions, animals with hemoabdomen resulting from hemangiosarcoma may have acanthocytes (large arrows) that are diagnostically useful. Mesothelial cells (arrowhead) and a nucleated erythrocyte are also present (small arrow). Wright stain.

Acute blood loss does not typically result in iron deficiency since iron stores are usually adequate for increased erythropoiesis. However, chronic blood loss over weeks to months is almost always associated with iron deficiency.

Chronic blood loss (iron deficiency anemia)

Iron is a critical component of the hemoglobin molecule, which is made up of four heme groups surrounding a globin polypeptide group, forming a tetrahedral structure. Heme accounts for 4% of the weight of the molecule, and is composed of a ringlike organic compound known as a porphyrin to which an iron atom is attached. Iron is the site of the attachment with oxygen (O_2). Iron must be in the reduced ferrous state (Fe^{2+}) to bind with O_2, forming oxyhemoglobin. The hemoglobin carrying iron in the ferric state (Fe^{3+}) cannot carry oxygen, and is referred to

as methemoglobin. Methemoglobinemia can be inherited due to a reductase defect, or can be acquired. Many of the oxidant drugs and chemicals that cause Heinz body anemia can also cause methemoglobinemia, and are discussed later.

Dietary iron is absorbed primarily in the duodenum in the form of ferrous iron, is transported across intestinal epithelial cells by divalent metal transporter 1 (DMT1), is exported by ferroportin, then bound to transferrin in the plasma where it is available for use or storage. Storage iron is primarily in the form of ferritin, which is soluble, and hemosiderin, which has more iron than protein, is insoluble, and stainable within macrophages of the liver, spleen, lymph nodes, and bone marrow. To prevent excessive iron in the body, which can be hepatotoxic, iron uptake from the intestine is regulated by the hormone hepcidin, which is produced by the liver. When iron stores are adequate or high, hepcidin binds to ferroportin and decreases its production or destroys it. The iron then remains in the intestinal epithelial cell when it is shed into the gut lumen. When iron stores are low, hepcidin production and secretion are decreased, thus increasing iron uptake from the intestine into the plasma. Inflammatory cytokines upregulate hepcidin production. Ferroportin is also present in the membranes of hepatocytes and macrophages. Hepcidin, therefore, not only affects serum iron concentration through its effects on intestinal epithelial cells but also causes sequestration of iron within macrophages and hepatocytes, preventing efflux of iron into plasma. This role of hepcidin in anemia of inflammation is discussed in Chapter 8. Upregulation of intestinal iron absorption in patients with iron deficiency is often not sufficient to restore adequate plasma iron, therefore oral iron supplementation as therapy is often not adequate (see "Therapy" below).

Chronic blood loss results in iron deficiency anemia, and in adult animals is the most common cause of iron deficiency anemia. Inadequate dietary iron does not occur in adult animals that are fed a commercial pet food diet but may be seen in dogs and cats that are fed a vegetarian diet without appropriate iron supplementation. The dietary iron requirement for adult dogs and cats is estimated at 80 mg/kg dry matter and is even higher in puppies and kittens. Iron deficiency anemia commonly occurs in neonates of all domestic animal species due to inadequate dietary iron intake, since milk contains little iron and growth rates are high. This anemia is often referred to as the "physiologic anemia of neonates." Anemia is particularly severe in baby pigs that have no access to iron-containing soil but also occurs in kittens, puppies, foals, and calves. When blood loss is ongoing, iron stores are depleted relatively quickly. One milliliter of blood contains 0.5 mg of iron; normally 1 mg of iron is absorbed and excreted daily but iron intake must be much higher, since animals absorb only a very small fraction of available dietary iron. Iron deficiency anemia is quite common in dogs, less common in ruminants, and relatively rare in cats and horses.

Gastrointestinal bleeding is the most common cause of chronic blood loss. Causes of chronic gastrointestinal blood loss include neoplasms such as lymphoma, leiomyomas, leiomysarcomas, and carcinomas; gastrointestinal ulcers, usually as a result of the use of ulcerogenic drugs such as glucocorticoids, nonsteroidal anti-inflammatory drugs, and salicylates; hypoadrenocorticism; inflammatory bowel disease; and intestinal parasites such as hookworms. Heavy infestations of ectoparasites that utilize blood, such as fleas and some lice, can also lead to iron deficiency anemia. Overuse of blood donors may also lead to manifestations of iron deficiency, although the degree of anemia may be very mild. Rarely, thrombocytopenia or inherited hemostatic defects can lead to chronic blood loss. Iron deficiency is usually categorized into three stages: storage iron deficiency, iron deficient erythropoiesis, and iron deficiency anemia. Once anemia occurs, clinical signs include pallor, lethargy, and weakness, and are somewhat variable, depending on the underlying cause of the blood loss and the severity of the anemia. Pica, particularly eating dirt (geophagia), has been observed in dogs with iron deficiency anemia. Iron deficient humans also exhibit pica, including pagophagia, the compulsive eating of ice.

Laboratory findings

The hallmark of iron deficiency anemia is a decreased MCV or a subpopulation of microcytic cells (see Chapters 1 and 6). Microcytosis occurs because erythrocyte precursors continue to divide in an attempt to reach their full hemoglobin content. Additional divisions result in smaller than normal erythrocytes. Examination of the erythrocyte histogram or computer graphic generated by the electronic cell counter is often useful, because subpopulations of microcytic erythrocytes can be observed, even when the MCV is within the reference interval (see Chapter 6). The MCV of reticulocytes is also decreased, since even immature iron deficient erythrocytes are smaller than normal. The red cell distribution width (RDW), which describes the width of the size distribution, is usually increased when subpopulations of microcytic erythrocytes are present, and will often be increased before the MCV decreases below the reference interval. Although one might expect the Mean cell hemoglobin concentration (MCHC) to be decreased in these patients, since the cells contain less hemoglobin than normal, it is commonly within the reference interval.

The anemia is usually regenerative with reticulocytosis but may become nonregenerative in the late stages. Quite commonly, the bone marrow response may be inadequate due to underlying anemia of inflammation, since many of these animals have concurrent inflammation related to their bleeding lesions. Reticulocyte indices can be determined with flow-cytometry type electronic cell counters. These indices, especially average reticulocyte hemoglobin content (CHr, also known as RETIC-HGB when determined

by certain analyzers) and reticulocyte volume (MCVr) are good indicators of iron deficiency anemia, as both are decreased quite early in patients with iron deficiency, usually before changes in conventional indices. However, reticulocyte hemoglobin content and other reticulocyte indices are also decreased with other types of functional iron deficiency such as is seen with anemia of inflammatory disease or portosystemic shunts, although the decreases are usually not of the same magnitude as is seen with iron deficiency anemia. It may be of more value to use diagnostic cutoffs based on the magnitude of abnormality, rather than the reference interval, when differentiating true iron deficiency from functional iron deficiency. Other useful reticulocyte indices for detecting iron deficient erythropoiesis include reticulocyte hemoglobin concentration (CHCMr), percentage of reticulocytes with decreased CHCMr (%Hypo-r), variability in reticulocyte size (RDWr), and variability in CHCMr (HDWr).

Blood film examination is diagnostically useful, particularly in the late stages of iron deficiency anemia. Erythrocytes of most species, other than cats, may appear pale, with increased central pallor, and sometimes only a thin rim of hemoglobin is present (Figure 9.3). Membrane abnormalities are common, including keratocyte and schistocyte formation, presumably due to increased susceptibility to oxidative damage (see Chapter 6). Initially the erythrocyte develops what appears to be a blister or vacuole where inner membrane surfaces are crosslinked across the cell. These lesions subsequently enlarge, break open to form "apple-stem cells" and keratocytes, spiculated red cells with

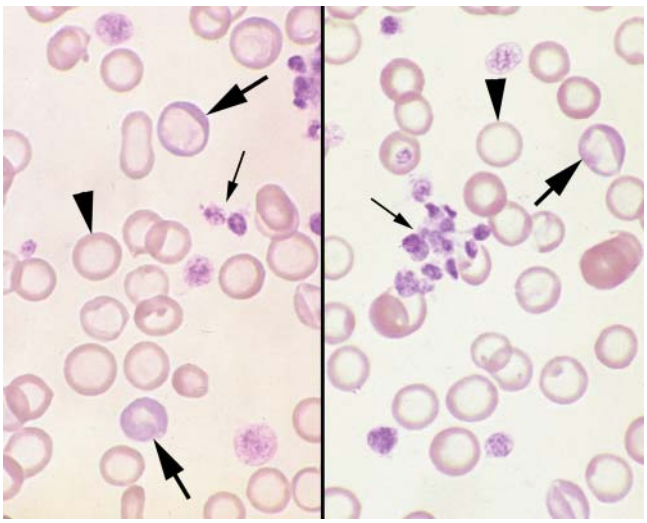

Figure 9.3 Blood film from a dog with iron deficiency anemia and hypochromic erythrocytes (arrowheads). Note the presence of polychromatophilic erythrocytes (large arrows), indicating that the anemia is regenerative. Animals with iron deficiency anemia commonly have increased platelets (small arrows), some of which may be large. Wright stain.

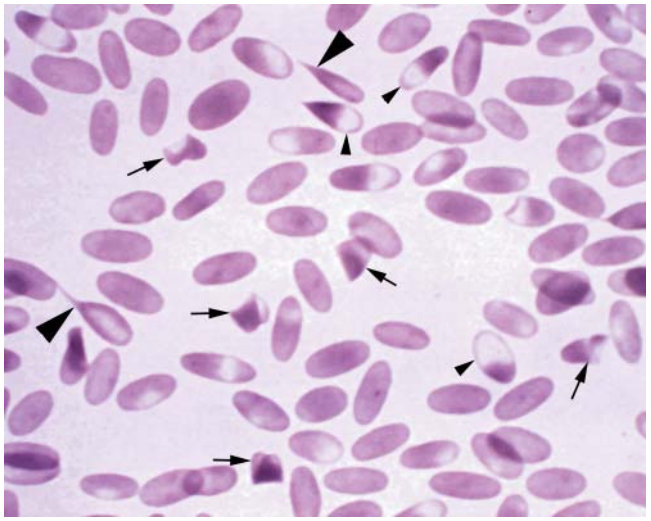

Figure 9.4 Blood film from a llama with iron deficiency anemia. Typical morphologic abnormalities associated with iron deficiency in llamas include dacryocytes (large arrowhead), folded erythrocytes (arrows), and eccentric pallor (small arrowheads). Wright stain.

two or more pointed projections. The projections from the keratocytes may then fragment from the cell, forming schistocytes. Erythrocytes are thin, and folded cells may be seen, particularly in llamas (Figure 9.4).

Thrombocytosis is present in approximately 50% of iron deficient patients, and many have increased platelet size and increased platelet aggregation. The mechanism for the increased platelet concentration is not well understood but may be due to increased erythropoietin or other cytokines. While inflammation can cause thrombocytosis, the thrombocytosis seen with iron deficiency will occur independent of inflammation. Megakaryopoiesis in iron deficient rats has been shown to be altered, with increased megakaryocyte ploidy and size and accelerated megakaryocyte differentiation. Studies in mice have shown that iron deficiency causes megakaryocyte/erythroid precursor cells to selectively differentiate into megakaryocytes rather than erythroid cells. It has been theorized that iron deficient thrombocytosis may have evolved to maintain or increase the coagulation capacity in patients with chronic bleeding. Another theory is that by making megakaryocytes rather than erythrocytes, iron is conserved for more important functions.

Other laboratory findings in patients with iron deficiency include decreased serum iron concentration, decreased transferrin (a glycoprotein in plasma that transports iron between compartments) saturation, and low storage iron. Serum iron concentration is usually lower in animals with iron deficiency than it is in animals with anemia of inflammation. Total iron binding capacity, a test for measuring the amount of transferrin available to transport iron, is usually normal in iron deficient dogs and cats, although it is usually increased in other species with iron deficiency.

Iron is stored as either ferritin or hemosiderin. Although ferritin is primarily an intracellular iron storage compound, it can be detected in serum. Hemosiderin, on the other hand, is insoluble, and can only be detected by staining cells and tissues. Thus, storage iron can be evaluated by measuring serum ferritin, or by examining a bone marrow aspirate and noting lack of hemosiderin in macrophages. Disadvantages of serum ferritin are that it is available from few laboratories, is species-specific, and since it is an acute phase reactant protein, tends to increase whenever inflammation or liver disease are present. Special iron stains, such as Prussian blue, are not necessary in order to visualize hemosiderin in the bone marrow (see Chapter 15). The absence of hemosiderin in feline bone marrow aspirates is not significant, since hemosiderin is rarely seen in aspirates of bone marrow from normal cats. Hypoproteinemia is seen in approximately one-third of animals with chronic blood loss, as protein production sometimes cannot keep pace with loss.

For practical purposes, the combination of low serum iron in a patient with a decreased MCV and anemia is usually adequate to diagnose iron deficiency anemia, and should trigger additional diagnostic procedures to determine the source of blood loss, such as testing the feces for occult blood. An excellent review of diagnosis of iron metabolism disorders in dogs and cats has been published [1].

Therapy

Treatment consists of finding and treating the source of blood loss. Iron supplementation with intramuscular injectable iron dextran in iron-deficient neonates is useful, especially baby pigs, which are usually given 200 mg iron. Iron dextran is absorbed by the lymphatic system within days. Iron dextran can be given at a dose of 10 mg elemental iron per kg body weight weekly to dogs, and at a dose of 50 mg per cat once every 3–4 weeks. An initial small dose of intramuscular iron is recommended in case a hypersensitivity reaction were to occur. Although oral iron supplementation is commonly used to treat iron deficiency, it is often of little value, particularly in dogs and cats, because commercial pet food usually contains more iron than can be absorbed by the intestine. However, intestinal absorption of iron increases dramatically when animals are iron deficient. Oral iron should not be given to neonatal animals, especially kittens, since it can be toxic. If oral iron is administered, it should be in the ferrous state, such as ferrous sulfate or ferrous gluconate. Ferrous sulfate can be administered at a dose of 15 mg iron salt per kg body weight (5 mg elemental iron per kg) divided every 8–12 hours. Side effects are gastric irritation.

Differential diagnoses

Other causes of microcytosis include portosystemic shunts, which are vascular connections between the portal and systemic circulation that divert portal blood around the liver. The cause of the microcytosis in these animals is not well understood but is associated with abnormal iron metabolism, perhaps similar to anemia of inflammatory disease and possibly related to decreased hepatic production of proteins involved in iron metabolism; a few of these patients may actually have iron deficiency anemia secondary to chronic blood loss. The anemia, if present, is usually mild, and although serum iron may be decreased, storage iron is usually normal to slightly increased. Approximately two-thirds of dogs and one-third of cats with portosystemic shunts have microcytosis.

Animals with anemia of inflammation usually have normocytic anemias, but occasionally the MCV will fall below the reference interval. While serum iron is decreased in these animals, storage iron is normal to increased (see "Anemia of Inflammation," Chapter 8).

Finally, some dogs of the Asian breeds such as Shiba Inus, Akitas, chow chows, and Shar Peis normally have microcytosis without anemia. The microcytosis is apparently not associated with the high red cell potassium content seen in some Akitas.

Blood destruction (intravascular or extravascular hemolysis)

Immune-mediated hemolytic anemia

Immune-mediated hemolytic anemia (IMHA) is a consequence of increased red cell destruction, either as a result of antibody directed against erythrocytes, or immune complexes attaching to erythrocytes. IMHA is usually a markedly regenerative anemia, with increased polychromasia (reticulocytosis). However, in some instances, the anemia is nonregenerative as a result of antibody formation against RBC precursors, with destruction of polychromatophilic erythrocytes or earlier red cell precursors. Nonregenerative immune-mediated anemia is also referred to as precursor-targeted immune-mediated anemia (PIMA) and is discussed in Chapter 8. While most affected dogs and cats with PIMA eventually respond to immunosuppressive therapy, the time from onset to a regenerative response is usually several weeks to months. Other potential causes of a lack of regenerative response may include underlying anemia of inflammation with iron sequestration, and functional iron deficiency, in which the rate of iron release may not keep up with the increased rate of erythropoiesis.

The onset may be acute or gradual. IMHA is often classified as primary (idiopathic), or secondary, if concurrent disease is present. Often the cause is never determined, but in some instances it can be related to other disorders or events, such as infections, other immune-mediated disorders, modified live virus vaccination, neoplasia, particularly of the lymphoid system, bee stings, snake envenomation, zinc toxicosis, and administration of drugs. Whether snake and bee venoms actually induce immune-mediated

destruction or simply cause erythrocytes to become sphere-shaped is controversial (see "Differential Diagnoses" below). Drugs that have been associated with IMHA are numerous and include penicillin, cephalosporins, trimethoprim-sulfamethoxazole, levamisole, and amiodarone; in these cases, immune-mediated destruction occurs due to either the drug binding directly to erythrocytes (penicillin), or by the formation of drug-antibody immune complexes, which also may bind to red blood cells. Red cell parasites such as large or small forms of *Babesia* and *Mycoplasma haemocanis* may induce IMHA in dogs (see "Erythrocyte Parasites" below).

RNA sequencing of whole blood from IMHA-affected untreated dogs found overexpressed genes in pathways related to neutrophil function, coagulation, and hematopoiesis. The most highly overexpressed gene was a phospholipase scramblase, which mediates the externalization of phosphatidylserine from the inner to the outer leaflet of cell membranes. This family of genes has been shown to be important for programmed cell death of erythrocytes as well as the initiation of the clotting cascade. However, some of the changes in gene expression that were observed may possibly be found in dogs with any type of regenerative anemia or inflammatory response. Interestingly, no genes for infectious agents were found in this study [2]. Future studies will likely be performed to further evaluate the role of phospholipase scramblases in the pathogenesis of canine IMHA.

IMHA is the most common cause of hemolytic anemia in the dog in the United States, and has been described in horses, cattle, and cats. Breeds of dogs more commonly affected include cocker spaniels, springer spaniels, poodles, Old English sheepdogs, flat-coated retrievers, and collies, and the disorder is slightly more common in females than in males. In horses, IMHA has been associated with penicillin and other antibiotic administration, clostridial infections, and neoplasia, but primary IMHA has been reported, sometimes in conjunction with immune-mediated thrombocytopenia. In cats, IMHA has been most commonly associated with *Mycoplasma haemofelis* infection, feline leukemia virus, and lymphoproliferative and myeloproliferative disease. IMHA has been reported in cattle with theileriosis and anaplasmosis, which is not surprising, since antibody is likely to be directed against the erythrocyte parasite. However, primary IMHA has been reported in a few cattle.

Mechanisms of red cell destruction can be due to either erythrophagocytosis or intravascular hemolysis. Macrophages have receptors for antibody as well as complement (C_3b), and removal of erythrocytes by macrophages occurs in multiple organs, including the spleen, bone marrow, and liver. Rarely, monocytes that have phagocytized erythrocytes may be observed on blood films (Figure 9.5). Partial erythrophagocytosis by macrophages results in the formation of spherocytes, the hallmark of IMHA. Spherocytes appear small, although their volume is normal, because

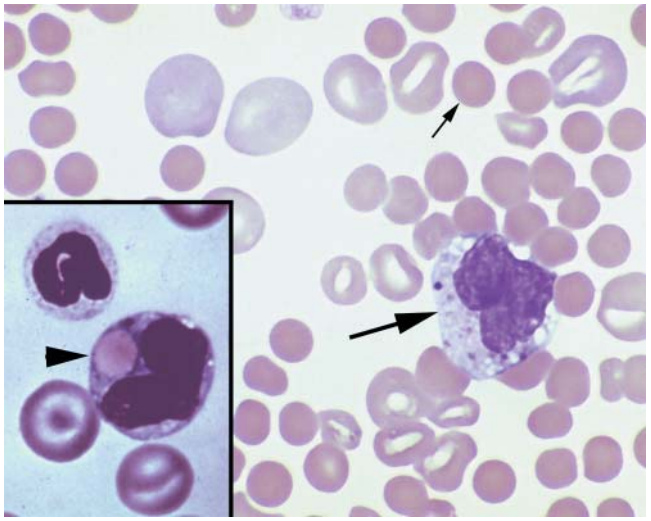

Figure 9.5 Blood film from a dog with immune-mediated hemolytic anemia. Numerous spherocytes (small arrow) are present. Rarely, monocytes may be observed that contain hemosiderin (large arrow) or phagocytized erythrocytes (inset, arrowhead). Wright stain.

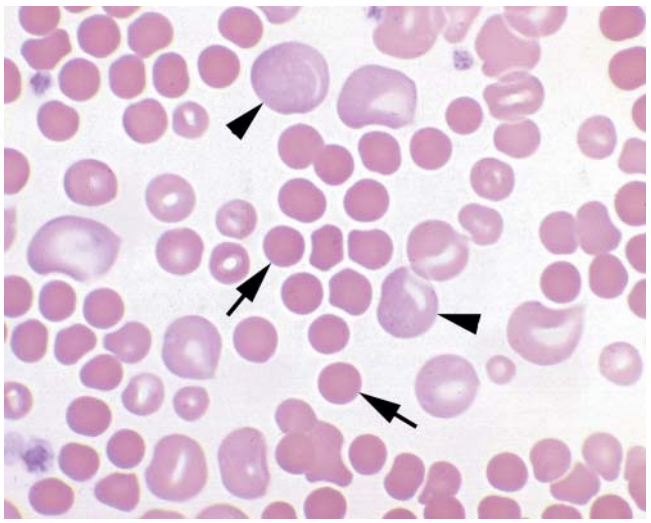

Figure 9.6 Blood film from a dog with immune-mediated hemolytic anemia. The polychromatophilic erythrocytes (arrowheads) indicate that the anemia is regenerative; numerous spherocytes (arrows) are present, as is agglutination. Wright stain.

they are sphere-shaped, lack central pallor, and appear to be dense (Figure 9.6). They have a shortened half-life because they are not as deformable as normal biconcave disk-shaped erythrocytes. They exhibit increased saline fragility, which may be diagnostically useful. Spherocytes are difficult to detect in species in which the red cells normally lack central pallor. They are, however, readily detectable in dogs, although imperfect spherocytes, which have a small amount of central pallor, are sometimes missed. If complement fixation goes to completion, resulting in membrane attack complex formation, intravascular lysis occurs. In these

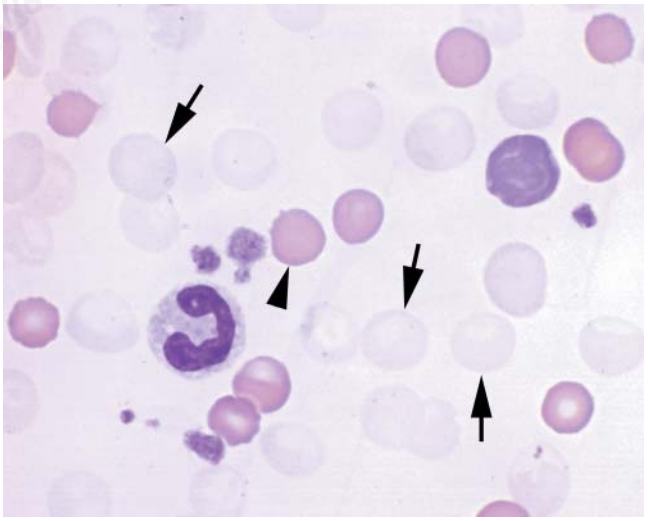

Figure 9.7 Blood film from dog with intravascular hemolysis secondary to immune-mediated hemolytic anemia. Numerous spherocytes (arrowhead) and lysed "ghost" erythrocytes (arrows) are present. Wright stain.

instances, ghost erythrocytes are occasionally observed on blood films (Figure 9.7). Hemoglobinemia, hemoglobinuria, hyperbilirubinemia, and bilirubinuria are often present.

Antibodies associated with IMHA are usually IgG or IgM, but IgA has also been reported to bind to erythrocytes. Usually the antibody is attached to erythrocyte membrane glycoproteins. If IgM is involved, agglutination of erythrocytes can usually be observed on the blood film, and may be grossly evident in the blood tube. IgG is sometimes referred to as an incomplete antibody, since it usually does not result in intravascular hemolysis or agglutination, but rather predisposes to erythrocyte phagocytosis by macrophages. The presence of antibody can be detected by performing a Coombs test (see Chapter 1 and below). Antibodies against erythrocytes are sometimes classified as either warm, which is common, or cold reactive, which is rare. Warm antibodies react most strongly at body temperature, and cold antibodies react more strongly at cold temperatures. Cold agglutinin disease may result in red blood cell agglutination in distal extremities such as the tips of the ear pinnae, tail tip, nose, and digits, with subsequent obstruction of small vessels and necrosis. Hemolytic anemia is sometimes associated with this syndrome, which has been described in the dog and cat.

Clinical signs and laboratory findings

Clinical signs are variable and often include lethargy, splenomegaly, fever, and icterus, as well as other general signs associated with anemia, such as pale mucous membranes, dyspnea, tachycardia, and systolic heart murmur if the anemia is severe. If the anemia is acute, animals may present in a state of collapse, whereas animals with a more chronic onset may accommodate to the anemia, and show much less severe clinical signs.

Laboratory findings vary but always include a decreased packed cell volume, red blood cell count, and hemoglobin concentration indicative of anemia. If intravascular hemolysis is present, hemoglobinemia, hemoglobinuria, hyperbilirubinemia, and bilirubinuria may be present. Additionally, the hemoglobin concentration may be falsely increased relative to the packed cell volume, thus falsely increasing the MCHC.

Blood film examination almost always reveals spherocytosis, which is the most diagnostically useful laboratory finding in these patients. Blood films should be evaluated for spherocytes in the counting area, since erythrocyte flattening at the feathered edge can appear similar to spherocytosis (see "Spherocytes," Chapter 6). More than three spherocytes/oil immersion field is suggestive of IMHA.

Agglutination may be present and can be differentiated from rouleaux formation by mixing one drop of blood with four drops of isotonic saline; agglutination will persist in the presence of saline while rouleaux formation will disperse (see "Agglutination," Chapter 6). Agglutination can be confirmed in samples with equivocal results (due to marked rouleaux formation) by washing erythrocytes three times in a 1 : 4 ratio with room temperature saline. Agglutination may be so marked that it can be seen grossly on the blood film or on the side of the ethylenediaminetetraacetic acid (EDTA) tube. If agglutination is present, the MCV may be falsely increased, since agglutinated red cells (doublets and triplets) may be counted as large cells by impedance electronic cell counters (see Chapter 1). The MCV will also be increased if reticulocytosis is present but often does not exceed the reference interval.

The leukogram is almost always inflammatory, with a mature neutrophilia, increased bands, and monocytosis. This inflammatory response was once thought to be due to release of colony stimulating factors from activated macrophages. More recently, the degree of neutrophilia, as well as increased immature neutrophils, has been thought to correlate with the amount of tissue damage secondary to hypoxia and thromboembolic disease.

Platelet concentration may be decreased because of concurrent immune-mediated destruction (Evans syndrome) or secondary DIC. Because both subclinical and clinical DIC are commonly associated with IMHA, other laboratory tests that may be abnormal are those that are used to diagnose DIC, including a prolonged activated partial thromboplastin time, prolonged one-stage prothrombin time, decreased antithrombin activity, increased fibrin(ogen) degradation products concentration, and increased D-dimer concentration.

Bone marrow aspiration is usually not indicated in IMHA but is commonly performed in patients in which the anemia is nonregenerative. In these cases, an apparent maturation arrest of the erythroid series, often at the rubricyte stage, may be present, due to destruction of more mature forms of

erythrocytes. Metarubricytes and polychromatophilic erythrocytes are often decreased to absent in the marrow from such patients, and occasionally, increased erythrophagocytosis and phagocytosis of nucleated erythrocytes may be observed.

A Coombs test may be useful for diagnosis. A species-specific antiglobulin reagent (Coombs serum) is added to a saline-washed suspension of the patient's erythrocytes. Agglutination results if the red cells are coated with autoantibody. However, if agglutination is already present, a Coombs test is not indicated. In some cases in which agglutination is observed, the Coombs test is falsely negative, presumably because the IgM antibody is eluted from the erythrocytes during the washing process. The Coombs test was first developed for use in humans in 1945 by R.R.A. Coombs, a veterinary immunologist in the Department of Pathology at Cambridge University, who hypothesized that antibody to human globulin could be synthesized by rabbits inoculated with human globulin, and this sera could then attach to globulin binding to erythrocytes, resulting in agglutination. This test is also known as the direct antiglobulin test (DAT). The Coombs test has numerous limitations in domestic animals because of false-negative and false-positive results, both of which are common. False-negative results occur due to the following: low concentration of antibody bound to erythrocytes, improper antiglobulin to antibody ratio, not incorporating the drug that is suspected of inducing the antibody response, and improper temperature. False-positive results occur when various types of disease cause immune complexes or complement to bind to erythrocytes, without resulting in anemia. False positives are particularly common in cats. Previous treatment with glucocorticosteroids may cause a negative result, and previous blood transfusion may cause a positive result. A more sensitive enzyme linked immunosorbent assay (ELISA) to detect immunoglobulins bound to erythrocytes has fewer false-negative results. However, this direct enzyme-linked antiglobulin test (DELAT) may also be falsely positive, is laborious, and not available in most laboratories. Direct immunofluorescence (DIF) flow cytometry is more sensitive (but less specific) than the Coombs test, can be used to determine the class of antibody present, detects the percentage of erythrocytes bound with antibody, and can thus be used to monitor response to therapy.

Azotemia may be present, either prerenal or renal, if intravascular hemolysis is severe. Free hemoglobin binds to haptoglobin, but when the available haptoglobin is saturated, hemoglobinuria secondary to hemoglobinemia occurs. Acute renal failure may be due to either erythrocyte membrane antigen-antibody complex deposition or direct toxicity of free hemoglobin to renal tubular cells.

Differential diagnoses

IMHA can usually be easily differentiated from other types of hemolytic anemia by the presence of spherocytes on blood film from patients with IMHA. However, spherocytes occasionally may be seen in dogs with rattlesnake envenomation (Figure 9.8) and bee envenomation (see Section VII, Case 18). Spheroechinocytes and type III echinocytes are seen commonly in dogs with rattlesnake envenomation (see Chapter 6); spherocytes may be present after the echinocytic changes have disappeared. It is likely that spherocyte formation is simply a result of membrane alterations induced by phospholipase A_2 (PLA_2) present in the snake venom. Bee venom contains melittin and a PLA_2 that is very similar to that found in snake venom, both of which have been shown to induce hemolysis, both *in vivo* and *in vitro*, through a chemical mechanism associated with echinocyte formation at low doses and spherocyte formation at higher doses. Melittin also induces band 3 clustering, and delayed hemolytic anemia could be due to antibody formation against altered erythrocyte membranes.

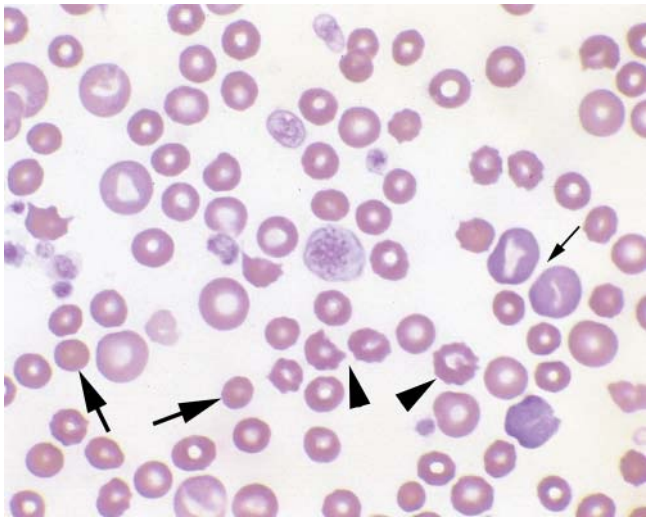

Figure 9.8 Spherocytes (large arrows) in a blood film taken from a dog several days following rattlesnake envenomation. The dog previously had echinospherocytes, and some spiculated erythrocytes remain (arrowheads). The anemia is regenerative, as indicated by the polychromatophilic erythrocytes (small arrow). The dog is recovering from thrombocytopenia; a giant "young" platelet is in the center of the field. Wright stain.

Spherocytes, along with spheroechinocytes and type III echinocytes, may also be observed in horses with clostridial infections presumably as a result of the bacterial phospholipase hydrolyzing erythrocyte membrane phospholipids (sphingomyelin and lecithin), producing lysolecithin, an echinogenic agent. These cases may be confusing, as clostridial infections in horses have been associated with IMHA, diagnosed by the presence of spherocytes, autoagglutination, and positive Coombs test. However, clostridial organisms also can directly induce hemolysis through the release of toxins. It is also possible that phospholipases may be able to induce immune-mediated hemolysis, likely as a result of attachment of antibody to altered erythrocyte membranes.

IMHA may be mistakenly diagnosed in horses with Heinz body anemia, possibly because collapse of the erythrocyte membrane following eccentrocyte formation results in erythrocytes that appear similar to spherocytes. However, an alternative explanation is that immune-mediated destruction of erythrocytes with spherocyte formation occurs, since Heinz body formation may result in band-3 clustering with secondary antibody attachment. Spherocyte formation secondary to band-3 clustering is also seen in dogs with zinc toxicosis. Interestingly, dogs with zinc toxicosis are Coombs negative, and it has been hypothesized that during the erythrocyte washing process, zinc is removed, band 3 is returned to a dispersed distribution, and antibodies are eluted, resulting in a negative test. Finally, animals that have had incompatible blood transfusions may develop some degree of IMHA and spherocytosis, and animals that have fragmentation of erythrocytes may have spherocytosis, as the fragments may "round-up" and appear to be small spherocytes. Spectrin deficiency has been reported in Dutch golden retrievers; some, but not all, affected dogs had spherocytosis.

Prognosis

Mortality rates vary, and are reported to range from 25% to 50%. Although some reports suggest that dogs that are autoagglutinating or have intravascular hemolysis have the highest mortality, this is controversial. Thromboembolism is a common finding in dogs that die. Recurrence of IMHA or other immune-mediated disorders such as immune-mediated thrombocytopenia is relatively common.

Therapy

Differentiation of spontaneous (primary) IMHA from secondary IMHA associated with a trigger factor is an important component of treatment and prognosis. Initial treatment of dogs consists of glucocorticosteroids (usually prednisone, 2–3 mg/kg per os every 12 hours), which decreases antibody production, T cell activity, and diminishes macrophage function. Dexamethasone is often used in horses, and has been reported to be effective in cattle. Disadvantages of glucocorticoids include predisposing patients to infection, thromboembolic disease, and polyuria and polydipsia. Combination treatment may be warranted in dogs that are not responsive to or are intolerant of glucocorticoids; other immunosuppressive drugs may allow tapering of the glucocorticoid. Therapeutic modalities may include azathioprine, danazol, cyclosporine, cyclophosphamide, bovine hemoglobin solution, or human immunoglobulin. However, in one retrospective study, no difference in mortality was detected between the use of multiple immunosuppressive agents and the use of glucocorticoids alone, and in fact the risk of death was slightly lower (30%) with glucocorticoids alone than the overall mortality rate of 50%. In addition, the use of cyclophosphamide and bovine hemoglobin solution has been associated with increased risk of death, and are currently not recommended. Danzol, a synthetic androgen, and cyclosporine, an immune response inhibitor, have been reported to be of no benefit with respect to reducing mortality. Some immunosuppressive drugs, other than the glucocorticoids, may injure marrow, resulting in a transient loss of regenerative response, and some drugs may not be effectively metabolized with severe anemia, making them more toxic than usual. Dogs usually respond to glucocorticoid therapy within 1 week, although dogs with antibody directed against erythrocyte precursors usually take longer to respond. The dosage of glucocorticoids is gradually decreased once the PCV increases, and can sometimes be discontinued 2 or 3 months after the PCV returns to normal. In some cases, however, low dose therapy (0.5 mg/kg per os every other day) with prednisone or prednisolone may be required indefinitely.

Fluid therapy is indicated, particularly in patients with intravascular hemolysis, and lactic acidosis secondary to anemia should be corrected. In addition, therapy is recommended to inhibit thrombosis, particularly pulmonary thromboembolism, a common cause of death in dogs with IMHA. The American College of Veterinary Internal Medicine has published a consensus statement of guidelines for therapy of IMHA in dogs [3]. A very brief summary of their guidelines follows.

1. Packed red cells or whole blood transfusions should be given to dogs that have severe clinical signs of decreased tissue oxygen delivery. Even if dogs have no clinical signs, transfusion should be given when the PCV decreases to 12% or less. Bovine hemoglobin solutions and frozen plasma are not recommended.

2. Predinisone or prednisolone at a dose >2 mg/kg is strongly recommended. Dose should be decreased to <2 mg/kg d if the PCV is stabilizing. Once the patient is stable, the dose should be decreased by 25% every 3 weeks. A typical duration of 3–6 months of prednisone or prednisolone should be anticipated. Monitoring for iatrogenic Cushing's syndrome and infections secondary to immunosuppression should be done.

3. A second immunosuppressive drug should be given if the dog is not responding to glucocorticoids or is experiencing serious glucocorticoid side effects. Recommended second immunosuppressive drugs are azathioprine, cyclosporine, or mycophenolate mofetil. Cyclophosphamide should not be given.

4. Heparin is recommended to prevent thromboembolism, and therapy should be monitored. If antiplatelet drugs are administered, clopidogrel is recommended over aspirin.

5. If gastroprotectant therapy is given to prevent ulceration secondary to glucocorticoids, a proton pump inhibitor is recommended.

In summary, IMHA is a very important cause of morbidity and mortality in dogs and occurs much more frequently in dogs than in other species. The American College of

Veterinary Internal Medicine has published a consensus statement on the diagnosis of IMHA in dogs and cats that emphasizes recognition of triggering factors [4].

Neonatal isoerythrolysis

Neonatal isoerythrolysis (NI) is a form of IMHA that occurs in newborn animals secondary to maternal antibodies against the neonate's bloodgroup antigen attaching to the neonate's erythrocytes, with subsequent erythrocyte hemolysis. The maternal antibodies are usually produced after sensitization of the mother with blood group-incompatible erythrocytes, usually from the blood of a previous fetus gaining access to maternal circulation but sometimes from vaccinations that contain erythrocytes or from mismatched blood transfusions. The disorder is most common in horse and mule foals but occurs in less than 1% of thoroughbreds. The disorder rarely occurs in puppies, kittens, piglets, and calves. Cats are unique, in that antibodies against kitten erythrocytes can be produced with no previous exposure of the queen to incompatible erythrocytes. In domestic animals, the maternal antibody gains access to the neonate's blood following ingestion of colostrum containing antibody. Hemolytic anemia has been reported in lambs fed bovine colostrum during the first few days of life, and the anemia appears to be immune-mediated.

Affected animals are normal at birth, but within 24–48 hours they become weak, lethargic, pale, and anemic, with icterus and dyspnea. Hemoglobinemia and hemoglobinuria may be present, as well as splenomegaly and hepatomegaly. Thrombocytopenia and DIC may also occur. Immune-mediated neutropenia in conjunction with IMHA has also been reported in a foal. In foals, approximately 90% of all cases of NI are attributable to the Aa or Qa antigen, but other antigens may be involved. The occurrence in mule foals may be due to a xenoantigen. It is possible that all mule pregnancies (donkey sire × horse dam) are incompatible with regard to this factor and a potential for NI exists in all cases.

Laboratory diagnosis

Diagnosis is usually made by confirming the presence of maternal antibodies on the neonate's erythrocytes by a Coombs or a hemolytic test. Blood from pregnant mares can be tested 2 weeks prior to foaling for the presence of antibodies in order to predict the likelihood of NI in the foal. If the dam is sensitized, then her colostrum can be withheld from the foal for the first 48 hours of life, substituting another mare's colostrum.

Treatment

Treatment consists of blood transfusion if the animal is severely anemic. If the mare's blood is used, the erythrocytes must be washed extensively to remove antibody-containing plasma. Glucocorticoids may be helpful in reducing the rate of clearance of antibody coated erythrocytes.

Erythrocyte parasites

Microorganisms that directly infect erythrocytes may result in intravascular hemolysis or extravascular hemolysis, and some may not cause hemolytic anemia. Traditionally, hemoparasites have been detected by examination of blood films. However, the development of highly sensitive and specific polymerase chain reaction (PCR) assays to detect small quantities of organisms has made diagnosis much more accurate for many of these diseases, in some cases even before the onset of clinical signs. The majority of the hemoparasites cause anemia by immune-mediated extravascular hemolysis. Antibody against the organism, immune complexes, or complement bound to erythrocytes results in phagocytosis by macrophages. However, *Babesia* and *Theileria* species cause intravascular hemolysis. Specific hemoparasites are discussed below.

Hemotropic mycoplasmas

Hemotropic mycoplasmas are pleomorphic bacteria that parasitize erythrocytes of many domestic animal species. These organisms are small (approximately 0.3 μm in diameter), lack a cell wall, and stain gram-negatively. They adhere loosely to the surface of the erythrocyte membrane, and in many species, fall off easily, therefore appearing in the plasma. They were originally discovered in laboratory rodents in the 1920s and assigned to the *Bartonella* genus. Approximately one decade later they were reclassified into the order Rickettsiales in the family Anaplasmataceae, and either to the genus *Haemobartonella* or *Eperythrozoon* on the basis of whether they occurred more commonly as "ring forms," and whether they were found free in the plasma. If they fulfilled both of the previous criteria, they were assigned to the genus *Eperythrozoon*. These characteristics are now considered insignificant. With the advent of DNA sequencing and phylogenetic analysis based on ribosome gene sequence comparisons, these organisms have been reclassified as members of the genera *Mycoplasma*.

The first description of such bacteria in an anemic cat was published in 1942, and was initially named *Eperythrozoon felis* and shortly thereafter renamed *Haemobartonella felis*. Three strains of the organisms previously called *H. felis* have been recognized. The "large" or Ohio strain has been renamed *M. haemofelis*, and the "small" California strain has been named *Candidatus Mycoplasma haemominutum*. A third strain, *Candidatus Mycoplasma turicensis*, was originally identified in a Swiss cat but is now known to also have a worldwide distribution. Assays based on PCR technology are the most sensitive and specific diagnostic tests available for these organisms. Of the feline mycoplasmas, *M. haemofelis* is the most pathogenic species, and causes hemolytic anemia in immunocompetent cats. The presence of *Candidatus Mycoplasma turicensis* and *Candidatus Mycoplasma haemominutum* is not always associated with anemia. However, *Candidatus Mycoplasma haemominutum* has been

associated with fever, anorexia, lethargy, and anemia and is likely a primary pathogen. *Candidatus Mycoplasma turicensis* has reportedly not been seen by light microscopy, likely due to the small numbers of parasites present but possibly due to its smaller size (0.25 μm). It has been morphologically characterized using electron microscopy. Two other species, *Candidatus Mycoplasma haematoparvum* and *Candidatus Mycoplasma haematoparvum*-like, have been detected in cats using ribosomal gene analysis, but their pathogenicity is not known.

Haemobartonella canis has been renamed *M. haemocanis*. *Eperythrozoon suis*, *Eperythrozoon wenyoni*, and *Eperythrozoon ovis* have been renamed *Mycoplasma haemosuis*, *Mycoplasma wenyonii*, and *Candidatus Mycoplasma ovis*, respectively. The eperythrozoon in alpacas and llamas, previously not named, has been named *Candidatus Mycoplasma haemolamae*. The designation *Candidatus* is reserved for incompletely described members of taxa, to give them provisional status, and is eventually dropped.

Mycoplasma haemofelis

Mycoplasma haemofelis appears as small (0.3 μm) dark blue rods or ring forms on the surface of erythrocytes; it is more easily seen at the feathered edge of the blood film where the erythrocytes are flattened (Figure 9.9). Agglutination of erythrocytes may be present, as the presence of the organism on erythrocytes results in an IMHA. *M. haemofelis* is quite pathogenic, and can cause severe, sometimes fatal, hemolytic anemia. It is transmitted through infected blood, presumably by blood feeding arthropods such as fleas and ticks, cat bites, and iatrogenic exposure, and is present throughout the world. The organism is also transmitted from queens to kittens, either in utero, at birth, or by nursing. The parasitemia is intermittent, making diagnosis by blood film examination sometimes difficult. A PCR assay is much more diagnostically sensitive than blood film examination.

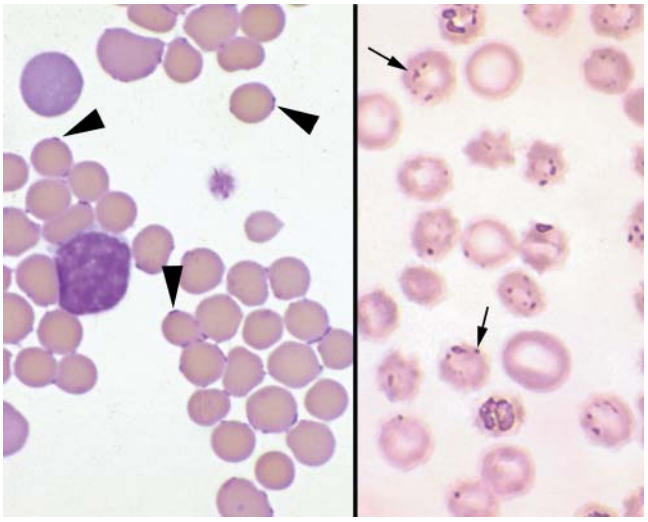

Figure 9.9 Left. Blood film from an anemic cat with *Mycoplasma haemofelis* (arrowheads), previously known as *Haemobartonella felis*. Right. Erythrocyte parasites are sometimes mistakenly diagnosed when artifacts are on erythrocytes (arrows). Artifacts may be caused by stain precipitate or staining the blood film before it is dry. Wright stain.

Clinical signs include those of anemia, including splenomegaly, fever, lethargy, and sometimes icterus. Concurrent disease, immunosuppression, or splenectomy may predispose animals to acute infection. The anemia is regenerative unless underlying disease, sometimes related to feline leukemia virus, is present that would inhibit erythropoiesis. Infected cats should be examined for the presence of feline leukemia virus and feline immunodeficiency virus.

Treatment consists of blood transfusion if the anemia is severe. Prednisone (2 mg/kg per os every 12 hours) will suppress the immune-mediated destruction of erythrocytes, but its use is controversial. Doxycycline (5 mg/kg per os every 12 hours for 4 weeks) is effective against the organism, but cats that recover may become latent carriers. Toxicity of doxycycline may include fever, gastrointestinal disturbances, and rarely, esophageal stricture formation. Enrofloxacin (5–10 mg/kg per os every 24 hours) a fluoroquinolone anti-Mycoplasma antibiotic, has been shown to be effective against *M. haemofelis*, but a rare complication is acute blindness. An excellent update on therapy of feline hemoplasmosis has been published [5].

Mycoplasma haemocanis

Mycoplasma haemocanis, formerly known as *Haemobartonella canis*, is an opportunistic organism, usually causing disease only in splenectomized or severely immunosuppressed dogs. It is closely related phylogenetically to *M. haemofelis*, with 99% homology of the 16SrRNA gene. Dogs that are splenectomized develop active infections if they are transfused with infected blood, or if they have latent infections. Active infection may manifest days to weeks after splenectomy. The microorganism appears somewhat different than *M. haemofelis*, in that they appear as small chains of cocci across the surface of the erythrocyte. The chain commonly branches, and appears Y-shaped (Figure 9.10). Clinical signs include those of anemia, and icterus is rarely present. Treatment consists of 5 mg/kg doxycycline orally twice daily for 3 weeks. *Candidatus Mycoplasma haemominutum* and *Candidatus Mycoplasma haematoparvum* have been reported in dogs, as well. *M. haemocanis* has also been shown to be transmitted vertically.

Haemoplasmas of ruminants

Mycoplasma wenyonii also occurs worldwide, and similar to *M. haemocanis* in dogs, usually only causes severe anemia in immunosuppressed or splenectomized cattle. The organism may be transmitted iatrogenically, by using the same syringe and needle in multiple animals in feedlot situations. Very large numbers of organisms can be seen on blood films, many

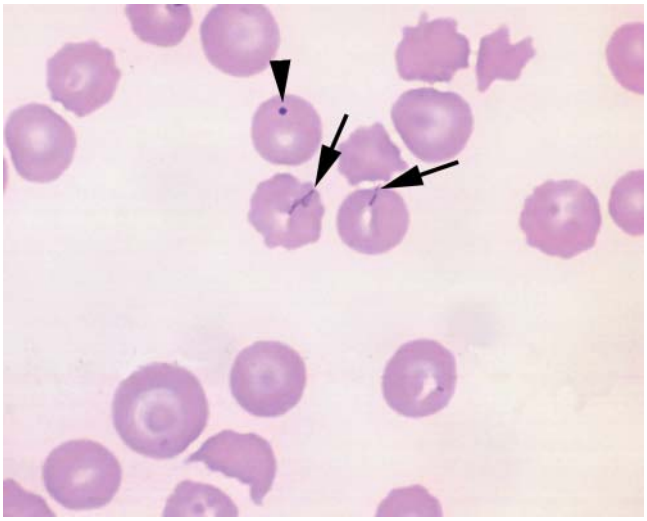

Figure 9.10 Blood film from an anemic splenectomized dog. Note the presence of *Mycoplasma haemocanis* (arrows) (previously *Haemobartonella canis*). Howell-Jolly bodies (arrowhead) are usually increased in splenectomized animals. Wright stain.

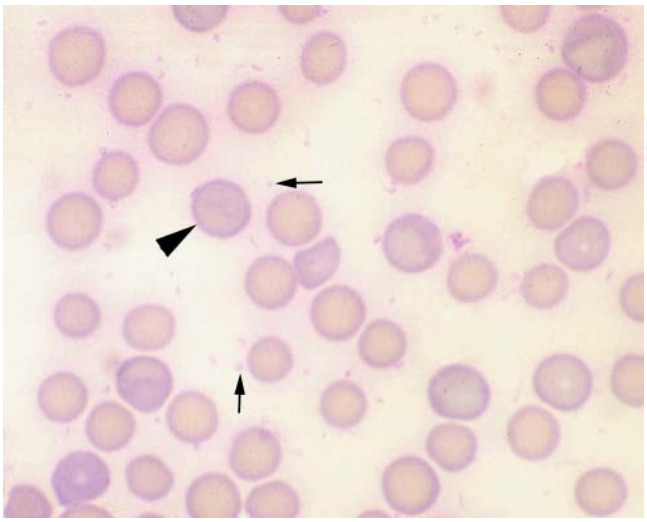

Figure 9.11 Blood film from a cow with hind limb and teat edema. Many *Mycoplasma wenyonii* (previously *Eperythrozoon wenyonii*) organisms are present in the background (small arrows). *Polychromasia* (arrowhead) is present, indicating regeneration. Wright stain.

of which are free in the plasma, in cattle that are not anemic (Figure 9.11). However, a syndrome has been recognized in cattle that are heavily parasitized, which includes dependent edema and lymphadenopathy. Although the haemoplasma of sheep and goats, formerly known as *E. ovis* (Figure 9.12) is generally considered nonpathogenic in adults, its role as a cause of anemia in lambs is controversial. It has been renamed *Mycoplasma ovis*. There is considerable genetic diversity in haemoplasmas of ruminants, and additional

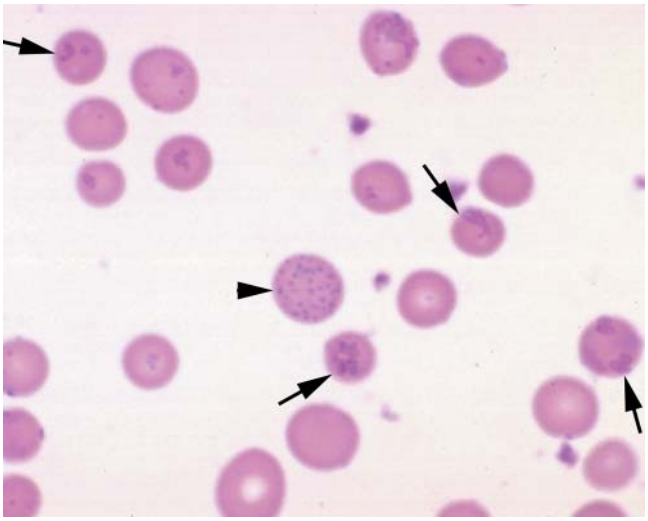

Figure 9.12 Blood film from a sheep with *Eperythrozoon ovis* (arrows). This organism will be renamed *Mycoplasma ovis*. Wright stain.

ones have been described, such as *Candidatus Mycoplasma haemobos*.

Mycoplasma suis

At least three species of *Mycoplasma* have been described in pigs: *Mycoplasma suis*, *Mycoplasma parvum*, and *M. haemosuis*. *M. suis* is associated with porcine hemoplasmosis and is pathogenic in very young pigs, as well as pigs that have been splenectomized, causing severe hemolytic anemia and sometimes death. In older animals, infection is associated with poor weight gain. The organisms appear similar to those in cattle, with many free organisms present on blood films (Figure 9.13). Baby pigs are usually treated with a single

dose of long acting oxytetracycline (25 mg). Tetracycline is sometimes added to hog food to prevent the acute form of the disease.

Mycoplasma haemolamae

Haemoplasmas in llamas and alpacas appear to be opportunists that proliferate in animals doing poorly, and usually only cause a mild anemia. The organism appears similar to that in cattle (Figure 9.14).

Anaplasmosis

Bovine anaplasmosis, first characterized by Sir Arnold Theiler in 1910, and caused by the intraerythrocytic rickettsia *Anaplasma marginale*, is the most prevalent tickborne disease of cattle and occurs worldwide. *Anaplasma centrale* causes a milder less virulent form of disease, and occurs in south America, the Middle East, and South Africa. *A. marginale* has also been reported in deer, elk, and bison. *Anaplasma ovis* has been reported in goats and sheep, and causes hemolytic anemia. The organism appears similar to *A. marginale*. The organisms are transmitted by ticks, biting flies, and iatrogenically. *A. marginale* appears as a small (0.5–1 μm) dark blue inclusion on the margin of erythrocytes (Figure 9.15). *A. centrale* appears similar but is in a more central appearing location on erythrocytes. Infection with the organism can cause a fatal hemolytic anemia; older animals are usually more severely affected. The mechanism of anemia may be immune mediated. Untreated cattle that survive may become chronic carriers. Diagnosis can be made by PCR assays, as well as examination of blood films. Therapy consists of long acting oxytetracycline, but the most efficient method to control anaplasmosis is by vaccination using live *A. centrale*, which is capable of inducing significant protection against the more virulent *A. marginale*. However, these methods of control have numerous limitations and improved approaches are needed. Inactivated or subunit vaccines and alternative pharmacological interventions are being developed. The *Anaplasma* genus has been expanded to also include *Anaplasma phagocytophilum* (formerly known as *Ehrlichia phagocytophila*, *Ehrlichia equi*, and the agent of human granulocytic ehrlichiosis), Anaplasma *bovis* (formerly *Ehrlichia bovis*), and *Anaplasma platys* (formerly *Ehrlichia platys*).

Piroplasmosis

The order Piroplasmida are obligate intracellular hemoprotozoan parasites that are transmitted by ticks. They are classified into three families based on the type of vertebrate cells in which they develop. Theileriidae infect mammals, first developing in leukocytes, then erythrocytes; Babesiidae infect mammals and some birds but develop only in erythrocytes; Hemohormidiidae infect fish and reptiles, where they develop in nucleated red blood cells. The word piroplasm comes from Latin pirum, meaning pear, as the organisms are often pear-shaped. Two piroplasmid genera, *Babesia* and *Theileria*, are responsible for some of the most important diseases of domestic and wild animals and are discussed below. The genus *Cytauxzoon* is closely related to *Theileria* and is also discussed below. The piroplasm stages in the erythrocytes are morphologically very similar. *Theileria* and *Cytauxzoon* were originally thought to differ from one another by the location of schizogony within the host cells. Schizogony of *Cytauxzoon* spp. occurs in macrophages, whereas *Theileria* schizogony was thought to take place exclusively in lymphocytes. It is now known that *Theileria* species can also infect and transform macrophages. The

mechanism of anemia is primarily immune mediated, with antibodies directed against the organisms. However, damage to and alteration of the erythrocyte membrane likely also triggers immune-mediated erythrocyte destruction.

Babesiosis

Babesia spp are tick-borne protozoan parasites that infect erythrocytes of domestic and wild animals, as well as humans, often causing a potentially lethal hemolytic anemia. The disease is named after the Romanian biologist, Victor Babes, who isolated the organism from cattle in 1888. In 1893 it was discovered that the organism was transmitted by ticks and was the cause of Texas cattle fever. Babesiosis was considered an animal disease until it was discovered in a Yugoslavian cattle farmer in 1957.

Canine babesiosis is associated with hemolytic anemia, thrombocytopenia, and other manifestations of systemic inflammation, including liver, lung, pancreas, kidney, heart, and brain dysfunction, and is caused by numerous species that were previously identified by their morphologic appearance and size. Classification by size is thought by some to be problematic, because piroplasms undergo marked morphological changes during their development in erythrocytes. Large forms were classified as *Babesia canis*, and small forms were classified as *Babesia gibsoni*. Large forms (2–5 μm) appear as single, paired, or tetrad oval erythrocyte inclusions that stain lightly basophilic with an eccentric nucleus (Figure 9.16). Small forms (1–3 μm) of *Babesia* appear as round organisms (Figures 9.17 and 9.18). Usually only a few erythrocytes on blood films contain organisms, and they tend to be concentrated at the feathered edge of the blood film. While babesiosis may be diagnosed by blood film or buffy coat film examination, PCR is much more sensitive and specific. In areas where PCR is not available, acridine orange fluorescent dye staining method has been shown to be more sensitive and specific than Wrights-Giemsa stains.

Using molecular methods, it has now been shown that several genetically distinct species cause disease in dogs, including *B. canis*, *Babesia vogeli*, *Babesia rossi*, *B. gibsoni*, *Babesia conradae*, and *Babesia vulpes*. These various species have been shown to have different susceptibility to anti-protozoal drugs, thus identification by PCR should be done. Large forms (*B. canis*, *B. vogeli*, *B. rossi*) are susceptible to imidocarb dipropionate (Imizol, Merck Animal Health) and diminazine aceturate; the latter has serious side effects and is not available in the United States. The small forms

(*B. gibsoni*, *B. conradae*, *B. vulpes*) are relatively resistant to imidocarb dipropionate but are sensitive to a combination of the hydroxynaphthoquinone atovaquone and the antibiotic azithromycin, although they may remain carriers. A thorough discussion of therapy for canine babesiosis has been published [6].

Canine babesiosis is becoming increasingly common in the United States. *B. vogeli* is transmitted by *Rhipicephalus sanguineus*, the brown dog tick, and is pandemic in the southeastern United States, particularly in greyhounds, and is also found in the Caribbean, South and Central America, the Mediterranean, the Middle East, Asia, and Australia. It usually only causes severe hemolytic anemia and life-threatening disease in young dogs or dogs that are heavily parasitized, although adult greyhounds have more serious clinical signs. Infected dogs are often co-infected with *Ehrlichia canis*, *A. platys*, and *Hepatozoon canis*, since the same species of tick is responsible for transmission of all four diseases. Another species, *B. rossi*, is more pathogenic, and is in South Africa. A third species, *B. canis* is found in Europe, the United Kingdom, and parts of Asia, and is intermediate in pathogenicity.

B. gibsoni, a small form of *Babesia*, also can inflict severe disease, and is endemic in northern Africa, the Middle East, southern Asia, and parts of the Caribbean, and is increasingly observed in the United States, particularly in the Southeast and Midwest. Since 1999 *B. gibsoni* has been reported in numerous states east of the Mississippi River. The disease is primarily seen in American pit bull terriers and Staffordshire terriers. Many dogs survive the acute phase and become chronic carriers. Prevention includes aggressive tick control. The high prevalence in the pit bull breed is now thought to be due to direct blood transmission. *B. conradae*, a small *Babesia* originally thought to be *B. gibsoni*, was described in California dogs in 1991. This organism causes severe disease, including hemolytic anemia, icterus, vasculitis, thrombocytopenia, hepatitis, glomerulonephritis, and reactive lymphadenopathy. *B. vulpes* (also known as *Babesia microti*, *Babesia annae* and *Theileria annae* (see "Theileriosis" below) is found in dogs in Europe and North America and is a common infection in wild red foxes. *B. vulpes* appears to be more resistant to therapy. Because many dogs with babesiosis are Coombs positive and exhibit erythrocyte agglutination, a differential diagnosis is IMHA. Hyperglobulinemia, thrombocytopenia, and neutropenia are commonly observed, therefore canine monocytic ehrlichiosis must also be considered as a differential diagnosis, as these are common laboratory findings in that disease as well.

Feline babesiosis is rare compared to canine babesiosis, and occurs in numerous regions of the world. Small *Babesia* species infecting cats include *B. felis*, *B. cati*, and *B. leo*. Large *Babesia* species including *B. herpailuri* and *B. pantherae* have been reported in wild felids. Numerous species of both large and small *Babesia* normally occurring in dogs have also been reported in cats, many of which are clinically healthy. For example, 13% and 4% of clinically healthy cats tested on the Caribbean island of St. Kitts, West Indies were positive for *B. vogeli* and *B. gibsoni*, respectively. Severe disease is seen in cats infected with *B. felis* in South Africa. In contrast, disease caused by other *Babesia* species is usually mild and chronic.

Bovine babesiosis is mainly caused by *Babesia bovis* and *Babesia bigemina* in tropical and sub-tropical regions of the world. *B. bovis* is usually considered more virulent than *B. bigemina*, and has a higher mortality. Cause of death is usually hemolytic anemia. Adults are usually more severely affected than calves. *Babesia divergens* is primarily responsible for bovine babesiosis in Europe and may also infect immunocompromised humans. Other *Babesia* species have been infrequently reported in cattle. Bovine babesiosis if of economic importance in both the beef and dairy cattle industries, and remains poorly controlled in many parts of the world. *B. bovis* can be transmitted transplacentally, and should be considered as a differential diagnosis of fetal loss, stillbirth, and neonatal death in cattle where babesiosis occurs. Babesiosis in small ruminants such as sheep and goats is also of economic importance in tropical and subtropical areas. *Babesia motasi* and *B. ovis* are pathogenic, while *Babesia crassa*, *Babesia foliata*, and *Babesia taylori* are mild to nonpathogenic.

Equine babesiosis (piroplasmosis) is caused by two species, *B. equi* (more recently referred to as *Thelieria equi*) and *Babesia caballi*, and occurs in many parts of the world. Placental transmission has been documented, and is a cause of fetal death or neonatal infection. Horses commonly recover but become persistently infected carriers.

Theileriosis

Theileriosis is probably the most significant tick-borne disease to affect domestic ruminants in Africa. Although hemolytic anemia is common, piroplasm parasitemia does not correlate with disease severity. Many clinical and pathologic manifestations are related to proliferation of transformed leukocytes, with associated necrosis, thromboembolism, body cavity effusions, and lung edema. When infected ticks feed on their mammalian host, sporozoites enter mammalian leukocytes and divide to form multinucleated schizonts (Figure 9.19). These may be seen within leukocytes on blood films, as well as aspirates of lymph node and other tissue. Some schizonts undergo asexual reproduction (merogony) to form merozoites that undergo maturation; they then induce leukocytolysis and subsequently infect erythrocytes to form piroplasms, which are small (1 μm) and appear signet-ring- or comma-shaped. Schizonts can also induce pseudo-neoplastic proliferation of leukocytes, usually lymphocytes but likely also monocytes/macrophages, that disseminate to various organs. *Theileria* species are classified as pathogenic (schizont "transforming" leukocytes)

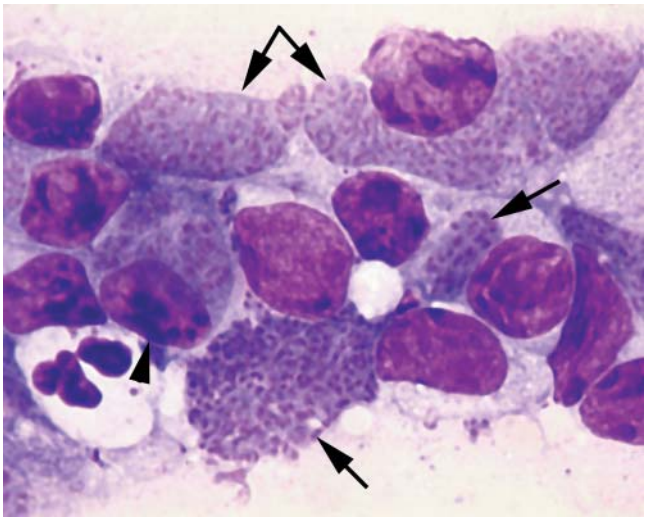

Figure 9.19 Lymph node aspirate from a cow with theileriosis. Lymphocytes are filled with schizonts (arrows). Wright stain.

or benign to mildly pathogenic ("nontransforming"). The pathogenic theilerias cause disease via transformation of host leukocytes to induce blastogenesis, uncontrolled proliferation, and widespread leukocyte dissemination. Transformed leukocytes appear atypical and are difficult to distinguish from neoplastic cells. Nuclei are indented, lobed, sometimes multiple, with prominent nucleoli, and abundant often vacuolated cytoplasm. Numerous cells in mitosis may be seen in aspirates or imprints of lymph nodes or other tissue.

Theileria parva, the cause of East Coast fever in eastern, central, and southern Africa, is responsible for the deaths of more than a million cattle per year, as well as reductions in growth rate and productivity. *Theileria annulata* causes bovine tropical theileriosis in North Africa, southern Europe, and large parts of Asia. Numerous "benign" typically leukocyte nontransforming species have been described in cattle, such as *Theileria taurotragi*, *Theileria mutans*, and *Theileria buffeli/orientalis*, but these can occasionally become leukocyte transforming. For example, *T. taurotragi* can cause an atypical fatal disease characterized by significant leukocyte transformation, proliferation, and invasion of the brain and spinal cord. Theileriosis also impacts wildlife in Africa. Although most *Theileria* species are nonpathogenic in wild ungulates, including deer and elk in North America, they may have pathogenic theileriosis with significant death rates that seriously impact endangered species, particularly in Africa. Small domestic ruminants such as sheep and goats also contract theileriosis. *Theileria ovis*, *Theileria lestoquardi, and Theileria annulate* have been reported, with *T. lestoquardi* causing the most significant disease.

Equine theileriosis, usually referred to as equine piroplasmosis, is caused by *T. equi*; this organism was formerly named *Babesia equi* (see earlier discussion under "Babesiosis"). The clinical signs of equine babesiosis and theileriosis are similar and include fever, anemia, inappetence, edema, icterus, hepatomegaly, splenomegaly, and occasionally abortion and death. *T. equi* appears smaller in erythrocytes than does *B. caballi*.

The literature on canine theileriosis is quite contradictory, and it seems that the species infecting dogs are nonleukocyte transforming. As mentioned previously, *B. vulpes*, also known as *B. microti*, *B. annae* and *T. annae*, is now considered a *Theileria* by numerous parasitologists; red foxes are considered the primary intermediate host of this organism. *T. annulata* was detected in an asymptomatic dog, and *T. equi* was identified in dogs in various countries.

Rangeliosis

Rangelia vitalli is a piroplasm for which there are conflicting reports as to whether it is in the family Theileriidae or Babesiidae, but since it infects leukocytes and endothelial cells, as well as erythrocytes, it is most likely from the family Theileriidae, if that distinction between the two families remains valid. *R. vitalli* causes severe anemia and thrombocytopenia in dogs and is transmitted by the tick *Amblyomma aureolatum*. Canine rangeliosis has been reported in Argentina, Uruguay, and Brazil. Common clinical signs include splenomegaly, hepatomegaly, lymphadenopathy, icterus, hematochezia, and pinnal bleeding. The organism appears similar to *B. vogeli* on blood films.

Feline cytauxzoonosis (bobcat fever)

Cytauxzoon felis is a protozoan piroplasm within the same family as *Theileria*. Like *Theileria*, merozoites (piroplasms) infect erythrocytes, while a tissue phase, the schizonts, infect and fill leukocytes, primarily monocytes/macrophages, within and surrounding blood vessels throughout the body. While cytauxzoonosis was first described in 1948 in African wild ungulates, the organism was likely a *Theileria* species. Cytauxzoonosis was initially reported in cats from Missouri in 1976 and is primarily in the southeastern and central United States but has been more recently reported in South America, and a less virulent species of *Cytauxzoon* has been reported in Europe. The organism is transmitted by the ticks *Amblyomma americanum* and *Dermacentor variabilis* in America. Although erythroparasitemia may occur following blood inoculation such as with a blood transfusion, the tissue phase of the organism and disease do not develop. Bobcats, Florida panthers, and Texas cougars, which serve as natural reservoirs, usually have persistent asymptomatic infections, although bobcats occasionally have fatal disease. Fatal cytauxzoonosis has also been described in a Bengal tiger and white tiger. The disease is often fatal in untreated domestic cats, although they too can have subclinical infections and act as reservoirs. Pathologic findings include thrombosis of numerous vessels as a result of distended macrophages occluding vessels. Clinical findings include acute lethargy, anorexia, fever, and icterus. Although the organism causes a

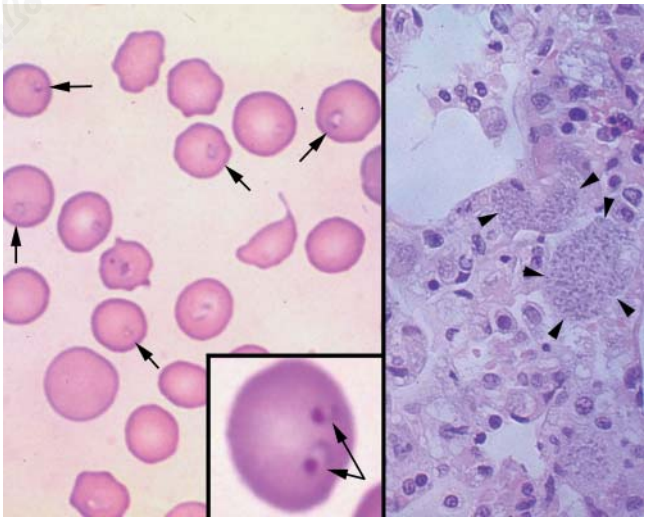

Figure 9.20 Left. Feline blood film with *Cytauxzoon* piroplasms in erythrocytes (arrows). Wright stain. Right. *Cytauxzoon* schizonts in macrophages of the same cat. H&E stain.

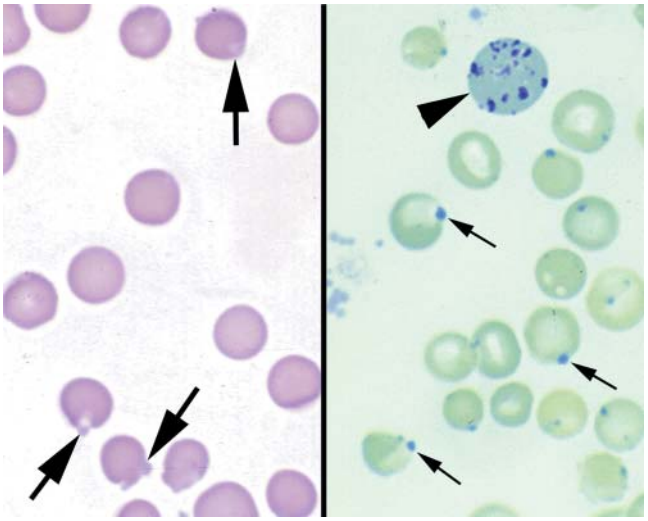

Figure 9.21 Left. Blood film from a cat with Heinz body anemia. Heinz bodies appear pale and are more apparent when they protrude from the edges of the erythrocytes (arrows). Wright stain. Right. Brilliant cresyl blue-stained blood film. Heinz bodies appear as medium-blue structures on the edges of the erythrocytes (arrows). A reticulocyte is also present (arrowhead).

hemolytic anemia, the anemia may be nonregenerative and is sometimes accompanied by leukopenia and thrombocytopenia. Diagnosis is made by finding the signet-ring-shaped piroplasms in erythrocytes in blood films relatively late in the course of the disease or by finding the schizonts in macrophages by cytologic or histopathologic examination of spleen, liver, lymph node, or bone marrow (Figure 9.20), or by PCR assay, which is very sensitive and specific. Historically, cytauxzoonosis was considered a fatal disease in domestic cats, but with recent advancements in therapy, and possibly less virulent strains of the virus, survival rates have markedly improved. Survival rates of 60% have been reported in cats treated with the combination of atovaquone (15 mg/kg PO q 8 hours) and azithromycin (10 mg/kg PO q 24 hours) in conjunction with supportive therapy to prevent clot formation.

Heinz body anemia

Erythrocytes are particularly susceptible to oxidative damage, both because they carry oxygen and because they may be exposed to various chemicals in plasma. Oxidants that are constantly generated include hydrogen peroxide (H_2O_2), superoxide free radical (O_2^-), and hydroxyl radicals (OH). When oxyhemoglobin is converted to methemoglobin (ferric state to ferrous state), superoxide radicals react with hydrogen peroxide, producing hydroxyl radicals. Formation of reversible and irreversible hemichromes then occurs. Reversible hemichromes include hemoglobin hydroxide and dihistidine ferrihemochrome. These reversible hemichromes can be converted back to methemoglobin and reduced hemoglobin. If irreversible hemichromes are formed, the hemoglobin denaturation continues, and aggregates of irreversible hemichromes are formed. These aggregates are called Heinz bodies, first recognized by Heinz in 1890 in humans and animals exposed to coal-tar drugs. Heinz bodies appear as small eccentric pale structures within the red cell and may protrude slightly from the red cell margin on Wright-stained blood films (Figure 9.21). They are usually large and single in cat erythrocytes (Figure 9.22) and small and multiple in dogs. When stained with vital stains such as new methylene blue or brilliant cresyl blue, Heinz bodies appear as blue structures (see Chapter 6).

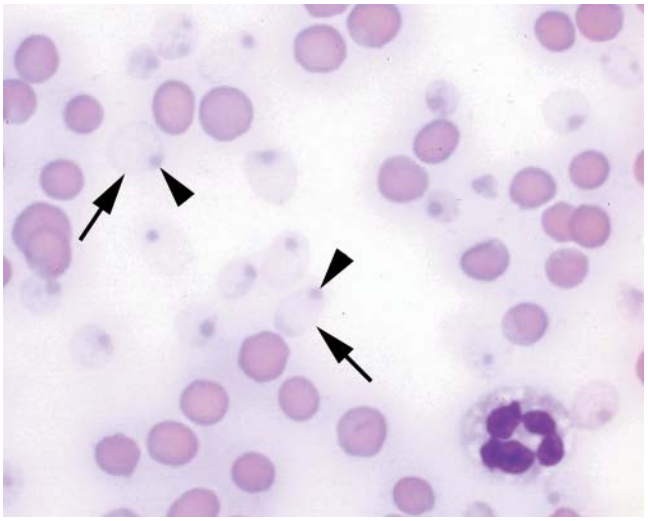

Figure 9.22 Blood film from an anemic cat with acetaminophen toxicosis. Note the lysed "ghost" erythrocytes (arrows). The Heinz bodies (arrowheads) are very apparent in the ghost cells. The pink background is due to hemoglobinemia. Wright stain.

The sulfhydryl groups on the globin portion of the molecule are also susceptible to oxidative damage, and although Heinz bodies may form by oxidation of these sulfhydryl groups, hemichrome formation is likely more important. Hemichromes have an affinity for membrane protein band 3. The protein band 3-hemichrome complex causes membrane protein band 3 to form clusters, both on the inside and outside of the erythrocyte membrane. This external clustering of protein band 3 creates a recognition site for autoantibodies. Erythrocytes with attached antibody are then phagocytized by macrophages. The clustering of protein band 3 and associated autoantibodies may be the best explanation for why animals with Heinz body formation may also have spherocyte formation and agglutination, such as has been described in zinc toxicosis and methylene blue toxicosis in dogs, and red maple leaf toxicosis in horses. Alternately, erythrocytes may have a spherocyte-like appearance because of collapse of the erythrocyte membrane following eccentrocyte formation. Some oxidants may affect the erythrocyte cytoskeleton, resulting in eccentrocyte formation without Heinz body formation. Features of eccentrocytes include shifting of hemoglobin to one side of the cell, loss of normal central pallor, and a clear zone outlined by a membrane (Figure 9.23).

In addition to formation of protein band 3-hemichrome complexes, spectrin-hemoglobin crosslinking also occurs, increasing erythrocyte membrane rigidity and decreasing deformability, ultimately making the erythrocyte more susceptible to removal. Heinz bodies may also be removed by the spleen, with the remaining portion of the erythrocyte returning to circulation. Hemichrome binding to the erythrocyte membrane also may stimulate proteolysis, contributing to breakdown of erythrocyte membrane integrity.

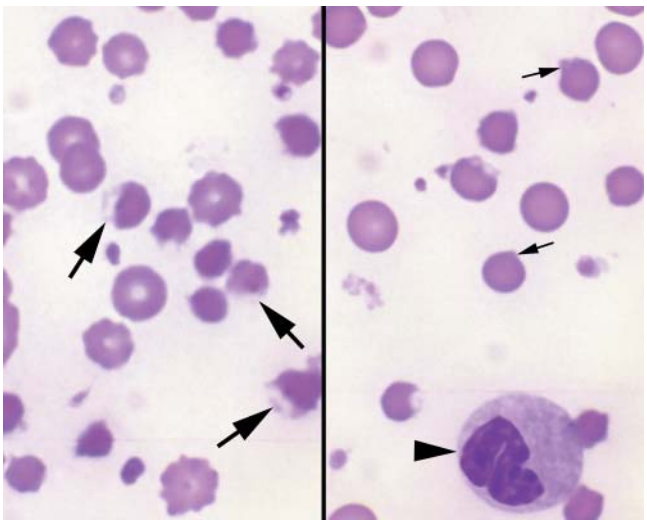

Figure 9.23 Blood film from a cow with oxidant-induced anemia. Note the eccentrocytes (large arrows) and Heinz bodies (small arrows). A neutrophil is present (arrowhead).

Oxidative injury occurs when enzymes and substrates used in the pathway to reverse oxidative processes are depleted, absent, or inhibited. Normally approximately 3 % of the hemoglobin is oxidized to methemoglobin daily, but even that small amount is constantly being reduced back to hemoglobin by a reduced nicotinamide-adenine dinucleotide (NADH)-dependent methemoglobin reductase enzyme within erythrocytes. Methemoglobin forms at higher concentrations when oxidative compounds are increased. Other enzymes also protect against oxidative damage to erythrocytes. These include superoxide dismutase (SOD), a zinc and copper containing enzyme that converts superoxide to hydrogen peroxide and water. Nicotinamide-adenine dinucleotide phosphate (NADPH) maintains glutathione in the reduced state, and glucose-6-phosphate dehydrogenase (G6PD) plays an important role in the initial steps of the pathway. Glutathione has an easily oxidizable sulfhydryl group that acts as a free-radical acceptor to counteract oxidant damage. Glutathione peroxidase catalyzes the conversion of hydrogen peroxide to water, producing oxidized glutathione, which is in turn reduced by glutathione reductase. Selenium is an important component of glutathione peroxidase. Finally, catalase is an enzyme that converts hydrogen peroxide to water and O_2 and may be more important than glutathione peroxidase.

Cats are considered to be more susceptible to Heinz body formation than other domestic species for a number of reasons, including differences in their hemoglobin structure, and normal cats commonly have a small percentage of circulating erythrocytes that contain Heinz bodies. Feline hemoglobin has eight sulfhydryl groups, compared with four in dogs and two in most other species. Many causes of oxidative damage to erythrocytes resulting in Heinz body or eccentrocyte formation have been reported, including oxidant drugs and chemicals, oxidant-containing plants, inherited enzyme deficiencies, and nutritional deficiencies. Treatment depends on predisposing cause of Heinz body formation. Many of the oxidative compounds that result in Heinz body formation also cause methemoglobinemia, which when severe is characterized by brown discoloration of blood and cyanosis. These oxidants are discussed in more detail below.

Plants

Allium family (onions, chives, leeks, and garlic)

Onion, chive, leek, and garlic ingestion may result in Heinz body anemia and eccentrocyte formation in most species of domestic animals. Sources of onions and garlic include the feeding of cull onions to cattle and sheep, ingestion of wild onions by horses, and ingestion of raw, cooked, dehydrated onions, and baby food containing onion or garlic powder, by dogs and cats. The oxidative compounds in onions and garlic are aliphatic sulfides, specifically allyl and propyl di-, tri-, and tetrasulfides, with the allyl compounds being more potent

than the propyl. These compounds decrease G6PD activity in erythrocytes, which in turn curtails the regeneration of reduced glutathione needed to prevent oxidative denaturation of hemoglobin. Interestingly, the allyl derivatives are also thought to be effective in increasing tissue activities of cancer-protective enzymes such as quinone reductase (QR) and glutathione S-transferase (GST), thus decreasing the risk of cancer in humans who ingest these vegetables. Moreover, aged garlic extract is sometimes used to treat sickle cell anemia, because the extract is thought to contain antioxidants that prolong the life of sickle red blood cells.

Although the feeding of cull domestic onions (*Allium cepa*) appears to be reasonably safe in sheep, cattle may develop onion toxicosis. Sheep have been fed an exclusive onion diet, and although they initially developed a Heinz body hemolytic anemia with approximately 25% reduction in packed cell volume, there was no significant decrease in pregnancy or lambing rate, body condition, or fleece weight. Adaptation to an exclusive onion diet in sheep is thought to be due to a strong marrow response to the anemia, as well as modification of rumen metabolism of sulfoxides; one study showed that there was a marked increase in the number of sulfide-metabolizing bacteria (*Desulfovibrio* spp). Conversely, rumen microorganisms that convert sulfur containing amino acids to oxidants have been reported to exacerbate onion- and brassica-induced Heinz body anemia. One study showed that sheep fed onions (50 g/kg body weight/day) for 15 days developed more severe Heinz body hemolytic anemia than did the sheep fed the equivalent amount of onions with 5 g/d ampicillin sodium salt.

Feedlot cattle, on the other hand, can be fed a diet containing up to 25% cull onions on a dry-matter (DM) basis. Although a decrease in PCV occurs due to Heinz body-related hemolysis, the PCV returns to normal within 30 days after onion feeding is discontinued. Average daily gain and feed conversion ratios are not affected. It is thought, however, that the 25% (DM) probably approaches the toxic threshold for onion consumption in cattle. Onions should be mixed in a balanced ration, and cattle should not be allowed free access to the onions, as they may eat them preferentially.

Onion ingestion is the most common cause of Heinz body and eccentrocyte formation in dogs, and is a relatively common cause of clinical and subclinical anemia. In one study in which dogs were fed 5.5 g/kg body weight dehydrated onions, 70% of the erythrocytes contained Heinz bodies at 24 hours, and eccentrocytes were also common. Packed cell volume dropped approximately 20% by day 5. There appears to be some variation in individual susceptibility to the effects of onion ingestion in dogs. Erythrocytes with high concentrations of reduced glutathione, such as is seen in some Japanese Shiba dogs, may be more susceptible to oxidative damage produced by onions. Garlic will also induce Heinz body and eccentrocyte formation in dogs.

Ingestion of onion soup and baby food containing onion powder has also been shown to produce Heinz body anemia in cats. In one study, as little as 0.3% onion powder significantly increased Heinz body formation; some commercial baby food may contain up to 1.8% onion powder on a dry weight basis.

Brassica (cabbage, kale, rape)

Ingestion of plants belonging to *Brassica* species may result in Heinz body anemia in ruminants. These plants contain s-methyl-L-cysteine sulfoxide, which is metabolized to the oxidant dimethyl disulfide by rumen bacteria. *Brassica* species not only have a high sulfur content, which reduces copper availability, but also are low in copper and zinc concentration. While this copper deficiency may play a role in oxidative hemoglobin damage, copper deficiency has not been shown to exacerbate susceptibility of lambs to brassica anemia. As with onion toxicosis, the severity of the Heinz body anemia is proportional to the quantity of brassica in the diet. A maximum concentration of 30% DM for *Brassica* species consumption is recommended to avoid significant anemia.

Wilted red maple leaves (Acer rubrum)

Severe Heinz body anemia and possibly death in horses, ponies, llamas, and zebras may be caused by ingestion of wilted or dried (not fresh) red maple leaves. Eccentrocyte formation and hemolysis may occur without concurrent Heinz body formation. Other findings commonly include methemoglobinemia, hemoglobinuria, hemoglobinuric nephrosis, and hepatic necrosis. The oxidative compound, thought to be gallic acid, causes a rapid depletion of glutathione; leaves are toxic when administered at doses of 1.5 g/kg of body weight or more. Therapy consists of ascorbic acid, fluids, and blood transfusions, if necessary.

Drugs and chemicals

Acetaminophen (paracetamol)

Acetaminophen (Tylenol; paracetamol) ingestion is probably the most common cause of Heinz body anemia in cats. Owners, unaware of its toxic effects, often give the anti-inflammatory human drug to cats. Acetaminophen is metabolized in part by glucuronide conjugation; cats have limited ability to form acetaminophen glucuronides, probably due to very low activity of the liver enzyme acetaminophen UDP-glucuronosyltransferase, thus resulting in increased oxidant metabolites of acetaminophen. As a result, glutathione concentration is decreased and oxidative damage to erythrocytes occurs. Other findings commonly include methemoglobinemia, with associated brown discoloration of blood and cyanosis, and hepatic necrosis. The toxic dose of acetaminophen in cats is 50–60 mg/kg body weight. (One Extra Strength Tylenol Gelcap contains 500 mg acetaminophen, and one Extra Strength Excedrin contains 250 mg acetaminophen.) To confirm the diagnosis,

acetaminophen concentrations can be determined on serum. Treatment consists of providing glutathione donors, such as N-acetylcysteine, orally. Acetaminophen-induced Heinz body anemia also occurs in dogs; the toxic dose is approximately 150 mg/kg body weight.

Propylene glycol

Propylene glycol, sometimes used as an additive in semi-moist pet food, causes Heinz body formation in cats but does not cause an anemia when ingested in those small quantities. However, cats eating such diets may be more susceptible to other additional causes of oxidative injury. Even though overt anemia may not occur, red cells with Heinz bodies have a reduced life span.

Zinc

Ingestion of zinc-containing materials, including United States Lincoln pennies produced since 1983 that are 98% zinc by weight, other metal objects such as nuts and bolts in animal carriers, zinc toys, and zinc oxide containing ointments have been reported to cause Heinz body anemia in dogs. The mechanisms by which zinc results in oxidative damage and Heinz body formation are unclear but are thought to be due to zinc interference with glutathione reductase. Zinc is known to play a role in band-3 clustering, thus directly damaging the erythrocyte membrane. As a result of this clustering, opsonization of antibody and spherocyte formation may occur. Zinc also damages other organs, including the liver, kidneys, and pancreas (see Section VII, Case 22).

Copper

Copper toxicosis in ruminants, especially sheep, results in Heinz body hemolytic anemia (Figure 9.24). Copper accumulates in the liver of animals ingesting high concentrations of copper. This copper is released following stress, resulting in a hemolytic crisis. Copper deficiency has also been associated with Heinz body formation.

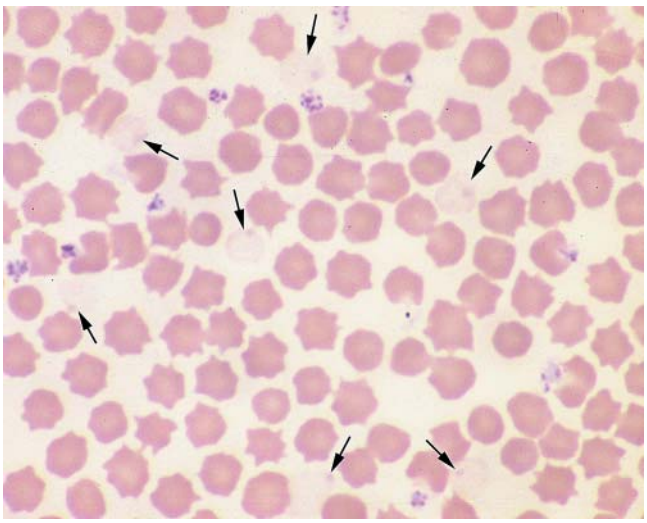

Figure 9.24 Blood film from a sheep with copper toxicosis. Note the Heinz bodies (arrows), which can be seen within "ghost" erythrocytes.

Selenium deficiency

Selenium deficiency in ruminants, associated with grazing on selenium deficient soils in certain parts of the world, including New Zealand and the Florida Everglades, has been associated with Heinz body anemia. Selenium deficiency has also been associated with reduced activity of glutathione peroxidase in erythrocytes of humans that live in selenium deficient areas, including New Zealand and Finland. It is speculated that reduced glutathione peroxidase activity may be the mechanism of the Heinz body anemia in selenium-deficient cattle.

Methylene blue

Methylene blue was historically used as a urinary antiseptic in cats, and commonly resulted in Heinz body anemia with chronic administration. More recently, it has been associated with Heinz body anemia in river otters that were fed bait fish that had been kept in water containing methylene blue, which is used to detoxify ammonia in fish tanks. Interestingly, methylene blue is the drug of choice in the treatment of methemoglobinemia in humans and most domestic animals. There is no evidence to suggest that single therapeutic doses of methylene blue cause hemolytic anemia, even in cats.

Crude oil

Ingestion of crude oil by marine birds results in Heinz body anemia, one of the primary mechanisms of toxicity associated with the ingestion of crude oil by birds.

Other chemicals

Multiple other chemicals, such as naphthalene, a mothball ingredient; propofol, an intravenous anesthetic; phenazopyridine, a urinary analgesic; phenothiazine, an anthelmintic; ecabapide, a gastroprokinetic drug; benzocaine, a local anesthetic; and phenylhydrazine, an oxidative compound commonly used to experimentally induce hemolytic anemia, have been reported to cause Heinz body anemia. Skunk spray, which contains thiols and other oxidizing agents, can also cause Heinz body anemia in dogs.

Diseases

Heinz body formation is increased in specific disease states in cats and may contribute to anemia. Diabetes mellitus, hyperthyroidism, and lymphoma have been correlated with Heinz body formation. Diabetic cats in particular may have marked Heinz body formation. In one study, these diseases together accounted for nearly 40% of cats with Heinz body formation. Ketoacidotic cats had significantly more Heinz bodies than nonketotic diabetic cats. Percentage

of Heinz bodies in diabetic cats is directly correlated with plasma beta-hydroxy-butyrate concentration, indicating that ketones are associated with oxidative hemoglobin damage in cats. This is likely a potential source of *in vivo* oxygen radical generation in animals with ketosis, such as may be seen in postparturient cattle.

Hypophosphatemia-induced hemolysis

Severe hypophosphatemia, usually less than 1 mg/dL, has been reported to induce hemolysis in several species of animals, as well as humans. Erythrocyte glycolysis is inhibited by hypophosphatemia, primarily by decreasing intracellular phosphorus that is required for the enzyme glyceraldehyde phosphate dehydrogenase. This results in decreased glycolysis, leading to decreased erythrocyte adenosine triphosphate (ATP) concentrations, and subsequent hemolysis. In some cases, this appears to be due to decreased glutathione, and increased susceptibility to oxidative injury. The most well-recognized syndrome of hypophosphatemia-induced hemolysis is postparturient hemoglobinuria in cattle. Causes in small animals include hypophosphatemia related to diabetes, and enteral alimentation (refeeding syndrome). Severe hypophosphatemia can be life-threatening, not only because of hemolysis but also owing to depression of myocardial function, rhabdomyopathy, seizures, coma, and acute respiratory failure.

Postparturient hemoglobinuria

Postparturient hemoglobinuria in cattle is a sporadic disease of multiparous, high-producing dairy cows characterized by intravascular hemolysis, anemia, and hemoglobinuria. It usually occurs within 4 weeks of calving. Most, but not all, cows with this syndrome are hypophosphatemic at the time of anemia. It is theorized that previous hypophosphatemia predisposes erythrocytes to injury and oxidative damage, primarily by decreasing ATP and glutathione. Experimental hypophosphatemia (1 mg/dL) in postparturient cattle results in a decrease in erythrocyte ATP by 50% and a decrease in glutathione by 30%. The syndrome is complex, because some of the postparturient cattle with hemolytic anemia have Heinz body anemia, and some have ketoacidosis due to their nutritional status prior to and immediately following calving. Ketones are associated with oxidative hemoglobin damage, and may be a potential source of *in vivo* oxygen radical generation.

Hypophosphatemia in diabetic cats

Hypophosphatemia is sometimes present in diabetic animals due to phosphorus loss in the urine of polyuric animals. Several instances of hypophosphatemia-induced hemolysis have been reported in cats. Similar to the situation in cows with postparturient hemoglobinuria, diabetic cats may also be ketotic and have Heinz body anemia; in those cases, the hemolysis may be due to hypophosphatemia, ketosis, or a combination, since ketosis predisposes to Heinz body formation. Hypophosphatemia resulting in hemolytic anemia has also been reported in cats with hepatic lipidosis.

Enteral alimentation in cats – refeeding syndrome

A retrospective study of cats with hypophosphatemia revealed that hypophosphatemia can occur 12–72 hours after initiation of enteral alimentation. In this study, the nadir for phosphorus concentrations ranged from 0.4 to 2.4 mg/dL. Hemolysis occurred in six of the nine cats that were hypophosphatemic. In a more recent retrospective study, 100% of 11 cats developed anemia following refeeding, and 7 required blood transfusions. Many of the affected cats had hepatic lipidosis. Refeeding syndrome with accompanying hypophosphatemia is well documented in human medicine. In response to insulin release following refeeding, phosphorus is taken up by cells, resulting in decreased serum phosphorus. Hypokalemia, hypomagnesemia, and hypoglycemia are also commonly associated with refeeding syndrome.

Microorganisms (other than erythrocyte parasites)

Bacteria

Clostridial and leptospiral infections may result in hemolytic anemia. *Clostridium perfringens* Type A (and rarely D) infections results in a hemolytic anemia in lambs and calves, sometimes referred to as "yellow lamb disease" or "enterotoxemic jaundice." The bacteria produces a phospholipase, which hydrolyses cell membrane phospholipids of erythrocytes, as well as those of other cells. Clinical signs include lethargy, fever, pale mucous membranes, anemia, hemoglobinuria, and icterus. Necropsy findings include evidence of intravascular hemolysis, renal hemoglobin casts, intestinal mucosal necrosis, hepatic necrosis, and petechial and ecchymotic hemorrhages. *C. perfringens* has been associated with IMHA in horses.

Clostridium haemolyticum, an anaerobic motile, sporulating, rod-shaped bacterium, causes hemolytic anemia in cattle and occasionally sheep that is sometimes referred to as "bacillary hemoglobinuria" or "red water disease," which is acutely fatal. The disease, first described in 1916, occurs in summer and early fall, is commonly associated with liver fluke migration, and is endemic in swampy areas of numerous countries, including the United States. Other causes of decreased liver perfusion, including other bacterial infections or liver biopsy, may also predispose to the growth of the clostridial organism. Clinical signs include those of anemia, lethargy, arched back, bloody diarrhea, fever, dyspnea, and occasionally hemoglobinuria. The organisms is mainly found in soil of areas with poorly drained pastures and alkaline pH, where viable spores can survive for years. Bacterial spores are ingested and reside in macrophages of the liver. Anaerobic conditions within the liver, usually resulting from liver fluke migration, result in growth of

the bacteria and production of toxic enzymes, including lecithinase, that metabolize lipids and protein in cell walls. Hemolysis and necrosis of other cells, including endothelial cells and hepatocytes, result in death. Necropsy findings include pale and icteric mucous membranes, foci of hepatic necrosis, hemorrhages, thoracic and abdominal effusion, hemoglobinuria, renal hemoglobin casts, and edema.

Leptospirosis (*Leptospira pomona*) may cause hemolytic anemia in young calves and lambs but is almost never a feature of the disease in adult animals; leptospirosis very rarely causes hemolytic anemia in dogs, although thrombocytopenia is common. The mechanism of the anemia may be toxins produced by the bacteria that act as hemolysins, but it is more likely an IMHA, probably IgM mediated. Necropsy findings in lambs include icterus, hemoglobinuria, renal tubular necrosis with hemoglobin casts, and hepatocellular necrosis.

Viruses

The equine infectious anemia (EIA) virus may result in hemolytic anemia in the acute stage of the disease. The anemia is likely immune mediated as a result of the virus binding with the erythrocyte membrane and activating complement. Later in the disease the anemia is nonregenerative, possibly similar to anemia of inflammatory disease. EIA was first described in 1843, and in 1904 was shown to be caused by a filterable agent (a virus) that was transmitted by blood, usually by insect vectors such as horse flies and deer flies. It is also referred to as "swamp fever." Diagnosis is made by detecting antibody against the EIA virus, using a Coggins test or a competitive ELISA test.

Water intoxication-induced hemolysis in calves

Water intoxication resulting in hemolysis, hemoglobinuria, pulmonary edema, brain edema, convulsions, coma, and death may occur in calves that have unlimited access to water following its unavailability. Water intoxication may cause death within 2 hours, but most calves survive with no permanent ill effects. Cause of hemolysis is decreased osmolality of plasma. It has been theorized that water intoxication-induced hemolysis occurs in calves from 4 to 5 months of age because osmotic fragility of their erythrocytes is greatest at that age, possibly related to the residual presence of iron deficient erythrocytes. The disorder is rare in adult cattle; severe dilutional hyponatremia resulting in cerebral edema is usually the cause of death, rather than hemolysis.

Hereditary membrane defects and metabolic disorders

Either inherited membrane defects or enzyme deficiencies leading to metabolic disorders may result in hemolytic anemia. Inherited erythrocyte membrane defects reported in domestic animals include hereditary spherocytosis, hereditary elliptocytosis, hereditary stomatocytosis, and membrane transport defects. However, hereditary elliptocytosis in dogs, which is caused by a hereditary protein 4.1 deficiency, results in increased osmotic fragility, elliptocytosis, membrane fragmentation, microcytosis, and poikilocytosis but does not result in anemia (see Chapter 6).

Membrane defects

Hereditary spherocytosis (HS) results in hemolytic anemia, spherocytosis, and splenomegaly. Hereditary spherocytosis has been reported in people, mice, dogs, and cattle. In cattle, HS is due to hereditary band 3 deficiency, an autosomal dominant trait that has been reported in Japanese black cattle. Band 3 protein is the most abundant protein in mammalian erythrocyte membranes, and functions include anion exchange across the membrane, as well as maintenance of normal erythrocyte shape. Cattle homozygous for the trait lack band 3 protein in their erythrocyte membranes, have a mild anemia, spherocytosis, hyperbilirubinemia, splenomegaly, and growth impairment. The disease is more severe in calves; adults are relatively normal. Heterozygotes have a partial deficiency of band 3, mild spherocytosis, and compensate for their hemolytic anemia with increased erythrocyte regeneration. Hereditary spherocytosis may also be due to spectrin deficiency. Spectrin is the major constituent of the cytoskeletal network underlying the erythrocyte plasma membrane. It associates with band 4.1 and actin to form the cytoskeletal superstructure of the erythrocyte plasma membrane. This complex is anchored to the cytoplasmic face of the plasma membrane via another protein, ankyrin, which binds to beta-spectrin and mediates the binding of the whole complex to the transmembrane protein band 3. The interaction of erythrocyte spectrin with other proteins through specific binding domains lead to the formation of an extensive subplasmalemmal meshwork that is thought to be responsible for the maintenance of the biconcave shape of erythrocytes, for the regulation of plasma membrane components and for the maintenance of the lipid asymmetry of the plasma membrane. Spectrin deficiency has been reported in a family of Dutch golden retrievers.

Hereditary stomatocytosis has been reported in miniature schnauzers, chondrodysplastic Alaskan malamutes, and in the Drentse patrijshond breed of dogs that also have hypertrophic gastritis (see Chapter 6). These disorders have different underlying causes in these three breeds, and the schnauzers do not have anemia, although their red cell survival time is slightly shortened.

A Coombs negative chronic intermittent hemolytic anemia has been reported in Abyssinian and Somali cats. Clinical signs and laboratory findings include mild to severe anemia, splenomegaly, increased MCV, and the presence of a few stomatocytes. Osmotic fragility of erythrocytes is markedly increased. Some of the cats improved following

splenectomy. The specific cause of the hemolytic anemia is not known, but a membrane defect is suspected.

Animals with erythrocyte membrane transport defects, especially those with defects in transport of amino acids involved in glutathione metabolism, may develop hemolytic anemia (Heinz body anemia) when exposed to oxidants. Some Finnish Landrace sheep have red cell glutathione deficiency, inherited as autosomal recessive. Cysteine uptake and glutathione synthesis are impaired, and glutathione concentration in erythrocytes is only 30% of normal. A similar defect is thought to be common in thoroughbred horses but does not cause anemia. Some Japanese Shiba and Akita dogs have erythrocytes with high potassium, low sodium concentrations, due to retention of Na,K-ATPase in mature erythrocytes, inherited as an autosomal recessive trait. Some of these dogs have an increased concentration of reduced glutathione in their erythrocytes, which protects the cells against oxidative damage by acetylphenylhydrazine, but increases the risk of oxidative damage by onions (see "Heinz Body Anemia").

Metabolic disorders

Inherited erythrocyte enzyme defects result in abnormalities in metabolic pathways, often resulting in hemolytic anemia. Energy in mature mammalian erythrocytes is generated exclusively by anaerobic glycolysis, also known as the Embden-Meyerhof (EM) pathway, since they have lost their mitochondria, and thus their oxidative phosphorylation capabilities. Briefly, metabolism of glucose produces ATP, which is used to maintain erythrocyte shape, deformability, membrane transport, and synthesis of purines, pyrimidines, and glutathione. Many enzymes are involved in anaerobic glycolysis, including phosphofructokinase (PFK) and pyruvate kinase (PK). Deficiencies of both of these enzymes have been described in domestic animals. Erythrocyte enzyme deficiencies do not usually lead to a shortened life expectancy, other than PK deficiency in dogs, and occasionally PFK deficiency in dogs having a hemolytic crisis. These hemolytic anemias are usually very regenerative and must be differentiated from more common causes of hemolytic anemia such as IMHA, hemotrophic parasites, or Heinz body anemia.

Pyruvate kinase deficiency

PK deficiency is the most common enzymopathy in humans and dogs, and was first recognized in Basenji dogs in 1971. Since that time, it has been reported in beagles, West Highland white terriers, Cairn terriers, miniature poodles, pugs, Labrador retrievers, and various other breeds. Clinical signs include those of anemia, such as exercise intolerance. The anemia is very regenerative, and half or more of the erythrocytes on the blood film may be reticulocytes. The MCV may be markedly increased due to the reticulocytosis. Hepatosplenomegaly may be present. Affected dogs die of myelofibrosis, secondary hemochromatosis, or hepatic failure by 3–5 years of age. Myelofibrosis and osteosclerosis are a consistent finding in PK-deficient dogs but do not develop in PK deficient people or cats. In certain breeds (basenjis, West Highland white terriers) in which the mutation is specific, diagnosis can be made by PCR-based tests. Bone marrow transplantation has been shown to correct the disorder and prevent the development of osteosclerosis. PK deficiency in cats has been described in various breeds, including Abyssinian, Somali, and domestic short hair cats. The hemolytic anemia is mild to moderate, slightly to strongly regenerative, and intermittent. Splenectomy has been reported to reduce the severity of hemolytic anemia. Additional signs include lethargy, weakness, weight loss, jaundice, and occasionally splenomegaly. Laboratory findings in addition to anemia may include hyperglobulinemia, hyperbilirubinemia, and increased serum liver enzymes activity. Osteosclerosis does not develop in cats.

Phosphofructokinase deficiency

PFK deficiency is a rare genetic disorder in humans, and has been described in English springer spaniels, American cocker spaniels, whippets, Wachtelhunds, and mixed-breed dogs. The cocker spaniel had an ancestor that was bred in a kennel that also had English springer spaniels, and the mixed-breed dog was thought to be part English springer spaniel. The mutation in the first described dogs was identical. Other missense mutations have been described in Wachtelhunds. It is inherited as an autosomal recessive trait, and is also referred to as glycogen storage disease type VII, since the enzyme deficiency also results in a lack of lactate production and accumulation of sugar phosphates and glycogen in muscle. Intermittent severe intravascular hemolysis is triggered by mild alkalemia; even mild respiratory alkalosis caused by hyperventilation and panting may precipitate a hemolytic crisis. Moreover 2,3-diphosphoglycerate (2,3-DPG), a compound that decreases the oxygen affinity for hemoglobin, thus making oxygen more available to tissues, is generated in the EM pathway. PFK deficiency results in a deficiency of 2,3-DPG, which results in tissue hypoxia of affected dogs. However, this tissue hypoxia stimulates erythropoietin production, and thus, except when in hemolytic crisis, these dogs are not anemic. Clinical signs include excitement or exercise-induced hemolytic anemia and occasional mild muscle cramping. Life expectancy can be normal if hemolytic crises are avoided. The disorder can be identified in affected dogs, as well as carriers, by a PCR-based DNA test that is specific for the English springer spaniel mutation.

Glucose-6-phosphate dehydrogenase deficiency

The pentose phosphate pathway (PPP) generates reduced nicotine adenine dinucleotide phosphate (NADPG), which is protective against mechanical and metabolic insults, particularly oxidants. G6PD is the rate-limiting enzyme in the

PPP. In humans, G6PD deficiency is inherited as an X-linked disorder, which causes hemolytic anemia, particularly following exposure to oxidants. Hemolytic anemia caused by G6PD deficiency has been described in an American saddle bred colt, as well as a dog. Morphologic abnormalities in the colt included eccentrocytosis, and the colt's dam, which was a heterozygote for the disorder, also had eccentrocytes on her blood film.

Hereditary methemoglobinemia

Methemoglobin is not able to bind oxygen because the iron moiety of the heme group has been oxidized to the ferric state (see "Heinz Body Anemia"). Approximately 3% of hemoglobin is oxidized to methemoglobin each day, but this methemoglobin is reduced back to hemoglobin, primarily by the enzyme NADH-methemoglobin reductase. Inherited deficiencies of this enzyme have been described in numerous breeds of dogs and cats. This disorder does not cause significant problems in dogs and cats, other than increased risk associated with anesthesia. Glutathione reductase deficiency has been described in horses, and even in the absence of oxidants, resulted in a mild hemolytic anemia with eccentrocyte formation and methemoglobinemia. Horses in one report had normal methemoglobin reductase activity, but activity was reduced in a separate case.

Porphyrias

Hemoglobin synthesis occurs in erythroid precursors, where protoporphyrin, iron, and globin molecules are brought together and assembled into functional hemoglobin. Synthesis of the heme portion of the molecule is complex, and requires numerous enzymes. Inherited deficiencies of these enzymes result in an accumulation of porphyrin precursors, as well as a failure to adequately synthesize hemoglobin, and the disorders are known as erythropoietic porphyrias, which have been described in humans, cattle, swine, and cats. Some of the erythropoietic porphyrias result in hemolytic anemia. Hepatic porphyrias are caused by different enzyme deficiencies, and to date have been discovered only in humans; the liver is the site of synthesis for enzymes containing heme, such as catalase, cytochromes, and peroxidase.

Another inherited disorder, erythropoietic protoporphyria, is due to a defect of the enzyme heme synthetase (ferrochelatase). This disorder has been described in Limousin and Blonde d'Aquitaine cattle, and the only clinical manifestation is severe photosensitivity with intense pruritus. Anemia, porphyrinuria, and discolored teeth are not observed. Inheritance of erythropoietic protoporphyria is recessive in cattle and only occurs in homozygotes, unlike in humans in whom the heterozygous condition results in clinical signs.

Toxins, especially lead, may destroy many of the enzymes involved in the synthesis of heme. These toxicoses lead to a decrease in heme synthesis, as well as an excess of heme precursors, which are eliminated in increased concentration in the urine. These toxicoses are referred to as porphyrinurias.

Clinical signs associated with porphyrias vary, depending on the specific enzyme abnormality, and the amount of residual activity of the affected enzyme. Porphyrins are reddish-brown in color, have a characteristic red fluorescence when exposed to ultraviolet light, and stain various tissues, including teeth and bones; congenital erythropoietic porphyria in cattle was called "pink tooth" at one time. The porphyrins in these animals are excreted excessively in all body fluids, including urine, feces, saliva, sweat, and tears. One of the most common abnormalities is photosensitivity resulting in photodermatitis, particularly evident on light colored areas of the skin. This is due to excitation of porphyrins by ultraviolet light, and subsequent transfer of oxygen to tissues, causing oxidation of cellular lipids, proteins, and organelles.

Bovine congenital erythropoietic porphyria

Bovine congenital erythropoietic porphyria has been reported in Holsteins and Shorthorns, and is caused by a partial deficiency of uroporphyrinogen III cosynthetase (UROgenIII Cosyn), resulting in an accumulation of uroporphyrin I and coproporphyrin I, which accumulate in tissues, and are excreted in urine and feces in increased quantities. Clinical signs include pigmentation of tissues including teeth, anemia, and photosensitization. The disorder is inherited as an autosomal recessive trait. Affected animals have hemolytic anemia that is regenerative, and blood film findings are those of a regenerative anemia in cattle, including polychromasia, macrocytosis, anisocytosis, basophilic stippling, and increased nucleated erythrocytes. Affected calves have a particularly striking regenerative response, with many nucleated erythrocytes present. Erythrocyte life span is shortened, due to both the heme synthesis disorder, as well as the porphyrin-related damage to erythrocyte membrane lipids. Ultraviolet light may increase severity of hemolysis, due to exposure of erythrocytes while in surface capillaries. The disease has been almost completely eliminated in cattle.

Porphyria of cats

Two forms of porphyria have been described in cats. One type, described in a family of Siamese cats, is due to a partial deficiency of UROgenIII Cosyn, and is similar to the disorder in humans and cattle. Affected cats had photosensitivity and severe hemolytic anemia, as well as renal disease. The renal disease was characterized by mesangial hypercellularity and proliferation and ischemic tubular injury. Membrane-enclosed lamellar bodies were present in cytoplasmic and extracellular locations of various tissues, similar to those seen in lysosomal storage disorders.

A second type of porphyria has been described in domestic cats in which the clinical signs are only discoloration of teeth and urine due to the presence of uroporphyrin,

coproporphyrin, and porphobilinogen. Anemia and photosensitization are not present. The disorder in domestic cats is inherited as autosomal dominant.

Porphyria of swine

Porphyria has been described in affected swine, which have discoloration of teeth and excessive uroporphyrin in the urine. Affected swine are not anemic and photosensitization is not present. The specific defect is not known, and no animals are currently available for study. The disorder is inherited as autosomal dominant.

10 Classification of and Diagnostic Approach to Erythrocytosis

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Erythrocytosis, sometimes referred to as polycythemia, is an increase in the concentration of erythrocytes in the blood as evidenced by an increased packed cell volume (PCV) or hematocrit, red blood cell count, or hemoglobin concentration. Because the term polycythemia implies that all blood cells, including platelets and leukocytes, are increased in concentration, the term erythrocytosis is more accurately descriptive. In domestic animals with primary or true erythrocytosis (polycythemia vera), usually only the erythrocytes are increased in concentration, unlike in humans in whom platelet and leukocyte concentrations are typically also increased.

Erythrocytosis may be either relative or absolute. Relative erythrocytosis may occur due to decreased plasma volume or erythrocyte redistribution. Examples of the former include dehydration and body fluid shifts. The latter is the result of splenic contraction seen most commonly in excitable animals such as cats and horses. Absolute erythrocytosis is caused by an actual increase in the red cell mass and may be primary or secondary. Secondary absolute erythrocytosis results from overproduction of erythrocytes secondary to increased erythropoietin (EPO) concentration, which in turn is secondary to either generalized hypoxia, localized renal hypoxia due to a renal lesion resulting in inappropriate erythropoietin increase, or overproduction of erythropoietin by a tumor. Absolute primary erythrocytosis (polycythemia vera) is a disorder in which erythropoiesis occurs independent of the EPO concentration. Primary erythrocytosis is a well-differentiated myeloproliferative disorder that is usually diagnosed in domestic animals by excluding relative and secondary erythrocytosis.

Erythrocyte production (erythropoiesis) is regulated by the glycoprotein cytokine EPO, which was discovered in 1977. Erythropoietin production occurs primarily in peritubular fibroblast-like interstitial cells in the kidney that are regulated by an elaborate oxygen-sensing mechanism that was discovered in the early 1990s. The erythropoietin receptor (EPOR) was discovered in 1989. Erythropoietin drives erythropoiesis by stimulating this receptor on the surface of erythrocyte precursors. The EPOR is bound to an intracytoplasmic essential partner, Janus kinase 2 (JAK2) tyrosine kinase. Following activation of JAK2, signaling molecules enter the nucleus of the erythroid precursor to activate numerous target genes that promote erythroid precursor expansion and survival, regulate maturation, mediate iron uptake, and regulate feedback inhibition of EPOR signaling to prevent excessive red-cell production. Erythropoiesis is reviewed in detail by Bhoopalan et al. (see "Suggested Reading").

Relative erythrocytosis

Relative erythrocytosis caused by fluid shifts or dehydration

Patients with relative erythrocytosis caused by a reduction in plasma volume usually have a concurrent increase in plasma protein. In addition, clinical evidence of dehydration usually is present. Some dehydrated animals, however, may have normal or decreased plasma protein concentration resulting from decreased protein intake, decreased protein production by the liver, or increased protein loss via the kidney, gastrointestinal tract, or cutaneous lesions (see Chapter 30). Moreover, fluid shifts may occur so rapidly, such as in patients with acute gastrointestinal disease or severe acute hyperthermia, that the classic clinical signs of dehydration may not be apparent. Relative polycythemia is treated by diagnosis of and therapy for the underlying disease and by replacement of fluids and electrolytes.

Relative erythrocytosis caused by transient increase in red cell mass secondary to splenic contraction

Splenic contraction causes only a modest increase in PCV, usually to no greater than 60%. Erythrocytosis as a result of splenic contraction typically is seen only in animals that normally have a high PCV, such as some poodles, greyhounds, and dachshunds. Splenic contraction may occur secondary to exercise, or it may be a response to epinephrine release in animals that are excited or in pain. Plasma protein concentration is not increased, and the presence of fear, pain, or excitement at the time of blood collection usually is apparent. An excitement leukogram also may be present, as evidenced by a mature neutrophilia and lymphocytosis; occasionally, mild thrombocytosis also is noted. Transient erythrocytosis has no clinical significance, and the red cell concentration reverts to normal in a short period of time.

Absolute erythrocytosis

Absolute erythrocytosis can be either secondary or primary.

Secondary absolute erythrocytosis

Secondary absolute erythrocytosis caused by generalized hypoxia or hypoxemia (physiologically appropriate erythrocytosis)

Physiologically appropriate polycythemia is observed when inadequate tissue oxygenation triggers an increase in erythropoietin production, which in turn stimulates erythrocyte production and release so that more oxygen can be carried to the tissues. Generalized hypoxia and hypoxemia (reduced PaO_2) may be seen in animals with severe chronic heart or lung disease. Congenital heart disorders that result in shunting of blood away from the lungs are associated more often with erythrocytosis than in acquired heart disease. Severe lung disease also may result in hypoxemia, but it must be of chronic duration to induce polycythemia. Other causes of hypoxemia include living at very high altitude, alveolar hypoventilation, and severe obesity. Polycythemia associated with hypoxia without hypoxemia occurs in people with certain rare inherited hemoglobinopathies, but hemoglobinopathies have not been reported in domestic animals. Acquired chronic hemoglobinopathies (e.g., carboxyhemoglobinemia secondary to carbon monoxide poisoning or methemoglobinemia) may induce polycythemia as well.

Secondary absolute polycythemia caused by hypoxemia is diagnosed by detecting decreased PaO_2 and oxygen saturation. The reference interval for PaO_2 varies somewhat with the altitude. At sea level, the lower end of the reference interval is 80 mmHg, and oxygen saturation is 92%; at approximately 6000 ft above sea level, the lower end of the reference interval is 74 mmHg. Usually, the PaO_2 must be less than 60 mmHg to induce polycythemia. Imaging of the heart and lungs as well as other diagnostic procedures to detect cardiopulmonary disease can then be used to establish a more definitive diagnosis.

Secondary absolute erythrocytosis caused by increased erythropoietin production (physiologically inappropriate polycythemia)

Physiologically inappropriate erythrocytosis occurs when erythropoietin production is increased in the absence of generalized tissue hypoxia. In dogs, hematocrits as high as 82% have been reported with secondary erythrocytosis. Erythropoietin production may be increased in patients with renal lesions such as tumors that induce localized renal hypoxia. Increased production of erythropoietin or of an erythropoietin-like substance by nonrenal tumors such as hepatoblastomas in horses, nasal fibrosarcoma, lymphoma, intestinal leiomyosarcoma and schwannoma in dogs, and hemangiosarcoma in a cat have been reported, but paraneoplastic erythropoietin production is rare. Animals with physiologically inappropriate polycythemia have normal to slightly decreased PaO_2 and oxygen saturation. Mild hypoxemia may be present as a result of poor perfusion, and patients usually have increased serum erythropoietin concentration. Other diagnostic procedures to evaluate the kidneys, such as imaging, renal aspiration cytology or biopsy, and urinalysis, should be performed.

Primary absolute erythrocytosis

Familial primary erythrocytosis

Familial primary erythrocytosis is very rare and has been described in humans and cattle. In humans, the autosomal dominant disorder is associated with various mutations in the gene encoding the EPOR that result in truncation of the intracellular domain of the receptor with subsequent hypersensitivity to erythropoietin. The disorder is autosomal recessive in cattle.

Acquired (neoplastic) primary erythrocytosis (polycythemia vera)

Acquired primary absolute erythrocytosis (polycythemia vera) is a well-differentiated clonal myeloproliferative disorder in which erythrocytes proliferate uncontrollably, producing an increased hematocrit. Median PCV was 70% in one series of 18 cats with primary erythrocytosis, and ranges from 65% to 85% have been reported in dogs. Unlike most other types of hematopoietic neoplasia, the neoplastic erythroid cells are morphologically normal and have a normal maturation sequence. In humans with polycythemia vera, an abnormal proliferation of neutrophils and platelets often accompanies erythrocyte proliferation, resulting in leukocytosis and thrombocytosis. An abnormal proliferation of cells other than red blood cells is rarely observed in domestic animals; thus, in dogs and cats, the disorder is now

referred to as primary erythrocytosis, rather than as primary polycythemia or polycythemia vera.

Humans with polycythemia vera have an increased risk of thrombosis and eventual marrow fibrosis or transformation into acute myeloid leukemia. The median age at diagnosis is 60 years, and the disorder is more common in males. The presence of an acquired recurrent mutation within the JAK2 gene has been identified in more than 97% of human patients with polycythemia vera. This mutation (V617F) results from a somatic G to T mutation and the resultant amino acid substitution of valine to phenylalanine in the pseudokinase domain of JAK2 that is known to have an inhibitory role, resulting in hyperactivation of erythropoietin-induced cell signaling. Detection of the mutation is a major diagnostic tool in humans for polycythemia vera diagnosis. Identical mutations of the JAK2 gene giving rise to active JAK2 kinase have been shown in dogs with polycythemia vera, suggesting a common mechanism for the human and canine disease.

While the disorder continues to be diagnosed by excluding other causes of erythrocytosis, it is likely that detection of the mutation may soon be used for diagnosis. Most cases of primary erythrocytosis in domestic animals have been reported in dogs and cats, but a few have been reported in horses, cattle, a ferret, and a llama.

Clinical findings

Clinical findings may be secondary to the underlying cause of the erythrocytosis or may result from the increased number of erythrocytes per se. In animals with relative erythrocytosis, dehydration or excitement may be clinically evident. In animals with secondary absolute erythrocytosis caused by hypoxia, clinical signs associated with congenital heart disease (e.g., murmurs, cyanosis) or with pulmonary disease (e.g., cyanosis, dyspnea, abnormal lung sounds) may be observed. In animals with secondary absolute erythrocytosis caused by inappropriate erythropoietin production, clinical signs associated with renal disease often are not apparent.

Clinical signs associated with erythrocytosis are secondary to increased blood volume and viscosity. They include deep-red mucous membranes, sometimes with slight cyanosis. Increased blood viscosity may result in sluggish blood flow and subsequent decreased tissue perfusion and oxygen transport as well as hemorrhage and thrombosis. Mild to severe central nervous system signs associated with decreased oxygen transport, such as lethargy, ataxia, blindness, or seizures, also may be observed. In a series of 18 cats with primary erythrocytosis, seizures and mentation changes were the most common presenting signs (10 of 18).

Polyuria and polydipsia occasionally are reported and are thought to result from impaired release of vasopressin. Splenomegaly rarely is observed in domestic animals. However, human patients commonly have splenomegaly, may have generalized pruritis, and eventually may develop marrow fibrosis and lymphoid neoplasia.

Diagnostic approach

When PCV is increased, one should consider if the patient is excited or dehydrated and then perform a second complete blood count to confirm that the finding is repeatable. If the total protein concentration also is increased, the erythrocytosis likely is relative, secondary to dehydration and decreased plasma volume. Sometimes, however, animals with rapid fluid shifts, such as those with gastrointestinal disease, may not have an increased total protein. Moreover, total protein may be decreased or normal in dehydrated animals that have decreased protein intake, production, or increased loss.

If relative erythrocytosis is excluded, secondary absolute polycythemia due to hypoxemia from congenital heart disease or pulmonary disease should be considered. Hypoxemia is best diagnosed by performing an arterial blood gas analysis to determine the PaO_2 and oxygen saturation. If the PaO_2 is less than 60 mmHg, then hypoxemia likely is the cause of erythrocytosis. Pulse oximetry can also be used to estimate oxygenation, and if oxygen saturation is below 92%, arterial blood gas should be performed. Imaging using thoracic radiographic and ultrasonic examination will provide additional information.

If hypoxemia is excluded, secondary absolute erythrocytosis caused by increased erythropoietin production should be considered. Tumors of the kidney are the most common cause of increased erythropoietin production. In these cases, imaging with renal ultrasonography or intravenous urography is indicated. Serum erythropoietin concentration usually is increased in animals with hypoxemia or inappropriate erythropoietin production and is normal to decreased in animals with primary erythrocytosis (Table 10.1). Erythropoietin concentrations appear to be more useful in dogs than in cats. If secondary erythrocytosis caused by inappropriate erythropoietin production is excluded, then the likely diagnosis is primary erythrocytosis.

Table 10.1 PaO_2 and erythropoietin in animals with erythrocytosis.

Erythrocytosis	PaO_2	Erythropoietin
Relative	Normal	Normal
Secondary		
Caused by hypoxemia	Decreased	Increased
Caused by inappropriate erythropoietin production	Normal	Increased
Primary	Normal	Normal or decreased

Other laboratory findings are not particularly helpful. Affected humans commonly have neutrophilia and thrombocytosis, but these findings are rare in domestic animals. Neutrophilia associated with stress or inflammation is a more likely finding. Other than mild increased cellularity and mild erythroid hyperplasia, bone marrow aspirates usually are normal in appearance. Measuring total red cell mass with a dye technique or radioisotope-labeled erythrocytes, though infrequently performed, can help to establish a more definitive diagnosis. Due to the abnormally high PCV in patients with erythrocytosis from any cause, hypoglycemia may be erroneously diagnosed if using a point-of-care blood glucose meter.

Therapy

Relative erythrocytosis is treated by therapy for the underlying disease and correction of dehydration with fluid therapy. The underlying disorder also is treated in animals with secondary erythrocytosis caused by hypoxemia or inappropriate erythropoietin production. Phlebotomy may be contraindicated in animals with hypoxemia, because the erythrocytosis is physiologic. If the PCV is very high in these patients, however, then tissue perfusion may be impaired, and phlebotomy may be helpful.

Primary erythrocytosis is commonly treated – and often with long-term success – by performing repeated phlebotomy to maintain the PCV in the high-normal range. Injectable iron may need to be given to avoid iron deficiency anemia. Chemotherapy to decrease red cell production is usually useful; oral hydroxyurea is the most common such treatment. Dose and frequency are variable, depending on the response. A reported complication in cats is methemoglobinemia and Heinz body anemia. While radioactive phosphorus has been used with success in some cases, it is now very rarely used. Survival time in cats with primary erythrocytosis managed with a combination of phlebotomy and hydroxyurea has been reported to be greater than 17 months, with some cats living more than 5 years after diagnosis. JAK2 inhibitors have been developed and used with some success in humans. A veterinary oncologist should be consulted for up-to-date treatment options.

11 Introduction to Leukocytes and the Leukogram

Glade Weiser
Loveland, CO, USA

Interpretation of leukocyte concentrations in blood provides insight regarding potential processes that may be occurring in the patient. The complete set of numeric data in the leukocyte profile, along with any noted morphologic abnormalities, is known as the leukogram. The leukogram consists of about half of the numerical data in the complete blood count (CBC). An abnormal leukogram usually leads to identification of a pathologic process (e.g., inflammation) but not to establishment of a specific diagnosis. Interpretation of leukocyte abnormalities into a process coupled with clinical findings, however, may lead toward a diagnosis.

To interpret leukocyte patterns in disease, one must first learn the normal characteristics of the leukogram as a basis for recognizing abnormal patterns. This chapter presents background information regarding the normal leukogram that is necessary for building skills in its interpretation.

Common blood leukocytes: general functions and morphology

This section reviews pertinent characteristics of blood leukocytes, such as general functions and morphologic features, including species variations in morphology.

Neutrophils

Neutrophils participate in inflammatory responses by means of chemoattraction into tissue sites of inflammation and phagocytosis of organisms and other foreign material. After phagocytosis, lysosomal granules fuse with phagosomes to kill organisms and then degrade the material by enzymatic digestion.

Neutrophil morphology is introduced in Figure 11.1. The neutrophilic metamyelocyte is not present in normal blood. It has a bean-shaped nucleus that, as it matures, changes to the horseshoe shape that is characteristic of the band neutrophil. The band nucleus has smooth, parallel sides and no constrictions in the nuclear membrane. The band neutrophil may be present in normal blood in small concentrations. Segmented neutrophils are normally the nearly exclusive circulating form and have a horseshoe-shaped nucleus with variable degrees of indentation and constriction along its perimeter (Figure 11.1). As the nucleus develops constrictions, it may fold into various shapes (Figure 11.2). Neutrophils have numerous small, very poorly stained granules. These vary among individual animals from colorless, invisible granules to lightly staining granules. Neutrophilic granules of the cow often stain faintly pink, giving the cytoplasm a slightly orange-pink tint overall (Figure 11.3). Neutrophils observed in cytologic samples may on occasion have altered staining of the neutrophilic granules. The granules may appear more prominent and stain pink. This change is most likely to be observed in neutrophils exudated in airway samples.

Lymphocytes

Blood lymphocytes represent a diverse set of lymphocyte subpopulations, but these subpopulations cannot be distinguished by blood-film examination or by techniques routinely used in clinical veterinary laboratories. The subpopulations include B lymphocytes, which are responsible for humoral immunity, and T lymphocytes, which are responsible for cell-mediated immunity and cytokine responses. T lymphocytes may be further classified as T-inducer (i.e., helper; CD4-bearing) cells and T-cytotoxic/suppressor (CD8-bearing) cells. Null cells are a third population present at small concentrations. Null cells consist of at least several lymphocyte subtypes, including large granular lymphocytes, natural killer cells, and other cells with killer activity. Lymphocyte subtypes may be differentiated by surface immunoglobulin and cluster designation (i.e., CD) markers; however, this technology is not yet part of the routine hemogram. These measurements are currently made in specialized laboratories, usually in cases of leukemia

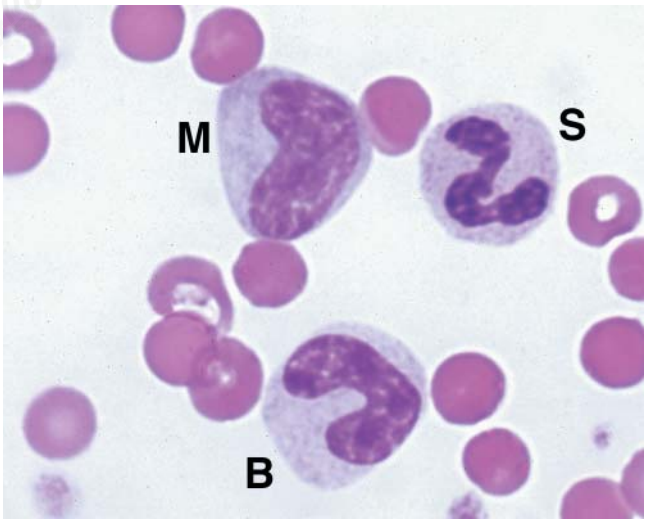

Figure 11.1 Neutrophil maturation sequence commonly seen in blood. The segmented or mature neutrophil (S) has an irregular nuclear membrane, with one or more constrictions. Note the small, faintly staining neutrophilic granules in the cytoplasm. The neutrophilic granules vary in prominence from animal to animal. The band neutrophil (B) has a horseshoe-shaped nucleus with smooth, parallel sides. The metamyelocyte (M) has a bean-shaped nucleus. Wright-Giemsa stain, high magnification.

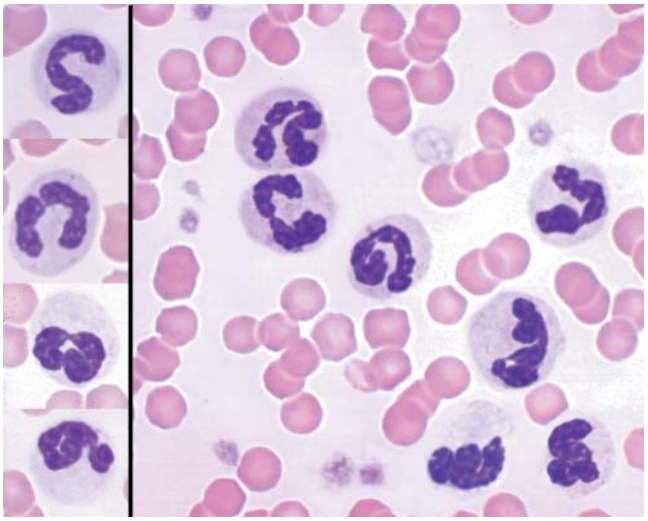

Figure 11.2 Representative segmented neutrophils illustrating variation in nuclear shape. Segmented neutrophils start with the horseshoe-shaped nucleus of the band cell. As the neutrophil nucleus develops more constrictions, it may more easily fold into various shapes. Note the "S"-shaped and horseshoe-shaped nuclei in the upper left. Then, note the various nuclear shapes that result from folding and superimposition of the folded nucleus on itself. Cells are arranged in this figure with greater degrees of folding moving toward the bottom. Wright-Giemsa stain, high magnification.

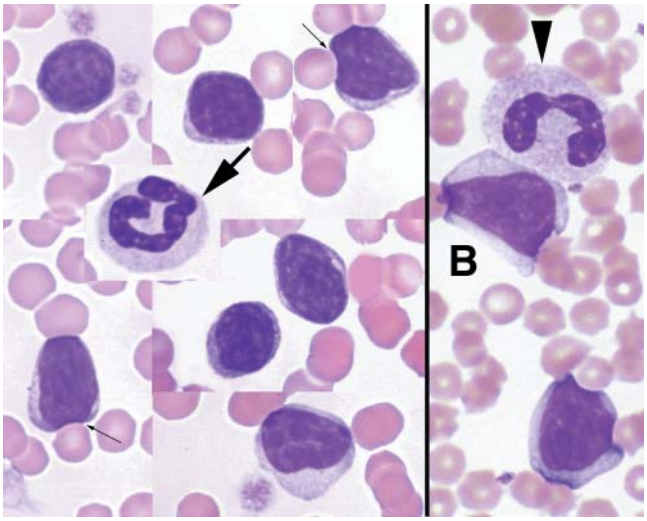

Figure 11.3 Variation in normal lymphocyte morphology in comparison to neutrophils. In the left panel, note that the lymphocyte nucleus may vary from round to oval. The cell shape, including the nucleus, may be indented by adjacent erythrocytes (thin arrows). The amount of cytoplasm varies from virtually none to a modest amount. Lymphocytes in most species have smaller diameter than adjacent neutrophils (thick arrow). An exception is indicated in the right panel: bovine lymphocytes (B) may be larger in diameter than lymphocytes of other common species and may have the same diameter as that of adjacent neutrophils (arrowhead). Note that the bovine neutrophil has slightly pink neutrophilic granules. Wright-Giemsa stain, high magnification.

(see Chapter 14). Such laboratories may provide special procedures for quantitation of certain subpopulations (e.g., B- and T-cell concentrations).

Lymphocytes are recognized by a round to oval nucleus and a minimal amount of clear, almost colorless cytoplasm. The amount of cytoplasm may be variable, as illustrated in Figure 11.3. Normal circulating lymphocytes have smaller diameters than those of neutrophils. In ruminants, lymphocytes may be more irregular in size and have diameters equal to those of neutrophils (Figure 11.3). Less common forms of lymphocytes include reactive lymphocytes and granular lymphocytes (Figure 11.4). Reactive forms likely are B cells capable of producing immunoglobulin. They have intensely basophilic cytoplasm, and the nucleus may be more irregularly shaped. In addition, the nucleus may have a cleft or an amoeboid shape. Large reactive lymphocytes are observed normally in juveniles of most species. Granular lymphocytes have a small number of pink-purple granules. These are large granular lymphocytes, some of which are thought to be natural killer or T cells. Large granular lymphocytes are most commonly observed in normal ruminant blood.

Monocytes

Monocytes also participate in inflammatory responses. Monocytes in blood are regarded as intermediate on a continuum of maturation. Monocytes migrate into tissues, where

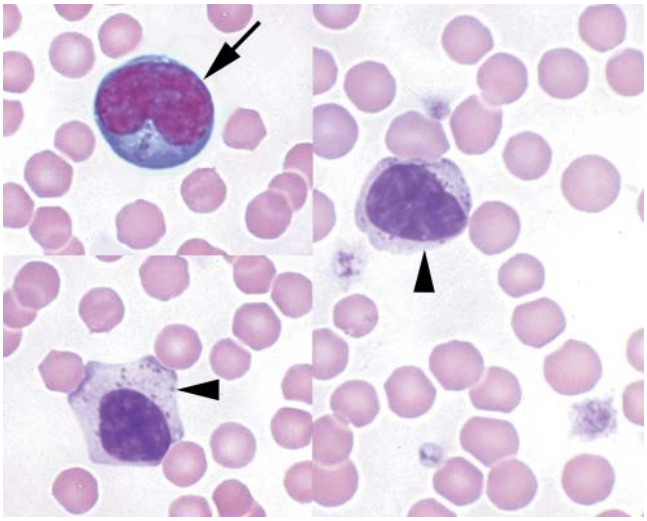

Figure 11.4 Variations in lymphocytes less commonly seen in blood. The reactive lymphocyte (arrow) is characterized by royal-blue cytoplasm. Its nuclear shape may be irregular, often with an indentation or cleft. Large granular lymphocytes (arrowheads) have an increased amount of light-staining cytoplasm, with a sparse sprinkling of azurophilic granules. The granules may vary in size. Large granular lymphocytes are most frequently seen in normal ruminants. Wright-Giemsa stain, high magnification.

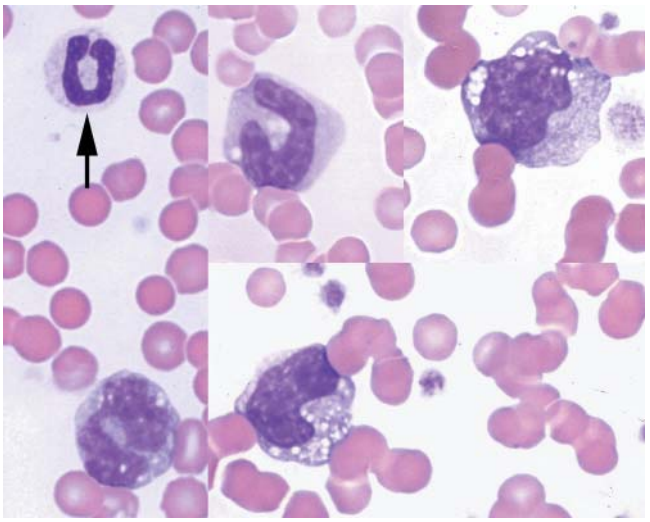

Figure 11.5 Variation in blood monocyte morphology; note the cells not marked by an arrow. Monocytes are typically larger than neutrophils (arrow). Monocytes may have cytoplasmic vacuoles, but this is not consistent. The monocyte nucleus is highly variable in shape: it may be round to bean-shaped to amoeboid-shaped, or it may be horseshoe-shaped and even segmented (like the nuclei of neutrophils). Inexperienced observers frequently confuse monocytes with horseshoe-shaped nuclei for neutrophils. The consistent features of monocytes are larger diameter than an adjacent neutrophil (arrow) and darker blue-gray cytoplasm compared with neutrophils. Wright-Giemsa stain, high magnification.

they continue to develop into macrophages. Mononuclear phagocytes may phagocytize bacteria, larger complex organisms (e.g., yeast and protozoa), injured cells, cellular debris, and foreign particulate debris. These cells play an important immunoregulatory function by presenting processed antigen to T lymphocytes. These cells are also responsible for normal erythrocyte destruction, associated metabolic iron recycling, and some mechanisms of pathologic erythrocyte destruction.

Monocytes are the most misidentified cell on blood films, particularly in the veterinary hospital laboratory. The nucleus may be of almost any shape, including oval-, bean-, ameboid-, or horseshoe-shaped (like that of neutrophils). The chromatin pattern may be slightly less condensed than that of neutrophils. The key distinguishing features are a larger diameter and more grayish coloration to the cytoplasm compared with adjacent neutrophils (Figure 11.5). The cytoplasm may contain extremely fine, light-purple granules. When uncertainty exists regarding monocyte identification, view at low power to make cell-to-cell comparisons (Figure 11.6). At low power, monocytes will stand out as larger cells. Species differences in monocyte morphology are not remarkable.

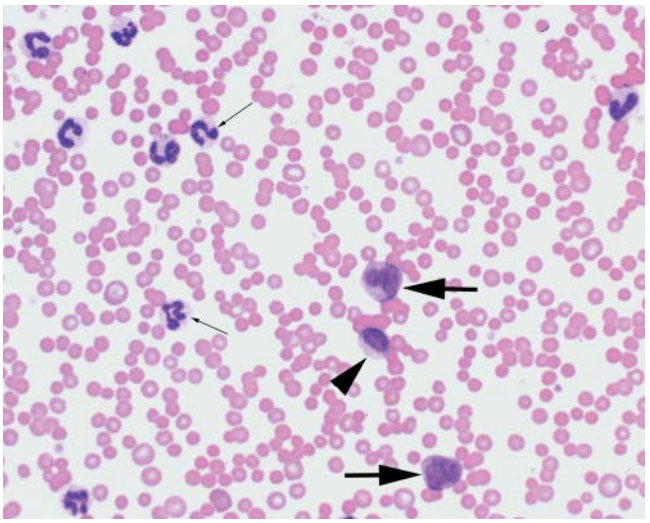

Figure 11.6 Low-magnification comparison of neutrophils and monocytes. When in doubt regarding identification of monocytes, use a lower magnification to make cell-to-cell comparisons that may be difficult at higher magnification. Note that the two monocytes (thick arrows) have larger diameters than the representative neutrophils indicated by thin arrows. A lymphocyte (arrowhead) is smaller than the adjacent neutrophils. Wright-Giemsa stain, low magnification.

Eosinophils

The functions of eosinophils are not well understood, even though a considerable number of studies and observations have been reported. Eosinophils contain proteins that bind to and damage parasite membranes, and they are responsible for providing a defense mechanism against larval

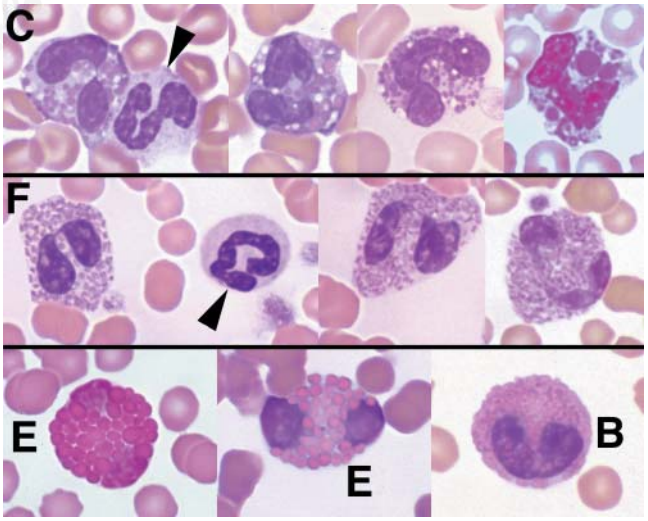

Figure 11.7 Species variation in eosinophil morphology. Representative neutrophils are shown for comparison (arrowheads). Eosinophils are typically larger in diameter than neutrophils. Canine eosinophils are shown in the top band (C). Note the variation in eosinophil granule size in dogs, which also may have eosinophil granules that appear to dissolve during the staining process, leaving a clear space that resembles a cytoplasmic vacuole. Feline eosinophils are shown in the middle band (F). Eosinophil granules of the cat are shaped like barrels or short rods. The density of the granularity may vary as shown. Large animal eosinophils are indicated in the bottom band. Equine eosinophils (E) have large, brightly staining granules that may obscure the nucleus, whereas bovine eosinophils (B) have smaller, brightly staining granules that are densely packed within the cytoplasm. Wright-Giemsa stain, high magnification.

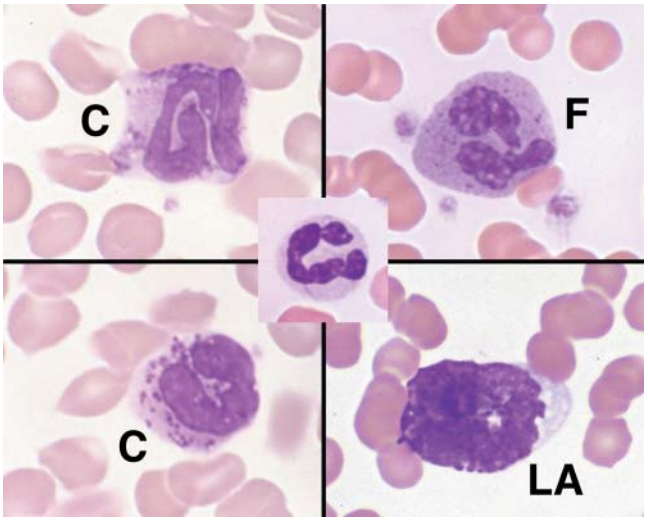

Figure 11.8 Species variation in basophil morphology. A representative neutrophil is shown in the center for comparison. Basophils are larger in diameter than neutrophils. Canine basophils (C) are poorly granulated. Note the sprinkling of basophilic granules in the cytoplasm. Feline basophils (F) have cytoplasm packed with large, poorly staining gray granules that are arranged like pavement stones. Large animal basophils (LA) have numerous dark-staining granules that often obscure the nucleus. Wright-Giemsa stain, high magnification.

stages of parasitic infestation. They are also involved in the modulation of allergic inflammation and immune-complex reactions.

Eosinophils vary in morphology among species (Figure 11.7). The nucleus is segmented (like that of neutrophils). The hallmark feature of eosinophils is prominent, red-orange granules that are tinctorially similar to erythrocytes. Canine eosinophils have highly variable granule size and number per cell. On rare occasions, a few large granules the size of erythrocytes may be present. Eosinophil granules also may wash out during the staining process, leaving what appears to be an empty vacuole; this observation is most pronounced in greyhound dogs. Feline eosinophils are densely packed, with uniform, rod- or barrel-shaped granules. Equine eosinophils have a raspberry appearance because of numerous round, large granules that may obscure the nucleus. Ruminant eosinophils have uniform, numerous round granules.

Basophils

The function of basophils is, basically, unknown. Basophils contain histamine and heparin. The cytoplasmic membrane has bound immunoglobulin E, like mast cells; however, their pathophysiologic role in the circulation is unknown. No convincing evidence has been reported that blood basophils migrate into tissues and become tissue mast cells. Concentrations of basophils in the circulation are very low, and they usually are not encountered in the routine differential count.

Basophils are larger in diameter than neutrophils. The nucleus is segmented (like those of other granulocytes). The granule morphology varies among species (Figure 11.8). Dogs have a small number of dark-violet granules. Cats have large, faint-gray granules that form a pavement-stone arrangement. Large animal basophils are packed with dark-violet granules that are so numerous they often obscure portions of the nucleus.

Reference values: the normal leukogram

The approach to interpretation of the leukogram involves a series of steps to arrive at a conclusion regarding what is normal or abnormal. Interpretive attention should focus only on the absolute values within the differential count data (see Chapter 1). When examining the hematology report, one should look first at the total leukocyte concentration. The total leukocyte concentration is only used to calculate absolute differential concentrations; it is not directly interpreted. For interpretation purposes, the total concentration only provides some gross guidance for what to anticipate when interpreting the differential concentrations. If the total count is decreased, examine the absolute concentration of each

Table 11.1 Reference intervals for absolute leukocyte concentrations of common domestic animal species.

Leukocyte	Dog	Cat	Horse	Cow	Sheep	Pig
Total WBC (cells/μL)	6 000–17 000	5 500–19 500	5 500–12 500	4 000–12 000	4 000–12 000	11 000–22 000
Differential WBC: band neutrophils (cells/μL)	0–300	0–300	0–100	0–100	0–100	0–800
Segmented neutrophils (cells/μL)	3000–11,500	2500–12,500	2700–6700	600–4000	700–6000	3200–10,000
Lymphocytes (cells/μL)	1000–5000	1500–7000	1500–5500	2500–7000	2000–9000	4500–13,000
Monocytes (cells/μL)	0–1200	0–800	0–800	0–800	0–800	200–2000
Eosinophils (cells/μL)	100–1200	0–1500	0–900	0–2400	0–1000	100–2000
Basophils (cells/μL)	Rare, 0–100	Rare, 0–100	0–200	0–200	0–300	0–400

WBC, white blood cell.

cell type to determine which are deficient. If the total count is increased, examine the absolute concentration of each cell type to determine which are present in excess. Even if the total concentration is normal, examine the absolute concentration of each cell type to determine if any abnormalities in distribution are present. Identified abnormalities in the absolute concentrations of individual leukocyte types are then interpreted into processes (see Chapter 13).

Reference values are given in Table 11.1. These values are patterned after general guidelines that have been used for decades (from the original work of Schalm) and are similar to those used by most veterinary laboratories. A more comprehensive, population-based set of reference intervals generated by newer technology for automated cell counting is needed. This has been done in some teaching hospital laboratories for specific automated systems used in the respective settings. Improved precision of automated cell counting as well as improved procedures for statistical analysis may provide more useful interpretive guidelines in the future.

The clinician interprets leukocyte abnormalities by learning to examine the individual differential leukocyte concentrations and then noting any morphologic abnormalities or abnormal cell types present that should not be present in normal blood. Differential leukocyte concentrations are reported in cells per microliter for each cell type. Abnormal nucleated cells include blasts, nucleated erythrocytes, mast cells, and immature granulocytes. Morphologic abnormalities include inherited and transiently acquired morphologic changes. Abnormal morphology is presented in Chapter 13.

12 Neutrophil Production, Trafficking, and Kinetics

Glade Weiser
Loveland, CO, USA

General trends regarding the trafficking and kinetics of neutrophils in blood have been observed. Although species differences are not well studied, there are notable kinetic differences that affect interpretation of concentration changes in response to inflammatory disease. It is important to appreciate that rapid and dramatic changes in blood neutrophil concentration can occur. An understanding of neutrophil production and kinetic behaviors is useful to interpret the timing of responses to disease and the possible sequential changes between hemograms.

Production of granulocytes

Neutrophils are produced almost exclusively in the active bone marrow of healthy, adult domestic animals. Some production may be found in extramedullary sites, most notably the spleen, in juvenile animals. With long-standing increased demand for neutrophils (e.g., in chronic inflammatory disease), extramedullary production may be observed in adult animals. This will be most prominent in the spleen, but it may also be seen in the liver and lymph nodes in extreme cases.

Neutrophils originate from the pluripotential stem cell system, which gives rise to a more differentiated stem cell that has the capacity to create granulocytes and monocytes (GM stem cells). A subpopulation of these GM stem cells enters a pathway of committed differentiation of blood granulocytes, consisting of neutrophils, eosinophils, and basophils. The stem cells are not morphologically distinct, because they are present in small numbers and are probably morphologically indistinguishable from small lymphocytes. Once a cell makes this entry commitment, it undergoes both proliferative and maturational events to propagate blood granulocytes. These proliferative and maturational events are associated with morphologically recognized stages of granulocytes. Recognition of the general progression of these stages is important in the evaluation of bone marrow samples and the identification of cells in blood in response to disease. The morphologic stages of granulocytes are indicated in Figure 12.1.

The myeloblast is the first recognizable cell that is committed to granulocyte production. Myeloblasts are difficult to distinguish morphologically from primitive blasts of other cell lineages. Once committed, the myeloblast produces primary (i.e., azurophilic) granules, the presence of which identifies the progranulocyte stage. At subsequent stages of maturation, the primary granules change their staining character and become indistinguishable in conventional blood stains. In the next stage, the myelocyte begins to produce secondary (i.e., specific) granules that identify whether the cell will be a neutrophil, eosinophil, or basophil. Historically, the naming of the specific granules and the cell type has related to the dye component of the polychrome blood stains taken up by the specific granule. Neutrophil granules have neutral staining affinity; because of poor dye affinity, the granules are very faint or not visible. Eosinophil granules have an affinity for the orange-red dye and stain intensely orange-red. Basophil granules have affinity for basic dyes and stain intensely dark violet. Myeloblasts, progranulocytes, and myelocytes have the ability to undergo cell division as well as to mature from one stage to the next. These stages are relatively rich in ribosomes, giving the cytoplasm a bluish tint. Nuclear features include round to oval shape and relatively fine chromatin pattern.

More mature stages are characterized by the loss of ability to undergo cell division and include metamyelocytes, bands, and segmented granulocytes. Maturation consists mostly of progressive nuclear condensation and change in nuclear shape. The cytoplasm loses most or all of its bluish tint as the ribosome content decreases. The metamyelocyte has a nucleus that has developed an indentation. The band cell nucleus forms a horseshoe shape and has smooth, parallel

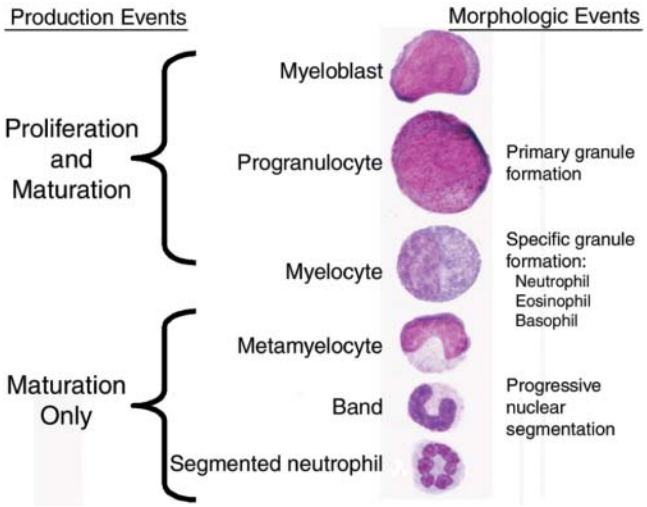

Figure 12.1 Morphologic features of stages of neutrophil maturation. Six morphologic stages are identified on a continuum of maturation, as indicated by the named cells. Cells capable of both cell division and maturation are at the top; cells capable of maturation only are at the bottom. Major changes associated with maturation are indicated on the right. (See text for a more complete description.)

nuclear membranes. The segmented or mature neutrophil progressively develops indentations or constrictions in the nuclear membrane. The progressive nuclear condensation results in a coarser chromatin with a darker, irregular staining pattern. See Chapter 11.

Maturation and orderly production

Production normally results in a progressive increase in the relative numbers of more mature stages, as indicated in Figure 12.2. This results from the combined events of proliferating early forms, which amplify both the number of cells and the progress toward more mature stages. In the process, each myeloblast may produce approximately 16–32 segmented neutrophils. The pattern of production seen in the marrow is a mixture of a relatively small number of primitive cells, a larger number of intermediate stages, and even more numerous later mature stages. This progression of a few immature cells to many more mature cells is described as orderly production. Both normal production and accelerated production in response to increased granulocyte demand have this orderly appearance. Cells are also delivered to the blood in this orderly fashion (see the discussion of left shift in Chapter 13). Disorderly production is characterized by a disproportionate relative number of primitive forms and a relative decrease or absence of more mature forms. Disorderly production is one of the features used to identify certain pathologic patterns (e.g., myeloproliferative disorders).

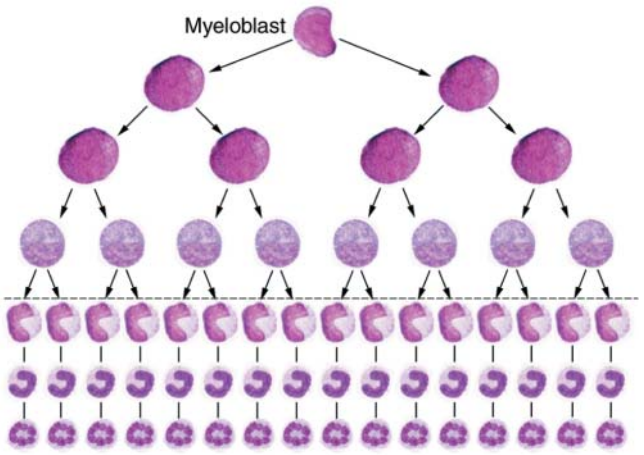

Figure 12.2 Orderly production of neutrophils in bone marrow. Note the progressive increase in relative cell numbers as maturation progresses. The myeloblast may give rise to approximately 16–32 cells before proliferative ability is lost. Cell stages above the dashed line are capable of cell division; cell stages below the dashed line are only capable of maturation. Please refer to Figure 12.1 for reference to cell stages.

Neutrophil pools and trafficking

To understand neutrophil responses in disease, it is helpful to visualize a set of compartments and pools consisting of bone marrow, blood, and tissues, as depicted in Figure 12.3. The bone marrow compartment may be conceptually divided into a stem cell pool, a proliferative pool, and a maturation and storage pool. The proliferative pool consists of neutrophils at stages during which they still have the ability to undergo cell division and is largely responsible for the amplification of cell numbers. The maturation and storage pool consists of cells having lost the ability to divide and that are completing morphologic maturation. These cells may accumulate to create a modest storage reserve that is variable in size, which depends on the species. The storage capacity is greatest in dogs, least in ruminants, and intermediate in cats and horses.

Neutrophils make a unidirectional migration to the blood compartment, which is divided into the circulating and margination pools. The circulating pool is located in large vessels in which no interaction normally occurs between neutrophils and the endothelial lining of the vessel. Blood samples taken by venipuncture are from the circulating pool. The margination pool consists of the microcirculation. Cells may move bidirectionally between the circulating and margination pools. Neutrophils interact with the endothelial lining of small vessels and capillaries by their property of stickiness. Neutrophils may then unidirectionally migrate into adjacent tissue spaces (i.e., the tissue compartment). It is in the tissue compartment that neutrophils participate in their host-defense purposes.

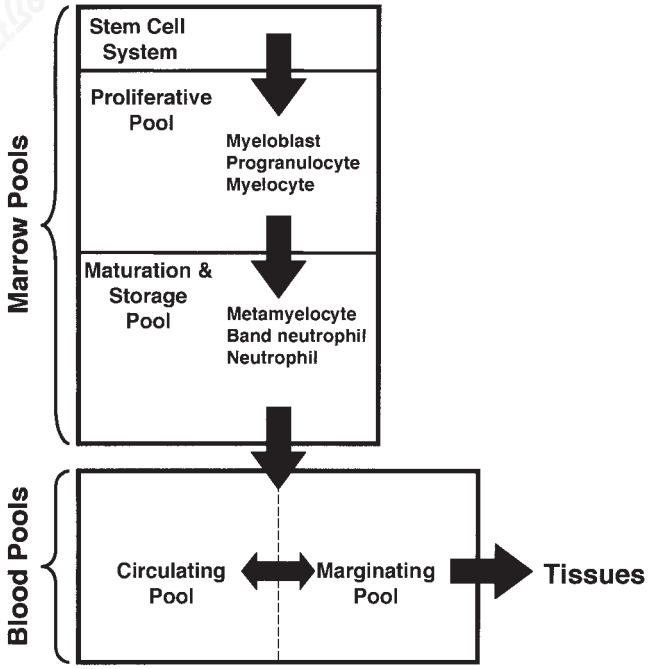

Figure 12.3 Bone marrow and blood neutrophil pools. Single arrows indicate unidirectional movement of cells; double arrow indicates bidirectional movement of cells. (See text for description of various compartments and progress through them.)

All neutrophil responses in disease may be understood as being mechanisms and disturbances occurring in this set of pools. They are discussed in detail in Chapter 13.

Growth factors and regulation of production and blood concentration

In health, the concentration of neutrophils in the blood is regulated to stay within a relatively narrow concentration range compared with the range that is possible in disease. Regulation of production is mediated by a complicated set of cytokines and growth factors, a simplified version of which is shown in Figure 12.4. The family of cytokines and growth factors depicted in Figure 12.4 work in concert at various stages to regulate neutrophil production. Colony-stimulating factor (CSF) is a group of characterized molecules; most notable are granulocyte-CSF and GM-CSF. These factors originate from numerous and diverse sites, including mononuclear cells, endothelium, fibroblasts, and other cell types. Mononuclear cells at sites of inflammation are probably the most important source of CSF and may modulate the release of CSFs from the other cell types. Interleukins (ILs) also participate in stimulation of production. The release of neutrophils from the marrow space to blood may be accelerated by IL-1, tumor necrosis factor (TNF), and leukocytosis-inducing factor (LIF). Because of variation in

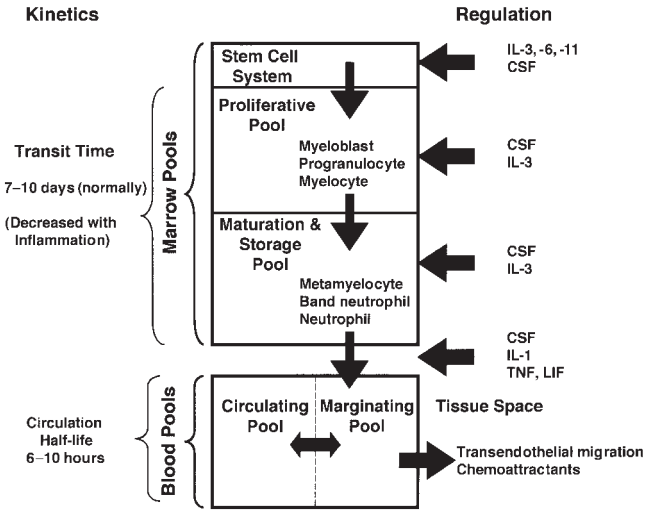

Figure 12.4 Bone marrow and blood neutrophil pools. Kinetic information is given on the left and regulation information on the right. Neutrophil production is regulated by a concert of growth factors and cytokines that act at multiple sites. The transit time is normally 7–10 days but may be shortened with increased demand. The circulation half-life is approximately 6–10 hours.

experimental conditions and methods, LIF may be the same as IL-1 and TNF.

In the normal steady state, production is balanced by the transendothelial migration of neutrophils into tissues. This balance yields blood neutrophil concentrations in the normal range. Increased levels of growth factors and cytokines are responsible for marked acceleration of the events to produce neutrophils in response to inflammation. This may result in a dramatic increase in neutrophil production and delivery to blood. Migration into the site of inflammation is accelerated and focused by chemoattractants that are released in the inflammatory lesion. The net result is an increase in the flux of neutrophils from the bone marrow to the inflammatory lesion. After resolution of the inflammatory lesion, blood neutrophil concentrations return to normal over a period of time likely measured in days. This suggests the presence of some negative-feedback mechanism, but its nature is currently unknown.

Neutrophil kinetics

Some basic information about the kinetics of neutrophils in various pools is helpful in the interpretation of sequential changes in the leukogram. The transit time for production and the circulation time in blood are the two key benchmarks for neutrophil kinetics.

The transit time is the amount of time needed for the myeloblast to complete the maturational events and become a segmented neutrophil in blood (see Figure 12.4). In the

normal steady state, the transit time is approximately 7 days. When the bone marrow is stimulated by the inflammatory response, the transit time may become as short as 2–3 days.

The circulation time is the amount of time between release of the neutrophil to the blood and its subsequent egress into tissues. Neutrophils randomly migrate into tissues, so their circulation time is variable and not related to cell age. The circulation time is approximately 6–10 hours, encompassing some species variation. This means that the blood neutrophil pools are renewed approximately 2–3 times per day. The circulation time may be shortened considerably when neutrophils are consumed at a more rapid rate (e.g., at a site of inflammation). Given the rapid rate of blood neutrophil renewal in blood, marked changes in the blood neutrophil concentration may occur very rapidly in response to disease. The magnitude of these changes in the cell concentration that may be observed on hemograms sampled only hours apart is often dramatic and surprising. Application of neutrophil kinetics and trafficking knowledge is important and further developed in principles of leukocyte response interpretations in Chapter 13.

13 Interpretation of Leukocyte Responses in Disease

Glade Weiser
Loveland, CO, USA

To communicate about leukocyte responses, one must first become familiar with the descriptive terminology associated with abnormal patterns of cell concentrations in blood. To identify and interpret leukocyte responses, the rules for interpreting abnormal concentration patterns as indicators of disease processes must be learned. This chapter presents terminology, abnormal morphologic features encountered in the laboratory, and guidelines for interpretation of leukocyte patterns.

Terminology of abnormal leukocyte concentration patterns

Suffixes

Abnormal concentrations are described using a variety of suffixes attached to the name of the cell type(s) involved.

The suffix -penia refers to a decreased concentration of the cell type in blood. A general term, cytopenia, refers to a decrease in leukocyte concentration in a nonspecific manner. Cytopenias that are important for interpretation include neutropenia, lymphopenia, and eosinopenia. Cytopenia does not apply to monocytes, because a decreased concentration of this cell type is not important. It also does not apply to band neutrophils, metamyelocytes, basophils, metarubricytes, and other abnormal cells because the absence of these cells in blood is normal.

The suffixes -philia or -cytosis refer to an increased concentration of the cell type in blood. Examples include:

- Neutrophilia or neutrophilic leukocytosis
- Eosinophilia
- Basophilia
- Monocytosis
- Lymphocytosis
- Metarubricytosis.

Left shift

Left shift refers to an increased concentration of immature neutrophils in blood. This usually indicates band neutrophils, but metamyelocytes and earlier forms may accompany increased bands. (See Figure 11.1 for neutrophil and left-shift morphology.) A left shift may occur with neutrophilia. A left shift also may occur with neutropenia; this indicates a more severe consumption of neutrophils by a more aggressive inflammatory lesion or an early repopulation of blood following a reversible stem cell injury. An orderly left shift suggests an inflammatory stimulus; in this case, the term orderly means that the concentration of each cell stage decreases with the degree of immaturity of the cell stage.

Leukemia

Leukemia refers to the presence of neoplastic cells in the circulation. The neoplastic cell type that is present more specifically designates the classification of the leukemia present. The classification may be determined by a combination of cell population morphologic differentiation features seen on the blood film, surface marker cytometry panels, and immunocytochemistry reactions (see Chapter 14). Examples include myelomonocytic leukemia and lymphocytic leukemia. The concentration of neoplastic cells may vary from detectable on blood film scanning to extremely high.

Proliferative disorder

Proliferative disorder is a nonspecific term for a hematopoietic cell neoplasm that is distributed in blood, bone marrow, other tissues, or a combination of these and other sites. Proliferative disorders are classified into lymphoproliferative and myeloproliferative categories. The distinction between the lymphoid and bone marrow stem cell systems is somewhat artificial, but these two classes of proliferative disorders

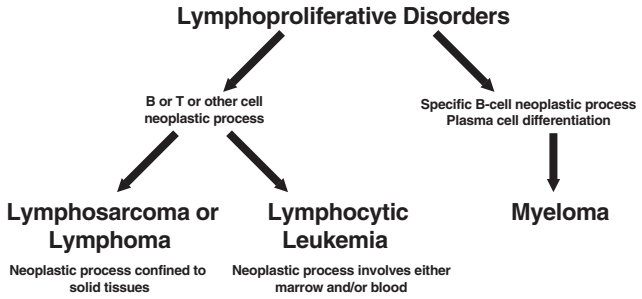

Figure 13.1 Organization and general terminology for lymphoproliferative disorders. See text for discussion.

have different biologic behavior, case management protocols, and prognosis. Proliferative disorders are discussed separately in Chapters 15 and 16.

Lymphoproliferative disorders

Lymphoproliferative disorders, which are characterized in Figure 13.1, are neoplastic processes with lymphoid cell differentiation. If the neoplasm is confined to solid tissues, it is termed lymphosarcoma or lymphoma. If it involves blood and/or bone marrow, it is termed lymphocytic leukemia. A specific form with plasma cell differentiation is termed myeloma, which is usually associated with production of a monoclonal immunoglobulin that may be detected in blood. Immunoglobulin light chains also may be detected in urine. More extensive and detailed classifications of lymphoproliferative disorders based on cellular morphology and immunophenotyping are available (see Chapters 14–16 and "Suggested Reading").

Myeloproliferative disorders

Myeloproliferative disorders arise from the bone marrow stem cell system. More extensive and detailed classifications of myeloproliferative disorders based on cellular morphology and surface markers are available (see Chapters 14–16 and "Suggested Reading"). The recognized lines of differentiation and associated terminology for specific myeloproliferative disorders are detailed in Figure 13.2. Note that more differentiation pathways are recognized for myeloproliferative disorders than for lymphoproliferative disorders. Granulocytic, monocytic, and erythroid differentiations are the most common myeloproliferative disorders; the others are rare.

In recent years, it has become apparent that confirmation of lymphoproliferative disorders or identification of cell lineage in proliferative disorders is limited with morphology. Occasionally, the distinction between reactive and neoplastic lymphoid proliferation is difficult. Primitive blasts having no specific differentiating morphologic features may be difficult to impossible to classify by morphology alone.

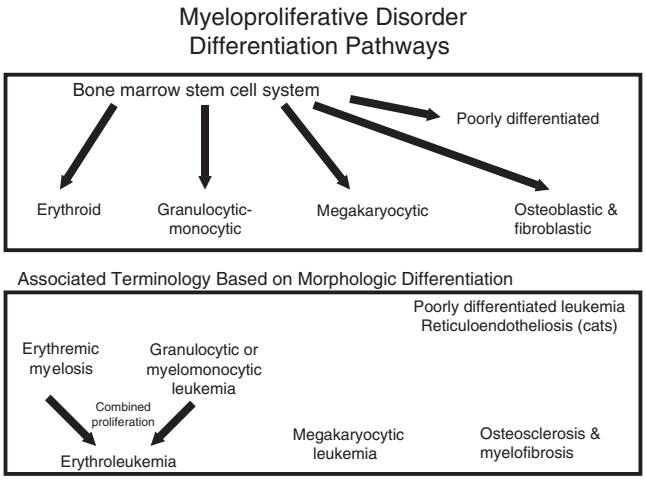

Figure 13.2 Organization and general terminology for myeloproliferative disorders. The top box shows general differentiation pathways based on morphologically recognized cell lineages. The bottom box shows historical and commonly applied terminology for the myeloproliferative disorders based on morphologic identity. See text for discussion.

These are often called lymphoid on initial examination. It has been learned that lymphoid, monocytic, granulocytic, and megakaryocytic blasts can be morphologically indistinguishable. Immunocytochemistry and flow cytometry are now used to identify cell lineage when it is important for treatment considerations. These procedures use panels of chemistry reactions and/or antibody labeling to identify either cytoplasmic activities or surface markers to aid in classification. Furthermore, these tools may be used to determine lymphocytic subpopulation identification. This is the subject of Chapter 14.

Acquired changes in leukocyte morphology

Neutrophil toxic change

Neutrophil toxic change may be observed in association with inflammatory responses. The term toxic change is unfortunate, because it originated from early observations that these alterations in cell morphology were associated with toxemia in human patients. The term implies that the cells are injured or impaired. We now understand that the morphologic change is attributable to altered bone marrow production and that the cells have normal function. When an inflammatory stimulus is delivered to the bone marrow (see Figure 12.4), neutrophils are produced at an accelerated rate. As a result, the cells may have increased amounts of certain organelles that are present during early development. The principal manifestation is cytoplasmic basophilia (Figure 13.3). This is attributable to a larger-than-normal

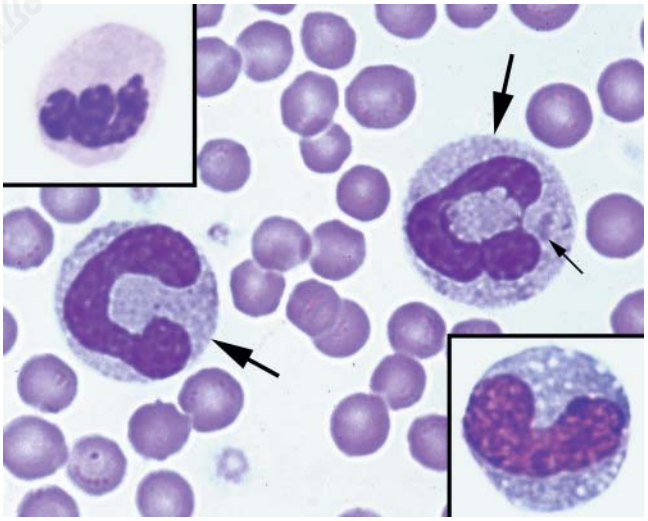

Figure 13.3 Neutrophils with marked toxic change (arrows). Note prominent cytoplasmic basophilia. A Döhle body is indicated by the thin arrow. A toxic neutrophil with fine cytoplasmic vacuolation is shown in the lower right inset. For comparison, a normal neutrophil is shown in the upper left inset. Wright-Giemsa stain, high magnification.

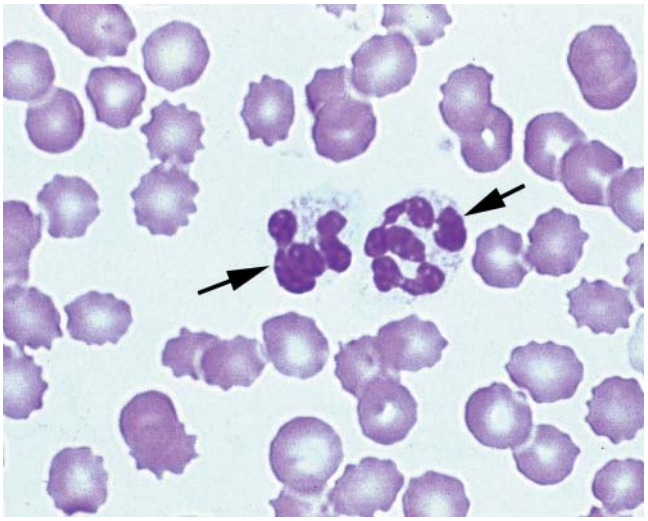

Figure 13.4 Neutrophils with hypersegmentation (arrows). Note the nuclear constrictions to a filament of chromatin that separates approximately 5–7 chromatin lobes. Wright-Giemsa stain, high magnification.

complement of ribosomes. Other, less common manifestations accompanying cytoplasmic basophilia include Döhle bodies and cytoplasmic vacuolation. Döhle bodies are aggregates of endoplasmic reticulum and appear as gray-blue cytoplasmic precipitates. Döhle bodies are seen more commonly in cats (Figure 13.3).

The interpretation of toxic change is that neutrophils are made under conditions of accelerated production that occurs as part of the inflammatory response. As a result, toxic change often accompanies other quantitative changes in the inflammatory leukogram presented later in this chapter.

Neutrophil hypersegmentation

Neutrophil hypersegmentation is the normal progression of nuclear maturation in the neutrophil. The progression from band shape to segmentation to hypersegmentation is a continuum that occurs in a matter of hours. Normally, the process of continued segmentation and, finally, pyknosis occurs in neutrophils after egression to tissues. Hypersegmentation observed on the blood film results from longer than normal retention of neutrophils in the circulation (Figure 13.4). The interpretation of hypersegmentation is relatively unimportant (it is usually associated with steroid effect on the leukogram presented in this chapter).

Neutrophil degeneration

Neutrophil degeneration is a description ordinarily applied to neutrophils from samples other than blood (e.g., cytopathologic specimens). Neutrophils exposed to an unhealthy environment outside of blood may rapidly degenerate. This is accelerated in cytopathologic specimens, which either have a bacterial component or are from epithelial surfaces such as skin, airways, or the gastrointestinal tract (Figure 13.5). Features include cytoplasmic vacuolation and nuclear swelling seen as a loss of chromatin pattern and light staining. These changes may progress to cell lysis. It

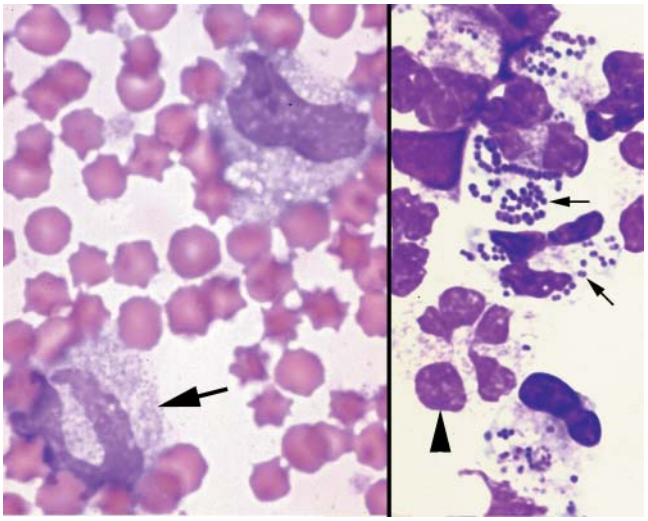

Figure 13.5 Neutrophil degeneration. The left panel shows neutrophil (arrow) degeneration on a blood film that is an artifact of aging in the collection tube before blood-film preparation. Note the swollen chromatin that results in lighter staining and loss of chromatin detail. The right panel shows neutrophils in various stages of degeneration in a cytologic preparation. This results from an unhealthy environment that is created, in part, by numerous bacteria (thin arrows). A neutrophil with chromatin swelling and loss of detail is indicated by the arrowhead. Wright-Giemsa stain, high magnification.

is an artifact in blood seen on the blood film if that film is made from blood that has aged for 12 hours or longer after collection from the animal (Figure 13.5). In blood, it therefore is interpreted as an artifact of improper sample handling.

Leukocyte agglutination

Leukocyte agglutination is an immunoglobulin-mediated agglutination of leukocytes *in vitro*. It may affect either neutrophils or lymphocytes. This phenomenon does not occur in the animal at body temperature, and it likely has no pathologic consequence *in vivo*. It is thought to be attributable to a cold-reacting immunoglobulin that acts at temperatures well below body temperature. When the blood cools to room temperature or below, this abnormal immunoglobulin binds to its leukocyte target and bridges cells into agglutinated particles. It therefore occurs in the blood tube after collection from the patient. Its importance is that it may result in a falsely low total white-blood-cell concentration, because agglutinated leukocytes may not be counted properly by instruments. It is observed on scanning the blood film (Figure 13.6).

Lymphocyte vacuolation

Lymphocyte vacuolation may be an acquired change associated with ingestion of certain plants containing the toxic substance swainsonine. An example is locoweed ingestion in horses or cattle. The appearance is similar to that of lymphocyte vacuolation associated with inherited storage disorders (discussed later; see Figure 13.11).

Inherited abnormalities of leukocyte morphology and function

Inherited abnormalities of neutrophil morphology and/or function

Inherited abnormalities of neutrophil morphology include Pelger-Huët anomaly, Birman cat neutrophil granulation anomaly, mucopolysaccharidoses, and Chédiak-Higashi syndrome.

Pelger-Huët anomaly

Mature, hyposegmented neutrophils are seen in heterozygotes for Pelger-Huët anomaly. These cells have an immaturely shaped nucleus (i.e., band or myelocyte form) but a coarse, mature chromatin pattern (Figure 13.7). Neutrophils function normally, and affected animals are healthy. Typically, no segmented neutrophils are seen in blood films from these animals. Eosinophils are also affected and appear as band forms. The importance of recognizing Pelger-Huët anomaly is to prevent misidentification of a major left shift and misinterpretation as an inflammatory response in an otherwise apparently healthy, affected individual.

Birman cat neutrophil granulation anomaly

Neutrophils from affected cats contain fine eosinophilic to magenta-colored granules (Figure 13.8). This anomaly is inherited in an autosomal recessive manner. Neutrophil function is normal, and cats are healthy. This granulation must be distinguished from toxic granulation, which is

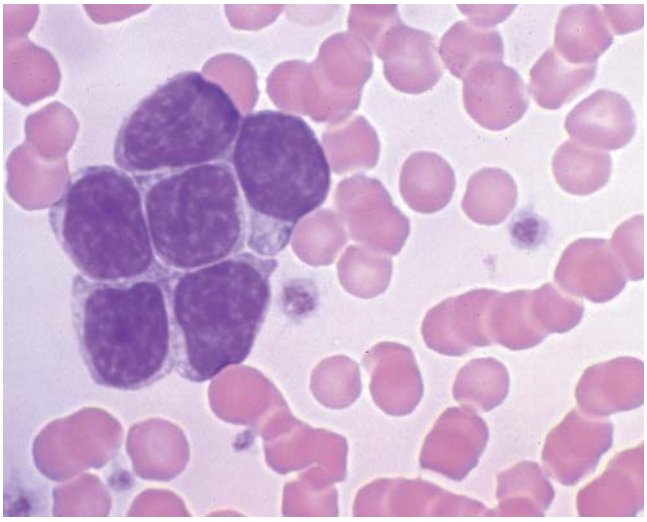

Figure 13.6 Leukoagglutination involving lymphocytes. Note the tight adherence of cells in a cluster. Multiple clusters are observable at low magnification. These cell clusters result in falsely low white-blood-cell counts when present in the counting fluid diluent (see text). Wright-Giemsa stain, high magnification.

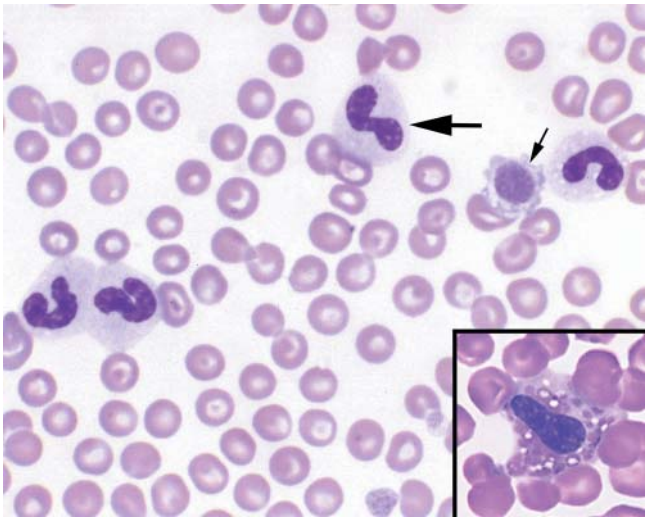

Figure 13.7 Granulocytes from a dog with Pelger-Huët anomaly. Four hyposegmented neutrophils (thick arrow) are present. The lower right inset shows a hyposegmented eosinophil. A macroplatelet, present by coincidence, is indicated by the thin arrow. Wright-Giemsa stain, high magnification.

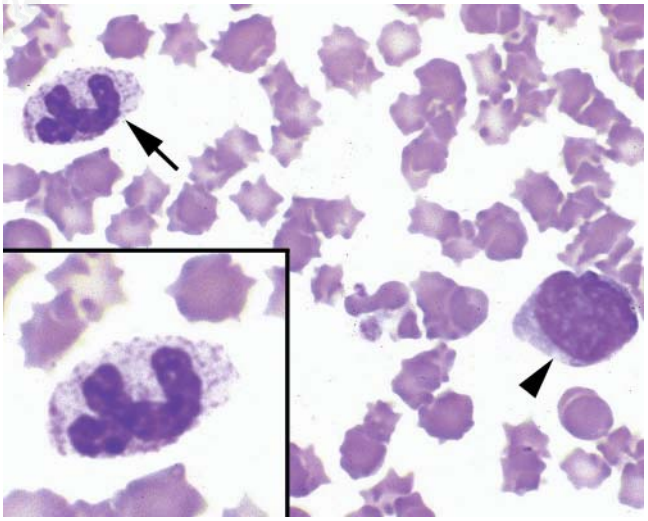

Figure 13.8 Granulated neutrophil from a cat with Birman cat neutrophil granulation anomaly (arrow). The lower left inset shows an enlarged view of the same cell. Note the fine granulation as compared with mucopolysaccharidosis (see Figure 13.9). Lymphocytes (arrowhead) are not affected. Wright-Giemsa stain, high magnification.

rare, and from that seen in neutrophils from cats with mucopolysaccharidosis (MPS), which usually is coarser.

Mucopolysaccharidoses

Neutrophils from animals with MPS typically contain numerous distinct, dark-purple or magenta-colored granules (Figure 13.9). Lymphocytes also usually contain granules and vacuoles.

MPS is a group of heritable, lysosomal storage disorders caused by a deficiency of lysosomal enzymes needed for the stepwise degradation of glycosaminoglycans (i.e., mucopolysaccharides). Common features include dwarfism (except feline MPS I), severe bone disease, degenerative joint disease including hip subluxation, facial dysmorphia, hepatomegaly (except feline MPS VI), corneal clouding, enlarged tongue (canine MPS), heart-valve thickening, excess urinary excretion of glycosaminoglycans, and metachromatic granules (i.e., Alder-Reilly bodies) in blood leukocytes. These granules are more distinct in MPS VI and VII than in MPS I. Granules usually are not apparent when stained with Diff-Quik. The disease is progressive, with clinical signs becoming apparent at 2–4 months of age. Affected animals may live several years, but locomotor difficulty is progressive.

Chédiak-Higashi syndrome

Neutrophils in cats affected by Chédiak-Higashi syndrome have large, fused, lysosomes that stain lightly pink or eosinophilic within the cytoplasm (Figure 13.10). Approximately one in three or four neutrophils contain one to four fused lysosomes. Eosinophilic granules appear slightly plump and large. These cats have a slight tendency to bleed, because platelet function is abnormal. Although neutrophil function is also abnormal, cats are generally healthy. The syndrome has been reported in cats of Persian ancestry and is inherited in an autosomal recessive manner.

Bovine leukocyte adhesion deficiency (BLAD)

Bovine leukocyte adhesion deficiency is a lethal, autosomal recessive disorder identified in Holstein cattle. The defect is

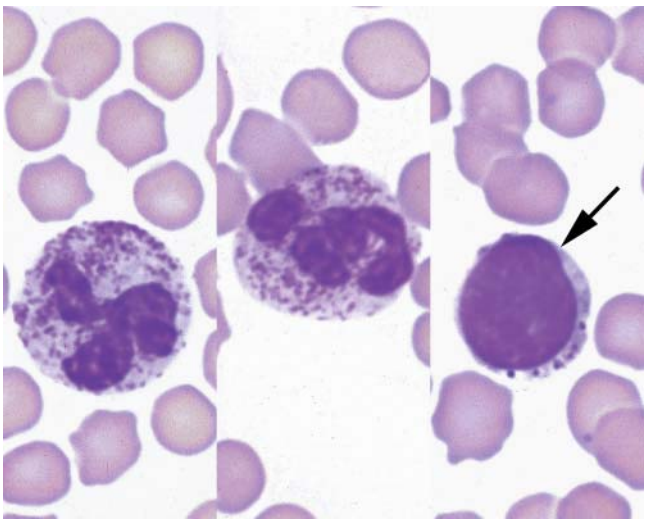

Figure 13.9 Granulated leukocytes from a cat with mucopolysaccharidosis VI. Note the prominently granulated neutrophils at the left and center. A lymphocyte with sparse granulation is typical of mucopolysaccharidosis (arrow). Wright-Giemsa stain, high magnification.

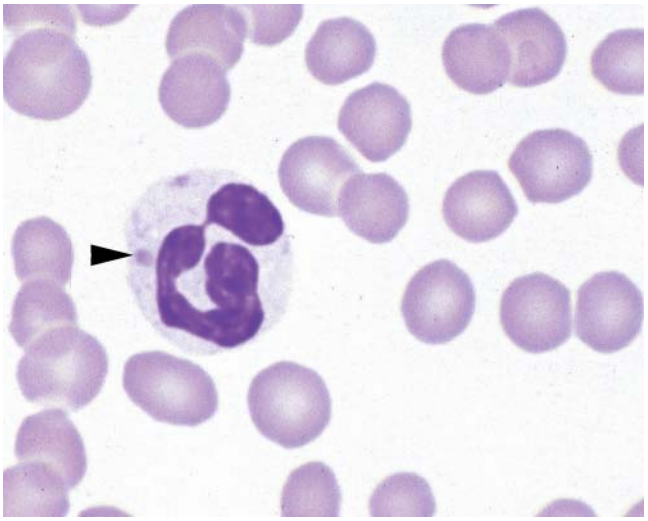

Figure 13.10 Neutrophil from a cat with Chédiak-Higashi syndrome. Note the large eosinophilic granule in the cytoplasm (arrowhead). Wright-Giemsa stain, high magnification.

a mutation in the CD 18 gene. This results in neutrophils with a deficiency of beta-2 integrin surface molecules that are essential for normal leukocyte adherence and emigration into tissues; hence there is a functional defect. Clinical signs of "poor doing" appear at 1–2 weeks of age. Affected calves may appear stunted and have signs related to respiratory and gastrointestinal tracts. They are predisposed to recurring bacterial infections and typically do not live beyond 2–8 months of age. A hematologic feature is marked, persistent neutrophilia (often >100,000/μL) with no left shift. On examination of tissues, there are few neutrophils, except within vessel lumens, because they persist in the circulation and have impaired entry into the tissues. Testing is available to detect carriers. Incidence of the defect is decreasing due to testing for the carrier state and removal of carriers from breeding stock.

Inherited abnormalities of lymphocyte morphology

Cytoplasmic vacuolization is the most significant inherited abnormality of lymphocytes and usually is associated with lysosomal storage disorders (Figure 13.11). Those lysosomal storage diseases described in domestic animals that result in vacuoles within the cytoplasm of lymphocytes include MPS (also have granules in neutrophils); G_{M1} and G_{M2} gangliosidosis (G_{M2} gangliosidosis also has granules in lymphocytes and neutrophils) (Figure 13.12); alpha-mannosidosis; Niemann-Pick types A, B, and C; acid-lipase deficiency; and fucosidosis. All these disorders, except for MPS and acid-lipase deficiency, result in severe, progressive neurologic disease that is ultimately fatal.

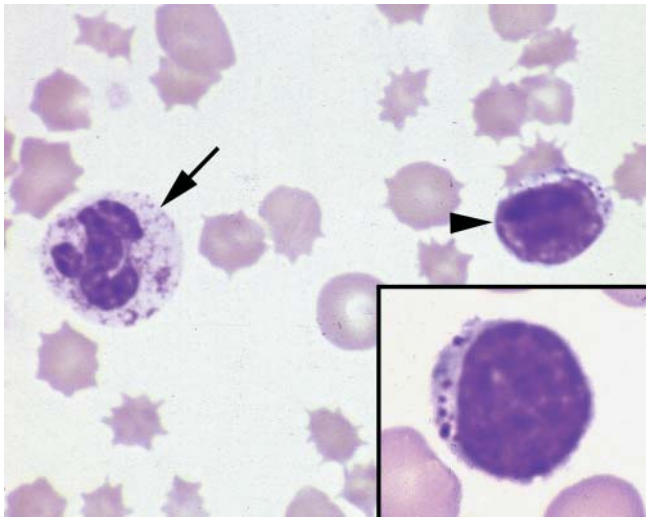

Figure 13.12 Leukocytes from a cat with G_{M2} gangliosidosis. Neutrophils (arrow) may have granulation similar to that seen with mucopolysaccharidosis. Lymphocytes (arrowhead) also have small numbers of granules with some degree of cytoplasmic vacuolation. The lower right inset shows an enlarged lymphocyte. Wright-Giemsa stain, high magnification.

Interpretation of leukocyte responses

Perspective

Most leukocyte response patterns are not interpreted into specific diagnoses, although leukemias may be an exception. Instead, responses are interpreted into basic processes occurring in the animal. These processes must then be coupled with other clinical information to work toward a clinical diagnosis.

Hematologic response to inflammation

Inflammation is the most important – and one of the most common – blood leukocyte responses. The nature of the response is best understood by considering a modified neutrophil trafficking model (Figure 13.13). It also may be helpful to review the steady-state neutrophil trafficking model in Chapter 12 (see Figure 12.3). When inflammation is established, an orchestra of chemical mediators modulates many events. Vasodilation and chemotactic substances work to increase the egress of neutrophils from the local marginated pool into the inflammatory lesion. Cytokines released from local mononuclear cells (see Figure 12.4) make their way to the bone marrow, where they increase the rate of release of maturing neutrophils and the rate of production by increasing stem cell entry, proliferative events, and maturation events. The net result is that the marrow response dramatically increases the delivery rate of neutrophils to blood. In summary, a complete cycle of consumption, production, and release is activated, with the goal

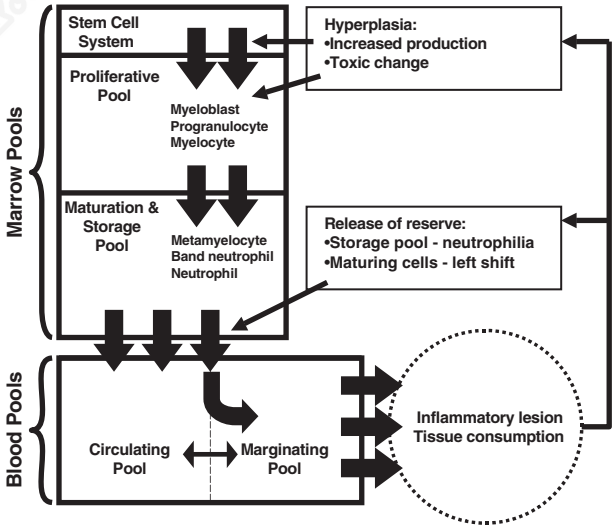

Figure 13.13 Modified neutrophil trafficking model illustrating effects of the inflammatory response on blood and bone marrow. Note the cycle of events leading to increased neutrophil delivery to blood and tissues at the inflammatory site: release of mediators from an inflammatory lesion, increased marrow hyperplasia, increased delivery from marrow to blood, and increased consumption at the site of inflammation.

of delivering a supply of neutrophils to the inflammatory lesion until it resolves.

The pattern of neutrophil concentrations seen in blood may vary from severely decreased to markedly increased. It is helpful to think of the pattern being dependent on a balance between consumption by the lesion and production and release by the marrow (Figure 13.14). This balance may

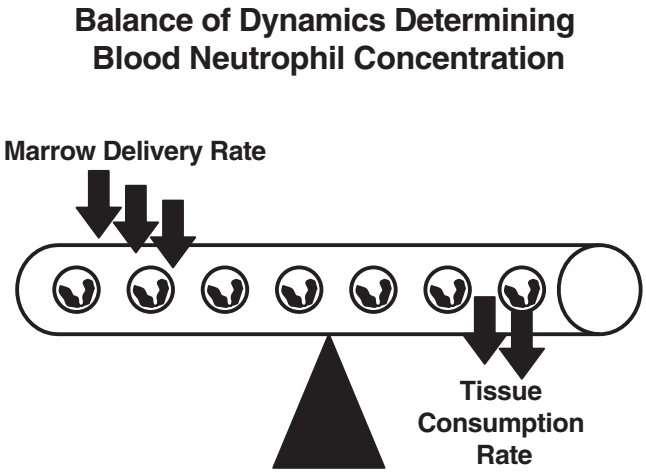

Figure 13.14 Balance between production and consumption. All inflammatory processes may be understood as a balance between marrow delivery and inflammatory-site consumption. When marrow delivery exceeds consumption, blood neutrophilia develops. When tissue consumption exceeds marrow delivery, neutropenia with a left shift develops.

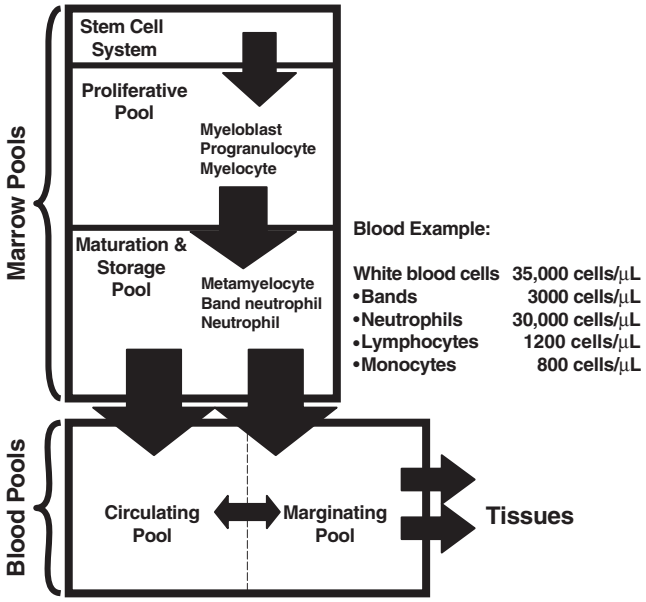

Figure 13.15 Modified neutrophil trafficking model used to illustrate a moderate inflammatory response. Also illustrated is an example of the balance between production and consumption. Note that in this case, marrow delivery exceeds tissue consumption. The example is described as leukocytosis caused by neutrophilia (30,000 cells/μL) and a left shift (3000 bands/μL). The neutrophil pattern is interpreted as inflammation.

explain all neutrophil concentration patterns encountered during inflammation. In small animals, most inflammatory processes result in some degree of neutrophilia, indicating that marrow releases more cells to blood than are consumed at the site of inflammation. This is illustrated using the neutrophil trafficking model in Figure 13.15. Inflammatory patterns manifesting in neutrophilia may be regarded as mild to severe responses that are managing the lesion. The severity of the process may be roughly predicted by the magnitude of the left shift and the presence of toxic change in neutrophils.

Very severe – and typically acute – inflammatory lesions, on the other hand, may consume neutrophils more rapidly than the neutrophils can be delivered to blood. When this occurs, neutropenia develops, as shown in the neutrophil trafficking model in Figure 13.16. In this case, a left shift is expected. At one or more time points, the concentration of bands and other left shift cells may be greater than that of segmented neutrophils.

The balance between neutrophil consumption and delivery by bone marrow is affected by species differences, as outlined in Table 13.1. Species may vary in the amount of neutrophil reserve and in the proliferative capacity of the marrow. Dogs have the largest reserve and the greatest ability to produce neutrophils; cows and other ruminants form the other extreme. Cats and horses are somewhat intermediate in their capacities to deliver cells to blood.

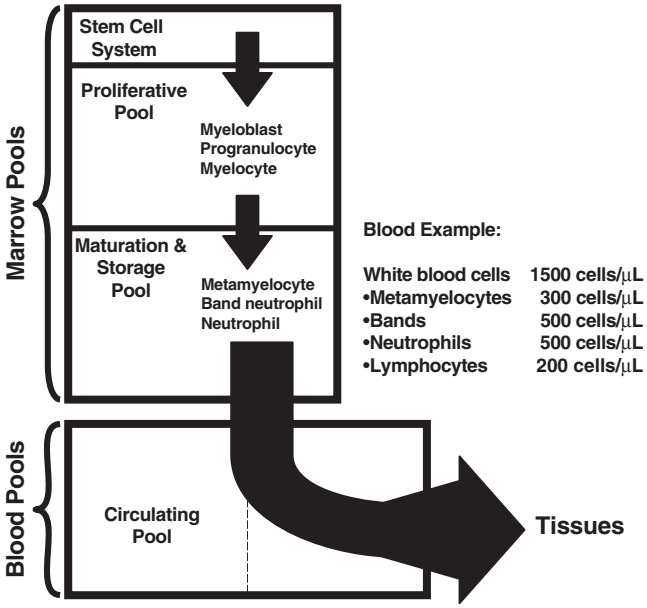

Figure 13.16 Modified neutrophil trafficking model used to illustrate a severe inflammatory response. Also illustrated is an example of the balance between production and consumption. Note that in this case, tissue consumption exceeds marrow delivery. The example is described as leukopenia caused by neutropenia (500 cells/μL) and a left shift (300 metamyelocytes/μL and 500 bands/μL). The neutrophil pattern is interpreted as severe, acute inflammation.

Table 13.1 Comparative bone marrow contribution to neutrophil trafficking and relationship to ranges of neutrophilia seen with the inflammatory response in various species.

Species	Marrow reserve	Regenerative capacity
Dog	Relatively high	Rapid
Cat	Intermediate	Intermediate
Horse	Intermediate	Intermediate
Cow	Relatively low	Slow
	Range of possible neutrophilia (neutrophils/μL)	
Dog	20,000–120,000	
Cat	20,000–60,000	
Horse	15,000–30,000	
Cow	10,000–25,000	
	Interpretation of neutropenia during acute inflammation	
Dog	Very severe lesion	
Cat	Very severe lesion	
Horse	Probable severe lesion	
Cow	Usual findings, regardless of severity	

These differences translate into magnitudes of neutrophilia that can occur with inflammatory disease in each species. They also influence how neutrophil concentrations are interpreted with respect to chronicity and severity of the process in various species. For example, in chronic, closed-cavity inflammatory processes, neutrophilia may go as high as 120,000 cells/μL in dogs, but a corresponding process in cows will result in a maximum of approximately 25,000 cells/μL. Cats and horses will be intermediate, as indicated in Table 13.1.

Similarly, bone marrow behavior influences how neutropenia is interpreted during acute inflammation. Because of the canine ability to deliver cells to blood, neutropenia only occurs with inflammatory states involving severe consumption. Neutropenia caused by inflammation may be regarded as a medical emergency in dogs; to some extent, this is also true in cats and horses. Neutropenia in cows is interpreted differently. Because of the minimal neutrophil reserve in this species, the expected response in the acute bovine inflammatory leukogram is neutropenia. Acute inflammatory lesions in cows consume neutrophils from the blood and marrow within a matter of hours. The result may be profound neutropenia that lasts for a few days. After that time, repopulation of blood with neutrophils, with a left shift, occurs as the marrow production increases.

Factors modulating the magnitude of neutrophilia in the inflammatory response

The type of inflammatory lesion may influence the balance between consumption and marrow release. Acute inflammation is a lesion with increased local blood flow and swelling. This results from inflammatory mediators that promote local vascular dilation. Chemotactic factors released within the lesion in conjunction with the vascular events have ample opportunity to promote consumption of neutrophils. An example is cellulitis associated with a bite wound, which results in a balance between consumption and production that is reasonably well matched. The blood inflammatory pattern then consists of mild to moderate neutrophilia with a variable left shift, depending on the severity of the lesion. Acute peritonitis due to gut rupture is an example of a major consumer of neutrophils that may exceed the marrow capacity for production; in this example, it is possible to see neutropenia with a prominent left shift.

Chronic, walled-off inflammatory lesions, on the other hand, may result in very high neutrophil concentrations. Examples include pyometra in dogs or a chronic, walled-off abscess that does not resolve. These are also known as closed-cavity inflammatory lesions (as opposed to diffuse inflammation; discussed above). These lesions continue to stimulate the marrow to achieve maximal production; however, the rate of consumption is curtailed by the nature of the lesion, thus tipping the balance toward production exceeding

consumption. In these cases, neutrophil concentrations may approach 70,000–120,000 cells/μL in dogs.

Excitement response: epinephrine release

The excitement response is an immediate change associated with epinephrine release and is also known as the "fight-or-flight" response. Epinephrine release results in cardiovascular events that, in turn, result in increased blood flow through the microcirculation, particularly in muscle. Strenuous exercise just before bleeding may have the same effect. This results in a shift of leukocytes from the marginated pool to the circulating pool, as depicted in the neutrophil trafficking model (Figure 13.17). On the leukogram, this manifests as an approximate doubling of leukocytes and is noted in the neutrophils and/or lymphocytes. Within the neutrophil population, no left shift occurs, because mature cells in the microcirculation being flushed to the circulating pool cause the neutrophilia.

The excitement response is recognized most frequently in cats. Lymphocytosis up to a maximum of approximately 20,000 cells/μL is the prominent feature of the feline excitement response. Mature neutrophilia may occur if the resting neutrophil concentration was at the upper end of normal before initiation of the excitement response. In large animals, the excitement response is recognized in association with exercise before bleeding or events that may induce excitement, such as trucking or movement through chutes for blood collection. The excitement response is least common in dogs, because this species is usually accustomed to physical handling related to blood collection.

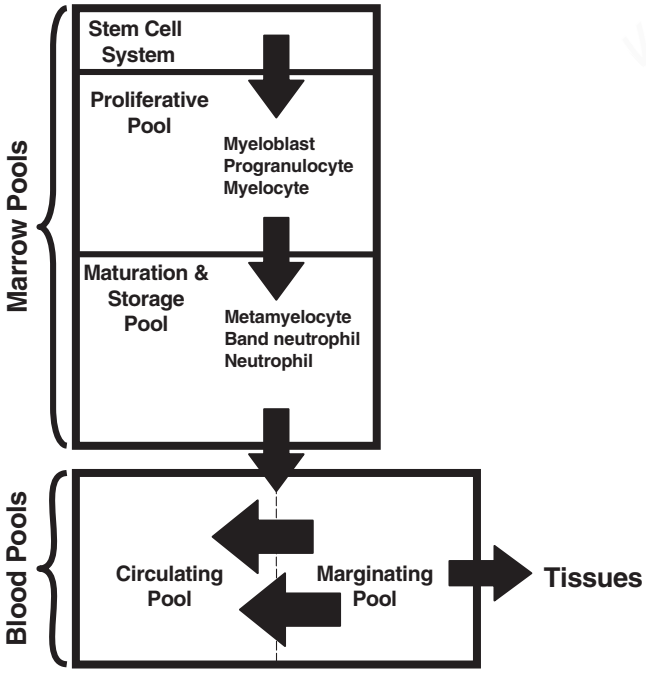

Figure 13.17 Modified neutrophil trafficking model used to illustrate the excitement response. Note that the change involves cell movement from the marginating pool to the circulating pool, resulting in an approximate doubling of resting leukocyte concentrations. Marrow delivery and tissue consumption are unchanged.

Stress response: corticosteroid release or administration

This is likely the most common leukocyte response. Physiologic stress is a body response mediated by release of adrenocorticotropic hormone by the pituitary gland and resultant release of cortisol by the adrenal gland. This occurs in response to major systemic illnesses, metabolic disturbances, and pain. Examples of conditions eliciting the stress response include renal failure, diabetic ketoacidosis, dehydration, inflammatory disease, and pain associated with trauma. The response may be detected in the leukogram by changes in multiple cell types.

The most consistent change is lymphopenia. Steroids may induce lymphocyte apoptosis and may alter patterns of recirculation. The second most consistent change is an approximate doubling of the circulating neutrophils. Steroids cause decreased stickiness and impaired margination, resulting in slightly longer than normal retention in the circulation. As a result, hypersegmentation may be observed. When the resting neutrophil concentration is in the upper 50th percentile of the normal range, neutrophilia is expected. A left shift will not occur unless inflammation is superimposed. Eosinopenia is the next most consistent change. Monocytosis is variable and occurs most consistently in dogs. The importance of interpreting the steroid leukogram is to look for an underlying physiologic disturbance (if it has not yet been recognized) and to avoid interpreting a simple steroid pattern as inflammation. An inflammatory condition may frequently cause a combined inflammatory and steroid response. The inflammatory component will take priority in determination of the magnitude of neutrophilia and any associated left shift. The steroid component may only be recognizable by the concurrent presence of lymphopenia.

Lastly, it is important to note that a steroid response not being present in a very sick animal should prompt the consideration of hypoadrenocorticism (i.e., Addison disease; see Chapter 33).

Summary: approach to neutrophilia

In summary, neutrophilia has three causes. Thus, it is useful to develop an orderly approach to looking at the leukogram to rapidly arrive at the proper interpretation of the neutrophilia. The flowchart in Figure 13.18 develops this approach. When neutrophilia is identified, one should next examine the leukogram for the presence of a left shift. If a left shift is present, the interpretation is inflammation. If a left shift is not present, the lymphocyte concentration should be examined. If lymphopenia is found with a neutrophilia and no left shift, the interpretation is steroid

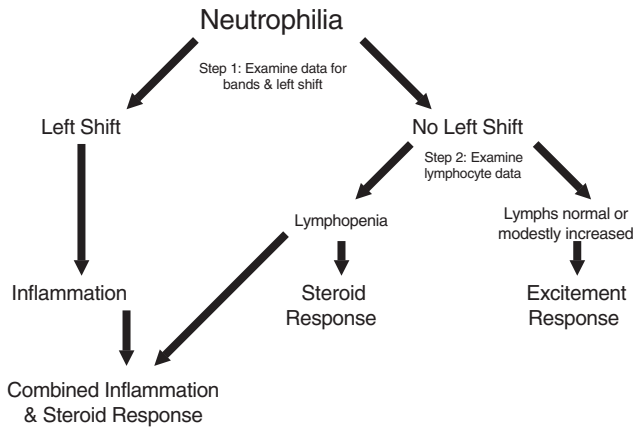

Figure 13.18 Summary flow chart for interpretation of neutrophilias. When neutrophilia is seen, the observer should examine the data for a left shift (step 1). If a left shift is present, then the interpretation is inflammation. If no left shift is present, then the observer should examine the lymphocyte data (step 2). Lymphopenia in conjunction with a mature neutrophilia indicates a steroid response. If the lymphocyte concentration is normal to increased, an excitement response should be considered. Also, note that an inflammatory pattern may have a superimposed steroid response that is recognized as lymphopenia occurring in conjunction with the inflammatory pattern.

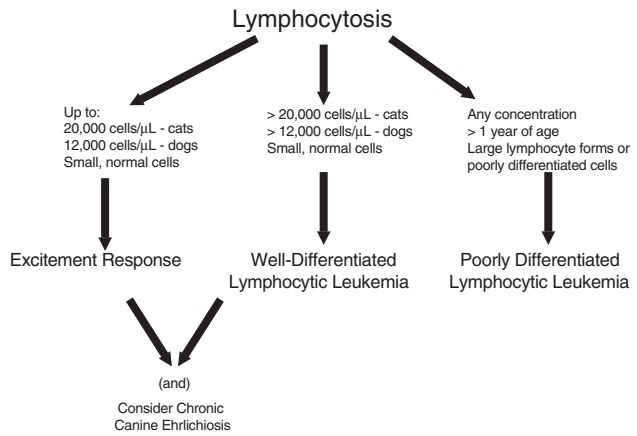

Figure 13.19 Summary approach to interpretation of lymphocytosis. This flow chart may be useful for distinguishing the excitement response from lymphocytic leukemias based on lymphocyte concentration and morphology guidelines. Inflammatory disease is rarely associated with lymphocytosis; however, chronic canine ehrlichiosis is an exception. See text for discussion.

response. If the lymphocyte concentration is upper normal or increased within certain limits, the interpretation of excitement response should be considered. Keep in mind that clear neutrophilia with a left-shift inflammatory pattern may have a superimposed steroid response; this is identified by the presence of lymphopenia in conjunction with the neutrophil inflammatory pattern.

Lymphocytosis

Lymphocytosis has two common causes. The first is the excitement response (discussed above), and the second is lymphocytic leukemia. The approach to interpreting lymphocytosis involves analysis of both cell concentration and cell morphology (Figure 13.19). The lymphocyte morphology should be critically examined when lymphocytosis is present. If the cell concentration is only modestly increased and the cells are morphologically small, normal-appearing lymphocytes, then an excitement response should be considered. As a guideline, this modest increase is suggested to be a lymphocyte concentration of up to approximately 12,000 and 20,000 cells/µL in dogs and cats, respectively. If the concentrations exceed this guideline or the animal was not excited, then a lymphocytic leukemia should be considered. Repeating the hemogram the next day while making note of the possibility of excitement during blood collection also may be helpful. When the lymphocyte concentration is of this magnitude with normal morphology, the confirmation of the diagnosis of leukemia is usually difficult. It involves exclusion and more extensive diagnostics; see Chapter 14. The higher the concentration, the greater the probability that the cause is a lymphoproliferative disorder with leukemia.

A common misconception is that lymphocytosis may occur with chronic inflammatory diseases. This concept likely is extrapolated from the knowledge that inflammatory disease results in an immune system response that includes lymphoid hyperplasia. This process does occur, but the expansion is confined to lymphoid tissues and rarely manifests as lymphocytosis in blood. An exception is the chronic form of canine ehrlichiosis, which has been documented to occasionally result in lymphocytosis and also a possible monoclonal gammopathy. The monoclonal gammopathy is expected to be superimposed on an underlying polyclonal gammopathy. When the lymphocytosis is examined, a high proportion of large granular lymphocytes (see Figure 11.4) may be observed. In dogs, chronic ehrlichiosis should be considered in an endemic region coupled with appropriate clinical signs when there is a lymphocyte concentration up to about 30,000 cells/µL.

Abnormal lymphocyte morphology in conjunction with lymphocytosis makes the diagnosis of leukemia less difficult. Abnormal morphology generally means lymphocyte forms that are normally not found in blood. These cells have one or more features of a cell undergoing proliferation, as opposed to the small, resting lymphocyte that is ordinarily seen in blood (Figure 13.20). These features may include a diameter larger than that of adjacent neutrophils, a fine chromatin pattern resulting in a lighter-staining nucleus, a visible nucleolus, and increased cytoplasm (Figures 13.20 and 13.21). If cells with abnormal features for blood, e.g., prolymphocytes and/or lymphoblasts, are present in the

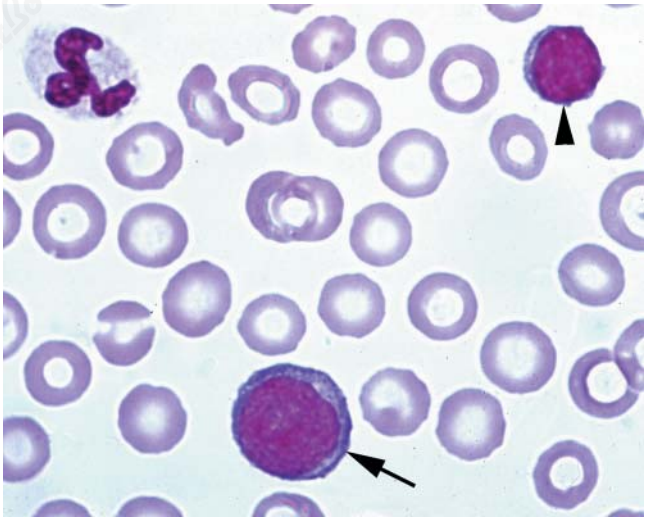

Figure 13.20 Lymphocyte morphology in relationship to evaluation of lymphocytosis. Normal blood lymphocyte morphology consists of small, resting lymphocytes (arrowhead). Note that the diameter is less than that of adjacent neutrophils, the chromatin is condensed, and cytoplasm is scant. An abnormal lymphocyte (arrow) in blood suggests a lymphoproliferative disorder involving blood. Note the increased size, increased cytoplasm, and more fine chromatin pattern. This cell also has a visible nucleolar ring in the nucleus. Wright-Giemsa stain, high magnification.

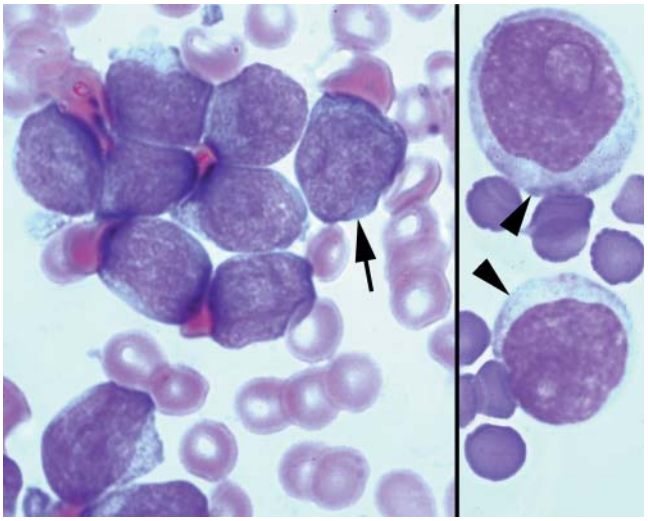

Figure 13.21 The left pane shows large, abnormal lymphocytes (arrow) from a dog with lymphoblastic leukemia (~70,000 lymphocytes/μL). Note the fine, granular chromatin pattern as well as the occasional, faint nucleoli and the large size. The right panel shows two lymphoblasts (arrowheads) from a cat with lymphoblastic leukemia. Note the large cell size, fine chromatin pattern, and prominent nucleolar rings. Wright-Giemsa stain, high magnification.

circulation, leukemia is a diagnostic consideration even with normal to mildly increased lymphocyte concentrations. Molecular diagnostics for lymphoproliferative disorders and lymphocytic leukemia are presented in Chapter 15.

Bovine persistent lymphocytosis may occur in cattle infected with bovine leukemia virus (BLV). Persistent lymphocytosis is defined as a lymphocyte concentration of greater than 7500 cells/μL on two or more hemograms. The morphology may be normal. Persistent lymphocytosis is part of a continuum in BLV-infected cows that eventually may progress to a diagnosis of lymphocytic leukemia or lymphosarcoma. Historically, hemograms, with an emphasis on the lymphocyte concentration, have been used as a screening test for BLV infection.

Neutropenia

Neutropenia resulting from acute inflammatory consumption

Neutropenia resulting from overwhelming consumption by an inflammatory lesion was discussed earlier (with the inflammatory response). Neutropenia resulting from consumption is associated with a left shift. Toxic changes are also expected within a few days of the onset of the process. An alternative form of consumptive neutropenia is immune-mediated neutropenia in which immunoglobulin that recognizes epitope(s) on the neutrophil surface or adsorbed onto the surface results in destruction of both circulating neutrophils and late stages of maturation within the marrow. This may result in profound neutropenia not associated with a demonstrable inflammatory lesion.

Neutropenia resulting from stem cell injuries

The various stem cell injuries may be considered modifications of the neutrophil trafficking model in Figure 13.22. Stem cell injuries have numerous causes, ranging from very acute, transient injury of variable duration to permanent, irreversible injuries. Stem cell injuries are nonspecific in that all cell lines of marrow are involved. Evidence of marrow failure manifested in blood is related to the duration of the injury in relationship to the circulating time or life span of various cell types. Because neutrophils are renewed in blood most rapidly, neutropenia develops first with a stem cell injury. Thrombocytopenia is seen second, because platelets last approximately 7 days in the circulation. Nonregenerative anemia occurs last because of the relatively long erythrocyte life span.

Neutropenia caused by reversible stem cell injuries

Several acute, transient stem cell injuries are caused by the tropism of viruses for rapidly dividing cells. Canine parvovirus and feline panleukopenia are notable examples; these result in injury to intestinal lining, lymphoid cells, and the bone marrow stem cell system. Profound neutropenia is attributable to two mechanisms. First, stem cell injury

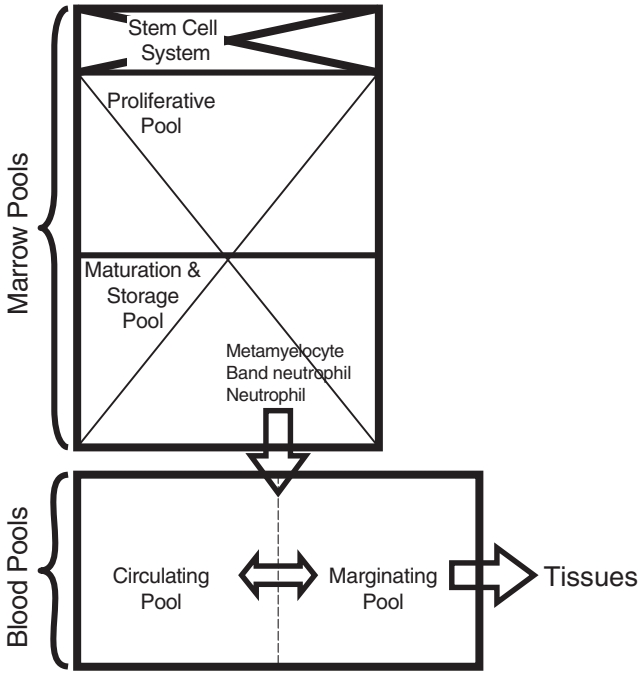

Figure 13.22 Modified neutrophil trafficking model used to illustrate neutropenias caused by stem cell injury. Injury occurs to the stem cell system, which results in a lack of recruited cells to proceed through the proliferative and maturation stages. The end result is interruption in the supply of neutrophils to blood. Because tissue consumption is not interrupted, profound neutropenia in the blood pools may occur within a few days or less.

results in transient failure of production. Second, neutrophil consumption increases at the site of gastrointestinal injury. The stem cell injury involves all marrow cell lines but is so transient that marrow repopulation occurs before thrombocytopenia and nonregenerative anemia can develop. If anemia is observed, it likely is caused by blood loss into the gastrointestinal tract. Acute neutropenia persists for only 24–48 hours. During the short period of neutropenia, a left shift is not observed. As the marrow repopulates, a left shift with progressively increasing neutrophil concentration is observed as recovery progresses. An inflammatory pattern, consisting of neutrophilia and left shift, is usually observed during recovery.

Reversible stem cell injury of varying duration also has numerous causes. These generally are present for days or longer; thus, varying degrees of thrombocytopenia and nonregenerative anemia accompany the neutropenia. One group of causes is chemicals or drugs that injure rapidly dividing cells. Most chemotherapeutic drugs are in this category. Estrogen overdosage and phenylbutazone administration are characterized toxicities in dogs. Very high, repeated doses of estradiol may cause stem cell injury in dogs, but not in cats. Historically, an alternate form of a long-acting, potent estrogen – estradiol cypionate – has been used to prevent unwanted pregnancies in dogs. This drug has been used safely in small doses to treat incontinence. Naturally occurring estrogen toxicity may occur in ferrets if ovulation is not stimulated. Phenylbutazone, a common medication for pain and lameness that is used safely in horses, may cause marked stem cell injury in dogs. An example of an infectious cause is ehrlichiosis in dogs; ehrlichiosis may induce cytopenias, possibly by an immune-mediated mechanism that appears to act on cells in the marrow.

Neutropenia caused by irreversible stem cell injuries

This category of stem cell injury may be regarded as a continuum of proliferative abnormalities of the bone marrow stem cell system. The underlying nature and mechanism of these injuries are poorly understood. Causes include feline leukemia virus, idiopathic hypoproliferative disorders, myelodysplasias, and myeloproliferative disorders. Because these are long-standing disorders, any combination of neutropenia, nonregenerative anemia, and thrombocytopenia may occur. These relatively irreversible stem cell injuries are considered in detail in Chapter 15.

Approach to neutropenia

The approach to interpretation of neutropenia is summarized in Figure 13.23. The observer should first determine if the neutropenia is associated with a left shift. If a prominent left

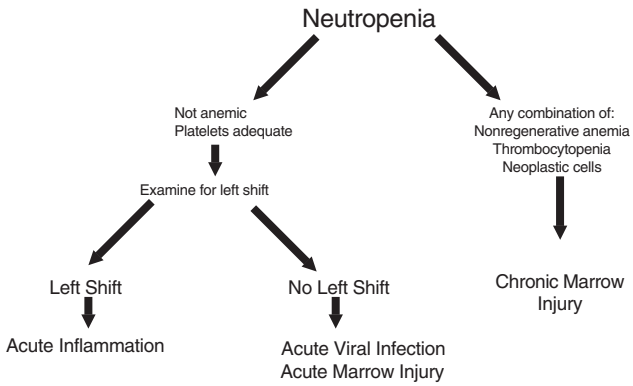

Figure 13.23 Summary approach to interpretation of neutropenia. This flow chart may be useful for distinguishing the various causes of neutropenia. When confronted with neutropenia, the observer should first examine the platelet and erythrocyte data for evidence of production problems. If these cell lines appear to have normal production, then a selective neutropenia is present. The observer should next examine the data for a left shift. If a left shift is found, then the interpretation is severe, acute inflammation (e.g., see Figure 13.16). If no left shift is found, then an acute failure to produce neutrophils should be considered (as in Figure 13.22). If the neutropenia is accompanied by evidence of failure to produce other cell lines (e.g., platelets and/or erythrocytes), then a more chronic marrow injury should be considered. The presence of neoplastic cells may indicate an underlying hematopoietic cell neoplasm and is also a possible cause of marrow failure. See text for discussion.

shift is observed with toxic change, then an inflammatory disease or recovery from viral marrow injury is the cause of the neutropenia. If no left shift is seen, then the other cell lines should be assessed. If any combination of thrombocytopenia, nonregenerative anemia, or evidence of hematopoietic cell neoplasia is found, then marrow injury should be considered.

Lymphopenia

Lymphopenia is usually attributable to a steroid response; other causes are uncommon to rare. Lympholytic acute viral infections induce lymphopenia that is accompanied by neutropenia; however, neutropenia is the more important finding. Combined immunodeficiency syndrome of Arabian foals is an inherited disorder with severe deficiency of both T- and B-cell lymphocyte functions. The lymphocyte concentration may be used as a screening test for this disorder in newborn Arabian foals. A lymphocyte concentration of greater than 1000 cells/μL is a finding that rules out the disease. If lymphopenia is found, more confirmatory tests may be performed.

Monocytosis

Monocytosis is a relatively unimportant change. It may accompany both acute and chronic inflammatory responses. Monocytosis that accompanies an inflammatory response is interpreted as a response to increased demand for mononuclear cells in tissues. Monocytes in blood are regarded as immature cells that become macrophages after migration to tissue sites. Monocytosis also may occur in the steroid response, particularly in dogs.

Eosinophilia

Eosinophilia is interpreted as a nonspecific response that requires consideration of parasitism, hypersensitivity, or an unusual lesion producing eosinophil chemoattractants such as mast cell tumor. Tissue-invading parasitisms are frequently associated with eosinophilia. Notable examples include heartworm disease and hookworm infestation in dogs. Inflammation at epithelial surfaces rich in mast cells (e.g., skin, respiratory tract, gastrointestinal tract) may be associated with eosinophilia, particularly if a component of hypersensitivity is present. Examples include fleabite allergic dermatitis, inhalant allergen disease or asthma-like syndromes, feline hypereosinophilic syndromes, and poorly characterized gastroenteritis that may have an allergic component.

Basophilia

Basophilia is uncommon. In fact, basophils are so rare in normal animals that they usually are not encountered in the 100-cell microscopy differential. The interpretation of basophilia is unknown or not clear. It most frequently accompanies eosinophilia. When this happens, it is described as eosinophilia and basophilia, but it is eosinophilia that is interpreted as indicated earlier.

14 Molecular Diagnostics of Hematologic Malignancies

Emily D. Rout and Anne C. Avery
Department of Microbiology, Immunology, and Pathology, Colorado State University, Fort Collins, CO, USA

Overview

Hematologic malignancies are a broad group of neoplasms arising from bone marrow derived cells. These include tumors derived from lymphocytes (lymphomas, lymphocytic leukemias, and plasma cell tumors) and from myeloid lineage cells (chronic myelogenous leukemia and other myeloproliferative disorders, acute myeloid leukemia, and mast cell tumors). This chapter will focus primarily on lymphoid tumors.

There are more than 15 subtypes of lymphoma and leukemia described in dogs, and they are highly variable in their presentation and outcome. This is because each different subtype of tumor is derived from a normal lymphocyte at a different stage in development with different function and oncogenic potential. For example, canine acute T-cell leukemia is a tumor of an immature T cell developing in the bone marrow or thymus. This disease has a dismal prognosis, even with aggressive chemotherapy. Canine T-zone lymphoma (TZL), on the other hand, is a tumor of mature, activated, or memory T cells and has a very good prognosis.

The goal of the testing described in this chapter is to (i) differentiate neoplastic from reactive lymphocytes and (ii) determine what subtype of lymphoma or leukemia is present to provide prognostic information for owners to help them make decisions about treatment.

Clonality testing

Lymphocytes have unique DNA sequences

The development of cancer is the result of a series of genetic mutations that render a cell resistant to growth controls. The cell divides unchecked, resulting in a tumor mass that is derived from that single original cell, and harboring the mutations – unique DNA sequences – of the original cell. Lymphocytes are further unique in the body in that even normal lymphocytes carry a genetic fingerprint specific to that individual cell. During lymphocyte development, the genes that encode antigen receptors (immunoglobulin for B cells and T-cell receptor for T cells) are assembled at random from a pool of genes. The random nature of this process means that each B and T cell will have a genetically unique antigen receptor. Additionally, nucleotides are trimmed or added at the junctions between genes, further increasing diversity. When these cells divide, as a result of antigenic stimulation or cancer, the daughter cells inherit the antigen receptor genes. The detection of oncogenes and unique lymphocyte genes gives us a very powerful diagnostic tool for detecting malignancy and for making predictions about prognosis and treatment.

Generation of antigen receptors in lymphocytes

To understand how the unique DNA sequences in lymphocytes can be used for diagnostic purposes, it is first important to understand how these sequences are generated. Lymphocytes develop in the bone marrow (B cells) with T cells finalizing their development in the thymus. The job of these cells is to identify the millions of different foreign antigens carried by potential pathogens. To accomplish this, lymphocytes have developed a system to generate enormous diversity in the antigen binding portion of their receptors. The B-cell immunoglobulin receptor for antigen is an antibody that consists of a heavy chain and a light chain, and the T-cell receptor for antigen is called the T-cell receptor, also consisting of two polypeptides (alpha and beta, or gamma and delta). Each of these proteins is a heterodimer with each protein chain encoded by a different gene. The genes encoding these two proteins use the same process for generating diversity, so only antibody heavy chain genes will be discussed.

The antigen binding region of an antibody (the variable region) is generated by bringing together three different genes – V (variable) genes, D (diversity) genes, and J (joining) genes. In the dog, there are 89 variable region genes

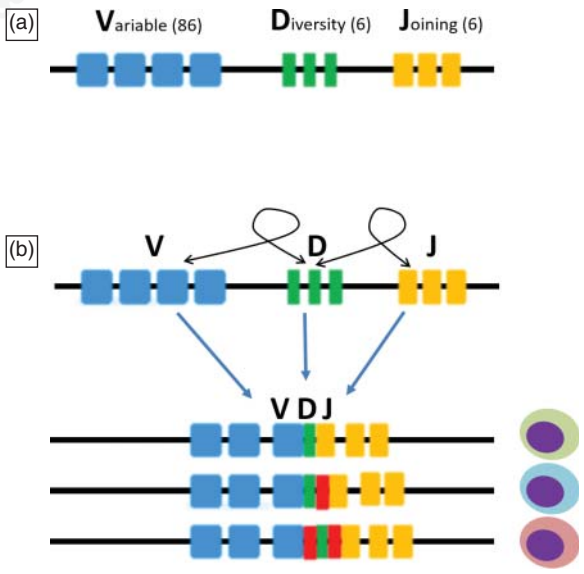

Figure 14.1 Arrangement of immunoglobulin gene segments on canine chromosome 8. (a) There are approximately 89 variable region genes (V, blue), 6 diversity genes (D, green), and 6 joining genes (J, orange). The black line between genes indicates noncoding DNA. This diagram is not to scale. (b) During B-cell development in the bone marrow, DNA between D and J and V and D genes is excised to bring together one V, one D, and one J gene. During this process, varying numbers of nucleotides are added between the genes (red). This process results in different B cells having immunoglobulin gene rearrangements of different lengths. The three VDJ gene rearrangements here would be found in three different B cells.

found on chromosome 8. Each gene is approximately 300 bases long, but the genes are separated by thousands of bases of noncoding DNA. Dogs have 6 D genes, ranging from 12 to 30 bases, and 6 J genes of approximately 50 bases (see http://www.imgt.org). The arrangement of the genes is shown schematically in Figure 14.1.

The arrangement of genes in Figure 14.1a is called the germline configuration. This is the arrangement of genes found in all cells of the body except fully developed B cells. During the development of a B cell, the V, D, and J genes of the antibody heavy chain are brought together so they form one contiguous gene in a process called recombination. Recombination is essentially random, so that any V can be combined with any D and any J. While V region genes have similar sequences, they are not identical. The same is true for D and J genes – they are similar to one another but not identical.

This random recombination alone creates a tremendous number of different genes, but in addition, nucleotides can be added between segments during the process, or trimmed from the ends of V, D, and J genes (Figure 14.1b). The process is again random. Thus, any given B cell will have not only a unique concatenation of V, D, and J genes, but within this new rearrangement will be further diversity as a result of nucleotides being added and trimmed. The result is that virtually every newly developed B cell will carry a unique DNA sequence. The length of the new VDJ gene rearrangement will also be different because of the addition and trimming of nucleotides. The same is true for T cells, because the T-cell receptor beta and delta gene loci are also composed of multiple V, D, and J genes. The antibody light chain genes and T-cell receptor alpha and gamma genes all undergo a similar process, with the exception that none of these gene rearrangements contain a D [1] gene.

Clonal versus polyclonal lymphocyte expansion

When mature lymphocytes with their unique antigen receptors encounter an antigen recognized by those receptors, they are stimulated to divide. The progeny cells contain the same antigen receptor gene rearrangement. Similarly, if a lymphocyte becomes neoplastic at some time during its development and divides unchecked, all of the progeny cells of this cancer will have the same antigen receptor gene rearrangement.

The response to a pathogen will involve hundreds to thousands of molecularly different B and T cells. This is because even the simplest pathogen is composed of multiple proteins, which can be recognized by the antigen receptors of many different lymphocytes. Even a single protein has many different antigenic structures and can stimulate the division of multiple lymphocytes. This response would be called polyclonal. Cancer, on the other hand, is characterized by the unrestricted division of a single cell, called clonal proliferation. Thus, a population of lymphocytes that are all the progeny of a single clone is most likely cancer, and a population of lymphocytes that have multiple different types of cells (called polyclonal) is most likely reactive.

The ability to distinguish a clonal from a polyclonal population of lymphocytes has many diagnostic applications. For example, a dog with dental disease presents to his veterinarian because his mandibular lymph nodes are enlarged. The enlarged lymph nodes can be due to antigenic stimulation by a heavy burden of oral pathogens. Other clinical factors, however, may raise concern for lymphoma – these can include age, breed, and cytologically suspicious cells. To distinguish a purely reactive process from a neoplastic one, it is possible to determine if the lymphocytes are mainly derived from a single clone (neoplastic) or multiple lymphocytes. The assay used to make this distinction is called a clonality assay and can also be called PARR (PCR for antigen receptor rearrangements) [2].

Molecular biology of the PARR assay

The PARR assay measures the size of all of the gene rearrangements in a collection of lymphocytes. If all of the lymphocytes have the same-sized gene rearrangement, the lymphocytes are considered clonal (Figure 14.2). If, however, there are multiple-sized gene rearrangements, then the population is polyclonal. To accomplish this, DNA is

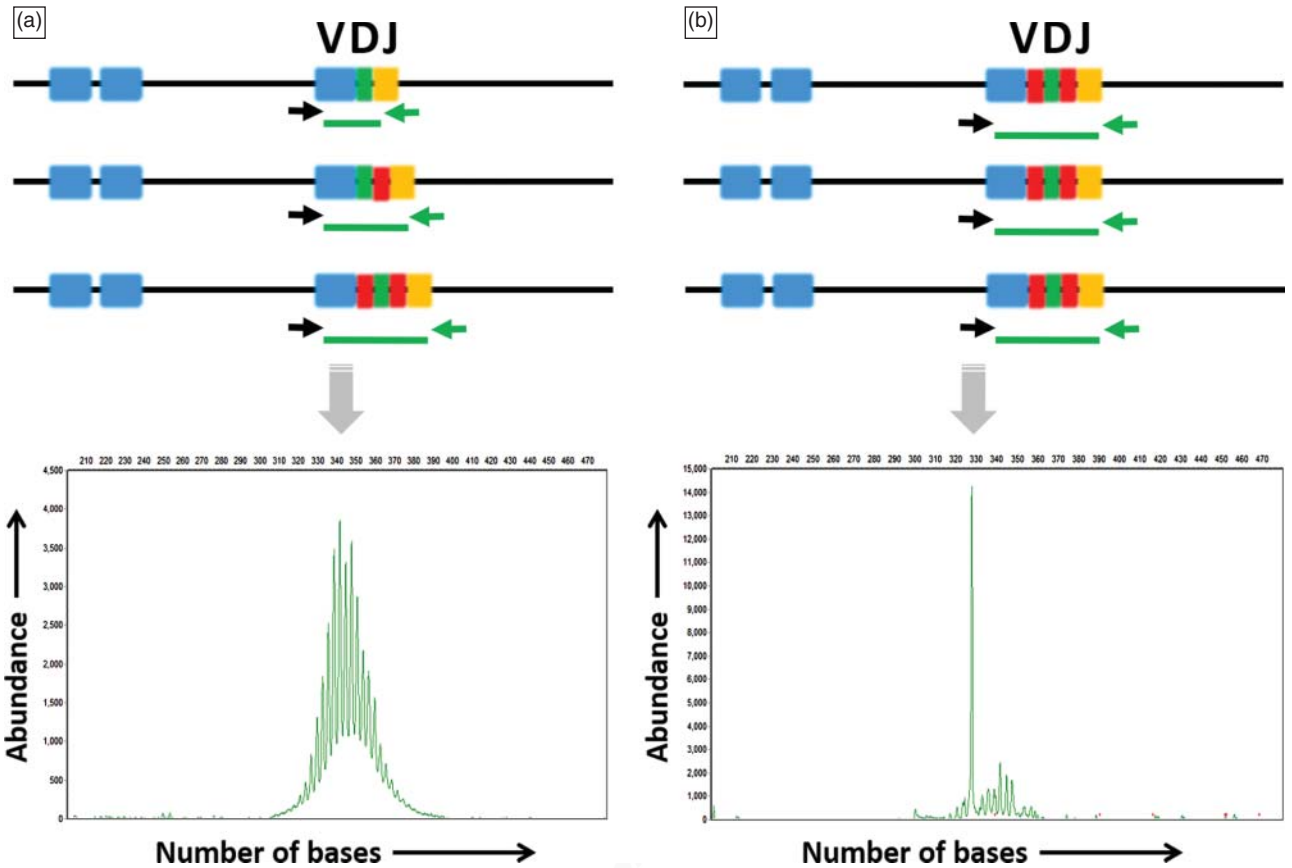

Figure 14.2 Placement of PCR primers and separation of PCR products by size. PCR primers (indicated by the arrows) placed as shown will amplify the VDJ gene rearrangement. One primer is conjugated to a fluorescent molecule (green). (a) Multiple-sized PCR products will be amplified when DNA is extracted from normal lymphocytes. The bottom histogram depicts separation of PCR products by size. (b) A single-sized PCR product is observed when the majority of DNA is derived from neoplastic lymphocytes, all of which are derived from the same original clone and carry the same-sized immunoglobulin gene rearrangement.

extracted from the lymphocytes in question – for example in the case above, a dog with enlarged mandibular nodes and dental disease, lymphocytes would be collected by aspiration from the mandibular node. Polymerase chain reaction (PCR) primers that will amplify the entire VDJ rearrangement will be added as shown in Figure 14.2.

The resultant DNA products are separated by size using any one of a variety of methods. A dominant single-sized product indicates that the population of cells was derived from a single clone. On the other hand, the presence of products of multiple sizes indicates that a heterogeneous population of lymphocytes is present, and the process is most likely reactive. Figure 14.2 shows the results of the PARR assay analyzed by capillary gel electrophoresis to demonstrate what each of these two results would look like. In practice, only 1–10% of the cells in any given sample need to be neoplastic for the result to be interpreted as clonal. This is because the remaining non-neoplastic cells are so heterogeneous that the PCR products from these varied cells are outcompeted by homogeneous product from the neoplastic cells. This idea is not necessarily intuitive but has been demonstrated experimentally.

Interpretation and uses of the PARR assay

The PARR assay is used when there is suspicion of lymphoma by cytology or histology but not a definitive diagnosis. Some common reasons for carrying out the assay are enlarged lymph nodes where the cytology or histology cannot definitively conclude that lymphoma is present, pleural or peritoneal fluid characterized by occasional suspicious-looking cells, and the presence of atypical-appearing lymphocytes on a peripheral blood film.

In most cases, the assay is performed by using multiple sets of PCR primers – some of which detect immunoglobulin gene rearrangements, and some of which detect T-cell receptor gene rearrangements. B-cell lymphomas will be characterized by single-sized PCR products when the immunoglobulin primers are used, but multiple products or no products at all when T-cell receptor primers are used. T-cell lymphomas, conversely, will be characterized by single-sized products

when T-cell receptor primers are used and multiple or no products when immunoglobulin primers are used. Thus, the nature of the clonal PCR product is a clue to the lineage of the neoplasm. As with any assay, there are exceptions to this rule, but for most cases, the clonally rearranged gene reflects the lineage of the tumor. Plasma cell tumors and multiple myeloma are B-cell-origin tumors and will have clonally rearranged immunoglobulin genes.

Not all cases of lymphoma and leukemia can be detected by PARR. This is because there are likely to be V and J region genes whose sequences differ enough from the PCR primers that the primers will not bind. If the patient's tumor uses one of these V or J genes, then no amplification of tumor DNA will be seen. Therefore, as with many tests, the PARR assay cannot be used to rule out neoplasia, only to support a positive diagnosis.

Detection of genetic alterations in cancer cells

Principles

Almost all human cancers can be characterized by an array of genetic aberrations. These include chromosomal translocations, which bring two genes together that normally exist on different chromosomes, duplications or deletions of a part or a whole chromosome, and mutations within individual genes. Detection of such genetic changes is common practice in human oncology and is used for making an initial diagnosis as well as identifying clinically relevant subtypes of disease – subtypes that will be more or less aggressive or that will respond to specific targeted therapies.

Routine genetic testing in veterinary medicine is uncommon but likely to increase significantly in the next few years because of the enormous amount of genetic information available from high-throughput sequencing studies of veterinary cancers. Currently, there are commercially available tests for individual mutations in canine mast cell tumors and transitional cell carcinomas.

Testing for the *CKIT* mutation in mast cell tumors

Approximately 20% of canine mast cell tumors harbor a mutation in a gene called *CKIT* [3]. *CKIT* is the tyrosine kinase receptor for the growth factor called stem cell factor. The mutations result in the *CKIT* gene being permanently phosphorylated, resulting in a constitutive "on" signal. This means that the cells are continuously being stimulated to divide.

The most common mutations in this gene are called internal tandem duplications, in which a small segment of the gene is duplicated, such that a given sequence is repeated in tandem. One of these mutations is found in exon 11, where a variable-length segment is duplicated, creating a slightly larger version of the gene [4]. The mutation is readily detectable by PCR amplification of exon 11, since it will result in a larger product. Figure 14.3 shows the placement of PCR primers and what the product will look like.

Detection of an internal tandem duplication in mast cell tumors can provide objective prognostic information. High-grade mast cell tumors, a designation determined by the histologic appearance of the tumor, tend to be more aggressive and require more intensive therapy. Low-grade mast cell tumors may be cured by surgical excision alone. Many mast cell tumors, however, fall in the gray area

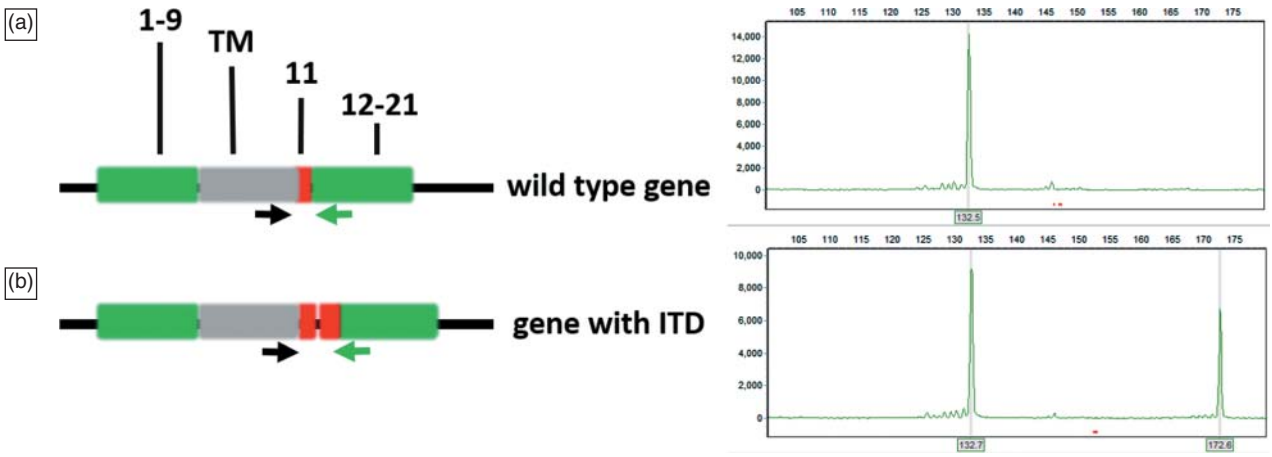

Figure 14.3 PCR amplification of c-kit exon 11. (a) The *CKIT* gene consists of 21 exons, which are indicated by numbers. Exons 11–21 are intracellular, TM = transmembrane (exon 10). PCR amplification with primers surrounding exon 11, indicated by the arrows, results in a single product shown in the histogram on the right. This is the wild-type form of the gene. (b) The *CKIT* gene with an internal tandem duplication (ITD) of exon 11 (red) is amplified with the same primer set. The ITD results in a larger-size PCR product shown in the histogram on the right. Both the smaller, wild-type product and the larger one are present because only one copy of the gene is mutated. In addition, there is invariably normal tissue in any mast cell tumor sample.

between low- and high-grade histologically, and the histologic assessment of the degree of aggressiveness of these tumors may differ between pathologists. Detection of *CKIT* mutation may help shift the designation of a tumor being more likely high grade, with a less positive prognosis. There is also conflicting data about the use of this mutation to guide the choice of chemotherapy [5].

CKIT mutations are relatively straightforward to detect because the mutation changes the size of the PCR product. Some cancers will have predictable, single-base mutations that do not change the size of the PCR product. Standard sequencing can detect such mutations, but sequencing is generally too labor-intensive and insensitive for clinical purposes. An example of this type of mutation is the *BRAF* mutation – this is found in 80% of cases of canine transitional cell carcinoma. The single nucleotide change found in the canine gene is equivalent to a *BRAF* mutation common in a variety of human cancers and causes constitutive activation of the BRAF protein. BRAF is a serine/threonine kinase that activates a series of downstream signaling pathways to drive cellular metabolism and proliferation. Detection of the *BRAF* mutation relies on a technique called droplet digital PCR [6], which is a sensitive method for detecting such changes. The *BRAF* mutation is unusual, however, in that it is the same in all tumors. Most mutations affecting oncogenes will not be found in exactly the same site but would be seen in a variety of locations within the gene. As noted below, these kinds of mutations will be best detected using high-throughput or next-gen sequencing methods.

High-throughput sequencing in diagnostics

The PCR methods described above for detection of clonally rearranged antigen receptor genes and mutation analysis will almost certainly be replaced by high-throughput or next-gen sequencing techniques in the coming years. These are techniques that will allow for sequencing of multiple genes (including entire genomes) simultaneously. Oncology research increasingly focuses on mutational "landscapes" in tumors, which involve cataloging an array (tens to hundreds) of individual mutations to characterize individual neoplasms. The technology is readily available, but a great deal of additional research on the effects of individual mutations in hematopoietic and other forms of cancer is necessary before such testing is appropriate.

Flow cytometry

In the context of hematologic malignancy, flow cytometry is used to identify proteins on the surface of lymphocytes, although the technology has a large variety of other uses. As discussed above, lymphoma and leukemia are the result of unchecked expansion of a single cell. The progeny cells resemble the original cancerous clone. Therefore, another way to determine if a population of lymphocytes is neoplastic would be to show they are all the same phenotype – all B cells, CD4 T cells, or CD8 T cells. This is not equivalent to showing that the cells are all derived from the same clone, but in practical terms, homogeneous expansion of a single lymphocyte subset is usually neoplastic, because reactive processes will result in the expansion of many different lymphocyte subtypes. Thus, if the lymphocytes in a mandibular lymph node aspirate consist of 98% B cells, the process in that node is almost certainly neoplastic. If the lymph node aspirate, however, consists of 30% B cells, 50% CD4 T cells, and 20% CD8 T cells, this finding is more consistent with a reactive process – response to infection or autoimmune disease or response to a metastatic tumor of nonlymphoid origin. In addition to evaluating the proportions of different lymphocyte subsets, flow cytometry can detect aberrancies of lymphocyte populations, including a lymphocyte population composed of atypically large-sized lymphocytes or a population that has aberrant protein expression on the cell surface.

Cell surface antigens

Most proteins found on the surface of hematopoietic cells are identified by a number, preceded by the letters "CD" (CD stands for "cluster of differentiation," a term that partly reflects the fact that different proteins are expressed at different points in the life of a cell). CD3, CD4, CD5, and CD8 are all proteins found on the surface of T cells and were among the earliest identified. CD21 and CD22 are proteins found on B cells but not on T cells. Monoclonal antibodies specific for virtually all CD antigens are available for both people and mice, and a significant repertoire is also available for dogs, horses, cattle, and sheep. There are fewer antibodies for cats. These antibodies are generally (but not always) species specific – an antibody to canine CD4 will not recognize feline CD4, and vice versa.

To determine how many CD4 T cells, CD8 T cells, and B cells there are in any given collection of lymphocytes, commercially available monoclonal antibodies are incubated with the cells in question (e.g., cells from a lymph node aspirate). The antibodies are conjugated to fluorescent molecules that come in a large array of different colors. Thus, if the antibody to CD4 is conjugated to a red molecule, cells that have red fluorescence are CD4+ T cells. If the antibody to CD8 is conjugated to a green molecule, cells that have green fluorescence are CD8+ T cells. A flow cytometer is used to count the number of cells bearing different fluorescent molecules, and the process of enumerating cells of different subtypes is called *immunophenotyping*.

Principles of flow cytometry

Flow cytometry is the analysis of cells and particles in liquid suspension. Flow cytometers are equipped with one or more lasers, which emit light of a single wavelength. The suspension to be analyzed is focused into a narrow stream that passes in front of the laser one particle or cell at a time. When a cell passes through the beam, several aspects of the interaction between the cell and the light are recorded by detectors. First, the cell scatters light in several ways. The *forward light scatter* is an estimate of the size of the cells – large cells produce greater forward light scatter. The complexity of a cell's cytoplasm is indicated by the *side scatter*. Cells such as eosinophils and neutrophils, with granules in their cytoplasm, have high side scatter, whereas lymphocytes, which have little cytoplasm, have low side scatter (Figure 14.4a).

The other important parameter detected by the flow cytometer is the amount and color of the fluorescent molecules bound to the cell. That characteristic is determined by which, if any, monoclonal antibodies specific for CD antigens have bound. The laser light is a single wavelength of light, which excites the fluorescent dye. That dye then emits light of a narrow spectrum – what our eyes would see as green, red, blue, etc. A detector records the amount of fluorescence for each cell that passes in front of the laser and stores it together with forward and side-scatter information. The amount of fluorescence is proportional to the number of antibody molecules on the cell, which is proportional to the number of CD proteins recognized by that antibody. This principle is illustrated in Figure 14.4b.

Clinical applications of flow cytometry

Flow cytometry is most useful for determining if an expanded population of lymphocytes is neoplastic (homogeneous) or reactive (heterogeneous). Flow cytometry can identify the lineage of a neoplasm, and it can also provide prognostic information in some cases. An example is shown in Figure 14.5. These are two cases of T-cell lymphoma. Figure 14.5a shows a flow cytometry study of a lymph node from a dog with a T-cell neoplasm called T-zone lymphoma (TZL). Figure 14.5b shows flow cytometry of a lymph node from a dog with a different form of T-cell lymphoma called peripheral T-cell lymphoma (PTCL). While both dogs have T-cell lymphoma, they are two entirely different forms of T-cell lymphoma with different antigenic characteristics. They also have vastly different outcomes.

TZL is an indolent disease, sometimes not requiring treatment. It is characterized by T cells that do not express the pan-leukocyte antigen CD45 and that express high levels of class II MHC. PTCL, on the other hand, is an aggressive disease with a poor outcome. Most dogs require multiagent chemotherapy and have a median survival of 5 months. PTCL is characterized by T cells that do express CD45 but do not express class II MHC. Flow cytometry is a noninvasive way of distinguishing these two types of T-cell lymphoma and providing prognostic information for veterinarians and owners [7].

Immunocytochemistry

There are some circumstances where flow cytometry is not possible, or where the antigens to be assessed are not on the surface of the cell. In these cases, immunocytochemistry (ICC) can be used to evaluate antigen expression. The equivalent technique in formalin-fixed biopsy tissue is called immunohistochemistry.

Like flow cytometry, ICC uses antibodies specific for different antigens to determine the nature of the cells of interest.

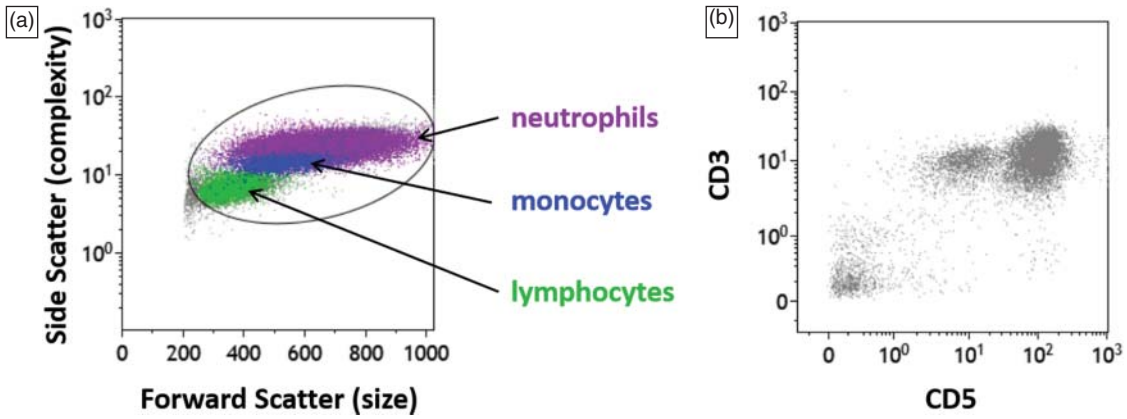

Figure 14.4 Flow cytometry of canine peripheral blood. (a) Light scatter properties of canine peripheral blood. Each dot represents a cell, and each cell is plotted along the *x* and *y* axes based on their forward and side light scatter properties. Light scatter values do not have units. In this example, forward scatter is a linear scale and side scatter a log scale. Side scatter is also often depicted on a linear scale. (b) Expression of two T-cell proteins on the surface of lymphocytes, CD3 and CD5. This histogram shows that the majority of cells express both proteins, but a subset of cells express lower levels of CD5. This illustrates how flow cytometry can be used to determine the relative abundance of proteins on the surface of cells.

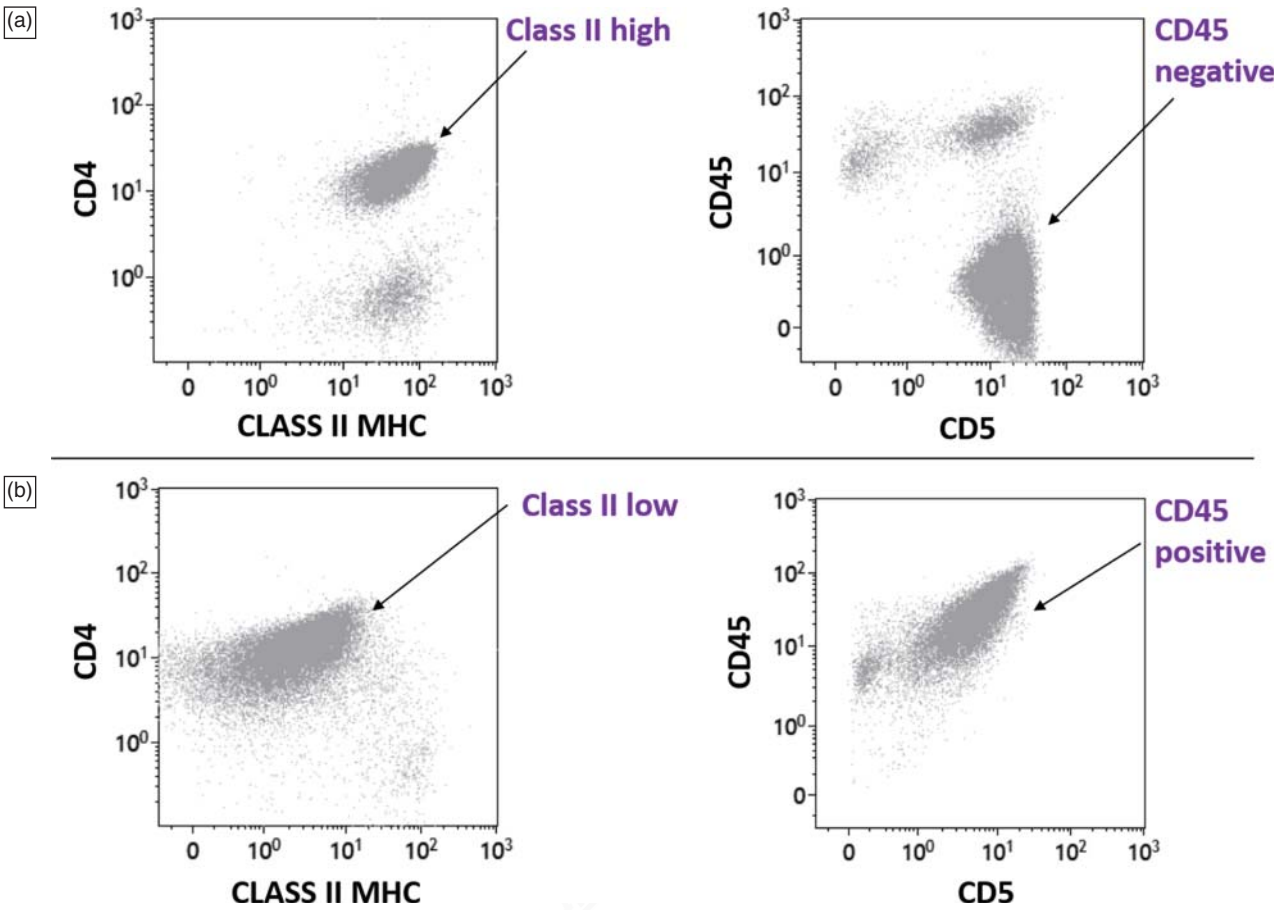

Figure 14.5 Two different types of T-cell lymphoma with different outcomes. This figure shows the expression of two proteins that are found on all normal peripheral canine lymphocytes (CD45 and class II MHC), and two proteins found on normal canine T cells (CD4 on a subset of T cells and CD5 on all T cells). (a) A T-zone lymphoma that expresses the T-cell antigen CD4 and high levels of class II MHC (left) but does not express CD45 (right). (b) A peripheral T-cell lymphoma that expresses the T-cell antigen CD4 and low levels of class II MHC (left) but expresses normal levels of CD45 (right).

However, ICC differs from flow cytometry in a number of ways: (i) the results are usually visualized with an enzymatic reaction that causes a color change that can be seen under the microscope when an antibody binds to a cell, rather than by fluorescence; (ii) ICC is performed on cytology slide preparations from bone marrow, blood, and tissues and does not require fresh, viable cells; (iii) the process of staining cells for ICC results in permeabilization of the cells so that antibodies can bind to antigens found in the cytoplasm or nucleus; and (iv) with typical methods, only one antigen can be detected at a time, which is a significant limitation of the technique, though methods have been developed that are capable of detecting multiple antigens at once.

An example illustrating the utility of ICC is shown in Figure 14.6. A dog with significant leukocytosis was examined by cytology and determined to have a lymphoid neoplasm with an uncertain lineage. A new sample was submitted for flow cytometry, but the flow cytometry assay found that the cells did not express proteins typically found on B cells or T cells, leaving a question as to their origin. They could be highly aberrant neoplastic B or T cells, which have lost expression of normal cell surface proteins, or a different cell type such as plasma cell. In this case, ICC of a blood smear revealed that the cells express the protein MUM1 (also called IRF4), which is most commonly seen in plasma cells or B cells differentiating toward plasma cells. Because this antigen is located in the nucleus, it cannot be detected by conventional flow cytometry techniques but is readily detectable by ICC.

Flow cytometry is by far preferable to ICC in most circumstances, because the ability to identify and quantify the expression of many antigens simultaneously means that a tumor can be subclassified into prognostically important groups. Typically, ICC only evaluates a small number of proteins, and while it can be used to determine if a tumor is T or B cell in origin, it cannot be used to subtype them. The two diseases shown in Figure 14.5, for example, cannot be distinguished by ICC.

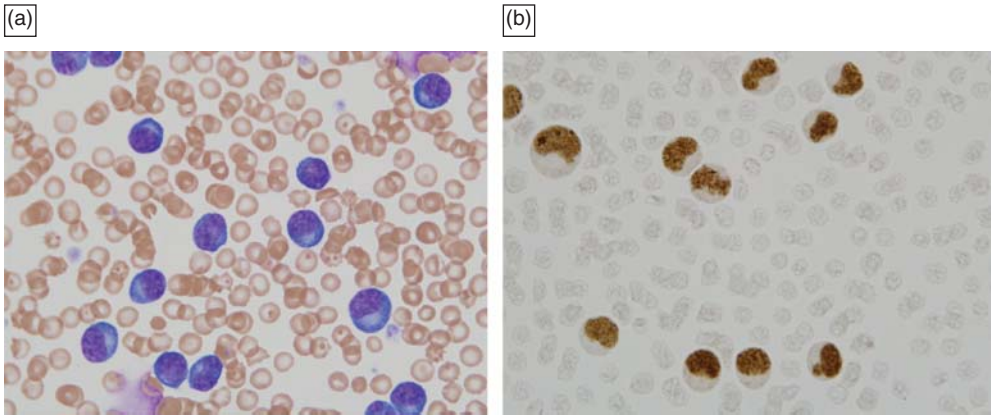

Figure 14.6 Peripheral blood from a dog with leukemia and circulating neoplastic cells of undetermined origin. Flow cytometry of the peripheral blood showed that the cells did not express any cell-surface, lineage-specific antigens (CD3, CD5, CD4, CD8, CD21). (a) Wright-Giemsa stain of the peripheral blood smear. (b) Immunocytochemistry showing MUM1/IRF4 staining with nuclear localization, indicating that these cells are most likely plasma cells.

Summary

Molecular diagnostic techniques such as clonality, detection of oncogenes, and flow cytometry can be used to diagnose lymphoma and leukemia. Many of these assays are widely available and now used routinely. They can provide objective confirmation of diagnoses made by cytology and histology and can help clarify an equivocal diagnosis made by more subjective methods. It is likely that a great many more molecular diagnostic assays will become available within a few years because rapid sequencing technologies allow for much more efficient identification of oncogenes and other genetic alterations in cancer.

Case Example 14.1. Homogeneous lymphocyte expansion

A 13-year-old female Chihuahua presents for a routine dentistry. Presurgical blood work showed that her lymphocyte count was 10,235 cells/μL, but all her other complete blood count (CBC) and biochemical data were normal. Her physical exam did not detect enlarged lymph nodes. No other imaging was performed. The lymphocytes were described as small and mature. Differentials for lymphocytosis of mature-appearing cells in dogs include lymphoproliferative disease, thymoma, Addison's disease, and chronic infection (particularly *Ehrlichia canis* infection).

Flow cytometry is a good diagnostic test in this case, because it will tell you the phenotype of the lymphocytes and may provide prognostic information. The results showed that 75% of the cells in the blood were B cells, resulting in a B-cell count of 7723 cells/μL (normal for this reference lab is <724 cells/μL) (Figure 14.7). T-cell counts were within normal range. This homogeneous expansion of small B cells is most consistent with B-cell chronic lymphocytic leukemia, which is common in older, small-breed dogs [8]. This disease often has an indolent clinical course.

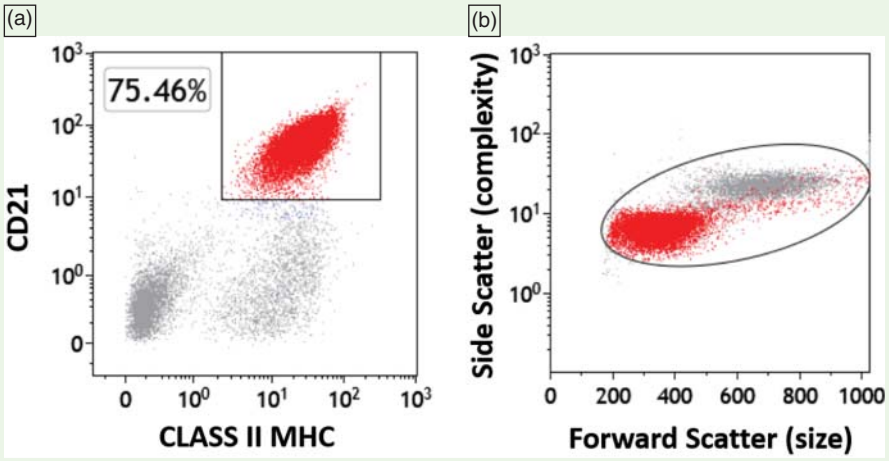

Figure 14.7 Flow cytometry of peripheral blood from a patient with B-cell chronic lymphocytic leukemia. (a) B cells are identified by expression of CD21 and class II MHC. The gate drawn around these cells indicates that 75.46% of all the cells in the blood are B cells. (b) In this plot, the B cells identified in (a) are colored red so that their light scatter properties can be visualized. The B cells are small lymphocytes, as can be seen by comparison with the neutrophils (gray cells).

Case Example 14.2. Heterogeneous lymphocyte expansion

A dog presents as above (same signalment and blood work). In this case, however, the results show that there are 2000 B cells/μL (normal high 724 cells/μL), 4000 CD4 T cells/μL (normal high 2063 cells/μL), and 4000 CD8 T cells/μL (normal high 968 cells/μL). In this case, there is a heterogeneous expansion of all lymphocyte subsets. Although this finding doesn't rule out leukemia, it is more consistent with a reactive or physiologic process. Given the normal biochemical data, atypical Addison's disease involving only glucocorticoid deficiency would be one possibility. Thymomas typically involve expansion of T-cell subsets but not B cells, so this would be lower on the differential list. Chronic infection, including chronic *E. canis*, would also be a consideration.

To further investigate the possibility that one of the three lymphocyte subsets was neoplastic, the PARR assay was performed (Figure 14.8). Amplification of the immunoglobulin and T-cell receptor gene rearrangements indicates that there are polyclonal, not monoclonal, B- and T-cell populations in this dog's blood. This finding indicates that this is most likely a reactive or physiologic process, consistent with the flow cytometry results.

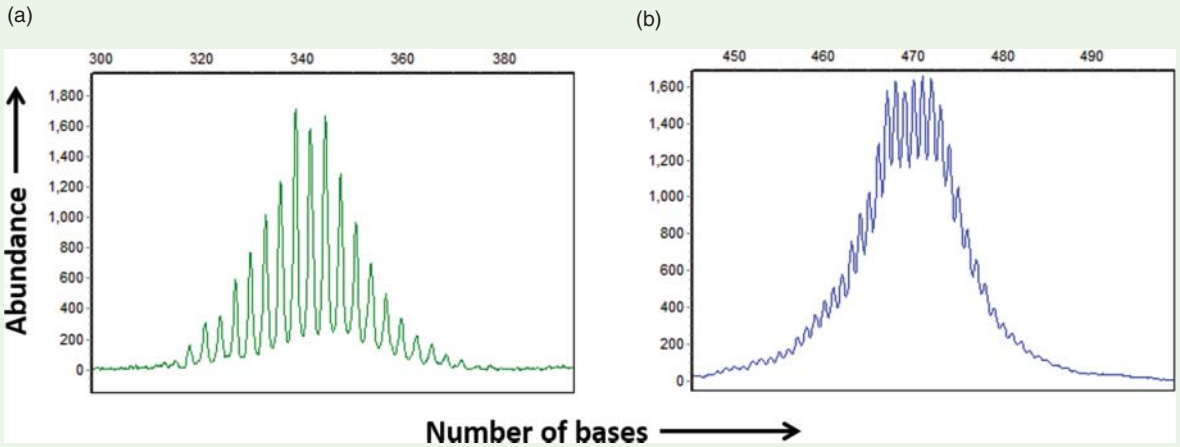

Figure 14.8 PCR for antigen receptor rearrangements showing that the B and T cells in the peripheral blood of a dog with a heterogeneous lymphocyte expansion are polyclonal, exhibiting multiple different-sized PCR products. (a) PCR products detected when DNA from the peripheral blood is amplified by primers specific for immunoglobulin heavy chain V and J genes. (b) PCR products detected when DNA from the peripheral blood is amplified by primers specific for the T-cell receptor gamma V and J genes.

Case Example 14.3. Cells with an abnormal phenotype

An 11-year-old golden retriever presents with adult-onset demodex and a lymphocyte count that is just outside the normal range (5500 lymphocytes/μL). The remainder of the blood work is normal. Mandibular lymph nodes palpate larger than normal and firm. Flow cytometry of a lymph node aspirate is shown in Figure 14.9.

The results indicate that there is a population of T cells with an aberrant phenotype – the cells do not express the pan-leukocyte antigen CD45, which is found on all normal cells in a lymph node. The presence of a marked expansion of aberrant lymphocytes is diagnostic for neoplasia. Furthermore, the specific type of neoplasm can be determined because loss of CD45 expression is the hallmark of TZL. This indolent disease is common in golden retrievers and in most cases progresses slowly [9].

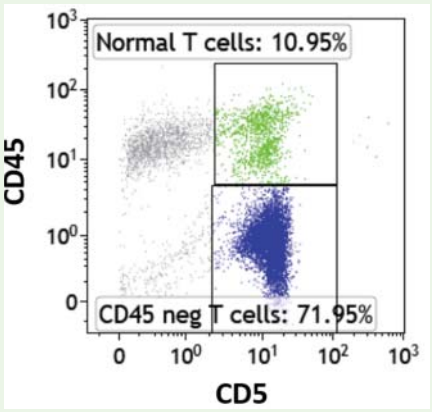

Figure 14.9 Flow cytometry of a lymph node from a dog with T-zone lymphoma. Normal T cells express CD45 but only comprise 11% of this lymph node. The majority of cells are T cells (CD5+) that do not express CD45. This abnormal phenotype can be considered diagnostic for T-zone lymphoma.

15 Laboratory Evaluation of Bone Marrow

Mary Anna Thrall[1] and Glade Weiser[2]
[1]Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis
[2]Loveland, CO, USA

Cytologic evaluation of a bone marrow aspiration biopsy specimen is helpful in animals with unexplained hematologic abnormalities when a diagnosis cannot be established based on examination of the blood. Examples of such abnormalities include nonregenerative anemia, neutropenia, thrombocytopenia, gammopathy, and suspicion of neoplastic marrow disease (e.g., lymphoma). In horses, bone marrow aspirates are useful to determine if anemias are regenerative, because equine species do not release immature erythrocytes into the blood. Contraindications to bone marrow aspiration are few, but marrow aspirates from the ribs or sternum of horses with clotting disorders have resulted in death because of hemothorax or cardiac tamponade. Hemorrhage usually can be prevented in thrombocytopenic animals by applying pressure to the aspiration site for several minutes. Bone marrow aspiration technique is discussed in Chapter 2.

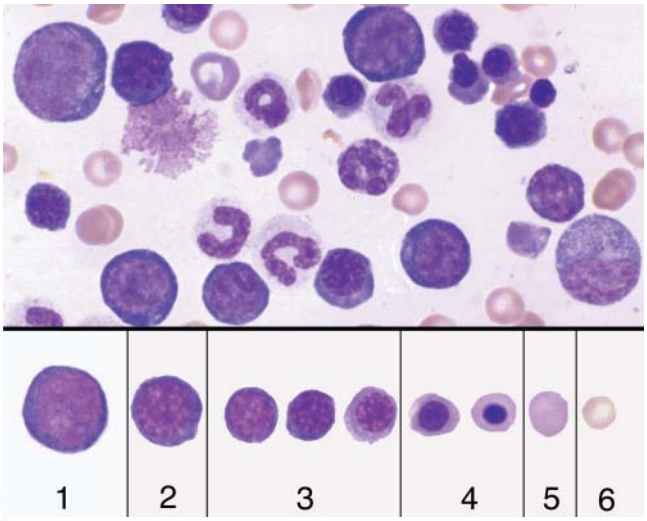

Figure 15.1 Top. Bone marrow aspirate from a dog showing numerous erythroid precursors with round nuclei, coarse chromatin, and blue- to hemoglobin-colored cytoplasm. Bottom. Maturation stages of erythroid precursors, from immature to mature. 1, rubriblast; 2, prorubricyte; 3, rubricytes; 4, metarubricytes; 5, polychromatophilic erythrocyte; 6, mature erythrocyte. Wright stain.

Cells encountered in bone marrow films

Erythroid series

Erythroid precursors tend to have round nuclei, coarse chromatin, and moderate to deep blue cytoplasm that becomes more pink in color as hemoglobin is produced by more-differentiated cells. The developmental stages of the erythroid series, from immature to mature, are the rubriblast, prorubricyte, rubricyte, metarubricyte, polychromatophilic erythrocyte, and mature erythrocyte (Figure 15.1).

Rubriblasts are the most immature cells that are recognizable in the erythroid series. These cells are relatively large, have round nuclei, slightly coarse chromatin, and nucleoli. The nucleus : cytoplasm ratio is high, with a scant amount of deeply basophilic cytoplasm. A clear Golgi zone may be present as well.

Prorubricytes, which are the next stage in erythrocyte maturation, have a round nucleus, slightly more coarse chromatin, and no visible nucleolus. The cytoplasm is slightly less blue, and it is also more abundant than that of the rubriblast.

Rubricytes are the most mature stage of maturation in which mitosis can still occur. These cells have smaller nuclei, very coarse chromatin, and blue to blue-pink (i.e., polychromatophilic) cytoplasm.

Metarubricytes are the most mature cells of the erythroid series that still contain a nucleus. The nucleus is very small, dark, and dense, and the cytoplasm is either polychromatophilic or the red-orange color of mature erythrocytes. Nuclei are extruded from metarubricytes, thereby resulting in polychromatophilic erythrocytes.

Polychromatophilic erythrocytes are anucleate, blue-pink in color, and larger than mature erythrocytes. They also may contain nuclear remnants (i.e., Howell-Jolly bodies). When stained with supravital stains (e.g., new methylene or brilliant cresyl blue), their mRNA and organelles clump,

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Companion website: www.wiley.com/go/thrall/veterinary

thereby resulting in blue-staining dots and fibrils (i.e., reticulum) throughout the cells. When stained in this manner, polychromatophilic erythrocytes are termed reticulocytes.

Mature erythrocytes are red-orange in color. Evaluation of mature erythrocyte morphology in bone marrow preparations usually is not indicated, but it can be diagnostically useful in that abnormalities such as red cell parasites, spherocytes, or hypochromasia occasionally may be observed. Such abnormalities are typically confirmed by blood film review.

Granulocyte (myeloid) series

Granulocytic precursors tend to have irregularly shaped and, sometimes, eccentric nuclei, with fine to stippled chromatin patterns and abundant, lavender-colored cytoplasm. At certain stages of maturation, they contain azurophilic (i.e., red-purple) to pink granules within the cytoplasm. As the cells mature, the nuclei elongate, from amoeboid or round in shape to kidney-bean- or horseshoe-shaped to segmented. The developmental stages of the myeloid series, from immature to mature, are the myeloblast, progranulocyte (promyelocyte), myelocyte, metamyelocyte, band granulocyte, and segmented granulocyte (Figure 15.2). When the maturation process is hastened, whether resulting from inflammation or other causes, the cytoplasm of the myeloid precursors at all stages of maturation is more basophilic and sometimes vacuolated.

Myeloblasts are subclassified into type I and type II. Type I myeloblasts, which are the most immature cells that are still recognizable in the granulocytic series, are large cells with round to oval nuclei, finely stippled or smooth nuclear chromatin, one or more nucleoli, a small amount of moderately blue cytoplasm, and no azurophilic granules. The nucleus usually is centrally located, and the nuclear outline may be slightly irregular. The nucleus : cytoplasm ratio is high (>1.5), and the cell size is approximately 1.5–3.0 times greater than the red cell diameter. The cytoplasm has a "ground-glass" appearance and, rarely, contains small vacuoles. Type II myeloblasts are very similar to type I, except that some small, azurophilic granules (primary granules) are scattered in the cytoplasm and the nucleus may be central or eccentric.

Promyelocytes are cells with smooth or slightly stippled nuclear chromatin, with or without a nucleolus, and many distinct azurophilic granules dispersed in slightly to moderately blue cytoplasm. The nucleus is central or eccentric. Prominent nucleoli may be present, even in cells with a high concentration of granules. A clear Golgi zone may be present as well.

Myelocytes, which are the last maturation stage in which mitosis can occur, are smaller than progranulocytes, have round to oval nuclei, light blue cytoplasm, and no primary granules within the cytoplasm. In these cells, the primary granules have been replaced by secondary (i.e., specific) granules, which are difficult to see in neutrophil precursors but are very distinct in eosinophil and basophil precursors. Eosinophil precursors contain pink (i.e., eosinophilic) granules, and basophil precursors contain azurophilic to dark purple granules (Figure 15.3).

Metamyelocytes have kidney bean–shaped nuclei. The cytoplasm is similar in appearance to that of myelocytes.

Band granulocytes have nuclei that are curved and elongated, with parallel sides. Some chromatin clumping is present, and the cytoplasm is similar to that of myelocytes and metamyelocytes.

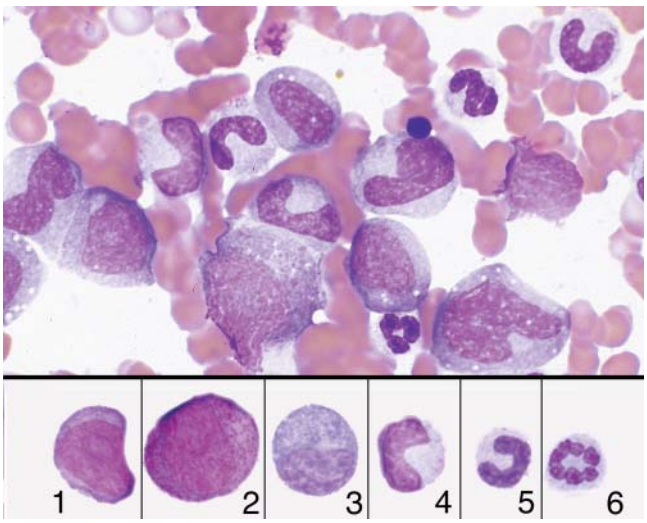

Figure 15.2 Top. Bone marrow aspirate from a dog showing numerous granulocytic (myeloid) precursors. Note the irregularly shaped nuclei, fine chromatin patterns, and lavender-colored cytoplasm. Bottom. Maturation stages of myeloid precursors, from immature to mature. 1, myeloblast; 2, promyelocyte; 3, myelocyte; 4, metamyelocyte; 5, band neutrophil; 6, segmented neutrophil. Wright stain.

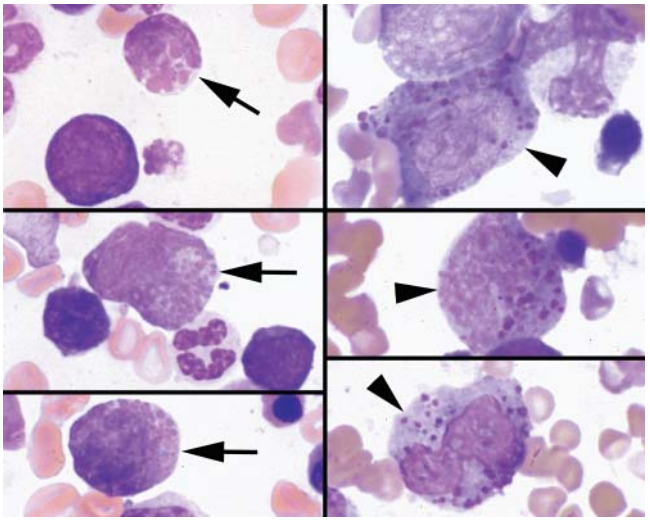

Figure 15.3 Left. Various maturation stages of eosinophil precursors (arrows). Right. Various maturation stages of basophil precursors (arrowheads). Granules may obscure the nucleus, thus making identification of specific maturation stage difficult. Wright stain.

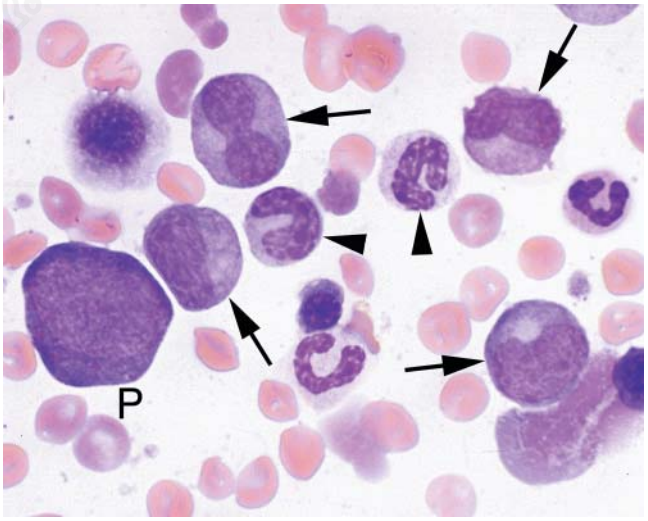

Figure 15.4 Bone marrow aspirate from dog with granulocytic and monocytic hyperplasia. Monocyte precursors (arrows) are difficult to distinguish from granulocytic precursors (arrowheads). Chromatin pattern is more coarse in granulocytic precursors. P, progranulocyte. Wright stain.

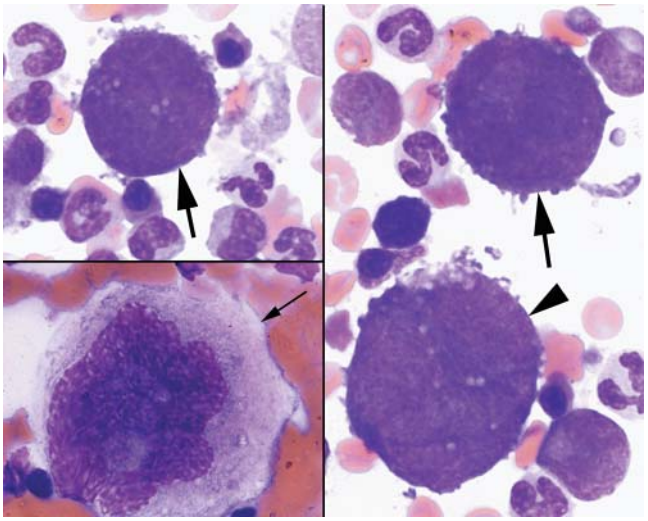

Figure 15.5 Various maturation stages of megakaryocyte series. Large arrows, megakaryoblasts; arrowhead, promegakaryocyte; small arrow, mature megakaryocyte. Wright stain.

Segmented granulocytes have lobulated or markedly constricted nuclei, with large and dense chromatin clumps. The cytoplasmic characteristics are generally similar to those of myelocytes, metamyelocytes, and bands.

Monocyte series

Cells of the monocyte series are relatively few in concentration, and they are very difficult to distinguish from those of the myeloid series in normal marrow. A distinctive feature is their irregular nuclear outlines. Monoblasts appear similar to myeloblasts, and promonocytes appear similar to myelocytes and metamyelocytes. Mature monocytes have the same appearance as monocytes in blood (Figure 15.4). Monocyte precursors usually are recognizable only in animals with monocytic leukemia.

Monoblasts are large cells with round, irregular or folded nuclei and finely reticular nuclear chromatin, one or more prominent nucleoli, and a moderate amount of basophilic, agranular cytoplasm. A Golgi zone often is prominent at the site of nuclear indentation. The nucleus : cytoplasm ratio usually is less than that of myeloblasts.

Promonocytes are large cells with cerebriform nuclei and prominent nuclear folds, stippled or lacy chromatin, and no distinct nucleolus. They also have more abundant and less basophilic "ground-glass" cytoplasm than that of monoblasts.

Megakaryocyte series

Megakaryocytes are very large cells, and their cytoplasmic fragments become platelets, which are important in the clotting process. Although these cells undergo mitosis, they do not divide, thus becoming very large and multinucleated, with as many as 16 or more nuclei. The nuclei are not separate entities, however, and they appear as a large, multilobulated structure in the center of the cell. The developmental stages of the megakaryocyte series, from immature to mature, are the megakaryoblast, promegakaryocyte, and megakaryocyte (Figure 15.5).

Megakaryoblasts are first recognizable when their size exceeds that of other types of precursors. The nuclei usually appear to be more dense than those of other types of blast cells, and the cytoplasm usually is deeply basophilic.

Promegakaryocytes have from two to four nuclei, which usually are connected by thin strands of nuclear material and deep blue agranular cytoplasm. They also usually are several-fold larger than rubriblasts or myeloblasts.

Megakaryocytes are very large (diameter, 50–200 μm), with numerous nuclei that form a lobulated mass of nuclear material. The cytoplasm stains more lightly than that of promegakaryocytes. As megakaryocytes mature, they become larger, gain more nuclei, and contain cytoplasm that becomes granular and, sometimes, light pink in color. Naked nuclei of megakaryocytes commonly are observed in bone marrow films.

Other cells

Small lymphocytes in bone marrow appear as they do in blood, with a round and usually indented nucleus, a diffuse chromatin pattern without visible nucleoli, and scant, light blue cytoplasm. They are slightly smaller than neutrophils (Figure 15.6). Plasma cells are differentiated lymphocytes that produce immunoglobulin, and they are similar in size to neutrophils. The appearance of plasma cells is very similar to that of rubricytes, except that the cytoplasm of plasma cells is light blue and more abundant, with a clear Golgi zone adjacent to the often-eccentric nucleus

sometimes being apparent (Figure 15.6). The nuclei are round, with very coarse and dense chromatin, and nucleoli are inapparent. The cytoplasm of plasma cells occasionally may contain either very eosinophilic material (i.e., "flame cells") or round, clear to light blue structures that represent immunoglobulin (i.e., Russell bodies). Plasma cells that contain Russell bodies are called Mott cells (Figure 15.7).

Lymphoblasts rarely are seen in the bone marrow aspirates from normal animals, and their presence often is indicative of a lymphoproliferative disorder. Lymphoblasts are small to large cells with a round to oval nucleus, finely stippled to slightly course nuclear chromatin, one or more nucleoli, and a small to moderate amount of pale blue cytoplasm without azurophilic granules. The nuclear outline may appear to be slightly indented or irregular. The nucleus : cytoplasm ratio usually is greater than that of myeloblasts. Lymphoblasts are distinguished from myeloblasts by the slightly more coarse chromatin, less cytoplasm, and the absence of azurophilic granules. Lymphoblasts may appear similar to rubriblasts, but the nuclei of lymphoblasts are less perfectly round.

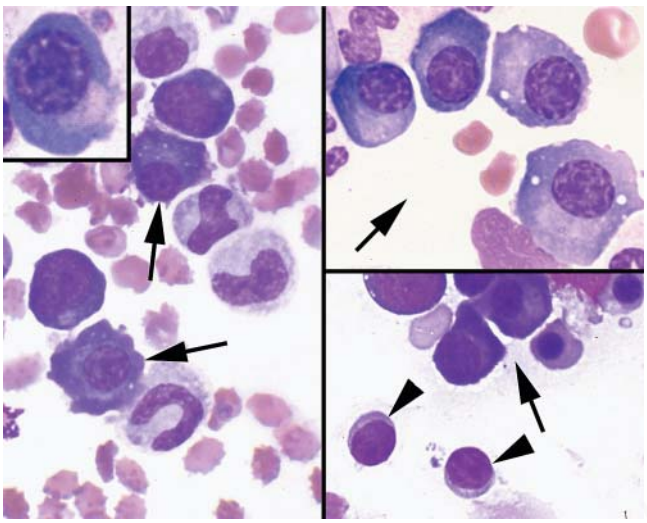

Figure 15.6 Plasma cells (arrows) have a variable appearance, depending on thickness of preparation and degree of flattening of the cells. Flattened plasma cells usually appear to have abundant cytoplasm and obvious, clear Golgi areas. Inset. Higher magnification of a plasma cell. Note the coarse chromatin and clear Golgi area. Lymphocytes (arrowheads) have a small amount of cytoplasm. Wright stain.

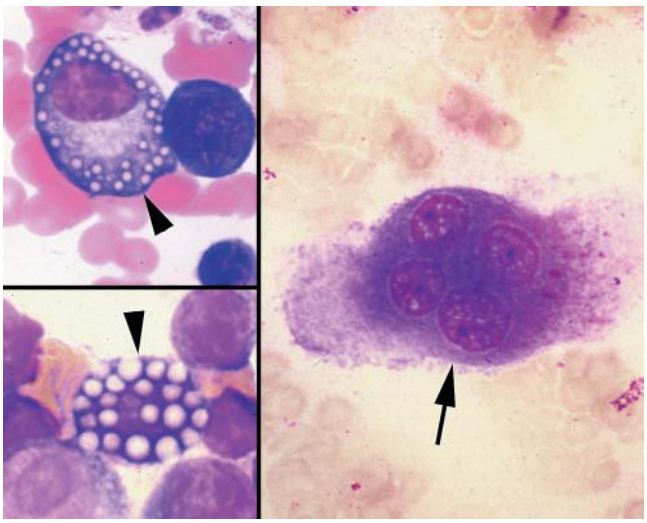

Figure 15.7 Left. Vacuolated plasma cells (Mott cells) containing packets of immunoglobulin (Russell bodies). Right. Osteoclast, which can be differentiated from a megakaryocyte because the osteoclast nuclei are separate rather than lobulated. Wright stain.

Macrophages derive from monocytes and are present at a low concentration in normal bone marrow. The appearance of macrophages is highly variable. The nuclei usually are round to slightly kidney bean in shape, and the nucleoli usually are small and inconspicuous. The cytoplasm is gray-blue and usually vacuolated; small, pink granules may be present in the cytoplasm as well. Macrophage nuclei may contain several small nucleoli. Macrophages commonly phagocytize cellular debris, including nuclei that have been extruded from metarubricytes, and they often contain hemosiderin, which is a red cell breakdown product containing iron.

Osteoblasts and osteoclasts may be seen in the bone marrow aspirates from young animals and from those in which bone remodeling is occurring. Osteoclasts are very large, multinucleated cells that may appear similar to megakaryocytes, but their nuclei are individual and not connected to each other (unlike those of megakaryocytes). The cytoplasm is basophilic, and may contain a few pink to azurophilic granules. Osteoclasts are specialized macrophages that derive from monocytes, and they function in the lysis of bone (Figure 15.7). Osteoblasts are similar in appearance to plasma cells but are larger (Figure 15.8). They have eccentric, round to oval nuclei that appear to be falling out of one end of the cell; they also have abundant basophilic cytoplasm and a clear Golgi area. Small pink or azurophilic granules may be present in the cytoplasm as well.

Mast cells are easily recognized in the bone marrow, and although rarely observed, they normally are present at very low concentrations. Mast cells are large, round, and discrete cells with abundant small metachromatic granules in the cytoplasm (Figure 15.8). They usually can be distinguished from basophil myelocytes, because mast cell granules are smaller and more numerous. Mast cells are more apparent and, possibly, increased in concentration in bone marrow that is hypocellular, such as that which may be seen with ehrlichiosis. When mast cells are abundant, infiltration by mast cell neoplasia is likely.

Fibrocytes and fibroblasts are seen only infrequently, even in aspirates from animals with myelofibrosis, because they do not exfoliate easily. The nuclei are round to oval, and the cytoplasm is lightly basophilic and spindle-shaped.

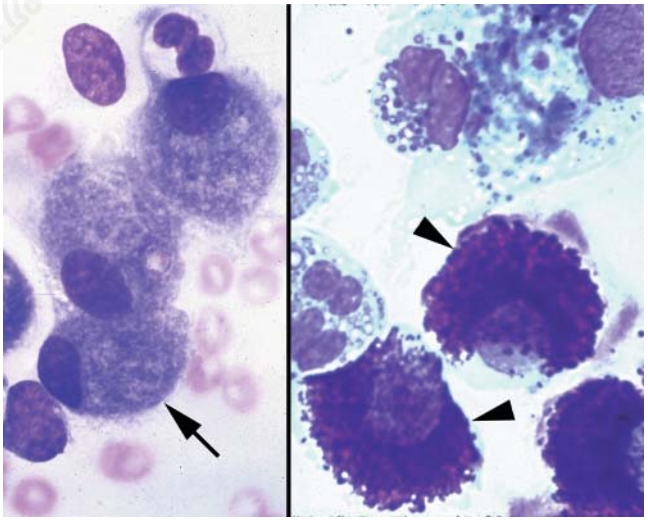

Figure 15.8 Left. Osteoblasts, which have a similar appearance to plasma cells but are larger, with a less condensed chromatin pattern and less distinct cytoplasmic margins (arrow). Right. Mast cells with abundant cytoplasmic granules that tend to obscure the round nucleus (arrowheads). Wright stain.

Cytochemistry and immunophenotyping

Cytochemical reactions sometimes are useful in the process of cell identification. These stain reactions are based on various cell types having different amounts, distribution, and types of enzyme activities. The stains most commonly used include peroxidase, Sudan black B, chloroacetate esterase, α-naphthyl acetate esterase, α-naphthyl butyrate esterase, and alkaline phosphatase (ALP). Peroxidase, Sudan black B, and chloroacetate esterase are myeloid (i.e., granulocytic) markers. The nonspecific esterases α-naphthyl acetate esterase and α-naphthyl butyrate esterase, which can be inhibited by sodium fluoride, and are monocyte markers, but their staining patterns vary. Monocytes may have a few small, round granules that stain positive for Sudan black B. Reactivity for ALP is somewhat confusing, however, because ALP positivity is rare in the immature neutrophils of normal animals but ALP-positive myeloid cells are common in animals with acute myelogenous leukemia. Moreover, ALP activity is present in some types of lymphoid cells as well as in cells with monocytic differentiation in animals with acute myelomonocytic leukemia. Cytochemical staining of blood and bone marrow films can facilitate the classification of neoplastic cells, but in many cases, negative staining occurs, perhaps because of abnormalities in hematopoietic differentiation that are associated with the neoplastic process.

Immunophenotypic analysis is based on using monoclonal antibodies that are directed against antigens on the surface of hematopoietic cells to determine the phenotypic profile of those cells, thus identifying the cell type. Very little sample quantity usually is necessary, and flow cytometric analysis using the antibodies makes the technique relatively simple to perform. Briefly, monoclonal anti bodies directed against cell surface proteins are conjugated to fluorescent molecules and then mixed with the cells, after which the cells are analyzed by flow cytometry. Flow cytometry provides information regarding the size of the cells, expression of any particular surface protein, and concentration of the surface protein. Phenotypes of both normal and neoplastic cells are continuously being classified as more monoclonal antibodies become available. Immunophenotyping likely will eventually replace cytochemistry for use in the classification of hematopoietic cells. See Chapter 14 for more discussion.

Evaluation and interpretation of bone marrow films

Bone marrow films must be evaluated and interpreted in conjunction with the analysis of concurrent complete blood count (CBC) data. For example, if an animal has a decreased platelet concentration (i.e., thrombocytopenia), the megakaryocyte concentration is particularly important to evaluate.

Cellularity

The low-power (×10) objective should be used to scan the slide at ×100 magnification to assess the degree of cellularity and amount of fat that is present (Figure 15.9). Hemodiluted marrow samples are difficult to evaluate for cellularity. Normal marrow cellularity varies, but in general, approximately 50% of the marrow consists of fat and 50%

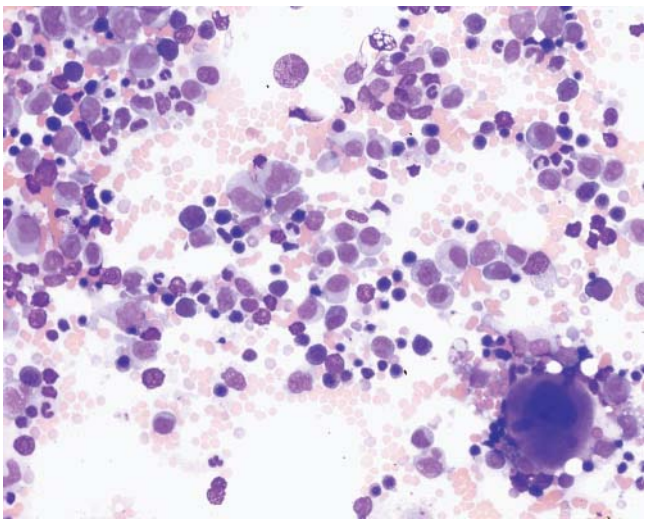

Figure 15.9 Bone marrow aspirate from a dog, low magnification. The degree of cellularity is adequate to increased. Cellularity is judged by the density of sheets of cells, as exemplified in this figure, or by estimating the ratio of fat to cells in particles. Wright stain, low power.

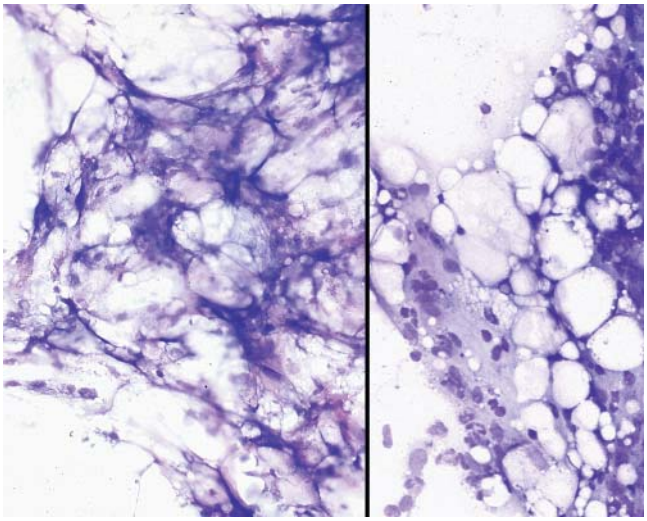

Figure 15.10 Bone marrow aspirate from a cat with generalized marrow hypoplasia, low magnification. Right. Numerous adipocytes are present, with very little hematopoietic cellularity. Left. Broken adipocytes and stroma are present, with few hematopoietic cells. Wright stain, low power.

of cells. Cellularity is increased when production in either the myeloid or the erythroid cell line is increased in response to cell loss, destruction, or consumption. Abnormal causes of increased cellularity include lymphoproliferative and myeloproliferative disorders as well as other neoplastic disorders. Overall cellularity may be decreased with disorders such as myelofibrosis, certain infectious agents (including *Ehrlichia* sp. in dogs and feline leukemia virus [FeLV]), estrogen toxicity (in dogs and ferrets), drug toxicities (including some commonly used chemotherapeutic agents), chemicals that are toxic to the marrow, radiation, and immune-mediated disorders in which stem cells are destroyed (Figure 15.10). A decrease in cellularity is termed hypoplasia, and a complete absence of cells is termed aplasia. Hypoplasia of only one cell line is relatively common, whereas aplasia usually involves all cell lines. Erythroid or myeloid aplasia is rare. Histopathologic evaluation of a core biopsy specimen is indicated when the cellularity is very low or cannot be determined by examination of the marrow aspirate.

Megakaryocytes

Using the low-power (10×) objective, the megakaryocyte concentration should be estimated as either increased (i.e., hyperplasia), decreased (i.e., hypoplasia), or adequate. Interpretation of this estimate depends on the platelet concentration in the blood. Areas with high cellularity normally contain at least a few megakaryocytes, and unless the sample is markedly hemodiluted, at least 5–10 megakaryocytes should be present on the slide. In animals with increased platelet consumption (e.g., animals with disseminated intravascular coagulopathy) or destruction (e.g., animals with immune-mediated thrombocytopenia), the megakaryocyte concentration in the marrow should be increased. Animals with megakaryocytic hyperplasia may have as many as 50 or more megakaryocytes in cellular areas of the slide. Increased concentrations of megakaryoblasts, promegakaryocytes, and smaller, more immature megakaryocytes typically are seen with megakaryocytic hyperplasia. In thrombocytopenic patients with megakaryocytic hyperplasia, the platelet size usually is increased because of the early release of platelets; this increase in size is analogous to the increased size of immature erythrocytes. Animals that are thrombocytopenic because of the lack of platelet production have very few – or even no – megakaryocytes in the marrow film. Megakaryocytic hypoplasia without erythroid and myeloid hypoplasia is rare and may be caused by immune-mediated destruction of megakaryocytes.

Myeloid : erythroid ratio

Using the ×10 objective, appropriate areas that are not too thick and in which cells are not broken can be chosen for further examination of the bone marrow using the ×50 or ×100 oil objectives (to magnify 500- and 1000-fold, respectively). At these higher magnifications, erythroid and myeloid precursors can be identified, and the myeloid : erythroid (M : E) ratio can be estimated (Figure 15.11). Usually, estimation of this ratio is just as informative as actual quantification. To quantify the M : E ratio, 300–500 nucleated cells are classified as being either myeloid or erythroid. This classification should be performed while examining several different areas, because some fields may be predominantly granulocytic and other areas predominantly erythroid.

Normal M : E ratios differ with the species, but in general, they range from 0.5 : 1 to 3 : 1. Decreased or increased production of either cell line shifts the M : E ratio, and such shifts

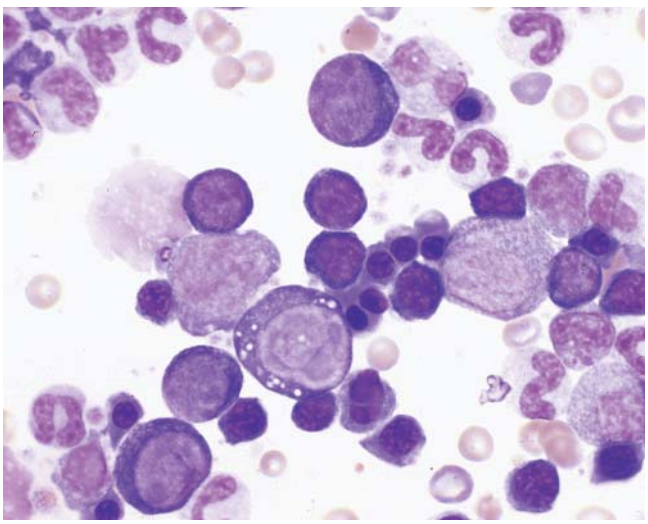

Figure 15.11 Bone marrow aspirate from a dog. Both myeloid and erythroid precursors are present, with a normal myeloid : erythroid ratio of approximately 1. Wright stain.

must be interpreted in light of the CBC results, particularly the packed cell volume and the neutrophil concentration. For example, if the M : E ratio is increased, the animal is anemic, and the blood neutrophil concentration is normal, then the ratio is increased because of a decrease in red cell production rather than an increase in neutrophil production. Conversely, if the animal is not anemic and the neutrophil concentration is increased, then the increased M : E ratio results from an increased neutrophil production rather than a decreased erythrocyte production.

Decreased M : E ratio

A decreased M : E ratio may be indicative of increased red cell production, such as that seen with a regenerative anemia (i.e., erythroid hyperplasia); a decreased neutrophil production (i.e., myeloid hypoplasia); or a combination of the two (Figure 15.12). Myeloid hypoplasia without erythroid hypoplasia is rare but, when present, usually is associated with myelodysplasia or myeloproliferative disorder.

Increased M : E ratio

An increased M : E ratio may be indicative of increased granulocyte production (i.e., myeloid hyperplasia), decreased in red cell production (i.e., erythroid hypoplasia), or both (Figure 15.13). Granulocytic hyperplasia usually results from inflammation, but it also may be seen in animals with immune-mediated destruction of neutrophils and in those recovering from viral-induced marrow damage, such as parvovirus infections in dogs (i.e., parvoviral enteritis) and cats (i.e., panleukopenia). Causes of erythroid hypoplasia are discussed in Chapter 8 and include renal failure, endocrinopathies, and anemia of inflammatory disease. Anemia of inflammatory disease (i.e., anemia of chronic disease) is one of the more common causes of mild erythroid hypoplasia in domestic animals. Granulocytic hyperplasia and increased iron stores (i.e., hemosiderin) also usually are seen in the marrow from these patients. Pure red cell aplasia is rare but, when present, usually is caused by immune-mediated destruction of very early erythroid precursors.

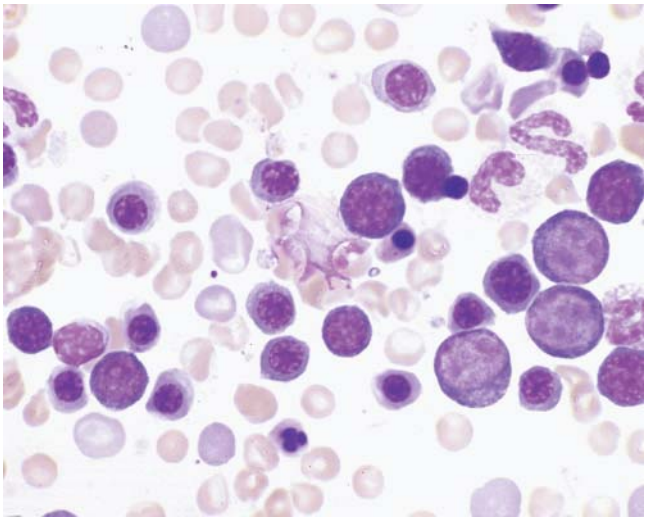

Figure 15.12 Bone marrow aspirate from a dog with regenerative anemia. The myeloid : erythroid ratio is decreased because of increased red cell production (erythroid hyperplasia). Wright stain.

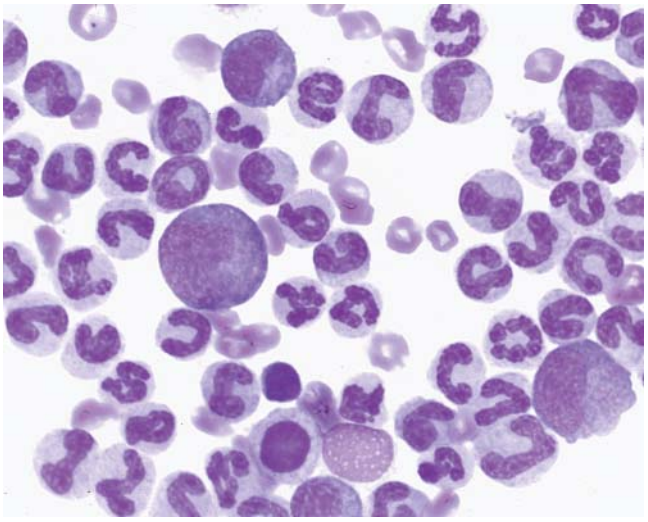

Figure 15.13 Bone marrow aspirate from a dog. The myeloid : erythroid ratio is markedly increased because of increased granulocyte production (myeloid hyperplasia). Wright stain.

Orderliness of maturation

The orderliness and completion of maturation in erythroid and myeloid cells should be determined. Blast cells divide to ultimately produce 16–32 mature cells. Thus, approximately 80–90% of the cells should be more mature forms (i.e., metamyelocytes, bands, and neutrophils in the myeloid series, and rubricytes and metarubricytes in the erythroid series), and polychromatophilic erythrocytes should be present. Orderly progression of maturation usually is referred to as a "pyramid," with the few immature forms comprising the top and the numerous more mature forms comprising the broad bottom (Figure 15.14).

Disorderly maturation of erythroid and myeloid precursors commonly is seen in animals with leukemia and myelodysplasia, but it also may be seen in animals with nonneoplastic conditions. An apparent arrest in maturation of the erythroid series, often at the rubricyte stage of maturity, may be seen in animals with immune-mediated destruction of immature erythroid cells. These animals do not have a typical regenerative response, such as that usually seen in animals with immune-mediated hemolytic anemia. Metarubricytes and polychromatophilic erythrocytes often are decreased to absent in the marrow from such patients.

A similar apparent arrest of maturation in the granulocytic series, which often occurs in conjunction with marked

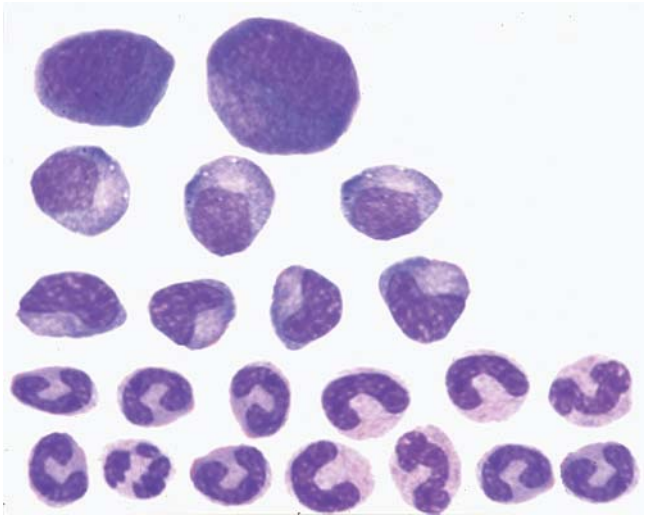

Figure 15.14 A normal "pyramid," illustrating an orderly maturation of myeloid precursors. A few very immature cells form the top of the pyramid, with numerous more mature cells forming the bottom.

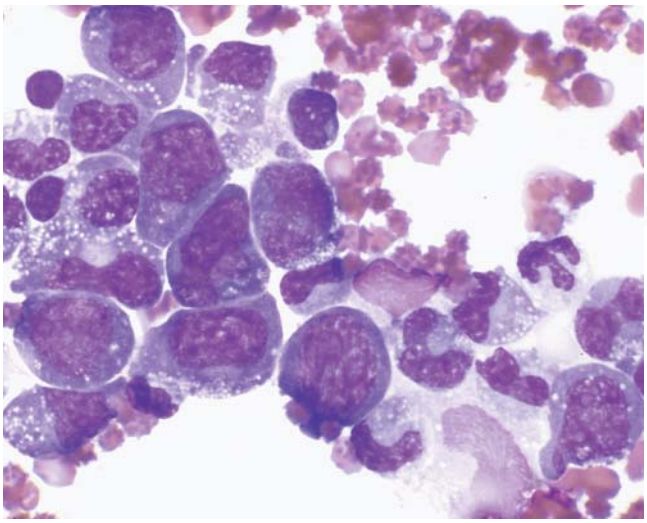

Figure 15.15 Bone marrow aspirate from a dog with immune-mediated neutropenia. Marked myeloid hyperplasia is evident, with an increased proportion of more immature granulocyte precursors and few mature granulocytes because of the immune-mediated destruction of more mature cells. Note that the cytoplasm is basophilic and vacuolated, likely because of the increased rate of cell production. Wright stain.

myeloid hyperplasia, commonly is seen in marrow aspirates from animals with immune-mediated neutropenia (Figure 15.15). This "arrest" may appear at any stage of granulocytic maturity, but it often occurs at the metamyelocyte stage. Marrow from animals with immune-mediated destruction can appear similar to that from patients with granulocytic leukemia, but the concentration of myeloblasts usually is lower in those with immune-mediated disease. Other conditions that cause disorderly maturation of granulocytes include marked inflammatory disease (with consumption of more mature forms) and recovery from viral-induced neutropenia.

Macrophages and iron stores

Macrophages (i.e., histiocytes) normally are present in small concentrations (<1% of nucleated cells), and phagocytosis of red cells and nuclear debris by macrophages occasionally may be seen in normal animals. The concentration of macrophages may be increased in animals with immune-mediated disorders, and macrophages that have phagocytized nucleated red cells, platelets, and neutrophils occasionally are observed (Figure 15.16). Other causes of increased cell destruction, such as marrow necrosis secondary to drugs, toxins, or radiation, may result in increased macrophage concentration. In these cases, other morphologic evidence of necrosis, such as pyknosis and increased cytoplasmic vacuolation, usually is observed.

A marked increase in the concentration of macrophages may be seen in animals with hemophagocytic syndrome, which also is called hemophagocytic histiocytosis and is a condition characterized by a benign, histiocytic proliferation secondary to infectious, neoplastic, or metabolic diseases. One retrospective study [1] found hemophagocytic syndrome in 3.9% of dogs that had bone marrow aspiration. This syndrome is associated with cytopenia of at least two cell lines and greater than 2% hemophagocytic macrophages in the marrow. It must be distinguished, on the basis of red cell morphology (i.e., lack of spherocytes and agglutination) and a negative Coombs test, from the much more commonly occurring immune-mediated diseases. Macrophages are a prominent cellular component in the marrow from animals with hemophagocytic syndrome, and they appear

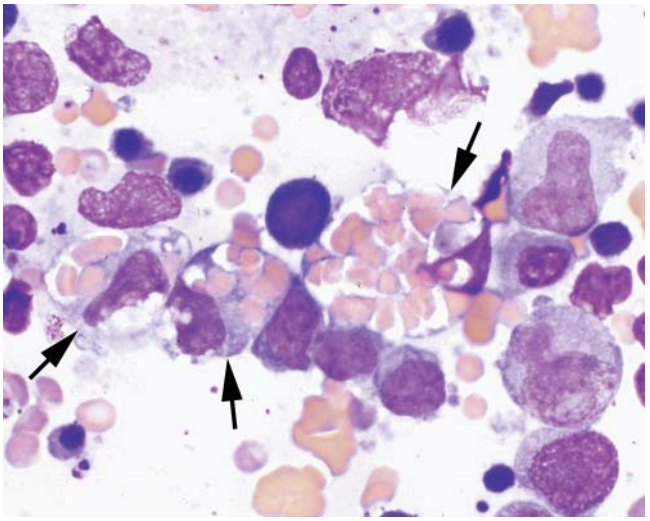

Figure 15.16 Bone marrow aspirate from a cat. Macrophages (arrows) are increased and have phagocytized many erythrocytes. This degree of phagocytic activity is abnormal and suggestive of either immune-mediated destruction of red cells or hemophagocytic syndrome. Wright stain.

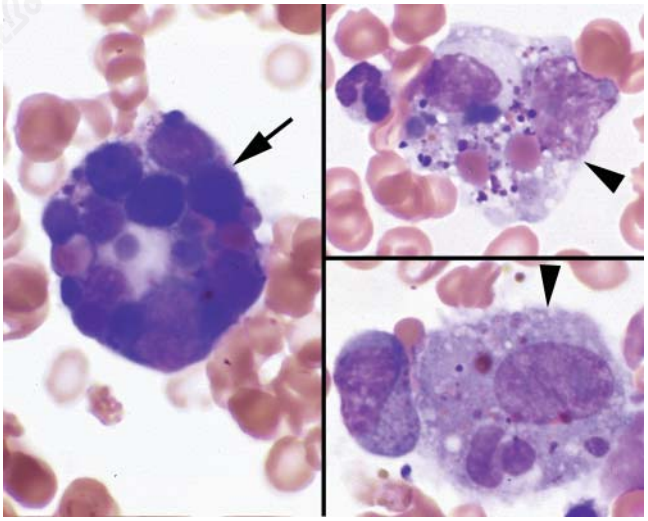

Figure 15.17 Bone marrow aspirate from a dog. Left. A macrophage (arrow) that has phagocytized erythrocytes as well as nucleated erythrocytes. Upper right. A macrophage (arrowhead) that has phagocytized erythrocytes, a large nucleated cell, platelets, and cellular debris. Lower right. A macrophage (arrowhead) that has phagocytized a neutrophil and contains hemosiderin. Phagocytosis of platelets and immature cells may be seen with immune-mediated disease and with hemophagocytic syndrome. Wright stain.

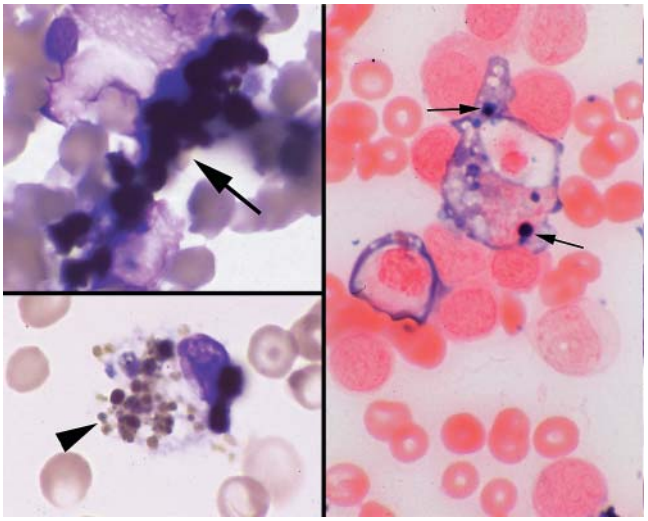

Figure 15.18 Bone marrow aspirate from a dog. Upper left. A clump of hemosiderin (storage iron; arrow) from a broken macrophage. Wright stain. Lower left. A macrophage (arrowhead) containing hemosiderin. Wright stain. Right. Prussian blue iron stain, showing the presence of blue-staining iron (small arrows).

to be normal and well differentiated, with amoeboid nuclei and abundant, light blue cytoplasm. Many macrophages are observed with phagocytized hematopoietic cells within their cytoplasm (Figure 15.17). Dogs with hemophagocytic syndrome often exhibit fever, icterus, splenomegaly, hepatomegaly, and diarrhea, and those with infection-associated hemophagocytic syndrome are thought to have a better survival rate than dogs with other causes of hemophagocytic syndrome. An increased concentration of macrophages also is seen in animals with malignant histiocytosis, which is a neoplastic proliferation of histiocytes (see below).

The presence or absence of hemosiderin (i.e., iron stores) in macrophages should be noted (Figure 15.18). Special stains for iron, such as a Prussian blue stain (Figure 15.18), usually are not necessary, because hemosiderin can be readily visualized with use of Romanowsky stains. Hemosiderin rarely is seen in the marrow aspirates from normal cats, but it usually is abundant in that from normal dogs and horses. Animals with iron deficiency anemia lack iron stores in the marrow, and animals with anemia of inflammatory disease may have increased iron stores.

Other cells

The presence and percentage of other types of cells, such as lymphocytes and plasma cells, should be noted as well. In animals that have been antigenically stimulated, the plasma cell concentration may be markedly increased, and the plasma cells may be present in small groups. Normally, approximately 2% or less of the marrow cells are plasma cells. Approximately 15% or less of the cells observed in a bone marrow film from healthy dogs may be lymphocytes, whereas as much as 20% of the cells may be lymphocytes in normal cats. The concentrations of plasma cells and lymphocytes in the bone marrow film usually vary from one area of the film to the next.

Microorganisms

Microorganisms occasionally may be found in bone marrow aspirates. Bacteria very rarely are seen, but *Histoplasma capsulatum* (Figure 15.19), *Toxoplasma gondii* (Figure 15.20),

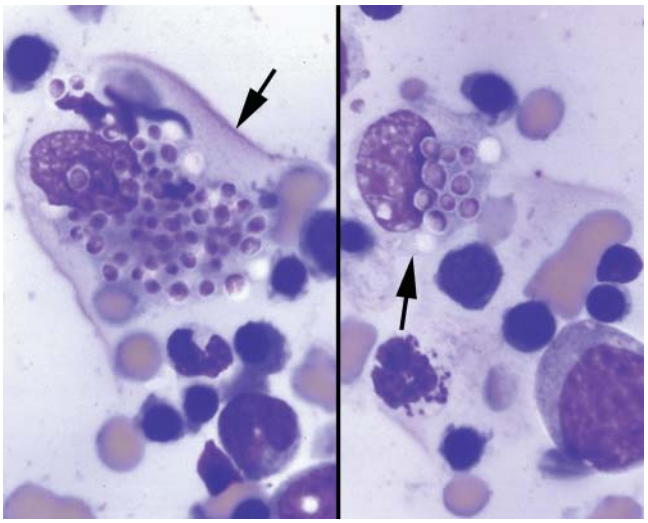

Figure 15.19 Bone marrow aspirate from a cat. Macrophages (arrows) contain numerous *Histoplasma capsulatum* organisms, which are round yeast cells with a well-defined, thin capsule. Wright stain. Source: Specimen courtesy of Antech Diagnostics.

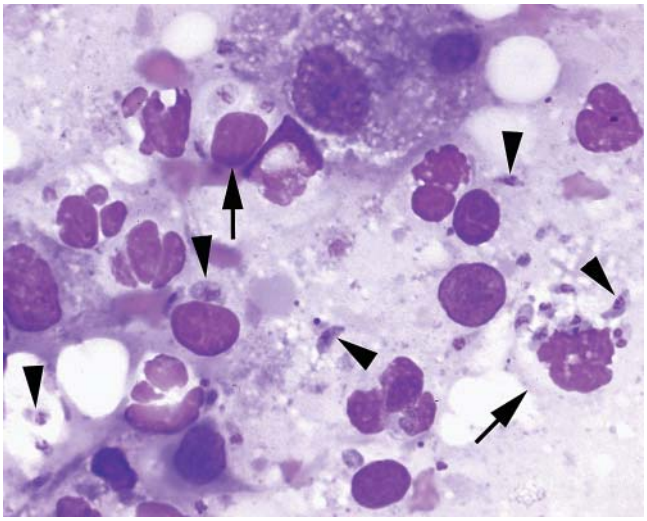

Figure 15.20 Bone marrow aspirate from a cat. Macrophages (arrows) contain trophozoites of *Toxoplasma gondii*. Individual trophozoites (arrowheads) have a characteristic crescent shape and a central nucleus. Wright stain.

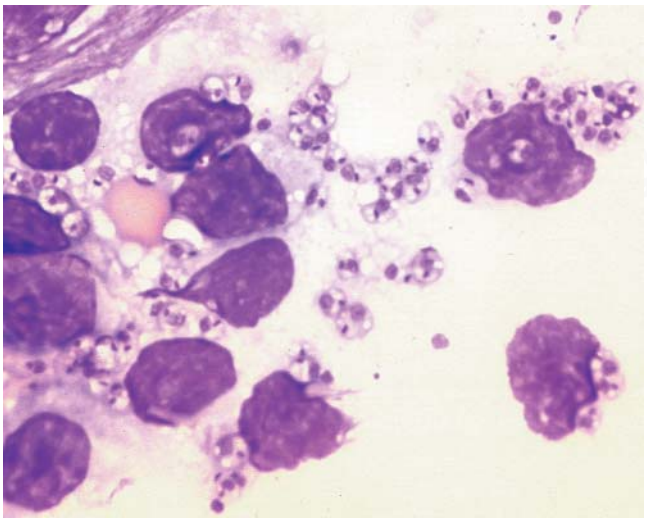

Figure 15.21 Bone marrow aspirate from a dog. Note the broken mononuclear cells with numerous *Leishmania donovani* organisms. These organisms are oval, with a typical, dark-staining, rod-shaped structure (kinetoplast). Wright stain.

Leishmania donovani (Figure 15.21), *Cytauxzoon felis*, and rarely, *Ehrlichia* sp. can be observed. Red cell parasites such as *Mycoplasma* sp. or *Babesia* sp. also may be observed in marrow aspirates.

Stem cell disorders of marrow

Reversible stem cell injuries

Reversible injury is transient in nature and, therefore, usually manifests as neutropenia because of the short half-life of neutrophils in blood (see Chapter 12). Causes include viral injury, drugs or chemicals, and chemotherapeutic drugs, such as doxorubricin, that injure rapidly dividing cells. Although neutropenia is recognized initially, thrombocytopenia and nonregenerative anemia may occur if the injury lasts for more than 1–2 weeks. In general, if the animal does not have complications associated with the cytopenias, the stem cell system can be expected to recover and repopulate the blood with normal concentrations of cells.

Some drugs and chemicals apparently are directly cytotoxic to stem cells. Drugs that have been associated with stem cell injury in animals include estrogen (in dogs and ferrets), phenylbutazone (in dogs), and albendazole, which is a broadspectrum anthelmintic (in dogs and cats). Estrogen toxicosis may occur in bitches given exogenous estrogen for mismating, termination of pseudopregnancy, or urinary incontinence. Myelosuppression may occur either from administration of excessive amounts of estrogen or from an idiosyncratic sensitivity to estrogen. Endogenous estrogen, either because of Sertoli cell tumors in male dogs or cystic ovaries in female dogs, also may result in bone marrow suppression. Because ferrets are induced ovulators, marrow suppression from endogenous estrogen is a common and potentially fatal disorder in this species. The mechanism of estrogen toxicosis is unclear but is thought to result from secretion, by thymic stromal cells, of an estrogen-induced substance that inhibits stem cells. Marrow suppression is paradoxically preceded by an initial thrombocytosis and neutrophilia.

Other drugs may induce cell destruction by immune-mediated mechanisms. In dogs, trimethoprim-sulfadiazine, cephalosporin, and phenobarbital have been associated with pancytopenia that may be immune-mediated. Methimazole, which is used for treating cats with hyperthyroidism, is associated with neutropenia and thrombocytopenia in approximately 20% of the cats given this drug. Stem cell injury that is drug related and immune-mediated usually responds to discontinuation of the drug. Idiopathic immune-mediated stem cell injury usually responds to immunosuppressive therapy; however, it may take several weeks to respond and, often, requires long-term treatment for resolution.

Myelofibrosis may develop in response to various types of marrow injury. Any agent that is directly toxic to hematopoietic cells presumably may damage the microvasculature of the marrow, thereby leading to necrosis and subsequent fibrosis. Myelofibrosis also has been associated with myeloproliferative and lymphoproliferative disorders, other types of neoplasia, chronic hemolytic anemia secondary to pyruvate kinase deficiency, radiation, and other unidentified causes.

Irreversible stem cell injuries

In contrast to reversible stem cell injuries, irreversible injuries result from an intrinsic defect in proliferative

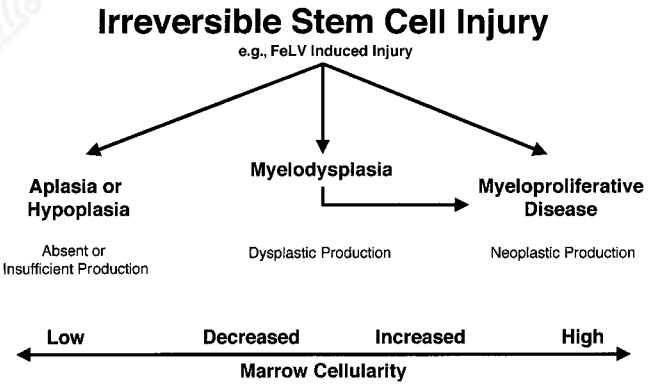

Figure 15.22 Organizational diagram of irreversible stem cell disorders. Myelodysplasia may progress to neoplasia over time. Expected cellularity of proliferative abnormalities is indicated at the bottom.

behavior or regulation of stem cell entry into differentiated hematopoiesis. These types of injuries generally are regarded as being irreversible, because they do not spontaneously correct themselves and therapeutic intervention almost never corrects the proliferative abnormality (with the exception of bone marrow transplantation, in which defective stem cells are replaced by normal donor stem cells). The causes of this form of stem cell injury are not well understood. The best-characterized causative association in domestic animals, however, is infection with FeLV in cats. In other domestic animals, the cause almost always is unknown. Chronic exposure to benzene-related chemical compounds is an employment hazard in humans and, rarely, may cause similar injury in animals. Radiation also may induce such an injury in a number of species. Manifestations of stem cell injury are highly variable (Figure 15.22). These manifestations are best regarded as being a continuum, from lack of cell production on one extreme to uncontrolled, neoplastic proliferation at the other. In the middle of this continuum is dysplastic cell production, which usually is associated with one or more cytopenias and with subtle morphologic abnormalities of the blood cells. Many cases likely begin as dysplasia and then, with time, progress to either hypoplasia or neoplasia. The stage observed at the initial examination is variable, depending on when during the course of the disease the animal is presented to the veterinarian. (More detailed descriptions of the points on this continuum are presented in Chapter 16.)

Aplasia or hypoplasia

Marrow aplasia is a relatively rare disorder in dogs and cats. Causes include chronic ehrlichiosis, Parvovirus, and FeLV infections; drug and toxin exposure; and idiopathic causes. Diagnosis is based on cytopenias in the blood and hypoplastic to aplastic bone marrow, with the marrow space replaced by adipose tissue. Treatment is dependent on determining the underlying cause of the bone marrow failure, and the outcome is variable. The hematologic result may be either somewhat selective, severe, and nonregenerative anemia (i.e., pure red cell aplasia or hypoplasia) or pancytopenia in which neutropenia and thrombocytopenia accompany the anemia (i.e., aplastic anemia). Establishing the morphologic diagnosis depends on the examination of marrow particles or histopathology to distinguish the hypocellularity from a hemodiluted marrow sample. Plasmacytosis of the marrow, in conjunction with the lack of hematopoietic cells, is often present with chronic ehrlichiosis, and is sometimes so marked that it must be distinguished from multiple myeloma (see Chapter 14). Most cases of pure red cell aplasia in dogs, as well as those that are not associated with FeLV in cats, likely are immune-mediated, and many respond to immunosuppressive therapy.

Dysmyelopoiesis

Dysmyelopoiesis is defined as a hematologic disorder characterized by the presence of cytopenias in the blood and dysplastic cells in one or more hematologic cell lines in the blood or bone marrow. The causes of dysmyelopoiesis include acquired mutations in hematopoietic stem cells (myelodysplastic syndromes) congenital defects in hematopoiesis, and secondary dysmyelopoietic conditions associated with various diseases, drugs, or toxins. Causes of secondary dysmyelopoiesis include immune-mediated hematologic diseases, lymphoid malignancies, and exposure to chemotherapeutic drugs. Secondary dysmyelopoiesis is also referred to as nonneoplastic syndromes of ineffective hematopoiesis in which dysmorphic maturation of cells occurs. Without methods to confirm clonality by cytogenetic analysis, the diagnosis of neoplastic myelodysplasia in dogs is based on light microscopic examination of bone marrow films (see Chapter 16). The characteristic morphologic and cytochemical features of neoplastic myelodysplasia and nonneoplastic ineffective hematopoiesis in dogs are discussed elsewhere in detail [2].

Neoplastic disorders involving bone marrow other than lymphoproliferative or myeloproliferative disorders

Mast cell leukemia may be seen in dogs and cats with systemic mastocytosis secondary to mast cell tumors (Figure 15.23). Although examinations of bone marrow aspirate commonly are performed to stage mast cell tumors, involvement of the marrow by mast cell tumors very rarely is observed. Buffy coat examination for mast cells also rarely is useful, because circulating mast cells occasionally may be seen in animals without mast cell tumors. The current recommendation is that bone marrow aspiration not be performed for routine staging but may be indicated for those dogs having either an abnormal CBC or presenting for tumor regrowth, progression, or new occurrence.

Malignant histiocytosis is a rapidly progressive – and ultimately fatal – proliferative disorder of the mononuclear

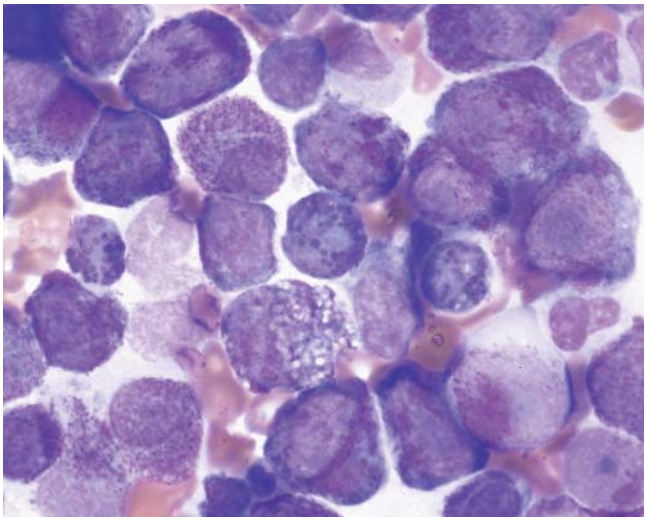

Figure 15.23 Bone marrow aspirate from a dog with poorly differentiated mast cell leukemia. Almost all of the cells present are mast cells with metachromatic cytoplasmic granules. This dog also had mast cells on the blood film. Wright stain.

phagocyte system that has been described in adult dogs, including Bernese mountain dogs and other breeds. An increased incidence of the disorder has been suggested to occur in the golden retriever and flat-coated retriever breeds. The disorder often is characterized by the systemic proliferation of large, pleomorphic, single, and multinucleated histiocytes with marked cellular atypia and phagocytosis of erythrocytes and leukocytes. The bone marrow as well as lung, lymph nodes, liver, spleen, and central nervous system commonly are involved. Positive reactivity of neoplastic cells to histiocytic markers (e.g., lysozyme and α_1-antitrypsin) can be demonstrated by immunohistochemistry (IHC). This immunohistochemical reactivity aids in the differentiation of neoplastic histiocytic cells from lymphoid and epithelial neoplasms, and it is important for establishing a definitive diagnosis of the neoplasm. The cellularity of bone marrow aspirates containing neoplastic histiocytes is consistently very high. These histiocytes are pleomorphic, large, discrete, and markedly atypical mononuclear cells, and the nuclei are round to oval or reniform. Features of malignancy include marked anisocytosis and anisokaryosis, prominent nucleoli, bizarre mitotic figures, marked phagocytosis of erythrocytes, leukocytes, other tumor cells, and moderate amounts of lightly basophilic, vacuolated cytoplasm (Figure 15.24). The presence of multinucleated giant cells also is supportive of the diagnosis. Other findings vary and may include erythroid hypoplasia, with prominent cytophagia of marrow elements, or generalized marrow hypoplasia, with neoplastic infiltration of atypical histiocytes and marked phagocytosis. Hematologic abnormalities such as anemia and mild to marked thrombocytopenia also may be present, correlating with marrow changes.

Epithelial and mesenchymal tumors rarely metastasize to the bone marrow. Epithelial tumors (i.e., carcinomas) tend to form groups of cohesive cells that are easy to distinguish from normal hematopoietic cells (Figures 15.25 and 15.26). Metastatic sarcomas are more difficult to diagnose, however, and are characterized by large, discrete, spindle-shaped cells that meet multiple criteria for malignancy (Figure 15.27). These cells must be distinguished from fibroblasts that may be observed in myelofibrosis.

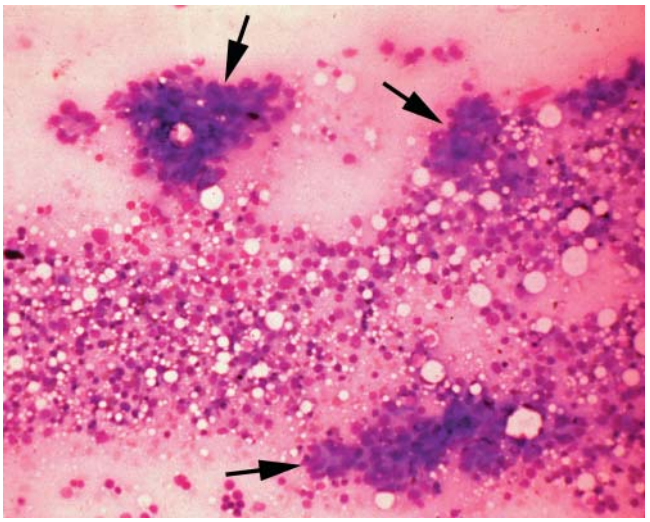

Figure 15.25 Bone marrow aspirate from a dog with metastatic mammary carcinoma, low magnification. The islands of cells (arrows) are neoplastic epithelial cells and can be differentiated from the normal hematopoietic cells by their tendency to adhere to each other. Wright stain. Low power.

16 Lymphoproliferative Disorders and Myeloid Neoplasms

Mary Anna Thrall
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Overview of myeloproliferative and lymphoproliferative disorders (leukemia)

Leukemia, a neoplastic proliferation of hematopoietic cells within the bone marrow, is defined by the presence of neoplastic blood cells in the peripheral blood, or bone marrow, and is classified broadly into myeloid neoplasms and lymphoproliferative disorders. The diagnosis of these disorders is established based on finding characteristic cells in the blood or bone marrow and associated hematologic abnormalities. Specific cell types are identified by their morphologic appearance in Wright-stained blood and bone marrow films, cytochemical staining properties, electron microscopic appearance, and monoclonal antibody binding to surface antigens. In some cases, cells may appear so morphologically undifferentiated that classifying the disorder into either the myeloproliferative or the lymphoproliferative category may be difficult (Figure 16.1). Myeloid neoplasms include neoplastic proliferation of erythrocytes, granulocytes, monocytes, and megakaryocytes. Multiple cell lines may be neoplastic if the affected stem cell is multipotential; an example is myelomonocytic leukemia, in which both neutrophils and monocytes have been neoplastically transformed. Lymphoproliferative disorders include acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia (CLL), and multiple myeloma.

Leukemias are also classified according to the concentration of neoplastic cells that are circulating in the blood. With leukemic leukemias, many neoplastic cells are circulating, thereby resulting in a markedly increased nucleated cell count. In patients with subleukemic leukemias, however, the nucleated cell count is near normal, with only a few neoplastic cells circulating. No circulating cells are observed on blood films from patients with aleukemic leukemia. Establishing the diagnosis of leukemia when few or no cells are circulating usually is based on examination of the marrow aspirate.

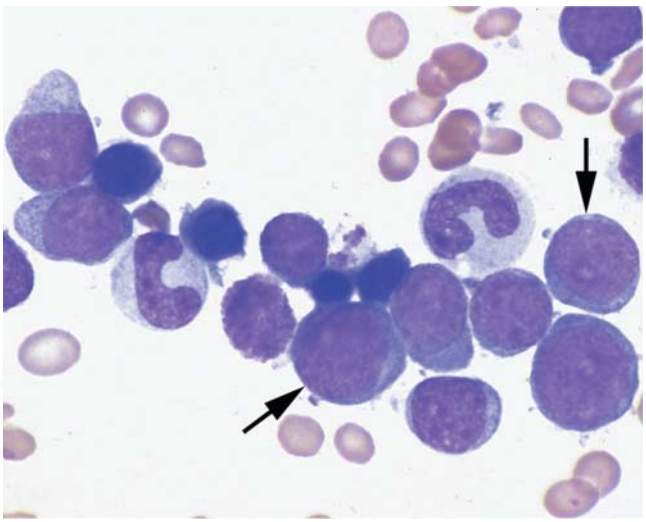

Figure 16.1 Bone marrow aspirate from a cat. Large undifferentiated cells (arrows) are difficult to classify based on their morphologic appearance. Cells may be lymphoblasts or type 1 myeloblasts. Wright stain.

Leukemias are also classified as either acute or chronic based primarily on the maturity or degree of neoplastic cell differentiation as well as by the clinical course. The neoplastic cells in acute leukemias are immature, often with an apparent nucleolus (blast), and the patient survival time usually is quite short. By definition, 20% or more blast cells in the marrow is diagnostic of acute myeloid leukemia (AML). The percentage of blast cells in the blood, however, is quite variable in these patients. Acute leukemias can be either myeloid (AML) or lymphoid (ALL), and neoplastic cells in most cases of acute leukemias express CD34, a marker for hematopoietic stem/precursor cells that also functions in cell migration. See Chapter 14 for discussion of CD (cluster of differentiation) protein expression on cell surfaces that identify various types of hematopoietic cells by using antibodies against those proteins. Both myeloid

and lymphoid acute leukemias occur most commonly in middle-aged dogs (median age is 7–8 years). Differentiating acute lymphoid from myeloid leukemia can be difficult and is based on morphology, expression of cell surface proteins, and cytochemistry. Some cells do not express cell-lineage proteins and remain unclassified. Chronic leukemias are characterized by the predominance of mature, more well-differentiated cells in the blood and marrow, and the patient survival time is longer. Neoplastic cells commonly can be found in organs other than the bone marrow in patients with leukemia. The spleen may be involved, and the liver and lymph nodes also may contain neoplastic cells (Figure 16.2).

Numerous genetic mutations have been identified in people with leukemia, and prognosis and therapy are often determined by the type of genetic mutation. Genetic mutations similar to those seen in people have been described in small numbers of dogs with lymphoid and myeloid leukemia, as well as in dogs with lymphoma. Several genes, including TRAF3 (tumor necrosis factor receptor associated factor 3), a negative and positive regulator of innate and adaptive immune responses, and POT1 (protection of telomeres protein 1), a telomere length regulator, are mutated in some cases of canine B cell lymphoma and may be involved in the pathogenesis. An excellent review of gene expression and mutational features of canine lymphoma and leukemia has been published [1]. The most recent version of the World Health Organization (WHO) classification system for human hematopoietic malignancies uses a combination of immunophenotyping, chromosomal aberrations, mutational analysis, and gene expression profiling to identify different types of leukemia.

In one study of 210 dogs with leukemia, 51 had ALL, 33 had AML, 61 had CLL, and 65 had grade V lymphoma with involvement of bone marrow [2]. Anemia, neutropenia, and thrombocytopenia were more common and severe in dogs with acute leukemias than in dogs with stage V lymphoma or chronic leukemias. Similar results were observed in a series of 64 dogs [3]. Twenty-five dogs had ALL, 22 had AML, and 17 had CLL. Golden retriever dogs in the study population were overrepresented in comparison with a control population of dogs. Various types of leukemias are discussed in more detail below.

Myeloid neoplasms

Myeloid neoplasms are cancers of hematopoietic cells, and are distinct from cancers of lymphoid cells. They manifest as either a lack of normal blood cells, or an increase in neoplastic cells in blood. While lymphoid leukemia may predominantly affect bone marrow, it is not referred to as a myeloid neoplasm. Myeloid neoplasms include cancers associated with both rapid and gradual disease progression. Percentage of blast cells in marrow is used to distinguish rapid (acute) from gradual (chronic). The rapidly progressing myeloid cancers are referred to as AMLs, and the myeloid cancers with more gradual progression are classified as either myelodysplastic syndromes (MDSs) or myeloproliferative neoplasms (MPN) (formerly termed "chronic leukemias").

Myelodysplastic syndromes

MDS is a variable manifestation with some subtle, morphologic changes in blood cells. The hematologic manifestations almost always involve some form of cytopenia, and this may include any single abnormality or combination of nonregenerative anemia, thrombocytopenia, and neutropenia. Cellularity of marrow is variable. The marrow may be hypocellular, of normal cellularity, or hypercellular, thereby making it difficult to distinguish this condition from a myeloproliferative disorder. Characteristic morphologic abnormalities include large, highly variable erythroid precursor size and dysynchrony of nuclear and cytoplasmic maturation events (Figure 16.3). The disturbed erythroid production in cats commonly leads to establishment of marked macrocytosis and increased erythrocyte volume heterogeneity (i.e., anisocytosis) seen as a widening of the erythrocyte histogram. Cats that are positive for feline leukemia virus (FeLV) infection may have mean red cell volumes of 70 fL or greater (reference interval, 40–55 fL) and macrocytic anemias have also been associated with feline immunodeficiency virus (FIV). Macrocytosis also has been reported in dogs with myelodysplasia. Other features in blood may include extreme platelet macrocytosis

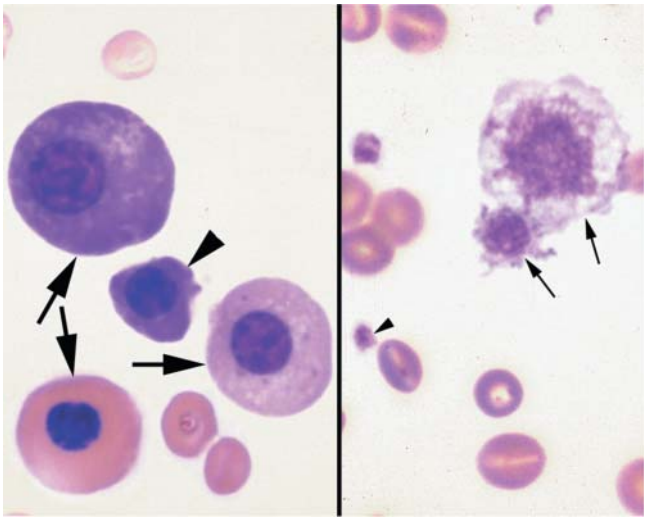

Figure 16.3 Left. Bone marrow aspirate from a cat with myelodysplasia. Note the three rubricytes with dysynchrony of nuclear and cytoplasmic maturation (arrows) and the more normal-appearing metarubricyte (arrowhead). Right. Blood film from a cat with myelodysplasia. Note the giant atypical platelets (small arrows) and the normal-appearing platelet (small arrowhead). Wright stain.

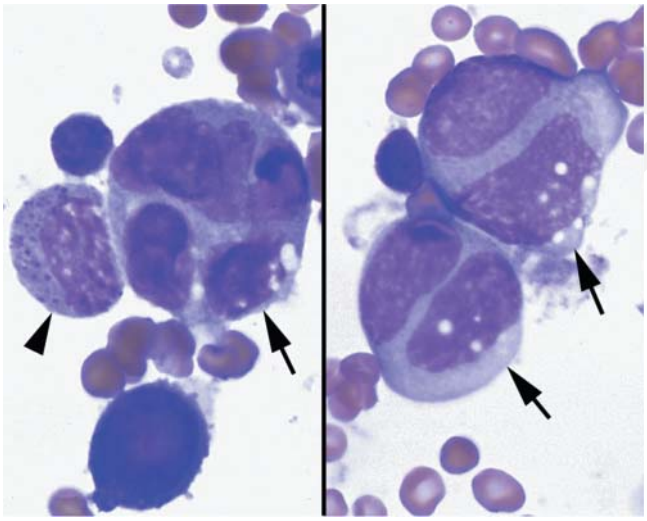

Figure 16.4 Left. Bone marrow aspirate from a cat with myelodysplasia. Note the dysplastic megakaryocyte (arrow) and the granulocytic precursor with retained primary granules (arrowhead). Right. Dysplastic megakaryocytes with hypolobulation of the nuclei (arrows). Wright stain.

(Figure 16.3). Megakaryocyte differentiation may be altered as well, with both hypo- and hyperlobulation of nuclei (Figure 16.4). Neutrophils of unusually large diameter may be observed, with nuclear changes that may include both hyper- and hyposegmentation (Figure 16.5). Very early precursors are not found in blood.

Several prognostic scoring systems based on number of bone marrow blast cells, cytogenetic findings, number of hematopoietic lines affected by cytopenia, and transfusion

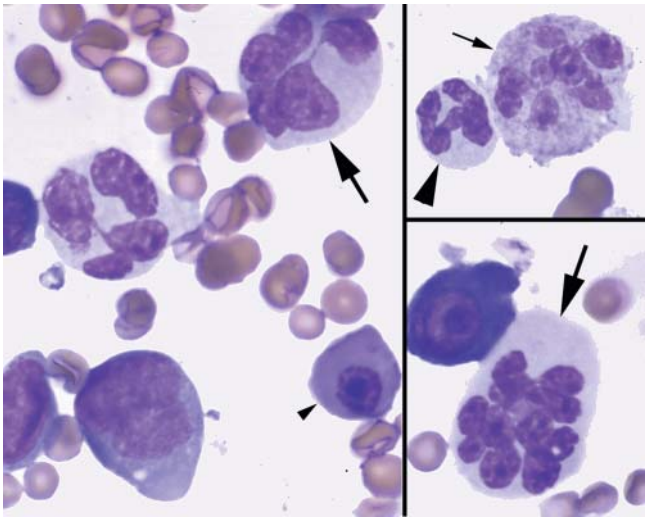

Figure 16.5 Bone marrow aspirate from a cat with myelodysplasia. Left and lower right. Note the giant hypersegmented neutrophils (arrows) and megaloblastic erythrocyte precursor (small arrow head). Upper right. Note the giant hypersegmented neutrophil (small arrow) and the neutrophil of normal size (large arrowhead). Wright stain.

dependence have been developed for use in humans with MDS. Classification schemes used for animals are quite simple in comparison. The Animal Leukemia Study Group in 1991 recommended two MDS categories: MDS (M:E >1.0) and MDS-erythroid (M:E <1.0). Since that time, recommendations for three subtypes have been made: (i) myelodysplastic syndrome with excess blasts (MDS-EB) has blast cell percentages in marrow that are equal to or greater than 5% but less than 20%; (ii) myelodysplastic syndrome with refractory cytopenia (MDS-RC), which has blast cell counts of less than 5%, can have an indolent course; (iii) MDS-ER (M:E ratio <1.0), which has a poor prognosis and short survival time. In general, high blast percentages (>5%) multiple cytopenias, and marked morphologic atypia are usually considered negative prognostic markers.

Other differential diagnoses for hypercellular marrow and cytopenias include the recovery stage of marrow damage, such as might be seen with parvovirus infection; immune-mediated disease, with destruction of more mature cells; and consumption of neutrophils due to an overwhelming inflammatory process.

MDSs have been reported in cats, dogs and one horse. Miniature dachshunds appear to have a higher incidence of myelodysplasia than do other breeds. Cats with myelodysplasia are commonly positive for FeLV. FIV has also been associated with myelodysplasia and is referred to as FIV-myelopathy. Clinical signs usually include lethargy, anorexia, and weight loss. Animals may die within weeks of diagnosis, without progression to leukemia, but overt leukemia is a common sequela. In a retrospective study of 152 bone marrow aspirates in cats that were performed for cytopenias or suspected leukemia, 15% were diagnosed with MDS.

Overview of acute myeloid leukemias and myeloproliferative neoplasms

AML is a neoplasm of hematopoietic cells resulting in rapid progression of disease. MPN comprise various types of clonal neoplastic conditions of hematopoietic tissue characterized by gradual disease progression. In general, these neoplasms are characterized by bone marrow hypercellularity, loss of orderliness in maturation, and a tendency for neoplastic cells to be released into the blood. Myeloid neoplasms are more common in cats than in other domestic animals and, as mentioned, usually are associated with FeLV infection. Hematopoietic precursors are infected by FeLV, and viral proteins are thought to interact with host cell products that are important in cell proliferation, resulting in recombination or rearrangement events involving host gene sequences that encode products involved in the normal regulation of cell growth. FIV also appears to be associated with stem cell disorders of cats, although FIV does not directly infect myeloid or erythroid precursors. The mechanism probably relates to infection of other cells in the bone marrow microenvironment or to the virus or viral antigen affecting hematopoiesis in some way. Cats with FIV are approximately five times more likely to develop leukemia.

Clinical signs usually relate to the crowding out of normal hematopoietic cells in the bone marrow, but they may also result from the infiltration of different organs by neoplastic cells. Lethargy, weakness, pallor, bleeding, shifting leg lameness, and bone pain frequently are seen, as are hepatomegaly and splenomegaly. Typical CBC findings include an increased nucleated cell count, neoplastic cells in the peripheral blood, nonregenerative anemia, and thrombocytopenia, although thrombocytosis may be present, particularly in cats. Other abnormal laboratory findings are variable, depending on the type and degree of organ dysfunction.

The response of these disorders in dogs and cats to therapy usually is disappointing, and the prognosis is poor, particularly in animals with AML. Chemotherapeutic drugs may produce remissions of very short duration (usually only a few weeks). Types of recommended chemotherapy differ with the type of leukemia and the species. A veterinary oncologist should be consulted for advice on new protocols for therapy. Bone marrow transplantation offers the potential for a complete cure but is expensive and requires intensive care. Cats that are negative for FeLV and FIV and have a sibling that can serve as a marrow donor are reasonably good candidates for bone marrow transplantation. Animals with MPN have a longer survival time after the diagnosis is established, but they almost always eventually develop a terminal blast crisis and die.

Classification of acute myeloid leukemias (AMLs)

AML is morphologically and biologically variable. Most cases of AML in humans are associated with genetic abnormalities that affect myeloid cellular proliferation and maturation. Thus, cytogenetic analysis is a routine component of the diagnosis in people, and plays a significant role in treatment modality and prognosis. Traditionally, AMLs in domestic animals have been characterized as being granulocytic (i.e., myeloid, neutrophilic), myelomonocytic (i.e., neutrophils and monocytes), monocytic, eosinophilic, basophilic, megakaryocytic, erythroid, or erythroleukemia (i.e., erythrocytes and granulocytes). Diagnostic criteria have varied considerably, however, and agreement on nomenclature and classification of hematopoietic neoplasms has been lacking. In the 1970s, a group of French, American, and British (FAB) leukemia experts in human medicine divided AML into subtypes, M0 through M7, based on the type of cell the leukemia develops from and how mature the cells appear, primarily based on morphology of the leukemia cells with routine blood staining. Because of potential differences in response to various treatment protocols and prognosis, in 1991 an animal leukemia study group standardized the definitions for AMLs by using a human classification scheme based primarily on the number and morphology of blast cells in Wright-stained blood and bone marrow films. To classify a myeloproliferative or myelodysplastic disorder, 200 cells are differentiated to calculate an M:E ratio and to determine the percentages of blast and other cell types. Blast cell percentages in the bone marrow are calculated in relation to all nucleated cells as well as to nonerythroid cells. Lymphocytes, macrophages, mast cells, and plasma cells are excluded for all-nucleated-cell counts, and erythrocyte precursors are excluded for nonerythroid cell counts. At the time of this study, 30% blasts in the marrow was considered the lowest percentage that could be present and still diagnose AML. Our physician counterparts, in collaboration with oncologists, have since constructed a new WHO standard, which lowered the blast threshold from 30% to 20% for diagnosing AML. The AML alphanumeric designations (M1, M2, etc.) described below have been largely discontinued in humans as numbers of subtypes have increased. The veterinary system established in 1991 has also been revised to lower the blast threshold to 20%.

The most recent modification by the WHO in 2016 classifies AML into the following categories: (i) AML with genetic (gene or chromosome) abnormalities (of which at least 11 have been identified), (ii) AML with myelodysplasia-related changes, (iii) AML related to previous chemotherapy or radiation, (iv) AML not otherwise specified (NOS), (v) myeloid sarcoma, (vi) myeloid proliferations related to

Down syndrome, and (vii) undifferentiated and biphenotypic acute leukemias that are not strictly AML and have both lymphocytic and myeloid features, sometimes called mixed phenotype acute leukemias (MPALs). Subgroups of "AML not otherwise specified" is similar to the previous FAB classification and include AML with minimal differentiation (FAB M0), AML without maturation (FAB M1), AML with maturation (FAB M2), acute myelomonocytic leukemia (FAB M4), acute monoblastic/monocytic leukemia (FAB M5), pure erythroid leukemia (FAB M6), acute megakaryoblastic leukemia (FAB M7), acute basophilic leukemia, and acute panmyelosis with fibrosis AML that develops in cats with FeLV and is most similar to the human "AML with myelodysplasia-related changes," but most of the cases in domestic animals are comparable to "AML not otherwise categorized." The alphanumeric designations and blast threshold should be formally reassessed by veterinary clinical pathologists and oncologists as to their accuracy and usefulness. Prognosis in humans with AML is primarily based on types of chromosomal translocations, types of gene mutations, cell marker expression, age, leukocyte concentration, presence of infection, prior diagnosis of myelodysplasia, and if leukemic cells have invaded the central nervous system.

Cytochemical stains that can identify myeloid-associated enzymes such as alkaline phosphatase and chloroacetate esterase, and immunophenotyping, as discussed earlier, may be useful adjuncts in the classification of leukemia (Figures 16.6 and 16.7). Flow cytometry can be used to identify surface antigens typical of myeloid origin such CD11b, CD11c, and CD14. Cells of myeloid origin do not express T or B cell markers. The clinical relevance of cytomorphologic, cytochemical, and immunophenotypic characterization of acute myeloproliferative diseases in animals remains to be determined, although given the importance of karyotyping in human AML, prognostically significant chromosomal abnormalities are likely present in animals with AML. Moreover, the classification of leukemia in a patient, especially cats with FeLV, may change as the disease progresses; for example, red cell leukemia may convert to erythroleukemia or acute myelogenous leukemia. A classification scheme showing historically used terminology, current terminology, and a summary of bone marrow findings is presented in Table 16.1.

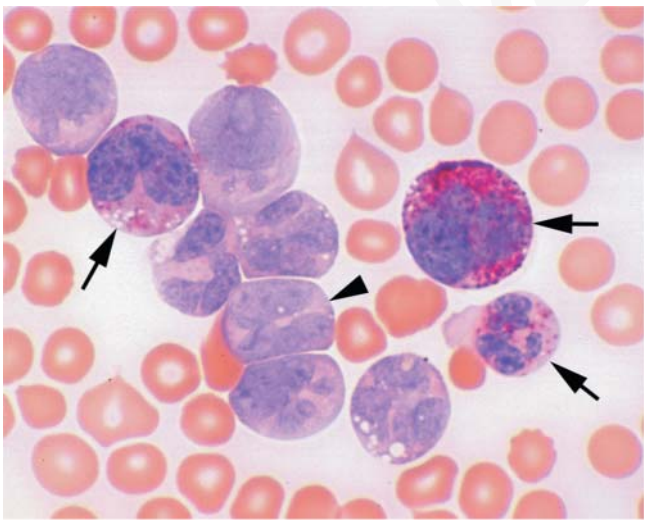

Figure 16.6 Blood film from a dog with myelomonocytic leukemia (M4) stained with chloracetate esterase (CAE), a granulocyte marker. Note the metamyelocyte and neutrophil with red-staining granules in the cytoplasm (arrows). Several monocytes (arrowhead) are present that do not stain positive with CAE. Source: Specimen courtesy of Dr. Wendy Sprague, Colorado State University.

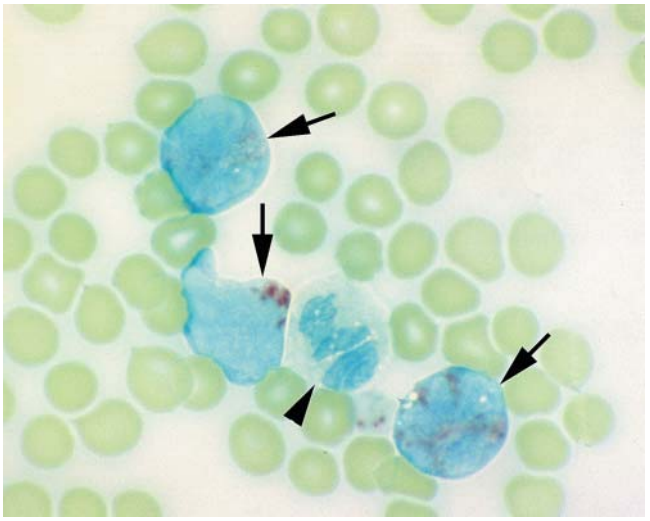

Figure 16.7 Blood film from dog with myelomonocytic leukemia (M4) stained with α-naphthyl butyrate esterase (ANBE), a monocyte marker. Note the brown-staining granules in the monocytes (arrows) and the neutrophil (arrowhead) that does not stain with ANBE. Source: Specimen courtesy of Dr. Wendy Sprague, Colorado State University.

Undifferentiated leukemia (M0)

The diagnosis of undifferentiated leukemia is established when approximately 100% of the cells in the bone marrow are blast cells that cannot be properly classified according to the usual morphologic and cytochemical criteria. The diagnosis can be based on electron microscopy, ultrastructural cytochemistry, or immunophenotyping. Included in this category are cases of what previously were termed reticuloendotheliosis in cats, in which a predominance of blast cells have pseudopodia, eccentric nuclei, and sometimes, features of both erythroblasts and myeloblasts (Figures 16.8 and 16.9). Some cells may contain azurophilic granules. If the neoplastic cells do not appear to be maturing toward erythroid or myeloid cells, they are categorized as being undifferentiated.

Table 16.1 Classification of leukemias.

Historical terminology	FAB	Description
Acute leukemias (≥20% blasts in marrow)		
Reticuloendotheliosis	AUL	Acute undifferentiated leukemia, myeloid and erythroid features
Granulocytic leukemia	M1	Myeloblastic leukemia with differentiation
Granulocytic leukemia	M2	Myeloblastic leukemia with neutrophilic differentiation
Myelomonocytic leukemia	M4	Combination of myeloblasts and monoblasts
Monocytic leukemia	M5a	Monocytic leukemia without differentiation
Monocytic leukemia	M5b	Monocytic leukemia with differentiation
Erythroleukemia	M6	Combination of myeloblasts and rubriblasts
Erythremic myelosis	M6Er	Erythroid leukemia
Megakaryoblastic leukemia	M7	Increased megakaryoblasts in blood and marrow
Chronic myeloid leukemias (<20% blasts in marrow)		
Chronic granulocytic leukemia		Mature neutrophilia, left shift, similar to granulocytic hyperplasia
Chronic myelomonocytic leukemia		Combination of mature neutrophilia, left shift, and monocytosis
Chronic monocytic leukemia		Mature monocytosis in blood and bone marrow
Chronic eosinophilic leukemia		Eosinophilia with left shift, basophilic predominance in marrow
Chronic basophilic leukemia		Basophilia with left shift, basophilic predominance in marrow
Essential thrombocythemia		Marked increase in platelets, megakaryocytic hyperplasia in marrow
Polycythemia vera (erythrocytosis)		Mature erythroid proliferative disorder, erythroid hyperplasia
Lymphoid leukemia		
Acute lymphoblastic leukemia		Lymphoblasts in blood or bone marrow
Chronic lymphocytic leukemia		Lymphocytosis, >30% lymphocytes in marrow

FAB, French-American-British.

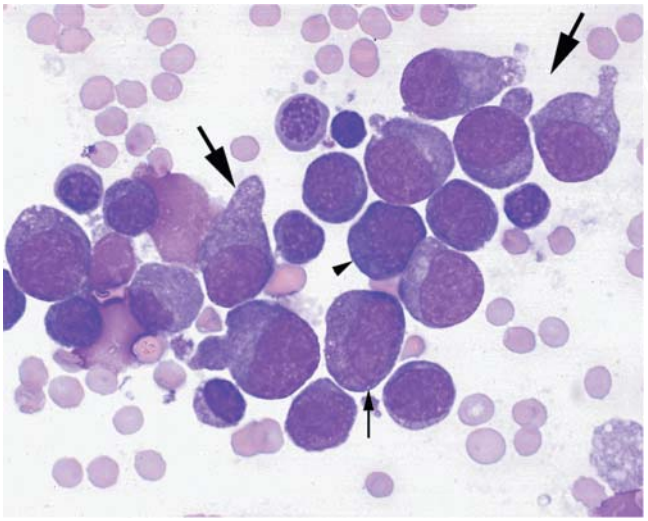

Figure 16.8 Bone marrow aspirate from a cat with undifferentiated leukemia. The cells have features of both erythroid and myeloid precursors. Cytoplasmic pseudopodia (large arrows) typically are present. Note the cell with obvious erythroid characteristics (arrowhead) and the cell with myeloid features and primary granules (small arrow). Wright stain.

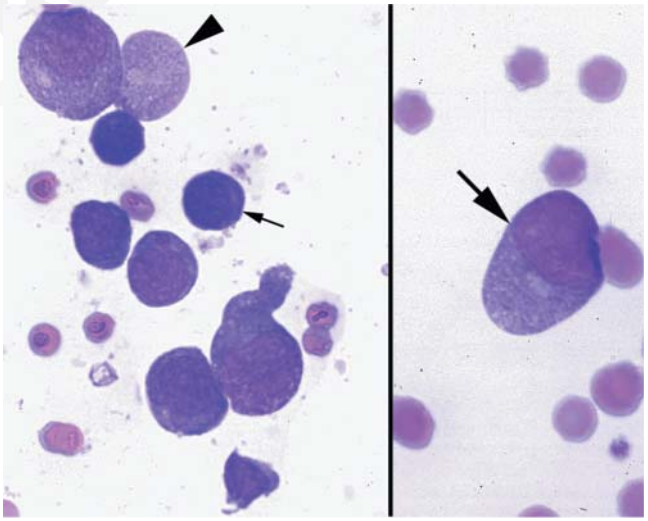

Figure 16.9 Left. Bone marrow aspirate from a cat with undifferentiated leukemia. Note the cytoplasmic pseudopodia that has detached from the cell (arrowhead). When present in blood, these cytoplasmic fragments may be mistaken for platelets. Note the rubricyte (small arrow) as well. Right. Blood film from a cat with undifferentiated leukemia. Note the typical undifferentiated cell with primary granules and an eccentric nucleus (large arrow). Wright stain.

Myeloblastic leukemia (M1)

The predominant cell in the bone marrow in animals with myeloblastic leukemia is the type I myeloblast; type II myeloblasts are only seen infrequently (Figure 16.10). Both types of blasts comprise more than 90% of all nucleated cells. Differentiated granulocytes (promyelocytes to neutrophils and eosinophils) comprise less than 10% of the nonerythroid cells.

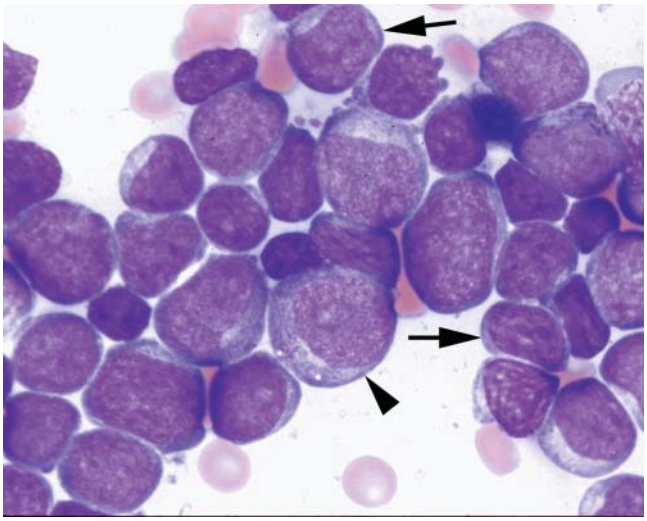

Figure 16.10 Bone marrow aspirate from a dog with granulocytic (myeloblastic) leukemia (M1). Almost all of the cells present are type 1 myeloblasts (arrows). A type II myeloblast with cytoplasmic primary granules (arrowhead) is present as well. Type I myeloblasts are morphologically similar to lymphoblasts, and without the presence of more differentiated cells, immunophenotyping may be necessary to correctly classify the leukemia. Wright stain.

Myeloblastic leukemia with maturation (M2)

Myeloblasts constitute from more than 20% to less than 90% of all nucleated cells, with a variable number of type II myeloblasts being present (Figures 16.11 and 16.12). Differentiated granulocytes comprise more than 10% of the nonerythroid cells, usually with a predominance of promyelocytes.

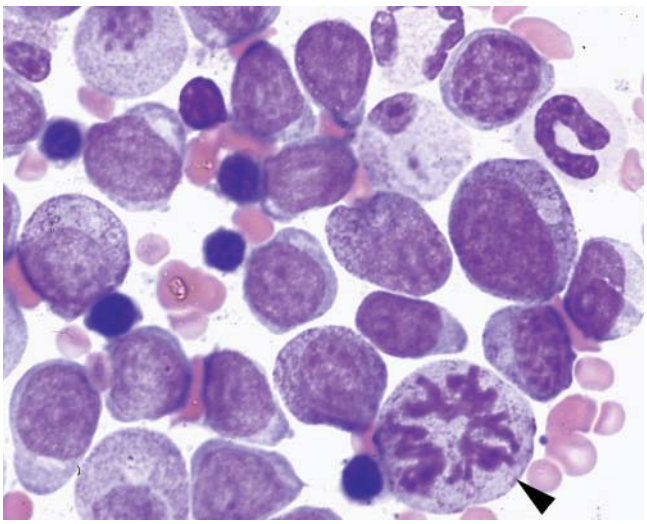

Figure 16.11 Bone marrow aspirate from a cat with granulocytic (myeloblastic) leukemia (M2). Numerous type II myeloblasts with cytoplasmic granules are present, as is a cell in mitosis (arrowhead). Note that cells are more differentiated than those seen in marrow aspirates of patients with M1. Wright stain.

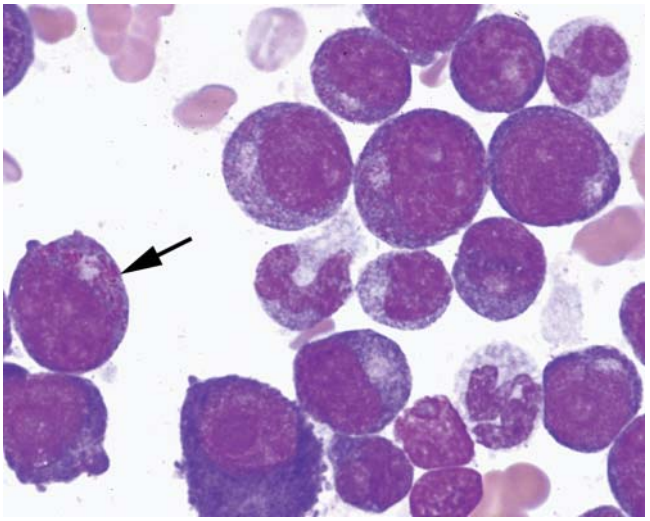

Figure 16.12 Bone marrow aspirate from a cat with granulocytic (myeloblastic) leukemia (M2). Note that most of the cells present are type II myeloblasts or progranulocytes (arrow). Most of these cells have clear Golgi areas. A few more differentiated myeloid precursors are present as well. Wright stain.

Myeloblastic leukemia with maturation and atypical granulation of promyelocytes (M3)

Although myeloblastic leukemia with maturation and atypical granulation of promyelocytes is one of the classifications for human leukemia, no such cases have been reported in domestic animals. This type of myeloblastic leukemia is characterized by either hypergranular, hypogranular, or microgranular promyelocytes with folded, reniform, or bilobed nuclei.

Myelomonocytic leukemia (M4)

Myeloblasts and monoblasts together constitute more than 20% of all nucleated cells, and differentiated granulocytes and monocytes comprise more than 20% nonerythroid cells (Figures 16.13 and 16.14).

Monocytic Leukemia (M5)

The predominant population is monocytic, as determined by the characteristic nuclear morphology and confirmed by cytochemical staining for nonspecific esterase. Monoblasts and promonocytes constitute more than 80% of nonerythroid cells in M5a (Figures 16.15 and 16.16), while M5b has more than 20% to less than 80% monoblasts and promonocytes with prominent differentiation to monocytes (Figures 16.17 and 16.18). The granulocytic component is less than 20%.

Erythroleukemia (M6)

The erythroid compartment in M6 is more than 50%, and the myeloblasts and monoblasts combined are less than 20% of all nucleated cells. The M6 classification is recognized

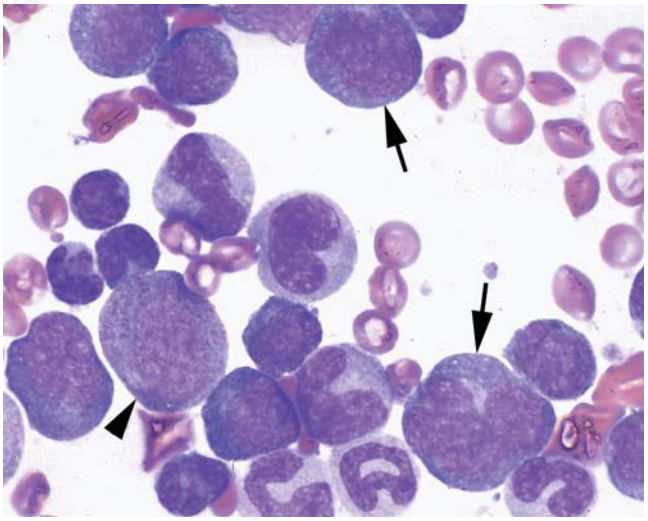

Figure 16.13 Bone marrow aspirate from a dog with myelomonocytic leukemia (M4). Both monocyte precursors (arrows) and myeloid precursors (arrowhead) are present. Wright stain.

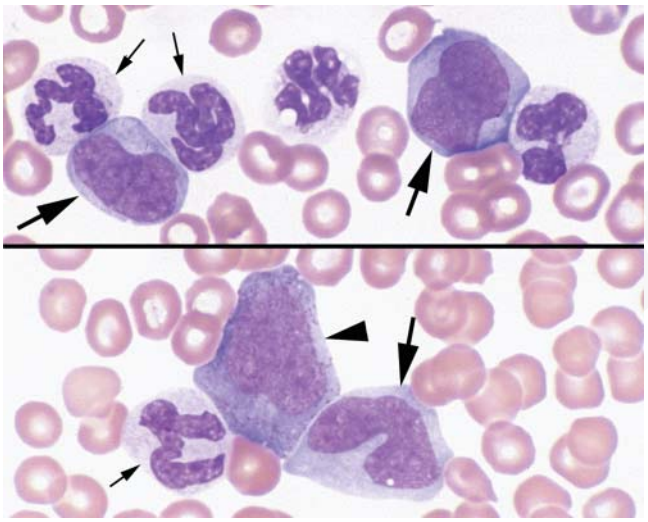

Figure 16.14 Blood film from a dog with myelomonocytic leukemia (M4). Top. Note the monoblasts (large arrows) and normal-appearing, segmented neutrophils (small arrows). Bottom. Note the segmented neutrophil (small arrow), monocyte (large arrow), and type II myeloblast (arrowhead). Wright stain.

when either of the following criteria are met: myeloblasts and monoblasts constitute more than 20% of nonerythroid cells, or blast cells (including rubriblasts) constitute more than 20% of all nucleated cells. An M6Er designation is used to define the latter situation when there is a predominance of rubriblasts in the erythroid component. Myeloproliferative disorders of erythroid precursors may fall under the designation of M6Er or MDS-Er, because the erythroid component constitutes more than 50% of all nucleated cells and the blast cell concentration, (including rubriblasts) may

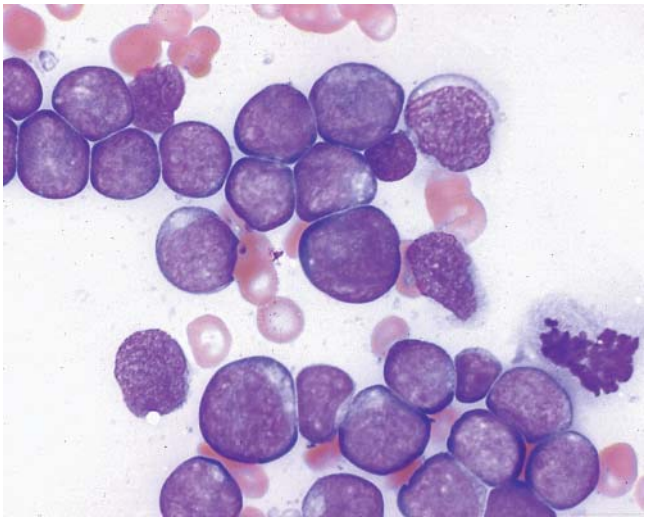

Figure 16.15 Bone marrow aspirate from a dog with monocytic leukemia (M5a). Almost all of the cells present are undifferentiated monoblasts. These cells appear to be morphologically similar to lymphoblasts and type I myeloblasts, but immunophenotyping and cytochemistry determined this was a very undifferentiated type of monocytic leukemia. Wright stain.

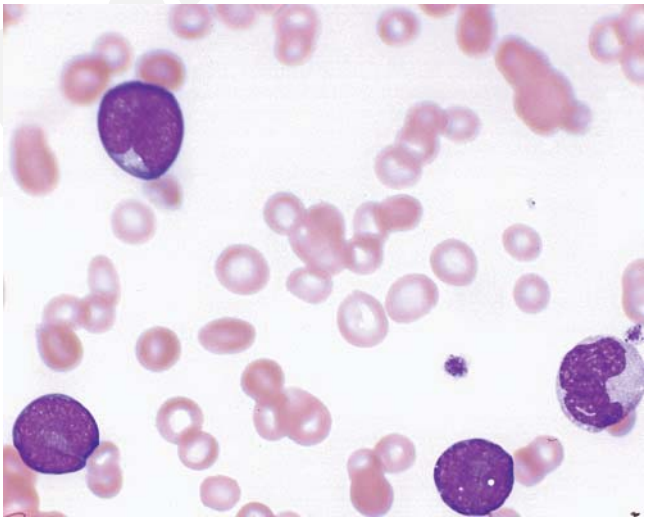

Figure 16.16 Blood film from a dog with monocytic leukemia (M5a). Cells were classified as monoblasts based on the presence of other cells that appeared to be differentiating to monocytes as well as on the results of cytochemical analysis and immunophenotyping. Wright stain.

constitute more than 20% (i.e., M6ER) or less than 20% (i.e., MDS-Er) (Figures 16.19 and 16.20).

Megakaryoblastic leukemia (M7)

More than 20% of all nucleated cells or nonerythroid cells is comprised of megakaryoblasts in the M7 stage. An increased concentration of megakaryocytes may be present as well, and megakaryoblasts usually are detected

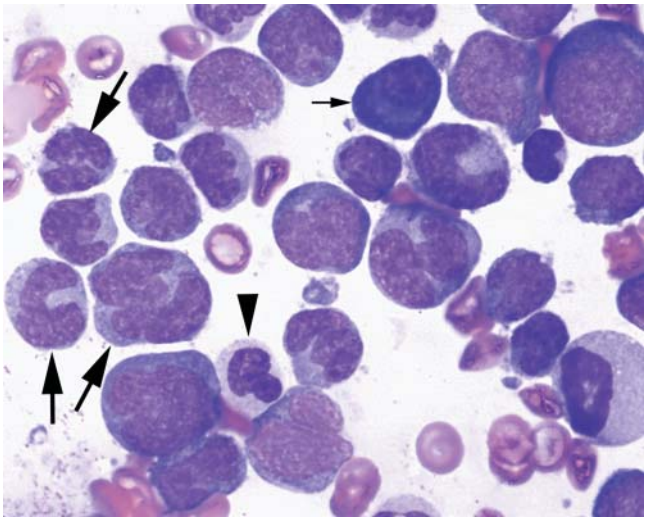

Figure 16.17 Bone marrow aspirate from a dog with monocytic leukemia (M5b). Note the numerous monocytes in various stages of maturation (large arrows), the segmented neutrophil (arrowhead), and the plasma cell (small arrow). Wright stain.

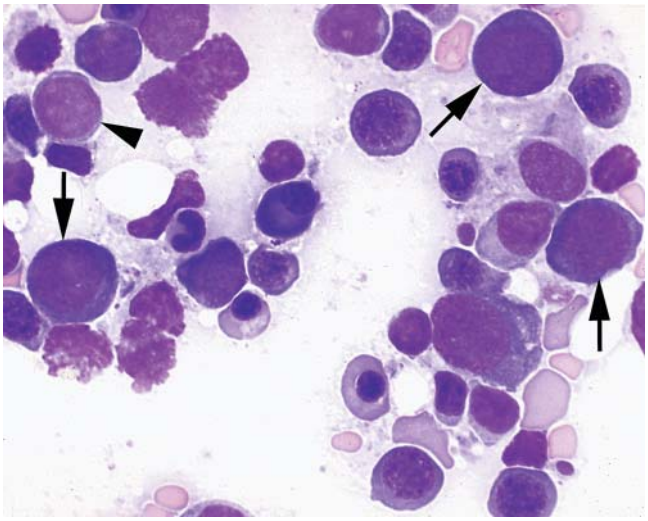

Figure 16.19 Bone marrow aspirate from a cat with erythremic myelosis (M6Er). Almost all of the cells present are erythroid precursors. Note the rubriblasts (large arrows) and the nonerythroid blast (arrowhead), which probably is a myeloblast. Wright stain.

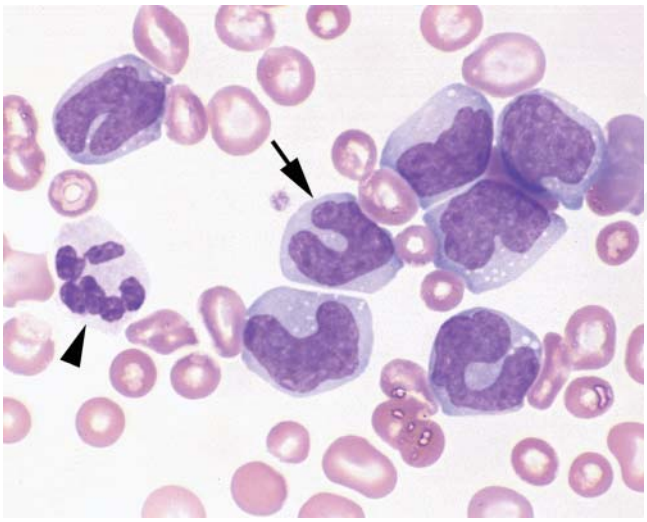

Figure 16.18 Blood film from a dog with monocytic leukemia (M5b). Note the numerous monocytes (large arrow), and compare the blue color of the cytoplasm and density of the nuclear chromatin with that of a segmented neutrophil, which has more dense nuclear chromatin and pink cytoplasm (arrowhead). Wright stain.

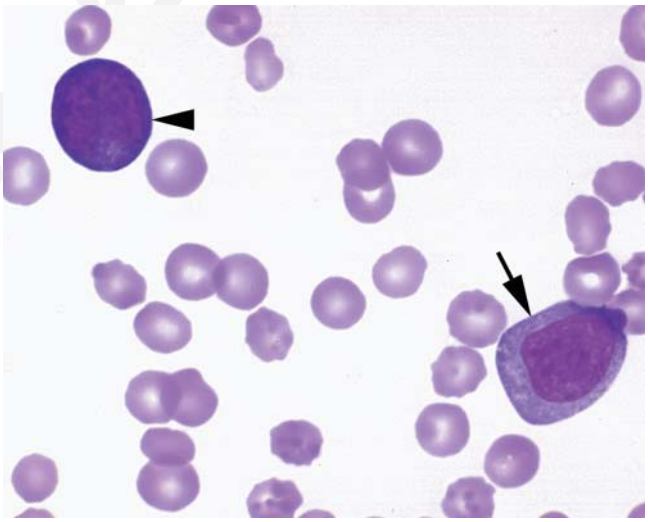

Figure 16.20 Blood film from a dog with erythroleukemia (M6). Note the rubriblast (arrowhead) and myeloblast (arrow). Also note the typical lack of polychromasia, because the erythroid precursors do not mature normally. Wright stain.

in the blood (Figure 16.21). Animals often are thrombocytopenic, although thrombocytosis has been reported. Immunohistochemical techniques to detect reactivity for factor VIII–related antigen and platelet glycoprotein IIIa sometimes are necessary to definitively identify megakaryoblasts. Primitive megakaryoblasts may also stain positive for acetylcholine esterase, a specific cytochemical marker for this cell line. This leukemia is rare in animals. While most cases of AML are rapidly fatal in domestic animals, one dog survived 2 years while being treated with chemotherapy for acute megakaryoblastic leukemia.

Dendritic cell leukemia

Dendritic cell leukemia has been reported in one dog with what appeared to be disseminated malignant histiocytosis. The cells appeared similar to histiocytes and flow cytometry of the abnormal circulating cells revealed CD1c, CD11c, and major histocompatibility complex (MHC) Class II expression without expression of CD11d or lymphoid markers, consistent with myeloid dendritic antigen-presenting cells.

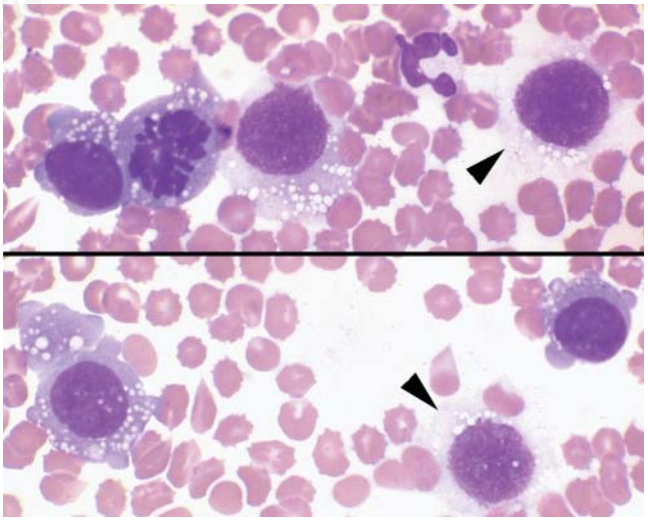

Figure 16.21 Blood film from a dog with megakaryoblastic leukemia (M7). Top. Note the numerous megakaryoblasts (arrowhead), one of which is in mitosis. Also note the abundant vacuolated cytoplasm with ruffled borders. Bottom. Note the broken megakaryoblast (arrowhead). Wright stain.

Chronic myeloproliferative neoplasms

Myelopoliferative neoplasms in people are classified as chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), polycythemia vera (PV), essential thrombocythemia (ET), primary myelofibrosis (PMF), chronic eosinophilic leukemia (CEL) and CEL not otherwise specified (CEL, NOS), mastocytosis, and myeloproliferative neoplasm unclassifiable (MPN, U). The phenotypic diversity among these neoplasms is attributable to various chromosomal translocations and genetic mutations. Best characterized and first discovered among these mutations is a gene mutation that codes for a tyrosine kinase with increased enzymatic activity, resulting from a translocation between chromosomes 9 and 20 called the Philadelphia chromosome that is associated with CML, which is often treated successfully. Other mutations have been discovered for most of the other types of MPN. CML in people is a clonal stem cell disorder with proliferations involving several or all of the hematopoietic cell lineages, and is characterized by neutrophilia, basophilia, and eosinophilia. CNL in people is rare, and characterized by a marked leukocytosis composed of segmented neutrophils and band forms. Polycythemia and essential thrombocythemia have a relatively indolent course that results in a slight decrease in lifespan. Polycythemia in people may transform to AML. PMF is characterized by proliferation of megakaryocytes and granulocytic precursors, with progressive myelofibrosis. CEL and CEL, NOS result in persistent blood, bone marrow and tissue eosinophilia and must be distinguished from hypereosinophilia. Mastocytosis in people results from clonal expansion of mast cells, and is divided into localized or diffuse cutaneous mastocytosis, and systemic mastocytosis with variable involvement of bone marrow. Systemic mastocytosis has three possible manifestations: accumulations of mast cells in lymph nodes, spleen, liver, and GI tract with an indolent course; mast cell leukemia with a rapid course, and mast cell sarcoma with development of mast cell leukemia. Most of the unclassifiable MPN are early stages of other types of MPN that have not developed diagnostic features. This section presents a brief discussion of these relatively rare disorders in animals. Polycythemia vera, a chronic myeloproliferative disorder of erythrocytes, is discussed in Chapter 10.

In animals, the diagnosis is usually based on clinical and morphologic features. Cells are usually relatively normal to mildly dysplastic. CMLs can be difficult to distinguish from hyperplasia as a result of inflammation, and in the case of polycythemia vera, must be distinguished from other causes of erythrocytosis.

Chronic granulocytic (myelogenous) leukemia

The disorder that has been historically described in dogs and cats as CML more closely resembles human CNL, as neutrophilia predominates, and there is usually an absence of eosinophilia and basophilia. The morphologic equivalent of human CML has not been described in detail in animals. These chronic leukemias are rare in domestic animals and are characterized by marked neutrophilia, a left shift that often is disorderly, and anemia. A monocytosis may be present as well. CML has been reported more frequently in dogs than in cats. Dysgranulopoiesis may be present and include hypersegmented nuclei and giant metamyelocytes

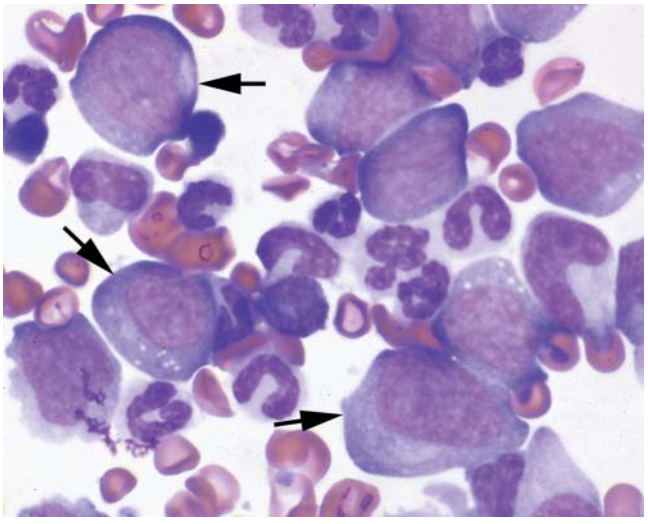

Figure 16.22 Bone marrow aspirate from a dog with chronic myelogenous leukemia. Note the increased concentration of myeloblasts (arrows). Although some degree of maturation to segmented neutrophils is occurring, the maturation appears to be disorderly. Very few erythroid precursors were present in the marrow, and none are present in this field. Wright stain.

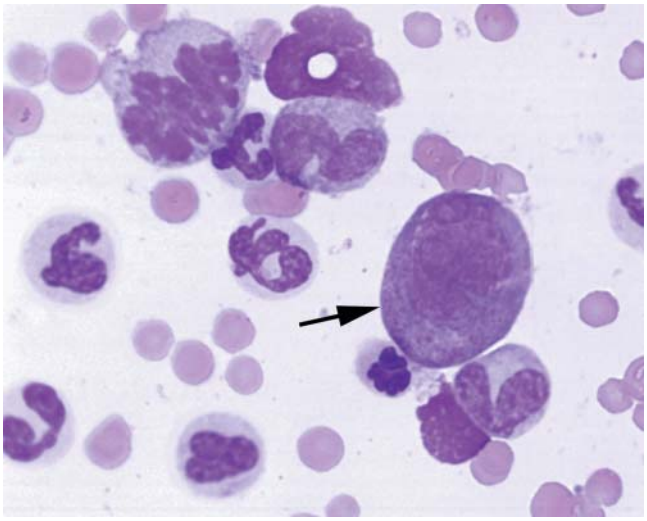

Figure 16.23 Blood film from a dog with chronic myelogenous leukemia in blast crisis. Note the cell in mitosis (upper left corner) and the myeloblast (arrow). The nucleated cell concentration in this dog was 150,000 cells/μL^{-1}. Wright stain.

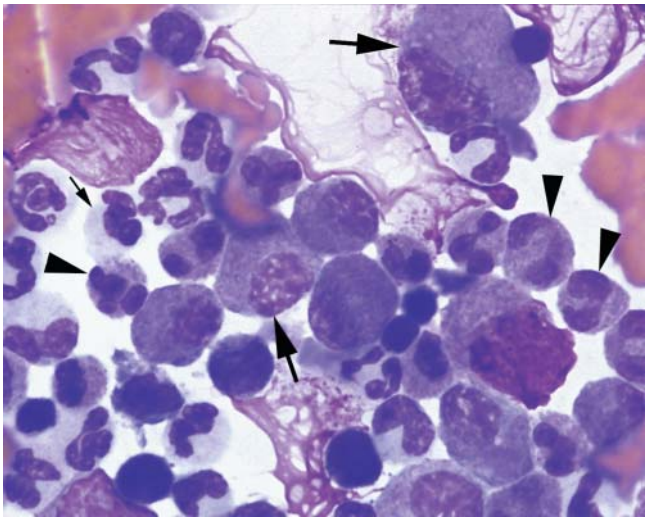

Figure 16.24 Bone marrow aspirate from a cat with eosinophilic leukemia or hypereosinophilic syndrome. Note the eosinophil precursors (large arrows) and the numerous, mature eosinophils (arrowheads). For comparison, note the neutrophil (small arrow). Wright stain. Source: Specimen courtesy of Antech Diagnostics.

and bands (Figure 16.22). These leukemias, however, can be differentiated from MDS by the marked leukocytosis in the blood. Inflammatory responses can mimic MPN, and such "leukemoid reactions" often are misdiagnosed as leukemias. Marrow examination may not be helpful in distinguishing the two, because marked inflammatory leukograms can be associated with marked granulocytic hyperplasia and a pronounced increase in the M : E ratio and the orderliness of maturation may be disrupted. Histopathologic evaluation of the spleen and liver is not always helpful, because these organs may exhibit marked granulopoiesis with some types of inflammatory disease. Animals with MPN usually eventually develop a disorderly left shift, and have a "blast crisis," during which myeloblasts appear in the blood (Figure 16.23). Animals with MPN also usually develop much more severe anemia than animals with inflammatory disease.

Differential diagnoses for a marked neutrophilia >50,000/μL and occasionally >100,000/μL include paraneoplastic responses, leukocyte adhesion deficiency (LAD), granulocyte-colony stimulating factor administration, infection with *Hepatozoon americanum*, and inflammation secondary to infections or immune mediated disease. LAD has been described in people, dogs, cats, and cattle. LAD is an autosomal recessive disorder caused by mutations in the integrin beta-2 subunit (ITGB2) gene resulting in a deficiency of the leukocyte integrin that is expressed on all leukocyte surface membranes, mediate strong neutrophil adhesion, and serve as co- receptors for activation of T-lymphocyte proliferation. The disorder results in chronic and overwhelming infections and poor wound healing. Affected animals are often young, since they may die before adulthood unless treated with antibiotics. They have a persistent marked mature neutrophilia; increased immature neutrophil concentration is not usually observed. Neutrophils may be hypersegmented due to aging within the circulation. Monocytosis and lymphocytosis may also be observed.

Eosinophilic leukemia

Eosinophilic leukemia is rare but has been reported primarily in FeLV-negative cats. It is characterized by eosinophilia, immature eosinophils in the blood, eosinophil predominance in the marrow (Figure 16.24), and infiltration of various organs with eosinophils. This disorder is difficult to differentiate from feline hypereosinophilic syndrome, in which the same characteristics can be seen, although the eosinophilic left shift may be more orderly with hypereosinophilic syndrome. Intestinal involvement is typical as well. Recent reports are suggestive that the separation between the two disorders may be artificial, and that they both may represent a neoplastic proliferation of eosinophils. Clinical signs are similar to those seen in animals with other myeloproliferative disorders. Typically, however, they also include thickened bowel loops, diarrhea, and vomiting, because the intestine usually is infiltrated. Most cats die within 6 months of the diagnosis being established, but hydroxyurea in combination with prednisone may prolong survival.

Chronic basophilic leukemia

Chronic basophilic leukemia is very rare but has been reported in dogs, cats, horses, and a calf. Abnormal blood findings include marked basophilia with an orderly left shift of the basophilic series, anemia, and occasionally thrombocytosis. Multiple organs usually are infiltrated. Chronic

basophilic leukemia must be differentiated from mast cell leukemia. Basophils have segmented nuclei, whereas mast cells have round nuclei. Basophilic myelocytes, however, may be difficult to differentiate from mast cells, and animals with systemic mast cell neoplasia may have a mild basophilia.

Essential thrombocythemia

Essential thrombocythemia is a very rare chronic myeloproliferative disorder that is characterized by a marked increase in the platelet concentration (>1,000,000). Platelets may appear atypical, with hypo- or hypergranularity, and giant forms may be present. The concentrations of megakaryocytes and megakaryoblasts usually are increased in the bone marrow as well. The platelet concentration may be increased secondary to many other disorders, such as iron deficiency anemia, inflammation, antineoplastic drug therapy, corticosteroids, and neoplasia (particularly lymphoma).

Lymphoproliferative disorders

Although the term lymphoproliferative disorder can be used to describe any abnormal proliferation of lymphoid cells, it more commonly is used to describe neoplastic proliferations. Tumors that derive from lymphocytes or plasma cells are classified as lymphoproliferative, or lymphoid neoplasms. Lymphoproliferative disorders are more common than myeloproliferative disorders in domestic animals. As with myeloproliferative disorders, cats with certain types of lymphoproliferative disorders usually test positive for FeLV, FIV, or both. Lymphoproliferative disorders generally are categorized as primary lymphoid leukemia, lymphoma, or plasma cell tumors, including multiple myeloma and solitary plasma cell tumors. In turn, the leukemias can be classified as either acute or chronic, as discussed earlier, and are termed ALL or CLL. Clonality testing using polymerase chain reaction for rearrangements in the complementarity-determining region 3 of the immunoglobulin heavy chain of B lymphocytes (B cell receptor) and the T cell receptor of T lymphocytes helps distinguish between clonal and nonclonal expansions of lymphocytes. Another way to determine if a population of lymphocytes is neoplastic is to show that they are all of the same phenotype (all B cells or all T cells) using monoclonal antibodies to cell surface proteins and flow cytometry (see Chapter 14). Interestingly, clonally rearranged T and B cell receptors can be seen in a high percentage of dogs with AML, suggesting that clonality testing alone should not be used to distinguish AML from ALL.

Lymphoid leukemia differs from malignant lymphoma primarily in the anatomic distribution. Solid neoplastic masses are present in lymphoma but are less common in patients with primary lymphoid leukemia. At least 10–25% of dogs and cats with lymphoma develop leukemia, however, and some investigators report that approximately 65% of dogs with multicentric lymphoma are leukemic at the time of presentation (if the determination of leukemia is based on the evaluation of blood, bone marrow aspirates, and marrow core biopsy specimens). Dogs with lymphoid leukemia also commonly have lymph node and spleen involvement. While lymphoid leukemia is usually defined as proliferation of neoplastic lymphoid cells in the bone marrow, they may originate in the spleen, and may or may not be circulating in the peripheral blood.

Acute lymphoblastic leukemia (ALL)

ALL is characterized by the presence of lymphoblasts in the blood and bone marrow (Figures 16.25–16.28). In both ALL and the leukemic phase of multicentric lymphoma (stage V), however, lymphoblasts can be found in the blood and bone marrow, thereby making these two disorders difficult to differentiate. A general rule is that if lymphadenopathy is not present, the disorder most likely is ALL rather than lymphoma. Approximately half of the dogs with ALL, however, also have lymphadenopathy. As with the myeloproliferative disorders, clinical signs relate either to a lack of normal hematopoietic cells or to the infiltration of organs by neoplastic cells. Common findings include pale mucous membranes, splenomegaly, and hepatomegaly, lethargy, and weight loss. Common CBC abnormalities include anemia, thrombocytopenia, lymphocytosis, and lymphoblasts in the blood.

Lymphoblasts usually can be differentiated from other types of immature cells based on their characteristic morphology, as described earlier. Occasionally, however, certain types of lymphoblasts (e.g., large granular lymphoblasts) may contain a few fine to coarse azurophilic granules (Figure 16.29). These cells may be difficult to distinguish from myeloblasts, in which case immunophenotyping (using

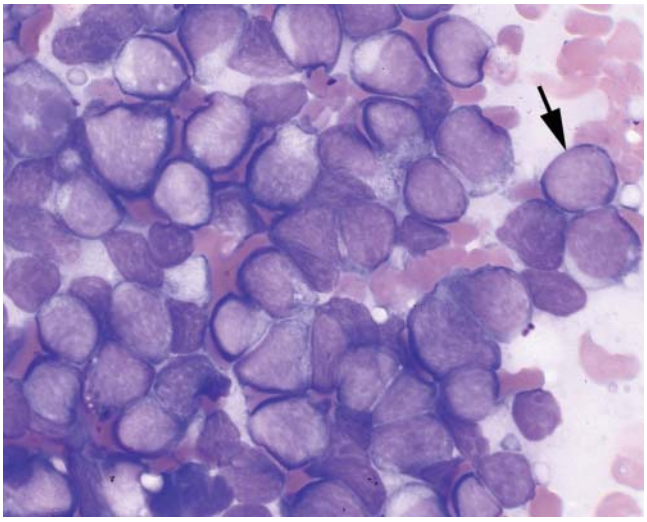

Figure 16.25 Bone marrow aspirate from a dog with acute lymphoblastic leukemia. Note that normal hematopoietic cells are absent, having been replaced by lymphoblasts (arrow). Wright stain.

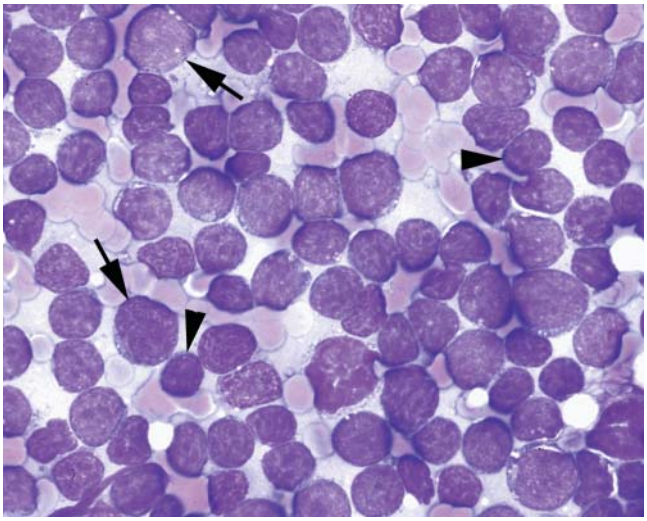

Figure 16.26 Bone marrow aspirate from a dog with acute lymphoblastic leukemia. Numerous intermediate-sized lymphoid cells are present and have completely replaced the normal marrow elements. Note the lymphoblasts (arrows) and lymphocytes (arrowheads). Wright stain.

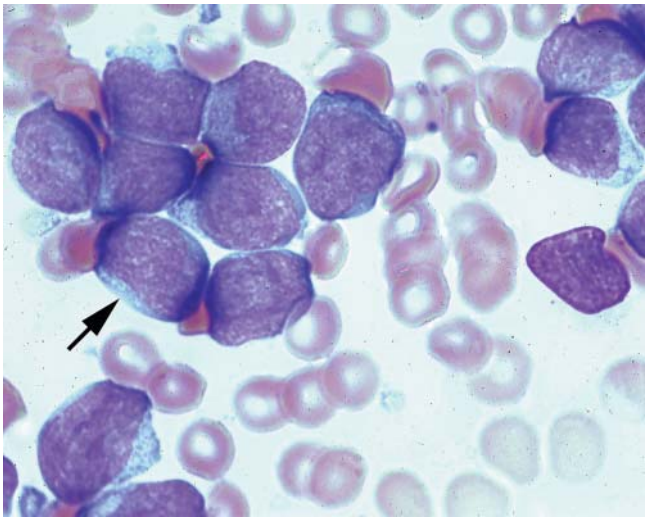

Figure 16.28 Blood film from a dog with acute lymphoblastic leukemia and a nucleated cell count of 300,000 cells/μL^{-1}. All of the cells present are lymphoblasts (arrow). Note the large size, high nucleus : cytoplasm ratio, and nucleoli with the nuclei. Wright stain.

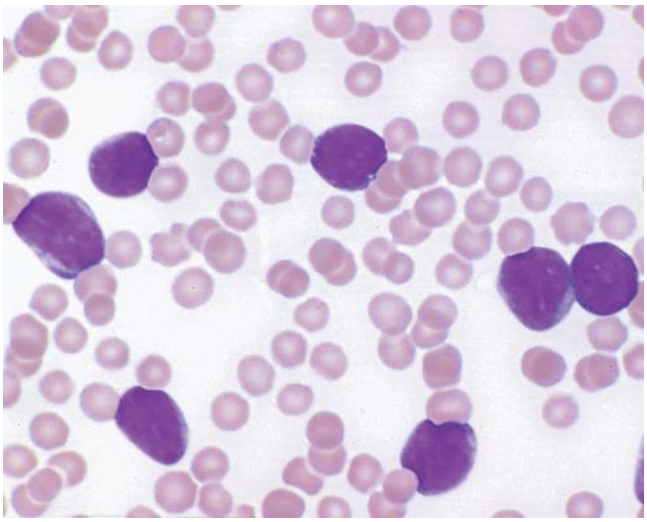

Figure 16.27 Blood film from a dog with acute lymphoblastic leukemia. Note the numerous large lymphoblasts. Wright stain.

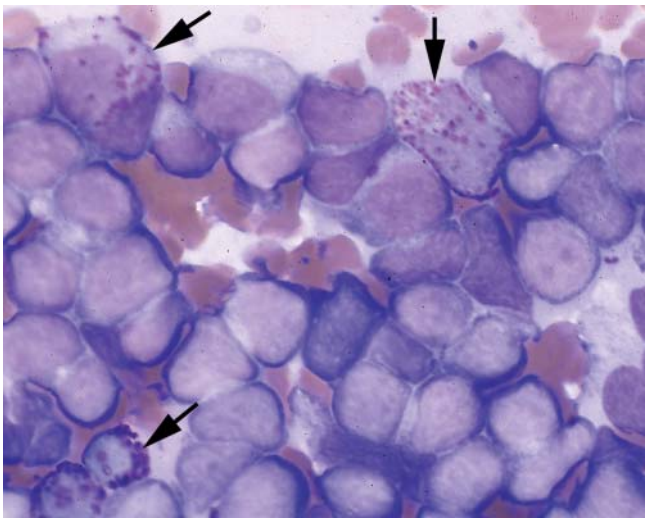

Figure 16.29 Bone marrow aspirate from a dog with lymphoblastic leukemia. Note the presence of a few cells with azurophilic granules within the cytoplasm (arrows), which are referred to as large granular lymphoblasts. These granules make this type of leukemia difficult to distinguish from M1 based on cell morphology alone. Wright stain.

monoclonal antibodies directed against proteins on the surface of leukocytes) may be very helpful. Large granular lymphocytes (LGL) leukemias of T cell origin are seen occasionally in cats with T cell lymphoma of the intestine (see Section VII, Case 13). Cytochemical reactions also may be helpful, because lymphoblasts typically are negative for most of the cytochemical stains except nonspecific esterase. Middle-aged to older dogs are usually affected. Cats are usually younger and FeLV positive. The majority of ALLs and leukemias associated with stage V lymphoma in dogs were thought to be of B cell origin, although one study found that the prevalence of B and T immunophenotypes in ALL and CLL was not statistically different [3]. Conversely, some authors are of the opinion that almost all cases of ALL are of T cell origin and that some cases were erroneously classified as B-ALL based on expression of CD79a, which does not have high lineage fidelity [1].

In a retrospective study of 50 dogs with ALL, the majority were of T cell lineage and approximately 1/3 had mediastinal lymphadenopathy. Age ranged from 2 to 14 years of age with a median of 7 years. Sixty-eight percent of

dogs were anemic, 86% were thrombocytopenic, 22% were markedly neutropenic, and the median leukemic cell count was 73,500/μL. Hypercalcemia was seen in six dogs, all of which had T cell leukemia [4].

Chemotherapy, usually involving a combination of vincristine, cyclophosphamide, and prednisone, may result in remission in approximately 1/3 of patients with ALL, although usually of very short duration. The clinical course is typically rapid and progressive. Improvement in survival times will require substantial advances in chemotherapy protocols and the use of more targeted therapeutic agents. In people with ALL, cytogenetic discoveries have led to targeted therapy against oncogenes that have dramatically improved survival times, and analogous discoveries in dogs and cats will likely lead to better outcomes.

Chronic lymphocyte leukemia (CLL)

CLL is much more common than ALL, and T-CLL is more common than B-CLL. In animals with CLL, the lymphocytes are small and appear well-differentiated (Figure 16.30). CLL is more common in dogs than in other domestic animals. This type of leukemia, however, must be differentiated from physiologic lymphocytosis in excited cats (usually kittens and young adult cats), in which the absolute lymphocyte count may reach 20,000 cells/μL^{-1}. Other differential diagnoses include lymphocytosis induced by chronic antigenic stimulation, such as that seen in dogs with chronic ehrlichiosis. Lymphocytosis is rare and usually mild (<10,000 lymphocytes/μL^{-1}) with other types of antigenic stimulation, however. Lymphocytosis predominated by LGL may be seen in animals with ehrlichiosis or T-CLL.

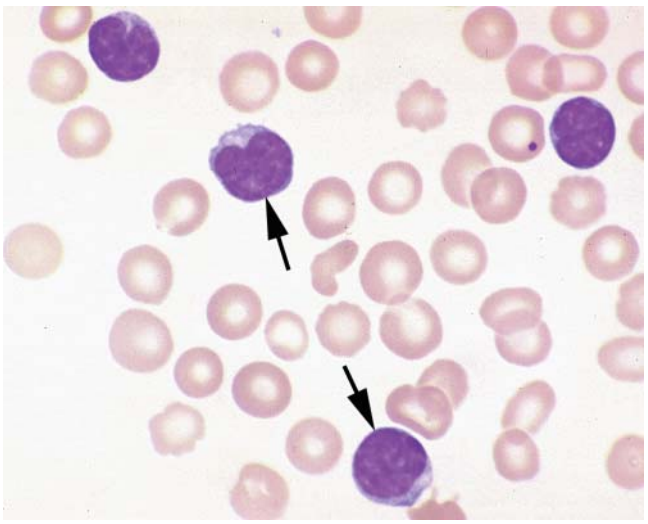

Figure 16.30 Blood film from a dog with chronic lymphocytic leukemia. Note the relatively small, normal-appearing lymphocytes (arrows). The diagnosis of leukemia was based on the high concentration of small lymphocytes in the blood (40,000 cells/μL^{-1}) and by polymerase chain reaction results. Wright stain.

Mild to moderate lymphocytosis has been reported as an infrequent finding in cats infected with *Bartonella henselae*. The list of major differentials for persistent nonneoplastic lymphocyte expansion in adult dogs and cats is short and includes tick-borne disease, especially canine monocytic ehrlichiosis, hypoadrenocorticism, and thymoma. Persistent lymphocytosis of small, mature, or reactive lymphocytes is most commonly the result of CLL or lymphoma. The first step in distinguishing nonneoplastic from neoplastic lymphocytosis is immunophenotyping by flow cytometry to determine the phenotypic diversity of the circulating cells. Clonality testing using the polymerase chain reaction for antigen receptor rearrangements assay is a useful second step in cases in which the phenotype data are equivocal. Once the diagnosis of malignancy has been established, the immunophenotype (see Chapter 14) also provides prognostic information in dogs.

Clinical signs and abnormalities found in ill animals are similar to those seen in animals with other types of leukemia, including lethargy, anorexia, pale mucous membranes, lymphadenopathy, splenomegaly, and hepatomegaly. However, some animals are asymptomatic, and the lymphocytosis is discovered during a wellness examination or presurgical screening. The most striking CBC abnormality is the lymphocytosis, which may range from increased slightly above the reference interval to greater than 300,000/μL^{-1}. Anemia and thrombocytopenia may be present, but the anemia usually is not as severe as that seen in animals with ALL. The concentration of small lymphocytes in the marrow is greater than normal, being reported to range from 25% to 93% of cells. Monoclonal gammopathies occasionally are seen in animals with CLL. A small percentage of dogs and people with CLL develop an aggressive diffuse large B cell lymphoma (Richter's syndrome) [5].

Three primary subtypes of CLL, based primarily on immunophenotyping, have been reported: (i) T-CLL, which is the most common form in dogs and cats, with cells in the many cases being $CD3^+/CD8^+$ granular lymphocytes; (ii) B-CLL ($CD21^+$), which is the next most common subtype; and (iii) atypical CLL, which represents a combination of immunophenotypes. Patients that have CD34+ cells are typically classified as having ALL. Some of the dogs with T cell leukemia have LGL leukemia, and T cells sometimes proliferate in the spleen. Most dogs with T-zone lymphoma, an indolent disease with long survival times, have leukemia (see chapter 45). This T-cell leukemia is unique in that the cells express CD21, which is a B-cell marker. Immunophenotyping provides an objective method for determining prognosis in dogs with CLL. Expression of CD34 predicts poor outcome with much shorter survival compared with other phenotypes. Within the CD8+ phenotype, dogs presenting with a >30,000 lymphocytes/μL^{-1} have significantly shorter median survival than those presenting with <30,000 lymphocytes/μL^{-1}. Within the T cell leukemias,

dogs with CD4-8-5+ leukemia and dogs with the CD8+ T cell phenotype have a similar survival time. A CD21+ B cell lymphocytosis composed of large cells was associated with shorter survival time than those with smaller circulating cells. In another study, old dogs with B-CLL survived longer than young dogs, and anemic dogs with T-CLL survived a shorter time than dogs without anemia.

B cell chronic lymphocytic leukemia (B-CLL) is the most common hematopoietic malignancy in people, and B cell leukemia in dogs may provide an animal model as the disease appears to be similar in dogs and people. Unlike the human disease, canine B-CLL cells do not express CD5. In people with B-CLL, analysis of the immunoglobulin genes has been crucial in understanding pathogenesis and prognosis, and preliminary studies show that these analyses may also be useful in dogs [6]. In a retrospective study of 491 dogs with B-CLL, the median age was 11 years and small breeds had significantly greater odds of having B-CLL [7]. Lymphadenopathy was present in 46%, splenomegaly in 51%, hepatomegaly in 29%, and visceral lymphadenopathy in 23%. Twenty-six percent of dogs were anemic, 26% were hyperglobulinemic, and only 5% were hypercalcemic. The median lymphocyte concentration was 24,600/µl with a range of 5000-812,544/µL, and the median percentage of lymphocytes that were B cells was 94%. Neutropenia and mild thrombocytopenia were rarely observed (1% and 7% respectively). English bulldogs had a unique presentation in that they were diagnosed at a median age of 6 years, and expressed lower class II MHC and CD25.

Therapeutic intervention is controversial, because untreated animals may live for months to years. Recommendations for chemotherapy in dogs and cats include a combination of chlorambucil and prednisone; long remissions and survival can be achieved. The median survival time for dogs is more than 1 year. Survival time has been reported to be significantly different in untreated dogs with CLL (~450 days), as compared to that of dogs with ALL (~65 days). CLL in cats is rarely associated with FeLV infection.

Enzootic bovine leukosis

Enzootic bovine leukosis, the most common neoplastic disease of cattle, is a B cell lymphoproliferative disorder of cattle that is caused by the bovine leukemia virus (BLV), an oncogenic retrovirus that infects lymphocytes and can result in a persistent lymphocytosis, and sometimes leukemia and lymphoma. The virus is transmitted through the blood, either iatrogenically or by biting flies. It is also spread vertically, either through the placenta or by colostrum. Virus specific antibodies are found in serum and milk. No vaccine is available, and therapy is not instituted. It occurs worldwide and is a significant problem for the beef and dairy cattle industries. Diagnosis is usually made by detecting the antibody to the virus or detecting the virus by quantitative PCR. Approximately 40% of cow-calf beef herds and 10% of individual beef cows in the US are BLV seropositive. Approximately 70% of BLV infected animals are asymptomatic carriers of the virus. Approximately one-third of infected cattle develop a benign form of nonmalignant persistent lymphocytosis of untransformed lymphocytes, characterized by increased concentration of $CD5^+$ IgM^+ B cells. Because absolute lymphocyte concentration is significantly increased by BLV infection, even in clinically healthy cattle, reference intervals should be derived from animals that are not infected with BLV and patient BLV status must be considered for meaningful interpretation of lymphocyte concentration.

Less than 5% of infected cattle develop malignant B cell lymphoma originating from mono- or oligo-clonal accumulation of B cells after a usually long period of latency. This malignant form of B cell lymphoma is predominantly detected in cattle over 4–5 years of age, although calves as young as 3 months of age have been reported. Lymph nodes, spleen, and other organs such as the heart, intestine, kidney lung, liver and uterus may be involved. BLV infection causes abnormal immune function, even in clinically healthy animals, affecting both the innate and adaptive immune system and altering proper functioning of uninfected cells.

Plasma cell myeloma (multiple myeloma, disseminated plasma cell neoplasia)

Plasma cell myeloma is a relatively rare lymphoproliferative neoplasm in which plasma cells or their precursors proliferate abnormally (Figures 16.31–16.33). As implied by the term multiple myeloma, plasma cells proliferate in the bone marrow at multiple sites. Plasma cell myeloma, also referred to as disseminated plasma cell neoplasia, accounts

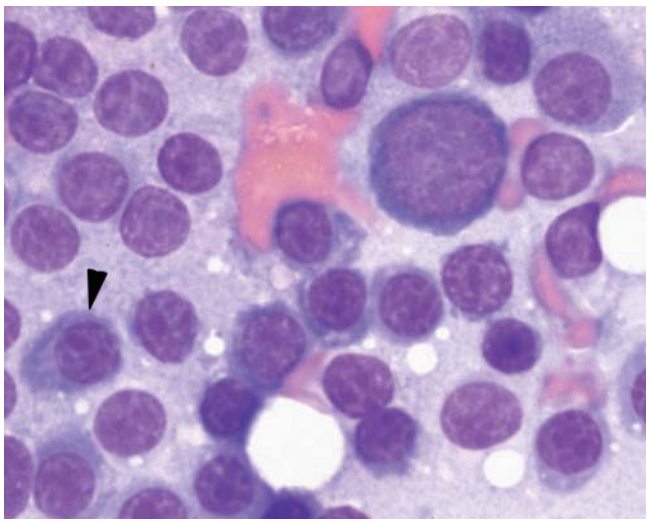

Figure 16.31 Bone marrow aspirate taken at autopsy from a dog with plasma cell myeloma. Almost all of the cells present are plasma cells. Note the more typical plasma cell with an eccentric nucleus and abundant cytoplasm (arrowhead). Wright stain.

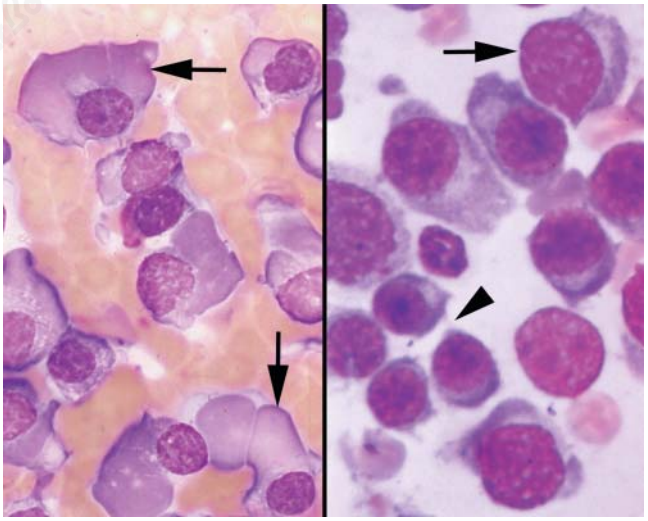

Figure 16.32 Left. Bone marrow aspirate from a dog with plasma cell myeloma. These plasma cells have eosinophilic-colored cytoplasm that is ruffled, and they sometimes are referred to as flame cells. The cytoplasm is filled with immunoglobulin. Right. Bone marrow aspirate from a dog with plasma cell myeloma. Note the variation in cell size, ranging from the large, immature plasma cell with loose chromatin (arrow) to the small cells with more condensed chromatin (arrowhead). Wright stain.

for approximately 10% of all hematopoietic malignancies in dogs and people. The incidence of multiple myeloma in cats is thought to be even less than that in dogs and usually is not associated with FeLV or FIV infections. Plasma cell myeloma has been reported infrequently in horses and twice in swine.

Neoplastic plasma cell proliferations are commonly detected on bone marrow films, but plasma cells only rarely are seen on blood films. When circulating neoplastic plasma cells are present, the survival time usually is less. Markedly increased plasma cell concentration in the bone marrow (>20% of all nucleated cells) often results from plasma cell neoplasia, but plasma cell proliferation also may occur secondary to chronic antigenic stimulation such as is seen with canine monocytic ehrlichiosis. Neoplastic plasma cells often are seen in large aggregates and sometimes appear slightly abnormal or immature, with occasional multinucleated plasma cells being present. Neoplastic cells may appear to be very well-differentiated, however, in which case they are difficult to distinguish from normal plasma cells. Plasma cells occasionally may have a ruffled eosinophilic cytoplasmic margin that appears similar to a flame; these are termed flaming plasma cells or flame cells (Figures 16.32 and 16.33). When plasma cells are poorly differentiated, they may be difficult to differentiate from other types of neoplastic cells, including lymphocytes, osteoblasts and malignant histiocytes. Immunocytochemistry using a monoclonal mouse anti-human MUM1 (multiple myeloma oncogene 1) antibody can be used to help identify plasma cells.

Plasma cells derive from B-lymphocytes and typically secrete immunoglobulins. A very common manifestation of plasma cell myeloma is a monoclonal or biclonal gammopathy, usually immunoglobulin G or A but, occasionally, immunoglobulin M (Figure 16.34). Patients with a monoclonal gammopathy may or may not be hyperglobulinemic. The immunoglobulins synthesized by malignant plasma cells also are known as paraproteins or monoclonal proteins (M-proteins). Serum protein electrophoresis (SPE) using a densitometer detects M-proteins, which are usually represented by a peak taller than albumin (see "Protein Electrophoresis" in Chapter 1). SPE can be performed using either agarose gel electrophoresis (AGE) or capillary zone electrophoresis (CZE) based techniques. Immunotyping is another electrophoretic-based technique that uses labeling antibodies to identify immunoglobulin fractions within a serum sample. Immunofixation using gel electrophoresis

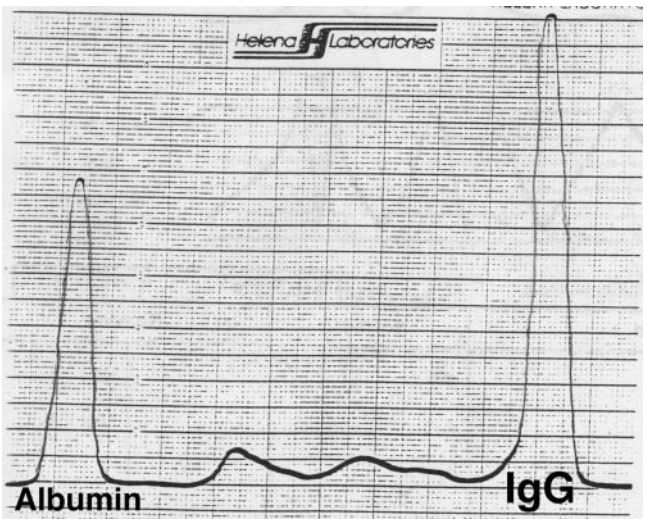

Figure 16.34 Protein electrophoretogram from a dog with plasma cell myeloma and monoclonal gammopathy. Note the monoclonal immunoglobulin (IgG) spike at the right. Albumin is represented by the smaller spike to the left. Wright stain.

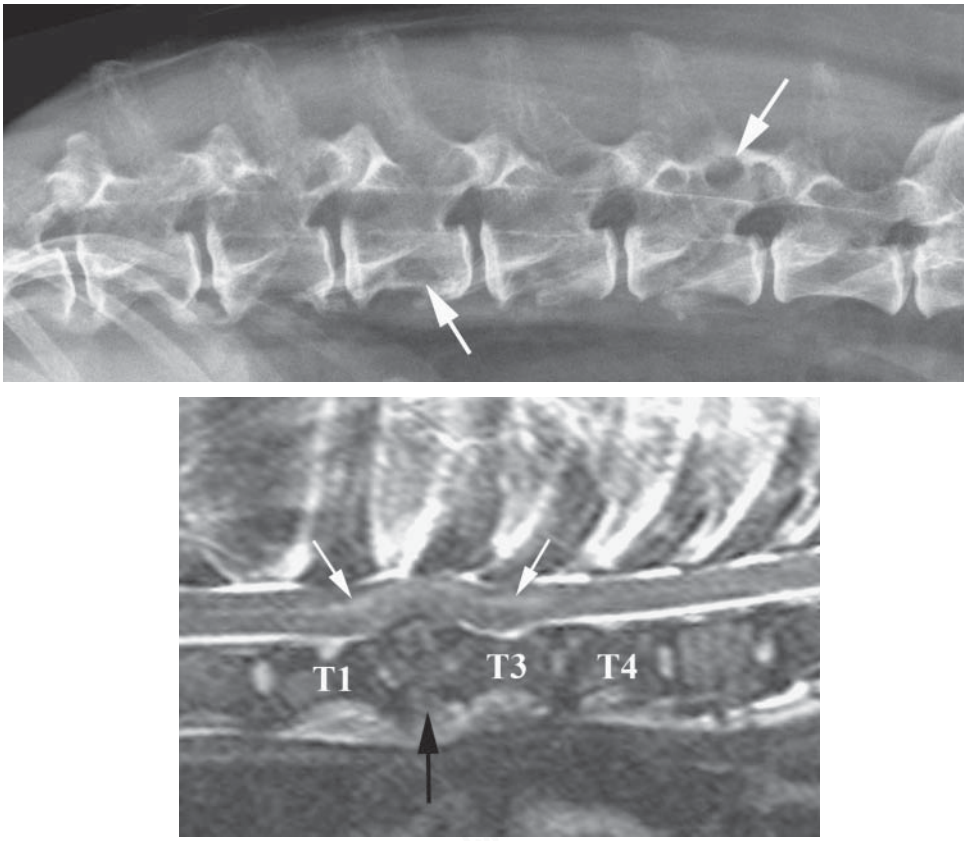

Figure 16.35 (a) Lateral lumbar radiograph of a dog with multiple myeloma. There are numerous small lucencies in the spinous processes and larger lucent lesions in the body of L3 and the lamina of L5 (white arrows) due to bone effacement from neoplastic cells. (b) Sagittal T2-weighted magnetic resonance image of the thoracic spine of a dog with multiple myeloma. Effacement of the second thoracic vertebral body by neoplastic cells has led to a pathologic fracture. Note the foreshortened irregular shape (black arrow) compared to the adjacent normal first, third, and fourth thoracic vertebrae (T1, T3, and T4, respectively). A portion of the fractured vertebra is protruding into the vertebral canal and causing spinal cord compression. The increased signal (whiteness) of the spinal cord (white arrows) is due to edema and inflammation. Vertebral fracture causing paralysis or paresis is a relatively common complication of multiple myeloma. Source: Courtesy Dr. Donald Thrall, North Carolina State University.

defines M-proteins typically composed of both heavy and light chains and evaluates IgG, IgA, and IgM heavy chain and light chain. In summary, AGE, CZE, and species-specific immunofixation can be used alone or in combination to detect M-protein.

Rarely, the neoplastic plasma cells produce only the light chain component of the immunoglobulin that readily passes through the glomerulus due to its small molecular size. Thus, a monoclonal gammopathy is not seen and these patients often go undiagnosed. The Bence-Jones proteins are not detected on dipsticks for urine protein, which are specific for detecting albumin. However, the light chain immunoglobulins can be detected by sulfosalicylic acid precipitation and confirmed by urine protein electrophoresis that will show a urine monoclonal gammopathy. Even more rarely, dogs with multiple myeloma will not have evidence of M-proteins in either their blood or urine. These nonsecretory myelomas (NSM) are further categorized as either "true" NSM, in which the neoplastic plasma cells are not synthesizing M-proteins, or "false" NSM, in which the plasma cells are not releasing M-proteins or the M-protein cannot be measured by conventional methods. Other diagnostic features of plasma cell myeloma include Bence-Jones protein (i.e., light chains of immunoglobulins) in the urine, and radiographic evidence of osteolysis (Figure 16.35). Two or three of these four features traditionally are considered to be essential for the diagnosis of plasma cell myeloma. However, diagnosis of multiple myeloma in humans no longer requires the documentation of complete M-proteins, since nonsecretory myelomas comprise up to 5% of all cases of multiple myeloma in people.

Differential diagnoses include canine monocytic ehrlichiosis, a disease with which a monoclonal gammopathy may very rarely be seen, usually within a polyclonal gammopathy. Dogs with ehrlichiosis commonly have a markedly increased concentration of plasma cells in the bone marrow. Other disorders in which monoclonal gammopathies have been reported include B cell chronic lymphocytic leukemia, B cell lymphoma, extramedullary plasmacytoma, and feline infectious peritonitis (rarely).

Plasma cells do not normally proliferate, but oncogenic mutations impart cell proliferation capability that results in progressive disease that eventually becomes symptomatic. Clinical signs associated with multiple myeloma are usually associated with plasma cell infiltration of the bone marrow and other organs or with increased concentration of circulating immunoglobulins, which may result in increased viscosity of the blood (i.e., hyperviscosity syndrome). Lethargy, anorexia, lameness, bleeding from the nares, paresis, polyuria, and polydipsia are relatively common. Fundoscopic changes such as retinal hemorrhages and engorged retinal blood vessels commonly are observed as well. Renal disease is relatively common and usually associated with the abnormal proteins interfering with tubular and glomerular function, but it sometimes occurs secondary to hypercalcemia with subsequent calcification of renal tissue. Central nervous system impairment may result from serum hyperviscosity and subsequent sludging of blood in small vessels. Bleeding diatheses, which are seen in approximately one-third of dogs with multiple myeloma, may result from thrombocytopenia, but it also can result from the abnormal immunoglobulins interfering with platelet function. Common findings in feline multiple myeloma include atypical plasma cell morphology, hypocholesterolemia, anemia, bone lesions, and multiorgan involvement. In one retrospective study, all of the affected cats examined had noncutaneous, extramedullary tumors of the spleen, liver, or lymph nodes.

Mephalan, an alkylating agent, is usually used to treat multiple myeloma in dogs, often in combination with prednisone. Response rate is usually good, with a mean survival time of approximately 18 months to 3 years. Mephalan or cyclophosphamide sometimes in combination with prednisone are preferred therapy for multiple myeloma in cats; cyclophosphamide is usually tolerated better than mephalan. Reported survival times in treated cats average approximately 1 year. Animals with multiple myeloma that are azotemic or have severe anemia, neutropenia, or thrombocytopenia usually have a shorter survival time. Hypercalcemia, Bence-Jones proteinuria, plasma cell leukemia, and extensive bony lesions also are associated with a poorer prognosis. In humans, stem cell transplantation offers significantly improved prognosis and survival rates.

17 Disorders of Hemostasis

James Meinkoth
Department of Veterinary Pathobiology, Oklahoma State University, Stillwater, OK, USA

Hemostasis is the physiologic cessation of bleeding. Patients demonstrating excessive or abnormal bleeding are fairly common in veterinary practice and are often presented as emergencies. A few simple laboratory tests are available that help to determine two things:

1. Whether the bleeding is the result of a defect in hemostasis versus local tissue disease (tissue trauma, neoplasia, infection, etc.).

2. In the event that a hemostatic defect *is* present, localize the problem to a particular segment of the hemostatic system and thus narrow the list of potential differentials that may be causing the presenting problem.

This chapter will (i) review the physiology of hemostasis to the level required to interpret common tests of hemostasis, (ii) discuss some clinical information that must be considered in a patient presenting for excessive bleeding, (iii) describe the routine tests used to evaluate hemostasis, and (iv) discuss some of the most common diseases in veterinary medicine that result in abnormal bleeding.

Review of physiology of hemostasis

The physiology of hemostasis is amazingly complex and can be quite intimidating. Fortunately, it is not necessary to know a tremendous amount of detail to appropriately interpret the common hemostatic tests. A quick overview of hemostasis will be presented followed by a bit more detail about each of the major steps. The process of hemostasis is reviewed here at a basic level with specific details added when they pertain to a relevant disease process. Far more detailed reviews are available for those who are interested (and slightly masochistic) and wish to pursue the topic in more depth [1–7].

The "big picture" overview

Blood is normally maintained in a fluid state within vessels, but if vascular injury occurs, then rapid hemostasis is necessary to prevent severe bleeding. The hemostatic system is amazingly efficient and able to (i) respond rapidly, thus limiting the amount of bleeding, and also to (ii) limit coagulation to the site of injury, which prevents pathologic coagulation or thrombosis. The essential components that are required for hemostasis to occur, *blood platelets* and certain proteins called *soluble coagulation factors*, are present preformed within circulation and available to act if vascular injury occurs.

Coagulation does not normally occur without vascular injury because the coagulation factors are mostly present in an inactive form and the endothelial cells that line all blood vessels function both *passively and actively* to inhibit clotting. The normal endothelial lining of blood vessels is a *nonthrombogenic surface* (meaning it does not activate platelets or coagulation factors) and also actively produces factors that inhibit the various components of hemostasis. In contrast to the endothelium, the connective tissues (e.g., collagen), which are just under the endothelial cells and thus termed the *subendothelium*, are extremely thrombogenic and start the hemostatic process when exposed by vessel injury. The endothelial cells surrounding a site of injury may actively switch from a nonthrombogenic state to a thrombogenic state, at least temporarily. They do this by reducing production or expression of inhibitors of hemostasis and expressing or secreting other components that promote the activation of platelets and coagulation factors.

> ***Major concept:*** There are always processes both favoring and opposing hemostasis occurring simultaneously. This leads to some confusion when first reading the details of hemostasis. Whether or not clotting occurs at any given time depends on the balance of these forces. Much of this balance is dependent on the function of the endothelial cells. Having both processes occurring at low levels all the time and opposing each other allows the process to be started and stopped faster than if they were dormant and needed to be "geared up."

Step 1: primary hemostasis

The initial event in hemostasis following vascular injury is a reflex constriction of local blood vessels. This limits blood flow in the affected area to reduce bleeding. It also slows the

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Companion website: www.wiley.com/go/thrall/veterinary

flow of platelets and coagulation factors, keeping them from being swept away from the area after they are activated. The first cellular event is that platelets bind to subendothelial collagen exposed at the area of the injury; this is called *platelet adhesion*. After adhesion, platelets become activated. Activated platelets quickly (i) change shape to spread out and cover more surface area, (ii) expose certain membrane receptors for adhesive proteins, and (iii) secrete substances called *platelet agonists*. These agonists recruit and activate additional platelets. Soon, newly arrived platelets bind to other platelets, a process called *platelet aggregation*. Platelet aggregation continues until a mass of platelets (*platelet plug*) completely fills the defect. The process of forming a platelet plug at the site of injury is referred to as *primary hemostasis*.

Step 2: secondary hemostasis

The initial platelet plug may transiently stop the bleeding but is not very stable. It is sufficient to stop bleeding only from very small wounds. With larger wounds, hydrostatic pressure within blood vessels would disrupt the platelet plug leading to *rebleeding*. This is where the soluble coagulation factors come in. The soluble coagulation factors are a group of proteins mainly produced by the liver. They are traditionally identified by roman numerals (i.e., Factor II) with the addition of an *"a"* (i.e., Factor IIa) to indicate the active form. They also have common names, some of which are used more frequently than the roman numerals (Table 17.1). These proteins are mostly proteases, secreted in an inactive proenzyme form, that cleave and thus activate each other in a sequential order termed the *coagulation cascade*.

The end result of the coagulation cascade is that fibrinogen (a.k.a., Factor I) is converted to fibrin at the site of the platelet plug. Fibrin is an adhesive protein that forms long strands and can bind to both other fibrin strands (called *cross-linking*) as well as platelets. This forms a fibrin mesh around the platelets within the platelet plug. Fibrin acts like a biological glue to stabilize the platelet plug and permanently stop bleeding. The process of coagulation factors working in sequence to produce fibrin to stabilize the platelet plug is called *secondary hemostasis*.

Major concept: Why is it important to divide this process into primary and secondary hemostasis? First, the types of clinical signs seen with defects of primary hemostasis are often sufficiently different from those seen with defects of secondary hemostasis, so that you can predict which system is affected from the clinical signs. Second, most basic laboratory tests evaluate either primary or secondary hemostasis, so you must know what physiologic functions are being tested. Finally, the potential disease processes that must be considered for any given clinical problem (i.e., the differential diagnoses) are different depending on which portion of the hemostatic process is affected.

Step 3: fibrinolysis (clot breakdown)

Eventually, after the underlying damage is repaired, the formed clot is broken down so that blood flow through the vessel is restored. This process is called *fibrinolysis*, and it is the result of the enzyme *plasmin*, which cleaves the fibrin clot at various places. As this occurs, small fragments of cleaved fibrin termed *fibrin degradation products (FDPs)* are released into circulation. These can be measured in the blood and are an indicator of clot breakdown. One specific group of FDPs are called *D-dimers*. These can be measured by a test that is currently used to detect the formation and breakdown of clots at an accelerated rate within the vasculature.

Details about primary hemostasis (platelet plug formation)

von Willebrand factor and platelet adhesion

As mentioned earlier, the first cellular event in hemostasis is platelet adhesion to collagen in the subendothelium. This adhesion requires a serum protein called *von Willebrand factor (vWf)*. vWf is not one of the soluble coagulation factors and is not directly involved in secondary hemostasis. It is produced primarily by vascular endothelial cells and to some degree by megakaryocytes and ends up stored inside platelet granules. vWf is an adhesive protein that can form long strands. It binds both to exposed collagen at the site of vessel injury and also to receptors on platelet membranes. In doing this, it acts to link platelets to the vessel wall (Figure 17.1). While other proteins, such as fibrinogen, can also bind to both platelets and the vessel wall, vWf is the only protein that can adequately mediate platelet adhesion in the high sheer force created by flowing blood within areas of the vasculature.

As the endothelial cells make vWf, they secrete it both from their basal surface, where it binds to subendothelial collagen, and from their luminal surface, where it ends up in circulation (Figure 17.2). Circulating vWf does not bind platelets, or it would result in thrombosis. vWf must bind subendothelium first, which causes a conformational shift allowing it to bind platelets. In addition, the endothelial cells store vWf within intracellular granules. This stored vWf can be released following injury. Thus, when endothelial cells are removed as a result of injury, vWf is already present bound to the exposed collagen as well as in the blood flowing over this defect. In addition, it is released from the endothelial cells surrounding the injury and the platelets that are recruited to the site. All of these processes results in a high concentration of vWf at the site of injury, which is important for effective platelet adhesion. von Willebrand disease (vWd) is a genetic deficiency of vWf. It is common in both humans and dogs and results in defective primary hemostasis and bleeding tendencies.

Fibrinogen and platelet aggregation

Platelet aggregation, the process of platelets binding to other platelets in the growing platelet plug, is mediated primarily

Table 17.1 Coagulation factors: common names and their functions.

Factor number	Common name	Pathway involved	Comments/function
Factor I	Fibrinogen	Common	Converted by thrombin to the adhesive protein fibrin as the final step of coagulation cascade Also active in primary hemostasis (mediates platelet aggregation)
Factor II	Prothrombin	Common	Proenzyme Active form cleaves fibrinogen (also activates many other factors as amplification loop) Vitamin K dependent
Factor III	Tissue factor, tissue thromboplastin	Extrinsic[a]	Lipoprotein that can be expressed on cell membrane of various cells Serves a cofactor for FVII, initiating extrinsic coagulation cascade
Factor IV	Calcium	All	Required for surface dependent coagulation factors to bind to phospholipid surfaces of platelets and participate in coagulation reactions
Factor V	Proaccelerin	Common	When activated, serves as cofactor for Factor X
Factor VI	—	—	There is no Factor VI
Factor VII	Proconvertin	Extrinsic	Proenzyme Active form activates Factor X (and Factor IX) Vitamin K dependent
Factor VIII	Antihemophilic factor	Intrinsic[b]	When activated, serves as cofactor for Factor IX
Factor IX	Christmas factor	Intrinsic	Proenzyme Active form activates Factor X Vitamin K dependent
Factor X	Stuart-Prower factor	Common	Proenzyme Active form activates Factor II Vitamin K dependent
Factor XI	Plasma thromboplastin antecedent	Intrinsic	Proenzyme Active form activates Factor IX
Factor XII	Hageman factor	Intrinsic	Proenzyme Active form activates Factor XI (and other contact factors)
Factor XIII	Fibrin-stabilizing factor	Common	Cross-links fibrin strands, thus stabilizing them
Prekallikrein	Fletcher factor	Intrinsic	Proenzyme Active form activates Factor XII
HMWK[c]	Fitzgerald factor	Intrinsic	Cofactor Activates Factors XII, XI

[a]The extrinsic pathway is now typically referred to as the "tissue factor pathway."
[b]The intrinsic pathway is now typically referred to as the "contact pathway" or "surface dependent pathway."
[c]HMWK = high molecular weight kininogen.

by fibrinogen (Figure 17.1). vWf can act in platelet aggregation also, but fibrinogen is present in the blood in much higher concentrations than vWf. Fibrinogen is also stored in platelet granules and released during platelet plug formation to further increase the concentration of this protein at the site of the platelet plug. Remember that fibrinogen, which helps bind platelets to each other, is what will be converted to fibrin by the secondary hemostatic system to stabilize the platelet plug, so it makes sense to have it within the platelet plug.

While deficiencies in fibrinogen would obviously lead to defects in primary hemostasis, they also affect the secondary hemostatic system, so it is not usually considered in the differential of a patient with a defect in only primary hemostasis. Inherited deficiencies or abnormalities of fibrinogen are extremely rare in veterinary medicine. Acquired

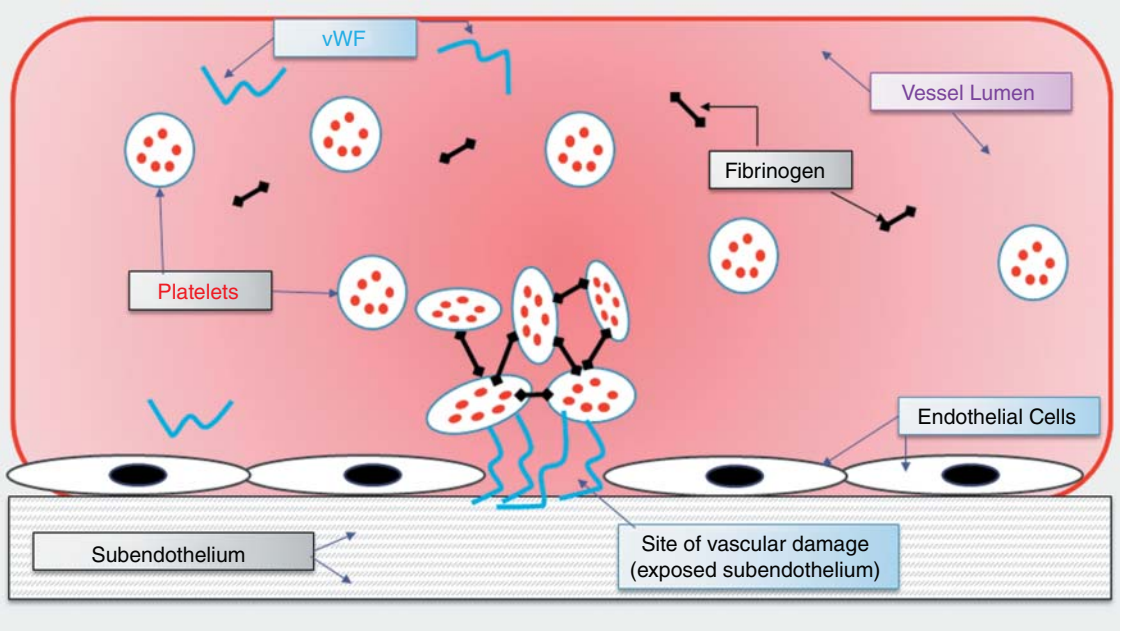

Figure 17.1 Schematic of components of primary hemostasis or production of the platelet plug. vWf (blue lines) mediates the adhesion of platelets to the exposed subendothelium following vascular damage. Fibrinogen (black arrows) mediates platelet aggregation to other platelets.

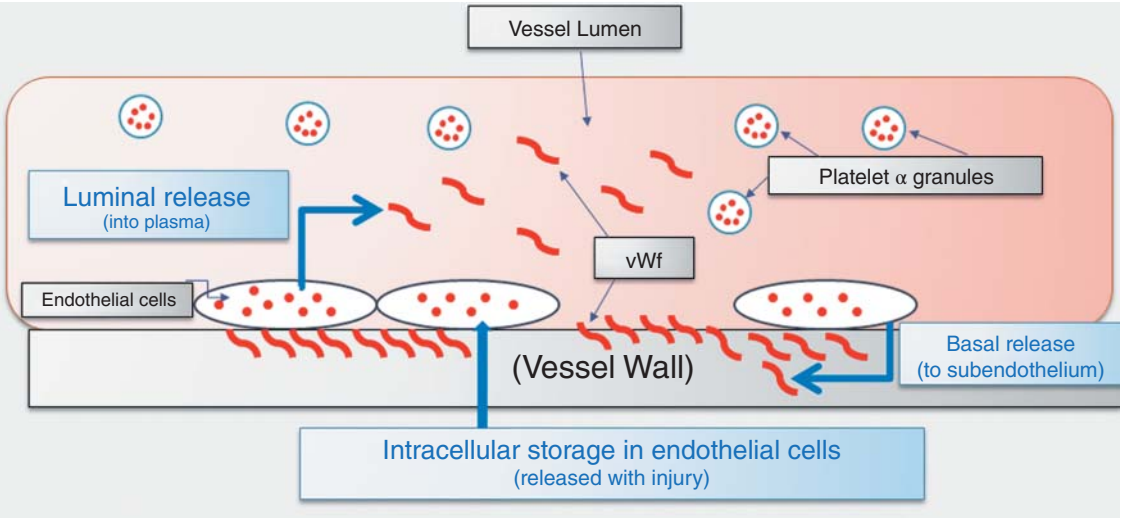

Figure 17.2 Schematic of vWf production. The production, storage, and release of vWf work together to create high concentrations of vWf at the site of platelet plug formation. vWf from endothelial cells is released both into the plasma and into the subendothelium. In addition, both platelets and endothelial cells contain vWf within intracellular granules. This stored vWf can be released during platelet plug formation to further increase the local concentrations.

deficiency of fibrinogen can occur due to excessive consumption in the disease *disseminated intravascular coagulation (DIC)*, which is discussed in more detail later.

Platelet numbers and function

The platelets themselves play an active part in hemostasis. First of all, adequate numbers of platelets are needed for the platelet plug to form. Thrombocytopenia, a decreased platelet concentration, is extremely common and is the most common cause of abnormal bleeding seen in veterinary medicine.

In addition to having sufficient platelets, they must be functional since they actively participate in both primary and secondary hemostasis. Platelet activation and normal platelet function are very complex, and much of the detail is beyond what is needed for interpretations of hemostatic tests. As a simplified overview, platelet functions involve (i) expression of surface membrane receptors, (ii) release

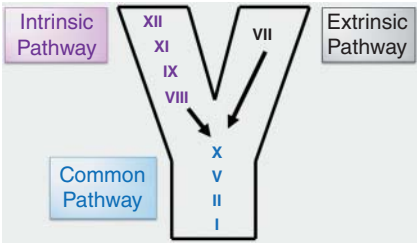

Figure 17.3 Schematic of the coagulation factor pathways, as they relate to coagulation testing results. Physiologically, the extrinsic pathway (a.k.a. tissue factor pathway) is of primary importance, and the intrinsic pathway serves primarily in amplification of the process. Also, there is cross-over between the two pathways as Factor VII (extrinsic pathway) may directly activate Factor IX (intrinsic pathway) in addition to its downstream activation of Factor X.

of granule contents, and (iii) initiation of a variety of intracellular signaling pathways.

Platelet function: surface receptors

Platelet receptors allow them to (i) bind to adhesive proteins and thus participate in adhesion and aggregation and (ii) respond to platelet agonists resulting in activation (Figures 17.3 and 17.4). The receptor for vWf is platelet *glycoprotein Ib* (GP Ib) and the receptor for fibrinogen is *glycoprotein IIb/IIIa* (GP IIb/IIIa). Inherited mutations of these receptors can lead to abnormal bleeding, with GP IIb/IIIa being most important in veterinary medicine. There are receptors for platelet agonists such as adenosine diphosphate (ADP) and thrombin. These receptors are the target of therapeutic interventions aimed at preventing thrombosis. An important example is the drug *clopidogrel* (Plavix®), which inhibits one of the ADP receptors.

Platelet function: granule contents

Platelets have dense granules and alpha granules, whose contents promote hemostasis and are released following platelet activation to increase their concentration in the microenvironment where the clot is forming. The *alpha granules* contain mainly a variety of adhesive proteins and coagulation factor proteins, while the *dense granules* contain nonprotein mediators of hemostasis (Table 17.2). Inherited defects of these granules and their release exist (e.g., Chédiak-Higashi syndrome), but these are extremely rare.

Platelet function: intracellular signaling pathways

Numerous intracellular biochemical pathways are initiated during platelet activation, which ultimately results in platelet shape change (allows the platelet to spread out and cover the defect), platelet cytoskeletal contraction (retracts and further strengthens the platelet plug), expression and activation of the previously mentioned membrane receptors (promotes aggregation), and release of the previously mentioned granules (further promotes adhesion, aggregation, and activation).

One important intracellular signaling pathway is arachadonic acid metabolism, which results in the production of thromboxane A2 (TXA2), a platelet agonist. This pathway is inhibited by aspirin and other NSAIDs, thus inhibiting platelet function. These drugs can be used therapeutically to prevent thrombosis but may also cause excessive bleeding.

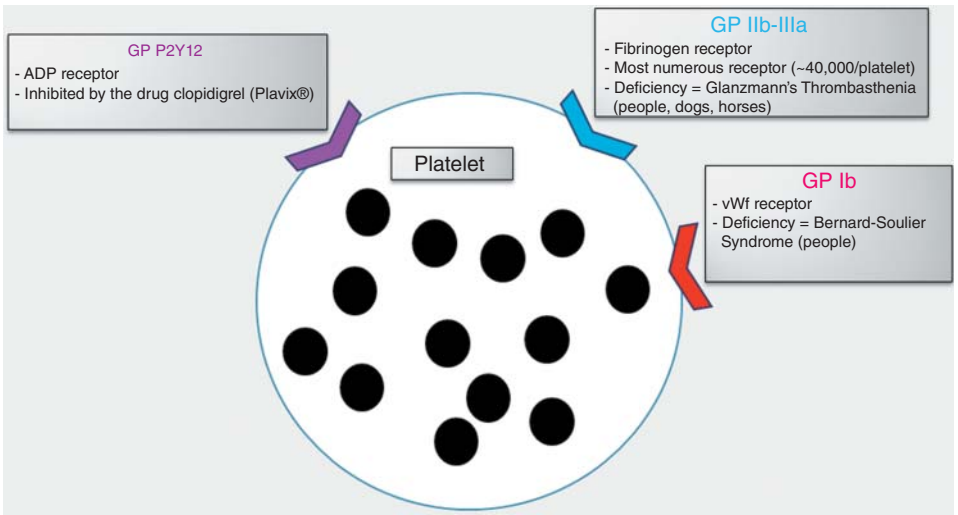

Figure 17.4 Selected platelet receptors and their ligands. There are many more receptors for both adhesive proteins (e.g., collagen receptors) as well as platelet agonists (e.g., additional ADP receptors, thrombin receptors), but these are the primary ones for which disease-causing mutations have been reported or pharmaceutical interventions have been directed. Platelet receptors are the targets of many new pharmacologic agents given the importance of thrombotic disease in people.

Table 17.2 Platelet granules and their contents.

Alpha granules contents	Dense granule contents
Adhesive proteins – vWf – Fibrinogen – Vitronectin – Fibronectin Coagulation factors – Factor V – Factor XI Growth factors – Platelet-derived growth factor – Endothelial cell growth factor – Epidermal growth factor Inhibitors of fibrinolysis – Plasminogen activator inhibitor	ADP Adenosine triphosphate Calcium Serotonin

Major concept: Physiologically, the major things required for primary hemostasis to occur are (i) normal subendothelium, (ii) adequate numbers of platelets, (iii) normal platelet function, (iv) von Willebrand factor, and (v) fibrinogen (Figure 17.1). However, abnormalities of subendothelium are extremely rare, and fibrinogen deficiency affects secondary hemostasis as well as primary hemostasis. So, neither of these are commonly considered in patients with disorders limited to primary hemostasis. *Thus, the main differential diagnoses for such patients are (i) thrombocytopenia, (ii) von Willebrand disease, and (iii) abnormal platelet function.*

Details about secondary hemostasis (fibrin clot formation)

Coagulation vs. hemostasis

As discussed previously, secondary hemostasis involves the sequential activation of a group of serum proteins, most of them proteases, with the ultimate goal of converting fibrinogen to fibrin, which stabilizes the platelet plug. This process of fibrin formation from activation of these serum proteins is termed *coagulation*. Thus, the terms "coagulation" and "hemostasis" are not technically synonymous although they often get used as such.

Coagulation pathways

Traditionally, coagulation has been thought of as existing in two completely separate "arms" (the *intrinsic* and the *extrinsic* pathways) that converge into a single *common* pathway. The intrinsic system was so named because its activation occurred from within (or *intrinsic* to) the vascular system, usually by exposure to negatively charged surfaces such as collagen exposed by endothelial damage. The extrinsic system was so named because it was activated by the *tissue factor (Factor III)*, which comes from outside (or *extrinsic* to) the vasculature. Tissue factor is constitutively expressed by many extravascular cells that are exposed following vascular injury, such as smooth muscle cells and fibroblasts. It is not normally expressed by endothelial cells but potentially can be under pathologic conditions. Thus, this system is activated when there is damage to or inflammatory activation of a portion of the vasculature. This classic scheme is outlined in Figure 17.3.

Physiologic coagulation vs. coagulation testing

It is now known that activation of the extrinsic pathway is by far the most important physiologic initiator of hemostasis and the intrinsic pathway primarily acts as an amplification loop following the formation of small amounts of thrombin. There is a lot of cross-over between these two systems as well as many feedback loops, which amplify the process and help coagulation to occur quickly. In reality, this division into two systems is largely artificial and based on some *in vitro* coagulation tests. However, these tests are still commonly used to evaluate hemostasis and so the classic scheme is still a useful concept to memorize for interpreting these tests. Fibrinogen (Factor I), thrombin (Factor II), and tissue factor (Factor III) are often referred to by their common names, while the other factors are typically referred to only by their roman numeral designation.

Memorizing the coagulation pathways

It is helpful to memorize which factors are in the various pathways when interpreting the results of coagulation testing. The intrinsic system can be easily remembered as the "Walmart" cascade (thanks to Drs. Rick Cowell and Ron Tyler). To make an item sell better, rather than selling it for $12.00, it is put on "sale" for $11.98. *The intrinsic cascade comprises Factors 12, 11, 9, and 8, in that order*. The common pathway is where the two others meet, so it is the *crossroads* or *"X" roads*. They meet at Factor X. For the rest of the common pathway, simply cut the number in half each time, eliminating any fractions. *The common pathway comprises Factors 10, 5, 2, 1 in that order*. Factor 7 is all by itself in the extrinsic pathway.

Production and function of the coagulation factors

With the exception of Factor III (tissue factor) and Factor IV (calcium), coagulation factors are predominantly synthesized by the liver and circulate in the blood as inactive precursors. Most of these factors are enzymes, which act to cleave the next factor in the system, activating it. Some factors are not proteases. Tissue factor (Factor III) is a membrane receptor expressed on several cell types. It functions as a cofactor for Factor VII, resulting in initiation of the extrinsic pathway following vascular injury. Factors V and VIII are cofactors that

act to increase the activity of some of the enzymatic factors (X and IX, respectively). Finally, fibrinogen, after conversion to fibrin, is an adhesive protein that stabilizes the clot and is the ultimate result of the cascade.

Factors II, VII, IX, and X are vitamin K–dependent factors, which is of tremendous clinical importance. When first produced by the liver, they are in an inactive form. They require the activity of vitamin K, which adds carboxyl groups to their glutamic acid residues (*"gamma carboxylation"*). This makes them fully functional by allowing them to interact with calcium and thus localize to phospholipid surfaces, typically the membranes of platelets and red cells incorporated into the platelet plug. Localizing the coagulation factors to phospholipid surfaces brings them into proximity, and thus the reactions occur far faster than if the factors were in solution.

Vitamin K antagonists, including some rat poisons, are a common cause of coagulopathy in veterinary medicine and one of the few easily treatable disorders of coagulation. Factor VII, one of the vitamin K–dependent factors, has a much shorter half-life than the other factors. In vitamin K antagonism, Factor VII becomes depleted first. This is important in interpreting the results of coagulation testing in cases of vitamin K antagonism.

Inhibitors of coagulation factors

There are naturally occurring inhibitors of the coagulation factors that serve to limit the action of these proteins to the site of vascular injury and prevent widespread activation of coagulation, which would lead to thrombotic disease.

Antithrombin

Antithrombin (previously referred to as Antithrombin III) is a protein that binds to and inactivates thrombin and also most of the other serine protease factors. The activity of antithrombin is enhanced by binding to heparin or heparan sulfates that are present on endothelial cells. This mechanism is the basis for use of heparin as an anitcoagulant, both therapeutically as well as in blood collection tubes.

Protein C

Protein C is a protease that cleaves and thus inactivates the coagulation factors that function as cofactors, Factor V and Factor VIII. Protein C is produced by the liver in an inactive form. Protein C is activated by thrombin but only when thrombin is bound to the protein *thrombomudulin*, which is expressed on endothelial cells. Thus, thrombin is a potent promoter of the coagulation cascade but can be switched to have an anticoagulant activity when bound to thrombomulin. Inherited Protein C deficiencies in humans result in thrombotic tendencies.

Tissue factor pathway inhibitor (TFPI)

The tissue factor pathway is the primary physiologic initiator of hemostasis, and TFPI is the primary regulator of this pathway. TFPI is a protein produced by endothelial cells but also many other cell types [2]. TFPI has separate binding sites for Factor Xa as well as Factor VIIa/tissue factor complex, thus inhibiting both the enzyme of the TF pathway as well as its substrate.

Details about fibrinolysis (fibrin clot breakdown)

Breakdown of the formed clot occurs concurrently with repair of the underlying defect in the vascular system. When this occurs completely, patency of the vessel and normal blood flow is restored. Similar to coagulation, this is a highly regulated process and one that should be limited to the site of clot formation and not occur systemically. Plasmin is formed as an inactive precursor called *plasminogen* by the liver. This precursor has affinity for fibrin and is incorporated into the clot as it forms. Plasminogen is converted to active plasmin by the enzyme *tissue plasminogen activator (TPA)*. TPA is produced by endothelial cells, but only when there are appropriate stimuli. So, TPA production is stimulated in close proximity to the clot. Furthermore, TPA only interacts with plasminogen that is bound to the fibrin clot, not free in plasma, so production of active enzyme is limited to its site of action rather than occurring systemically. As an added protection against systemic spread of fibrinolysis, there are circulating proteins (e.g., alpha-2-antiplasmin) that inhibit any active plasmin that escapes the fibrin clot. These circulating inhibitors cannot inactivate plasmin bound to fibrin, thus plasmin can perform its function at the appropriate site but is quickly inactivated should it break free from the clot.

"Orchestration" of hemostasis: role of endothelium

Much of the complexity of hemostasis and difficulty in understanding its processes are due to fact that each component has both activators and inhibitors, which often seem to be produced by the same cells, mainly endothelial cells. However, these seemingly contradictory responses actually make sense when you consider that they are occurring in cells in slightly different *locations* and they act in concert to simultaneously *promote rapid hemostasis* in the microenvironment where it is needed and also *prevent it from spreading* where it is not.

Under normal circumstances, endothelial cells actively produce many products that inhibit both primary and secondary hemostasis, which maintains blood in its normal fluid state (Table 17.3). When there is vascular damage, several things occur simultaneously: (i) anticoagulant functions are lost with removal of the endothelial cells, (ii) the strongly procoagulant subendothelial collagen is exposed, and (iii) the endothelial cells in the immediate site of the developing clot are stimulated to shift from having anticoagulant to procoagulant properties (Table 17.4). Endothelial cells farther away from the damage are not exposed to the associated stimuli and retain their anticoagulant nature, thus limiting the developing clots to the immediate site.

Table 17.3 Anticoagulant functions of resting endothelial cells.

Product	Function
Prostacyclin	Platelet inhibitor
Nitric oxide	Platelet inhibitor
ADPase	Degrades ADP, a platelet agonist
Heparan sulfate	Expressed on EC surface Activates antithrombin, an inhibitor of enzymatic coagulation factors
Thrombomodulin	Activates Protein C (via thrombin). Protein C inactivates Factors V, VIII
Protein S	Cofactor for Protein C
TPA	Activates fibrinolysis (plasminogen) breaking down any clot formed

Table 17.4 Procoagulant functions of activated endothelial cells.

Product	Function
vWf	Promotes platelet adhesion
Platelet activating factor	Platelet agonist
Thromboxane	Platelet agonist
Tissue factor	Stimulates extrinsic coagulation cascade
Plasminogen activator inhibitor	Inhibits TPA, inhibiting fibrinolysis
Reduced expression of heparin sulfate	Loss of anticoagulant activity
Reduced expression of thrombomodulin	Loss of anticoagulant activity

Clinical approach to the bleeding patient

Interpretation of laboratory test results always needs to be considered in terms of the clinical presentation of the patient and considering a differential diagnosis list of common potential underlying diseases. It is generally most productive if testing is done to answer a specific clinical question. Before discussing coagulation tests themselves, it is helpful to consider some of the clinical context.

Hemostatic defect vs. trauma-/disease-induced hemorrhage?

The first question when faced with a bleeding animal is whether the bleeding is due to (i) a generalized defect in hemostasis (these can be either congenital or acquired) or (ii) local tissue trauma/disease resulting in hemorrhage despite normal hemostatic function. For example, a dog with severe epistaxis may have a hemostatic defect such as thrombocytopenia or may have local nasal disease such as a nasal tumor, foreign body, trauma, or severe inflammatory disease. Physical exam findings, hemostasis testing and other tests such as imaging may help answer this question. However, some historical things and physical exam findings that should first be considered include

Has the animal had previous bleeding episodes? Numerous prior episodes of abnormal bleeding would make you consider a hemostatic defect, potentially congenital.

Has the animal had previous challenges, such as surgery, when it has not bled? This might make congenital defects less likely, although recently acquired hemostatic problems could not be ruled out.

Is the bleeding spontaneous or trauma induced? Spontaneous bleeding is more likely to be the result of a hemostatic defect than is bleeding induced by trauma. If the bleeding is trauma induced, consider if the severity/duration of bleeding is expected for the degree of trauma or if it seems exaggerated. Prolonged or more severe bleeding than expected following a minor insult would suggest a hemostatic defect.

Is the animal bleeding from multiple sites? This would also suggest the presence of a hemostatic defect, but it could possibly result from multifocal tissue damage, such as systemic vasculitis secondary to an infectious disease.

What is the color of the urine, feces? Bleeding can sometimes be occult. Bleeding into the gastrointestinal tract or urinary tract may not be easily recognized. Also, bleeding into body cavities can be occult and should be considered if there is evidence of pleural or peritoneal effusion.

Has the animal been exposed to drugs/diseases that affect hemostasis? For this, it is important to know the common causes of bleeding disorders. Certain drugs such as aspirin or NSAIDs may interfere with platelet function. Potential exposure to anticoagulant rodenticides is important to determine, especially in an animal housed outdoors or allowed to roam.

What species/breed is the patient? Certain breeds are predisposed to inherited hemostatic defects for which they are routinely screened, sometimes even if they are asymptomatic.

Primary vs. secondary hemostatic defects?

The clinical nature of bleeding is often different when there is a defect in primary hemostasis versus one of secondary hemostasis. Lab testing will help to confirm which portion of the hemostatic mechanisms are affected, but clinical findings are often highly suggestive.

Signs associated with defects in primary hemostasis

Petechiae are small, pinpoint hemorrhages in the skin or mucous membranes. Petechiae are strongly suggestive of a primary hemostatic defect; they do not generally occur in secondary defects. More specifically, they are more

commonly associated with *thrombocytopenia* rather than other primary defects such as platelet function defects or vWd. Petechiae may also occur with any disease that causes vasculitis, such as certain infectious diseases and immune-mediated vasculitis. *Ecchymoses* are larger cutaneous hemorrhages that may occur in either primary or secondary defects.

Bleeding due to primary hemostatic defects is usually from mucosal surfaces. Common sites include bleeding from the nose (epistaxis), gums, genitourinary tract (e.g., hematuria, vaginal bleeding), or gastrointestinal tract (evidenced as either "melena" or "hematochezia"). Slow, prolonged oozing of blood spontaneously or from small, minor wounds is common. These are often "nuisance" bleeds. The most clinically concerning bleed would be cerebral hemorrhage, a site where even a relatively minor bleed could have significant clinical consequences.

Signs associated with defects of secondary hemostasis

Bleeding from secondary defects is often overt hemorrhage from a single site. Large hematoma formation is classic. Ecchymoses and hematomas may arise from minor insults. While hematoma formation is common with defects of secondary hemostasis, hematomas are not specific. They may also occur with tissue trauma in animals with primary hemostatic defects. For example, a hematoma may form at the site of blood collection in a thrombocytopenic animal.

Bleeding into body cavities is another classic finding with secondary hemostatic defects. This may manifest as bleeding into the abdominal cavity (*hemoabdomen*), thoracic cavity (*hemothorax*), or synovial spaces (*hemarthrosis*). Body cavity bleeds are the most common presenting signs of animals with vitamin K antagonism. Animals may present with dyspnea if there is a hemothorax.

Tests used to evaluate hemostasis

Tests of primary hemostasis

Buccal mucosal bleeding time (BMBT)

This test is often referred to as simply the "bleeding time" [8]. The bleeding time is an in-clinic screening test that evaluates all of the primary hemostatic system. The bleeding time measures the amount of time it takes for bleeding to stop from a small standardized stab incision. Following the creation of the incision, the blood is wicked away with absorbent paper without disturbing the wound until bleeding ceases. The normal bleeding time for dogs is less than ~3.5 minutes. This test is not commonly performed on dogs and is rarely done in any other species [9].

Abnormal bleeding times result from any problem in primary hemostasis: thrombocytopenia, platelet function defects, or von Willebrand factor deficiency (von Willebrand disease). Some important considerations are listed below.

Reliability: Results are very operator dependent, so published reference intervals are only a general estimate. The more experience a person has with performing the test, the more consistent the results will be. Even with a trained person running the test, it is *not very sensitive,* and some animals with primary hemostatic defects will have a normal BMBT [10].

Equipment: To be accurate, the incision must be small and have a standardized length and depth. The incision must be small enough that the bleeding can be stopped with only the formation of a platelet plug (i.e., secondary hemostasis is not involved). Template bleeding time devices (Simplate® or Surgicutt®) must be used, and there are differences in results depending on the device used [11]**.** It is not acceptable to just use a scalpel blade and make a small cut since it is not possible to standardize the length and depth of incision in this manner. Also, many people try to measure the duration of bleeding after clipping a toenail. While some authors recommend this, the length of bleeding in this case is going to vary according to the depth of the cut.

Location: In people, the bleeding time is done on the skin of the forearm. In dogs, the skin is too thick and variable in thickness for this to work. The test must be done on the inner surface of the lip. The patient must be cooperative for this to be done without sedation.

Indications: This test is NOT run very often in clinics because most veterinarians are not trained on it, it is not very sensitive, and alternative testing exists for most diseases. The causes of primary hemostatic disorders are thrombocytopenia, vWd, and platelet function defects. Of these, thrombocytopenia is most common, and a complete blood count (CBC) is used to assess platelet numbers. If an animal is suspected of having vWd, a vWf assay can be run and will be more precise than a bleeding time. However, it is very difficult to test for platelet function problems. Most labs do not offer this testing, and the testing must be performed within a few hours of sample collection, so mailing the sample to a specialized lab is not an option. *Thus, BMBT may be run in patients who have signs of primary hemostasis but have a normal platelet count and vWf concentration, to indirectly document a platelet function disorder*.

It can be used as a presurgical screen if there is clinical concern for a primary hemostatic defect. It is also performed in emergency clinics or referral practices in animals with nonspecific bleeding signs to quickly assess if there is a hemostatic defect vs. bleeding from tissue trauma of some kind while awaiting the results of other tests. If an animal is markedly thrombocytopenic (<20,000/μL), then there is also no point in running the test since a low platelet count by itself can prolong the BMBT.

Platelet concentration (platelet "count")

A platelet count can be done using an automated hematology analyzer or can be estimated from a blood film (or BOTH!). *Thrombocytopenia is probably the most common cause of abnormal bleeding of any kind in veterinary medicine, particularly in dogs*. Therefore, a platelet count should be obtained in any bleeding animal. Platelet counts are typically run from blood submitted in ethylenediaminetetraacetic acid (EDTA) tubes for a CBC.

Platelet numbers must be extremely low for animals to show spontaneous hemorrhage. Normal platelet counts for most domestic species range from ~200,000–500,000/μL (horses typically have fewer with the lower end of reference interval being about 100,000/μL). In general, platelet concentration must drop to *below* 20,000/μL to induce spontaneous bleeding. Platelet counts *below* 50,000/μL can result in hemorrhage secondary to trauma.

Platelets easily clump in the tube. This is especially a problem in cats and in any species when there is difficulty with blood collection. *However, clumping can happen in any sample and should always be considered*. Furthermore, clumping can occur if the blood sample sits for hours before running the test. It is best if the platelet count is run within ~5 hours of blood collection. When platelets clump, the platelet count will be artificially low because the clumped platelets are not counted by the analyzer. Platelet clumps can be seen on the feathered edge of a blood film and should be noted in the comments section of a CBC if the sample is sent to a commercial lab. If significant platelet clumping is present, a new sample is needed to get an accurate platelet count. The count from the clumped sample can be considered a minimum number of platelets. If a CBC is performed and a blood film is not examined for clumping, any low platelet count is suspect.

Artifact due to platelet clumping is the most common cause of a low platelet count in cats and is common in all others species as well. More than half of all feline blood samples submitted for CBC can have low platelet counts due to clumping [12].

Automated platelet counts can also be inaccurate (depending on the specific analyzer methodology) when a high percentage of large platelets are present. This occurs when the analyzer cannot distinguish large platelets from erythrocytes. This is also common in cats, whose platelets tend to be large and whose red cells tend to be small. It also occurs in goats, which have very small red cells. Cavalier King Charles spaniels may have an inherited abnormality called *macrothrombocytopenia* in which many of their platelets are abnormally large [13–15]. The reported platelet counts in this breed are often artifactually very low. The true platelet count can be normal or may be low, but the total platelet mass ("*platelet-crit*," measured by some automated analyzers) is usually normal because the platelets present are larger than normal [16]. The condition is asymptomatic and animals do not have clinical bleeding episodes even if their true platelet count is somewhat decreased.

For the purpose of ruling out thrombocytopenia as a potential cause of bleeding in a patient when a platelet count is not available or when a low platelet count may be an artifact, platelet numbers can be estimated from a blood film. When viewing a slide using the 100×, oil immersion lens in the monolayer of a film, normal animals should have at least seven platelets per field on average. As an estimate, every platelet seen in a 100× field represents about 15,000/μL [17]. So, if an animal has an average of four platelets/hpf, its platelet count is probably ~60,000/μL. Since spontaneous hemorrhage does not occur until platelets decrease to <20,000/μL, an animal bleeding as the result of a thrombocytopenia will typically consistently have only ~0–2 platelets/hpf.

> ***Major concept:*** Automated platelet counts are the most commonly inaccurate result from a CBC. *Every* low platelet count should be confirmed by a review of a blood film – both looking at the feathered edge for clumps and looking at the number of platelets in the body of the film. *It is not acceptable to simply run the sample through an in-house hematology analyzer and trust that value.*

vWf assays

Assays for vWf concentration are performed in a few specialized labs. Most large diagnostic labs will either run it or relay it to the appropriate lab, but results often take a couple of days. Samples for vWf assay are typically submitted in citrate tubes (blue top) but may also be run from EDTA plasma. Ideally, samples should be centrifuged and the plasma removed and frozen until shipped, then shipped overnight with cold packs. vWf concentration has been shown to be stable through repeated freeze/thaw cycles and stable for at least 8 hours at room temperature when stored either as citrated plasma before freezing or whole blood before centrifugation [18–20].

Values are reported as "%," which refers to percent of "normal," rather than getting a specific quantity such as mg/dL. Labs running the assay collect plasma from a group of dogs and combine it into a *plasma pool,* which is arbitrarily designated as 100%. Because of this, results from a patient may be >100%. Reference intervals for vWf will vary from lab to lab, but typically >70% is normal. Most animals bleeding from vWd have values less than 30% [21].

Since vWd is an inherited condition, detecting carriers is often a concern of breeders. Asymptomatic carriers cannot be accurately identified by vWf concentration in the blood [22]. DNA tests are now available for many breeds of dogs (www.vetgen.com). DNA tests can determine if the animal

is carrying one or two genes for the vWd defect. DNA testing generally evaluates for a single specific mutation. There are literally hundreds of different mutations identified in humans, and many exist in animals. Fortunately, a single mutation accounts for most cases in any given breed. So, the DNA testing must be specific for the breed of patient.

Platelet function testing

Various tests of platelet function are run in certain specialized hemostasis labs. The standard test is called *aggregometry,* which tests the ability of the platelets to aggregate in response to the addition of various agonists known to activate platelets. Unfortunately, aggregometry is only run in a few research labs. Also, it is generally recommended that samples are run within 4 hours of collection, thus mailing samples, even by overnight courier, is not suitable [23]. Because of this, platelet function testing is difficult in the vast majority of practices. Platelet function defects often are presumed based on a diagnosis of exclusion. An animal that has an abnormal BMBT but normal platelet count and normal vWf levels probably has a platelet function defect.

There are newer automated analyzers available that test either (i) all of primary hemostasis similar to BMBT (e.g., PFA-100®),or (ii) all aspects of both primary and secondary hemostasis in whole blood (e.g. Sonoclot®) [24, 25]. These could be used in place of BMBT to test for platelet function defects, again by exclusion after combining results with a normal platelet count and BMBT. These are not yet widely available but are being used in some specialty practices. Over time, it is likely that more analyzers that screen for all aspects of hemostasis will become more common.

Tests of secondary hemostasis

Activated clotting time (ACT)

Performing the test

The ACT is an in-clinic test used as a screening test of secondary hemostasis**.** It is usually followed by definitive coagulation testing if a coagulopathy is indicated. The original ACT tubes made by Becton Dickinson (BD, Franklin Lakes, NJ) contained diatomaceous earth, but production of these tubes has been discontinued [26]. Currently available tubes may alternatively contain kaolin, glass beads, or multiple activators [26]. The premise is to activate Factor XII and initiate the intrinsic coagulation pathways. Performing the test is relatively simple. A sample of whole blood is collected into the ACT tube, which is kept at 37 °C. Ideally, this is done in a heat block but can be done by holding the tube in the operator's axilla [27]. The tube is checked every 10 seconds for evidence of clot formation. At the first sign of clot formation, the test is ended and the time recorded.

ACT tube manufacturers typically recommend a two-tube method using a Vacutainer needle. The first 2 mL of blood is collected in one tube that is discarded to remove blood potentially contaminated with tissue factor during venipuncture. A second tube is then filled from the Vacutainer needle and used for the test. However, studies to date have not shown a difference in results whether or not the initial blood is discarded, at least in healthy animals [26, 28]. It makes sense that the sample should be collected with minimal time and trauma.

Interpretation

Published studies using the original Becton Dickinson ACT tubes suggested times of <95–125 seconds for healthy dogs and <165 seconds for healthy cats [28–30]. A more recent study using currently available tubes suggested a reference interval of <80 seconds for dogs and less than <85 seconds for cats [26]. However, this is an operator-dependent test and depends not only on the brand of tube used but also on the ability of the operator to detect the first signs of a clot. Therefore, it is essential for reference intervals to be determined by each operator by performing the test on clinically healthy patients in their particular setting [29].

Because the ACT tube activates the intrinsic system, any deficiency of a coagulation factor in either the intrinsic or common pathways will prolong the ACT. Essentially the only factor that does not affect the ACT is Factor VII. This makes the ACT a good general screening test of secondary hemostasis.

The test is fairly insensitive, so any given coagulation factor must be reduced to less than ~5% of normal to prolong results. With vitamin K antagonism, one of the more common conditions for which the ACT test is used, the factor activities are dramatically inhibited, and ACT results are usually prolonged despite this insensitivity. In the ACT test, the phospholipid surface needed for the coagulation factor reactions to occur is provided by platelets. So, even though the test is not designed to evaluate platelet numbers, a severe thrombocytopenia (<10,000/μL) may potentially cause a mild prolongation of the ACT, although this is not well documented, and any effect is likely minor.

Activated partial thromboplastin time ("APTT" or commonly just "PTT")

This test evaluates the intrinsic and common pathways of coagulation. It tests the same pathways as the ACT but is a more precise and sensitive test. It is typically run along with a PT, which is discussed next.

Blood is collected in a citrate tube (blue top), spun down, and the plasma is used for testing. In this test and the PT, a reagent is added to provide a phospholipid surface, which eliminates the need for platelets. So, these tests will not be affected at all by a low platelet count.

For the partial thromboplastin time (PTT), a reagent is added to initiate the intrinsic coagulation cascade. Because the blood is collected in citrate, which is a calcium chelator, the reaction does not proceed since most of the enzymatic coagulation factors are calcium dependent. After the reagent

has been added to the plasma sample and allowed to incubate, sufficient calcium is added to overcome the action of the citrate, and the number of seconds that it takes for a clot to form is recorded. Because this test initiates the intrinsic coagulation cascade at Factor XII and ends with the formation of a fibrin clot (Factor I), the PTT will be prolonged with a deficiency of any one or more factors in either the intrinsic or the common coagulation pathway. Interpretation of both the PT and PTT is further discussed in the next sections.

One-stage prothrombin time ("OSPT" or commonly just "PT")

This concept of this test is similar to the PTT; however, the reagents activate the extrinsic system rather than the intrinsic system. So, this test evaluates the extrinsic and common pathways. Typically, the PT and PTT are both run on the same sample.

Some specific points about interpreting both the PT and PTT

Units reported

Both tests are reported in seconds. This is the number of seconds that it takes for a clot to form following addition of the final reagent, calcium. Increased values indicate that it took longer for a clot to form and suggest reduced concentrations of one or more factors in the affected pathway.

Relative sensitivity

For either the PT or PTT to be prolonged, the concentration of one or more of the coagulation factors tested must be below about 30% of normal. While this may seem to lack sensitivity, animals generally do not show evidence of bleeding unless coagulation factors are reduced to these same levels. Individual assays offered by various labs may vary in the methodology, reagents, and protocols used. Therefore, reference intervals from the individual labs may vary significantly and cannot be generalized.

Artifacts related to sample handling

Citrate tubes come in 3.2% and 3.8% concentrations. Historically, 3.8% was used in the United States, while 3.2% was standard in Europe, but now both tubes are commonly available in the United States. Studies in a limited number of dogs, both clinically healthy ones and those with hemostatic disorders, have not shown significant differences in results of PT or PTT tests between samples collected in 3.2 vs 3.8% citrate and run on various instruments [31, 32].

Underfilling the citrate tube with blood will result in a *relative excess* of anticoagulant (i.e., the same amount of citrate is in the tube but it is being diluted in less blood, so the concentration is higher). This can result in artificial prolongation of the PT/PTT. It is important to fill tubes to their intended volume. This effect may be more pronounced if using 3.8% citrate tubes [33].

A similar phenomenon occurs in animals with polycythemia. If a patient has a markedly increased hematocrit, there is less plasma for a given volume of whole blood. Less plasma volume again results in a relative excess of anticoagulant. Mild prolongations in PT and PTT are observed in animals with an increased hematocrit. Typically, however, coagulation testing is not being run on polycythemic patients.

Coagulation factors are labile. Ideally, the blood should be separated and plasma removed within 1 hour and the sample run within 4 hours. If the sample is to be mailed to an outside lab, the citrated plasma can be removed from the red cells and frozen. Although these recommendations make intuitive sense and are probably safest to ensure sample quality of all specimens, several studies of human samples suggest that most samples for PT and PTT may be stable for much longer periods, and plasma may be separated from the cells at 8–24 hours after collection with no clinically significant effect [34, 35]. Studies on canine samples suggest that valid PT and PTT results can be obtained from citrated plasma removed from red blood cells and stored for up to 48 hours when refrigerated or even at room temperature, at least in healthy animals [36].

Localizing a defect

By comparing the results of the PT and PTT, it is sometimes possible to localize which factors might be deficient. With a prolonged PTT (which tests intrinsic and common pathways) but a normal PT (which tests extrinsic and common), then one of the factors in the intrinsic pathway is deficient. The normal PT indicates that the common pathway is functioning normally. Conversely, if you have a prolonged PT but normal PTT, the problem is in the extrinsic pathway (Factor VII). If both are prolonged (which is the typical case), then the results do not localize the problem to a specific arm of the coagulation cascade, but the presence of a coagulopathy is confirmed. Either there is a deficiency in the common pathway or there are multiple factors being affected that involve both the intrinsic and extrinsic systems.

Specific factor analysis

If the results of the PT and/or PTT are abnormal, it is sometimes helpful to know the concentration of a specific coagulation factor. Some of the larger hemostasis labs offer these assays. Quantitative fibrinogen concentration (Factor I) is often included in a basic coagulation profile to test for reduced concentrations of fibrinogen resulting from increased consumption in disseminated intravascular coagulation. Specific factor analysis is also run on citrated plasma, so the same sample used to test PT/PTT can be used, if needed. Results for most factors are reported as % of a pool of plasma from normal animals, similar to vWf.

Tests of fibrinolysis (fibrin clot breakdown)

Fibrin(ogen) degradation products (FDPs) and D-dimers

Pathophysiology of D-dimer formation

FDPs refer to any of the various protein fragments produced when fibrin is cleaved by plasmin in the process of fibrinolysis. They can also be formed when fibrinogen (i.e., that which has not yet converted into fibrin and incorporated into a clot) is cleaved by plasmin.

D-dimers are a specific subset of FDPs. The fibrinogen molecule has three protein domains. There are two identical "D" domains on either end and an "E" domain in the middle. D-dimers are fragments that contain two "D" domains that have been cross-linked together. These can be formed only by the breakdown of cross-linked fibrin and not fibrinogen itself. Thus D-dimers are more specific to breakdown of clots and suggest that there is increased activity of concurrent coagulation and fibrinolysis. The D-dimer assay has essentially replaced the FDP test in clinical diagnostics. Citrated plasma is used for the D-dimer assay as with most other tests of coagulation.

Interpretation

In the normal animal, low levels of FDPs are constantly generated due to low levels of coagulation and fibrinolysis that occur normally to maintain vascular integrity as endothelial cells die and are replaced. These FDPs are quickly removed by macrophages in the liver and spleen. Thus, they are generally present in the blood in concentrations below detectable limits in healthy animals.

Increased concentrations of D-dimers indicate that coagulation and fibrinolysis are occurring at an accelerated rate. This usually occurs following formation of a large thrombus or multiple thrombi, which are subsequently degraded. *Thus, increased concentrations of FDPs or D-dimers is a marker of thrombotic disease*.

In addition to thrombotic disease, mild increases in FDP concentrations may be seen in animals with significant hemorrhage into body cavities (e.g., hemoabdomen) or tissues (e.g., trauma, postsurgery), as these conditions will result in subsequent coagulation and lysis of the clots. Increases can also occur with widespread inflammatory diseases, such as sepsis, which can also activate the coagulation system with subsequent fibrinolysis. Finally, since FDPs are cleared by the liver, animals with reduced hepatic function may have increased FDP concentrations as a result of reduced clearance [37, 38]. Thus, increased concentrations are not specific for thrombotic disease [37, 39].

The higher the concentration of D-dimers, the greater the likelihood of thromboembolic disease. Results up to 500–1000 ng/mL are often seen with trauma, postsurgery, liver disease, etc. If other findings suggest thromboembolism, mild to moderate increases up to this concentration may still be significant. Concentrations of 1000–2000 ng/mL or > 2000 ng/mL are more specific for thromboembolism because other conditions do not usually result in increases of this magnitude [37, 39].

Hemostasis profiles (or "coagulation profiles")

Clinics may run ACT tubes and potentially BMBT in-house as rapid screens to evaluate secondary and primary hemostasis, respectively. More comprehensive testing may be done through private laboratories or in-house analyzers. Laboratories will typically offer different coagulation profiles, with variable numbers of tests included, depending on the specific condition suspected. *A general screen might include a platelet count (as part of a CBC), PT, PTT, D-dimers, and quantitative fibrinogen*. This would provide a good general screen for the most common defects of primary hemostasis (i.e., thrombocytopenia), secondary hemostasis, and evidence of thrombotic disease including DIC. Specific tests such as vWf concentration are added based on clinical suspicion. A smaller profile including platelet count, PT, and PTT might be used as a presurgical screen in an apparently healthy patient.

Common hemostatic disease in veterinary medicine

Once hemostasis testing has (i) confirmed that a hemostatic defect is present and (ii) localized it to a condition affecting primary hemostasis, secondary hemostasis, or both, then the presenting findings of the patient can be compared with a differential list of common diseases to attempt a specific diagnosis. There are a few common conditions that will account for the majority of hemostatic defects seen in practice.

Diseases affecting primary hemostasis

Thrombocytopenia

Thrombocytopenia is a common cause of abnormal bleeding, particularly in dogs. Since it is easy to obtain a platelet count, this should always be part of the workup of a bleeding animal. There are many specific causes of thrombocytopenia, which results in a huge differential list for this specific finding. Mild to moderate thrombocytopenia (platelet counts not lower than 50,000/μL) can be seen with numerous bacterial and viral infections, neoplasia, following hemorrhage (where it results from both loss of platelets and also use of platelets in attempts to clot), secondary to vasculitis (where the platelets are used for repairing endothelium), following vaccination, and many other causes [40–44]. Often, the thrombocytopenia is not the major/only finding in a very ill animal with systemic disease. These conditions are generally recognized by their more prominent findings.

There are fewer conditions in which (i) the thrombocytopenia is severe enough to result in spontaneous bleeding

(i.e., less than 20,000/μL) and (ii) the thrombocytopenia and associated bleeding manifestations are the main or only abnormal finding in the patient. The major conditions that should be considered in these cases are:

a. *Rickettsial disease:* Many species of *Ehrlichia (E. canis, E. ewingii)* and *Anaplasma (A. phagocytophilum, A. platys)* can infect dogs [45]. These are regionally common diseases. Infection with these organisms can result in a marked thrombocytopenia in the acute stages of infection. Animals may present with petechiae or mucosal bleeding such as epistaxis. Thrombocytopenia may be severe (<10,000/μL) in the acute stages of infection. In chronic *E. canis* infection, there is sometimes a generalized hypoplasia of the bone marrow, and a pancytopenia may result. Rocky Mountain spotted fever also causes a thrombocytopenia, but it is usually not as severe as that seen with ehrlichiosis, although the clinical disease may be quite severe [46].
   Ehrlichia canis organisms are not typically present in numbers great enough to identify in peripheral blood films, although they may rarely be seen. Organisms are present in relatively greater numbers in acute *E. ewingii* and *A. phagocytophilum* infections [47, 48]. In endemic areas, these conditions may be identified by finding morulae in neutrophils on a peripheral blood smear. Even in these diseases, however, the parasitemia is short lived.
   Diagnosis is typically confirmed by running in-clinic tests (i.e. SNAP tests), antibody titers, or polymerase chain reaction (PCR) for detecting the DNA of the organism. It is important to consider that a positive antibody test means past exposure but not necessarily active disease.
b. *Immune-mediated thrombocytopenia (ITP):* Similar to immune-mediated hemolytic anemia, antibodies may be directed against platelet antigens and result in their removal. This is common in dogs but much less common in other species [40, 42, 43]. Like hemolytic anemia, ITP can be primary, in which there is no underlying cause detectable, or it can be secondary to other conditions such as administration of drugs, infections, or as a paraneoplastic response.
   Affected animals often have no other signs of systemic illness and are apparently healthy other than having a markedly decreased platelet count. ITP is often a diagnosis made by excluding other causes and then supported by response to treatment. It is possible to test for platelet surface-associated immunoglobulin by flow cytometry [49–51]. In addition to confirming an immune mechanism as the cause of the thrombocytopenia, patients are usually screened for possible underlying infectious (serology, PCR) or neoplastic (diagnostic imaging) causes.
c. *DIC:* In DIC, there first is widespread, uncontrolled activation of the hemostatic system throughout the body [52]. This is in contrast to normal hemostasis, which is limited to a site of vascular injury. If severe enough and prolonged enough, this widespread hemostatic response ends up consuming both platelets and coagulation factors, resulting in thrombocytopenia and reduced concentration of coagulation factors. DIC is thus initially *hypercoagulable* with thrombosis occurring throughout the body, but eventually the animal becomes *hypocoagulable* and may show hemorrhagic tendencies because of the depletion of platelets and coagulation factors. Because of this, DIC is sometimes called a *consumptive coagulopathy*.
   DIC is not a specific disease but is a common result of a variety of underlying disorders that share common properties of either inducing vascular damage, exposing massive amounts of tissue factor, or directly activating the intrinsic coagulation cascade. Common triggers for DIC include sepsis, widespread tissue trauma, heatstroke, neoplasia, and severe systemic inflammatory diseases such as pancreatitis or peritonitis [52, 53]. These diseases can cause widespread activation of hemostasis and overwhelm the normal regulatory processes that limit it in health.
   Animals with DIC are usually overtly clinically ill from their underlying disease. Along with the thrombocytopenia, there can be prolongations in the coagulation tests (PT, PTT) and increased concentrations of D-dimers. Not all tests are abnormal simultaneously in every case of DIC. This makes laboratory confirmation of DIC subjective, and there is no accepted consensus regarding a laboratory diagnosis of DIC in veterinary medicine [52, 53].
   In dogs with DIC, thrombocytopenia is reported in a greater percentage of cases than prolongations in PT or PTT. Evidence of excessive fibrinolysis from increased D-dimers is usually present. Other tests that are sometimes run to evaluate suspect cases of DIC are quantitative fibrinogen and antithrombin concentrations, both of which may be decreased if consumption is great enough to exceed production. Schistocytes may be noted in the peripheral blood of animals in overt DIC. In two reviews of cats with DIC, prolongations in PT, PTT were more frequent than thrombocytopenia [54, 55]. PTT was prolonged in 100% of the cats in both studies, while thrombocytopenia was detected in 50% or less of the cases. It is important to realize that the percentage of abnormal tests in all studies may depend significantly on the criteria used to define DIC and include or exclude cases. Given the lack of a "gold standard" to diagnose DIC, and considering the fact that it is a complication of underlying disease processes rather than a distinct entity unto itself, it may be more practical to think of DIC as a spectrum of activation (or loss of control of the activation) of the hemostatic system rather than something that is a dichotomous entity that is either "present" or "absent" [55]. DIC may be present with subclinical (compensated) or overt manifestations.

d. *Bone marrow disease:* The diseases listed previously each result in thrombocytopenia primarily as a result of increased consumption or destruction of platelets. Thrombocytopenia may also occur from decreased bone marrow production of platelets.

One of the most common causes of this type of thrombocytopenia is hematopoietic neoplasia of the bone marrow. With infiltration of the bone marrow by either lymphoma or acute leukemia, neoplastic cells can crowd out the normal hematopoietic tissue. This crowding out of normal bone marrow tissue by an abnormal cell type is termed *myelophthisis* or *myelophthisic disease*. Another less common cause of myelophthisis is myelofibrosis, in which the marrow is replaced by fibrous connective tissue. This is usually the result of prior bone marrow injury that has resulted in repair by fibrosis.

Apart from myelophthisic disease, toxic injury to marrow stem cells can result in lack of production of hematopoietic precursors and result in marrow hypoplasia or aplasia. A variety of drugs, including estrogen and chemotherapeutic agents, and even certain infectious diseases can be injurious to marrow stem cells. Depending on the specific drug or infectious agent, there may be a selective decrease of any one of the hematopoietic cell line (erythrocytes, leukocytes, or platelets), or there may be a reduction in multiple cell lines.

Because bone marrow disease often affects multiple cells lines, the index of suspicion for it should be increased in thrombocytopenic animals who also have a severe, nonregenerative anemia, neutropenia, or both. However, sometimes animals that appear to have widespread myelophthisic disease have only a single peripheral cytopenia. A bone marrow aspirate +/− core biopsy can allow evaluation of the number of megakaryocytes present and their maturation and help differentiate lack of production from either increased consumption or destruction of platelets as a cause of thrombocytopenia.

von Willebrand disease

vWd is predominantly an inherited deficiency of vWf [56]. Acquired deficiencies of vWf have been reported but are not common [56]. vWd is the most common of the *inherited* bleeding disorders in both humans and in dogs, having a far higher incidence than the more widely known hemophilia [56]. It has been reported in numerous breeds of dogs and is extremely common in certain breeds. At one point in time, it was estimated that up to 70% of Doberman pinschers had low vWf concentrations [57]. Other commonly affected breeds include Shetland sheepdogs, German shorthaired pointers, German wirehaired pointers, and Scottish terriers [58–61]. There are three forms of vWd (type I, type II, type III) described depending on whether there is strictly a quantitative decrease (type I), also a qualitative defect of the multimeric structure (type II), or complete absence (type III) of vWF [56, 57]. In dogs, the type of vWd present often depends on the breed affected, and the bleeding manifestations observed with type II and type III may be more severe.

Patients with vWd may present with mild to severe bleeding that is typical of primary hemostatic defect bleeds. Some patients will not show any bleeding tendencies unless stressed in some way, such as a surgical challenge or trauma. Diagnosis usually starts with an index of suspicion because of the breed or because the patient presents with mucosal-type hemorrhages and has a normal platelet count. The diagnosis is confirmed by assaying levels of vWf in plasma. Animals with vWd generally bleed only if the vWf concentration is below ~30% of normal [21]. Platelet counts will be normal unless the animal has lost significant amounts of blood, and even then, they will only be mildly decreased at most. The bleeding manifestations can be mild. Thus, despite being an inherited condition, many patients are not diagnosed until middle age or older. In people, diagnosis often is not made until the third or fourth decade of life.

Platelet function defects

Platelet function defects are termed either *thrombopathia* or *thrombopathy*. They are less common that thrombocytopenia. Platelet function defects can be acquired or inherited.

Inherited platelet function defects have been reported in several breeds of dogs (basset hound, otterhound, cocker spaniel, spitz, Great Pyrenees), cats (Persian), horses, and in Simmental cattle [62]. The defect in otterhounds, Great Pyrenees, and horses are all related to a lack of GPIIb/IIIa, the fibrinogen receptor. The defect in basset hounds, spitz dogs, and Simmental cattle results from an intracellular signaling defect that prevents normal platelet activation. Genetic testing is available for some of the breed-specific disorders.

Acquired platelet function defects can be seen with administration of certain drugs and with several disease states. Aspirin and other NSAIDs inhibit cyclooxygenase (COX), the enzyme involved in production of thromboxane, which is a platelet agonist. Most NSAIDs only reversibly inhibit COX. Thus, once the drug is cleared, platelet function returns to normal. Aspirin irreversibly inhibits COX, and since platelets are anucleate and cannot synthesize new enzyme, aspirin's effect on platelets is irreversible for the lifespan of the platelet. Common disease states in which there are acquired defects of platelet function include uremia, hepatic failure, and marked hyperproteinemia.

Animals with platelet function defects have normal platelet counts and normal vWf levels but may have a prolonged BMBT. As stated before, it is difficult to definitively diagnose because there are very few labs that do platelet function testing. Diagnosis is usually made by excluding other primary hemostatic defects in a bleeding animal and identifying an underlying disease known to affect platelet function.

Diseases affecting secondary hemostasis

Vitamin K antagonism

Pathogenesis

Vitamin K antagonism is a common problem in veterinary medicine and is probably the most commonly encountered disease affecting the coagulation proteins [63–66]. Factors II, VII, IX, and X are *vitamin K–dependent* coagulation factors. When these factors are first produced by the liver, they are inactive and need enzymatic action (carboxylation of glutamic acid residues) by vitamin K to become functional [67]. When vitamin K activates a single coagulation factor molecule, the vitamin K molecule itself becomes oxidized, and it is no longer functional. This oxidized vitamin K must be reduced back to its active form by an enzyme called *vitamin K epoxide reductase* to act on additional coagulation factor molecules (see Figure 17.5) [67]. Normally, one molecule of vitamin K is recycled many times by this enzyme and activates numerous coagulation factor molecules. Therefore, the body needs fewer molecules of vitamin K than if it was just used once. Vitamin K antagonists *do not inhibit the action of reduced vitamin K directly; instead, they inactivate the vitamin K epoxide reductase enzyme,* which regenerates the active form of vitamin K**.** Thus, when a molecule of vitamin K activates a single coagulation factor molecule, it becomes oxidized (nonfunctional) and is not reactivated. In this situation, all vitamin K molecules are quickly converted to their oxidized form, and no further activation of the vitamin K–dependent factors can occur.

An animal ingesting vitamin K antagonists initially has normal concentrations of fully activated factors, but no *new* factors can be activated. The concentration of active factors then starts to decline at a rate depending on their individual half-life, and bleeding manifestations begin once concentrations of any one or more factors drop below critical levels. Intoxication with vitamin K antagonists thus results in deficiencies of the active forms of Factors II, VII, IX, and X. However, the inactive forms continue to be produced and build up in the blood. These inactive coagulation factors are referred to as "PIVKAs" [proteins induced by vitamin k antagonism (absence)].

Diagnostic findings

Since the vitamin K–dependent factors are in the intrinsic, extrinsic, and common pathways, both PT and PTT are classically prolonged [63]. Because multiple factors in all pathways are affected, and because the concentration of active factors is markedly reduced, the prolongations in the tests are often dramatic. In many cases, an end point (clot) is not reached, and results are simply reported out as "greater than 100 seconds" or however long the lab establishes before stopping the test. Since Factor VII has the shortest half-life, it decreases most quickly. Therefore, testing very early after ingestion (within the first 24–48 hours) may show a prolongation of the PT before the PTT. Both tests will typically be markedly prolonged by the time clinical signs have developed. Platelet counts may be normal or may be mildly reduced if there is significant hemorrhage [63].

Other than signs related to their coagulopathy, these patients are not systemically ill. Animals typically present with body cavity hemorrhages. Dyspnea due to hemothorax is a common presenting finding [63, 64]. Hematoma formation may be noted at sites of venipuncture.

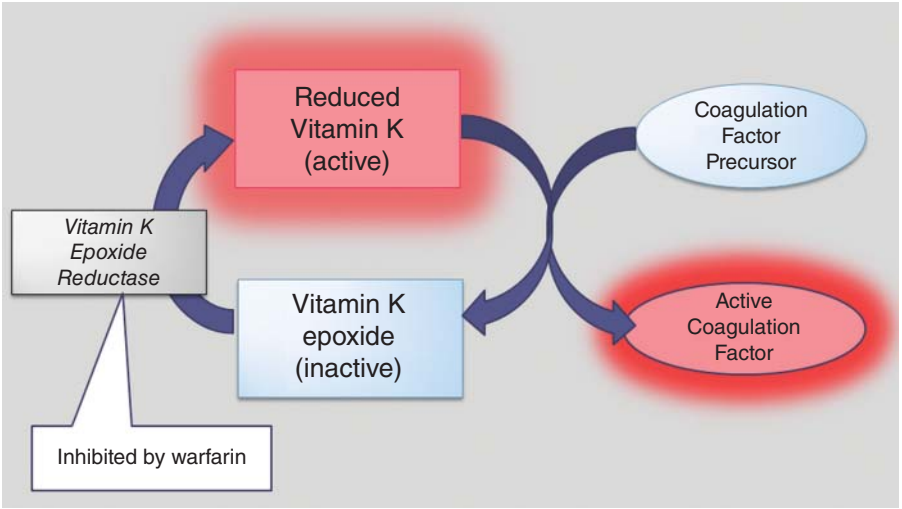

Figure 17.5 The vitamin K cycle. Vitamin K is needed for activation of precursors of Factors II, VII, IX, and X. When vitamin K activates a coagulation factor precursor, it becomes oxidized itself and is no longer functional until it is reduced back to its active form by the enzyme *vitamin K epoxide reductase*. Warfarin and warfarin-like molecules (including rodenticides) inhibit vitamin K epoxide reductase, resulting in reduced concentrations of the vitamin K–dependent factors.

Causes

Dietary deficiency of vitamin K is not generally a problem. Anticoagulant rodenticides are the most common source of vitamin K antagonism. These products are usually warfarin-like molecules, although some rodenticides have a completely different mechanism of action that does not affect hemostasis. The newer-generation anticoagulant rodenticides have a very long half-life that necessitates prolonged treatment with vitamin K. Ingestion of moldy sweet clover also causes a vitamin K antagonism in cattle. Since vitamin K is a fat-soluble vitamin and requires bile acids for absorption from the gut, vitamin K deficiency due to poor intestinal absorption can be seen in animals with severe cholestatic liver disease [66]. Sulfaquinoxaline, a coccidiostat, also has inhibitory effects on vitamin K.

Treatment

Since the inhibition is not direct, affected animals can be treated by administering active vitamin K. Response to administration of vitamin K is very rapid, usually within 24 hours [63, 65]. This rapid response occurs because the inactive PIVKAs are already produced and in circulation, simply requiring enzymatic activation. If faster response is needed in an acutely ill animal with life-threatening bleeding, administration of fresh or fresh-frozen plasma can provide active coagulation factors until the body has time to respond to vitamin K administration. Because even the newly administered vitamin K cannot be recycled as long as the antagonist is present, the animal must be treated for an extended time until the toxin is cleared from the body. The newer rodenticides have very long half-lives. Once treatment is discontinued, it is wise to screen the patient's PT at 48 and 96 hours after treatment is stopped to make sure there is no residual toxin remaining in the body [63].

Liver failure

Pathogenesis

Liver diseases of various types can result in reduced concentrations of coagulation factors by two different mechanisms. First, since all of the soluble coagulation factors are produced in the liver, liver failure can result directly in decreased production of these proteins. This generally requires a marked reduction in hepatic function, given the normal excess of functional capacity of most major organs in the body. Secondly, liver diseases that are cholestatic lead to a reduction in normal bile flow. Bile secreted by the liver into the intestines aids in fat absorption, so animals with cholestasis can have reduced fat absorption. Vitamin K is a fat-soluble vitamin, and cholestasis can result in decreased vitamin K absorption and deficiency.

Diagnostic findings

This is not usually a diagnostic challenge from the standpoint of trying to figure out why an animal is bleeding. Animals with liver disease severe enough to cause coagulation defects will usually have clinical signs (e.g., icterus) or lab findings (e.g., increased liver enzymes, increased bilirubin or abnormal liver function tests) that suggest liver disease.

More often, liver disease has already been recognized, and the concern is that the patient may have excessive bleeding from invasive procedures such as a liver biopsy. So, patients may be screened for coagulation abnormalities before a liver biopsy or other invasive procedure. Patients with severe cholestatic disease may be pretreated with vitamin K prophylactically before such a procedure. PT and PTT may both be prolonged since any or all of the factors may be deficient. Whether both are prolonged or just one depends on the severity of the hepatic dysfunction and relative reduction in the concentrations of the individual factors. Interestingly, many animals with chronic liver failure that have abnormal coagulation test results do not show significant bleeding manifestations following surgery or biopsy. Since the liver is involved in production and/or metabolism of both procoagulant factors as well as anticoagulant factors, evaluating only one arm, as is done with the PT and PTT, does not always reflects the true physiologic condition. Unfortunately, the results of the PT and PTT are not reliable in predicting which animals might bleed and which will not.

DIC

DIC was previously discussed under causes of thrombocytopenia. DIC is the one disease that commonly affects both primary and secondary hemostasis and should be considered in a clinically ill patient with both thrombocytopenia and evidence of a coagulopathy.

Inherited defects

Inherited defects of most of the coagulation factors have been reported, although none are common (Table 17.5) [68]. The most frequently encountered inherited defect is of Factor VIII. Given the intentional inbreeding associated with purebred animals, inherited defects may be propagated within a specific breed. However, once a condition is recognized, screening and selective breeding efforts often reduce the incidence, so the relative incidence of these diseases in a specific breed can change over time. Depending on the specific mutation involved, the magnitude of the decrease of the affected coagulation factor can be variable and thus so can the severity of clinical signs.

Diagnostic findings

Inherited coagulopathies usually have strong breed associations and may be associated with specific lines within a breed. An exception is Factor VIII deficiency, which has been reported in many different breeds of dogs as well as mixed-breed animals [68]. If dealing with a pure-breed dog, it is always worth researching to see if a certain inherited disorder has been reported in that breed.

Table 17.5 Inherited coagulopathies reported in animals.

Factor affected	Species/breed reported	Comments
Prekallikrein	Dogs: poodle Horses: Belgian, miniature horses	Not typically associated with clinical bleeding tendencies
Factor XII	Dogs: miniature poodle, Shar Pei Cats: DSH, DLH, Siamese, Himalayan	Not typically associated with clinical bleeding tendencies Relatively common in cats as an incidental finding of markedly prolonged aPTT
Factor XI	Dogs: springer spaniel, Weimaraner, Great Pyrenees, Kerry blue terrier Cats: DSH Cattle: Holstein	Clinical bleeding tendencies are generally mild
Factor X	Dogs: Jack Russell terrier, cocker spaniel Cats: DSH	Rare Severe clinical bleeding tendencies
Factor IX	Dogs: any breed, mixed breed Cats: any breed, mixed breed	Sex-linked, primarily seen in males De novo mutations relatively common resulting in cases with no prior familial history Second-most-common symptomatic, inherited coagulopathy (termed "*Hemophilia B*") Severity of clinical bleeding tendencies relates to residual factor activity, which is variable depending on specific mutation (hundreds identified in humans)
Factor VIII	Dogs: any breed (German shepherd common), mixed breed Cats: any breed, mixed breed Horses: any breed Sheep: White Alpine	Sex-linked, primarily seen in males De novo mutations relatively common resulting in cases with no prior familial history Most common symptomatic, inherited coagulopathy (termed "*Hemophilia A*") Severity of clinical bleeding tendencies relates to residual factor activity, which is variable depending on specific mutation (hundreds identified in humans)
Factor VII	Dogs: Alaskan Klee Kai, beagle, boxer, bulldog, dachshund, malamute, schnauzer Cats: DSH	Clinical bleeding tendencies are variable, even among related patients
Factor V	Not yet reported in animals	
Factor II	Dogs: boxer, English cocker spaniel	Rare In boxer, defect was functional (normal concentrations of an abnormal protein)
Factor I	Dogs: bichon frise, Borzoi, collie, Russian wolfhound Cats: DSH Goats: Saanen Sheep: Leicester	Acquired deficiencies (e.g., DIC, hepatic failure) are more common than inherited Both quantitative and function inherited defects are reported but uncommon Clinical bleeding tendencies range from mild to severe
Multiple: vitamin K–dependent factors	Dogs: Labrador retriever Cats: Devon rex Sheep: Rambouillet	Defect involves enzymes involved in vitamin K recycling leading to function deficiencies of vitamin K–dependent factors Clinical bleeding tendencies are moderate to severe Some cases respond to vitamin K administration

Sources: Based on Brooks M. Hereditary Coagulopathies In: Weiss DJ Wardrop KJ, ed. Schalm's Veterinary Hematology. 6th ed. Ames, IA: Blackwell, 2010; and Boudreaux, M. Hemostasis Lecture Notes 2011. Deer Park, NY: Linus Publications, Inc. 2011.

Animals with inherited coagulopathies usually do not have signs of systemic illness other than their bleeding manifestations, unless there is a concurrent illness. Bleeding manifestations common to most coagulation factor deficiencies include hemarthrosis, hematoma formation, and prolonged bleeding in response to minor injuries [68].

Animals with inherited coagulopathies should have normal platelet counts and other tests related to primary

hemostasis. The coagulation testing results will depend upon in which system the deficient factor is located. Deficiencies of factors in the intrinsic cascade typically have a prolonged PTT and normal PT, while Factor VII deficiency would be expected to have the opposite results. Common pathway factor deficiencies would be expected to have prolongations of both PT and PTT. Typically, the magnitude of the prolongation in these tests is not nearly as dramatic as that seen with rodenticide toxicity.

Of particularly note, Factor XII deficiency is well characterized in cats and fairly common compared to other inherited coagulopathies. Interestingly, these cats *do not* show abnormal bleeding episodes, and they are usually clinically asymptomatic despite having markedly prolonged PTT results. These cases are usually picked up on presurgical hemostasis testing.

18 Principles of Blood Transfusion and Crossmatching

Linda M. Vap[1] and Karl E. Jandrey[2]

[1]Department of Microbiology, Immunology, and Pathology, Colorado State University, Fort Collins, CO, USA
[2]Clinical Small Animal Emergency and Critical Care, University of California- Davis, Davis, CA, USA

The treatment advancements with blood products for veterinary patients are due not only to the improved access to blood products by the growth of commercial and in-house donor programs but also advances in point-of-care assessment to increase safety in storage and administration to the recipient. Many regional blood banks and improved or expanded local programs within hospitals deliver a safe product beyond fresh whole blood (FWB). Hospitals without ready access to a safe and steady supply of blood products should consider referring their patients to one of these centers. Emergency or specialty hospitals in most metropolitan and suburban areas likely host a small animal or equine blood donor program and blood bank, some even selling their blood commercially while complying with local laws. These centers house the people, materials, and equipment that host a functional and profitable blood bank. The increased access and development of patient-side blood type and crossmatch technology has also added to the feasibility and improved delivery of quality transfusion therapy for some species. This chapter discusses crossmatching and blood typing products commercially available.

Blood groups

Blood groups or types are classifications made based on species-specific antigens on the surface of erythrocytes and are important in inducing immune-mediated reactions in host animals during transfusion therapies. Antigens associated with platelets, leukocytes, and plasma proteins may be important as well. Naturally occurring alloantibodies against another blood type can be present in an animal's plasma despite lack of prior exposure to those erythrocyte antigens. More commonly, antibodies against erythrocyte antigens are induced in response to exposure, either via blood transfusion, transplacental exposure, or, in the case of neonatal isoerythrolysis (NI), through colostrum. Blood groups in the common domestic and pet exotic species are described here and presented in Table 18.1.

Dogs

The dog erythrocyte antigen or blood type system is known as the DEA system and has historically included DEA 1 (1 neg, 1.1, 1.2, 1.3) and DEAs 3–8. Recent reports indicate DEA 1.1 and 1.2 are the same antigen with varying strengths of expression [7, 8]. Furthermore, it has been shown that dogs with weak red-cell DEA 1 expression do not develop antibodies when transfused with those of strong DEA 1 expression [9]. Henceforth, DEA 1.1 and DEA 1.2 will be referred to as DEA 1. DEA 1.3 has been described in German shepherd dogs in Australia [10]. However, to the authors' knowledge, no further evidence has been published confirming its continued existence. The most important canine blood type is DEA 1, which is present in approximately 60% of the canine population [11]. While naturally occurring DEA 1 alloantibodies have not been described, this antigen will induce severe transfusion reactions in previously sensitized dogs. Other DEA alloantibodies are reportedly of limited clinical significance in dogs, unlike the situation in cats, but may exist in some dogs [11–13]. DEA 4 is a high-frequency antigen that can result in hemolytic transfusion reactions in DEA 4-negative dogs previously sensitized by DEA 4-positive blood transfusions [14]. In addition, DEA 7 may elicit an antibody response in dogs that lack it, and DEAs 3 and 5 are low-incidence antigens in which naturally occurring alloantibodies can occur; anti-DEA 3, 5, and 7 can result in delayed transfusion reactions [15–19]. The high-frequency *Dal* erythrocyte antigen was so named as it was originally identified after accidental sensitization of a Dalmatian dog by transfusion of *Dal*-positive blood. It has since been demonstrated as lacking in up to 12% of Dalmatians, 42% of Doberman pinschers, and 57% of Shih Tzus within North

Table 18.1 Antigens and pertinent factors in veterinary transfusion medicine.

Species	Major immunogenic antigens	Naturally occurring alloantibodies	Recommended donor type	First transfusion risks and recommendations	Matched transfused RBC half-life (d)
Dog	DEA 1	Rare; DEA 3, 5, 7; cold reacting	DEA 1 type-matched or DEA 1 negative for first transfusion. Crossmatch-compatible for repeat transfusions. *No* prior transfusion.	Low. Use of universal donor minimizes sensitization risk. Crossmatch if ≥4 d since prior transfusion.	24 [1]
Cat	A most common	Common. Anti-B, usually mild in type A cats.	Type A	Low if A/B type-matched. High if A/B type mismatched.	29–39 [2]
	B rare except select breeds.	Common. Anti-A, strong in type B cats.	Type B	Crossmatching always recommended.	
	AB very rare – in breeds that also have B.	No anti-A or anti-B	Type AB if available (rare); Type A		
	Mik	Anti-*Mik* reported in DSH	A/B type-specific crossmatch compatible	6% in type A/B-matched blood. Crossmatch recommended.	
Horse	Complex system of 30+ antigens in seven blood groups. Donkey RBC antigen.	Occur. Anti-Aa, -Qa most important. Probably none.	None. Aa/Qa negative or same breed class is best starting choice.	Considerable; use least incompatible. High neonatal isoerythrolysis risk for mule foals.	9 [3], 24–43 [4]
Cattle	Eleven blood groups: B and J most important. B very complex in ruminants.	Occasionally anti-J.	J-negative.	Low for first transfusion. Close match difficult. Hemolytic crossmatch recommended.	12–20 [5]
Sheep Goat	Seven blood groups in sheep: sheep R similar to cattle J; sheep B similar to cattle and goat B. Five blood groups in goat: similar to sheep.	Weak. Goat anti-R.	Not defined	Low for first transfusion. Hemolytic crossmatch recommended. Hemolytic crisis rare in sheep.	16 [6]
Ferret	None identified	None identified	Not applicable	No risk identified	Unknown

America, varying with geographical regions [20]. There is a relatively high potential for clinically important transfusion reactions in those breeds [21]. Since less than 3% of mixed and other breeds are type *Dal* -, extended blood typing to include Dal antigen is recommended when there is suspicion for a transfusion reaction in any breed [20].

Cats

Three blood types are routinely recognized in the feline AB blood group system. Type A is the most common and occurs in more than 95% of domestic shorthair (DSH) and domestic longhair (DLH) cats in the United States [12, 22]. Type B occurs with varied frequency (<5–25%) in the Abyssinian, Birman, Himalayan, Scottish fold, Somali, Sphinx, Maine coon, Norwegian forest, and Persian cat breeds, whereas the highest frequency (25–50%) has been reported in the British shorthair, Cornish rex, Devon rex, and Turkish angora/van breeds [12, 22]. A higher percentage of DSH/DLH cats in the west coast region of the United States, Europe, Japan, India, Turkey, and Australia are reportedly type B [12, 23, 24]; one report found up to 30% of DSH/DLH cats were type B in the United Kingdom [25]. To date, type B has not

been found in the Siamese, Burmese, Oriental shorthair, Tonkinese, American shorthair, or Russian blue breeds. Type AB is extremely rare but has been reported in DSH/DLH cats and in certain families of breeds in which type B blood also occurs, including the Abyssinian, Birman, British shorthair, Norwegian forest, Somali, Scottish fold, and Persian [26]. A novel erythrocyte antigen, *Mik*, has been described in DSH cats [27]. It is important to consider that geographical variation of feline blood types is significant, even in mixed-breed cats, and the risk of administering a potentially fatal type A or AB blood transfusion to a type B cat, at least in some populations, may be as high as one in five [25, 28].

Cats have naturally occurring anti-A, anti-B, and Anti-*Mik* alloantibodies [27, 29]. All type B cats have high serum concentrations of alloantibodies that are strong hemagglutinins and hemolysins against type A erythrocytes. Type A cats generally have weak hemagglutinins and hemolysins against type B erythrocytes. Newborn kittens have no alloantibodies because of their endotheliochorial placenta, but colostral transfer of immunoglobulin (primarily IgG) occurs. NI occurs in type A or AB suckling kittens born to type B queens with transfer of the anti-A alloantibodies via the colostrum [23, 29, 30]. Because DSH/DLH cats have a low frequency of type B blood, less than 2% of random matings produce litters at risk for NI, whereas Birman and Devon rex matings carry a risk of 15% and 25%, respectively, for producing NI [30]. The *Mik* antigen is clinically relevant in that approximately 6% of AB-matched blood transfusions can result in acute post-transfusion hemolysis if the patient blood is negative and the donor blood is positive for this antigen [27].

Horses and donkeys

The seven internationally recognized blood groups in the horse, A, C, D, K, P, Q, U, include more than 30 antigens [31, 32]. Because of various antigenic combinations, no universal donor exists. To minimize transfusion reactions, blood typing of the donor and recipient is ideal but often impractical. An earlier report indicating short transfused cell life span and limited utility of compatibility testing in horses has recently been refuted [4, 33]. At the very least, crossmatching prior to transfusion is recommended [34]. Aa and Qa alloantigens are extremely immunogenic; both are hemolysins, and most cases of NI are associated with anti-Aa or -Qa antibodies. In addition, anti-Aa and -Ca are agglutinating antibodies. It is important to note that Qa will not be detected with an agglutination test. Blood types vary among horse breeds, with Thoroughbreds and Arabians having a high prevalence of antigens Aa or Qa compared to other breeds, and Standardbreds lacking the Qa antigen [31, 35]. A unique donkey and mule erythrocyte antigen (donkey factor), not found in the horse, puts all mule pregnancies at risk for NI [36, 37]. Although erythrocyte antigens Aa or Qa have been associated with approximately 90% of equine NI cases [38], other antigens including Ab, Dc, Db, De, Dg, Pa, Qc, and Ua have rarely been associated with NI in foals [31, 35, 38, 39]. Reportedly, the anti-Ca antibody does not cause NI and, in fact, may actually prevent NI by removal of potentially sensitizing cells from the circulation [40].

Cattle, sheep, and goats

The 11 recognized blood groups in cattle are A, B, C, F, J, L, M, R, S, T, and Z with groups B and J being the most clinically relevant. The B group itself has more than 60 antigens, thereby making closely matched blood transfusions difficult. The J antigen is a lipid found in plasma that is not a true erythrocyte antigen; it is usually acquired to varying degrees early in life. Cattle with anti-J antibodies, despite having erythrocytes with a small amount of adsorbed J antigen that apparently type negative, can develop transfusion reactions when receiving J-positive blood [31, 41]. Vaccinations of blood origin (some anaplasmosis and babesiosis vaccines) may sensitize cattle to erythrocyte antigens that could result in NI in subsequent calves [31].

Seven blood groups have been identified in sheep (A, B, C, D, M, R, X). The B system has more than 52 factors [31]. The R system is similar to the J system in cattle (i.e., antigens are soluble and passively adsorbed to erythrocytes). The M-L blood group in sheep is related to active potassium transport in reticulocytes [42, 43]. The blood groups of the goat (A, B, C, M, J) are very similar to those of sheep, with the B system equally complex [44]. Many of the reagents used for blood typing of sheep also have been used to type goats.

Exotic pets

No blood groups have been identified to date in ferrets [45]. Blood transfusions can be administered safely without the need for crossmatching even when multiple transfusions are indicated, such as for severe estrus-induced aplastic anemia [46].

Little to no information is available on blood groups in rabbits and exotic pet species of birds or reptiles. In these cases, crossmatching prior to transfusion is recommended, and homologous transfusions using species-specific blood are advised. A low-volume simplified crossmatch procedure (see "Procedures for Crossmatching") can be used in these species, particularly for cases in which a prior transfusion has been administered [47, 48].

Donor selection

Blood typing should be performed to select permanent dog, cat, and horse blood donors. All donors should be healthy young adults that have never received a blood transfusion. In addition, donors must undergo routine physical examinations as well as hematology and clinical chemistry evaluations, receive vaccinations, and be tested free of blood parasites and other infectious diseases. There are

consensus statements in both the United States and Europe that have recommendations for prevention and monitoring of infectious disease potentially transmitted through blood donations from dogs and cats [49, 50]. Donors should have normal baseline packed cell volume (PCV) and total protein concentrations prior to any donation. Blood should be collected aseptically, usually via jugular venipuncture. To avoid interference with platelet function, donors should not be sedated with acepromazine. Blood collection methods for different species have been reviewed in detail elsewhere [17, 47, 48, 51–53].

Dogs

Dogs can donate approximately 15 mL of blood per kilogram (kg) of body weight every 6 weeks [17]. A history of prior transfusion precludes a dog from being a prospective donor [12], whereas a history of prior pregnancy does not [54]. For first-time transfusion recipients, donors negative for DEA 1 can be considered universal donors and, for this situation, routine typing for other blood types is not clinically warranted [12]. A dog is considered a universal donor when negative for DEA 1, 3, 5, 7, and positive for DEA 4 [11, 17]. To minimize potential sensitization of the recipient and improve the odds of identifying compatible donors, the use of universal donors is recommended when periodic transfusions are anticipated. Since about half of dogs are DEA 1-positive and testing for DEA 1 is a practical procedure, having DEA 1-positive donor blood available for DEA 1-positive recipients is prudent [11, 12]. A practical summary is that DEA 1-negative dogs are ideal for first-time transfusions regardless of recipient blood type, and DEA 1-positive donors should be limited to DEA 1-positive recipients.

Dog donors should be greater than 25–30 kg, bled less than once per month to prevent iron deficiency, and well nourished, including supplementation with oral iron if collected frequently. To ensure general good health, donors should have negative fecal and heartworm disease examinations. According to the American College of Veterinary Internal Medicine's (ACVIM) Consensus Statement, donors should test negative for transmissible infectious diseases including babesiosis, leishmaniasis (especially foxhounds) [55], brucellosis, ehrlichiosis, anaplasmosis, and neorickettsiosis. The Consensus Statement should be consulted for specific recommendations on diseases relevant to particular geographical regions, such as trypanosomiasis, bartonellosis, and hemoplasmosis [16].

Cats

Donor cats can donate between 10 and 12 mL of blood/kg body weight. Healthy adult cats can donate 45–60 mL every 6 weeks and usually require sedation for blood collection [52, 56]. Like dogs, donor cats should have negative fecal and heartworm disease examinations as part of a general health screening. Since the majority of cats in the United States are type A, donors should also be type A, but type B and AB donors may also be required depending on geography and breed prevalence. Because of the cat's naturally occurring alloantibodies, there is no universal cat donor. Donor cats should be negative for feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), cytauxzoonosis, and hemoplasmosis.

Horses

Adult horses can safely donate approximately 6–8 L of blood. Whole blood (WB) can be collected every 2–4 weeks and plasma collected every week if the erythrocytes are returned to the donor [57]. Donors should be in good health, and male donors may be preferred as they are less likely to have been previously sensitized [53]. Additionally, screening for equine infectious anemia and ensuring PCV and plasma protein concentrations are within normal limits are recommended. Mares that have been pregnant or foaled and horses that have received blood or erythrocyte-contaminated plasma transfusions should be excluded as potential donors. A totally compatible blood transfusion is unlikely to be achieved in the horse. Crossmatching to identify the least incompatible donor is recommended to minimize adverse transfusion reactions but will not identify all donor/recipient incompatibilities [34]. Because Aa and Qa erythrocyte antigens are extremely immunogenic, Aa- and Qa-negative donors are the best choice as donors to recipients of unknown blood type. In cases of NI, the dam's washed erythrocytes may be used for transfusion to severely anemic foals, whereas a transfusion from the sire to foal would be contraindicated [31, 58]. While blood transfusion can be life-saving to foals with NI, number and volume of transfusions must be limited; one study demonstrated that each administration of a blood product to a foal with NI increased its likelihood of *nonsurvival* by greater than eightfold, and administration of 4 or more liters (total volume) of blood products significantly increased the risk for liver failure in foals [59]. Mule foals with NI could receive a transfusion from a horse not previously sensitized by pregnancy against donkey factor, since horses are known to be free of naturally occurring antibodies against donkey factor, the implicated antigen in cases of NI in mules.

Cattle, sheep, and goats

Ruminants can donate 10–15 mL/kg of body weight. Closely matched transfusions are very difficult in cattle; first transfusions are generally low risk, but ideally a donor would be negative for the J antigen [41, 51]. Similarly, typing and matching blood for sheep or goat transfusions is impractical [60]. Prion diseases have been shown to be transmitted by blood transfusion in sheep [61] and should, therefore, be a consideration for disease screening prior to blood transfusion in ruminants.

Exotics

Large, vaccinated adult male ferrets are the best choice as blood donors and should have a normal PCV and total protein, be negative for Aleutian mink disease virus, and be screened for heartworm microfilaria [47, 62]. These ferrets can donate a total of 6–10 mL of blood depending on body weight [62]. When collected in anticoagulant solution containing citrate, phosphate, dextrose, and adenine (CPDA-1), stored blood should be used within 7 days of collection [63].

For pet birds and reptiles, since blood typing is not generally available, using a healthy donor of the same species as the recipient may minimize the likelihood or severity of transfusion reaction and will reportedly result in longer survival of transfused erythrocytes [48, 64]. Ideally a bird donor would be negative for chlamydiosis, psittacine beak and feather disease, and polyoma virus [47].

Indications for and general principles of transfusion therapy in dogs and cats

The prescription of blood products should be considered just like any other drug and requires a clear indication. Critical knowledge about the pros and cons of transfusion therapy is also necessary. The dose, administration, monitoring, and side effects must be clearly known to select the right product for the right patient at the right time. Commonly used products include WB, packed erythrocytes (packed red blood cells [PRBCs]), and a variety of plasma products including fresh frozen plasma (FFP), frozen plasma (FP), and plasma. The two most common reasons to use blood products are for the treatment of anemia (by increasing red blood cell [RBC] mass) or a secondary coagulopathy. RBC transfusions are commonly used to treat a patient's clinical signs of poor oxygen-carrying capacity determined by physical examination and clinicopathologic data such as hemoglobin concentration, PCV, or hematocrit. Other objective measures that may help in the decision-making process to trigger a transfusion include venous oxygen tension and lactate concentration. As oxygen delivery to the tissues falls but the tissue extraction remains the same, less venous oxygen is found in the measurement of PvO_2. However, this may also reflect increased oxygen demand by the tissues. Alternatively, an increase in lactate concentration is a readily available marker of poor perfusion.

Shock identified in a patient must first be resolved using isotonic crystalloids to improve perfusion while the best blood product is obtained. The transfusion should be considered as soon as the patient's cardiovascular status is jeopardized by the blood loss. Clinical signs include:

- Abnormal perfusion parameters: tachycardia, pale mucous membranes, prolonged capillary refill time, weak pulses, cold extremities, altered mentation.
- Signs of anemia: pale mucous membrane color and poor pulse quality, which may be difficult to differentiate from hypoperfusion/shock and need to be reassessed after initial isotonic fluid resuscitation.
- Downstream perfusion markers: increased lactate, decreased blood pressure, and urine output.
- Respiratory function: increased respiratory rate and effort, blood gas analysis.

Recent evidence from the human medical literature and adapted to clinical veterinary medicine (dogs and cats) considers treatment with PRBCs when the hemoglobin drops below 7 g/dL (or a PCV ≤ 20%) [65]. However, the acuity or chronicity of that anemia also plays a role in the decision making. Most patients with a Hgb below 4 g/dL (or a PCV ≤ 12%) require RBC transfusions due to life-threatening cellular energy depletion from inadequate oxygen-carrying capacity. A quick rule of thumb is to calculate the amount of RBCs needed to restore the PCV to 20–25%. This is a reasonable clinical goal to balance the costs and risks of a transfusion with the physiologic need for oxygen-carrying capacity to tissues. Most transfusions using 1 mL/kg PRBCs will raise the patient's PCV 1%. Alternatively, it takes 2 mL/kg to raise a patient's PCV 1% when using FWB. There are formulae in both dogs and cats that are more accurate [66, 67].

Patients with disorders of secondary hemostasis (e.g., hereditary factor deficiency, vitamin K antagonism) are unable to make sufficient fibrin to stabilize the platelet plug. Treatment with plasma for these patients attempts to normalize the timed coagulation tests that confirmed the presence of hemostatic dysfunction. The reader is referred to Chapter 17 for a review of hemostasis. The goal of therapy is to restore coagulation factors to levels that reduce the chance for hemorrhage to persist. In general, 10–20 mL/kg of FFP will restore coagulation factors to a level to normalize the coagulation tests. The improvement in clinical bleeding and the coagulation test results seem to parallel one another. FFP should be administered within 4 hours of thawing at a rate such that the patient is not at risk for fluid overload or acute hemolytic transfusion reaction.

Primary hemostasis is the formation of a platelet plug at the site of endothelial damage. Defects in primary hemostasis are most often caused by thrombocytopenia, von Willebrand disease, or thrombocytopathy (abnormal platelet function). Thrombocytopenia is much more common than thrombocytopathy (see Chapter 17 for details of hemostasis). The treatment of a defect in primary hemostasis involves the removal of the underlying cause if possible. Transfusion of platelets is challenging due to their reactive nature and special handling requirements. The donation of blood and placement into collection bags can activate platelets to form clumps. Platelets also activate at cold temperatures; therefore, all platelet transfusion must be completed using fresh blood products, either FWB, platelet-rich plasma, or a platelet concentrate. The access to platelet products is

very limited, which makes complete resolution of a primary hemostatic defect often best addressed in hospitals with specialized blood banks and hemostasis centers.

Blood products

Blood collected from donors is often processed into components, each with unique qualities that make them ideal in certain situations in transfusion therapy (see Figure 18.1).

Blood should be refrigerated in plastic blood collection bags containing 1 mL of anticoagulant for every 7 mL of blood. CPDA-1 is the anticoagulant of choice because it maintains higher levels of 2,3-disphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP), allowing for approximately 35 days of refrigerated shelf life [68]. Heparin activates platelets and is not recommended for blood collection, but if heparin is used as the anticoagulant (5 U per mL of blood) [17], blood must be used immediately. Blood collected for transfusion in pet birds must be administered immediately because use of available storage media will result in a blood product that contains dangerously high potassium concentrations [64].

The most common product used in practices without developed blood banks or high volume of purchased products is likely FWB (drawn and used within 6 hours). FWB contains RBCs, platelets, and plasma (and white blood cells unless leukoreduced) and is often used for patients that not only have anemia but also coagulation defects and need volume. Care must be taken if the patient does not need all three of these components. Monitor for and address volume overload while the patient is at an increased risk of immunologic transfusion reactions. WB may be stored for up to 1 month at 4°C. Stored whole blood (SWB) has viable RBCs only, as platelets quickly activate with cold and coagulation factors degrade during storage. More details on the preparation of blood components are available elsewhere [51, 52, 58, 69].

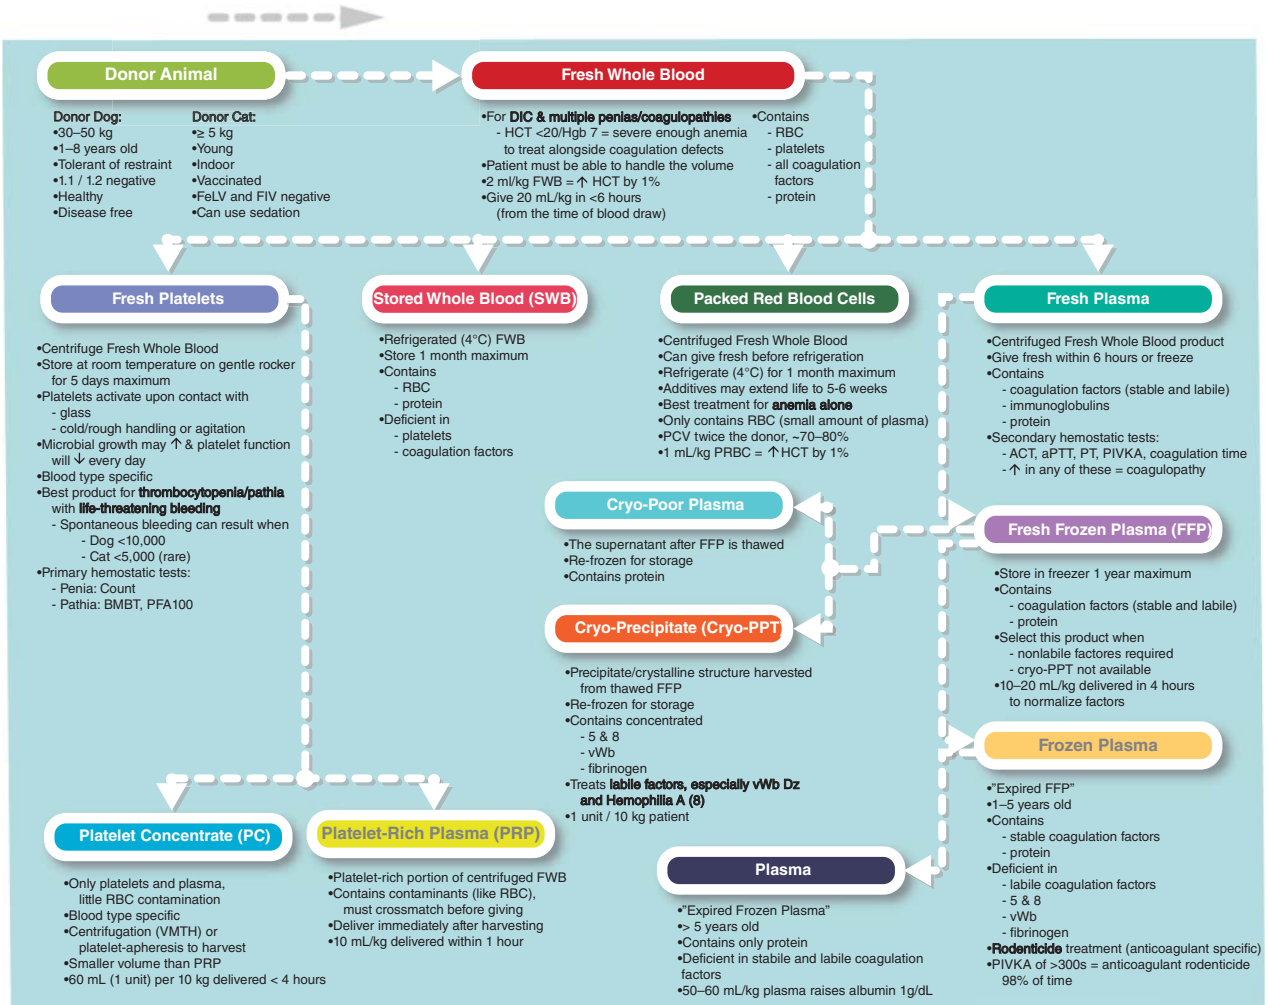

Figure 18.1 Blood component preparations.

When FWB is centrifuged and processed within 6 hours of collection, many products can be made. PRBCs, fresh plasma, and platelet products, each with unique processing and storage conditions, can be stored for later use. PRBCs are viable for about 1 month when stored at 4 °C. This product generally has a PCV twice that of the donor; thus, 1 mL/kg can raise the recipient's PCV 1%. Fresh plasma is more commonly frozen shortly after processing for thaw and use at the time it is needed. Fresh plasma or FFP has high concentrations of all coagulation factors. Calves, foals, puppies, and kittens with failure of passive transfer may benefit from FFP [51, 70, 71]. The concentration of labile factors (e.g., V, VIII, and von Willebrand factor) declines within the first year of storage. Therefore, after 1 year of FFP storage, the product is relabeled as FP. FP still has adequate concentrations of the stabile coagulation factors (II, VII, IX, X) for the treatment of vitamin K antagonist intoxication. FP maintains strong concentrations of these factors for up to 5 years [17]. After 5 years, FP products will not contain robust concentrations of coagulation factors for treatment of coagulopathies. Relabeled as plasma, it maintains adequate concentrations of plasma proteins and is a good source of albumin. To raise the patient albumin concentration, however, one generally needs to administer 50–60 mL/kg to raise the patient albumin concentration by 1 g/dL. Fresh platelet products require special handling and rapidly lose their function within their 5-day storage time [72]. Novel platelet ("freeze-dried," lyophilized, or bioengineered) products are in development and may be on the horizon for clinical practice in the near future [73].

Cryoprecipitate (Cryo-PPT) is a specialized product that requires a controlled freeze–thaw cycle. Cryo-PPT has the highest concentrations of the labile factors in the smallest amount of plasma. This is ideal for patients with von Willebrand disease or hemophilia A as a pretreatment or used perioperatively to prevent uncontrolled bleeding. The typical dose is 1 unit/10 kg.

Administration

The assumption for blood products is that they were collected and stored aseptically.

The following protocol for administration is adapted from the University of California, Davis, Veterinary Medical Teaching Hospital, Small Animal Intensive Care Unit.

Pretransfusion

- Blood transfusion can be administered intravenously or intraosseously in small patients (i.e., pediatrics or exotics).
- A blood type/crossmatch should be completed; ideally in dogs and horses, always in cats.
- FFP requires thawing at room temperature for 20 minutes before defrosting in warm water. (Note: FFP can be defrosted without thawing first in emergent situations.) Alternatively, use a commercial plasma thawer according to manufacturer directions.
- Set up a Y-type administration set with a filter for the blood. Attach blood bag with one of the two ports; the second one will be used for the 0.9% NaCl flush if indicated.
- If administering the blood product via syringe, insert an injection port into the bag. Draw the blood product into a syringe; attach a filter between the syringe and extension set.
- Place indwelling rectal temperature probe into the patient. Get a baseline TPR and vitals.

Transfusion

- Transfuse the blood product at 2.5–10 mL/kg/h. Usually, the transfusion is given in 4 hours to decrease the risk of bacterial contamination (rate of 2.5–10 mL/kg/h) using the lower rate at the beginning and increasing it if the patient tolerates the transfusion. In emergent situations, the blood product can be bolused more rapidly.
- Monitor temperature continuously and monitor respiratory rate, effort, and mentation every hour.
- Monitor vital parameters every 15–30 minutes for the first hour, and then every hour until the transfusion is completed.
- When transfusion is completed, flush the administration with 0.9% NaCl at the same rate until fluid line is mostly clear.

Post-transfusion

- Disconnect the blood administration set or fluid line from catheter and flush the catheter with heparinized saline.
- Draw blood for PCV/TP immediately, or up to an hour post-transfusion.

Transfusion reactions

The common clinical signs of a transfusion reaction are (in descending frequency) fever, vomiting, and hemolysis. The transfusion should be immediately stopped and investigated if these are observed. There is no specific treatment for these reactions; therefore, appropriate supportive and symptomatic treatments are recommended. True anaphylaxis is rare. Treat similar to any anaphylactic reaction including cessation of the administration of the product, intravenous fluid resuscitation, and epinephrine. Clinical signs, recommended investigatory steps, and treatments for hypersensitivity-related reactions are presented in Table 18.2. Additional details may be found elsewhere [11, 70].

Other causes of adverse reactions to blood product administration include many non-immune-mediated transfusion reactions. Hemolysis may occur by destruction of the donor RBCs before transfusion from inappropriate collection, storage, or administration [74]. Hemolysis will decrease the efficiency and efficacy of the transfusion. Intracellular

Table 18.2 Hypersensitivity-related reactions to blood products.

Hypersensitivity reaction	Clinical signs	Investigation	Discontinue the transfusion and then provide treatment(s) below
Type I: allergic	Urticaria, pruritus, angioedema	Transfusion history typically includes plasma products	Administer antihistamines or low dose of steroids.
Type I: anaphylactic shock	Cardiovascular collapse, dyspnea, seizures		Treat shock with IV fluid bolus, epinephrine.
Type II: hemolytic	Vomiting, hypotension, tachycardia, tachypnea, pyrexia	Examine patient samples for hemoglobinemia and/or hemoglobinuria; coagulation studies for evidence of DIC; repeat type and crossmatch of patient and donor; Coombs test	Treat symptomatically, IV fluids
Febrile: leukocyte and platelet sensitivity	Body temperature increase >1 °C	Rule out other causes of fever	Reassess patient, transfusion may be restarted at a slower rate

potassium is released into the product after RBC hemolysis and may contribute to hyperkalemia in the recipient. Hypothermia may occur if rapid transfusion occurs with an inappropriately warmed product. Because citrate binds calcium, massive transfusions of blood collected into CPDA-1 have the potential to cause hypocalcemia. The clinical signs of muscle tremors or weakness associated with hypocalcemia are treated with calcium gluconate infusion. Bacterial contamination of blood products is uncommon with proper handling but has been reported in the veterinary literature [74]. As mentioned previously, volume overload may occur, so close monitoring of the patient and use of appropriate component therapy will decrease the incidence.

How to type and crossmatch

In-house blood typing has become more common thanks to commercially available blood-typing products. Ethylenediaminetetraacetic acid (EDTA)-anticoagulated whole blood is generally required as other anticoagulants, such as heparin or citrate, have not been validated. Two popular typing methods amenable for in-clinic use include immunochromatography housed within a cartridge and agglutination performed on a card. These test for the DEA 1 antigen in dogs and A, B, or AB in cats and take just minutes to complete.

Cartridge methods are based on the migration of RBCs on a treated membrane under the capillary action of a buffer after undergoing lateral (RapidVet-H®, DMS Laboratories, Inc.) or vertical (Alvedia Quick Test®, Alice Veterinary Diagnostic) flow (Figure 18.2). These methods require a simple dilution of blood in provided diluent and application of sample to the test membrane. When the blood suspension has reached the control line, the reaction can be read.

Autoagglutination does not appear to interfere with typing results in dogs when using the cartridge system [75]. There is a similar system available for Ca typing in horses (Alvedia Quick Test, Alice Veterinary Diagnostic).

The card agglutination system (RapidVet-H) tests blood against antigens via a murine monoclonal antibody specific to DEA 1, which is lyophilized on the test card (Figure 18.3). Diluent is applied to the test card to reconstitute the lyophilized antibody and then one drop (or 10 µL) of the patient's blood is stirred into the mixture and the card is rocked, then evaluated for agglutination. Autoagglutination may interfere with interpretation of results. Alternatively, blood can be typed by sending a sample to an outside veterinary reference laboratory, and select locations offer a more complete typing service than available to the clinic setting.

Once the patient's blood type is determined, the next step is to crossmatch. Crossmatching is performed to help determine compatible red-cell products so as to reduce adverse transfusion reactions. A "major" crossmatch is performed to detect antibodies in the recipient's serum that may agglutinate or lyse the donor's erythrocytes. A "minor" crossmatch is performed to detect antibodies in the donor plasma directed against the recipient's erythrocytes. The antibodies detected may be naturally occurring or induced. The agglutination technique is adequate for the dog and cat [76], whereas testing for both agglutinating and hemolytic antibodies in the horse is necessary [32]. Cattle, sheep, and goats have minimal agglutinating antibodies, thus the use of a hemolytic test is warranted [41, 51, 76].

Figure 18.2 Immunochromatographic typing kit supplies (top) and column indicating type DEA 1 in a dog (bottom). Source: Courtesy of Alvedia.

A major crossmatch should always be performed in animals that have strong naturally occurring antibodies, as in cats, or in those that may have induced antibodies from prior transfusions. The latter is true even if the same donor blood is intended for repeated transfusion beyond a span of several days. The time required to mount an antibody response to transfused cells appears to vary slightly between species and author opinions. Erring on the side of caution, repeat crossmatching is recommended when there is a span of greater than 2 days in horses and cattle [51, 77] and 4 or more days in dogs and cats [78, 79] since a prior transfusion.

The minor crossmatch is considered less important, purportedly because the plasma volume is small in the donated product compared to the recipient, and is ultimately diluted, particularly when packed erythrocytes are transfused [80]. Exceptions have been documented when transfusing dogs [81] and horses [34]. Administration of packed erythrocytes may contain sufficient antibodies against recipient erythrocytes to induce adverse reactions in these species.

For exotic and feline species in which test volumes are limited, one can perform a simplified crossmatch procedure, as follows. For the major crossmatch, mix two drops of recipient plasma with one drop of blood from the donor on a clean glass slide at room temperature. Observe for macroscopic agglutination within 1 minute (Figure 18.4). Repeat the previous steps for the minor crossmatch using two drops of donor plasma and one drop of recipient blood. Grossly visible agglutination indicates incompatibility. Note that this method will not detect potentially fatal hemolytic antibodies [47, 78, 82].

Serum is preferred over EDTA plasma because plasma contributes to increased rouleaux formation and difficult interpretation of agglutination, particularly in the horse. Ideally, samples should be free of autoagglutination, hemolysis, and lipemia to aid in the interpretation of the reactions. When autoagglutination is present, or when no compatible units are available, transfusing the least incompatible unit may be a necessity, albeit not without significant risk. Test transfusing even a small volume of unmatched blood is an unsafe practice and never recommended [78].

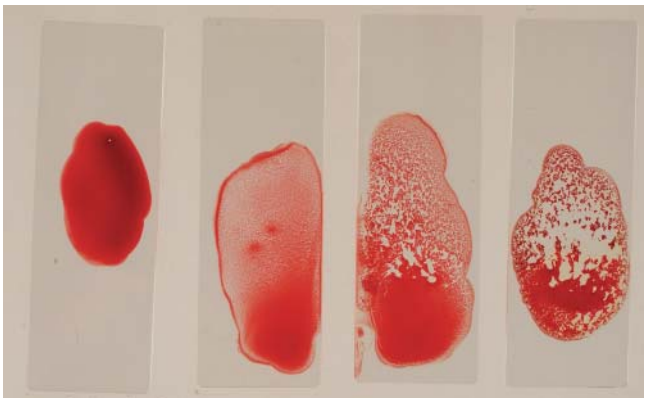

Figure 18.4 Slide crossmatch. Results demonstrate (from left to right) compatible (no agglutination), and 1+ to 3+ incompatible (agglutination) reactions.

Sample requirements and preparation for sending samples to reference laboratories

Large-animal blood typing requires ACD-anticoagulated blood for longer cell preservation. Usually, EDTA-anticoagulated whole blood is adequate for small-animal blood typing. Gently mix, not shake, samples collected with an anticoagulant immediately after collection. The EDTA-anticoagulated whole blood should be shipped cool (with, but not touching, a cold pack). Harvested patient serum is required for crossmatching; however, use of serum obtained from SST is not acceptable. Protect all samples from temperature extremes and ship by overnight delivery. Contact the reference laboratory to obtain specific requirements regarding sample type, handling, and shipping. Most laboratories performing parental exclusion typing supply blood collection kits or mailers. Harvested serum is required for antibody screening; handling is as for whole blood.

Appendix 18.1 Procedures for Crossmatching

Procedures

The procedure described here is modified from tube crossmatch standard operating procedures (SOPs) utilized by Colorado State University Veterinary Teaching Hospital, originally modified from that described by Jain [76], and

the University of California, Davis School of Veterinary Medicine.

Tube agglutination crossmatch

Application

The tube agglutination crossmatch is appropriate for dogs and cats and is used in conjunction with the lytic test for horses. In dogs previously transfused with nonuniversal donor blood, an extra autocontrol and major crossmatch tube can be set up and incubated at 4°C to detect cold reacting antibodies (i.e., anti-DEA 3, 4, 5, and 7) [15, 83]. Minor crossmatches are recommended for cats. Have a means of logging typing and crossmatching results available. A recipient autocontrol tube is included because some recipients may have autoagglutination interfering with the crossmatch. Donor autocontrols are optional, as currently healthy qualified donors should lack autoagglutination.

Procedure

1. Collect 0.5–2 mL whole blood in a clearly labeled EDTA and clot tube (not SST) from both the recipient and donor. If using a donor unit, a tubing segment (a.k.a. "pigtail") may be used for the source of erythrocytes and plasma.

2. Allow sufficient time for the nonadditive tube to clot. Centrifuge the tubes (~1000–1500 g for 3–5 minutes) to ensure the RBCs separate from the plasma and serum. If a centrifuge is not available, allow the RBCs to sediment in the EDTA tubes at room temperature for 1 or more hours.

3. Pipette off the serum/plasma into separate prelabeled glass test tubes.

4. Pipette 0.1–0.2 mL packed RBCs into saline-filled (phosphate buffered saline is recommended) 10×75 prelabeled disposable glass tubes (creating a 2–4% RBC suspension) for both the donor and recipient.

5. Centrifuge (45 seconds to 1 minute) to obtain a cell pellet, decant saline, and resuspend the pellet by gently flicking the bottom of the tube. A serofuge (e.g., Becton Dickinson or Clay Adams) with a fixed angle rotor is commonly used in blood bank facilities.

6. Wash the cells twice more (thrice for horses) by forcefully adding saline until the tubes are nearly full, and repeat step 5. After the last wash, resuspend the cells in saline to achieve a 2–4% erythrocyte solution.

7. Label clear glass tubes (typically 10×75 mm glass tubes are used) with "Donor Control," "Major," "Minor" (if performing), and "Recipient Control." To each of the following labeled tubes, add samples as described.

- Donor Control: two drops of the donor RBC solution and two drops of donor serum or plasma.
- Major: two drops of the donor RBC solution and two drops of the recipient's serum.
- Minor: two drops of the recipient RBC solution and two drops of donor plasma.
- Recipient Control: two drops of recipient RBC solution and two drops of recipient plasma.

8. Mix by flicking the bottom of each tube or gently shake the rack of tubes, and incubate at 37°C for 30 minutes.

9. Centrifuge at a low speed for 15–30 seconds.

10. Examine the supernatant for hemolysis and record if present.

11. Gently rock the tubes to resuspend the cells and observe how the cells disperse.

12. Hold the tubes up to an agglutination viewer (or light) to observe for macroscopic agglutination or complete hemolysis (Figure 18.5).

13. Log macroscopic agglutination reactions as negative, 1+, 2+, 3+, or 4+.

14. If there is no agglutination observed grossly, or strong rouleaux is suspected, transfer a small amount to a glass slide and then examine under low power of the microscope. Lower the condenser to increase the contrast.

18.1 Erythrocytes are evenly dispersed if no agglutination is present (Figure 18.6).

18.2 Microscopic agglutination appears as grape-like clusters of erythrocytes (Figure 18.7).

Figure 18.5 Tube crossmatch. Incompatible (2+ agglutination, left) and negative autocontrol (no agglutination, right).

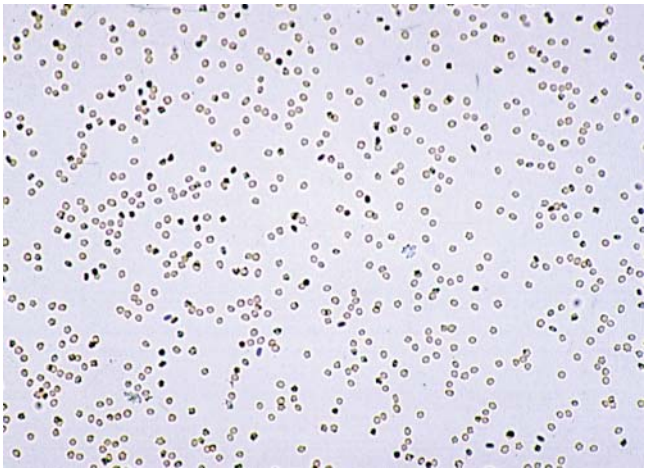

Figure 18.6 Negative microscopic agglutination. All the cells are evenly dispersed.

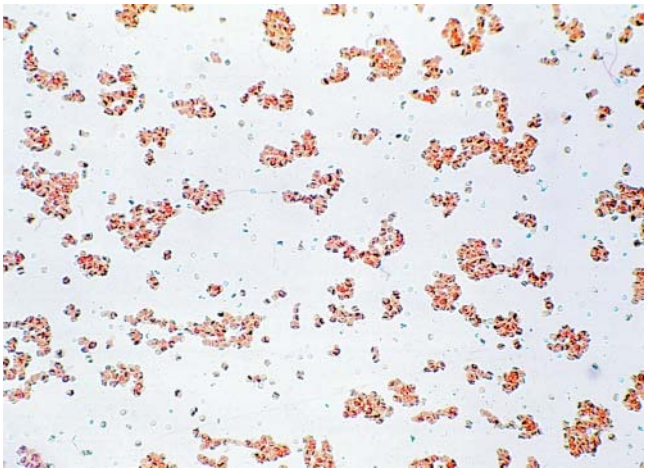

Figure 18.7 Microscopic 4+ agglutination. Note the irregular grape-like clusters. A microscopic reaction of this strength may also be detectable macroscopically as fine agglutination.

18.3 Rouleaux can be confused with agglutination. Rouleaux formation (Figure 18.8) is common in blood from horses and animals with high protein or globulin concentration, and it appears as stacks of coins. When strong, the stack may topple over on itself, mimicking agglutination.

Differentiate rouleaux from true agglutination with the following saline replacement procedure:

18.3.1 Centrifuge the tube for 15 seconds, remove the serum by pipette, and replace with two drops of PBS.

18.3.2 Mix and then centrifuge at 3400 rpm for 15 seconds.

18.3.3 Read for microscopic agglutination.

18.4 Saline replacement interpretation:

18.4.1 Erythrocytes should dissipate with rouleaux, whereas erythrocytes should remain in clusters with agglutination.

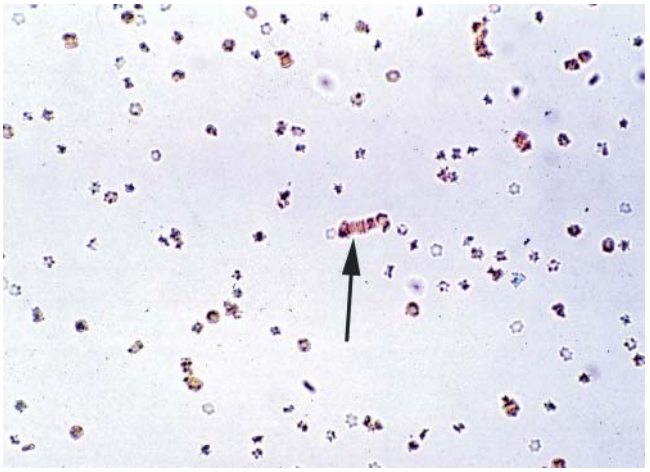

Figure 18.8 Rouleaux (con-stacking phenomenon). This must not be confused with agglutination, may indicate insufficient cell washing, and is common with equine samples.

15. Crossmatch interpretation:

19.1 Any macroscopic agglutination, significant hemolysis, or microscopic agglutination in the major or minor crossmatch (but not the control) indicates an incompatibility and the need to choose a new donor.

19.2 Slight hemolysis in canine crossmatches is nonspecific [76].

19.3 A negative result suggests the recipient is not likely to be at risk for an immediate transfusion reaction from the donor; however, it does not guarantee prevention of a delayed reaction.

19.4 Strong incompatibility in the minor crossmatch, as might be observed in mismatched cats, indicates the need to select a new donor; otherwise, packed or washed erythrocytes minimize transfusion of donor antibodies.

19.5 Agglutination in control tubes indicates autoagglutination or contaminated reagents, thereby rendering positive crossmatch tubes uninterpretable. Further patient workup such as Coombs testing may be warranted.

19.6 In horses, hemolysis in the agglutination test most likely indicates fragile or old cells rather than incompatibility. Therefore, hemolysis at this stage of testing in horses should be ignored; however, if all cells are hemolyzed, then agglutination is impossible to detect.

Hemolytic crossmatch test

Application

The hemolytic crossmatch test is required in crossmatching blood from goats, sheep, and cattle, because erythrocytes from these species tend not to agglutinate [51]. Most equine isoantibodies act as hemolysins; thus, performing both the agglutination and hemolytic test in horses is prudent. In this test, fresh rabbit serum is the source of complement. Because

all rabbits possess naturally occurring anti-erythrocyte antibodies, the antibodies must be removed before using the serum as a complement source.

The following procedure is modified from that described by Jain [76].

Procedure

1. Follow steps 1–4 of the agglutination crossmatch adding serum and cell suspensions to appropriately labeled tubes; if performing the agglutination and hemolytic crossmatches concurrently (as for horses), set up four additional tubes labeled to identify them as major hemolytic and minor hemolytic tubes and recipient and donor hemolytic control tubes.
2. Add one drop of rabbit complement (absorbed for horses, sheep, and goats; refer to the complement absorption procedure that follows) to the hemolytic phase crossmatch and control tubes.
3. Shake the rack to mix, and then incubate at 37°C for 30 minutes.
4. Centrifuge the tubes at 3400 rpm (1000 g) for 15 seconds. Observe the supernatant in each "hemolytic" tube for hemolysis; there is no need to check these tubes for agglutination.

Interpretation

A positive autocontrol indicates the presence of an autoantibody and may cause uninterpretable results in the crossmatch tubes. The major crossmatch is "incompatible" if the recipient's serum reacts with the donor's erythrocytes, and in this case, the donor blood should not be transfused. The minor crossmatch is incompatible if the donor serum reacts with the recipient's erythrocytes. In this case, only packed or washed erythrocytes are generally safe for transfusion.

Absorbed complement preparation; for use in the hemolytic crossmatch in horses, sheep, and goats [84]

Reagents

1. Lyophilized rabbit complement, unadsorbed (Pel-Freez Biologicals, Rogers, AR), store frozen.
2. $CaCL_2$-$MgCl_2$ solution, store refrigerated.
  a. $CaCL_2$, 14.7 g.
  b. $MgCl_2$, 20.35 g.
  c. Distilled H_2O, approximately 2 L.
3. Na2-EDTA solution.
  a. 74.4 g per 2 L of distilled H_2O.
  or
  b. Sequester-Sol® (Cambridge Diagnostic Products, Inc.).
4. PBS (Sigma Diagnostics, catalog no. 1000-3), store refrigerated.
5. Normal erythrocytes from the species to be tested, i.e., horse, sheep, or goat. (Two lavender-top [EDTA], 10 mL tubes from one donor are adequate.)

Procedure of the University of California, Davis Veterinary Genetics Laboratory

1. Dilute each of three vials of thawed rabbit complement with 1 mL of distilled water.
2. Add 1 part EDTA (0.3 mL) to 10 parts (3 mL) complement.
3. Centrifuge the EDTA-anticoagulated whole blood, and remove the plasma. Wash two aliquots of erythrocytes three times with PBS; make enough for two absorptions.
4. Add 1.1 mL of packed, washed erythrocytes to the complement solution. Incubate at room temperature for 30 minutes.
5. Harvest the complement solution, and repeat the absorption using fresh erythrocytes and incubating on ice instead of at room temperature for 30 minutes.
6. Centrifuge, collect absorbed rabbit complement (C′) into a flask on ice, and add 0.3 mL of $CaCL_2$-$MgCl_2$.
7. Aliquot the C′ in volumes of 0.5 mL in bullet tubes, and freeze at once. Label with the date and contents. Do not refreeze complement once thawed; use immediately or discard. (Do not store in a self-defrosting freezer, because the C′ thaws with each defrost cycle.)

Jaundiced foal agglutination test (colostrum crossmatch) [85]

The jaundiced foal agglutination test correlates highly with hemolytic blood group tests at 1 : 16 dilutions. Lower dilutions have poorer correlations because of the viscosity of colostrum [85].

Materials

1. Centrifuge (300–600 g).
2. Test tube rack.
3. Disposable glass test tubes (12 × 75 mm).
4. Saline.
5. Colostrum (or serum) and EDTA whole blood from mare (erythrocytes teased from clotted blood may be used).
6. EDTA whole blood from foal (erythrocytes teased from clotted blood may be used).

Method

1. Label tubes for 1 : 2, 1 : 4, 1 : 8, 1 : 16, and 1 : 32 dilutions for the foal.
2. Add 1 mL of saline to all tubes.
3. Add 1 mL of colostrum to the tubes labeled as foal 1 : 2. Mix and remove 1 mL of the dilution and then add to the next consecutive tube. Repeat the procedure, discarding 1 mL from the 1 : 32 tube. Discard tube labeled "1 : 8."
4. Add one drop of foal's whole blood to each tube and mix.
5. Centrifuge the tubes for 2–3 minutes at medium speed (300–600 g).
6. Invert all four tubes simultaneously (to make comparing reactions easier) and hold upside down, pouring out the liquid contents, and observe the status of the button of erythrocytes at the bottom of each tube. Grade for macroscopic

agglutination by observing how the cells flow down the side of the tube as follows:

0 No agglutination; cells flow easily.
1 Weak agglutination; cells in small clumps.
2 Strong agglutination; cells in large clumps.
3 Complete agglutination; cells remain packed in a button.

7. If no agglutination is present, report the test as being negative at all dilutions.
8. If agglutination is present, grade the reactions and continue with controls. (Controls may be set up along with the patient tubes during step 1 to save time.)

Controls

1. Foal autocontrol with 1 mL of saline and one drop of foal whole blood.
2. Mare colostrum/autocontrol, prepared by repeating steps 1 through 7 described earlier using colostrum and mare erythrocytes.

Interpretation

If all controls are negative, report the reactions of colostrum versus foal erythrocytes at all dilutions. A reaction at a dilution of 1 : 16 or greater is considered to be a high titer, and the colostrum should not be used. A positive foal autocontrol indicates autoagglutination and the possibility that the foal has already nursed. A positive mare colostrum/autocontrol indicates interference from the viscosity of the colostrum or a technical problem. Compare reaction grades for the same dilution between the mare autocontrol and the foal crossmatch tubes.

19 Mammalian Hematology: Laboratory Animals and Miscellaneous Species

Terry W. Campbell

Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado, USA

Blood collection and handling

Blood collection from small mammals can be challenging due to the small blood volume available for sampling. The manual or chemical restraint necessary to obtain a sample may alter the results of some laboratory tests. Blood collection studies in rats (*Rattus norvegicus)* used as laboratory animals have demonstrated that removal of 7.5% of the total blood volume over a 24-hour period did not have a biological effect, with complete recovery within 48 hours. The total blood volume of a rat has been determined to be 7.2 ± 1.19 mL/100 g body weight. Removal of blood volumes that exceed 7.5% will have a biological effect, the degree of which and time of complete recovery depend upon the amount removed. Blood collected up to 20% of the total blood volume of healthy rats does not affect the health of the rat.

In the clinical setting and for the ease of calculation, the maximum amount of blood that can be safely withdrawn from a single draw is presumed to be 1% of the animal's body weight or up to 10% of the total blood volume. This practice, however, may overestimate the safe amount that should be withdrawn during blood sampling. For example, on the average, a healthy 300 g rat has a total blood volume (based upon 7.2 mL/100 g body weight) of 21.6 mL. Removal of 7.5% of the total blood volume (considered to be a safe amount) represents 1.62 mL. If the same rat was sampled based upon 1% of the body weight, then the blood volume collected would be 3.0 mL or nearly twice the recommended safe amount. If up to 20% of the total blood volume can be safely removed from healthy rats, then a 4.32 mL blood sample could be obtained in the example above without causing ill effects. With this consideration, the 1% of the body weight rule for blood sample collection would indeed be within safe limits. This assumes the animal is healthy, and smaller blood volumes should be sampled when dealing with an unhealthy animal.

Total blood volumes reported for the mouse (*Mus musculus*) vary, with some reporting a range of 5–12 mL/100 g body weight and others a range of 7–8 mL/100 g body weight. The same guidelines recommended for laboratory rats likely apply to the laboratory mouse. Therefore, a 20 g mouse is likely to have a blood volume of 1.44 mL with a safe blood withdrawal volume of 0.1 mL. Using the 1% of the body weight guideline, the sample volume would be twice as much.

Although the blood volume will be restored within 48 hours of blood collection in most healthy mammals, it may take 2 weeks or longer for all of the blood constituents to return to normal and likely much longer in unhealthy animals. If blood collection is required more frequently than every 2 weeks, a smaller sample size such as 0.5% of the body weight (if using the 1% body weight rule) each week should be drawn. It is important to adhere to these recommended limits to prevent hypovolemic shock and anemia.

Blood collected from small mammals is typically placed in lithium heparin because the blood sample volume is small. The heparinized blood can then be used for hematologic studies and clinical chemistries.

The choice of blood collection method to be used is dependent upon the amount of blood required, frequency of sampling, technical skill of the one obtaining the sample, and parameters measured. A number of collection sites are used to obtain blood from small animals. Blood samples are often difficult to obtain from small mammals; they lack superficial vessels, and the deeper vessels may be covered with fat. In some cases, chemical restraint may be necessary to safely handle mammals for blood collection.

Most rodents will tolerate manual restraint alone for venipuncture; however, it is important to remember that the handling and restraint, as well as transport to the veterinary hospital and the hospital environment itself, are very stressful to these prey species. It is vital to approach these animals

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

calmly and confidently and to minimize visual, olfactory, and auditory stimuli.

Small rodents, such as mice and rats, that are accustomed to being handled can be grasped gently at the base of the tail and lifted with the opposite hand placed underneath the body for support. Aggressive rodents can be picked up by the base of the tail or scruff of the neck using rubber-tipped forceps or coaxed, head first, into an appropriately sized disposable plastic syringe cover or commercially available restraint device, leaving the tail exposed for blood collection.

Rats, mice, gerbils (*Meriones unguiculatus*), and other small rodents with tails can be restrained by grasping the base of the tail and placing it on the cage lid or similar rough surface, allowing the animal to attempt to move forward while grasping the surface with its forepaws. These animals, especially gerbils, should not be picked up by the tip of the tail due to the risk of degloving injury. The handler can quickly tuck the base of the tail between the third and fourth finger while firmly grasping the rodent by the scruff with the same hand holding onto the tail. A proper scruff-hold prevents the rodent from twisting or turning to bite the handler. The scruff-hold should be brief because it can impede respiratory movements and lead to asphyxiation as indicated by cyanosis of the pinna, nose, and paws.

Manual restraint of hamsters (*Mesocricetus auratus*) can be performed by gathering the loose skin over the scruff of the neck in one hand using the scruff-hold method for rats, mice, and gerbils. Because these rodents have an abundant amount of loose skin, caution should be taken as to gather enough skin to prevent the animal from turning and biting the handler. Therefore, care should be taken to gather enough of the hamster's loose skin into the scruff-hold such that the corners of the mouth are drawn back into a smile.

Large rats can be restrained by the thoracic encirclement method, using a commercially available restraint device, or in a towel. The thoracic encirclement method can be performed by grasping the rat by the base of the tail with the dominant hand followed by placement of the nondominant hand over the back of the rat and grasping the rat around the thorax with the head of the rat between the index and middle fingers. The body of the rat can be stabilized by the handler's other hand, arm, or body. Alternatively, the rat can be grasped around the thorax, immediately under the shoulder blades, while pushing the rat's forearms cranially with the thumb and index finger so they cross under the chin, preventing the animal from biting the handler. Commercially available plastic restraint devices allow for easier blood collection from rats.

Guinea pigs become distressed when a restraint attempt is made with the scruff-hold method used on other rodents. When picking up the guinea pig for examination or to move it from one area to another, a hand should be placed over the dorsum, behind the shoulders, while grasping the animal gently with the thumb and fingers around the rib cage. The hindquarters should be supported when lifting a guinea pig to prevent spinal injury. Because guinea pigs may become distressed if restrained in lateral or dorsal recumbency, chemical restraint is frequently used when obtaining blood samples.

A rabbit's hindquarters should be supported whenever it is restrained to avoid injury to its spine. Although manual restraint can be used when obtaining blood samples from a rabbit, the use of additional restraint devices helps to reduce the risk of injury to the patient and to the technician or veterinarian. A cloth cat restraint bag can be used to restrain a rabbit, or it can be wrapped in a bath towel with its head exposed.

The restraint method used for blood collection in a ferret depends upon the collection site and preference of the phlebotomist. Most restraint methods are comparable to those used to restrain a domestic cat during blood collection. For example, a ferret may be placed in dorsal or lateral recumbency with the head extended and the front legs pulled caudally when performing a jugular venipuncture, or the animal could be placed in sternal recumbency with the front legs pulled downward over the edge of the exam table with the head flexed in a caudal direction.

A number of published chemical protocols are available that can be used for the sedation, tranquilization, and anesthesia of small mammals. Inhalant anesthetics, such as isoflurane, are commonly used to provide rapid induction and anesthesia of small mammals for blood collection. Although anesthesia is often needed for adequate restraint to obtain samples from small mammals, the anesthesia alone may produce changes, such as decreased hematocrit (HCT), hemoglobin level, and red blood cell count (RBC), in the hemogram. For example, it has been demonstrated that 5 minutes of 4% isoflurane anesthesia results in a slight decrease in the erythrocyte parameters and potassium and increase in glucose. Similar results have been reported in the ferret. Coagulation times may also be affected by anesthesia. As a result, a limit of 3 minutes of 4% isoflurane anesthesia is recommended to avoid these changes.

In the clinical setting, the tail vein is the site of choice for blood collection from small mammalian patients with tails (e.g., mice and rats). The lateral tail veins run the length of the tail and are more readily visualized in nonpigmented animals. These veins can be dilated by placing the tail in warm water or under a heat lamp prior to blood collection. Vasodilation can also be accomplished by placing the animal in an isolator at 104°F for a few minutes or applying a warm water compress. "Milking" the vein by applying slight compression and stroking from base to tip in an attempt to push blood from the vein should be avoided, as this causes artifactual leukocytosis of the sample. A tourniquet can be placed at the base of the tail if necessary. After swabbing the venipuncture site with an appropriate disinfectant, a sterile hypodermic needle (25-gauge needle) or a sterile lancet is used to prick

the vein, allowing blood to be collected into a microcollection device, such as a microhematocrit or Microtainer (Becton Dickinson, Rutherford, NJ) tube as it drips from the needle hub or skin. Gentle pressure should be applied over the venipuncture site to stop the bleeding. Blood for hematology is collected into tubes containing an anticoagulant, such as ethylenediaminetetraacetic acid (EDTA) or heparin. Blood collected for clinical biochemistry analysis is collected into tubes containing heparin or no anticoagulant.

A blood sample can also be obtained from the ventral caudal (tail) artery of a rodent with a tail (e.g., mouse or rat) placed in dorsal recumbency and under a general anesthetic. The artery runs the length of the tail but is not readily visualized. The collection site is disinfected before inserting a 23–25-gauge needle (depending on the size of the animal) into the ventral midline of the tail, approximately one-third the distance from the body to the tip. The needle is inserted at a 30° angle, in a cranial direction, until blood begins to flow from its lumen. If bone of the ventral surface of the caudal vertebra is contacted, then the needle is withdrawn and redirected slightly until blood begins to flow through the needle. Blood can be collected in a microhematocrit tube as it flows from the needle hub. In larger rodents, such as rats, a 22-gauge or smaller needle attached to a 1 or 3 mL syringe with plunger removed is used to collect the sample. Blood fills the syringe from the pressure of the artery once the vessel has been penetrated. Although rarely needed, puncture of the tail artery can also be attempted for blood collection in ferrets. The artery is approached along the ventral midline of the tail with a 22- or 21-gauge needle directed toward the caudal vertebrae. The artery is usually located 2–3 mm under the skin. After blood collection, gentle pressure should be applied to the arterial puncture site for several minutes to prevent continued blood flow.

Blood may be collected from the lateral saphenous vein in small animals by applying digital pressure or a tourniquet above the stifle after clipping the hair. Shaving the hair from the lateral aspect of the tibia exposes the vein. The lateral saphenous vein is typically small and will easily collapse, making the collection of large sample volumes difficult. Blood can be collected from the lateral saphenous veins and dorsal metatarsal veins of small rodents, such as mice, rats, hamsters, gerbils, and guinea pigs. To induce vasodilation and facilitate blood collection, small rodents can be placed in an incubator set at 104 °F for several minutes, or a warm water compress (e.g., an exam glove filled with warm water and tied off) can be applied to the venipuncture site for about a minute. After clipping the hair, the venipuncture site is swabbed with an appropriate disinfectant solution. The lateral saphenous vein runs dorsoventrally down the leg and courses laterally over the tarsal joint. With the leg extended in traction, the handler generally applies digital pressure by gently squeezing the leg between the thumb and forefinger just proximal to the venipuncture site. Blood collection may be accomplished using a needle and syringe in larger animals, such as the rabbit, or the vessel may be pricked/punctured using a sterile needle or sterile lancet in smaller animals. With the needle and syringe method, a 23–25-gauge needle with attached syringe (1.0–3.0 mL) is inserted into the vein in a distal to proximal direction, and blood is collected by slow aspiration to avoid collapse of the vein. For the "free-flow" method, digital pressure is applied to dilate the vein before the vein is pricked using a sterile 20–23-gauge needle or sterile lancet. The free-flowing blood is collected in a microcollection device, such as a microhematocrit, Microtainer tube, Pasteur pipette, or a snap-cap microcentrifuge tube that contains an appropriate volume of anticoagulant solution. Following the collection method, gentle pressure should be applied to the venipuncture site to stop the flow of blood and to prevent hematoma formation. The dorsal metatarsal vein may also be used for blood collection, using the same techniques described for lateral saphenous venipuncture. The lateral saphenous may be used for collecting small amounts of blood for packed cell volume (PCV) or complete blood count in the ferret.

Blood collection from the retro-orbital venous plexus is often performed in rodents in research laboratories and requires technical skill and general anesthesia. A heparinized microhematocrit tube is placed in the medial canthus of the eye and directed under the globe to the orbital venous plexus. With the rodent in lateral recumbency, the microhematocrit tube is rotated along its long axis as it is advanced toward the venous plexus along the caudal one-half to two-thirds of the orbit. Following blood collection, pressure on the area is required for hemostasis.

Blood is often collected from blood vessels in the ear of rabbits because of the ease of blood collection and the use of a safer manual restraint method. The two primary vessels used for blood collection from a rabbit are the marginal ear vein, yielding small to moderate quantities of blood (depending on the experience and expertise of the phlebotomist), and the central auricular artery, from which a larger volume of blood can be collected. A 22–25-gauge needle can be used to puncture the vessel, and blood collection is performed by a simple drip method, vacuum ear bleeder, Vacutainer (Becton Dickinson) method, or with a syringe. Blood collected as it drips (drip method) from the needle hub into a microcollection device minimizes hematoma formation during sampling. Aspiration into a syringe or Vacutainer tube often results in collapse of the vessel in small rabbits. Blood is slowly aspirated into a syringe when using that method, and if blood flow stops, the procedure is briefly paused until the flow starts again or the needle is slowly rotated if the bevel has been closed off by the vessel wall. A vacuum ear bleeder method is performed by lacerating an ear vessel and placing the ear inside a flask with a side arm that is attached to a vacuum line and held firmly against the rabbit's head. This method is generally used for research rabbits where

large sample volumes are needed. The central auricular artery and the marginal ear vein(s) are located on the outer, haired surface of the ear. After the fur is plucked over the intended venipuncture site, the skin is cleansed with a disinfectant solution or alcohol (this may result in vasoconstriction). Ear vessels can be dilated prior to blood collection by applying a warm-water compress (e.g., a tied-off exam glove filled with warm water) over the ear for 1 minute; swabbing a small amount of oil of wintergreen to the vessel to be punctured and allowing 1–2 minutes prior to blood collection; administering acepromazine subcutaneously (0.5–1.0 mg/kg) about 15–20 minutes before venipuncture; or gently stroking ("milking") the vessel with the thumb and forefinger from the base of the ear toward the tip of the ear. Venipuncture of the marginal ear vein (typically the lateral one) is approached by directing the needle toward the base of the ear while the holder applies digital pressure to the base of the ear. Following the withdrawal of the needle from any of the venipuncture sites, gentle pressure should be applied with a cotton swab or sterile gauze pad for about 1–2 minutes to prevent hematoma formation.

Jugular venipuncture can be attempted in small mammals, although the jugular veins may be difficult to locate, and positioning the animals for the procedure can be stressful to them. Jugular venipuncture may require the use of sedation or general anesthesia is some mammals (e.g., ferrets, guinea pigs, hedgehogs, and rabbits). Blood collection in ferrets is commonly performed by jugular venipuncture, and simply allowing the ferret to lick food at the time of the procedure may be adequate to limit movement without the need of anesthesia. After the neck has been shaved and extended, blood is collected from the jugular vein using a 22–25- gauge needle and a 3 mL syringe. The jugular vein of ferrets is usually more lateral than those of dogs and cats and generally runs between the thoracic inlet and the angle of the mandible when the head and neck are extended. Often, the vein cannot be visualized, especially in large males. Blood collection from the jugular vein of hedgehogs usually requires sedation or anesthesia to prevent the animal from balling and to protect the handler from the animal's quills. Because the jugular vein is protected by thick skin in the ventral neck area, it can be difficult to sample blood from hedgehogs (*Atelerix albiventris*) using this technique.

Blood is frequently collected from the cranial vena cava in small mammals, especially the ferret, but may result in bleeding into the thoracic cavity. Chemical restraint is often used when performing venipuncture of the cranial vena cava to reduce movement during the procedure and the risk of laceration of the vessel by the needle resulting in significant internal hemorrhage. The animal, such as a ferret, is held in dorsal recumbency with the forelimbs held along its sides and the head and neck extended. A 25–27-gauge needle attached to a 3 mL syringe is inserted into the right sternal notch between the first rib and the manubrium, advanced caudally at a 30° angle to the body, and directed toward the left rear limb. The plunger is pulled back as the needle is slowly advanced or withdrawn, to allow blood to enter the syringe. Depending upon the depth of penetration of the needle, jugular venipuncture may actually occur using this technique in the ferret as the jugular vein lies just under the skin in the area of the sternal notch. The cranial vena cava is the most commonly used site for blood collection from hedgehogs and other small mammals using the same technique as described for the ferret. The heart in these animals, however, has a more cranial location compared to the ferret, and the phlebotomist must take this into consideration when using this approach.

General hematologic features of small mammals

The hematology of laboratory and other small mammals is similar to that of domestic mammals. However, obtaining meaningful reference values can be difficult because of variations associated with blood collection, environmental factors, and laboratory procedures. Blood collection often causes stress or requires chemical restraint. The hemogram can vary with age, environmental conditions, diet, gender, and reproductive status. Also, laboratory procedures and sample handling are not standardized, creating variability between data sets. Tables 19.1 and 19.2 provide suggested reference intervals for erythrocyte and leukocyte parameters, respectively, for small mammals.

The erythrocytes of mammals are small, compared to the nucleated erythrocytes of other vertebrates. The small, non-nucleated, biconcave shape minimizes the hemoglobin to surface distance during gas exchange and increases cell plasticity to improve movement through blood vessels, increasing oxygen delivery to tissues. The hemoglobin content and packed cell volume remain relatively constant among the mammals, but the total erythrocyte count and mean cell size varies. An inverse relationship between cell size and number exists. In general, only decreases greater than 10% in the erythrocyte parameters (RBC; hemoglobin concentration, Hb; and HCT) have biological significance.

The granulocytes of nondomestic mammals vary in appearance but can be classified as neutrophils or heterophils, eosinophils, and basophils. The heterophils of rabbits and some rodents were previously called pseudoeosinophils because their granules do not stain neutral with Romanowsky stains but are distinctly eosinophilic. Neutrophils of mice often have nonlobed nuclei, and those of normal primates appear hypersegmented. Cytochemical and ultrastructural features of cells differ between species. For example, lysozyme activity is lacking in the neutrophils of hamsters, and alkaline phosphatase activity is less in neutrophils of mice. Neutrophils of mammals are

Table 19.1 Erythrocyte parameters for laboratory animals and miscellaneous species (reference interval).

phagocytic; one of their primary functions is to destroy microorganisms. Circulating neutrophil concentration increases with inflammation, especially that associated with invading microorganisms such as bacteria. Toxic changes in neutrophils and heterophils represent accelerated marrow production and shortened maturation time and are represented by the presence of small basophilic Döhle bodies, increased cytoplasmic basophilia, and occasionally increased cytoplasmic vacuolation. Typically reduced nuclear segmentation (bands, left shift) accompanies these toxic changes

and can in most cases be viewed as a marker for presence of inflammation.

The granules of eosinophils become intensely eosinophilic with maturation as a result of the basic protein content. The ultrastructure of the granules in mammalian eosinophils reveals a distinct crystalline shape that varies with species; for instance, a trapezoidal pattern is found in the eosinophils of guinea pigs and true rodents, and a needle-shaped pattern is found in rabbit eosinophils. Mammalian eosinophils have phagocytic activity similar to that of neutrophils but are less effective. Mammalian eosinophils respond to metazoan infections (especially those involving helminth larvae), allergic inflammation (especially those associated with mast cell and basophil degranulation), and antigen–antibody complexes. Therefore, eosinophilia suggests one of these processes.

Mammalian basophils have characteristic cytoplasmic granules that are strongly basophilic in Romanowsky stained blood films. Unlike basophils of lower vertebrates, those of mammals tend to have lobed nuclei. The ultrastructural appearance of the granules varies with species; for instance, a coiled threaded pattern is observed in basophil granules from primates and rabbits and a homogenous pattern is observed in rodents. Basophils participate in allergic and delayed hypersensitivity reactions.

Mammalian monocytes generally are the largest leukocytes in peripheral blood films and do not vary grossly in appearance between species. The monocyte nucleus varies in shape, and the moderately abundant cytoplasm is typically light blue-gray. The granules, when present, are very fine and appear azurophilic in Romanowsky stained preparations. Monocytes engulf and degrade microorganisms, abnormal cells, and cell debris. Monocytes also regulate immune responses and myelopoiesis.

The appearance of mammalian lymphocytes varies depending upon the species, lymphocyte type, and degree of activation. Mammalian lymphocytes vary in size, color of cytoplasm (light to dark blue), and degree of nuclear chromatin condensation. Variability depends on the degree of antigenic stimulation and type of lymphocyte.

A variety of factors can influence the total leukocyte and differential counts of small mammals. These include circadian rhythm (time of day the sample is collected), time of last feeding, breed, and gender. In general, the leukocyte morphology of nondomestic mammals is a reliable indication of disease. The presence of immature cells, toxic neutrophils, and Döhle bodies is more reliable criteria for infectious diseases than are total leukocyte and differential counts, given the amount of information known regarding various strains and breeds.

The blood films of small mammals contain high numbers of platelets that appear as irregular oval (2–3 μm diameter) cytoplasmic fragments with inner more darkly and concentric outer lighter staining regions.

Hematologic features of rodents

Mice (*Mus musculus*) and Rats (*Rattus norvegicus*)

Hematologic parameters of mice and rats are influenced by a variety of factors, including site of sample collection, age, gender, strain, anesthesia, method of restraint, temperature, and stress. In rats, collection of blood from the heart results in a significant decrease in the erythrocyte and leukocyte counts, hemoglobin concentration, and HCT compared to samples taken from the retro-orbital venous sinus and tail. A distinct circadian rhythm affects peripheral leukocyte concentrations with an increase in circulating leukocyte concentration occurring during the light phase and a decrease during the dark phase. A distinct decrease in the total leukocyte count associated with a decrease in lymphocytes occurs in mice following the stress, such as occurs during transportation. Thus, it is difficult to establish reference hematologic values for mice and rats because of the large number of strains and variations in blood collection methods, handling techniques, and environmental conditions.

Published reference intervals for several strains of rats and mice are available, and the reader should refer to the "Suggested Reading" section at the end of this chapter. Erythrocytes of healthy rats and mice vary in size with a range between 5 and 7 μm in diameter; therefore, a marked anisocytosis is common (Table 19.1). Polychromasia is also common, with polychromatic cells representing 1–18% of the erythrocyte population (Figures 19.1 and 19.2). This is likely related to the relative short erythrocyte half-life of 56–69 days for rats, 41–52 days for mice, 50–78 days for hamsters, and 10 days for the gerbil. Hibernation (pseudohibernation) in hamsters prolongs the life span of their erythrocytes, and the end of hibernation generally reveals an increase in reticulocyte numbers. Adult rats and mice normally have a high degree of reticulocytosis with means that average between 2 and 5%; the young have even higher numbers ranging between 10 and 20%. Neonatal gerbils have erythrocyte counts that are approximately one-half adult values but increase to adult values by about 8 weeks of age. Gerbils up to 20 weeks old have a large number of circulating reticulocytes and erythrocytes with basophilic stippling and polychromasia, but these cells are also abundant in older gerbils and are likely associated with the short erythrocyte life span. Erythrocyte concentrations in females tend to be less than those of males. The normal PCV is 39–54% for rats and 35–45% for mice. The hemoglobin concentration generally ranges between 13.4 and 15.8 g/dL with a mean of 14.6 g/dL. Howell-Jolly bodies and nucleated erythrocytes are found in small numbers of erythrocytes in normal rats and mice (Figure 19.1). Rouleaux formation of erythrocytes is rarely seen, even with inflammatory disease.

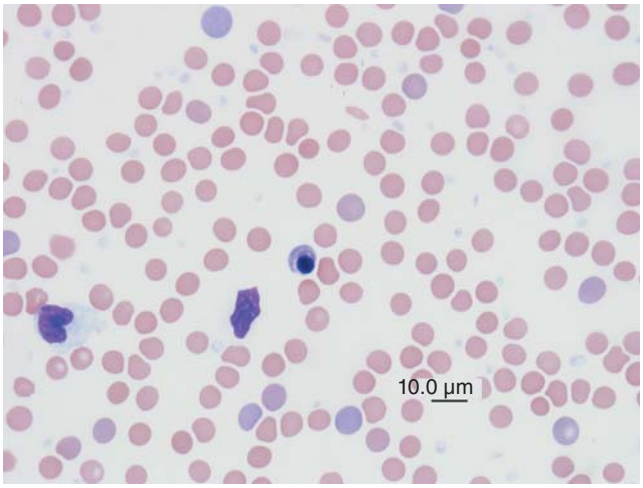

Figure 19.1 Polychromatic erythrocytes and a nucleated erythrocyte in the blood of a rat. Wright-Giemsa stain.

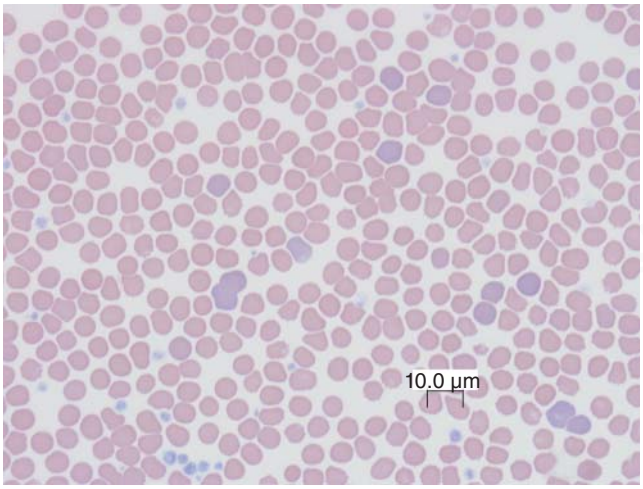

Figure 19.2 Polychromatic erythrocytes in the blood of a mouse. Wright-Giemsa stain.

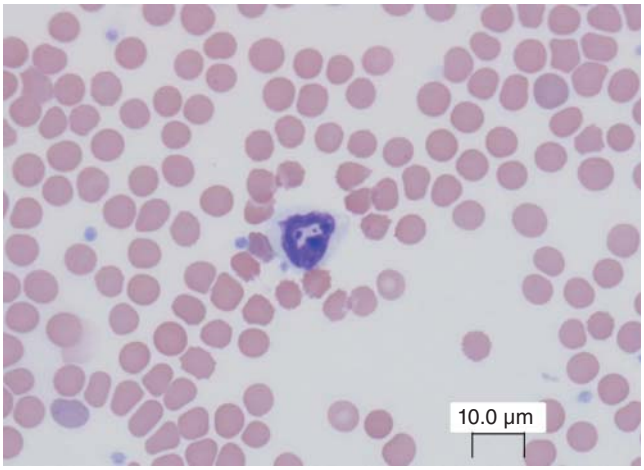

Figure 19.3 A neutrophil with a nucleus forming a ring in the blood of a mouse. Wright-Giemsa stain.

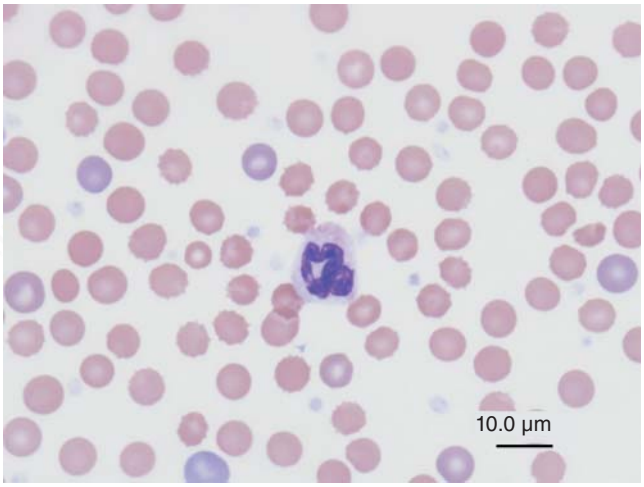

Figure 19.4 A neutrophil with fine, pink cytoplasmic granules in the blood of a rat. Wright-Giemsa stain.

Granulocytes of mice and rats often have nuclei without distinct lobes and typically have a horseshoe, sausage, or ring (doughnut) shape (Figures 19.3 and 19.5). The ring shape results from a gradually increasing hole that develops in the nucleus during maturation of the granulocyte. Nuclear segmentation occurs as the ring breaks during maturation and begins to form constrictions.

The nucleus of the neutrophil in rodents often has several indentations that result in a hypersegmentation. Band cells may be seen in normal animals, but this is usually seen in association with inflammation. Neutrophils with ring-shaped nuclei are considered to be associated with accelerated granulopoiesis. Neutrophils usually have a colorless cytoplasm but may contain a few dustlike red granules, thus appearing diffusely pink with Romanowsky stains (Figure 19.4). Hamster neutrophils (heterophils) have a lobed nucleus and dense pink cytoplasmic granules. Rat neutrophils measure 11 µm in diameter. In general, the neutrophil represents 12–38% of the leukocyte differential. Eosinophils have nuclei that are typically less segmented than those of neutrophils (often ring- or band-shaped), a basophilic cytoplasm, and numerous eosinophilic cytoplasmic granules that may be arranged in small clumps (Figure 19.5). In mice, eosinophils have large, round, nearly uniformly sized, reddish-brown to red granules with indistinct borders. In rats, eosinophils have small, round, reddish granules that fill the cytoplasm. In hamsters, the cytoplasm of eosinophils is tightly packed with rod-shaped azurophilic granules that create a narrow zone around the nucleus. Eosinophils generally compose 0–7% of the leukocyte differential. Basophils are present in small numbers (0–1%) and contain numerous basophilic granules. In rats, mice, and hamsters, basophils are rarely observed on peripheral

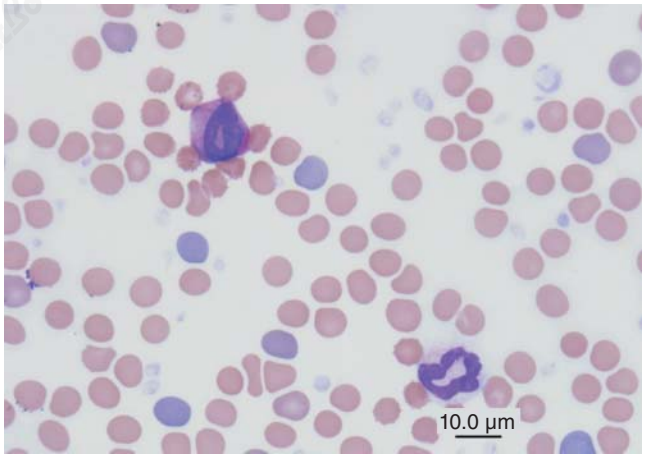

Figure 19.5 An eosinophil (cell on top) and a neutrophil each with a nucleus forming a ring in the blood of a rat. Wright-Giemsa stain.

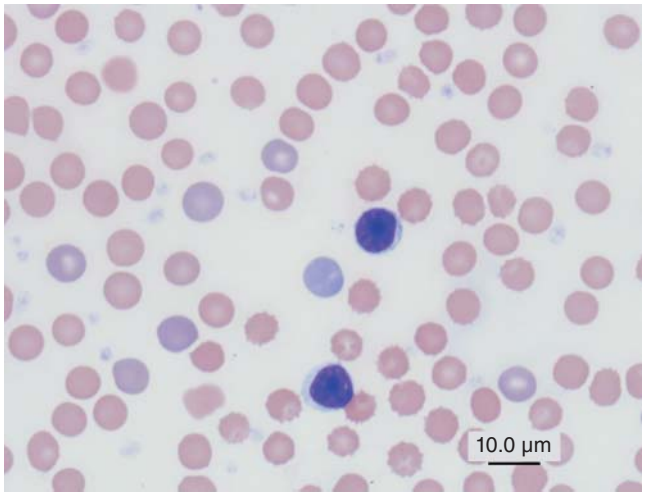

Figure 19.6 Lymphocytes in the blood of a rat. Wright-Giemsa stain.

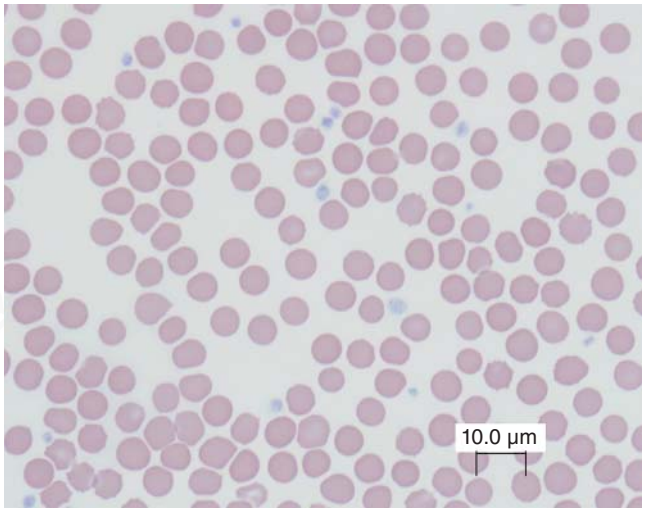

Figure 19.7 Numerous platelets in the blood film of a mouse. Wright-Giemsa stain.

blood smears. They lack tertiary granules but have larger and less numerous mature granules. Basophil nuclei are lobulated, and the cytoplasm contains large, round, purple granules that may be few in number or so numerous that they obscure the nucleus. Basophils should be differentiated from mast cells that may appear in peripheral blood, especially when cardiocentesis is performed. Basophil numbers appear higher in blood collected from the tail of mice and rats when excessive trauma is involved, such as laceration technique and compressing the tail to facilitate blood flow.

Lymphocytes are the predominant leukocyte in the peripheral blood of rats and mice, where they represent 60–75% and 70–80% of the leukocyte population, respectively (Figure 19.6). Likewise, lymphocytes comprise greater than 75% of the leukocyte population in the peripheral blood of hamsters and gerbils. The size of lymphocytes ranges from the size of erythrocytes to the size of neutrophils. The cytoplasm of lymphocytes stains light blue, and azurophilic cytoplasmic granules are occasionally found in large lymphocytes. The lymphocytes of hamsters are small round cells with a dark blue nucleus that fills most of the cell and is surrounded by a rim of lighter blue cytoplasm.

Monocytes (17 µm diameter) are the largest leukocyte found in the peripheral blood of rats and mice. They account for 1–6% of the leukocyte population in rats and 0–2% in mice. Monocytes have a variably shaped nucleus with the kidney-bean shape being the most common form. The abundant blue-gray cytoplasm often contains fine azurophilic granules and occasional vacuoles.

Leukocyte concentrations of mice and rats not only demonstrate a distinct diurnal variation but also vary markedly between strains; thus, lab results will vary by the time of day of blood sample collection and the strain. There is also an age-dependent variation in the neutrophil to lymphocyte ratio, with the lymphocyte concentration decreasing and neutrophil concentration increasing as a rodent ages. Acute stress in rats results in elevated serum corticosterone but with a normal neutrophil–lymphocyte ratio, whereas chronic stress (distress) yields the opposite – normal serum corticosterone concentrations with an elevated neutrophil–lymphocyte ratio.

Platelet concentrations in rodents tend to be high compared to those of larger domestic mammals (Figure 19.7). Platelet concentrations greater than 1×10^6 per µL are common.

Guinea pigs (*Cavia porcellus*)

Guinea pig erythrocytes are biconcave disks that, with a mean cell volume (MCV) of 84 fL, are larger in comparison to the erythrocytes of other common laboratory animal species. A moderate anisocytosis is common with cell widths ranging between 6.6 and 7.9 µm. The total erythrocyte

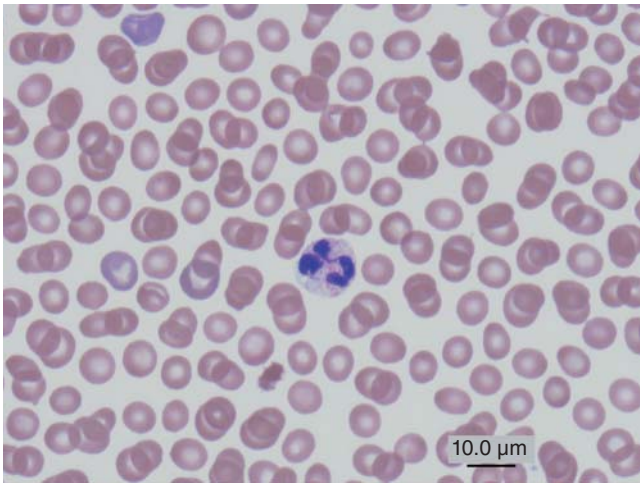

Figure 19.8 A neutrophil in the blood of a guinea pig. Wright-Giemsa stain.

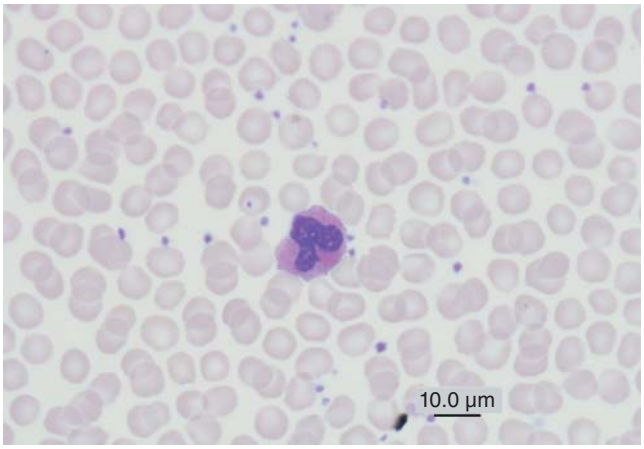

Figure 19.9 An eosinophil in the blood of a guinea pig. Wright-Giemsa stain.

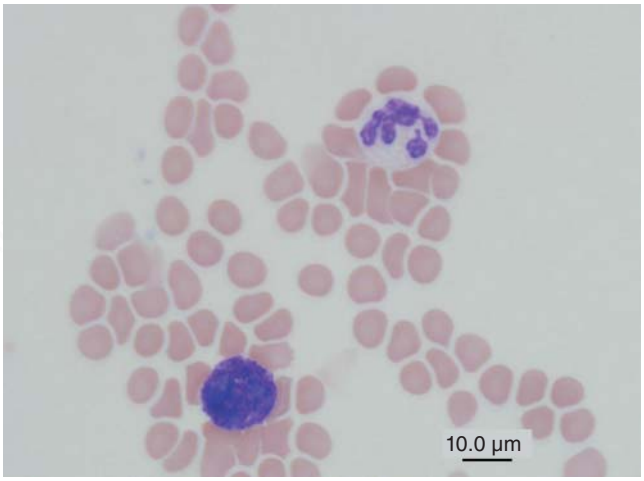

Figure 19.10 A basophil (cell on bottom) and neutrophil in the blood of a guinea pig. Wright-Giemsa stain.

count and the hemoglobin concentration of guinea pigs are generally lower than those of true rodents. Blood films from normal nonanemic guinea pigs exhibit polychromasia that varies with age: polychromatic erythrocytes may represent 25% of circulating erythrocytes in neonate, 4.5% in juvenile, and 1.5% in adult. Polychromasia and a macrocytosis characterize regenerative responses to anemia.

The neutrophils of guinea pigs measure 10–12 µm in diameter, have a pyknotic segmented nucleus, and contain pale cytoplasmic granules that stain eosinophilic that generally cause them to be referred to as heterophils or pseudoeosinophils (Figure 19.8). Although they stain differently than the neutrophils of domestic mammals with Romanowsky stains, the neutrophils of guinea pigs are equivalent in function. Guinea pig eosinophils (10–15 µm in diameter) are larger in size with less nuclear segmentation when compared to the neutrophils and have larger, rod-shaped (more pointed), bright red cytoplasmic granules, making eosinophils easy to differentiate from neutrophils (Figure 19.9). Basophils are slightly larger than heterophils, with a lobulated nucleus and many round variably sized reddish-purple to black cytoplasm granules (Figure 19.10).

Like those of rats and mice, lymphocytes are the predominant leukocyte in the differential of healthy guinea pigs, and small lymphocytes (approximately the size of erythrocytes) are the most common form. Large lymphocytes are almost twice as large as small lymphocytes, have a slightly smaller nucleus:cytoplasmic ratio, and often contain azurophilic granules. Approximately 3–4% of the lymphocytes or 1–2% of the total number of leukocytes in the peripheral blood of adult guinea pigs are large mononuclear cells that contain a single, large (1–8 µm wide) cytoplasmic inclusion referred to as a Kurloff body (Figure 19.11). These Foa-Kurloff cells are unique to cavies, such as guinea pigs, and are considered to be of lymphoid cells. The finely granular and occasionally vacuolated Kurloff bodies stain homogeneously red with Romanowsky stains, and because they consist of a mucopolysaccharide, they stain positive with toluidine blue, periodic acid–Schiff, and Lendrum stains. Their numbers appear to be influenced by sex hormones and occur in low numbers in immature male guinea pigs. The exact origin and function of these cells is unknown, although it has been speculated that they may function as natural killer (NK) cells in the general circulation or as protectors of fetal antigen in the placenta because their numbers can increase under the influence of increased estrogens. Guinea pig monocytes are morphologically similar to those seen in common domestic mammals. They are large cells with an oval to amoeboid nucleus having loose lacy chromatin and an abundant gray-blue cytoplasm.

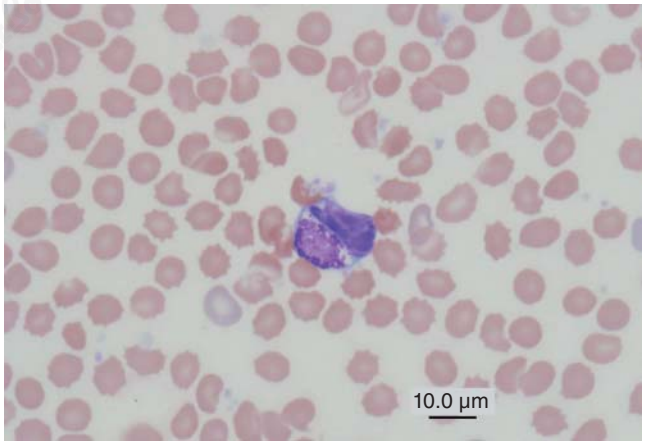

Figure 19.11 A lymphocyte containing a Kurloff body in the blood of a guinea pig. Wright-Giemsa stain.

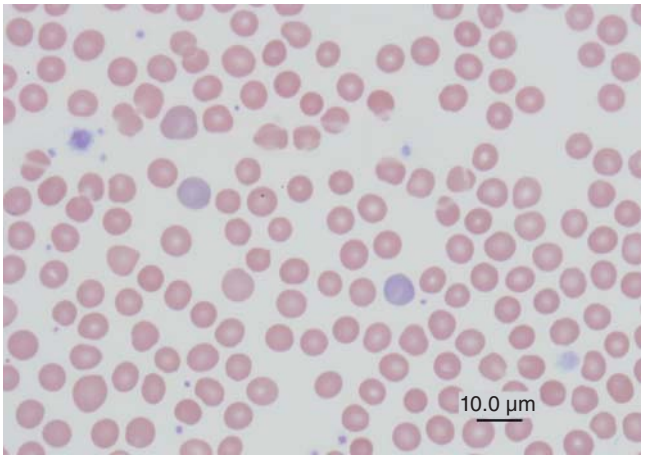

Figure 19.12 Erythrocytes in the blood of a rabbit. Wright-Giemsa stain.

Blood films of guinea pig contain large numbers of platelets. The normal platelet count ranges between 120 and 850/mm.

Other rodents

The hematologic features of hamsters (*M. auratus*), gerbils (*M. unguiculatus*), and chinchillas (*Chinchilla lanieger*) resemble those of mice and rats. As with rats and mice, polychromasia is a normal finding in blood film from hamsters and gerbils, and Howell-Jolly bodies are common. Nucleated red blood cells may account for up to 2% of the erythrocytes in blood films of normal hamsters. The neutrophils of chinchillas are typically hyposegmented and resemble neutrophils of dogs with the Pelger-Huet anomaly. Hamster neutrophils contain prominent round to rod-shaped eosinophilic cytoplasmic granules and are frequently referred to as heterophils. Lymphocytes are the predominate leukocyte in the differential of gerbils; however, a diurnal variation occurs in the numbers and types of leukocytes in the blood of hamsters. Leukocyte numbers of hamsters, a nocturnal animal, increase significantly at night when they are most active, with neutrophils rather than lymphocytes being responsible for the increase. Small and large lymphocytes are found in the blood of hamsters, but unlike other rodents, neutrophils tend to be the predominate leukocyte in the leukogram differential. Like the guinea pig, the chinchilla is normally lymphocytic; therefore, the hemic response in early inflammation often reveals an increase in heterophils and a decrease in lymphocytes with either a normal leukocyte count or a leukopenia.

Hematologic features of rabbits (*Oryctolagus cuniculus*)

The PCV of healthy rabbits generally ranges between 30 and 50%. The rabbit erythrocyte is a biconcave disk with an average diameter of 6.8 µm; however, the presence of erythrocytes with a range of 5.0–7.8 µm makes reporting of a significant anisocytosis a common finding in the hemogram of normal rabbits (Figure 19.12). Like rodents, polychromatic erythrocytes and reticulocytes are common in blood films of normal rabbits. Polychromasia is commonly observed in 2–4% of the erythrocyte population of normal rabbits. Nucleated erythrocytes and Howell-Jolly bodies are occasionally observed. The estimated half-life of rabbit erythrocytes is between 57 and 67 days. Male rabbits tend to have higher erythrocyte counts and hemoglobin concentrations than females. The total erythrocyte count, hemoglobin concentration, and HCT values can be significantly lower in pregnant rabbits in the third trimester compared to nonpregnant rabbits; however, the MCV value increases. Use of a general anesthetic does not appear to have an effect on the hematologic test results in rabbits. Erythrocyte fragility studies in rabbits based upon the sodium chloride concentrations indicate the first detectable hemolysis at 0.5–0.3% NaCl. As with most other species of mammals, a regenerative response to an anemia is characterized by increased anisocytosis, polychromasia, nucleated erythrocytes, and presence of Howell-Jolly bodies. Anemia is commonly associated with a variety of diseases in rabbits. Infectious diseases often result in increases in the number of nucleated erythrocytes.

Because the rabbit neutrophil contains small acidophilic granules and varying numbers of large red granules, it is generally referred to as a heterophil (or pseudoeosinophils in older literature). The smaller granules outnumber the larger granules by 80–90%. The rabbit neutrophil is between 10 and 15 µm in diameter. The polymorphic nucleus stains light blue to purple with Romanowsky stains. The cytoplasm of rabbit neutrophil typically stains diffusely pink with Romanowsky stains due to the fusion of the many small acidophilic granules (primary granules) (Figures 19.13 and 19.16). Rabbit neutrophils (heterophils) are ultrastructurally, functionally, and biochemically equivalent to neutrophils

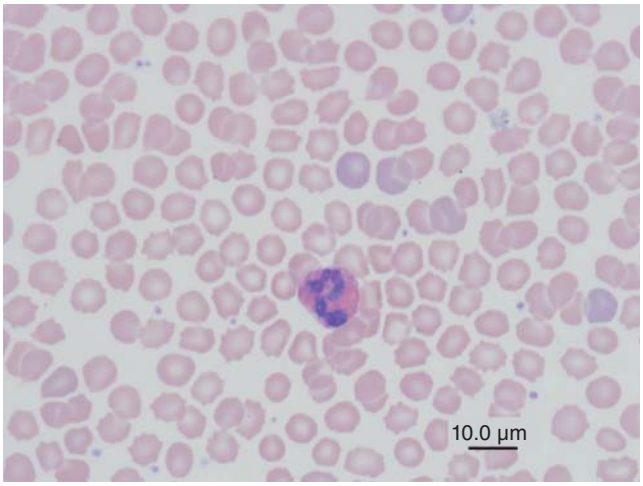

Figure 19.13 A neutrophil (heterophil) in the blood of a rabbit. Wright-Giemsa stain.

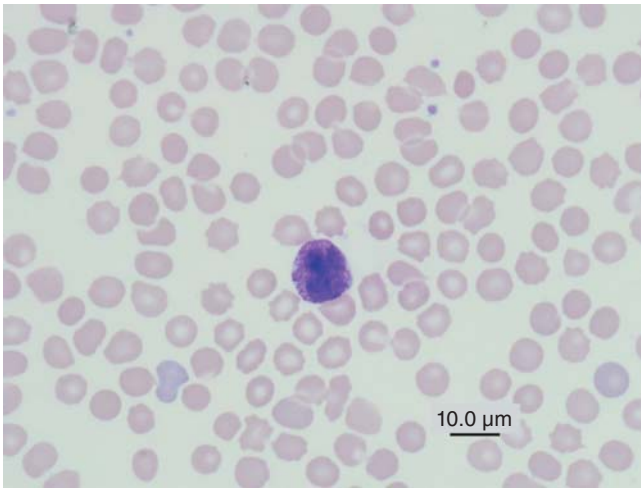

Figure 19.15 A basophil in the blood of a rabbit. Wright-Giemsa stain.

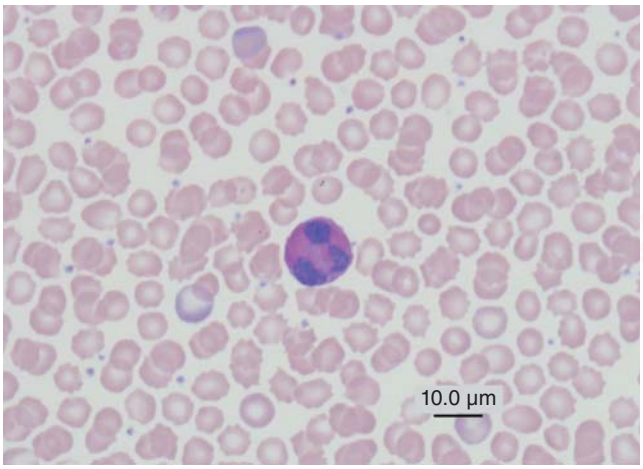

Figure 19.14 An eosinophil in the blood of a rabbit. Wright-Giemsa stain.

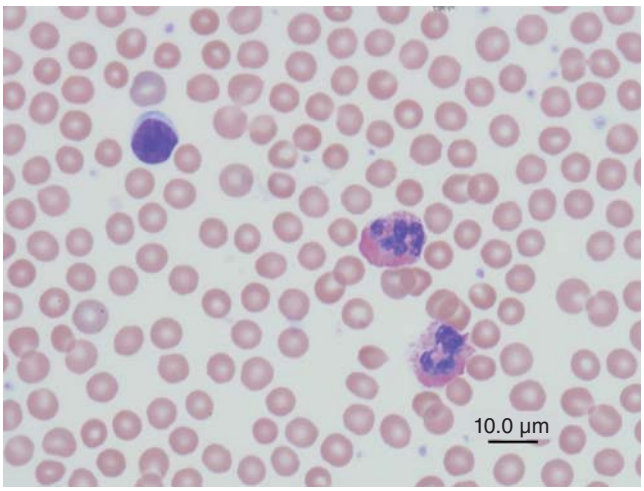

Figure 19.16 A lymphocyte and two neutrophils (heterophils) in the blood of a rabbit. Wright-Giemsa stain.

from other domestic mammals and humans. Occasional neutrophils with characteristics of the Pelger-Huet anomaly may be observed in blood films from normal rabbits. Rabbit neutrophils are easily distinguished from the eosinophils, which have large eosinophilic granules.

The eosinophils of rabbits are larger than the neutrophils and are between 12 and 16 µm in diameter (Figure 19.14). The large acidophilic cytoplasmic granules of the eosinophil are three to four times larger than those in the neutrophil and are more numerous in comparison, occupying much of the cytoplasm. Eosinophil granules are poorly defined and stain intensely pink to a dull pink-orange with Romanowsky stains, creating a tinctorial quality that differs from the neutrophil granules. The nucleus of the eosinophil is often bilobed to U-shaped. A low or absent eosinophil count is commonly observed in healthy rabbits.

Rabbits typically have more basophils than do other species; commonly 5% of the leukocytes are basophils, but they can be as high as 30% in rabbits with no apparent abnormalities. The rabbit basophil is about the same size as the rabbit neutrophil, and the purple to black metachromic cytoplasmic granules resemble those of basophils from other domestic mammals (Figure 19.15).

Rabbit lymphocytes are morphologically similar to those of other domestic mammals and humans. The majority of lymphocytes are small, between 7 and 10 µm in diameter; however, large lymphocytes between 10 and 15 µm in diameter may also be present (Figure 19.16). Azurophilic granules are often commonly present in the cytoplasm of the large lymphocytes.

Rabbit monocytes are similar to those found in other domestic mammals. The nucleus varies from lobulated to

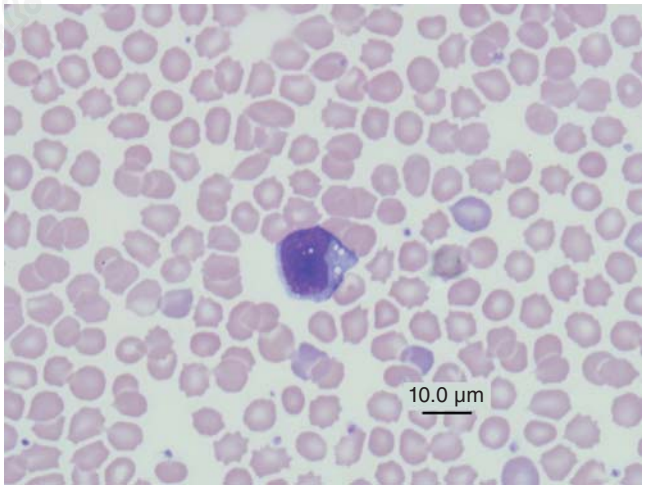

Figure 19.17 Monocytes in the blood of a rabbit. Wright-Giemsa stain.

bean-shaped, and the cytoplasm stains blue and may contain a few vacuoles (Figure 19.17).

The normal leukocyte concentration of rabbits is typically reported to range between 7000 and 9000/µL. Variations occur with age, restraint methods, methods of blood collection that may alter the neutrophil:lymphocyte (N:L) ratio, pregnancy, circadian rhythms (diurnal fluctuations and variation within a month), nutritional status and dietary differences, and differences in gender and breed. The number of circulating neutrophils is lower in the early morning and highest in the late afternoon and evening, and the opposite occurs with lymphocyte numbers. A bimodal increase in the leukocyte concentration is seen with increasing age, with highest lymphocyte concentration occurring at 3 months of age, then slowly declining, and highest neutrophil concentrations occurring in older animals. The normal neutrophil:lymphocyte ratio of 33 : 60 at 2 months of age changes to 45 : 45 by 12 months of age. Therefore, rabbits younger than 12 months of age are expected to have lower N:L ratios than do older rabbits, which typically have equal numbers of neutrophils and lymphocytes. A stress response associated with restraint during blood collection procedures can result in as much as a 15–30% decrease in the total leukocyte concentration. A mature neutrophilia and lymphopenia characterize glucocorticoid-mediated changes in the leukogram. Pregnant rabbits demonstrate a slight increase in total leukocyte counts during the first half of gestation, owing to an increase in lymphocyte numbers; however, a significant decrease can occur in the second half, owing to a decrease in lymphocytes and/or neutrophil numbers. Rabbits exposed to 28 °C (82.4 °F) for 1–3 hours are found to have an elevated PCV, lymphocytopenia, and leukocytosis.

Rabbits generally do not develop a leukocytosis with bacterial infections but will have a reversal of the N:L ratio; N:L ratio reversal is also associated with increases in serum cortisol concentrations. Therefore, evaluation of the N:L ratio appears to be the more reliable indicator of inflammatory disorders than are total leukocyte concentrations. Rabbits with acute infections may demonstrate a leukopenia with a normal leukocyte differential. Rabbits with septicemia and overwhelming bacterial infections often demonstrate a leukopenia with a degenerative left shift.

Rabbits presenting with an infectious disease do not typically have a higher white blood cell (WBC) count but rather have a shift from lymphocyte-predominant to neutrophil-predominant differential counts. Sometimes rabbits with acute infections may have a normal differential count but a decrease in total WBC count. Leukemias are infrequently reported in rabbits, usually presented as lymphoblastic leukemia. In cases of septicemia and in overwhelming bacterial infections, leucopenia with a degenerative left shift will be observed.

Rabbits with acute infectious processes commonly reveal a decrease in thrombocytes and an increase in nucleated erythrocytes.

Hematologic features of ferrets (*Mustela putorius*)

The hematology of ferrets resembles that of domestic carnivores. Ferrets are commonly anesthetized to restrain them for blood collection. The use of inhalant anesthetics such as isoflurane, enflurane, and halothane results in significant and rapid decreases in the RBC, HCT, and hemoglobin concentration. As much as a 33% decrease in the hemoglobin concentration occurs with the use of these inhalant anesthetics. Splenic sequestration and anesthetic-induced hypotension are possible causes for this response in ferrets. The erythron returns to normal within 45 minutes of recovery from the anesthetic. Either the use of manual restraint or injectable anesthesia such as ketamine or rapid blood collection following anesthetic induction (less than 3 minutes) is required to avoid this effect in the erythron.

Hematologic values of ferrets are similar to those of other domestic carnivores; however, the HCT, hemoglobin, and total erythrocyte and reticulocyte counts in ferrets are generally higher than those of domestic dogs or cats. The mean red blood cell diameter for ferrets is reported to range between 4.6 and 7.7 µm. The hemogram of domestic ferrets is influenced by gender and age. Young hobs (males) have lower RBCs, HCTs, and hemoglobin concentrations than adult hobs and young jills (females). Jills have a decrease in the HCT with age. The HCT of ferrets ranges between 30 and 61%, but usually averages between 40 and 50% for adult ferrets and between 32 and 39% for juvenile ferrets. The mean percentage of reticulocytes is reported to be 4%

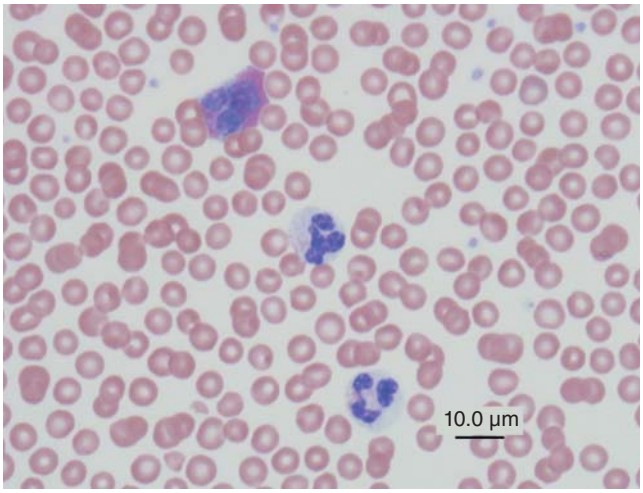

Figure 19.18 Two neutrophils and an eosinophil (cell on top) in the blood of a ferret. Wright-Giemsa stain.

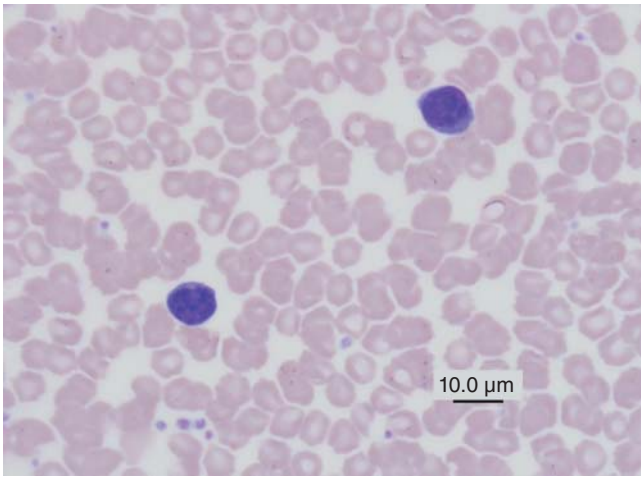

Figure 19.20 Lymphocytes in the blood of a ferret. Wright-Giemsa stain.

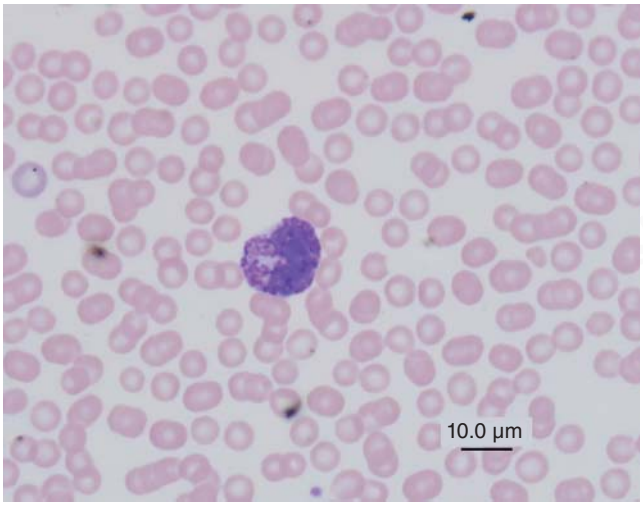

Figure 19.19 A basophil in the blood of a ferret. Wright-Giemsa stain.

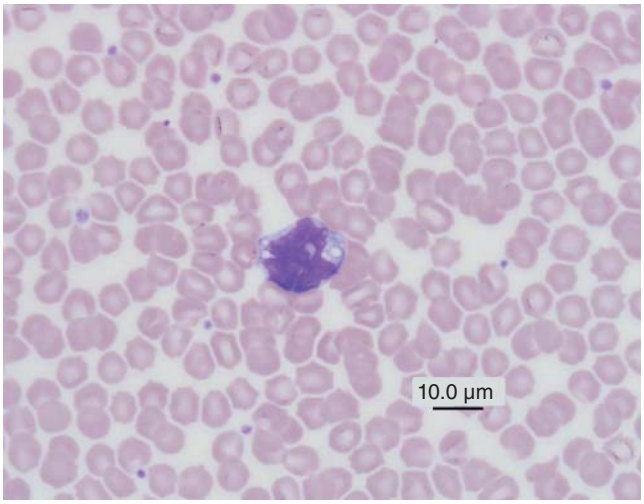

Figure 19.21 A monocyte in the blood of a ferret. Wright-Giemsa stain.

(range of 1–12%) in male ferrets and 5.3% (range of 2–14%) in female ferrets.

The morphology of ferret leukocytes is similar to that of dogs (Figures 19.18–19.21). The neutrophil is the predominant leukocyte in the peripheral blood of ferrets. The ranges in size for the various ferret granulocytes are 10–13 µm for neutrophils in males and 9–10 µm in females; and 12 and 14 µm for eosinophils and basophils, respectively, regardless of gender. The size of small lymphocytes ranges between 6 and 9 µm in male ferrets and 8 and 10 µm in females. Large lymphocytes and monocytes measure 11–12 µm and 12–18 µm in both sexes, respectively. Neutrophil concentrations are higher than lymphocyte concentrations in normal ferrets. Ferrets have an increase in neutrophil concentration and decrease in lymphocyte concentration with increasing age. The total leukocyte count of healthy ferrets can be as low as 3000/µL. In general, ferrets are unable to develop a marked leukocytosis with inflammatory disease, and concentrations greater than 20,000/µL are unusual and a left shift is rare.

Results of coagulation studies in ferrets vary depending upon methodology. For example, a significant prothrombin time was obtained using a manual method (12.3 ± 0.3 seconds) compared to an automated method (10.9 ± 0.3 seconds). Activated partial thromboplastin time; however was not significantly different between the two methods (18.7 ± 0.9 for the manual method and 18.1 ± 1.1 seconds for the automated method). Fibrinogen concentration for ferrets is reported as 107.4 ± 19.8 mg/dL and antithrombin activity is 96 ± 12.7%.

Common causes of nonregenerative anemia in domestic ferrets include malignant neoplasia such as lymphoma, systemic infections, and hyperestrogenism in intact females

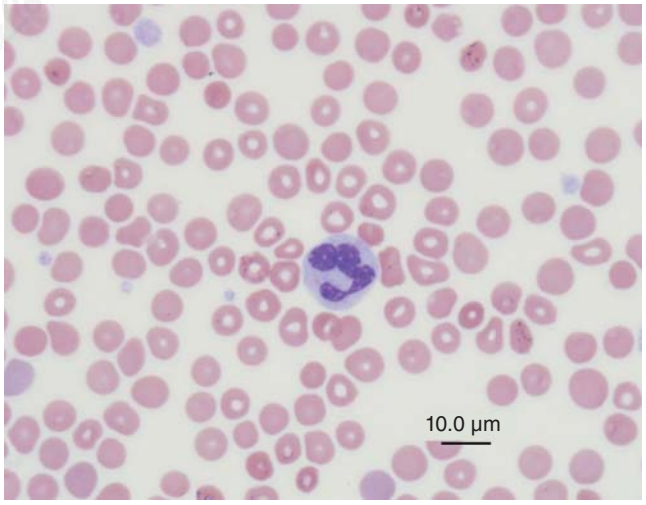

Figure 19.22 A neutrophil in the blood of a hedgehog. Wright-Giemsa stain.

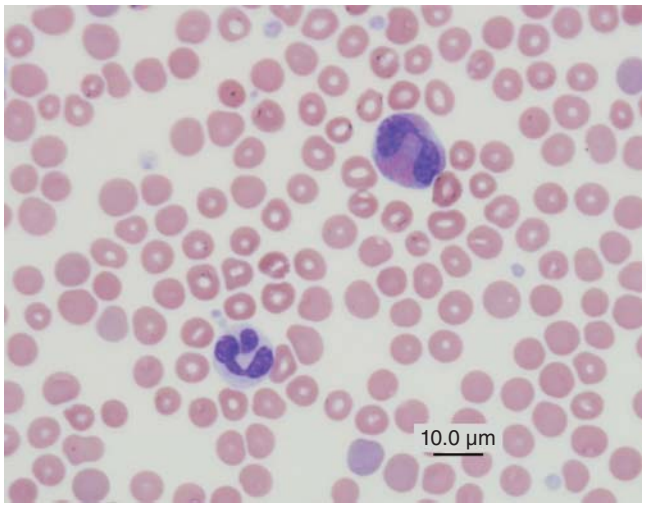

Figure 19.23 A neutrophil and eosinophil (cell on top) in the blood of a hedgehog. Wright-Giemsa stain.

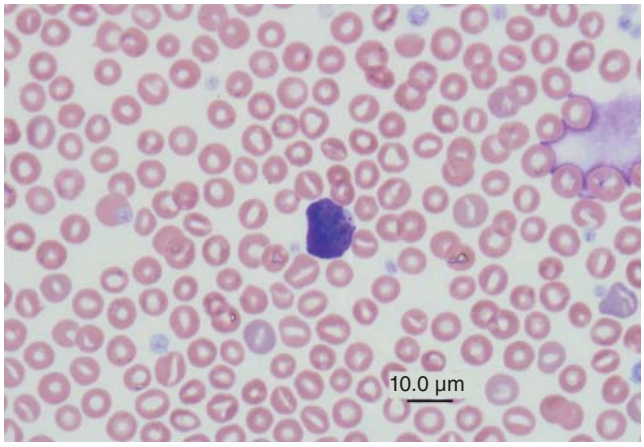

Figure 19.24 A basophil in the blood of a hedgehog. Wright-Giemsa stain.

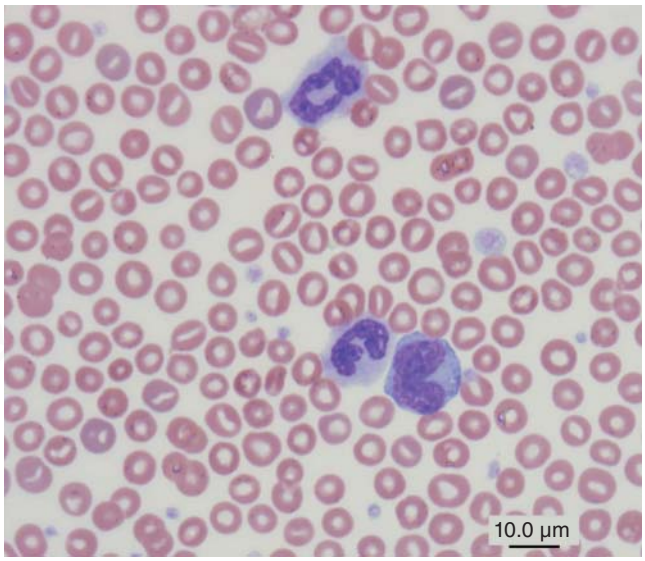

Figure 19.25 A neutrophil and monocyte (cell on the right) in the blood of a hedgehog. Wright-Giemsa stain.

(jills). Because jills are induced ovulators, an individual who does not breed during estrus may exhibit prolonged estrus throughout the breeding season. After a month of prolonged estrus, high levels of estrogen in the bloodstream may cause bone marrow suppression with leukopenia, thrombocytopenia, and aplastic anemia as indicated by a decrease in the PCV and total erythrocyte count. Jills in estrus with a PCV between 15 and 25% are given a guarded prognosis and those less than 15% a grave prognosis. Gastrointestinal ulcers are a common cause of blood loss anemia. Polychromasia is indicative of bone marrow erythroid hyperplasia in response to anemia.

Hematologic features of African hedgehogs (*Atelerix albiventris*)

The hematology of African hedgehogs resembles that of domestic carnivores (Figures 19.22–19.26). The morphology of erythrocytes and leukocytes is similar to that of other small mammals. Likewise, interpretation of changes in the hemogram is based upon those same changes in other small mammals.

Hematologic features of primates

The mature erythrocytes of primates are biconcave discs of approximately 7.5 µm in diameter. The red blood cell

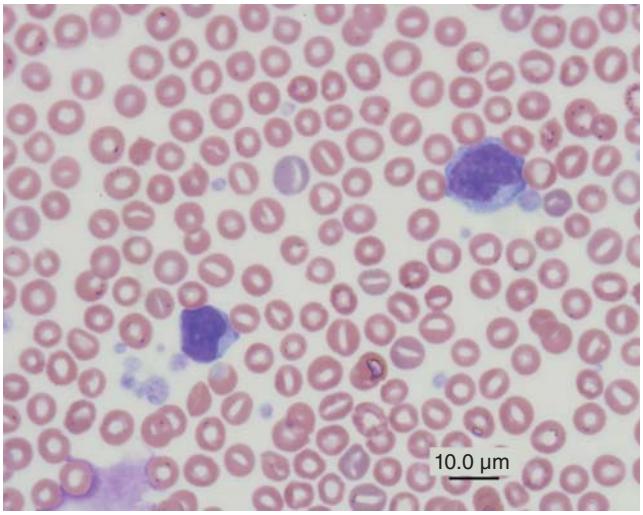

Figure 19.26 A lymphocyte (cell on the left) and monocyte in the blood of a hedgehog. Wright-Giemsa stain.

parameters of primates vary with age and gender. Neonates have higher total erythrocyte concentration, hemoglobin concentration, and PCV compared to adults. The erythron rapidly decreases as animals become subadults but then increases after puberty. Adult male primates have a higher erythrocyte concentration, hemoglobin concentration, and PCV compared with adult female primates. The reticulocyte concentration of most normal primates is less than 2.0%. Small numbers of Howell-Jolly bodies may be seen in the blood films from primates. Erythrocyte Rouleaux formation occurs with inflammatory disease.

Excitement and exertion associated with capture and restraint produce splenic contraction and a corresponding increase in the PCV. Use of an anesthetic (e.g., ketamine) reduces this effect.

Neutrophils of some primates, such as orangutans (*Pongo pygmaeus*), have very small eosinophilic granules, whereas those of others, such as chimpanzees (*Pan* sp.), have very small basophilic granules. Lymphocytosis, which is associated with restraint-related epinephrine release, can be prevented with use of ketamine anesthesia. Occasional binucleated lymphocytes are found in the blood of normal primates.

Leukocyte concentrations as great as 15,000 cells/µL are more typical of nonexcited primates; however, concentrations as great as 30,000 cells/µL can occur with excitement. An increased number of immature neutrophils (i.e., band cells) is indicative of inflammation. Most species demonstrate toxic neutrophils with inflammation associated with infections, and some species, such as rhesus monkeys (*Macaca mulatta*) and orangutans commonly exhibit neutrophil toxicity in the form of Döhle bodies. A marked, transient leukocytosis with lymphocytosis occurs in primates in response to antigenic challenges (e.g., adenovirus infection). Leukemia associated with high concentrations of large lymphocytes often has a viral etiology, such as *Herpesvirus saimiri* and RNA oncornavirus infection.

Blood parasites, including microfilaria and trypanosomes, commonly are present in wild-caught primates, especially New World monkeys. These parasites have a low virulence, however, and generally are considered to be an incidental finding. Plasmodium gametocytes and schizonts often appear as incidental findings in the erythrocytes of asymptomatic wild-caught primates. Gametocytes of *Hepatocystis*, which is a mildly pathogenic parasite, may be seen in the blood films of some African monkeys.

Hematologic features of minipigs

The hemograms of minipigs (e.g., pot-bellied pigs) do not vary significantly from those of domestic pigs. Therefore, hematologic studies of minipigs are interpreted in the same manner as those of domestic pigs. Erythrocyte spiculation, which is characterized by sharp, pointed projections from the cells, is common in the blood film of normal minipigs.

The neutrophils of pigs have irregularly stained nuclei with irregular margins, and they often are coiled and lack complete lobation. The cytoplasm of porcine neutrophils contains small, pink granules with Romanowsky stains. Porcine eosinophils have round to oval, orange cytoplasmic granules. The nucleus often appears to be a band. Normal minipigs have total leukocyte concentrations as great as 22,000 cells/µL because of the excitement leukocytosis associated with handling for blood collection. The lymphocyte concentration is greater than the neutrophil concentration in healthy pigs. Physiologic leukocytosis results from a transient neutrophilia and lymphocytosis. Minipigs, like other animals with low N:L ratios mount a lower leukocyte response than animals with high N:L ratios with inflammatory diseases; they may show only a reversal of the N:L ratio with mild inflammatory diseases. Marked neutrophilia is associated with more severe inflammatory diseases.

Hematologic features of camelids

The hematology of camelids, including camels, alpaca, and llamas, is similar to that of other mammals, except for the presence of numerous small, thin, flat, elliptical erythrocytes. Because the oval camelid erythrocytes are not biconcave discs as observed in most mammals, they lack central pallor. The flat contour lends them to a folding artifact. A few erythrocytes may contain rhomboid or hexagonal hemoglobin crystals, an intriguing but idiopathic and apparently nonpathogenic phenomenon. Camelids adapted to living at high altitudes, such as llamas, have erythrocytes

that function at low atmospheric oxygen tension without the development of polycythemia and dissociated high blood viscosity. The elliptical shape may allow for easier passage through the capillaries, and the thin, flat contour allows for rapid gas exchange. Camelid erythrocytes are small in volume, and their numbers are significantly more numerous than those of most mammalian erythrocytes, with an upper limit of normal that approaches 18 million/μL. Although camelids have high erythrocyte concentrations, their small size results in relatively small PCVs. Healthy llamas have small MCV, ranging between 20 and 30 fL, and a relatively high mean cell hemoglobin concentration ranging between 40 and 45 g/dL. Camelid erythrocytes are more resistant to hemolysis in hypotonic saline than those of other mammals.

Because erythrocyte concentration of camelid blood is often two to three times that of common domestic species, blood samples from these animals must be properly diluted to avoid analytical error when using impedance – or flow cytometry – methods for cell counting. Counting errors in these hematologic analyzers occur when cells pass through the aperture or in front of the laser in pairs rather than singly, causing the two small cells passing through the measuring device to be counted as one large cell. In addition, sizing thresholds may not be set sufficiently low enough to capture the smallest cells of the erythrocyte population; therefore, the instrument may report erroneously low erythrocyte counts with an accurate hemoglobin concentration. When this occurs, a physiologically impossible high mean corpuscular hemoglobin concentration (MCHC) will be reported, indicating instrument error if hemolysis and lipemia are not the cause. Published quality control guidelines are available to ensure the instrument is providing accurate results and the veterinarian is provided with reliable data.

The reticulocyte count in healthy camelid blood is low (less than 1 per 1000× field); however, when exposed to altitudes of 14,000 ft or higher, the number of reticulocytes may represent 1.5% of the erythrocyte population. They appear polychromatophilic with Romanowsky-type stains and are larger and plumper than the mature cells. The polychromatic nucleated erythrocytes (nRBCs), which are occasionally observed in healthy camelids, appear more rounded than more mature polychromatophilic erythrocytes and have a rounded nucleus.

Hypochromic, macrocytic anemia with or without evidence of regeneration may be associated with iron deficiency, chronic inflammation, endo- and ectoparasitism, and copper deficiency. An increase in the number of folded cells and microcytosis is suggestive of chronic iron deficiency. Morphologic erythrocyte irregularities such as dacryocytes (teardrop-shaped cells), spindloid cells, and irregular hemoglobin distribution may also be observed with iron deficiency but can also occur with anemia from other pathogeneses. Maple leaf toxicity resulting in Heinz body–related hemolytic anemia can occur with maple leaf toxicity in camelids. *Mycoplasma haemolamae* (previously known as *Eperythrozoon*) is identified under high-resolution light microscopy as a small rod or circular structure on the surface of the erythrocyte. Because this bacterium will fall off the cells within a few hours after collection, examination of freshly prepared films is crucial.

A reliable nucleated cell count (NCC), which includes neutrophils, lymphocytes, and nRBCs, can be obtained from most automated methods, which are preferred over manual methods for accuracy, precision, and reduced technical time. Eosinophil concentrations tend to run higher in camelids than many mammals, and when sufficiently high enough, they may also be accurately counted by automated methods. As a general rule of thumb, monocytes and basophils are present in proportions too low to be accurately measured, but this variability is rarely clinically significant. A quick scan of a blood film can assess whether automated differentials appear reasonable. Camelid neutrophils, lymphocytes, monocytes, eosinophils, and basophils resemble those of most other mammals on Romanowsky-stained blood films. Healthy camelids tend to have small, intermediate, and large lymphocytes that are represented by a relatively high proportion with granulated cytoplasm (most noticeable with the alcohol-based Romanowsky stains). Camelid eosinophils typically have hyposegmented nuclei.

Like many animals, young camelids tend to have higher lymphocyte counts as compared to adults. Also, a mature neutrophilia and lymphopenia is consistent with stress (an eosinopenia may also be present). A neutrophilia with a left shift is indicative of inflammation, often with the presence of toxic changes within neutrophils (indicating accelerated bone marrow production and shortened maturation time) and hyperfibrinogenemia.

Because camelid platelets tend to be smaller and more numerous than other mammalian species, some automated analyzers may not recognize them and report erroneously low results. Therefore, a semiquantitative (e.g., low or adequate) estimate from the blood film is often used in reporting platelet numbers.

Hematologic features of deer

Erythrocytes in most species of normal deer exhibit *in vitro* sickling. The erythrocytes circulate as round cells, but sickling occurs during preparation of blood films after blood collection. Sickling occurs when the cells are exposed to oxygen and also appears to be affected by pH. Nearly all erythrocytes sickle at a pH of 7.4. Sickling can be prevented, however, by acidifying the blood. Sickled cells appear as crescent, holly leaf, matchstick, and burr shapes depending on the hemoglobin variant. Deer blood contains several

hemoglobin types that polymerize or crystallize in the oxygenated state, thereby leading to sickle cell formation.

Excitement and stress during restraint result in high erythrocyte and leukocyte counts. Male deer have higher PCVs and erythrocyte counts compared with female deer. Erythrocytes in deer exhibit a high degree of Rouleaux formation with inflammatory disease.

Lymphocytes are the predominant leukocyte in normal deer. During the rutting period, male deer have higher neutrophil concentration compared with female deer.

20 Hematology of Birds

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

The original hematology studies in birds were based on Galliformes, such as chickens and turkeys, as the animal model; however, since that time, the majority of information concerning the hematology parameters of birds are based primarily on psittacines and raptors, two groups of birds most commonly presented to veterinarians in clinical practice. The normal values for the hematologic parameters of each species of bird have a broad range because of the influences of various intrinsic and extrinsic factors. In general, avian hematological values are subject to extensive variability resulting from different environment and management practices, which can affect physiological responses. For example, heterophil numbers are altered by seasonal changes, diurnal rhythm, gender and age, and diet. Normal hematologic values vary between the species as well. The different avian species from which blood samples are submitted to veterinary laboratories creates a significant logistical challenge to the development of clinically relevant normal values. Thus, published references should only be used as guidelines.

Avian hematology is approached in a manner similar to that of human and mammalian hematology, but a few differences require modification of the hematologic procedures. Major differences include the presence of nucleated erythrocytes, thrombocytes, and heterophil granulocytes in the peripheral blood of birds.

Collection and handling of blood samples

Blood collection should be performed safely and quickly. The stress associated with the capture and restraint of the avian patient, especially those that are ill or those not accustomed to being handled, can further compromise the health of the patient and may affect the hematologic indices. Proper restraint of birds has been previously described in other texts and is not discussed in complete detail. Many birds can be physically restrained without anesthesia for venipuncture. Cloth towels may be used to restrain most of the common pet psittacine and passerine birds. Birds should be held in an upright position or parallel to the floor and should not be held upside down because this may compromise their respiration. Birds must be able to move the keel (sternum) in order to breathe; therefore, excessive restraint around the body should be avoided to prevent asphyxiation. The wings and legs should be supported during the process of blood collection to prevent injury to those limbs. Many birds become tractable when the head is covered to reduce vision using a snug-fitting lightweight cloth or hood (birds used for falconry or those in raptor rehabilitation facilities often have properly fitting leather hoods available). Proper restraint of the avian patient should be safe for both the bird and the handler. Some species of birds are capable of inflicting serious injury to the handler. The talons of raptors and the spurs of Galliformes can injure handlers, so care should be taken to properly and safely restrain the legs of these birds during venipuncture. The beak of many birds can also serve as a weapon; therefore, proper restraint of the head is required to protect the handlers. Large birds, such as ratites, are especially dangerous as their kicks are potentially lethal to the handlers.

The amount of blood that can be safely removed from a bird depends on its body size and health status. A blood volume representing 1% or less of body weight usually can be withdrawn from healthy birds without detrimental effects. For example; a healthy, 80 g cockatiel (*Nymphicus hollandicus*) can easily tolerate removal of a 0.8 mL blood sample. The sample size taken from severely ill birds, however, must be reduced. For routine hematologic evaluations in birds, a sample size of 0.2 mL usually is adequate. A variety of collection methods have been used to obtain blood from birds, and the method chosen depends on the size of the bird, peculiarities of the species, preference of the collector, volume of blood needed, and physical condition of the patient.

Venous blood provides the best sample for hematologic studies. Blood collected from capillary beds (i.e., clipping of a toenail) usually results in abnormal cell distributions and contains both cells and other substances not found in

venous blood, such as tissue fluid, macrophages, and cellular debris. Veins commonly used for venipuncture include the jugular, basilic (cutaneous ulnar, wing, or brachial), and medial metatarsal (caudal tibial). Blood can be collected using a needle and syringe when performing venipuncture on the jugular or other large veins. A short (1 in. or smaller) 25–22-G needle attached to a 3–6 mL syringe commonly is used for jugular venipuncture. A needle with an extension tube, such as a butterfly catheter (Abbott Hospitals, North Chicago, IL), aids in stabilization of the needle during sample collection. Blood also can be collected after venipuncture by allowing it to flow through the needle and drip into a microcollection device. Collecting blood by allowing it to flow through the needle, rather than by aspirating it into a syringe, minimizes hematoma formation. A variety of these devices (Microtainer tubes, Becton-Dickinson, Rutherford, NJ) are available. Microcollection tubes containing ethylenediaminetetraacetic acid (EDTA) are available for hematologic studies, but they also are available as plain tubes, with or without a serum separator, and as tubes containing heparin (lithium heparin is preferred) for studies of blood chemistry.

Jugular venipuncture most commonly is used for collecting blood from birds, because most small birds do not have other veins that are large enough for venipuncture. The right jugular vein is the vein of choice for this procedure, because it either is the only jugular vein present or is the larger of the two jugular veins. The jugular vein tends to be highly movable and is surrounded by a large subcutaneous space that predisposes it to hematoma formation during venipuncture. Therefore, the jugular vein must be stabilized before attempting venipuncture. Following adequate restraint, extend the bird's head and neck to allow the jugular vein to fall into the jugular furrow along the lateral side of the neck (Figure 20.1). Lightly wet the feathers with alcohol to expose the featherless tract (apterium) that overlies the jugular furrow. With a few exceptions (pigeons and doves), the jugular vein is visible through the thin skin on the neck. Pressure should be applied to the jugular vein just cranial to the thoracic inlet to occlude and distend the vein, which will facilitate the blood-collection process. Jugular venipuncture should be performed using an appropriate-sized needle and syringe because the large flow rate and the volume of blood present make it difficult to collect blood as it flows from a needle alone. Introduce the needle into the vein and collect the blood sample by applying only enough negative pressure on the syringe to allow blood to enter the syringe. More vigorous aspiration will cause collapse of the vein, promote hematoma formation of the vessel, and may cause hemolysis of the sample. Collection of blood with vacuum tubes is not recommended because of the excessive negative pressure that occurs.

The basilic (cutaneous ulnar, wing, or brachial) vein is a blood collection site that may be used in medium to large birds. This method of blood collection will require

Figure 20.1 Jugular venipuncture in a parrot (*Amazona* sp.).

an assistant to restrain the bird and to apply pressure to the humeral area in order to occlude the vein, because proper restraint is crucial to prevent wing movement and hematoma formation. Typically, the bird is restrained in dorsal recumbency. One wing is then stretched away from the bird's body, with the elbow almost fully extended. Anesthesia may be required to facilitate restraint because many birds (i.e., psittacine birds) will struggle during this procedure. The basilic vein crosses the ventral surface of the humeral-radioulnar joint (elbow) directly beneath the skin and is easily visualized by wetting the area lightly with alcohol. Using an appropriate-sized needle, blood can be collected following cannulation of this vein either by aspiration into a syringe or by allowing the blood to drip from the needle hub into a microcollection tube (Figure 20.2). To prevent needle movement while aspirating blood into a syringe, the needle can be stabilized by the phlebotomist. This is accomplished by placing the index finger of the free hand alongside the ulna where the basilic vein crosses the elbow. The needle can then be supported as it rests on top of the index finger while it is guided into the vein. If necessary, additional support can be provided by placing the thumb of the free hand on top of the needle. A needle with an extension tube may also minimize needle movement when using a syringe. Hematoma formation is the most common complication associated with this procedure because of movement of the wing or the needle following venipuncture.

Venipuncture of the medial metatarsal (caudal tibial) vein is another common blood-collection method in medium to large birds. The medial metatarsal vein is located on the caudo-medial aspect of the tibiotarsus just above the tibiotarsus-tarsometatarsal joint and often hides beneath the calcaneal tendon. To access this vein, the bird should be restrained in dorsal or lateral recumbency, with the leg extended. Once the leg is extended and stabilized, a needle

Figure 20.2 Blood collection from the basilic vein in a parrot (*Amazona* sp).

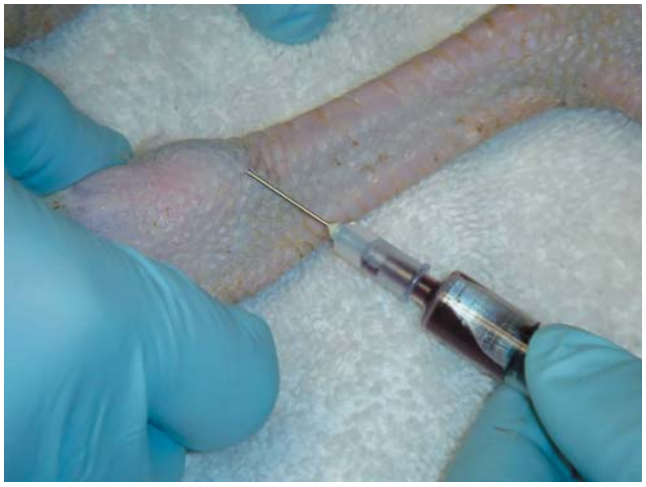

Figure 20.3 Blood collection from the medial metatarsal vein in a turkey poult (*Meleagris gallopavo*).

is introduced into the medial metatarsal vein at a shallow angle. Blood can be collected by aspiration into a syringe or by allowing blood to drip from the needle hub into a collection tube. Compared to venipuncture of the jugular and basilic veins, hematoma formation is typically minimal following venipuncture at this site because the leg is relatively easy to restrain, and the vein is protected by the surrounding muscles of the leg (Figure 20.3).

Clipping the toenail and lancet wounding are two other methods of blood collection, but these should be reserved for very small birds or for when attempts at venipuncture have failed. After alcohol cleansing, the toenail is clipped until blood flows freely for collection into a microcollection tube. After blood collection from the cut nail, hemostasis is accomplished by applying a hemostatic agent such as silver nitrate or ferrous subsulfate. Blood collection by this technique yields a poor sample for hematologic studies, however, because the blood is from the capillary bed and usually contains microclots, which interfere with cell counts. Capillary blood is also frequently contaminated with tissue fluid that affects hematologic data. Toenail clipping may result in temporary lameness because of nail damage. An alternative to nail clipping for blood collection from small birds is to collect blood after lancet wounding of vascular structures, such as the cutaneous ulnar vein, medial metatarsal vein, or external thoracic vein. After alcohol cleansing of the skin overlying the vein, the vessel is punctured through the skin using a lancet (i.e., needle), and the blood is allowed to drip into a microcollection tube.

Large volumes of blood can be collected from birds by cardiac puncture or occipital venous sinus puncture. These procedures are potentially dangerous, however, and should be reserved for birds that are used for research or are to be euthanized. Cardiac puncture can be performed using an anterior or a lateral approach. The heart is approached anteriorly by inserting a needle along the ventral floor of the thoracic inlet with the bird in dorsal recumbency. Care should be taken to avoid the ingluvies (crop) in some avian species. The needle is inserted near the "V" that is formed by the furcula, and it is directed toward the bird's dorsum and caudal toward the heart. Once the heart is penetrated, the vibration can be felt to ensure proper needle placement, and blood is then aspirated. In Galliforme birds, the heart can be approached laterally by inserting the needle in the fourth intercostal space near the sternum (keel) with the bird held in lateral recumbency. This approach, however, may vary with the species.

Blood collection from the occipital venous sinus requires use of evacuated glass tubes with appropriate needles and needle holders. The occipital venous sinus is located at the junction of the dorsal base of the skull and the first cervical vertebra, and it can be located by palpation while holding the bird's head firmly flexed and positioned in a straight line with the cervical vertebrae. A needle is inserted through the skin at a 30°–40° angle to the vertebrae. As soon as the needle penetrates the skin, the rubber stopper of the evacuated tube is perforated gently and the needle advanced until the sinus is reached. Penetration of the sinus results in a rapid flow of blood into the tube. Blood collection by puncture of either the heart or the occipital venous sinus requires proper restraint and technique to avoid permanent damage to the heart or brainstem – and even possible death of the patient.

The method of storage and handling of blood samples can have a significant influence on the hematological results. Blood samples collected without use of an anticoagulant require immediate processing. Dilutions for cell counting and preparation for blood films must be quickly performed with such samples. Because of the urgency for rapid processing of nonanticoagulated blood, most avian blood samples are collected into tubes containing an anticoagulant. EDTA,

heparin, and sodium citrate are commonly used, and each has both advantages and disadvantages. The anticoagulant of choice for avian hematology is EDTA, because it allows for proper staining of cells and does not tend to clump leukocytes. Hematologic testing, however, should be performed soon after blood collection to avoid artifacts, such as increased cell smudging, which is created by prolonged exposure to any anticoagulant. Excessive liquid anticoagulants dilute the blood sample, thereby resulting in artifactually decreased hematocrit and total cell concentrations, and excessive dry anticoagulants may cause shrinkage of red blood cells, thus affecting the hematocrit. Blood from certain avian groups, such as crows and jays, may show incomplete anticoagulation or partial hemolysis when collected in EDTA. Heparin has the advantage of providing anticoagulated blood for hematology and plasma for evaluations of blood chemistry. Heparinized blood, however, may result in improper staining of cells, thereby resulting in erroneous leukocyte counts and poor cellular morphology in stained blood films. Heparin also causes clumping of leukocytes and thrombocytes and resultant inaccurate cell counts. A 3.8% sodium citrate solution, used in a ratio of one part citrate solution to nine parts blood, is the anticoagulant of choice for coagulation studies; however, it should not be used for other hematologic evaluations. Consistent use of the same anticoagulant is an important consideration with serial evaluation of the hemogram in the avian patient. For example, it has been demonstrated that although most hematologic parameters are in agreement between blood samples collected into heparin and EDTA, plasma protein and the packed cell volume (PCV) are significantly lower and lymphocyte counts are significantly higher in the heparinized samples.

Blood sampled during field studies often does not have the advantage of immediate processing following blood collection; therefore, artifactual changes may occur during storage. The period of stability of the sample is influenced by temperature, time, and species. In general, avian blood samples collected into EDTA can be stored at 4 °C for up to 72 hours and provide reliable results for PCV, hemoglobin (Hgb) concentration, total red blood cell count (RBC), mean corpuscular hemoglobin (MCH) values, and mean corpuscular hemoglobin concentration (MCHC), and up to 30 hours with reliable results for mean corpuscular volume (MCV) and the total white blood cell count (WBC).

A stained blood film is an essential part of the hematologic examination because it provides the opportunity to determine the differential leukocyte count and allows assessment of pathologic abnormalities of the various blood cells. A properly made blood film should have areas with a cellular monolayer that contains evenly distributed individually dispersed cells. Blood films are made using blood with or without an anticoagulant and using a variety of techniques. Avian blood cells are easily ruptured with improper blood film preparation techniques; therefore, it is advisable to use precleaned, bevel-edged microscope slides to minimize cell damage during blood film preparation. The standard or push-slide method commonly used for preparing human and mammalian blood films can be used to create blood films for avian hematology. This method involves placement of a drop of blood near one end of a microscope slide that is supported by a solid surface, such as a countertop. The second (pusher or spreader) slide is placed on top of the first slide to form a "wedge" at a 30°–45° angle in front of the drop of blood. The pusher slide is backed into the drop of blood and quickly advanced forward in one rapid motion to create the blood film. This method usually provides good cellular distribution and adequate monolayer fields for proper slide evaluation; however, cells are commonly damaged when too much pressure is applied to the pusher slide. To minimize cell damage, a drop of commercially available purified bovine albumin can be applied to a glass microscope slide, followed by an equal amount of blood placed on top of the albumin prior to making the blood film. The albumin should not be allowed to dry before making the blood film. Another method of blood film preparation using the two-slide wedge technique may aid in minimizing cell damage. Hold the slides rather than allowing one of the slides to rest on a firm surface. The slide intended to contain the blood film is held in one hand while the pusher slide is held in the other hand (Figures 20.4–20.6). A drop of blood is placed near the end of the slide farthest from the person making the blood film, and the pusher slide is immediately placed in front of the drop of blood. The pusher slide is then quickly backed completely through the drop of blood while being held at an angle of approximately 30°–45° to the blood film slide. The direction of the pusher slide is immediately reversed toward the opposite end of the blood film slide to make the blood film. The pusher slide, therefore, is brought toward the person making the blood film rather than being pushed away. Most people have better control of the spreader slide when it is being pushed toward them as opposed to being pushed away. This step should be performed in one rapid motion that involves a flip of the wrist holding the pusher slide. The advantage of holding the slides rather than allowing the blood film slide to rest on a solid surface is that less downward pressure can be applied to the pusher slide when making the blood film, which creates less cell damage. Alternately, blood films can be prepared by using a slide and coverslip, or two coverslips. With proper attention to technique, these methods minimize cellular disruption and maintain good cellular distribution with monolayered areas for examination. These methods utilize a coverslip that is pulled across a drop of blood that has been placed on a glass microscope slide or another coverslip. Primary disadvantages of this method include the inability to use an automatic stainer and the potential for cell rupture

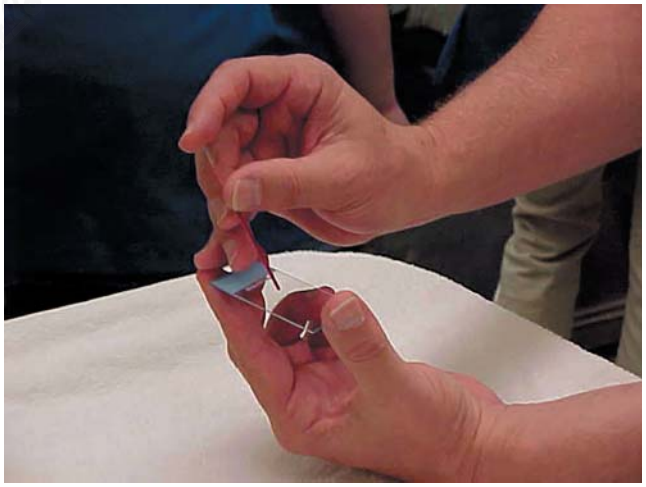

Figure 20.4 Making a blood film 1: The slide intended to contain the blood film is held in one hand.

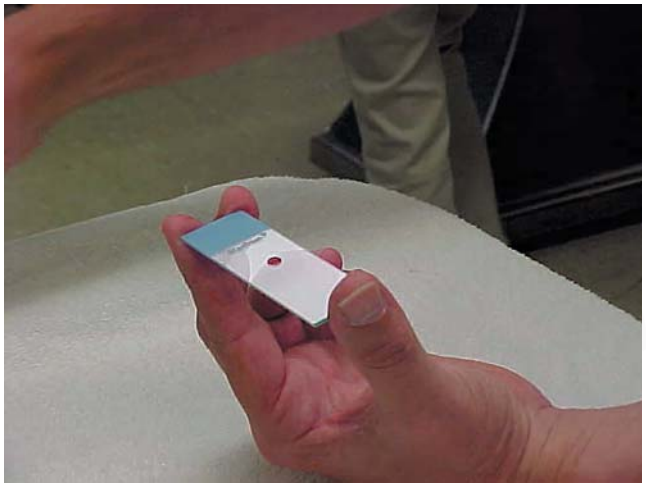

Figure 20.5 Making a blood film 2 : A drop of blood is placed near the end of the slide farthest from the person making the blood film.

(smudge cell formation) and improper cell distribution when improper technique is used.

Wright, Wright-Giemsa, Wright-Leishman, and May Grünwald-Giemsa stains have been used for staining air-dried, avian blood films for hematologic examination. Quick stains or modified Wright stains (Diff-Quik, American Scientific Products, Division of American Hospital Supply Corporation, McGraw Park, IL; Hemacolor, Miles Laboratories, Elkhart, IN) also can be used to stain avian blood films. Use of automatic slide stainers (Hema-Tek, Ames Division of Miles Laboratories, Elkhart, IN; Harleco Midas II, EM Diagnostic Systems, Gibbstown, NJ) simplifies the staining procedure and provides a means for consistency and high-quality staining of blood films. Automatic stainers remove much of the staining variation that occurs with hand-staining methods.

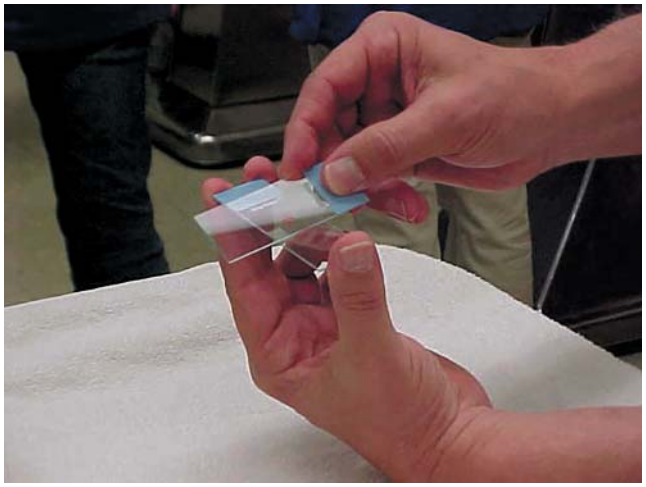

Figure 20.6 Making a blood film 3: The pusher slide is immediately placed in front of the drop of blood. The pusher slide is then quickly backed completely through the drop of blood while being held at an angle of approximately 30°–45° to the blood film slide. The direction of the pusher slide is immediately reversed toward the opposite end of the blood film slide to make the blood film. The pusher slide, therefore, is brought toward the person making the blood film rather than being pushed away.

Erythrocytes

Morphology

Evaluation of avian erythrocyte morphology involves observation of the cells in a monolayer ×1000 field in which approximately half the erythrocytes are touching one another. In general, such fields represent approximately 200 erythrocytes in most species of birds. Monolayer fields may be difficult to achieve, however, in severely anemic birds (i.e., films are too thin) or in poorly prepared blood films (i.e., films made too thick or thin). Avian erythrocytes should be evaluated on the basis of size, shape, color, nucleus, and presence of cellular inclusions. A semiquantitative scale can be used to estimate the number of abnormal erythrocytes based on the average number per monolayer ×1000 field (Table 20.1).

Mature avian erythrocytes generally are larger than mammalian erythrocytes but smaller than reptilian erythrocytes. Avian erythrocytes vary in size depending on the species, but they generally range between $10.7 \times 6.1\,\mu m$ to $15.8 \times 10.2\,\mu m$. Erythrocytes of adult *Coturnix* quail, for example, measure $11.06 \pm 0.70\,\mu m$ in length and $6.80 \pm 0.67\,\mu m$ in width in males and $11.40 \pm 0.63\,\mu m$ in length and $6.73 \pm 0.45\,\mu m$ in width in females. Mature avian erythrocytes are elliptical and have an elliptical, centrally positioned nucleus. Nuclear chromatin is uniformly clumped and becomes increasingly condensed with age. In Wright-stained blood films, the nucleus stains purple, whereas the cytoplasm stains orange-pink with a uniform texture (Figure 20.7).

Table 20.1 Semiquantitative microscopic evaluation of avian erythrocyte morphology.

	1+	2+	3+	4+
Anisocytosis	5–10	11–20	21–30	>30
Polychromasia	2–10	11–14	15–30	>30
Hypochromasia	1–2	3–5	6–10	>10
Poikilocytosis	5–10	11–20	21–50	>50
Erythroplastids	1–2	3–5	6–10	>10

Based on the average number of abnormal cells per 1000× monolayer field.

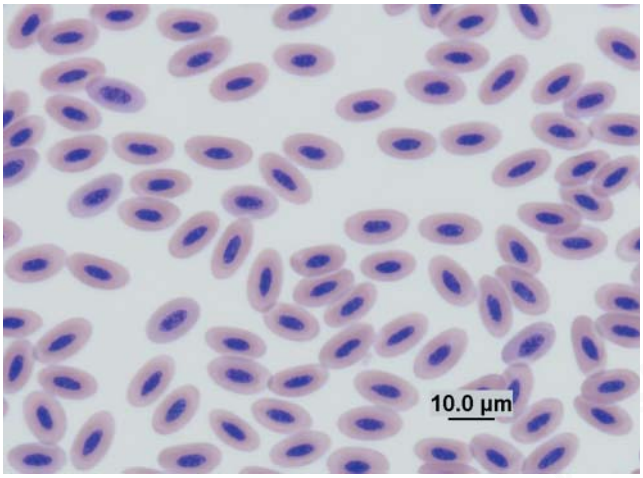

Figure 20.7 Normal erythrocytes in the blood film of a hawk (*Buteo jamaicensis*). Wright-Giemsa stain.

Variations from the normal erythrocyte morphology occur in blood films from normal healthy birds as well as those with medical disorders. Careful examination of erythrocyte morphology may reveal significant clues in the detection of disorders affecting avian erythrocytes. It is important to note, however, that the presence of atypical erythrocytes in a blood film may sometimes be associated with poor technique in blood film preparation. Disruption and/or smudging of avian erythrocytes are common artifacts of slide preparation. Severely ruptured cells result in the presence of purple, amorphous, nuclear material in the blood film. A semiquantitative scale can be used to estimate the number of abnormal erythrocytes based on the average number per monolayer ×1000 field (Table 20.1).

Changes in the size of avian erythrocytes include microcytosis, macrocytosis, and anisocytosis. A significant change in the mean size of the erythrocyte is reflected in the MCV. The presence of macrocytes or microcytes also should be noted during assessment of the blood film. The degree of variation in the size of erythrocytes (anisocytosis) can be scored from 1+ to 4+ based on the number of variable-sized erythrocytes in a monolayer field (Table 20.1). Erythrocyte subpopulations have been reported in ducks, in which larger erythrocytes (MCV 308 fL/cell) most likely represent those most recently released from the hematopoietic tissue and smaller cells (MCV 128 fL/cell) most likely represent the older, aging cells. Microcytic, hypochromic, nonregenerative anemia is often associated with chronic inflammatory diseases in birds, especially those with an infectious etiology.

Variations in erythrocyte color include polychromasia and hypochromasia. Polychromatophilic erythrocytes occur in low numbers (usually <5% of erythrocytes) in the peripheral blood of most normal birds. The degree of polychromasia can be graded according to the guideline presented in Table 20.1. The cytoplasm of polychromatophilic erythrocytes is weakly basophilic, and the nucleus is less condensed than in mature erythrocytes (Figure 20.8). Polychromatophilic erythrocytes are similar in size to mature erythrocytes, and they appear as reticulocytes when stained with vital stains such as new methylene blue.

Reticulocytes are the penultimate cell in the erythrocyte maturation series, and their presence in the peripheral blood of normal birds suggests that the final stages of red-cell maturation occur in circulating blood. Reticulocytes tend to be smaller in size and less elongated compared to the mature erythrocyte. For example reticulocytes of adult *Coturnix* quail measure 9.80 ± 0.77 µm in length and 8.23 ± 0.72 µm in width in males and 9.80 ± 0.77 µm in length and 7.73 ± 0.70 µm in width in females. Determination of the reticulocyte concentration can be made by staining erythrocytes with a vital stain such as new methylene blue. Reticulocytes have a distinct ring of aggregated reticular material that encircles the nucleus (Figure 20.9). As the cells mature, the amount of aggregated reticular material decreases and becomes more dispersed throughout the

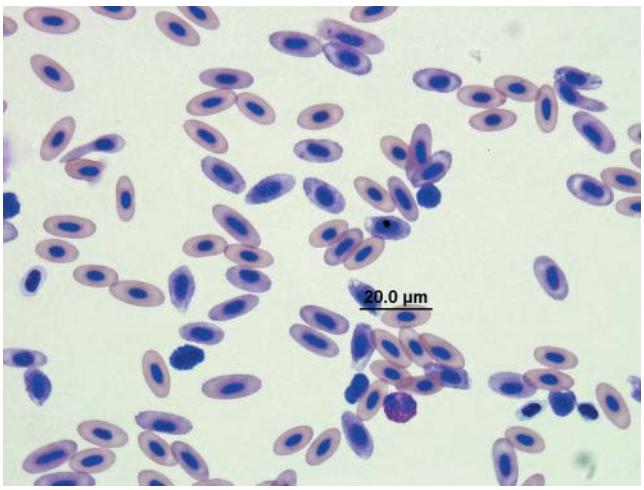

Figure 20.8 Polychromatic erythrocytes in the blood film of a hawk (*Buteo jamaicensis*). Wright-Giemsa stain.

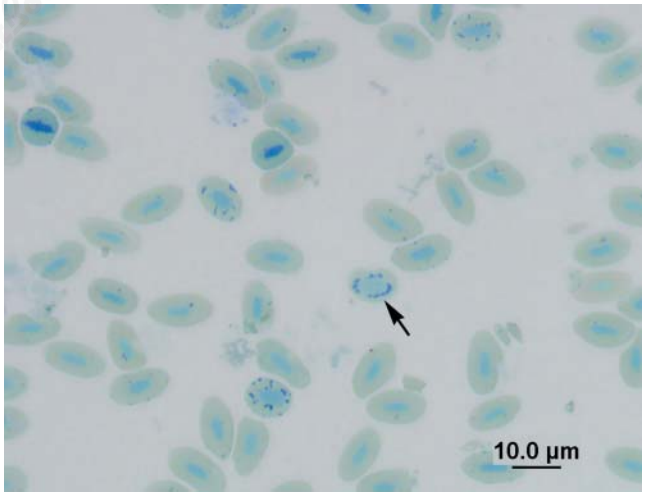

Figure 20.9 Reticulocyte (arrow) with a distinct ring of aggregated reticulum encircling the red-cell nucleus in the blood film of a parrot (*Psittacus erithacus*). Brilliant cresyl blue stain.

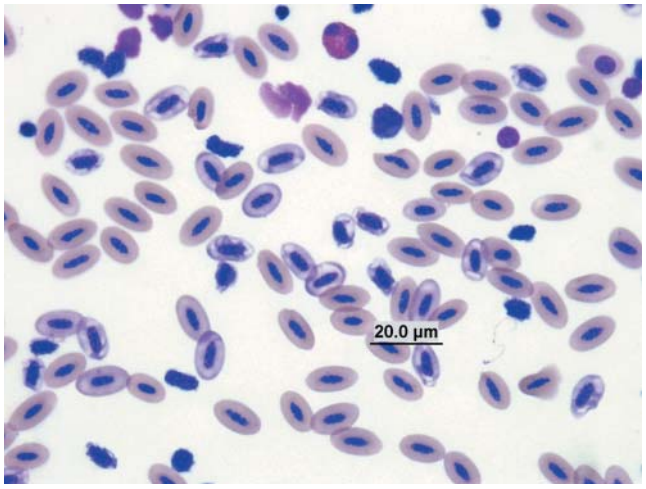

Figure 20.10 Hypochromatic erythrocytes in the blood film of a parrot (*Eclectus roratus*). Wright-Giemsa stain.

cytoplasm. With further maturation, the reticular material becomes nonaggregated, thereby resembling the "punctate" reticulocytes of felids. Most mature avian erythrocytes contain a varying amount of aggregate or punctate reticulum. Reticulocytes that reflect the current erythrocyte regenerative response, however, are those with a distinct ring of aggregated reticulum that encircles the red-cell nucleus. Significantly high numbers of these cells would represent a regenerative response to anemia.

Hypochromatic erythrocytes are abnormally pale in color compared with mature erythrocytes, and they have an area of cytoplasmic pallor that is greater than half the cytoplasmic volume (Figure 20.10). They also may have cytoplasmic vacuoles and round, pyknotic nuclei. A significant hypochromasia is reflected as a decrease in the MCHC and MCH values. The degree of hypochromasia can be estimated using the scale presented in Table 20.1.

In most species of birds, the shape of erythrocytes is relatively uniform. The degree of poikilocytosis can be estimated using the scale outlined in Table 20.1. Atypical erythrocytes occasionally are present in the peripheral blood of normal birds, and such erythrocytes may represent artifacts associated with preparation of the blood film. Careful examination of erythrocyte morphology may reveal significant clues in the detection of disorders affecting avian erythrocytes. As mentioned, the degree of polychromasia and reticulocytosis and the presence of immature erythrocytes in the peripheral blood aid in the assessment of red-blood-cell regeneration. The presence of many hypochromatic erythrocytes (i.e., 2+ hypochromasia or greater) indicates an erythrocyte disorder such as iron deficiency.

Atypical erythrocytes may vary in both size and shape. A slight variation in the size of erythrocytes (1+ anisocytosis) is considered to be normal for birds. A greater degree of anisocytosis, however, usually is observed in birds with a regenerative anemia and is associated with polychromasia. Likewise, minor deviations from the normal shape of avian erythrocytes (1+ poikilocytosis) are considered to be normal in the peripheral blood of birds, but marked poikilocytosis may indicate erythrocytic dysgenesis. Round erythrocytes with oval nuclei occasionally are found in the blood films of anemic birds and suggest a dysmaturation of the cell cytoplasm and nucleus, which may be a result of accelerated erythropoiesis. Automated methods of performing erythrocyte counts can calculate the degree of anisocytosis using the red cell distribution width (RDW), which measures variation in red blood cell size, or MCV. Normal psittacine RDW range between 10 and 11; whereas greater values indicate an increase in anisocytosis.

The nucleus may vary in its cellular location and contain indentions, protrusions, or constrictions. Anucleated erythrocytes (erythroplastids) or cytoplasmic fragments occasionally are found in normal avian blood films (Figure 20.11). The nucleus may contain chromophobic streaking, which suggests chromatolysis, or achromic bands, which indicate nuclear fracture with displacement of the fragments (Figure 20.12). Mitotic activity associated with erythrocytes in blood films suggests a marked regenerative response or erythrocytic dyscrasia. Perinuclear rings are common artifacts of improper slide preparation (e.g., exposure to solvent or formalin fumes, or allowing the slide to dry too slowly), and they represent nuclear shrinkage. Clear, irregular, refractile spaces in the cytoplasm occur when blood films are allowed to dry too slowly. This artifact, which is a form of erythrocyte crenation, should not be confused with avian blood parasites, such as gametocytes of *Hemoproteus* and *Plasmodium*. Disruption or smudging of avian erythrocytes is the most common artifact of slide

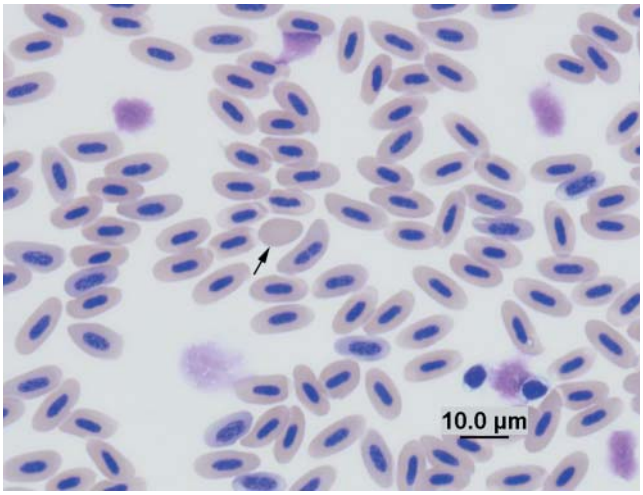

Figure 20.11 Erythroplastid (arrow) in a blood film of a budgerigar (*Melopsittacus undulatus*). Wright-Giemsa stain.

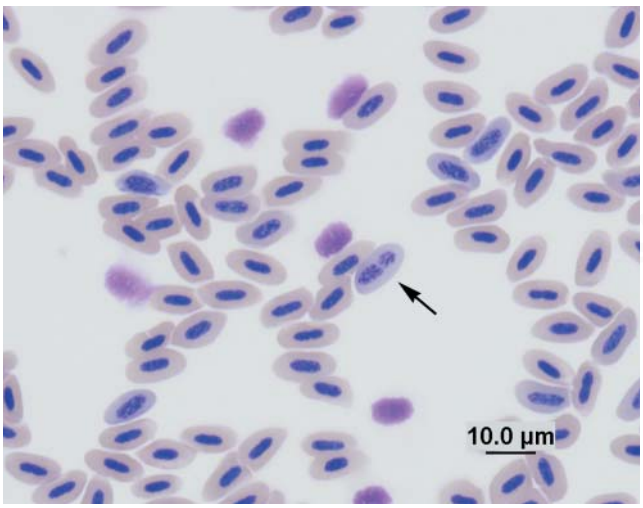

Figure 20.12 An erythrocyte nucleus exhibiting chromophobic streaking (arrow) in the blood film of a budgerigar (*Melopsittacus undulatus*). Wright-Giemsa stain.

preparation. Severely ruptured cells result in the presence of purple, amorphous nuclear material in the blood film.

Binucleate erythrocytes rarely occur in the blood films of normal birds. Large numbers of binucleated erythrocytes plus other features of red-blood-cell dyscrasia, however, suggest neoplastic, viral, or genetic disease.

Punctate basophilia is characterized by punctate aggregations of small, irregular, basophilic-staining granules throughout the cytoplasm of erythrocytes in Wright-stained smears. As in mammalian hematology, punctate basophilia is most likely associated with degenerative changes in ribosomal ribonucleic acid and is indicative of a response to anemia or, rarely, lead poisoning. Basophilic stippling can be affected by preparation and staining of the blood film. Using fresh blood without an anticoagulant or rapid drying of blood films made from EDTA-anticoagulated blood provides the best films for demonstrating basophilic stippling. Such stippling is less apparent when alcohol fixation of blood is used. Heinz bodies rarely are reported in birds and are the result of hemoglobin denaturation (oxidized hemoglobin). Heinz bodies appear as round to irregularly shaped, pale blue, cytoplasmic inclusions with new methylene blue stain; as round to irregular inclusions of densely stained hemoglobin with Wright stain; or as refractile inclusions in unstained erythrocytes. Agglutination of erythrocytes and erythrophagocytosis in blood films are rare abnormal findings that are suggestive of immune-mediated disease. Agglutination is represented by clumping of erythrocytes on the blood film. Red cell agglutination is best observed on low magnification. Erythrophagocytosis is identified by phagocytosis of whole red blood cells or iron pigment from hemoglobin degradation in the cytoplasm of leukocytes, typically monocytes.

Laboratory evaluation

Laboratory evaluation of avian erythrocytes involves the same routine procedures as that used in mammalian hematology, but with a few modifications. The standard manual technique for using microhematocrit capillary tubes and centrifugation (12,000 g for 5 minutes) can be used to obtain a PCV (hematocrit). Hemoglobin concentration is measured using the same methods for mammalian blood samples; however, removal of free erythrocyte nuclei by centrifugation is required.

The PCV is the quickest and most practical method for evaluating the red cell mass of birds. Much as in mammals, the PCV of birds is affected by the number and size of the erythrocytes, as well as changes in the plasma volume that do not affect total cell mass. These changes include increased plasma volume (hemodilution), decreased plasma volume (hemoconcentration), improper blood sampling (hemodilution), and epinephrine administration and hypothermia, which may result in hemoconcentration.

The total erythrocyte concentration in birds can be determined using the same automated or manual methods as those used for obtaining the total erythrocyte counts in mammalian blood. Automated cell counters provide a rapid, reliable method for obtaining total red-blood-cell concentrations. Two manual methods for obtaining total red-blood-cell count in birds are the erythrocyte Unopette (Becton-Dickinson) method used in mammalian hematology and the Natt-Herricks method, which involves preparation of Natt-Herricks solution to be used as a stain and diluent (Table 20.2). A 1:200 dilution of the blood is made using the Natt and Herricks solution and red-blood-cell diluting pipettes. After mixing, the diluted blood is discharged into a hemacytometer counting chamber, and the cells are allowed to settle for 5 minutes, to the ruled surface, before counting.

Table 20.2 Natt and Herricks solution and stain.

Sodium chloride (NaCl)	3.88 g
Sodium sulfate (Na SO_4)	2.50 g
Sodium phosphate (Na_2HPO_4)	1.74 g
Potassium phosphate (KH_2PO_4)	0.25 g
Formalin (37%)	7.50 mL
Methyl violet	0.10 g

Bring to 1000 mL with distilled water and filter through Whatman #10 medium filter paper.

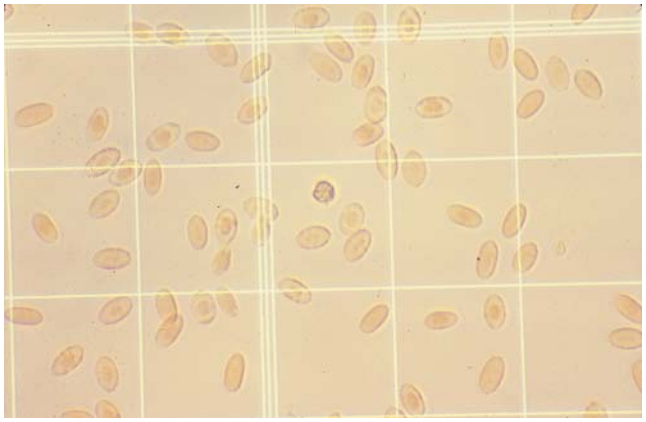

Figure 20.13 Appearance of avian erythrocytes and a leukocyte (center) in a hemocytometer using the erythrocyte Unopette method. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 200.

Erythrocytes located in the four corner and the central squares of the hemacytometer chamber are counted when using either of the manual methods (Figures 20.13 and 20.14). The number obtained then is multiplied by 10,000 to calculate the total red-blood-cell count per microliter (μL) of blood. Commercially prepared Natt-Herricks solution kit (Natt-Pette) makes the procedure easier and more accurate. The kit contains prefilled Natt-Herricks stain reservoirs, a pipette calibrated for 5 μL (to make the 1 : 200 dilution), and tips for the pipette. The diluted blood is then discharged onto the hemocytometer counting chamber and is allowed to settle for a minimum of 5 minutes before counting. With these stains, the oval erythrocytes show a small, dark blue nucleus that is surrounded by a colorless to faint pink cytoplasm. The total number of erythrocytes in the four corner and central squares in the central, large square of a Neubauer-ruled hemocytometer chamber is obtained using ×40 (high dry) magnification. The TRBC is calculated by multiplying the numbers of erythrocytes by 10,000.

The red blood cell indices (i.e., mean erythrocyte volume [MCV], MCHC, and mean cell hemoglobin [MCH]) can be calculated using standard formulas. However, the direct, electronic measurement of MCV appears to be more sensitive for detecting changes in the erythrocyte size in birds.

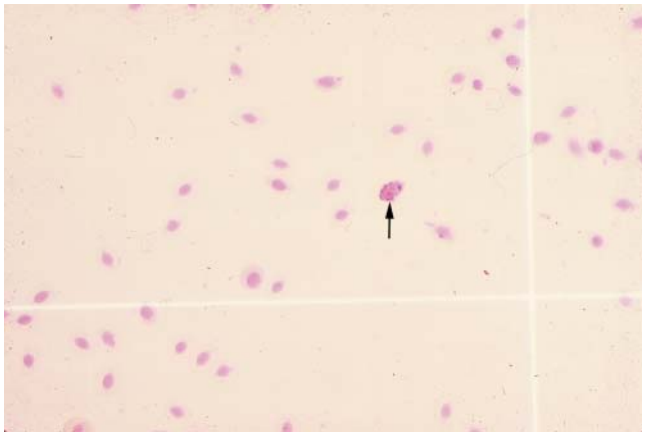

Figure 20.14 Appearance of avian erythrocytes and a granulocyte (arrow) in a hemocytometer using Natt and Herricks method. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 201.

Normal erythrocyte physiology

Normal reference values vary among species of birds; however, with a few exceptions, psittacine birds in captivity have similar erythrocyte parameters: PCV of 35–55%; RBC count of 2.4–5.0 × 10^6/μL; hemoglobin concentration of 11–16 mg/dL; MCV of 90–200 fL; and MCHC of 22–33% (Table 20.3).

It should be noted that a proportional relationship exists between Hgb concentration and PCV in avian blood samples. A simplified relationship of Hgb (g/dL) = 0.30 × PCV provides a reasonable estimate of Hgb concentration from the PCV of birds from the orders Anseriformes, Columbiformes, Falconiformes, Galliformes, Passeriformes, Psittaciformes, Sphenisciformes, and Strigiformes, but a separate relationship of Hgb = 0.217 × PCV + 6.69 might be warranted for the order Phoenicopteriformes.

The total erythrocyte concentration and PCV of birds are influenced by species, age, sex, hormonal influences, hypoxia, environmental factors, and disease. In general, the total erythrocyte count, PCV, and MCV increase with age. The Hgb does not appear to be affected by age; therefore, a decline in MCHC is a function of the increase in MCV.

Total erythrocyte counts and PCV tend to be higher in male compared to female birds. The reason for this may be a hormonal effect where estrogen depresses erythropoiesis, whereas androgens and thyroxin stimulate erythropoiesis. Variations in erythrocyte parameters associated with gender in birds are generally not statistically significant; however, reported differences between males and females have been reported and reflect a seasonal variation, where females tend to have higher PCV, Hgb, TRBC, and MCHC values compared to males in the prenesting period.

Table 20.3 Erythrocyte parameters for selected birds.

	PCV (%)	RBC ($\times 10^6/\mu L$)	Hgb (g/dL)	MCV (fL)	MCHC (%)

Studies with free-ranging ducks and geese have shown that averages for PCV, Hgb, TRBC, and MCHC values tend to be higher in the winter and prenesting period in adults regardless of gender compared to the postnesting period and fall. During migration, ducks tend to have slightly lower erythrocyte counts compared to wintering ducks and postnesting MCV averages for these birds tend to be higher in the winter or prenesting periods. Interestingly, these

changes also occur in captive ducks that are not able to migrate. Feather molting, a seasonal event, has an effect on the hemogram where the PCV, RBC, and Hgb have been shown to decrease in ducks during and after remige molt.

The normal erythrocyte parameters vary among avian species. For example, in Anseriformes, mallard ducks (*Anas platyrhynchos*), a dabbling duck, have higher average PCV and TRBC values in the winter and prenesting period compared to diving ducks (*Aythya* spp. and *Oxyura jamaicensis*); whereas, diving ducks have higher MCV values during the winter and prenesting period compared to mallards. In general, ducks tend to have higher TRBC values than geese, but geese have higher MCV and Hgb than ducks during the winter.

Birds, like mammals, respond to blood loss and blood destruction by increasing erythropoietin production, which stimulates erythropoiesis. Avian erythropoietin (a glycoprotein produced by the kidney) acts directly on the bone marrow to increase erythrocyte production. Avian erythropoietin does not stimulate mammalian erythropoiesis, however, and mammalian erythropoietin has no effect on avian hematopoiesis.

Avian hemoglobin has four iron-containing heme subunits, as with mammalian hemoglobin, but the protein moieties (i.e., globulins) are different. In avian erythrocytes, the phosphate compounds influencing the affinity of hemoglobin for oxygen also differ from those in mammals. The hemoglobin of mature birds contains myoinositol pentophosphate, not the 2,3-diphosglycerate as in mammals. Inositol pentophosphate causes hemoglobin to have a lower affinity for oxygen, and it shifts the oxygen dissociation curve to the right of the mammalian curve. Therefore, avian tissues can extract oxygen more readily from hemoglobin than mammalian tissues can.

Responses in disease

The normal PCV for many species of birds ranges between 35% and 55%. Therefore, a PCV of less than 35% suggests anemia, and a PCV of greater than 55% suggests dehydration or erythrocytosis (polycythemia). The latter condition can be differentiated by the total serum protein: increased total protein indicates dehydration, whereas normal or low total protein indicates erythrocytosis.

Typically, polychromatic erythrocytes make up 5% or less of the erythrocyte population in blood films from normal birds. The degree of erythrocyte polychromasia and reticulocytosis indicates the degree of erythrogenesis. Anemic birds with greater than 10% polychromasia (3+ and 4+ polychromasia) are exhibiting an appropriate regenerative response to their anemia. Those with a smaller response, however, are not. The number of reticulocytes also indicates a bird's current response to anemia. Therefore, the reticulocyte count can be used in conjunction with assessment of the degree of polychromasia to determine the bird's current erythropoietic response.

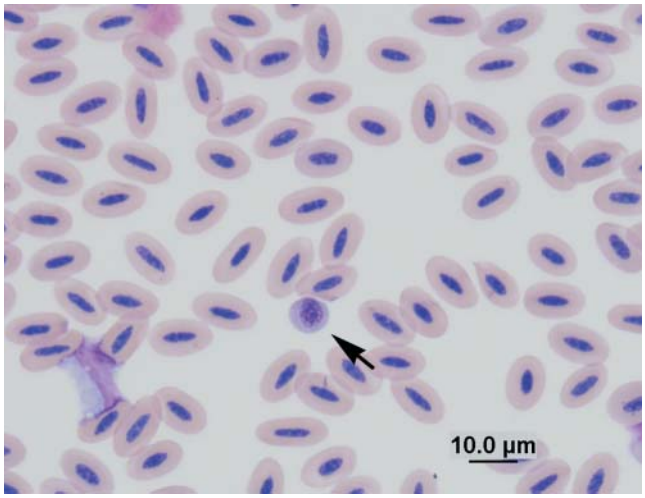

Figure 20.15 Immature erythrocyte (a mid-polychromatic rubricyte, arrow) in the blood film of an eagle (*Haliaeetus leucocephalus*). Wright-Giemsa stain.

Other evidence of active erythropoiesis is the presence of binucleate, immature erythrocytes and an increased number of normal, immature erythrocytes in the peripheral blood. Immature erythrocytes (i.e., rubricytes) in peripheral blood films in addition to increased polychromasia indicate a marked erythrocyte response (Figure 20.15). In cases of nonanemic birds, however, these cells indicate abnormal erythropoiesis. Immature erythrocytes also may suggest early release from the hematopoietic tissue after anoxic insult or toxicity (i.e., lead poisoning).

The causes of anemia in birds include blood loss (hemorrhagic anemia), increased red cell destruction (hemolytic anemia), and decreased red cell production (depression anemia). The most common causes of hemorrhagic anemia in birds include traumatic injury, bloodsucking parasites, coagulopathies, and hemorrhagic lesions of internal organs, such as ulcerated neoplasms, gastric ulcerations, and rupture of the liver or spleen. Heavy infestation with bloodsucking ectoparasites such as ticks or mites (i.e., *Dermanyssus* mites) or with gastrointestinal parasites such as coccidia can lead to severe blood loss anemia in birds. Coagulopathies that result in blood loss anemia usually are acquired and often are associated with toxicities such as aflatoxicosis or coumarin poisoning or severe liver disease such as papovavirus infections. Birds can tolerate acute blood loss better than mammals and diving and flying birds are more resistant to blood loss than nondiving birds such as Galliformes. The mobilization and restoration of fluid during the first 90 minutes after bleeding in chickens is approximately 13–17% of the initial blood volume per hour, which is twice that of dogs.

With hemolytic anemia, the destruction rate of erythrocytes is higher than normal resulting in an increase in erythrocyte production to compensate for the loss, which

is indicated by an increase in the presence of immature erythrocyte stages in the circulating blood. Hemolytic anemia can result from systemic or hematogenous bacterial infection (septicemia), infectious disease, hemoparasites, and toxicities. Most avian blood parasites have the potential to cause anemia in the host; however, the two parasites that most frequently are associated with hemolytic anemia are *Plasmodium* and *Aegyptianella*. Salmonellosis or spirochetoses commonly cause bacterial septicemia that result in severe hemolytic anemia. Toxicoses that lead to increased erythrocyte destruction include aflatoxins, certain plant chemicals (i.e., mustards), drugs, and petroleum products. Ingestion of petroleum products may produce a Heinz body anemia. Hemolytic anemia occurs in marine birds associated with oil pollution and is characterized by low red-cell indices and numerous immature erythrocytes. Heavy metals such as lead and zinc are associated with hemolytic anemia in a variety of avian species, and are considered by some authors as the most common cause of this condition in companion birds. Although rare, immune-mediated anemia may result in hemolysis, with red-cell agglutination being present in the blood film. Hemolytic anemias typically are characterized by a marked regenerative response. Although hemochromatosis usually does not affect the hemogram, a report by Rupiper and Read of a psittacine with hemochromatosis described a severe anemia with a marked regenerative response (4+ polychromasia and immature erythrocytes as early as prorubricytes). The hemochromatosis may have altered the maturation of erythrocytes as a result of defective iron uptake.

A nonregenerative, normocytic, normochromic anemia indicates decreased erythropoiesis (depression anemia), which can develop rapidly in birds with inflammatory diseases, especially those involving infectious agents. Birds appear to develop anemias from a lack of erythropoiesis more quickly than mammals, perhaps because of the relatively short erythrocyte half-life in birds compared with that in mammals. Although the avian erythrocyte life span varies with the species, it is generally shorter than those in mammals. For example, the erythrocyte life span is 28–35 days in chickens, 42 days in pigs, 35–45 days in pigeons, and 33–35 days in quail. The degree of polychromasia or reticulocytosis is poor to absent in birds with depression anemias. Infectious diseases frequently associated with depression anemia in birds include tuberculosis, aspergillosis, and chlamydophilosis. Chronic hepatic and renal disease and hypothyroidism can also result in a depression anemia. Neoplasia resulting in infiltration of neoplastic cells into the bone marrow can also cause a depression anemia. Treatment with myelosuppressive medication for neoplastic lesions can also lead to depression anemia. Nonregenerative anemia can also be associated with parasites, such as *Baylisascaris procyonis* infections. Chronic inflammation in birds is often associated with a marked nonregenerative anemia, leukocytosis, and heterophilia.

Hypochromasia can be seen with iron deficiency, chronic inflammatory diseases, and lead toxicosis. Hypochromatic erythrocytes frequently appear in the blood films from birds with chronic inflammatory diseases, presumably related to iron sequestration as part of the bird's defense against infectious agents. In such cases, hypochromatic cells often are observed in blood films before the red-cell indices (MCHC and MCH) suggest hypochromasia (Figure 20.10).

Heavy metal poisoning, especially with lead and zinc intoxication, can result in the appearance of immature and abnormal erythrocytes in the peripheral blood. Chronic lead toxicosis also may be associated with an in appropriate release of normal-appearing, immature erythrocytes into the peripheral blood of nonanemic birds (Figure 20.16). In this condition, the blood film reveals small, senescent, mature erythrocytes with pyknotic nuclei and immature erythrocytes (usually rubricytes) without the presence of normal, mature erythrocytes. This hematologic response resembles the inappropriate release of nucleated erythrocytes in the blood of nonanemic dogs affected by chronic lead poisoning. Basophilic stippling in the cytoplasm of erythrocytes may be seen with lead poisoning in birds but can also be associated with erythrocyte regeneration and hypochromic anemia. Changes in PCV, Hb, and MCHC occur in a predictable manner with increasing blood lead concentrations in birds. Erythrocyte morphological changes tend to occur when blood lead concentrations are greater than 3 mg/L and therefore are associated with severe lead toxicosis. A decreased MCHC is a more sensitive indicator of lead poisoning in birds than is hypochromasia.

A macrocytic, normochromic anemia occurs in birds with food restriction or folic acid deficiency. Folic acid deficiency

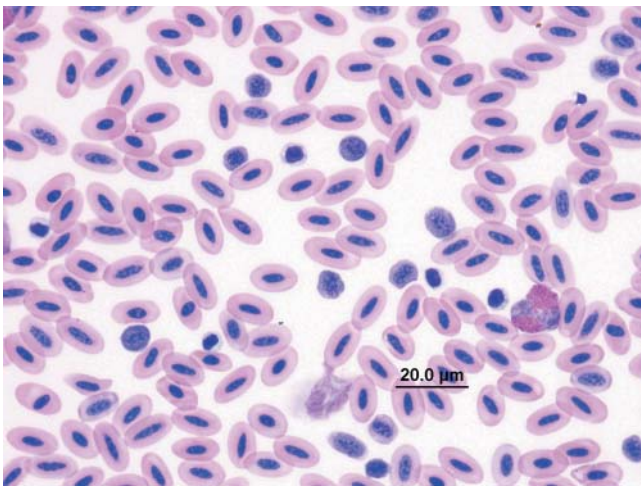

Figure 20.16 Marked numbers of immature erythrocytes and a heterophil in a blood film from a vulture (*Cathartes aura*) with a normal packed cell volume (46%). The vulture has lead poisoning. Wright-Giemsa stain.

causes defective DNA synthesis, thereby causing nuclear maturation to be out of step with hemoglobinization of the cytoplasm. Food restriction anemia also is associated with leukopenia, thrombocytopenia, abnormal erythrocyte shapes (marked poikilocytosis), and hypersegmentation of granulocytes.

Erythrocytosis (polycythemia) as indicated by an elevated PCV and erythrocyte count is rarely reported in birds. Relative polycythemia associated with redistribution of erythrocytes does not occur in birds because they do not store reserve erythrocytes in their spleens. The conditions associated with polycythemia in mammals most likely cause polycythemia in birds as well. A primary erythrocytosis (polycythemia vera) is a myeloproliferative disorder resulting in an absolute erythrocytosis and a rare condition in birds. Most reported cases of an absolute erythrocytosis (PCV usually >70%) in birds are secondary as a response to hypoxia that results in an increased production of erythropoietin. Disease conditions that lead to secondary polycythemia include chronic pulmonary diseases, cardiac disease, iron storage disease, rickets, renal disease or renal neoplasia, or a physiologic response to high altitude. A relative erythrocytosis associated with dehydration is responsible for most avian cases with an erythrocytosis.

The presence of numerous immature erythrocytes (especially rubriblasts) and abnormal-appearing immature erythrocytes in the peripheral blood of birds indicates erythrocytic neoplasia. Erythroblastosis in poultry with avian leukosis complex is an example of this condition.

The genotoxicity of cyclophosphamide and mitomycin-C cause a decrease in the PCV and the formation of erythrocytes with micronuclei and nuclear budding. The micronuclei are seen in erythrocytes at the rubriblasts and prorubricytes stages of development. These effects are seen up to day 8 following secession of cyclophosphamide therapy. Recovery is signaled by a large increase in immature erythrocytes with complete resolution by day 13. Thus, detection of nuclear budding and micronuclei in avian erythrocytes in blood films is an indication of exposure to a therapeutic or environmental genotoxin.

Leukocytes

Morphology

Leukopoiesis in normal birds appears to be similar to that in mammals, in that leukocytes are released into the peripheral circulation only when they are mature. Leukocytes in avian blood include lymphocytes, monocytes, and granulocytes. The granulocytes are classified as heterophils, eosinophils, and basophils. Heterophils are the most abundant granulocyte in most birds. The cytoplasm of normal, mature heterophils appears colorless and contains eosinophilic granules (dark orange to brown-red) with Romanowsky stains (Figures 20.16 and 20.17). The cytoplasmic granules typically are elongate (rod or spiculated shaped), but they may appear oval to round in some species. Heterophil granules frequently have a distinct central body that appears to be refractile. The granules may be affected by the staining process and appear atypical (i.e., poorly stained, partially dissolved, or fused). The nucleus of mature heterophils is lobed (usually two to three lobes) with coarse, clumped chromatin that stains purple. The nucleus often is partially hidden by the cytoplasmic granules.

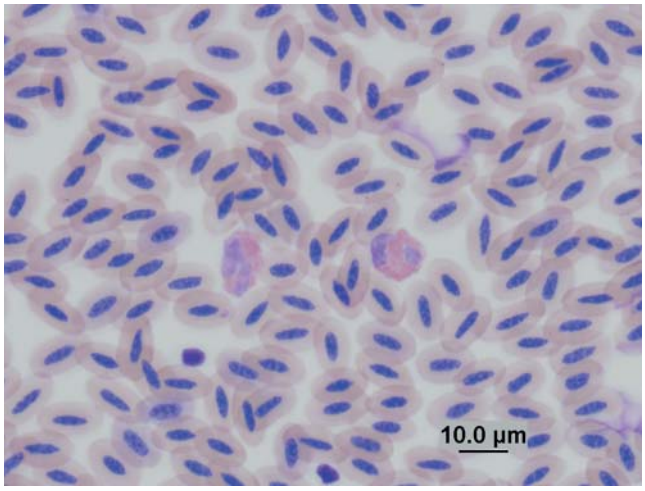

Figure 20.17 Normal heterophils in the blood film of an eagle (*Haliaeetus leucocephalus*). Wright-Giemsa stain.

Avian heterophils are considered to be functionally equivalent to mammalian neutrophils; however, there are differences. They actively participate in inflammatory lesions, and they are phagocytic. The cytoplasmic granules of heterophils contain lysozyme and proteins needed for bactericidal activity, although some avian species, such as chickens, have heterophils that lack peroxidase activity. Heterophils phagocytize microorganisms and destroy them by oxygen-dependent and -independent mechanisms. Although chicken heterophils lack the alkaline phosphatase, catalase, and myeloperoxidase needed for oxygen-dependent killing of microorganisms, they do consume oxygen and produce oxygen radicals and hydrogen peroxide, but to a lesser extent than in mammalian neutrophils. Therefore, avian heterophils rely more heavily on oxygen-independent mechanisms, lysozyme, and cationic proteins (i.e., acid hydrolases and cathepsin) to destroy microorganisms. Avian (chicken and turkey) heterophils do not respond to the chemoattractant formyl-methionyl-leucyl-phenylalanine (fMLP) as do mammalian neutrophils.

Ultrastructural studies of avian heterophils reveal primary, secondary, and tertiary granules. Primary granules are the most numerous, and they appear as electron-dense, fusiform rods (1.5 × 0.5 µm) with a circular central body.

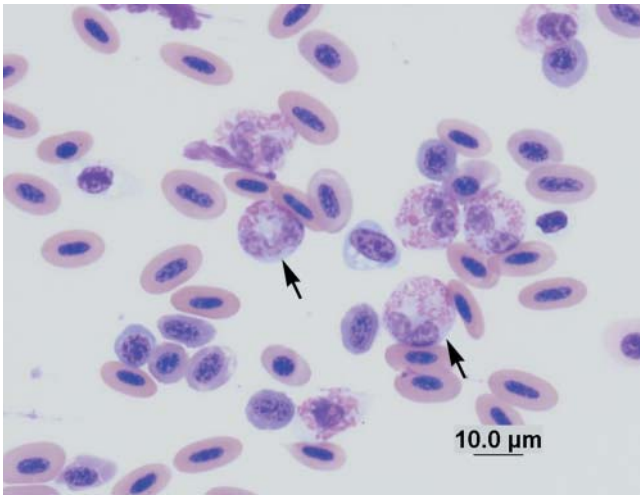

Figure 20.18 Heterophil metamyelocytes (arrows) in the blood film of a hawk (*Buteo regalis*). Wright-Giemsa stain.

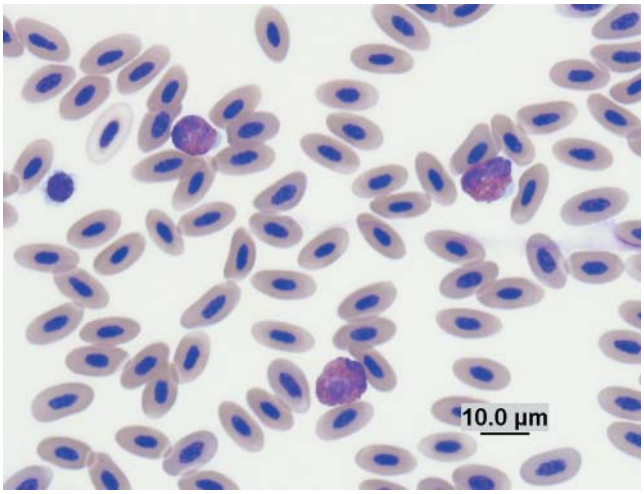

Figure 20.19 Mildly toxic (1+) heterophils (note the slight cytoplasmic basophilia) in the blood film of a macaw (*Ara chloropterus*). Wright-Giemsa stain.

Secondary granules (diameter, 0.5 µm) are less dense and contain eccentric inclusions composed of loose, filamentous material. Tertiary granules (0.1 µm) have a dense core that is separated from a membranous envelope of an electron-lucent area. Based on the results of biochemical evaluations of chicken heterophils, myeloperoxidase and alkaline phosphatase are absent. Chicken heterophil granules do not stain with alkaline phosphatase, peroxidase, Sudan black B, acid phosphatase, naphthol AS-D chloroacetate esterase methods, or periodic acid–Schiff. Small and medium granules may be seen ultrastructurally in avian heterophils, and these probably represent maturation stages of the cytoplasmic granules.

Abnormal appearing heterophils in blood films include both immature and toxic heterophils. Immature heterophils have increased cytoplasmic basophilia, nonsegmented nuclei, and immature cytoplasmic granules compared with normal, mature heterophils (Figure 20.18). Immature heterophils most frequently encountered in the blood are myelocytes and metamyelocytes. Heterophil myelocytes are larger than mature heterophils, and they have blue cytoplasm as well as secondary, rod-shaped granules, which occupy less than half the cytoplasmic volume, and a round to oval, nonsegmented nucleus. Heterophil metamyelocytes resemble myelocytes, except that the nucleus is indented and the rod-shaped granules occupy more than half the cytoplasmic volume. Band heterophils resemble mature heterophils, except that the nucleus is not lobed. It often is difficult to recognize a band cell because the nucleus is hidden by the cytoplasmic granules. Therefore, a true assessment regarding the concentration of band cells in avian blood films requires use of a nuclear stain, such as hematoxylin, which stains only the nucleus and not the cytoplasmic granules.

In response to severe systemic illness, avian heterophils exhibit toxic changes similar to those in mammalian neutrophils. Toxic changes in avian heterophils are subjectively quantified as to the number of toxic cells and the severity of toxicity, as in mammalian hematology. Toxic heterophils have increased cytoplasmic basophilia, vacuolization, abnormal granulation (degranulation, granules that appear deeply basophilic, and granules that appear to coalesce into large, round granules), and degeneration of the cell nucleus (Figures 20.19–20.22). The degree of heterophil toxicity can be rated subjectively on a scale of 1+ to 4+. A 1+ degree of toxicity or mild toxicity is assigned when heterophils exhibit increased cytoplasmic basophilia. A 2+ or mild to moderate degree of toxicity is assigned when heterophils have deeper cytoplasmic basophilia and partial degranulation. A 3+ degree of toxicity or moderate toxicity is assigned when heterophils exhibit deep cytoplasmic basophilia, moderate degranulation, abnormal granules, and cytoplasmic vacuolization, and a 4+ or marked degree of toxicity is assigned when heterophils exhibit deep cytoplasmic basophilia, moderate to marked degranulation with abnormal granules, cytoplasmic vacuolization, and karyorrhexis or karyolysis. The number of toxic heterophils are graded as few (5–10%), moderate (11–30%), and marked (>30%).

Most avian eosinophils are nearly the same size as heterophils in most blood films. For example, heterophils of adult *Coturnix* quail measure 10.22 ± 1.20 µm in diameter for males and 9.80 ± 1.14 µm in diameter in females compared to eosinophils that measured 9.76 ± 1.13 µm in diameter for males and 9.55 ± 1.23 µm in diameter in females. In contrast to mature heterophils, avian eosinophils in general have round, strongly eosinophilic cytoplasmic granules, although the granules in some species are oval to elongate. In general, eosinophil granules stain more intensely that

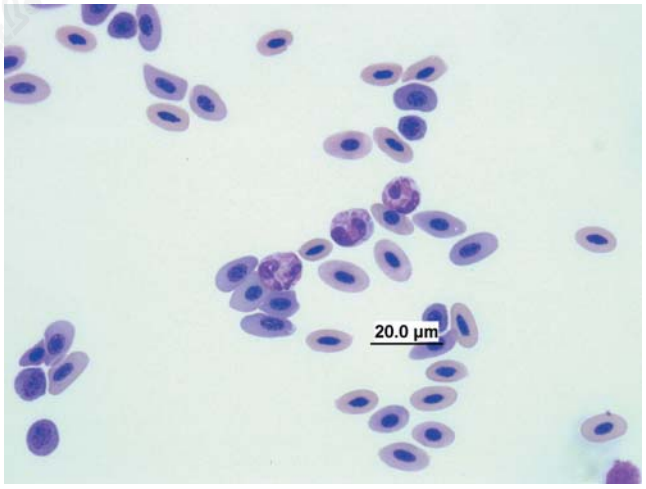

Figure 20.20 Moderately toxic (2+) heterophils (note the darker cytoplasmic basophilia and reduction of the number of rod-shaped cytoplasmic granules as indicated by increased visible cytoplasm) in the blood film of a hawk (*Buteo jamaicensis*). Wright-Giemsa stain.

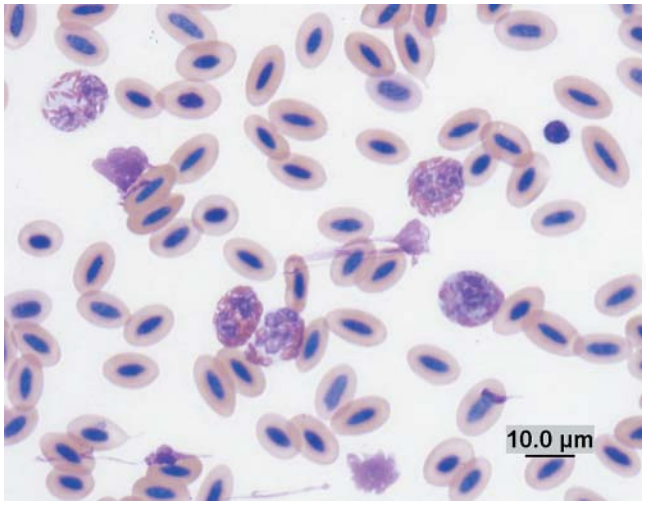

Figure 20.21 Moderately toxic (2+) heterophils (note the darker cytoplasmic basophilia and reduction of the number of rod-shaped cytoplasmic granules as indicated by increased visible cytoplasm) in two of the heterophils in the blood film of an eagle (*Haliaeetus leucocephalus*). Wright-Giemsa stain.

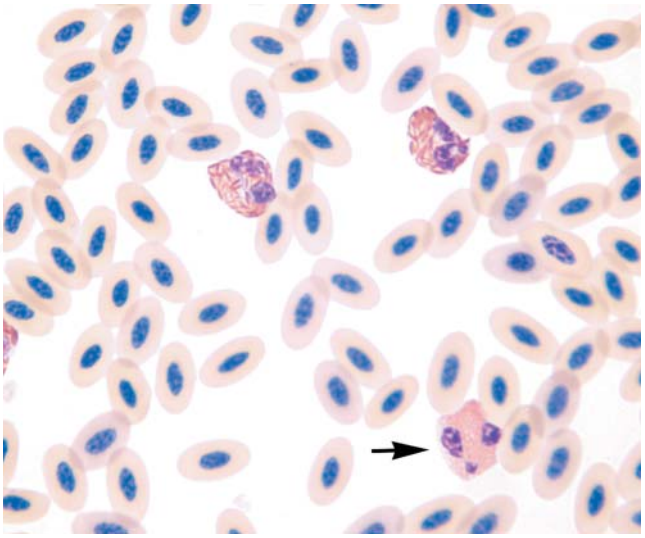

Figure 20.23 An eosinophil (arrow) and two heterophils in the blood film of a hawk (*Buteo jamaicensis*). Wright-Giemsa stain.

heterophil granules (Figures 20.23–20.25). The cytoplasmic granules of eosinophils lack the central, refractile body seen in many avian heterophils. The cytoplasm of eosinophils stains clear blue, in contrast to the colorless cytoplasm of normal, mature heterophils. The nuclei of eosinophils are lobed and usually stain darker than heterophil nuclei. The cytoplasmic granules of eosinophils frequently are affected by Romanowsky stains. The granules may appear to be large, swollen, and round, and they also may appear colorless or to stain pale blue (Figure 20.26). Eosinophils vary in appearance among species of birds.

Avian eosinophils have some features in common with mammalian eosinophils. The ultrastructure of avian eosinophils reveals large, spherical, primary granules and mature, rod-shaped, specific granules. In some birds, the specific granules possess a crystalline core, a prominent feature of mammalian eosinophils; however, this feature is missing in other species (e.g., chicken and duck). The larger primary granules most likely are precursors to the smaller, specific granules. Similar to mammalian eosinophils, specific granules possess a high concentration of arginine and enzymes, such as peroxidase, acid phosphatase, and arylsulfatase. Cytochemical staining of chicken eosinophils indicates a positive reactivity for peroxidase, acid phosphatase, and

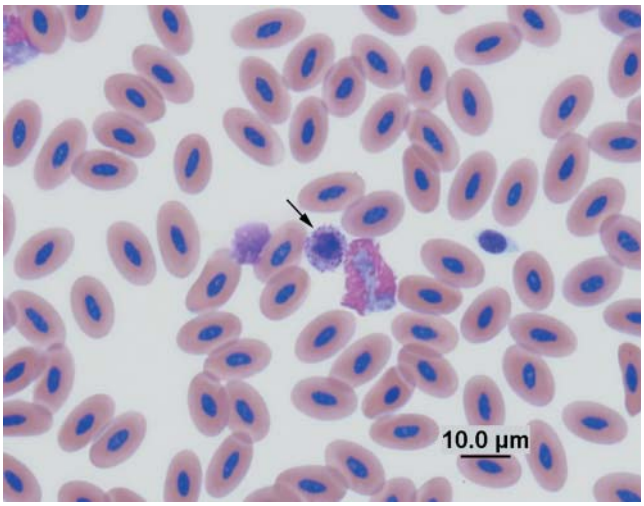

Figure 20.27 A basophil (arrow) and a heterophil in the blood film of a grebe (*Podiceps auritus*). Wright-Giemsa stain.

Sudan black B. Avian eosinophils (chicken and duck) contain major basic protein, a principal protein in mammalian eosinophils but not in mammalian neutrophils. Therefore, these reactions can be used to distinguish eosinophils from heterophils. Unlike heterophils, avian eosinophils, although they are immotile and nonphagocytic, do respond to fMLP by forming surface projections and clumping to form large aggregates. Avian eosinophils have been shown to participate in delayed hypersensitivity reactions, a feature not seen with mammalian eosinophils.

Avian basophils tend to be smaller than heterophils and eosinophils. For example, basophils of adult *Coturnix* quail measure 9.23 ± 1.35 µm in diameter for males and 9.55 ± 1.26 µm in diameter in females. Avian basophils contain deeply metachromic granules that often obscure the nucleus. The nucleus usually is nonlobed, thereby causing avian basophils to resemble mammalian mast cells (Figures 20.27 and 20.28). The cytoplasmic granules of basophils frequently are affected by alcohol-solubilized stains, and they may partially dissolve or coalesce and appear abnormal in blood films stained with Romanowsky stains. Avian basophils frequently are found in the peripheral blood, in contrast to mammalian basophils, which rarely are found in the blood films of normal animals. The function of avian basophils is not known. However, it is presumed to be similar to that of mammalian basophils and mast cells, because their cytoplasmic granules contain histamine. They also participate in acute inflammatory and type IV hypersensitivity reactions.

Avian lymphocytes resemble mammalian lymphocytes and generally come in two sizes, small and medium

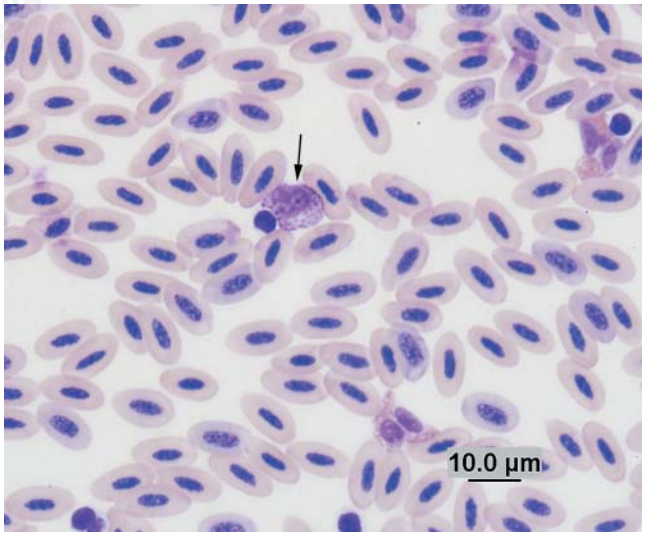

Figure 20.28 A basophil (arrow) in the blood film of a parrot (*Myiopsitta monachus*). Wright-Giemsa stain.

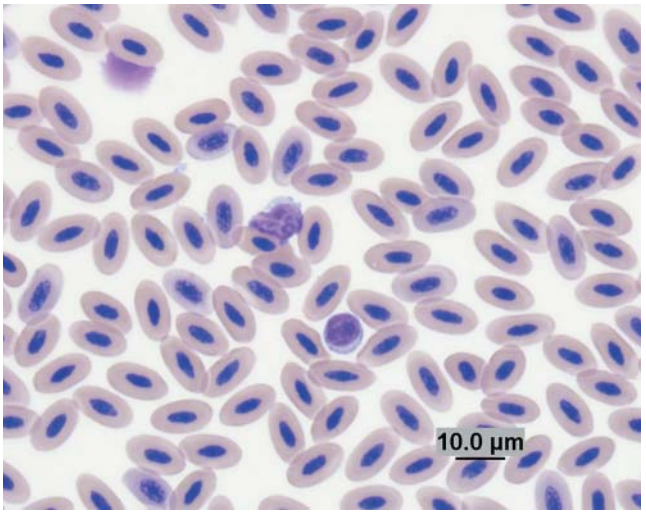

Figure 20.30 Medium lymphocytes in the blood film of a parrot (*Pionus menstruus*). Wright-Giemsa stain.

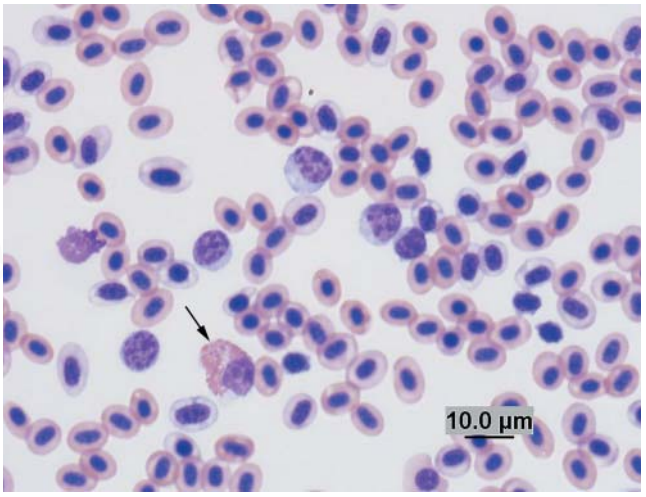

Figure 20.31 Large and medium lymphocytes and a heterophil (arrow) in the blood film of a macaw (*Ara glaucogularis*). Many of the erythrocytes are polychromatophils. Wright-Giemsa stain.

(Figures 20.29–20.33). Small lymphocytes of adult *Coturnix* quail measure 4.83 ± 0.24 µm in diameter for males and 4.86 ± 0.22 µm in diameter in females, whereas medium lymphocytes measure 7.73 ± 1.33 µm in diameter for males and 8.53 ± 1.40 µm in diameter in females. Typically, they are round cells that often show cytoplasmic irregularity when they mold around adjacent erythrocytes in the blood film. Lymphocytes have a round, occasionally slightly indented, centrally or slightly eccentrically positioned nucleus. The nuclear chromatin is heavily clumped or reticulated in mature lymphocytes, and the cytoplasm typically is scant, except in large lymphocytes, thereby giving lymphocytes their high nucleus:cytoplasm (N:C) ratio. Large lymphocytes that resemble those found in bovine blood films can also be found in the blood of normal birds. Large lymphocytes can be confused with monocytes, however, because of their size, cytoplasmic volume, and pale-staining nuclei. The lymphocyte cytoplasm usually appears to be homogenous and weakly basophilic (pale blue), and it lacks both vacuoles and granules. Cytoplasmic features are important when differentiating small lymphocytes from thrombocytes (Figures 20.29, 20.34–20.36). The latter have clear, colorless cytoplasm that often appears to be vacuolated, with a few distinct specific granules. Occasionally, cells in the blood films of birds have features of both thrombocytes and lymphocytes. These intermediate cells have small, round to oval

nuclei with coarsely clumped chromatin and moderately abundant, blue-tinged cytoplasm that lacks both vacuoles and granules. Cytochemical properties indicate these cells are lymphocytes.

Occasionally, lymphocytes may contain large distinct azurophilic granules or irregular cytoplasmic projections. Although sometimes considered to be natural killer cells, the significance of lymphocytes with azurophilic granules is not known. Irregular cytoplasmic projections are indicative of cellular degeneration, a significant finding if represented by the majority of lymphocytes.

Abnormal lymphocytes are classified as either reactive or blast-transformed lymphocytes. Reactive lymphocytes are small to medium lymphocytes with heavily clumped nuclear chromatin and deeply basophilic cytoplasm. Lymphocytes develop into reactive lymphocytes when antigenically stimulated. Blast-transformed lymphocytes are large lymphocytes with dispersed, smooth nuclear chromatin, which may contain nucleoli (Figure 20.37). They have basophilic cytoplasm that may exhibit a prominent, clear, perinuclear halo or Golgi zone. These lymphocytes have anaplastic features and may be neoplastic, but they also may result from immunologic stimulation. Plasma cells also can be found in the peripheral blood of birds. These are large B lymphocytes with eccentrically positioned mature nuclei, abundant, deeply basophilic cytoplasm and a distinct Golgi zone. Lymphocytes that contain prominent azurophilic granules are also considered to be reactive.

Avian monocytes typically are the largest leukocyte and they resemble their mammalian counterpart, varying in shape from round to ameboid. For example, monocytes of adult *Coturnix* quail measure 13.53 ± 0.74 µm in diameter

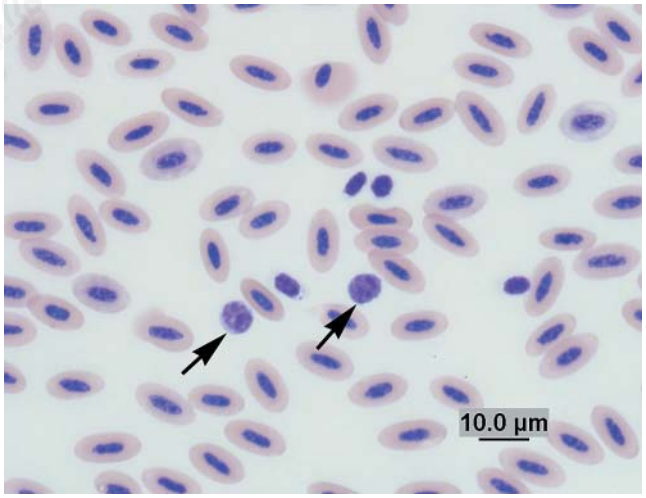

Figure 20.36 Lymphocytes (arrows) and thrombocytes in the blood film of a duck (*Anas platyrhynchos domesticus*). Wright-Giemsa stain.

for males and 13.26 ± 0.45 µm in diameter in females. Monocytes have abundant, blue-gray cytoplasm that may appear to be slightly opaque, and they contain vacuoles or fine, dust-like eosinophilic granules (Figures 20.38–20.40). Avian monocytes frequently exhibit two distinct zones in the cytoplasm: a light-staining perinuclear area, and a darker-staining area. The monocyte nucleus can vary in shape and is relatively pale, with less chromatin clumping compared with lymphocyte nuclei. The ultrastructure of avian monocytes and macrophages reveals a cytoplasmic membrane that is composed of blebs or filaments, a prominent Golgi apparatus, many ribosomes, and a variable number of pinocytic vesicles and lysosomes. Monocytes exhibit phagocytic activity and migrate into tissues to become macrophages. They possess biologically active chemicals that are involved in inflammation and oxidative destruction of invading organisms. Monocytes also have an important immunologic role in antigen processing.

Laboratory evaluation

Leukocyte counts may be obtained using manual and automated methods. However, significant differences may occur between the manual absolute and relative microscopic leukocyte differential count and the automated absolute and relative leukocyte count techniques. Manual methods for the determination of a leukocyte differential have a greater variability compared to automated methods. The presence of nucleated erythrocytes and thrombocytes in the blood of

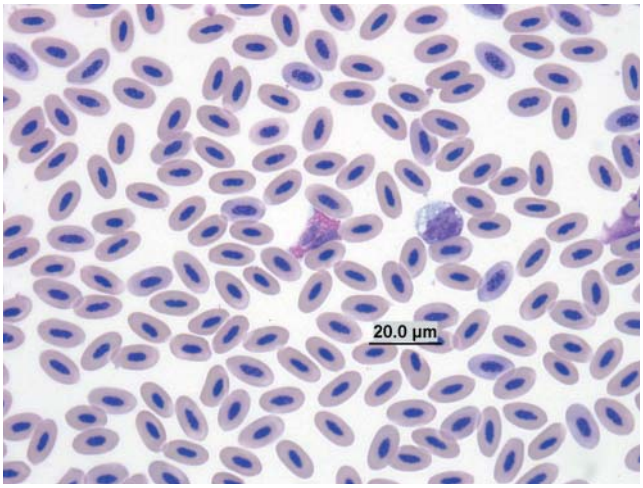

Figure 20.40 A monocyte and a heterophil in the blood film of a parrot (*Eclectus roratus*). Wright-Giemsa stain.

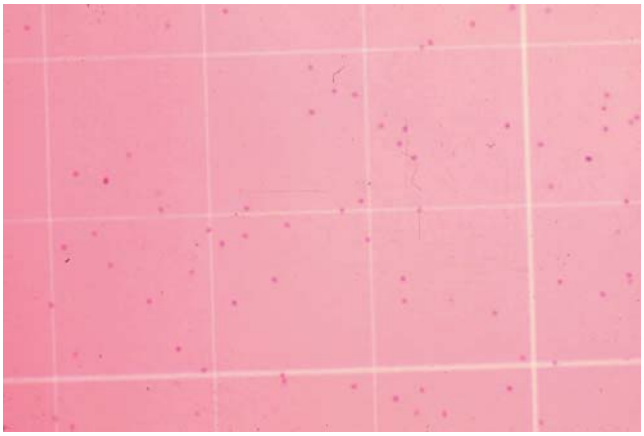

Figure 20.41 The appearance of acidophils stained with phloxine dye in a hemocytometer chamber, 100×. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 202.

lower vertebrates, such as birds, presents a challenge when attempting to apply the automated counting methods used for obtaining mammalian white blood cells counts. The fact that these animals have a nucleated erythrocyte that is similar in size to many of the leukocytes, small lymphocytes, and thrombocytes presents an additional challenge. Automated methods tend to yield a higher percentage of monocytes and lower percentage of basophils compared to manual methods when using avian blood; however, there appears to be no difference between the mean percentage of heterophils and lymphocytes. This makes automated methods suitable for determination of heterophil/lymphocyte (H/L) ratios in birds.

Direct and semidirect manual methods for obtaining total leukocyte concentrations in birds have been developed. A commonly used semidirect method involves the staining of avian heterophils and eosinophils with phloxine B as the diluent. Phloxine B commonly is used as a specific stain for eosinophils in mammalian blood. The procedure is simplified and made more accurate by using a commercially prepared Phloxine B solution kit (Eopette, Exotic Animal Solutions, Inc., Hueytown, AL). The kit contains prefilled Phloxine B stain reservoirs, a pipette calibrated for 25 µL to make the proper 1 : 32 dilution. The diluted blood is then discharged onto the hemocytometer counting chamber and is allowed to settle for a minimum of 5 minutes before counting. When properly prepared, only heterophils and eosinophils stain red with Phloxine B. The hemocytometer should be loaded immediately after proper mixing of the blood and phloxine diluent, because red blood cells also may stain after prolonged exposure. The red-stained cells are counted in both sides of the chamber (18 large squares) (Figure 20.41). Next, the total leukocyte concentration (TWBC/mm^3) is calculated after completing a leukocyte differential to obtain the percent heterophils and eosinophils on the stained blood film using the following equation:

$$\frac{(\text{Average count from } \textbf{both} \text{ sides of chamber} + 10\%)}{\%\text{heterophils} + \%\text{eosinophils on differential}} \times 32 \times 100 = \text{WBC/mm}^3$$

For example: The total number of eosin-stained cells counted in the nine large squares on both sides of a Neubauer-ruled hemocytometer chamber (total of 18 squares) is 80 and the differential leukocyte count revealed 35% heterophils and 2% eosinophils, then using the above formulas, the TWBC/mm^3 is 7611/mm^3 when rounded to the nearest whole number.

A direct method for obtaining total leukocyte concentrations in avian blood is to make a 1 : 200 dilution with Natt-Herricks solution (Table 20.2) using a standard red blood cell–diluting pipette or by adding 20 µL of blood to 4 mL of the Natt-Herricks solution (Figure 20.14). The total leukocyte concentration is obtained by counting all of the leukocytes (dark blue cells) in the nine large squares in the ruled area of the hemocytometer chamber using the following formula:

$$\text{TWBC/mm}^3 = (\text{Total cells in nine large squares} + 10\%) \times 200$$

Commercially prepared Natt-Herricks solution kit (Natt-Pette) makes the procedure easier and more accurate. The kit contains prefilled Natt-Herricks stain reservoirs, a pipette calibrated for 5 µL (to make the 1 : 200 dilution), and tips for the pipette. The advantage to this method is that a total erythrocyte and thrombocyte count also can be obtained using the same charged hemocytometer. A

disadvantage is that differentiating thrombocytes from small lymphocytes often is difficult, thus creating errors in the counts. Staining for 60 minutes in the Natt-Herricks solution, however, improves the differentiation between small lymphocytes and thrombocytes.

A second method for obtaining a direct total leukocyte count in birds is to dilute the anticoagulated blood 1 : 100 with 0.01% toluidine blue in phosphate-buffered saline before charging a Neubauer-ruled hemocytometer. Cells that are equal to or larger than the width of the erythrocytes are counted in the nine large squares of the hemocytometer. The total leukocyte count is calculated using the standard formula:

$$\text{TWBC/mm}^3 = \frac{\text{No. cells} \times 10 \times 100}{9}$$

Or, to simplify the math,

$$\text{TWBC/mm}^3 = (\text{Number of cells} + 10\%) \times 100$$

Toluidine blue stains leukocytes blue, erythrocytes pale orange, and thrombocytes pale blue. Counting cells that are equal to or larger than the width of erythrocytes should rule out thrombocytes, which tend to be smaller in width than erythrocytes. Small lymphocytes tend to be equal to or larger than the width of erythrocytes. Immature erythrocytes are distinguished from small lymphocytes by their round to irregular shape; their round, centrally positioned nucleus with dark, irregularly clumped chromatin; and their moderate volume of basophilic hyaline cytoplasm. A corrected total leukocyte concentration can be obtained when a large number of immature erythrocytes are present by using the following formula:

$$\text{Corrected TWBC/mm}^3 = \frac{\text{TWBC} \times 100}{100 + \text{No. immature RBCs per 100 leukocytes}}$$

With counting methods requiring use of a hemocytometer, the difference between the counts obtained from each chamber should not exceed 10% to ensure accuracy between the two sides. If the difference does exceed 10%, the procedure should be repeated. The semidirect method using the phloxine stain is easier to perform and is more precise for hemocytometer counting than the Natt and Herricks method. To our knowledge, no comparisons have been made for the toluidine blue method; however, the results should be similar to those with the Natt and Herricks method. Because the semidirect method using phloxine B stain for determination of total leukocyte counts in birds depends on the leukocyte differential, especially the number of heterophils and eosinophils, it likely becomes less accurate as the level of mononuclear leukocytes exceeds that of the granulocytes.

Accurate interpretation of leukocyte counts, especially when determined by the semidirect method, depends on the accurate identification and differentiation of leukocytes in the blood film. The leukocyte differential is performed during the microscopic evaluation of Romanowsky-stained blood films. Blood samples collected into heparin make it necessary to prepare the blood films immediately following sample collection in order to decrease the incidence of cell clumping. Whenever possible, preparing blood films using blood containing no anticoagulant is preferred. The differential leukocyte count is performed by counting a minimum of 100 leukocytes in a monolayer area in the blood film. The cells counted are those consecutively encountered as one moves from one counting field to the next. The cells are classified as heterophils, eosinophils, basophils, lymphocytes, and monocytes. The number of each cell type becomes a fraction of the total or a percentage of the leukocyte population. Absolute numbers of each cell type are obtained by multiplying the total leukocyte concentration by the percentage of that type of leukocyte from the differential count.

Responses in disease

Avian leukograms often vary widely between normal birds of the same species (Table 20.4). Because birds often become excited when handled, the blood collection process usually results in a physiologic leukocytosis, and this physiologic response increases the concentration of heterophils and lymphocytes in the peripheral blood. Normal total leukocyte reference intervals obtained from birds generally are broader than those obtained from domestic mammals. Thus, avian leukogram values must differ greatly from the normal reference intervals to have diagnostic significance.

In general, gender differences in the normal leukogram of birds are not clinically significant; however, age differences can be. Generally, percentages of heterophils and lymphocytes and absolute lymphocyte counts vary significantly between adult and juvenile birds where younger birds tend to have higher lymphocyte counts. The leukogram may also be affected by seasonal influences, especially in free-ranging birds. For example, the absolute leukocyte, heterophil, and lymphocyte counts of ducks decrease during and after the remige molt, a seasonal event.

Leukocytosis and heterophilia

A leukocyte differential aids in the assessment of a leukocytosis. Because leukocytosis often is caused by inflammation, a heterophilia usually is present as well. The magnitude of the heterophilia depends on both the cause and the severity of the inflammation: the greater the degree of heterophilia, the greater the severity of the inflammation. A leukocytosis and heterophilia can be associated with inflammation in response to localized or systemic infections caused by a spectrum of infectious agents (i.e., bacteria, fungi,

Chlamydophila, viruses, and parasites) and noninfectious causes (i.e., traumatic injury, foreign bodies, or toxicities). A marked leukocytosis and heterophilia often are associated with diseases produced by common avian pathogens, such as *Chlamydophila*, *Mycobacterium*, and *Aspergillus*. Persistent inflammatory leukograms may occur with long standing inflammation, such as the presence of granulomas. Viral diseases can also result in a marked leukocytosis; however, they are not typically associated with a heterophilic leukocytosis. These include avian leukosis virus, reticuloendotheliosis virus, Marek's disease (herpesvirus), myeloblastosis (retrovirus), and lymphoid leukosis (reticuloendotheliosis virus and avian leukosis virus).

An absolute leukocytosis with a moderate mature heterophilia and lymphopenia are typically the hallmarks of a stress leukogram. The mechanisms mediating these cellular changes are poorly defined in birds but appear to be associated with changes in endogenous corticosteroid levels. Corticosteroid levels change rapidly during stress; however, absolute leukocyte numbers change more slowly (30 minutes to 20 hours) in response to stress and are less variable but more enduring. Blood samples ideally should be collected quickly with minimal stress to the patient to avoid leukogram changes associated with handling. When working with wild birds, blood collection should be performed immediately after capture. An absolute leukocytosis may also occur when exogenous glucocorticoids are administered to birds. The stimulus for heterophil recruitment or mobilization arises from bone marrow interactions with the hypothalamic-pituitary-adrenal cortical axis.

Stressors increase the number of heterophils and reduce the number of lymphocytes. Consequently, the heterophil/lymphocyte ratio (H/L ratio) has been used as an index of stress in birds since the early 1980s. The H/L ratio has been shown to be a reliable indicator of stress associated with injury, reproductive cycles, and seasonal changes in birds in both captive and field situations. The H/L ratio appears to be the most accurate indicator of stress because it is less variable than the number of heterophils or lymphocytes alone. In free-living birds, H/L ratios may be more useful than a single measure of plasma corticosterone in assessing response to chronic stressors like injury or crowded conditions in the breeding colony, and H/L ratios have been shown to be a valuable tool to measure stress in passerine birds and to evaluate management practices for critically endangered passerines. In the poultry industry, H/L reference values of 0.20, 0.50, and 0.80 are characteristic of low, optimal, and high degrees of stress, respectively. However, there are limitations to the accuracy of the H/L ratio as an indicator of stress in birds. Recent studies suggest that the H : L ratio appears to be an unreliable indicator of stress owing to the lack of correlation between that ratio and plasma corticosterone concentrations. The magnitude of leukocytosis and heterophilia during disease or corticosteroid excess varies with the H : L ratio, with greater responses being seen in species with normal H : L ratios of 3.0 : 1 versus those with ratios of 0.5 : 1. Initially, species that normally have high numbers of circulating lymphocytes (e.g., Anseriformes) may show a leukopenia but, later (i.e., up to 12 hours) demonstrate typical leukocytosis, heterophilia, and lymphopenia. Species that normally have greater numbers of circulating heterophils (e.g., Galliformes) show a less dramatic change in the stress leukogram. The H/L ratio may vary with conditions that affect heterophil and lymphocyte numbers, such as age and inflammatory disease. There may also be species variation in the hemic response to corticosteroids and stress, which would in turn affect the magnitude of the; in some extreme circumstances, a bird may even exhibit a heteropenia and basophilia.

Although the nature of the immune response to bacterial infections in birds has not yet been fully elucidated, nonlymphoid cells, such as macrophages and heterophils, play a crucial role in immunity to bacteria. Therefore, increases in the numbers of heterophils and monocytes in the peripheral blood would be expected with bacterial infections. The degree of the inflammatory response present in the blood may be associated with the location of the bacterial infection. For example, psittacine birds with varying degrees and causes of sinusitis often exhibit normal complete blood cell counts or have only a mild inflammatory leukogram, perhaps because the lesions remained a focal one.

Common hematologic abnormalities associated with avian mycobacteriosis include mild to moderate nonregenerative anemia, marked to severe leukocytosis, heterophilia, lymphopenia, monocytosis, eosinophilia, and immature heterophils. Thrombocytosis has also been reported in birds with mycobacteriosis. Laboratory findings can be variable and reflect the stage of the disease, presence of concurrent illness, and species differences. Initial hematological results may be normal in some individuals. In such cases, repeat and serial complete blood cell counts may be useful in the diagnosis of mycobacteriosis. A leukocytosis with a moderate to marked monocytosis, with or without heterophilia, is supportive of possible mycobacteriosis. High leukocyte counts are typically seen in birds with advanced mycobacteriosis. When present, immature heterophils indicate a poor prognosis.

An inflammatory leukogram characterized by heterophilia and/or monocytosis is often associated with infections with *Chlamydophila* or mycotic infections, such as aspergillosis. The presence of toxic or immature heterophils indicates severe inflammation and a poor prognosis for survival.

An inflammatory leukogram characterized by heterophilia, lymphopenia, and monocytosis may be associated with neoplastic diseases such as squamous cell carcinoma, papillomatosis, and other neoplasias in birds. Bacterial or fungal infections within the lesions may be responsible for this; however, tissue necrosis and granulocyte breakdown

can also stimulate the inflammatory response. Some tumors may produce a hematopoietic factor capable of promoting a leukocytosis, which could cause an inflammatory leukogram.

Immature heterophils rarely are present in the peripheral blood of normal birds. When they do occur, however, their presence usually results from excessive peripheral utilization of mature heterophils with depletion of the mature storage pool in the hematopoietic tissue, which indicates a severe inflammatory response, especially when associated with a leukopenia. Marked increases in the concentration of immature heterophils also may result from granulocytic leukemia, which is a rare condition in birds.

Toxic heterophils are associated with severe, systemic illness such as septicemia, viremia, chlamydophilosis, mycotic infections, and severe tissue necrosis. The degree of heterophil toxicity usually indicates the severity of the bird's condition, and a marked number of 4+ toxic heterophils indicates a grave prognosis.

Hematological indicators of inflammation are species and etiology dependent; however, the presence of a mild to moderate anemia, heterophilia, monocytosis, and heterophil morphological atypia appears to be the most consistent hematologic changes associated with inflammation in birds. Interpretive guidelines have been developed for some species of birds. For example, in free-ranging black cockatoos (*Calyptorhynchus* spp.), anemia can be graded based upon a PCV of 30–35% as a mild anemia, 20–30% as moderate anemia, and less than 20% as severe anemia. A mild leukocytosis in black cockatoos is represented by a leukocyte count less than 25,000/μL, whereas a count between 25,000 and 40,000/μL and greater than 40,000/μL represent moderate and severe responses respectively. Significant heterophilias in black cockatoos are represented by counts less than 20,000/μL as mild, 21,000–30,000/μL as moderate, and greater than 30,000/μL as severe. Toxic heterophils were not a common finding in black cockatoos with inflammatory disorders.

In contrast to black cockatoos, the inflammatory response in falcons (*Falco* spp.) appears different. Normal falcons in general are reported to have a PCV between 37% and 53%, hemoglobin concentration between 12 and 21 g/dL, total leukocyte count between 3000 and 11,000 μL, and an absolute heterophil count greater than the absolute lymphocyte count. Falcons rarely exhibit a leukocytosis greater than 17,000/μL in response to inflammation regardless of the etiology. Aspergillosis, a common mycotic disease of birds, frequently causes a severe inflammatory disease in birds; however that response is variable between the species. For example, falcons (*Falco* spp.) with aspergillosis develop a relatively mild leukocytosis compared to *Buteo* hawks that demonstrate a severe leukocytosis.

Leukopenia

Leukopenia is associated with either consumption of peripheral leukocytes or decreased production. In many species of birds, an absolute heteropenia is the cause of a leukopenia. Heteropenia results from decreased survival of mature heterophils or from decreased or ineffective production. Leukopenias associated with heteropenias can occur with severe bacterial infections or certain viral diseases (e.g., Pacheco's parrot disease). Severe leukopenia is commonly associated with parrots infected with psittacine circovirus, where peracute infections can present with leukopenia, anemia, or pancytopenia. Leukopenia and heteropenia with the presence of immature heterophils suggest exhaustion of the mature heterophil storage pool because of excessive peripheral demand for heterophils, as seen with severe inflammation. A degenerative left shift is reflected by an absolute heteropenia in conjunction with immature heterophilia and toxicity that indicates either an overwhelming demand for heterophils in the periphery due to bacterial sepsis or viral disease, a reduced production of heterophils in the bone marrow, or an ineffective granulopoiesis due to maturation arrest. Degenerative left shifts and depletion are differentiated by the presence of toxic heterophils or by following the decreasing leukocyte count with serial leukograms. Bone marrow evaluation may be helpful in the rule-out of these conditions. In general, a degenerative left shift in the leukogram of a bird indicates a poor prognosis for survival. As discussed, leukopenia and lymphopenia can occur as an early, corticosteroid-induced leukogram response in some species of birds. Leukopenias and lymphopenia also may suggest a viral cause, although such causes have been poorly documented in birds. Leukopenia and lymphopenia has been associated with mycotoxins poisoning and other toxicities in birds. Leukopenia associated with a heteropenia, marked anemia, and thrombocytopenia (pancytopenia) suggests injury to the bone marrow, which can be associated with certain neoplastic conditions and other causes of bone marrow injury discussed below.

Heteropenia

Heteropenia is seen with acute inflammatory disease or in those with marked severity resulting from heterophils being consumed at a faster rate than being produced and released to peripheral circulation. A heteropenia with a left shift and toxic changes is indicative of an acute inflammatory response associated with excessive peripheral utilization of heterophils. Immune-mediated heteropenia, should it occur in birds, would result in a profound heteropenia in the peripheral blood and depletion of the maturation pool in the bone marrow. Injury to the stem cells in the bone marrow can occur with chemicals, drugs, or infectious agents, such as viral agents, that affect rapidly dividing cells resulting in a profound heteropenia. Stem cell injury would first appear as a profound heteropenia followed

by a thrombocytopenia and eventually a nonregenerative anemia. A heteropenia with a left shift, no anemia, and adequate thrombocytes is indicative of an acute inflammatory response with exhaustion of the mature heterophil storage pool caused by excessive peripheral utilization of heterophils. A heteropenia with no left shift, no anemia, and adequate thrombocytes is indicative of an acute viral infection or acute marrow injury. This has been shown with psittacine birds experimentally infected with the herpesvirus that causes Pacheco's disease that developed severe heteropenia. A heteropenia associated with a nonregenerative anemia and possibly a thrombocytopenia is indicative of a chronic marrow injury. Fenbendazole toxicity in birds produces a bone marrow toxicosis that results in a transient leukopenia, severe heteropenia, and anemia as the result of a compromise to cellular division impacting rapidly dividing. Leukopenia associated with a heteropenia, marked anemia, and thrombocytopenia suggestive of stem cell injury to the bone marrow can be associated with certain neoplastic conditions. Absolute heteropenia in conjunction with immature heterophilia and heterophil toxicity indicates either an overwhelming demand for heterophils in the periphery due to bacterial sepsis or viral disease, a reduced production of heterophils in the bone marrow, or ineffective granulopoiesis. This type of leukogram carries a poor prognosis.

Lymphocytosis

Lymphocytosis may occur with antigenic stimulation. An occasional reactive lymphocyte may be found in blood films from normal birds; however, many reactive lymphocytes suggest antigenic stimulation associated with infectious disease (Figure 20.37). Lymphocytosis also can occur with lymphocytic leukemia (e.g., avian leukosis). In some cases of lymphocytic leukemia, immature lymphocytes may be present in the blood film. A marked lymphocytosis in which most lymphocytes appear as small, mature lymphocytes with scalloped cytoplasmic margins also has been associated with lymphoid neoplasia.

Lymphopenia

Lymphopenia can occur with glucocorticosteroid excess, which may be more pronounced in some avian species than others. Immunosuppressive drugs other than corticosteroids, such as chemotherapeutic agents, may also cause lymphopenia. Lymphopenia may also be associated with toxicities, such as zinc intoxication. A lymphopenia with numerous atypical large lymphocytes containing scalloped cytoplasmic margins has been documented in birds with lymphoma.

Monocytosis

A monocytosis can be seen with acute and chronic inflammation and occurs with an increased demand for monocytes. Monocytosis in avian patients is typically associated with infectious and inflammatory disease, especially those associated with granulomatous inflammation. Other causes of monocytosis may include hemic reaction to a foreign body and certain nutritional deficiencies, such as zinc. Anemia and leukocytosis with increases in monocyte, heterophil, and basophil numbers are a common hematologic feature of chronic inflammation in birds. Early in the inflammatory process an initial leukocytosis and heterophilia generally occurs; however, some infectious agents may elicit an acute monocytosis. For example, acute *Mycoplasma* infections can result in heterophilia, lymphopenia, monocytosis, and eosinophilia. Anemia and monocytosis then develop as the inflammation becomes chronic. Organisms such as *Mycobacterium*, *Chlamydophila*, and fungi such as *Aspergillus* typically cause granulomatous inflammation in birds and are often associated with monocytosis. A profound nonregenerative anemia and severe monocytosis can occur with chronic clostridial infections. Neoplasia may cause monocytosis in some birds; for example, quail exposed experimentally to Rous sarcoma virus developed a leukocytosis as tumor growth developed. The leukocyte counts returned to normal in birds that showed regression of the tumors; however, those with progression of tumor growth continued to exhibit a leukocytosis with heterophilia, monocytosis, and lymphopenia.

Eosinophilia

Because the exact functions of avian eosinophils are not known, interpreting the cause of peripheral eosinophilia is difficult in birds. Although this avian granulocyte was given the name "eosinophil," avian eosinophils may behave differently than mammalian eosinophils. Studies have shown that avian eosinophils may participate in delayed (type IV) hypersensitivity reactions, which does not occur with mammalian eosinophils. Experiments using parasite antigens have failed to induce peripheral eosinophilias, although eosinophilias associated with gastrointestinal nematode infestations have been reported. The responses of avian eosinophils to inflammation are variable and have not been reliably associated with a specific etiology. Despite limited knowledge regarding the function of avian eosinophils, peripheral eosinophilia in birds can be loosely interpreted as being a response to internal or external parasitism or exposure to foreign antigens (i.e., hypersensitivity response). It has been noted; however, that parasitic infections may not elicit a peripheral eosinophilia in birds.

Eosinopenia

Eosinopenia may be difficult to document in birds. If present, it is expected to be associated with a stress response or with administration of glucocorticosteroids.

Basophilia

Basophilia is rare in birds. Because avian basophils produce, store, and release histamine, they may have a function

similar to that of mammalian basophils. Therefore, avian basophils may participate in immediate hypersensitivity reactions, release mediators for thrombocyte activation, cause smooth muscle contractions, initiate edema, and affect coagulation. Basophils appear to participate in the initial phase of acute inflammation in birds; however, this usually is not reflected as a basophilia on the leukogram. Peripheral basophilia may suggest early inflammation or an immediate hypersensitivity reaction in birds. A stress-related basophilia occurs in chickens subjected to food restriction, but this response may be age or duration dependent.

Thrombocytes and hemostasis

Morphology

Avian thrombocytes are nucleated cells that are the second most numerous cell (after erythrocytes) found in the blood. Thrombocytes are typically small, round to oval cells (smaller than erythrocytes) with a round to oval nucleus that contains densely clumped chromatin. The nucleus is more rounded than an erythrocyte nucleus and thrombocytes tend to have a high N : C ratio. They are generally the smallest cell in the peripheral blood but only slightly smaller than small mature lymphocytes. For example, thrombocyte measurements for adult *Coturnix* quail are 4.10 ± 0.30 μm in diameter for males and 4.06 ± 0.32 μm in diameter for females. Normal, mature thrombocytes have a colorless to pale gray cytoplasm, which often has a reticulated appearance. The appearance of the cytoplasm is an important feature in differentiating thrombocytes from small, mature lymphocytes (Figures 20.34–20.36 and 20.42). Cytoplasmic vacuolation can occur in activated or phagocytic thrombocytes. Thrombocytes frequently contain one or more distinct eosinophilic (dense) granules, which usually are located in one area of the cytoplasm. Thrombocytes participate in the hemostatic process and, like mammalian platelets; therefore, they secrete thromboplastin, which polymerizes fibrinogen in the formation of clots in blood coagulation. Activated thrombocytes occurring in aggregates may have indistinct cellular outlines or cytoplasmic pseudopodia, and may demonstrate degranulation of dense granules, cellular degeneration, and nuclear pyknosis. Ultrastructurally, the cytoplasm resembles that of mammalian platelets. The granules that frequently are seen in thrombocytes at light microscopy appear as aggregates of many small granules at electron microscopy. The dense granules contain primarily 5′-hydroxytryptamine, and they are an unlikely source of thromboplastin. Thrombocytes aggregated in clumps show degranulation of dense granules, cellular degeneration, and nuclear pyknosis. Avian thrombocytes contain a large amount of serotonin, and some studies suggest that they are capable of phagocytosis and may participate in removing foreign materials from the blood.

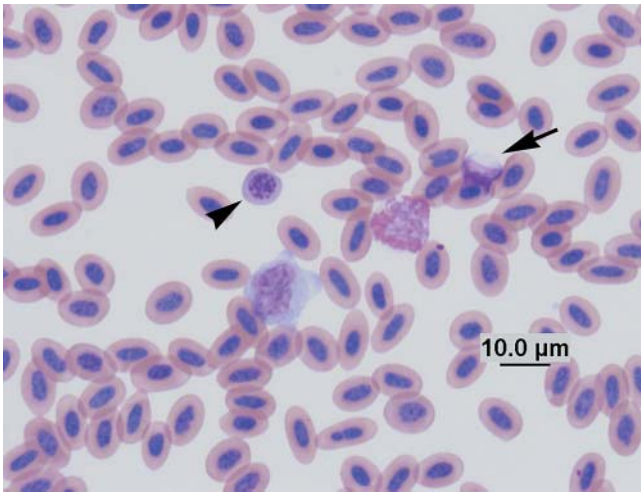

Figure 20.42 A monocyte, immature erythrocyte (mid-polychromatic rubricyte, arrowhead), medium lymphocyte (arrow), and heterophil in the blood film of a chicken (*Gallus gallus domesticus*). Wright-Giemsa stain.

Avian thrombocytes may play a role in innate immunity because they are capable of phagocytosis and may participate in removing foreign materials from the blood. Theoretically, even though thrombocytes are less phagocytic than heterophils, avian thrombocytes may act as a nonspecific "scavenging" phagocyte, capable of clearing a wide range of foreign objects, including bacteria. Therefore, thrombocytes may play a role in fighting bacterial infection, although the mechanisms, by which thrombocytes interact with, adhere to, or respond to bacteria are largely unknown. Light and electron microscopy has demonstrated that thrombocytes contain lysosomal vesicles and are actively phagocytic *in vitro* for vital dyes and Gram-positive bacteria. Oxidative burst activity has been demonstrated in avian thrombocytes after phagocytosis of bacteria. In some studies, oxygen radicals were detected in thrombocytes after activation by binding the monoclonal antibody 11C3 that targets the avian homolog of the platelet integrin GPIIb-IIIa. Further studies on how thrombocytes interact with other cells and the role of complement and Fc receptors in phagocytosis and antimicrobial activity are needed to determine specific roles of thrombocytes in avian immunity.

Laboratory evaluation

The thrombocyte concentration of most avian species studied ranges between 20,000 and 30,000 cells/μL, or 10–15 thrombocytes per 1000 erythrocytes. The actual thrombocyte concentration is difficult to determine, because thrombocytes tend to clump. Therefore, their concentration often is reported as either normal, increased, or decreased, based on estimates made from peripheral blood films. Approximately one to five thrombocytes can be seen in a monolayer ×1000 (oil-immersion) field in a blood film

from a normal bird, unless the thrombocytes clump excessively during preparation. Thrombocytopenia is suggested by thrombocyte numbers less than one per monolayer ×1000 field, and thrombocytosis is suggested by numbers greater than five in an average monolayer ×1000 field. A thrombocyte concentration can be obtained with the same hemocytometer used for obtaining total leukocyte and erythrocyte counts with the Natt and Herricks method. The number of thrombocytes counted in the central large square on both sides of the Neubauer-ruled hemocytometer is multiplied by 1000 to obtain the number of thrombocytes per microliter of blood.

Responses in disease

Avian thrombocytes are derived from mononuclear precursors in the bone marrow. Immature thrombocytes occasionally are present in the peripheral blood of birds. They are round to oval cells with round to oval nuclei and basophilic cytoplasm compared with mature thrombocytes (Figure 20.43). The mid and late immature thrombocytes most commonly are seen when immature cells are present. The presence of immature thrombocytes usually indicates a regenerative response to excessive utilization of thrombocytes.

Young birds tend to have relatively higher numbers of circulating thrombocytes than adult birds. Thrombocytosis associated with large thrombocytes has been reported in birds with chronic inflammation, which may be related to the thrombocytes' phagocytic role in inflammatory disease.

Thrombocytopenia is usually the result of decreased bone marrow production or excessive peripheral utilization or destruction, and may be associated with severe septicemia and possibly disseminated intravascular coagulation (DIC). Thrombocytosis associated with large thrombocytes has been reported in birds with chronic inflammation, which may be related to the thrombocytes' phagocytic role in inflammatory disease.

The initial hemostatic plug of birds is formed through the adhesion and aggregation of thrombocytes, and the secondary hemostatic plug develops through the coagulation cascade after injury to a blood vessel wall. Most clotting factors involved in avian blood coagulation are similar to those in mammals. Although evidence suggests an intrinsic clotting mechanism in some avian species, coagulation of avian blood appears to depend on the extrinsic clotting system, which involves the release of tissue thromboplastin (i.e., factor III). The extrinsic and common pathways can be evaluated using a one-step prothrombin time test. Avian brain thromboplastin is required for avian prothrombin time testing because commercially available mammalian sources of thromboplastin give unreliable results in birds. Studies suggest that the source of thromboplastin should be from the brain of the same species of bird as the patient for prothrombin time determinations. The normal prothrombin time for most birds is 13 seconds or less. Increased prothrombin time is produced by a defect in the intrinsic or common pathway of coagulation and is caused by a deficiency of factors V, VII, X, fibrinogen, and prothrombin (factor II). Increased prothrombin times in affected birds can be related to the presence and the severity of hepatic lesions. Whole blood (capillary) clotting times in birds usually are less than 5 minutes; however, normal values appear to range between 2 and 10 minutes. The whole-blood clotting time is more variable than the prothrombin time.

Blood parasites

The three genera of hemosporidian parasites most commonly found in the peripheral blood of birds are *Hemoproteus*, *Plasmodium*, and *Leukocytozoon*. Microfilaria of filarial nematodes are also commonly found in blood films of wild birds. Microfilaria are typically found between the cells, whereas the merozoites of *Hemoproteus*, *Plasmodium*, and *Leukocytozoon* invade erythrocytes and their gametocytes are found within the erythrocyte. In general, the presence of blood parasites in wild birds has no effect on the health of the bird, although combined infections with *Hemoproteus* and *Leukocytozoon* can produce a fatal anemia in young birds. Birds may be infected with a single blood parasite, or may have mixed infections based on examination of stained blood films. Populations of certain free-ranging species of birds in various parts of the world appear to be free of blood parasites, whereas birds in other areas often have multiple infections. Avian hemosporidian parasites can vary in their degree of host specificity and even have a broad host range likely relying on a key host species. Free-living birds may exhibit seasonal variation in the degree of parasitemia. The age and effects

of captivity may affect the occurrence of blood parasites in birds. For example, Blanco et al. reported that *Hemoproteus* and *Leukocytozoon* were more commonly found in birds held in captivity for longer than 365 days and *Leukocytozoon* was found more commonly in adults and juveniles than nestlings. Identification of avian blood parasites can usually be made using stains commonly used for evaluation of blood cells. Films made from fresh blood, without the addition of an anticoagulant, provide samples with fewer artifacts affecting the parasite.

Haemoproteus

Protozoan blood parasites of the genus *Haemoproteus* are common in many species of wild birds. The only forms of the parasite in the peripheral blood of birds are gametocytes, which range in size from small, developing, ring forms to the elongate, crescent-shaped, mature gametocyte that partially encircles the erythrocyte nucleus to form the characteristic "halter shape" (Figures 20.44 and 20.45). The mature gametocyte typically occupies greater than half the cytoplasmic volume of the host erythrocyte and it causes minimal displacement of the host cell nucleus; the nucleus is never pushed to the cell margin. *Haemoproteus* gametocytes contain refractile, yellow to brown pigment granules (hemozoin) that represent iron pigment deposited as a result of hemoglobin utilization. Macrogametocytes stain dark blue with Romanowsky stains and have iron pigment dispersed throughout the cytoplasm of the parasite, whereas microgametocytes stain pale blue to pink and have iron pigment aggregated into a spherical mass. Erythrocytes parasitized by *Hemoproteus* are larger than normal erythrocytes, which likely causes the cells to become fragile. PCR (polymerase chain reaction) analysis for *Hemoproteus* can be used to detect low parasitemia.

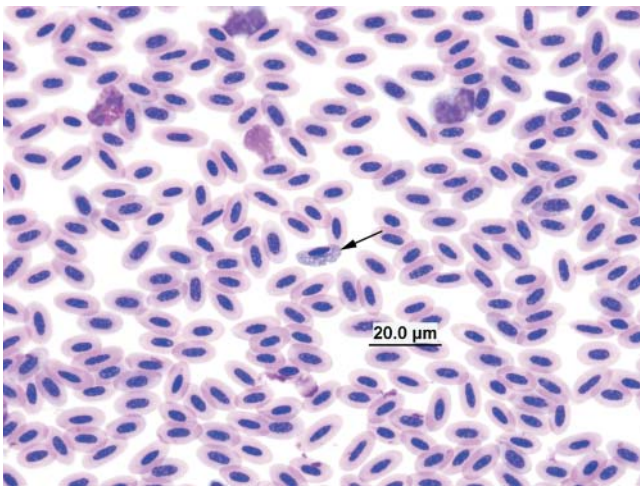

Figure 20.44 Haemoproteus gametocyte (arrow) in the blood film of a pigeon (*Columba livia domestica*). Wright-Giemsa stain.

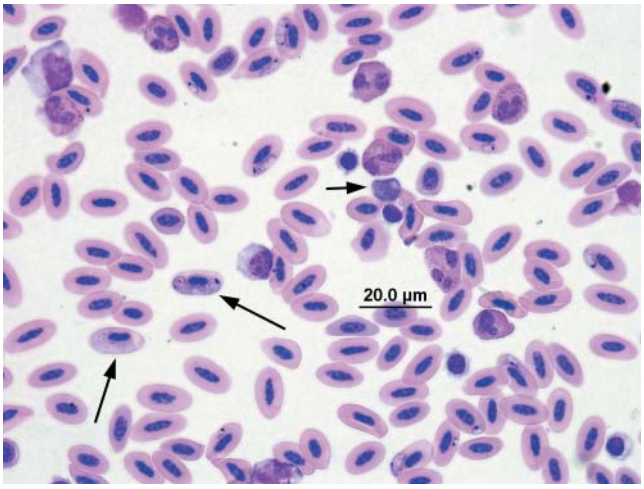

Figure 20.45 *Haemoproteus* gametocytes (long arrows) and an extracellular macrogametocyte (short arrow) in the blood film of an owl (*Bubo virginianus*). Wright-Giemsa stain.

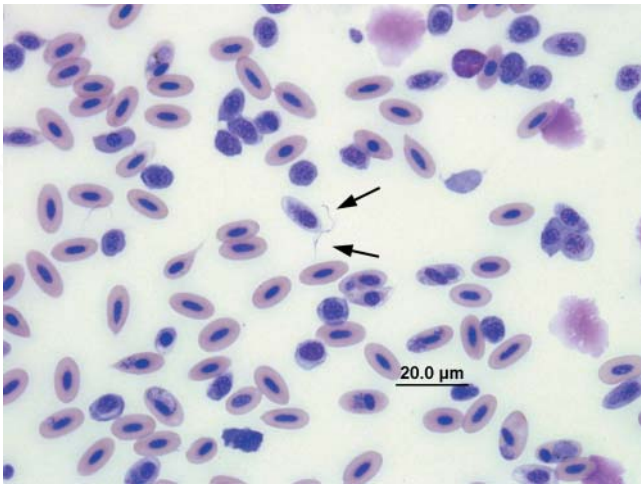

Figure 20.46 *Haemoproteus* gametocytes and an extracellular microgametocyte (arrows) in the blood film of a kestrel (*Falco sparverius*). Wright-Giemsa stain.

Occasionally, extraerythrocytic macrogametes and microgametes can be found in blood films, especially those made from blood collected several hours prior to preparing the film (Figures 20.45 and 20.46). Extraerythrocytic macrogametes are round and resemble the gametocytes normally seen within the erythrocyte. Microgametes are small spindle-shaped structures scattered throughout the blood film (Figure 20.46). Typically these forms are found in the midgut of the insect host following a blood meal but can appear in blood films when erythrocytes begin to deteriorate as the blood sample ages.

A banana-shaped ookinete, the zygote formed by the union of a macrogametocyte and a microgametocyte may

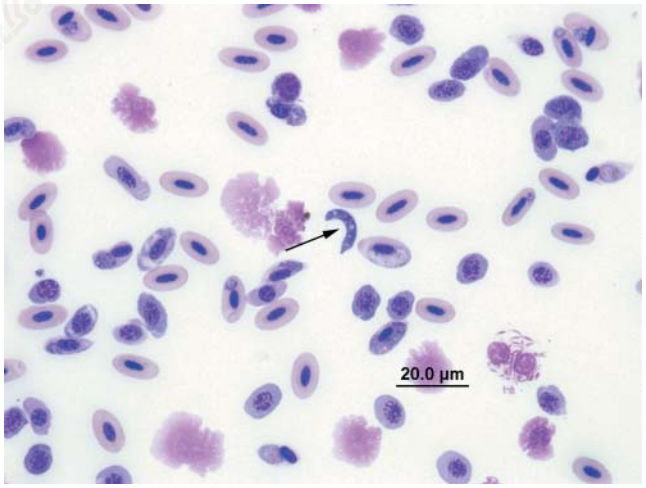

Figure 20.47 A banana-shaped ookinete (arrow) in the blood film of a kestrel (*Falco sparverius*). Wright-Giemsa stain.

also be found in the blood film (Figure 20.47). Macrogametocytes, microgametocytes, and ookinetes are rarely found in the peripheral blood films of animals and when this occurs, it is likely associated with a substantial delay between blood collection and preparation of the blood film. It is difficult to determine if the ookinete is from the *Hemoproteus* or another parasite, *Plasmodium*. A delay between blood collection and blood film preparation also creates an increased number of smudge cells on the blood film.

Bloodsucking insect vectors, such as hippoboscid flies (Hippoboscidae) and midges of the genus *Culicoides* (Ceratopogonidae), transmit *Haemoproteus*. The insect host ingests gametocytes when it feeds and the parasites then undergo a series of developmental stages to become sporozoites within the salivary gland. Sporozoites are injected into the new avian host when the insect feeds. The sporozoites enter the bird's vascular endothelial cells in various tissues (primarily the lung, liver, bone marrow, and spleen) and then undergo schizogony. *Haemoproteus* schizonts occasionally are found in cytologic or histologic samples of infected tissue, and they appear as large, round cysts containing numerous multinucleated bodies or cytomeres. Each cytomere produces numerous merozoites that escape into the bloodstream when the endothelial cell and cytomeres rupture. Merozoites enter erythrocytes to become gametocytes, which then are ingested by insect hosts to complete the cycle.

The pathogenicity of *Haemoproteus* generally is low, and parasitized birds rarely show evidence of disease. Clinical disease, however, can occur in certain avian species, such as pigeons, jays, and quail, nestlings, and in birds suffering from other diseases that, perhaps, result in immunodeficiencies. Mortalities associated with this parasite may also be the result of infections in aberrant hosts. The clinical signs include hemolytic anemia, anorexia, and depression. Hemolytic anemia is probably a sequela to lysis of the fragile parasitized erythrocyte as it passes through the fine trabecular network of the spleen. Other hematological changes that may occur during the erythrocytic phase of infection include leukocytosis, heterophilia, lymphocytosis, eosinophilia, and monocytosis. Death may be associated with severe anemia and hepatic necrosis resulting in hemorrhage related to megaloschizont-associated lesions (pre-erythrocytic stage) rather than the intraerythrocytic gametocytes. Hepatomegaly and splenomegaly may be observed at postmortem evaluation.

The degree of *Haemoproteus* parasitemia can be graded semiquantitatively based on the number of gametocytes per field when viewed under 400× magnification and used as an index to assess the recovery of birds, especially raptors, from traumatic injuries or diseases. A score of 0 is assigned if no parasites are observed, a 1 with less than 1 parasite, a 2 if 1–5 parasites, a 3 if 6–10 parasites, and a 4 if greater than 10 parasites. For example, an injured raptor that presents with *Haemoproteus* parasitemia score of 3 or 4 will dramatically drop to a score of 1 or 2 as it recovers from its injuries. Presumably, this represents an improved immune status of the bird. The intensity of the hematozoan infection can also be calculated from manual quantification of 2000 erythrocytes; however, the results from this method are significantly lower than the intensity calculated from digital quantification of 50,000 erythrocytes. The later allows for a precise method to quantify infections of low to moderate intensity.

Plasmodium

Parasites of the genus *Plasmodium* can be pathogenic and responsible for malaria, which affects certain species of birds (e.g., canaries, penguins, ducks, pigeons, raptors, and domestic poultry). Many avian species appear to be asymptomatic carriers of the parasite, however, and do not develop the clinical disease. Outbreaks of avian malaria occur sporadically in endemic areas, especially during seasons associated with increased mosquito populations. Clinical signs associated with avian malaria include anemia, anorexia, depression, and acute death. The hemogram often reveals hemolytic anemia, leukocytosis, and lymphocytosis. Hemoglobinuria or biliverdinuria also may occur. Splenomegaly and hepatomegaly often are seen on postmortem examination.

Blood smear examination is a definitive diagnostic method for detecting *Plasmodium* spp. because the intermediate forms (trophozoites, schizonts, and gametocytes) can be seen in the cells. In both *Plasmodium* spp. and *Hemoproteus* spp., refractile yellow-to-brown pigmented granules (hemozoin) are observed because schizonts ingest and metabolize hemoglobin resulting in refractile granule formation. Unlike *Haemoproteus*, stages other than the gametocyte, such as schizonts and trophozoites, can be found within erythrocytes, thrombocytes, and leukocytes (Figures 20.48–20.50). Certain *Plasmodium* sp. have round to irregular gametocytes that cause marked displacement of the host-cell nucleus,

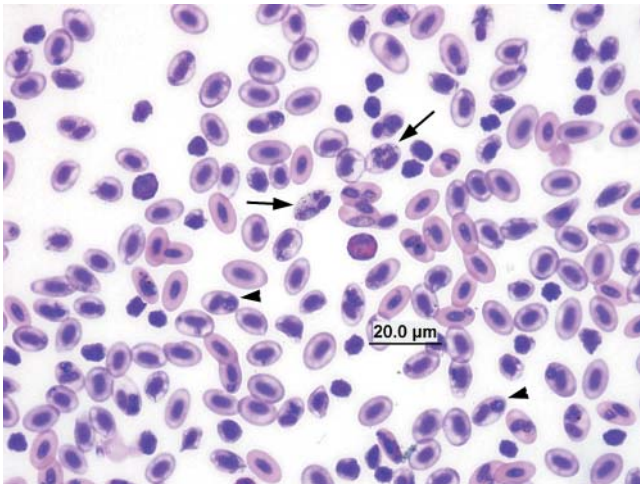

Figure 20.48 *Plasmodium* gametocytes (arrows) and schizogony (arrowhead) in the blood film of a skua (*Stercorarius skua*). Wright-Giemsa stain.

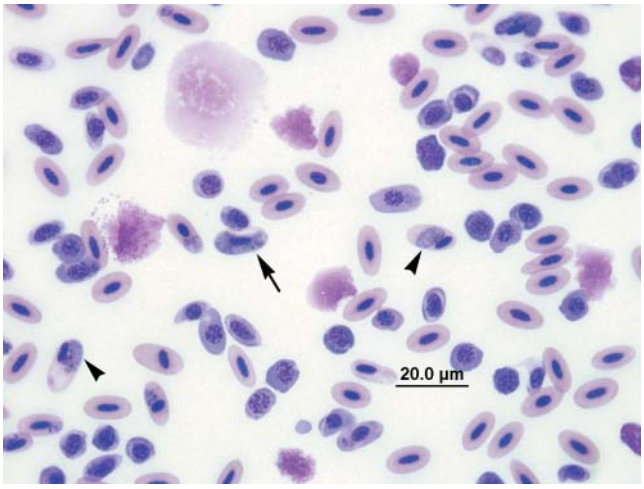

Figure 20.50 *Haemoproteus* gametocyte (arrow) and *Plasmodium* gametocytes (arrowheads) in the blood film of a kestrel (*Falco sparverius*) with marked polychromasia. Wright-Giemsa stain.

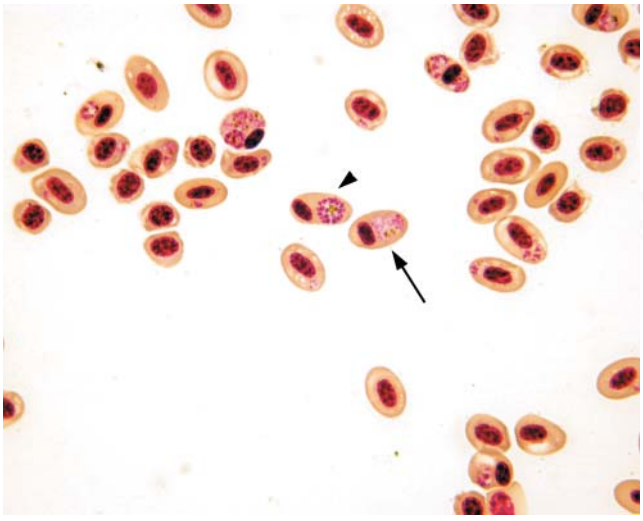

Figure 20.49 *Plasmodium* gametocytes (arrow) and schizogony (arrowhead) in the blood film of a skua (*Stercorarius skua*). Wright-Giemsa stain.

whereas other species have elongate gametocytes that do not displace the host-cell nucleus. Like those of *Haemoproteus*, *Plasmodium* gametocytes contain refractile, yellow to brown, iron pigment granules, which tend to be scattered, and macrogametocytes stain deeper blue than microgametocytes. *Plasmodium* trophozoites are small, round to oval, ameboid forms containing a large vacuole that pushes the parasite nucleus to one edge, thereby giving the trophozoite a "signet-ring" appearance. Schizonts are round to oval inclusions that contain several deeply staining merozoites; the number of merozoites is used to determine the *Plasmodium* species. Schizonts with developing merozoites exhibit clusters of merozoites that appear to be fused, which is in contrast to mature merozoites, which appear to be distinct bodies and separate from each other. Identification of the *Plasmodium* species depends on the location and appearance of the schizonts and gametocytes. The key features used to differentiate *Plasmodium* from *Haemoproteus* are the presence of schizogony in the peripheral blood, parasite stages within thrombocytes and leukocytes, and gametocytes causing marked displacement of the erythrocyte nucleus.

The organism is transmitted from infected to uninfected birds by mosquitoes (Culicidae) when, during feeding, sporozoites from the mosquito salivary glands invade host tissues and reproduce as schizonts to produce numerous merozoites. Unlike *Hemoproteus* spp., the merozoites of *Plasmodium* spp. penetrate erythrocytes, leukocytes, and thrombocytes and become ring-shaped trophozoites that mature into schizonts or infectious gametocytes. The schizonts rupture, killing the infected cells and releasing merozoites to infect more blood cells.

Leukocytozoon

Leukocytozoon, which is a protozoan parasite commonly found in the blood of wild birds, is identified by large, dark-staining macrogametocytes or light-staining microgametocytes on Romanowsky-stained blood films. The large gametocytes grossly distort the infected host cell, thereby elongating and distending the cell and making the identification of the cell difficult (Figure 20.51). The macrogametocyte appears as a parasite inclusion that occupies 77% of the area of the host cell-parasite complex. Microgametocytes are similar in morphology but are usually 5–10% smaller. Some parasitologists believe that immature erythrocytes rather than leukocytes, as suggested by the name of the parasite, serve as the host cell for *Leukocytozoon*. As with *Haemoproteus*, only the gametocytes of *Leukocytozoon* occur in the peripheral blood.

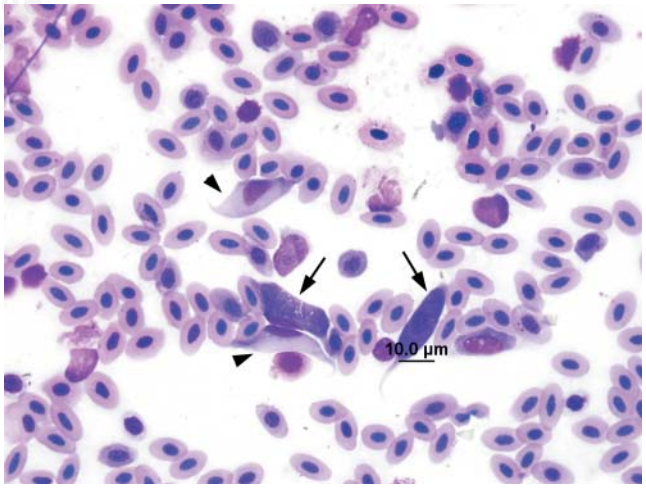

Figure 20.51 *Leukocytozoon* macrogametocytes (arrows) and microgametocytes (arrowheads) in the blood film of a hawk (*Buteo jamaicensis*). Wright-Giemsa stain.

Parasitized cells appear to have two nuclei: a dark-staining, host-cell nucleus that lies along the cell membrane, and a pale pink–staining, parasite nucleus that lies adjacent to the host-cell nucleus. *Leukocytozoon* gametocytes do not contain the refractile pigment granules seen in the gametocytes of *Haemoproteus* and *Plasmodium*. Appearance of the gametes in the peripheral blood can vary depending upon the species of *Leukocytozoon* present. For example, gametocytes *of Leukocytozoon sakharoffi*, the *Leukocytozoon* parasite of birds in the family Corvidae (crows, jays, and magpies), are round, and the host cell nucleus covers nearly 80% of the periphery of the parasite.

Leukocytozoon is transmitted by black flies (Simuliidae), which act as intermediate hosts and inject sporozoites into the blood of susceptible avian species. The sporozoites invade the endothelial and parenchymal cells of various tissues such as the liver, heart, and kidney, in which schizogony occurs. Primary schizogony typically occurs in the liver. When the schizonts mature they release thousands of merozoites, which then initiate a second generation of schizonts in the liver and in phagocytic cells throughout the body. The schizonts in phagocytic cells become very large and are called megaschizonts. The megaschizonts release millions of merozoites that can either initiate schizogony elsewhere or enter circulating erythrocytes (or perhaps leukocytes), where they develop into macrogametes or microgametes.

The pathogenicity of *Leukocytozoon* usually is low; however, certain species can be highly pathogenic for some birds, such as young waterfowl and turkeys. The clinical signs associated with this parasite include anemia, anorexia, and lelthargy. Clinical laboratory evaluation may reveal a hemolytic anemia, leukocytosis, and elevated serum enzymes such as aspartate aminotransferase or alanine aminotransferase, thereby suggesting hepatocellular necrosis. Postmortem findings may include splenomegaly and hepatomegaly with hepatic necrosis.

Microfilaria

Microfilaria are minute larvae of parasitic filarial nematodes measuring 5–7 µm in diameter and 200–300 µm in length that are commonly found in the peripheral blood of many species of birds. The adult filarial nematodes usually are not seen unless they occur in peripheral locations, such as in the fluid of distended joints. Adult filarial nematodes may occur anywhere within the body of birds, but they most frequently are seen in the air sacs, subcutaneously, or in the body cavities. Most of these parasites are considered to be nonpathogenic and cause little harm to their host.

Less common avian blood parasites

Other parasites that are seen less frequently in the peripheral blood of birds include *Atoxoplasma*, *Aegyptianella*, *Trypanosoma*, and *Borrelia*. *Atoxoplasma* is a coccidian parasite that often is found in passerine birds, which can be highly pathogenic, especially to canaries. It is transmitted directly via oocysts in the feces. Atoxoplasmosis is diagnosed on the basis of demonstrating characteristic sporozoites within the lymphocytes on peripheral blood films or cytologic imprints of the liver, spleen, or lung. The sporozoites appear as pale, eosinophilic, round to oval, intracytoplasmic inclusions within lymphocytes, monocytes, or macrophages in Romanowsky-stained preparations (Figure 20.52). The sporozoites indent the host lymphocyte nucleus, thereby resulting in a characteristic crescent shape. Sporozoites of *Atoxoplasma* lack pigment granules. Detection of *Atoxoplasma* in the peripheral blood can be improved by using a preparation of a buffy-coat film to concentrate the leukocytes for examination.

Aegyptianella is a minute parasite of avian erythrocytes that lacks pigment granules. It is a piroplasma that can affect

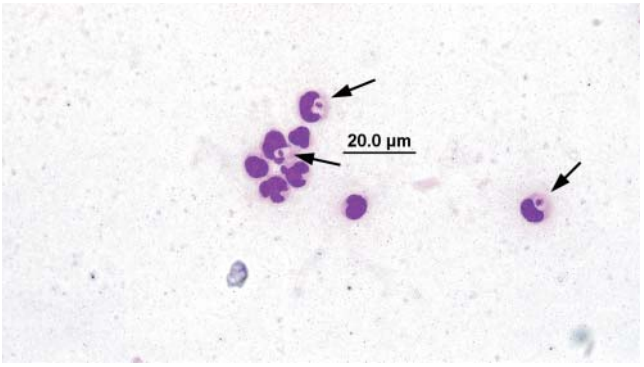

Figure 20.52 *Atoxoplasma* inclusions within lymphocytes from a buffy coat film of a thrush (*Garrulax chinensis*). Wright-Giemsa stain.

several avian species, usually those originating in tropical or subtropical climates. *Aegyptianella pullorum* occurs in chickens, geese, ducks, and turkeys. The organism is detected by demonstrating the developing forms within erythrocytes in blood films. Three forms can occur. One form, the initial body, is a small structure that is less than 1 mm in diameter and appears as a round, basophilic, intracytoplasmic inclusion similar to *Anaplasma marginale*. A second form is a round- to piriform-shaped inclusion with pale blue cytoplasm and a chromatin body at one pole resembling *Babesia*. The third form is a larger (2–4 µm), round to elliptical inclusion. *Aegyptianella* can be pathogenic, resulting in anemia, anorexia, and diarrhea. Postmortem findings include splenomegaly, hepatomegaly, and hepatic as well as renal degeneration.

Trypanosomes (*Trypanosoma*) occasionally are found in the peripheral blood of wild birds, especially passerines, Galliformes, waterfowl, and pigeons. They are transmitted by biting insects such as mosquitoes, hippoboscid flies, and blackflies or mites. Avian trypanosomes resemble those found in mammals. They have an undulating membrane, a slender, tapering posterior end, and a short, anteriorly directed flagellum. Trypanosomes usually are considered to be an incidental finding.

Borrelia anserina is the causative agent of avian spirochetosis, which can affect several species of birds, especially Galliformes and waterfowl. It is transmitted by arthropod vectors such as ticks and mites. *Borrelia* is a loosely spiraled spirochete that tapers into fine filaments and is found free in the plasma. During the acute stages of the disease, the organism is spiral shaped; however, as the disease progresses and the bird nears death, the organism may appear abnormal or clumped and often is difficult to find. In acute avian spirochetosis, affected birds are lethargic, anemic, and weak. Postmortem findings include splenomegaly and hepatomegaly. Birds recovering from the disease exhibit a regenerative anemia.

Hematopoiesis

Bone marrow

The bone marrow is the primary site for erythropoiesis, granulopoiesis, and thrombopoiesis during late embryonic development and hatched birds. In some adult birds, such as chickens, the hematopoietic activity of the bone marrow primarily is associated with erythropoiesis and, possibly, thrombopoiesis, with only a small reserve of granulopoiesis compared to that of mammalian bone marrow. Therefore, compared with mammals, granulopoiesis in mature birds is more diffuse and is found in a variety of tissues. During embryonic development, granulocyte stem cells colonize to create foci of granulopoiesis in the spleen, kidney, lungs, thymus, gonad, pancreas, and other tissues, including the bone marrow. The bone marrow also provides an environment for lymphocyte maturation. Because it is the most readily available source of hematopoietic tissue in birds, the bone marrow is used to evaluate disorders of blood cells. Cytologic evaluation of the bone marrow is indicated in avian patients with nonregenerative anemia, heteropenia, and other unexplained alterations involving the cellular elements in circulating blood.

Bone marrow collection

Marrow samples for cytologic evaluation can be successfully obtained in most avian species via bone marrow aspiration. The best source of bone marrow for most birds is the proximal tibiotarsus because the procedure at this location is relatively simple. Marrow may also be collected from the sternum (keel), however, and from most of the long bones, except the pneumatic bones. A general anesthetic usually is not required, but a local anesthetic can be used with caution in large birds. The type of biopsy needle used for aspiration depends on the size of the bird, location of the biopsy site, and preference of the cytologist. Biopsy needles commonly used for bone marrow collection in both domestic mammals and humans (Jamshidi bone marrow biopsy–aspiration needles and disposable Jamshidi Illinois-Sternal/Iliac aspiration needles, Kormed Corp., Minneapolis, MN) can be used for marrow collection in birds. The pediatric sizes are preferred, however, because of the relatively small bone size in most birds compared with mammals. Spinal needles containing a stylet can be used for marrow collection in very small birds.

The procedure for collecting bone marrow from the proximal tibiotarsus begins with application of a skin disinfectant, as for any surgical procedure. The medial or cranial aspect of the proximal tibiotarsus just below the femoral-tibiotarsal joint is a suitable location for aspiration because only a minimal amount of soft tissue overlies the bone in this area. After application of a local anesthetic, a small incision is made using a scalpel blade to facilitate passage of the needle through the skin. The needle with stylet is placed against the bone (Figure 20.53), and using gentle pressure and rotary movements, the needle then is advanced into the marrow cavity. A perpendicular approach to the bone should be used. The hand not being used to manipulate the needle is used to stabilize the tibiotarsus. Once the needle is positioned into the marrow cavity, the stylet is removed, and a 6–12 mL syringe is attached (Figure 20.54). Marrow is aspirated into the lumen of the needle by applying negative pressure to the syringe using the syringe plunger (Figure 20.55). Excessive or prolonged negative pressure should be avoided to minimize blood contamination of the marrow sample. Unlike collection of bone marrow from most mammals, avian marrow should not appear in the syringe (except in very large birds) because of the small marrow volume in

Figure 20.53 Placement of a spinal needle in the proximal tibiotarsus of a pigeon (*Columba livia*).

Figure 20.55 Aspiration of a bone marrow sample from a spinal needle placed in the proximal tibiotarsus of a pigeon (*Columba livia*).

Figure 20.54 Removal of the stylet from a spinal needle placed in the proximal tibiotarsus of a pigeon (*Columba livia*).

most birds. Therefore, the marrow sample is found in the lumen of the biopsy needle.

When aspiration is completed, the needle and syringe are removed from the tibiotarsus while making sure that negative pressure is not being applied to the syringe. The needle is removed from the syringe, and the syringe is filled with air to force the marrow from the lumen onto a glass microscope slide. A second glass microscope slide is placed atop of the marrow sample, and the marrow is allowed to spread between the two slides as they are pulled apart. Bone marrow samples also can be obtained from the keel (sternum) of some birds, such as Galliformes; the biopsy needle is introduced into the widest part of the sternal ridge in the manner as described for the proximal tibiotarsus.

Marrow core biopsies for histologic evaluation can be obtained from birds using a technique similar to that of marrow aspiration. Once the biopsy needle is introduced into the bone marrow space, the stylet is removed, and the needle is advanced deeper into the marrow cavity, toward the opposite cortex. Once the opposite cortex has been reached, the needle is twisted and redirected slightly to detach the marrow plug within the lumen of the needle. Gentle vacuum may be applied to the syringe to aid in holding the marrow plug in the needle as the needle is withdrawn from the marrow cavity. The marrow core sample is removed by reinsertion of the stylet (usually beginning at the tip of the needle) to push the sample out of the needle. Imprint films can be made from the core sample for cytologic evaluation before the sample is placed in 10% neutral-buffered formalin. A sample holder often is required to maintain the marrow core while it is being fixed in the formalin solution.

Examination of avian bone marrow

Bone marrow slides are stained with the same Romanowsky stains used for blood films. Interpretation of avian bone marrow begins with scanning of the marrow film using the 10× microscope objective to evaluate both the number and the distribution of cells. Because an actual cell count of a bone marrow sample cannot be obtained, the cellularity is estimated by evaluating the ratio of fat and cells in marrow particles and is compared with the cellularity of normal bone marrow. The degree of cellularity is estimated as poor, normal, or high.

The distribution of cells can be estimated as well. Myeloid, erythroid, and thrombocytic elements may appear to be normal, hypoplastic (decreased), or hyperplastic (increased). A more objective approach is to perform an actual differential count based on 1000 cells or more, but this is more time-consuming and may not provide more information.

In addition to estimating the degree of cellularity and evaluating the distribution of cell types in the marrow sample, the cytologist also should estimate the myeloid: erythroid (M : E) ratio. Any changes involving the maturation sequence of each cell line should be noted as well. The cell lines include erythrocytes, granulocytes (heterophils, eosinophils, and basophils), monocytes, and thrombocytes. Other cells that occasionally are found include lymphocytes, plasma cells, osteoblasts, and osteoclasts. The presence of abnormal cells also should be noted.

The normal M : E ratio varies with species; however, the ratio in most species is approximately 1.0. For example, the M : E ratio is 1.23 ± 0.17 in. blackheaded gulls (*Larus ridibundus*) where the mean percentage of erythroid cells is 39.91 ± 3.26%; of myeloid cells is 49.37 ± 4.86%; of thrombocyte precursors is 5.95 ± 0.79%; and all other cells is 4.77 ± 0.53%.

An accurate interpretation of the bone marrow response can be made only in conjunction with knowledge regarding the current peripheral blood cellular response. Therefore, a hemogram from a blood sample collected at the same time as the bone marrow sample should be evaluated.

Erythropoiesis

Avian erythropoiesis occurs within the lumen of the vascular sinusoids in the bone marrow. These sinuses are lined by elongated endothelial cells that are associated with the most immature cells of the erythroid series. The more mature cells are located in the lumen of the sinuses. The vascular sinuses communicate with a central vein.

Avian erythropoietin, which is a glycoprotein that differs structurally from mammalian erythropoietin, is necessary for the multiplication and differentiation of precursor stem cells committed to the erythroid series. Erythropoietin can be collected from the blood of anemic birds, and the site of its production is considered to be the kidney.

The stages of maturation in normal avian erythropoiesis appear to be similar to those of mammals. The terminology used for the different stages of erythrocyte maturation, however, varies in the literature. In general, seven stages are recognizable in red blood cell development based on findings with Romanowsky stains. These include rubriblasts (proerythroblasts), prorubricytes (basophilic erythroblasts), basophilic rubricytes (early polychromatic erythroblasts), early polychromatic rubricytes (late polychromatic erythroblasts), late polychromatic rubricytes (orthochromic erythroblasts), polychromatic erythrocytes, and mature erythrocytes. As erythroid cells mature, the nuclear size decreases, the chromatin becomes increasingly condensed, the nuclear shape changes from round to ellipsoid, the amount of cytoplasm increases, the hemoglobin concentration increases (resulting in increasing eosinophilia), and the cell shape changes from round to ellipsoid. Unlike mammalian erythrocytes, avian erythrocytes normally retain their nucleus.

Rubriblasts

Rubriblasts are large, round, deeply basophilic cells with a large, round, central nucleus that results in a high N : C ratio (Figures 20.56–20.58 and 20.60). The nuclear chromatin typically is coarsely granular, and large, prominent nucleoli or nucleolar rings are present. The cytoplasm is deeply basophilic, with clear spaces most likely representing mitochondria.

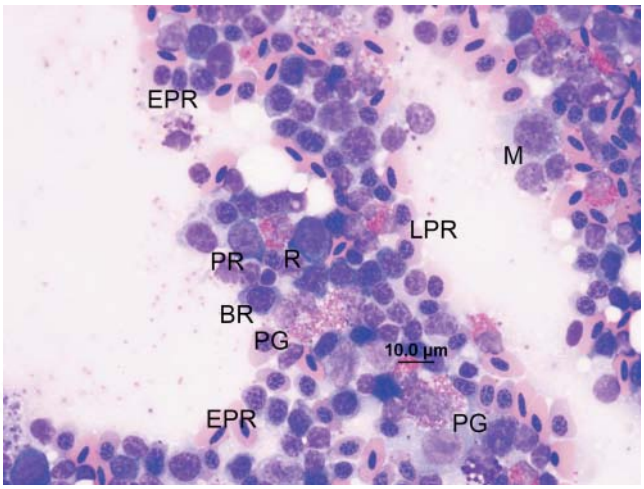

Figure 20.56 A rubriblast (R), prorubricyte (PR), basophilic rubricyte (BR), early polychromatic rubricytes (EPR), late polychromatic rubricyte (LPR), myeloblast (M), and progranulocyte (PG) in the bone marrow aspirate of a conure (*Aratinga solstitialis*). Wright-Giemsa stain.

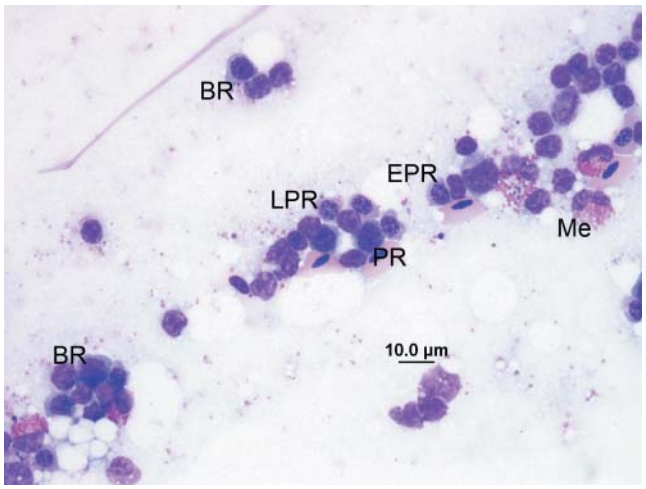

Figure 20.59 A prorubricyte (PR), basophilic rubricytes (BR), early polychromatic rubricyte (EPR), late polychromatic rubricyte (LPR), and metamyelocyte (Me) in the bone marrow aspirate of a conure (*Aratinga solstitialis*). Wright-Giemsa stain.

Prorubricyte

The prorubricyte resembles the rubriblast, but it lacks the prominent nucleoli (Figures 20.56 and 20.59). The N : C ratio is high, and the large nucleus usually is surrounded by a narrow rim of blue cytoplasm. The cytoplasm is predominantly basophilic but may contain spots of reddish material, suggesting the beginning of hemoglobin development. The cytoplasm lacks the mitochondrial spaces of the rubriblast.

Rubricyte

Rubricytes are round cells that are smaller than rubriblasts and prorubricytes. They can be divided into three stages, based primarily on the appearance of the cytoplasm. The basophilic rubricyte is the earliest rubricyte stage and is characterized by a homogenous, basophilic cytoplasm and a round nucleus with clumped chromatin (Figures 20.56–20.59). The next stage, the early polychromatophilic rubricyte, is smaller than the basophilic rubricyte and has a gray (basophilic to slightly eosinophilic) cytoplasm because of increased hemoglobin production (Figures 20.56–20.59). The nucleus of early polychromatophilic rubricytes contains clumped chromatin and is small in relation to the amount of cytoplasm. The final rubricyte stage, the late polychromatophilic rubricyte, is ellipsoid and has more eosinophilic (eosinophilic gray to weakly eosinophilic) cytoplasm than earlier stages (Figures 20.56–20.59). The nucleus of late polychromatophilic rubricytes varies from round to slightly ellipsoid, with irregularly clumped chromatin.

Polychromatophilic erythrocytes and mature erythrocytes

Cells in the final stages of erythropoiesis are the polychromatophilic erythrocyte and the mature erythrocyte. These cells are found in the peripheral blood of normal birds and were described earlier. The mature erythrocyte has a flattened, ellipsoid shape. The nuclear chromatin is condensed and transcriptionally inactive.

Granulopoiesis

Avian granulocytes appear to develop in a manner similar to those of mammals. The maturation stages have been described based on their morphologic appearance, primarily in chicken bone marrow. Thus, the study of avian hematopoiesis lags behind research in mammalian hematopoiesis, in which morphologic criteria are only

part of the overall evaluation. Avian granulocytes show a progressive decrease in size and cytoplasmic basophilia as they mature, which is similar to the granulocytes of mammals. Specific cytoplasmic granules appear during the later stages of development and then progressively increase in number, until a full complement is reached in the cytoplasm of the mature granulocyte. The nuclei of granulocytes initially are round and progress toward segmentation, except for basophils, which do not segment, and the nuclear chromatin becomes increasingly condensed with maturity. The developmental stages of avian granulocytes include, in order of maturation, myeloblasts (granuloblasts), progranulocytes (promyelocytes), myelocytes, metamyelocytes, band cells, and mature granulocytes.

Myeloblasts

Avian myeloblasts are large, round cells with a high N : C ratio (Figures 20.56, 20.58, 20.60, and 20.61). The cytoplasm stains a lighter blue than that of rubriblasts. Myeloblast nuclei typically are round, with delicate reticular (fine) chromatin and prominent nucleoli. Myeloblasts do not contain specific cytoplasmic granules and, possibly, represent a stage that is common to all granulocytes. Myeloblasts frequently are associated with other developing granulocytes, especially on imprints of bone marrow core biopsy specimens.

Progranulocytes

Avian progranulocytes are large cells with light blue cytoplasm and slightly eccentric nuclei (Figures 20.56 and 20.60). The N : C ratio is lower than that of myeloblasts because of an increase in cytoplasm. The nuclear chromatin often has a delicate reticular pattern. Nucleoli are absent, and nuclear margins may be indistinct. Progranulocytes contain primary granules that vary in appearance among the types of granulocytes. Heterophil progranulocytes contain primary granules that vary in color and shape. They often appear as orange spheres and rings or as deeply basophilic spheres and rings. Eosinophil progranulocytes contain only brightly staining, orange, primary granules, and they appear to lack the dark magenta granules and rings found in heterophil progranulocytes. Basophil progranulocytes contain basophilic granules that appear to be smaller than the specific basophilic granules and the immature granules of the heterophil series. Fewer ring forms are seen in basophil progranulocytes.

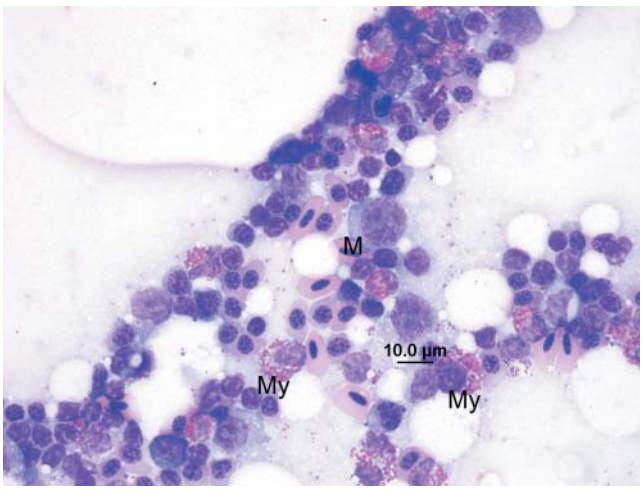

Figure 20.61 A myeloblast (M) and myelocytes (My) in the bone marrow aspirate of a conure (*Aratinga solstitialis*). Wright-Giemsa stain.

Myelocytes

Myelocytes are smaller than myeloblasts and progranulocytes, and they contain the secondary or specific granules of the mature granulocytes, thereby making identification of this cell somewhat simple (Figures 20.60 and 20.61). The round to oval nucleus of the myelocyte appears to be more condensed than the nuclei of myeloblasts and progranulocytes. Heterophil myelocytes typically are round cells, with a light blue cytoplasm that contains a mixture of rod-shaped specific granules and primary granules and rings. The eosinophilic, rod-shaped specific granules occupy less than half the cytoplasmic volume. Eosinophil myelocytes lack the deeply basophilic granules and rings that occasionally are found in early heterophil myelocytes. Basophil myelocytes contain basophilic specific granules that occupy less than half the cytoplasmic volume. The specific basophil granules have a slightly eosinophilic tinge, compared with the deep violet of the smaller primary granules that also may be present.

Metamyelocytes

Metamyelocytes are slightly smaller than myelocytes, have slightly indented nuclei, and possess specific cytoplasmic granules that occupy greater than half the cytoplasmic volume (Figure 20.59). Heterophil and basophil metamyelocytes have fewer primary granules than myelocytes and progranulocytes.

Band cells and mature granulocytes

Band cells resemble mature granulocytes, except that the nucleus appears as a curved or coiled band rather than segmented. Identifying band cells often is difficult, because the exact shape of the nucleus is obscured by specific cytoplasmic granules. A specific nuclear stain such as hematoxylin usually is required to determine the concentration of band cells. Because mature basophils lack a segmented nucleus, the band stage of basophils is not apparent. Mature granulocytes generally are the most abundant cell of each granulocytic cell line in the bone marrow of normal birds and were described earlier.

Thrombocytes

Avian thrombocytes appear to derive from a distinct line of mononuclear cells in the bone marrow, unlike mammalian

platelets, which are cytoplasmic fragments of large, multinucleated megakaryocytes. The thrombocyte series consists of thromboblasts, immature thrombocytes, and mature thrombocytes. Thromboblasts resemble rubriblasts, but they tend to be smaller, with round nuclei having fine to punctate nuclear chromatin and one or more nucleoli. The cytoplasm is scant, stains deeply basophilic, and may contain clear spaces. They tend to be round to oval, with cytoplasmic blebs.

Immature thrombocytes are divided into three groups – early, mid, and late immature thrombocytes – based on their degree of maturity (Figure 20.43). Early immature thrombocytes are intermediate in size between thromboblasts and more mature stages. They tend to be round to oval and have more abundant cytoplasm than thromboblasts. The cytoplasm is basophilic and may contain vacuoles. The nuclear chromatin is aggregated into irregular clumps. Mid immature thrombocytes are slightly elongate or irregular, with pale blue cytoplasm. Cytoplasmic dense granules and vacuoles occasionally are seen at this stage of development. The nucleus contains heavy chromatin clumping. Late immature thrombocytes are oval and slightly smaller than the mid immature stage. The cytoplasm stains pale blue, with vaguely defined, clear areas. Dense granules frequently are seen at one pole of the cell. The nucleus is oval and has densely packed chromatin. The mature thrombocyte is the definitive cell in the thrombocyte series and was described earlier.

Other cells in avian bone marrow

Monocytes and macrophages

Monocytopoiesis is poorly defined in birds. Granulocytic precursor cells may be similar to, or even the same as, monocytic precursor cells. Monocytes originating in hematopoietic tissues become the monocytes and macrophages found in blood and body tissues, respectively. A variety of tissues, notably bone marrow, embryonic yolk sac, and spleen, can produce macrophage colonies. Mature monocytes are described in the discussion of leukocytes. Macrophages within the bone marrow are involved with iron metabolism during hemoglobin synthesis and catabolism and may contain red cell breakdown products such as hemosiderin or hematoidin in their cytoplasm. Hemosiderin contains iron and may appear as gray to black granulation; hematoidin lacks iron and is a golden, crystalline material.

Lymphocytes

Aggregates of lymphocytes are found within the bone marrow of birds, although major sites of lymphopoiesis in adult birds are located in the spleen, liver, intestines, and cecal tonsils. Avian lymphocytes can be classified as B lymphocytes (providing humoral immunity) or T lymphocytes (responsible for cell mediated immunity), but these two cell types usually cannot be differentiated based on morphology alone. B lymphocytes differentiate in the bursa of Fabricius, and T lymphocytes differentiate in the thymus.

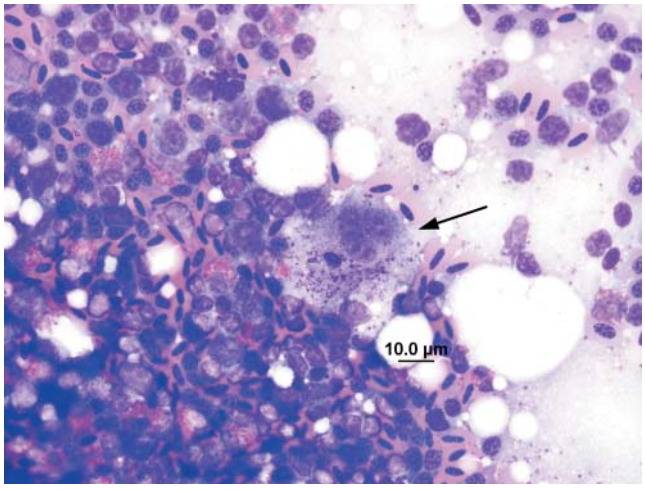

Figure 20.62 An osteoclast (arrow) in the bone marrow aspirate of a conure (*Aratinga solstitialis*). Wright-Giemsa stain.

Immature avian lymphocytes are larger than mature lymphocytes, and they are classified as either lymphoblasts or prolymphocytes based on morphology. Lymphoblasts have large nuclei with fine chromatin, and they contain one or more prominent nucleoli. The cytoplasm is relatively abundant and deeply basophilic. Prolymphocytes resemble lymphoblasts, but their nuclear chromatin is coarser and nucleoli are not present. Mature lymphocytes have coarse chromatin that typically is clumped. Cytoplasm is scant and stains light blue.

Osteoblasts

Avian osteoblasts are large cells found in the bone marrow that resemble those of mammals. They have abundant, lightly basophilic cytoplasm with a distinct, clear Golgi apparatus. The nucleus is round to oval and eccentrically located in the cell, contains reticular to coarsely granular chromatin, and possesses one or more distinct nucleoli. Osteoblasts are polygonal to fusiform, and they may have indistinct cytoplasmic margins.

Osteoclasts

Osteoclasts are large, multinucleated, giant cells with an ameboid shape (Figure 20.62). The cytoplasm is weakly basophilic and vacuolated, and red cytoplasmic granules may be present. Nuclei are round to oval and often contain prominent nucleoli.

Hematopoietic tissues other than bone marrow

Bursa of Fabricius

Based on research using domestic chicken and quail embryos, lymphoid cells first appear in the developing bursa of the

13–15-day embryo. Granulopoiesis also occurs in the developing bursa of the 12–13-day chicken embryo, but it disappears either at or just before hatching. The bursa reaches its maximum growth around 4 weeks after hatching then gradually undergoes involution during a 2–3-month period.

During development, the bursa contains numerous deeply basophilic, lymphoid precursor cells. Lymphoid precursors reach a maximum number in the 13–25-day embryo and then decline as lymphoid differentiation progresses. Lymphoid precursors may originate from an external source, such as the yolk sac or bone marrow. Seeding of the bursa with lymphoid precursor cells appears to occur in the 7–14-day embryo, depending on the species. Thus, the sole source of B lymphocytes in the adult bird are the self-regenerating aggregates of B lymphocytes that originated in the bursa and then spread to the spleen, liver, intestines, and cecal tonsils.

Thymus

The thymus is organized into a cortex consisting of densely packed lymphoid cells and a medulla. Lymphoid precursors originating from the yolk sac or bone marrow begin to colonize the thymus during the first 4–8 days of development, depending on the species. The influx of lymphoid precursors appears to last from 24 to 36 hours and then ends abruptly. The invasion of the thymus by precursors is followed by a 4–5-day refractory period before another influx occurs. This cyclic colonization of the thymus by lymphoid stem cells consists of two to three colonization periods, which may extend into the posthatchling period, depending on the species. This contrasts with colonization of the bursa, which occurs during a distinct, single episode in the embryo before hatching. T lymphocytes acquire their T antigen during a 24-hour period of development around the time of the second wave of colonization, between days 12–15 of embryonic life. T lymphocytes originating in the thymus spread to the spleen, liver, intestines, and cecal tonsils, and they are the predominant lymphoid cells of the spleen and peripheral blood of hatched birds.

Spleen

T and B lymphocytes appear at different locations in the white pulp of the spleen. The central arteries of the white pulp are surrounded by a periarteriolar lymphoid sheath, which is composed of densely packed T lymphocytes. Capillaries branching at right angles from the central arteries are surrounded by periellipsoid lymphoid tissue consisting of B lymphocytes. B lymphocytes also are found at the germinal centers located within the periarteriolar lymphoid sheath. During embryonic development, the spleen participates in erythropoiesis and granulopoiesis. Granulopoiesis becomes more predominant as the embryo matures. At hatching, however, the granulocytes begin to disappear, and by 3 days, they are replaced by lymphocytes.

21 Hematology of Reptiles

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado, USA

Evaluation of the hemogram and blood film is part of the laboratory evaluation of reptilian patients. Hematology is used to detect conditions such as anemia, inflammatory diseases, parasitemias, hematopoietic disorders, and hemostatic alterations. Hematologic evaluation involves examination of the erythrocytes, leukocytes, and thrombocytes in the peripheral blood.

When evaluating the hematologic responses of reptiles, external factors such as environmental conditions that may enhance or inhibit the animal's response to disease should not be overlooked. The cellular responses in the blood of reptiles are less predictable than those in the blood of endothermic mammals and birds whose cellular microenvironments are more stable. A number of intrinsic factors, such as age and gender, also affect the hematologic data from reptiles. In addition, a number of sample-handling factors, such as the site of blood collection, type of anticoagulant used, method of cell counting, and type of stain used, add to the variability of reptilian hemogram values. All of these factors complicate the establishment of normal reference values in reptiles. Therefore, total and differential leukocyte counts must differ greatly (i.e., twofold or greater increase or decrease) from normal reference values to be considered significant.

Blood collection and handling

Blood samples for hematologic and blood biochemical studies can be collected from reptiles using a variety of methods, with the choice depending on the peculiarities of the species, volume of blood needed, size of the reptile, physical condition of the patient, and preference of the collector. The site of blood sample collection will influence the hematologic values because lymphatic vessels often accompany blood vessels in reptiles; frequently a mixture of blood and lymph occurs with venipuncture of peripheral vessels. Lymph often appears as transparent fluid entering the syringe immediately prior to the appearance of blood. If this occurs, discard the syringe and attempt sample collection again. The quantity of lymphatic fluid that mixes with the blood sample is variable and will dilute the cellular components of the blood, resulting in lower packed cell volume (PCV), hemoglobin concentration (Hb), erythrocyte count (TRBC), and leukocyte count (TWBC).

The use of a general anesthetic may be required as a method of restraint for blood collection in some reptiles, such as chelonians that can hide within their carapace and plastron. A number of published chemical protocols are available that can be used for the sedation and anesthesia of reptiles. Ketamine hydrochloride used alone or in combination with xylazine or midazolam are commonly used anesthetics for this purpose. It has been shown that anesthesia with ketamine does not affect the hemogram in some reptiles.

Jugular venipuncture can be used to collect blood from reptiles, especially chelonians (turtles and tortoises), and is the preferred site of blood collection by some authors (Figure 21.1). Jugular venipuncture is a useful method for obtaining blood samples from large lizards, such as green iguanas (*Iguana iguana*) and monitor lizards (*Varanus* spp.). Blood collection via jugular venipuncture is recommended in some species of reptiles, e.g., chameleons, to minimize unwanted effects, such as skin darkening, which occurs with blood collection from other sites. One advantage of jugular venipuncture is that the chances of sample hemodilution with lymphatic fluid are minimized owing to the size of the vessels.

The jugular vein of certain species of tortoises (e.g., desert tortoise, *Gopherus agassizii*) may be visible; however, this vein is rarely visible in most species. Some species of chelonians have dorsal and ventral jugular veins that lie on either side of a large cervical lymphatic vessel (superficial jugular trunk), and the right jugular vein may be larger than the left in some species of reptile. Chelonians may be restrained by an assistant with the head and neck extended to expose the lateral

Figure 21.1 Blood collection by jugular venipuncture in a turtle (*Terrapene carolina*) using ultrasound to find the vein.

aspect of the neck. Chemical restraint may be required to aid in sample collection in some chelonians. The jugular vein (or veins) course caudally in a line extending from the angle of the mandible to the cranial carapacial inlet. The dorsal jugular vein extends from the dorsal edge of the tympanic membrane to the carapacial inlet when present. The jugular veins are relatively superficial; deep insertion of a needle may result in sample collection from the carotid artery.

The jugular vein of lizards lies deep along the lateral aspect of the neck. The vein is rarely visible and is approached blindly by directing the needle caudally along a line that runs behind the tympanum along the stretched neck of the lizard held in lateral recumbency. The right jugular vein is generally larger than the left, which is an aid to blood collection.

The supravertebral sinus (dorsal cervical venous, postoccipital, or occipital sinus) is a common location for obtaining blood samples in sea turtles. With the neck extended and the head held downward slightly, the sinus can be located just lateral to the cervical vertebrae. The sinus is approached by inserting the needle into the neck at a location one-third the distance from the base of the head to the carapace and one-third the distance from the dorsal midline to the lateral edge of the neck (Figure 21.2). This site can also be used for blood collection in freshwater turtles. A 20–22-gauge, 1–1 1/2 in. needle is inserted at a 30° angle, and the blood sample is collected with a syringe or evacuated tube. While the head is restrained, the needle is inserted just lateral to the dorsal midline on the right side of the neck.

The supravertebral vein is commonly used for blood collection in large crocodilians. The needle used for blood collection is inserted just behind the nuchal crest or occiput on the dorsal midline. Slight negative pressure is applied to the syringe as the needle is advanced until the sinus is entered. Spinal trauma is possible if the needle is inserted too deeply.

Figure 21.2 Blood collection from the supravertebral sinus (dorsal postoccipital vein) of a turtle (*Chelonia mydas*).

A dorsal vertebral blood vessel can be used to obtain a blood sample from large boid snakes (boas and pythons). With the back of the snake held in a tight flexed position, a needle is inserted between the vertebrae while negative pressure is applied to the syringe as the needle advances (Figure 21.3). Once blood enters the syringe, advancement of the needle is stopped and blood is collected into the syringe.

Figure 21.3 Blood collection from the dorsal vertebral vessels of a snake (*Boa constrictor*). Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 174.

Figure 21.4 Blood collection from the dorsal coccygeal venous sinus (dorsal coccygeal vein) of a turtle (*Trachemys scripta elegans*). Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 175.

Figure 21.5 Blood collection by venipuncture of the ventral coccygeal vein in the tail of a lizard (*Heloderma suspectum*) using the ventral approach.

A dorsal coccygeal venous sinus (dorsal coccygeal vein) is present in many species of chelonians and is located on the dorsal midline of the tail. Blood collected from this site is often diluted with lymph. Venipuncture requires an assistant to restrain the chelonian. Insert a 22–25-gauge needle attached to a 1–3 mL syringe on the dorsal midline at the base of the tail at a 30°–60° angle (Figure 21.4).

The ventral coccygeal vein (ventral caudal or tail vein) lies just ventral to the caudal vertebrae and is a common site for blood collection in reptiles, especially lizards, large snakes, and crocodilians. Blood samples may be collected using a 22–23-gauge, 1 in. needle inserted under a ventral scale on the ventral midline and directed toward the vertebrae (Figure 21.5). The location of the needle insertion should be some distance caudal to the vent (e.g., 25–50% of the distance from the vent to the tip of the tail in snakes) to avoid the hemipenes of males or musk glands of snakes. Slight negative pressure should be applied to the syringe as the needle is advanced. If the needle contacts bone (a vertebra) before blood enters the needle, withdraw the needle slowly and change the direction of the needle (either cranially, caudally, left, or right) until blood flows into the syringe. Lizards can be restrained for this procedure by holding them vertically, by allowing them to cling to a cage door, or by allowing the lizard to sit on a table with the tail extending over the edge. These methods of restraint are better tolerated by the reptile compared to restraining them in dorsal recumbency. A lateral approach can also be used, especially in lizards and crocodilians, by inserting the needle along the middle of the lateral aspect of the tail in an area where a natural groove or line created by muscles in the tail occurs (Figure 21.6). The needle tip should be placed just beneath the caudal vertebra and into the vein. Crocodilians

Figure 21.6 Blood collection by venipuncture of the ventral coccygeal vein in the tail of a lizard (*Iguana iguana*) using the lateral approach. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 175.

may be restrained on a tabletop, and either the ventral or lateral approach may be used. It should be noted that some lizards have tail autotomy (the ability to quickly shed the tail, usually as a defensive mechanism); therefore, part of the tail could be lost during the mishandling of these lizards for blood collection.

The subcarapacial (subvertebral) venous sinus may be used for blood collection in chelonians. The subcarapacial venous sinus is located caudal to the nuchal scute at the level of the eighth cervical vertebra and is made up of a collection of blood vessels (internal jugular vein, anterior pulmonic vein and artery, vertebral veins and arteries, and

Figure 21.7 Blood collection from the subcarapacial (subvertebral) venous sinus in a turtle (*Trachemys scripta elegans*) with the head pushed into the shell.

Figure 21.8 Blood collection by cardiocentesis of a snake (*Boa constrictor*).

subclavian veins and arteries) and lymphatic vessels. Blood collected from this site may not be adequate for hematologic evaluation because marked dilution with lymphatic fluid may occur. For sample collection, insert a needle dorsal to the neck at the carapacial inlet and angle it up toward the ventral aspect of the carapace (Figure 21.7). This can be performed with the head and neck extended or retracted. If the needle touches bone (either a vertebra or the carapace) before blood enters the syringe, withdraw the needle slightly and redirect it caudally. The major lymphatic vessels are located cranial to the venous sinus; therefore, subsequent attempts at sample collection should be made caudal to the site of the first attempt.

Blood may be collected from the ulnar (radiohumeral) venous sinus of reptiles. Blood is collected by extending the front leg of the reptile and inserting a needle at a perpendicular angle to the body behind the tendon that lies on the caudal aspect of the radiohumeral joint. Advance the needle toward the radiohumeral joint while applying gentle pressure to the attached syringe.

Cardiocentesis is commonly performed for blood collection from snakes. The exact location of the heart varies depending on the species but in general lies in the cranial one-third of the body. With the snake held in dorsal recumbency, the heart is located by palpation, by observing the movement of the ventral scutes for heartbeats, or by use of a Doppler. The heart can move cranially and caudally and should be stabilized at the apex and base during sample collection. A 22–23-gauge needle attached to a 3–6 cc syringe needle is inserted under (not through) the scute and advanced into the heart (Figure 21.8). The syringe typically fills slowly as the heart pulsates. Sedation of the snake prior to cardiocentesis is recommended to avoid excessive movement and possible cardiac trauma.

Cardiocentesis may be performed in other reptile species as well. Cardiocentesis of chelonians is performed by passing a needle through the plastron on the ventral midline at the junction of the humeral and pectoral scutes. A needle can be passed through the soft plastron of soft-shelled turtles (*Trionyx* spp.), neonates, or those affected by secondary nutritional hyperparathyroidism. Otherwise, an access hole may be drilled through the plastron with an 18–20-gauge needle in small chelonians; a sterile drill bit may be required for larger chelonians. Following sample collection, the hole should be sealed with an epoxy. If multiple samples are required, a larger hole can be drilled through the plastron and plugged with a rubber stopper from a blood collection tube. The rubber stopper must then be sealed in position with epoxy, and it serves as an access port to the heart for blood collection. Cardiocentesis is not recommended for routine blood collection from lizard species.

Other, less commonly used blood collection sites include the brachial vein or artery, the palatine-pterygoid vein, the ventral abdominal vein, and toenails. Blood collection from the brachial vein or artery is a blind approach and may be attempted in chelonians or lizards. Samples obtained by this method are often diluted with lymph, although blood collected from this site in tortoises may be more reliable for hematologic study than blood collected from the dorsal coccygeal. Blood can be collected from the palatine-pterygoid veins in the oral cavity of medium- to large-sized snakes but will require general anesthesia or an extremely cooperative patient. These veins are fragile and easily lacerated. Blood can be collected by syringe or by allowing the blood to flow from the needle hub into a microcollection tube. Lizards have a large ventral abdominal vein present on the ventral midline of the abdomen. This vein is easily located but can be easily lacerated, and hemostasis following venipuncture can be problematic. The needle is inserted through the

ventral midline usually just cranial to the umbilicus in a cranial-dorsal direction to reach the vein just below the body wall. The vein can be cannulated with a needle and blood collected from the needle hub into a microcollection tube or aspirated into a syringe. Blood collected from capillary beds (toenails) do not provide optimal samples for hematologic studies but may be the only procedure available for blood collection in very small reptiles (<30 g). The humane aspects of toenail clipping should be considered as this method causes pain and trauma to the patient. The toenail should be thoroughly cleaned and is clipped using nail trimmers. Blood is then collected into a microcollection tube. A styptic powder or solution should be applied to the clipped nail to aid in hemostasis.

The total blood volume of reptiles is estimated to range between 5% and 8% of the body weight. For example, the total blood volume of desert tortoises (*Gopherus polyphemus*), freshwater turtles (*Chelydra serpentina*), and marine turtles is 4.9–7.2%, 3.8–5.6%, and 5.2–7.9% of the body weight, respectively. Most reptile species can tolerate withdrawal of up to 10% of the total blood volume (1% of the body weight) without detrimental effects. The maximum blood sample volume recommended for collection from chelonians is 3 mL/kg body weight, and a smaller volume representing 0.5% of the body weight has been recommended for sick animals. Typically, only 0.2–0.3 mL of blood is required for routine hematologic studies; most reptiles will tolerate this loss.

Blood should be collected into an anticoagulant for hematologic evaluation. Lithium heparin is the anticoagulant of choice for many reptilian blood samples intended for hematologic evaluation because ethylenediaminetetraacetic acid (EDTA) can cause hemolysis, especially in chelonian blood. Lithium heparin will cause clumping of leukocytes and thrombocytes, which can make it difficult to obtain accurate cell counts. Evaluation of cell morphology may be difficult as well due to the clumping and because lithium heparin creates a blue tinge to blood films. Blood samples collected in lithium heparin do not stain well if several hours pass prior to processing. In some species of reptiles, such as the green iguana (*I. iguana*), Chinese water dragon (*Physignathus concincinus*), and perhaps most species of lizards, EDTA can be used and is considered to be the anticoagulant of choice, allowing for better staining of the cells and, therefore, making cell identification easier than when cells are exposed to heparin. To minimize staining artifacts associated with an anticoagulant, the blood sample should be processed as soon as possible after collection. Blood films should be quickly prepared from a drop of blood containing no anticoagulant that is taken from the needle immediately following collection to avoid interference during staining.

Some authors feel that preparation of blood films using the two-microscope slide wedge method is more likely to cause cell lysis than use of a coverslip method. It has been the experience of this author (Campbell) that coverslip smears can also result in excessive cell lysis; therefore, the method chosen appears to be a matter of technical skill. Experienced medical technologists working with blood collected from lower vertebrates, such as reptiles, routinely prepare blood films using the conventional methods using two microscope slides without creating cell lysis.

Erythrocytes

Morphology

Mature erythrocytes of reptiles are typically larger than erythrocytes of birds, bony fish, and mammals but are smaller than the erythrocytes of most amphibians. Erythrocytes of reptiles are blunt-ended ellipsoidal cells with permanent, centrally positioned, oval to round nuclei containing dense purple chromatin (Figure 21.9). Unlike the smooth nuclear margins of avian erythrocytes, those of reptiles tend to be irregular. The cytoplasm stains uniformly orange-pink with Romanowsky stains such as Wright's stain. Polychromatophilic erythrocytes have nuclear chromatin

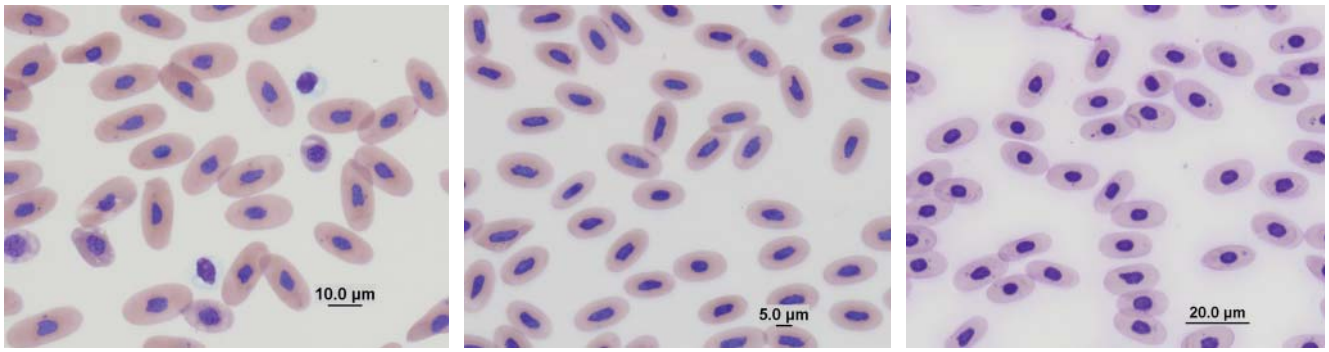

Figure 21.9 (a) Normal erythrocytes in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) Normal erythrocytes in the blood film of a lizard (*Chamaeleo calyptratus*). Figure 21.11 Immature erythrocytes (basophilic and midpolychromatic rubricytes) in the blood film of a chelonian (*Cuora amboinensis*). Wright-Giemsa stain.

that is less dense and cytoplasm that is more basophilic than mature erythrocytes (Figure 21.10). Immature erythrocytes are occasionally seen in the peripheral blood of reptiles, especially very young animals or those undergoing ecdysis. I'mmature erythrocytes are round to slightly irregular cells with large round nuclei and basophilic cytoplasm (Figures 21.10b and 21.11). The nucleus lacks the dense chromatin clumping of the mature cell. Immature erythrocytes often appear smaller than mature erythrocytes, probably because they are spherical in shape and have yet to become flattened ellipsoid cells. Mitotic activity associated with erythrocytes is common in the peripheral blood of reptiles (Figure 21.12).

Reticulocytes are detected by staining cells with a vital stain such as new methylene blue or brilliant cresyl blue. Reptilian reticulocytes, like avian reticulocytes, have a distinct ring of aggregated reticulum that encircles the red-cell nucleus (Figure 21.13). These cells best correspond to the polychromatophilic erythrocytes found in Romanowsky-stained blood films, and they probably are the cells that were recently released from erythropoietic tissues. Basophilic stippling commonly occurs in polychromatophilic erythrocytes stained with Romanowsky stains.

Round to irregular basophilic inclusions are frequently seen in the cytoplasm of erythrocytes in peripheral blood films from many species of reptiles (Figure 21.14). These inclusions most likely represent an artifact of slide preparation since blood films made repeatedly from the same blood sample often reveal varying degrees of these inclusions and are not considered to be clinically significant. Electron microscopy suggests these inclusions are degenerate organelles, such as clumping of the endoplasmic reticulum. Other artifacts found in the erythrocyte cytoplasm include vacuoles and refractile clear areas. These can be minimized with careful blood film preparation.

Laboratory evaluation

Laboratory evaluation of the reptilian erythron involves determination of the PCV, TRBC, and Hb of blood (see Table 21.1). The PCV is obtained by microhematocrit centrifugation. A PCV also can be calculated by electronic cell counters that are accurately adjusted for each species according to differences in erythrocyte sizes. Microhematocrit centrifugation, however, is the most practical method for obtaining PCVs of reptilian blood.

The total erythrocyte concentration of reptiles can be determined using the same automated or manual methods used for the determination of total erythrocyte counts in mammalian blood. Electronic impedance cell counters provide a rapid, reliable method for obtaining total red blood cell concentrations. Erythrocyte counts with electronic cell counters are slightly inflated by the inclusion of leukocytes and thrombocytes in the count; however, these additional cells are not significant in most samples as they make up approximately 0.1% of the peripheral blood cell population. Although rarely performed, manual methods for obtaining total red blood cell counts in reptiles can be obtained using the Natt and Herrick's method, which involves the

preparation of Natt and Herrick's solution to be used as a stain and diluent (see Chapter 20 on avian hematology).

Total hemoglobin concentration for reptiles is typically determined using the standard cyanmethemoglobin method with one modification: the cyanmethemoglobin reagent-blood mixture should be centrifuged prior to analysis. The free nuclei from lysed erythrocytes are removed before obtaining the optical density value, in order to avoid an overestimation of the hemoglobin concentration. Published hemoglobin concentration values for reptiles are usually low; often less than 10 g/dL.

After the primary hematologic indices (PCV, erythrocyte count, and hemoglobin concentration) have been determined, the secondary hematologic indices can be determined. These include the mean cell volume (MCV) or mean erythrocyte volume (MEV), mean cell hemoglobin (MCH), or mean erythrocyte hemoglobin (MEH), and mean cell hemoglobin concentration (MCHC) or mean erythrocyte hemoglobin concentration (MECH). The mean corpuscular volume (MCV) is an index of red cell volume. The mean corpuscular hemoglobin concentration (MCHC) is an index denoting the proportion of hemoglobin present in an average erythrocyte. Published MCV values for reptiles generally range between 160 and 950 fL (femtoliters, mm^3) and MCHC values typically range between 20 and 40 g/dL.

Reference intervals for the TRBC, Hb, and PCV are difficult to establish for reptiles and other ectotherms, as mentioned above. Intrinsic factors include species, gender, age, and the physiologic status of the reptile. Extrinsic factors include season, temperature, habitat, diet, disease, stress associated with captivity, and the venipuncture site. When establishing reference intervals, the intrinsic and extrinsic factors affecting the reference population must be documented in order to ensure that the physiologic data are collected

under consistent circumstances. It has been recommended that a minimum of 97 samples is required from a reference population to provide statistically meaningful intervals.

Disparity in erythrocytic values may be related to gender in some reptile species. Male reptiles typically have higher erythrocytic values than females; however, this is not always the case. Seasonal changes in environment, physical condition, and age can affect the hematologic parameters of reptiles. For example, adult crocodiles have higher red blood cell counts compared to juveniles, and the hemogram of free-ranging tortoises is influenced by physical condition, availability of forage, and the rainfall patterns of the environment. Significant seasonal variations in hematologic values have also been reported in snakes. The normal PCVs of green iguanas (*I. iguana*) housed outdoors with significant exposure to direct sunlight and a slightly higher environmental temperatures (80–100 °F) exhibit a slightly wider range (28–46%) compared to the PCV (25–38%) of the same species housed indoors exposed to artificial lighting and lower environmental temperature (74–95 °F). Hibernation will affect erythrocytic values in some reptile species. In general, erythrocyte values are highest prior to and lowest immediately after hibernation, although some reptile species do not appear to be affected by hibernation.

Chronic stressors such as captivity and inappropriate habitat or diet will affect the hemogram. The effects of acute stressors, such as capture, handling, and restraint for venipuncture, are unknown but are likely to affect erythrocyte values as well. In one study, captive-bred snakes had higher red blood mass compared to wild-caught snakes of the same species.

The site and method of blood collection can affect the hemogram. As previously mentioned, lymphatic vessels often accompany blood vessels in reptiles, commonly resulting in a mixture of blood and lymph during venipuncture. The subsequent lymphodilution of the blood sample will affect the hemogram by decreasing the PCV, Hb concentration, TRBC, and TWBC.

Responses in disease

Published normal PCVs of most reptile ranges between 15 and 55%. Values greater than 55% suggest either hemoconcentration or erythrocytosis (polycythemia), while a PCV less than 15% is suggestive of anemia if hemodilution of lymph is not a factor.

The causes of anemia in reptiles are similar to those described for birds and mammals. Anemia can be classified as hemorrhagic (i.e., blood loss), hemolytic (i.e,. increased red-cell destruction), or depression anemia (i.e., decreased red-cell production). Hemorrhagic anemias usually result from traumatic injuries or bloodsucking parasites; however, other causes, such as a coagulopathy or an ulcerative lesion, should be considered as well. Hemolytic anemia can result from septicemia, parasitemia, or toxemia. Bone marrow depression anemia (nonregenerative anemia) usually is associated with chronic inflammatory diseases, especially those associated with an infectious agent. Other causes that should be considered for nonregenerative anemia in reptiles include chronic renal or hepatic disease, neoplasia, chemicals, and possibly, hypothyroidism.

The degree of polychromasia or reticulocytosis in the blood films of normal reptiles generally is low, and it represents less than 1% of the erythrocyte population. This may be associated with the long erythrocyte life span (600–800 days in some species) and, therefore, with the slow turnover rate of reptilian erythrocytes compared with those of birds and mammals. The relatively low metabolic rate of reptiles also may be a factor. Young reptiles tend to have a greater degree of polychromasia than adults.

Slight anisocytosis and poikilocytosis are considered to be normal for most reptilian erythrocytes. Moderate to marked anisocytosis and poikilocytosis are associated with erythrocytic regenerative responses and, less commonly, with erythrocyte disorders. An increased polychromasia and number of immature erythrocytes is seen in reptiles responding to anemic conditions. Young reptiles or those undergoing ecdysis also may exhibit increased polychromasia and immature erythrocyte concentration. Erythrocytes exhibiting binucleation, abnormal nuclear shapes (anisokaryosis), or mitotic activity can be associated with marked regenerative responses (Figures 21.12b and 21.15). These nuclear findings, however, also may occur in reptiles awakening from hibernation or in association with severe inflammatory disease, malnutrition, and starvation. Basophilic stippling usually suggests a regenerative response, but it may also be seen in patients with lead toxicosis. Hypochromatic erythrocytes are associated with iron deficiency or chronic inflammatory disease, presumably in association with iron sequestration.

Erythrocytic intracytoplasmic inclusions in reptilian blood films can be caused by viruses or blood parasites (see section on blood parasites). Viral inclusions caused by an iridovirus

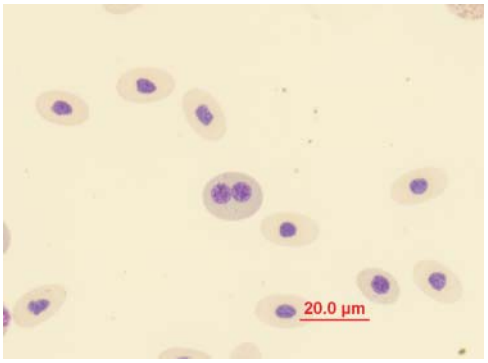

Figure 21.15 A binucleated erythrocyte in the peripheral blood of a chelonian (*Mauremys reevesii*). Wright-Giemsa stain.

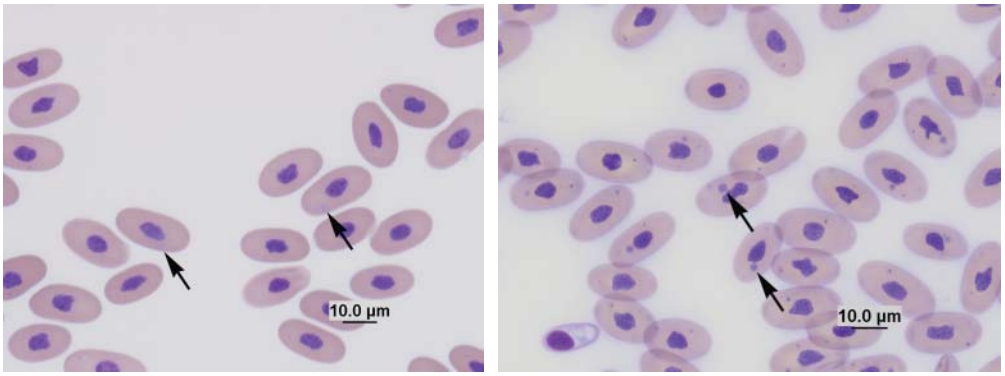

Figure 21.16 (a) Intracytoplasmic inclusions (arrows) in the erythrocytes in the peripheral blood of a snake (*Boa constrictor*) with inclusion body disease. Wright-Giemsa stain. (b) Intracytoplasmic inclusions (arrows) in the erythrocytes in the peripheral blood of a snake (*Boa constrictor*) with inclusion body disease. Diff-Quik stain.

are represented by snake and lizard erythrocyte viruses (formerly known as *Pirhemocyton*) and are identified as small round (punctate to oval) red-staining (Giemsa stain) inclusions that may be associated with rectangular or hexagonal translucent, crystalline, or albuminoid vacuoles. The iridovirus inclusion of box turtles appears as round to oval pink granular inclusions in the cytoplasm of leukocytes.

Inclusion body disease (IBD), suspected to be caused by an arenavirus, is a common and highly contagious disease seen worldwide in snakes of the families Boidae and Pythonida. Blood films from boid snakes affected with IBD may reveal inclusions within the cytoplasm of erythrocytes, lymphocytes, or heterophils. IBD inclusions stained with Wright–Giemsa appear as lightly basophilic homogenous intracytoplasmic inclusions of varying size and shape (Figure 21.16). The inclusions may stain darker with Diff-Quik stain. A lymphocytosis may also be present, presumably due to chronic antigenic stimulation from the infectious agent.

Leukocytes

Morphology

Classification of reptilian leukocytes can be problematic in part due the presence of morphologic variation among the different reptilian species. Classification can be further complicated by the presence of differing descriptive nomenclature in the literature. For example, some sources differentiate the reptilian granulocytes into three cell groups – eosinophils, azurophils, and neutrophils – while other sources only differentiate two – eosinophils and heterophils, or eosinophils and neutrophils. In general, the leukocytes of reptiles can be divided into two groups: the granulocytes and the mononuclear leukocytes. The granulocytes of reptiles can be further classified into two groups – acidophils and basophils – based upon their appearance in blood films stained with Romanowsky stains. The acidophils are further divided into heterophils and eosinophils. Heterophils and eosinophils may then be distinguished from each other by the shape and color of their granules. The basophils, lymphocytes, and monocytes found in reptilian blood closely resemble those of mammals and birds and are classified accordingly. A sixth cell type, the azurophil, is often described in the literature and could be considered to be a monocyte with azurophilic granules. Attempts using cytochemical staining reactions for normal leukocytes and thrombocytes in various reptiles have been made to help in the classification of reptilian leukocytes.

Reptilian heterophils generally are large (10–23 µm), round cells with a colorless cytoplasm containing eosinophilic (bright orange), refractile, rod- to spindle-shaped cytoplasmic granules (Figure 21.17). Occasionally degranulated heterophils can be found in the blood film of normal reptiles. The cell margins may appear irregular, and pseudopodia may be present under certain circumstances. The nucleus of the mature heterophil is typically eccentrically positioned in the cell and is round to oval with densely clumped nuclear chromatin. Some species of lizards (i.e., green iguanas, *I. iguana*) have heterophils with lobed nuclei. When toxic changes are present, the cytoplasm appears blue in color and contains abnormal purple-colored granules and vacuoles. Reptilian heterophils are functionally equivalent to mammalian neutrophils but probably behave like avian heterophils in that they rely primarily on oxygen-independent mechanisms to destroy phagocytized microorganisms. Except for a few species of snakes and lizards, reptilian heterophils do not stain for alkaline phosphatase, and are usually peroxidase negative.

Eosinophils in most reptilian blood films are large (11–17 µm) round cells with light blue cytoplasm, a round to oval to possibly lobed, slightly eccentric nucleus, and large numbers of spherical eosinophilic cytoplasmic granules

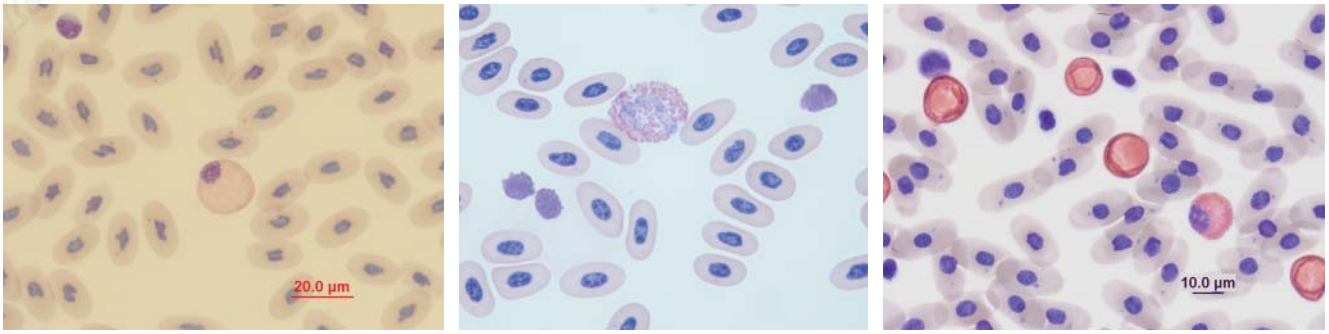

Figure 21.17 (a) A heterophil in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) A heterophil in the blood film of a lizard (*Salvator merianae*). Wright-Giemsa stain. (c) Heterophils in the blood film of a chelonian (*Mauremys mutica*). Wright-Giemsa stain.

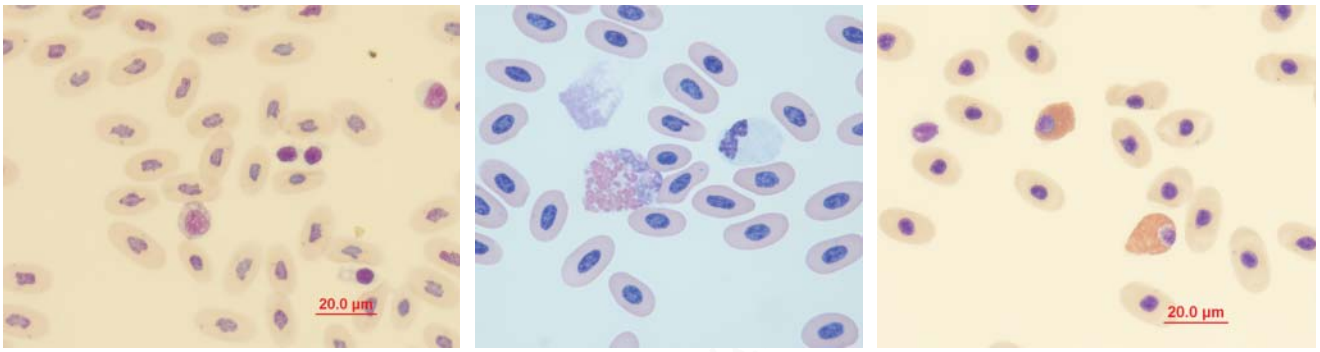

Figure 21.18 (a) An eosinophil in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) An eosinophil with pale blue granules (granulocyte on the right) and a heterophil in the blood film of a lizard (*Salvator merianae*). Wright-Giemsa stain. (c) An eosinophil (granulocyte on top) and a heterophil in the blood film of a chelonian (*Batagur borneoensis*). Wright-Giemsa stain.

(Figure. 21.18). The cytoplasmic granules of some reptilian species, such as iguanas, stain blue with Romanowsky stains, and will stain positive for peroxidase in some species of reptiles, allowing differentiation between eosinophils and heterophils (Figures 21.18b and 21.19). The nucleus is typically centrally located but may be eccentrically located in some cases. The size of the eosinophil is species variable. For example, snakes have the largest eosinophils and lizards have the smallest. Reptilian eosinophils contain glycogen, myeloperoxidase, and basic proteins. The latter are known potent toxins for parasites, especially helminthes, inactivating leukotrienes, and causing histamine release from mast cells.

Basophils are small (8–15 µm) round cells, typically smaller than heterophils and eosinophils, that contain variable numbers of round basophilic (i.e., dark blue to purple) metachromatic cytoplasmic granules (Figure 21.20). The nucleus is often obscured by the granules but when visible is nonlobed and slightly eccentric in position. Alcohol fixation and use of Romanowsky stains provide the best staining for reptilian basophils because basophil granules are frequently affected by water-based stains and will partially dissolve.

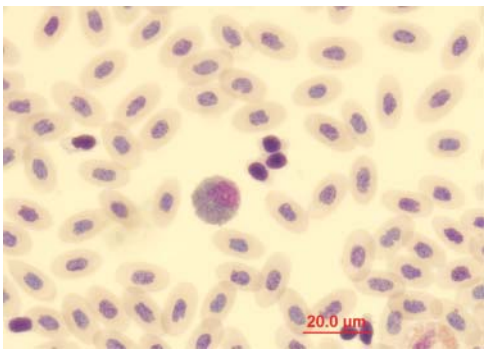

Figure 21.19 An eosinophil with blue cytoplasmic granules in the blood film of a lizard (*Iguana iguana*). Wright-Giemsa stain. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 74.

Species differences in basophil sizes do occur; lizards tend to have smaller basophils than those observed in turtles and crocodiles.

Reptilian lymphocytes resemble those of birds and mammals. They vary in size from small (5–10 µm) to large

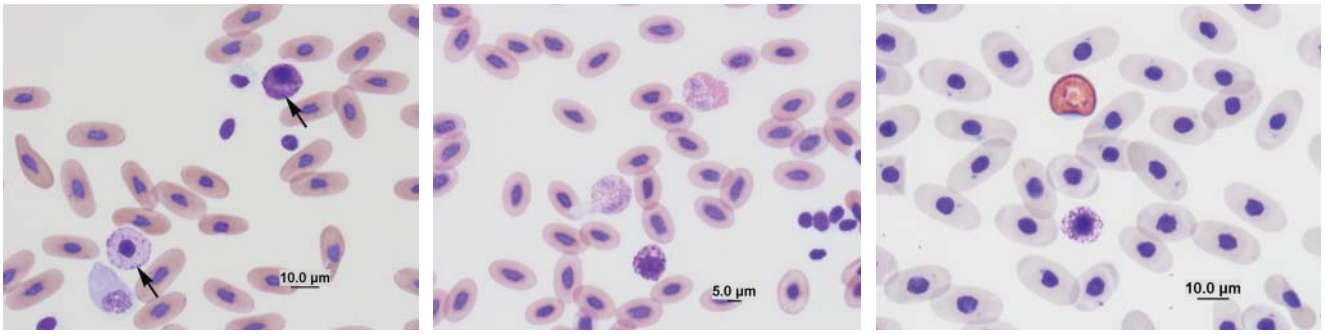

Figure 21.20 (a) Basophils (arrows), a monocyte, and thrombocyte in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) Basophil (granulocyte on the bottom) and heterophils in the blood film of a lizard (*Pogona vitticeps*). Wright-Giemsa stain. (c) Basophil (granulocyte on the bottom) and heterophil in the blood film of a chelonian (*Mauremys mutica*). Wright-Giemsa stain.

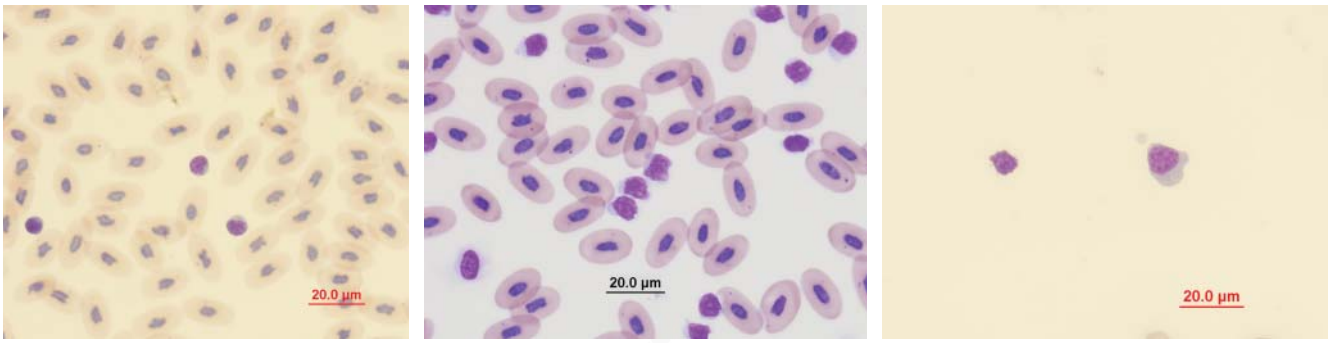

Figure 21.21 (a) Lymphocytes in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) Lymphocytes in the blood film of a lizard (*Pogona vitticeps*) with lymphocytosis. Wright-Giemsa stain. (c) A small and a large lymphocyte in the blood film of a chelonian (*Glyptemys insculpta*). Wright-Giemsa stain.

(15 µm). Lymphocytes are round cells that exhibit irregularity when they mold around adjacent cells in the blood film or fold at their cytoplasmic margin (Figure 21.21). They have a round or slightly indented nucleus that is centrally or slightly eccentrically positioned in the cell; nuclear chromatin is heavily clumped in mature lymphocytes. Typically, lymphocytes have a large nucleus: cytoplasm (N : C) ratio. The typical small, mature lymphocyte has scant slightly basophilic (pale blue) cytoplasm. Large lymphocytes have more cytoplasmic volume compared with small lymphocytes, and the nucleus often is pale staining. The cytoplasm of a normal lymphocyte appears to be homogenous and lacks both vacuoles and granules. Plasma cells may be observed in the blood film of reptiles, and are slightly larger than normal lymphocytes. The nucleus is eccentrically placed, is round to oval, and contains clumped chromatin. The cytoplasm of plasma cells stains deep blue, and a perinuclear halo representative of the Golgi is present (Figure 21.22).

Reptilian monocytes resemble those of birds and mammals and are generally the largest leukocytes in peripheral blood (often one-half to two times the size of erythrocytes

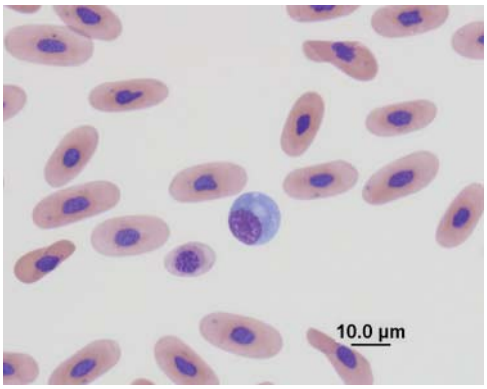

Figure 21.22 A plasma cell in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain.

in the same blood film) (Figure 21.23). Monocytes vary in shape from round to amoeboid, and contain a variably shaped nucleus that ranges in shape from round to oval to lobed or bean-shaped. The nuclear chromatin of the monocyte is less condensed and paler staining compared

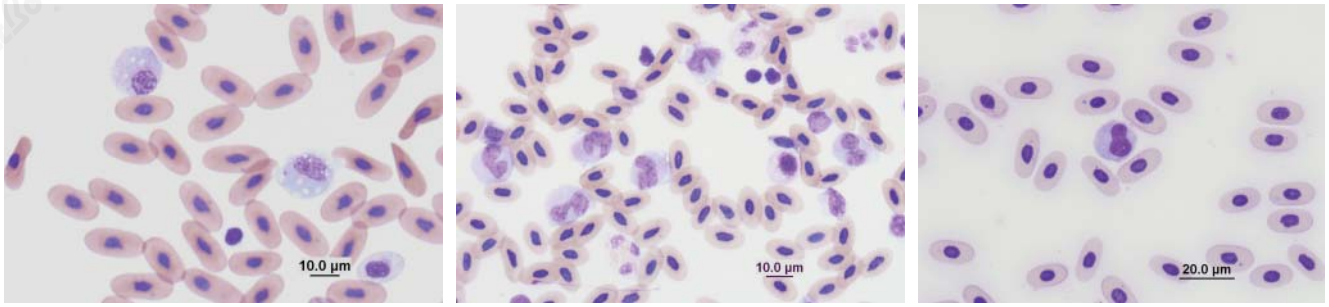

Figure 21.23 (a) Monocytes with azurophilic granules (azurophils) in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) Numerous monocytes in the blood film of a lizard (*Pogona vitticeps*) with monocytosis. Three heterophils, a basophil, two lymphocytes, and three thrombocytes are also present. Wright-Giemsa stain. (c) A monocyte in the blood film of a chelonian (*Terrapene carolina*). Wright-Giemsa stain.

to the nuclear chromatin of lymphocytes. The cytoplasm is abundant, stains pale blue-gray, and may be slightly opaque or foamy in appearance. Phagocytized material, vacuoles, or fine eosinophilic or azurophilic granules may be present in the cytoplasm of some monocytes. Monocytic cells of reptiles have been referred to as monocytes, monocytoid azurophils, azurophilic monocytes, or azurophils (Figure 21.23a). Azurophilic leukocytes are often noted in the blood film of reptiles, and historically there has been much confusion surrounding the classification and identification of these cells. Some consider azurophils to be unique to reptiles because they are often found in low numbers in the blood of lizards, chelonians, and crocodilians but in high numbers in snakes. The azurophil is described as an irregularly shaped cell that is slightly smaller in size than the monocyte. The nucleus is nonsegmented and is irregularly round to oval to bilobed. The nuclear chromatin is coarse in appearance. The cytoplasm is basophilic and darker than that of the monocyte, and may be described as blue to lavender in color. Small numbers of dull azurophilic granules of various sizes are present within the cytoplasm. Vacuolation and phagocytosed material may be present within the cytoplasm of these cells, and pseudopodia may be noted on the cell margins. The granulopoietic origin of the azurophil has not been documented. At various times in the literature, this cell has been classified as a granulocyte, a neutrophil, or a monocyte. By light microscopy, azurophils resemble the monocytes that contain azurophilic granules that are occasionally noted in the peripheral blood of mammals and birds, and ultrastructurally and cytochemically, these cells are similar to monocytes. There may be species differences in the characteristics of the cells. For example, the cytochemical properties of all monocytic cells (monocytes and azurophils) of green iguanas (*I. iguana*) are characteristic of monocytes but differ from those of snakes. The azurophils of snakes stain positive for peroxidase, Sudan black B, and PAS, whereas those of the green iguanas do not. Monocytic cells of other reptiles, even those from snakes, have cytochemical properties similar to those of green iguanas (*I. iguana*); however, there is some variability. For example, monocytic cells in some lizards stain positive for peroxidase, but those from alligators do not. Most, if not all, stain PAS and acid phosphatase positive. These facts support the hypothesis that azurophils should be considered monocytes and not a separate distinct cell type. There is little clinical advantage in separating azurophils from monocytes in the leukocyte differential of reptiles, and these cells should be counted as monocytes just as they are in mammals and birds. Azurophils could represent an immature form of the monocyte.

Laboratory evaluation

Evaluation of the reptilian leukogram involves determination of a total and a differential leukocyte count and examination of the leukocyte morphology on a stained blood film. Manual counting methods are used to obtain total leukocyte concentrations in reptiles for the same reasons they are used in avian hematology: the presence of nucleated erythrocytes and thrombocytes in the blood of reptiles precludes the use of electronic cell-counting procedures. Two manual methods commonly used to obtain a total leukocyte count in reptilian blood are the Natt and Herrick method and the phloxine B method (see Chapter 20 on avian hematology). In species of reptiles that normally have higher numbers of circulating lymphocytes than of heterophils, the Natt and Herrick method is preferred, because the accuracy of the phloxine B method relies on large numbers of heterophils and eosinophils.

Responses in disease

Establishment of reference values for the total leukocyte count and leukocyte differential is difficult in reptiles and other ectotherms for the same reasons described in the erythrocytes section. Physiologic adaptations to the intrinsic and extrinsic factors previously described may affect the leukogram of the individual reptile. The same guidelines used for establishing erythrocyte intervals should be considered when developing meaningful statistically accurate leukocyte

intervals. Intrinsic factors such as species, gender, age, and the physiologic status of the reptile will affect the leukogram. Differences in the leukogram may occur broadly across the reptile species but can occur within the same genus as well. For example, significant differences in heterophil, monocyte, and lymphocyte counts have been documented among different species of *Gallotia* lizards. Gender and age differences may affect the leukocyte parameters. For example, male crocodiles have higher total leukocyte and heterophil counts compared to females and adult crocodiles have lower total leukocyte counts compared to juveniles. The reproductive status of a reptile may also influence the hemogram. For example, female chameleons may demonstrate a heterophilia after egg-laying; however, being gravid in turtles appears to have no physiological effects on blood parameters or morphometrics. Extrinsic factors include season, temperature, habitat, diet, disease, stress associated with captivity, and even the venipuncture site. For example, factors including season, location, surgical radiotransmitter placement, and anesthetic state can influence blood parameters in snakes. The leukogram of free-ranging tortoises is related to seasonal and annual differences in rainfall patterns, forage availability, and physiological condition. Young crocodiles housed in low temperature (28 °C) environments for 10 days had lower total leukocyte and lymphocyte counts compared to young crocodiles housed in high temperature (38 °C) environments and both sets of these crocodiles had leukocyte counts that were abnormal compared to crocodiles housed at normal temperature (32 °C). Some species of reptile may not be affected by season or temperature; no differences in the pre- and posthibernation hematologic parameters were noted in temperate species of snakes. Stress associated with captivity may affect the leukogram of some reptile species. For example, captive-bred cobras have higher red blood cell parameters and lymphocyte numbers but lower monocyte (azurophil) and heterophil numbers compared to wild-caught cobras. Although the results of the hemogram may vary with the site of venipuncture in some species, it may have no effect in others.

The primary function of the heterophil is phagocytosis. In general, heterophils of most reptiles, like those of birds, do not stain positive with benzidine peroxidase and Sudan black B; therefore, they appear to produce less oxidative responses in their bactericidal function compared to mammalian neutrophils. There is evidence, however, that heterophils from some lizards may have oxidative properties similar to mammalian neutrophils based on their benzidine peroxidase activity. The percentage of heterophils in the leukocyte differential of normal reptiles varies with the species (Tables 21.2 and 21.3). Heterophils can represent as much as 40% of the leukocytes in some normal reptilian species. The heterophil concentration in reptiles also is influenced by seasonal factors. For example, the heterophil concentration is highest during the summer months and is lowest during hibernation.

Because the primary function of heterophils is phagocytosis, significant increases in the heterophil count of reptiles usually are associated with inflammatory disease, especially microbial and parasitic infections or tissue injury. Noninflammatory conditions that may result in heterophilia include stress (i.e., glucocorticosteroid excess), neoplasia, and heterophilic leukemia. The high initial leukocyte counts that commonly occur in cold-stunned turtles are likely a reflection of inflammation, immune response, physiologic stress, or systemic pathologic conditions.

Heterophils may appear to be abnormal in reptiles suffering from a variety of diseases. For example, heterophils may exhibit varying degrees of toxicity with inflammatory diseases, especially those involving infectious agents such as bacteria. Toxic heterophils exhibit increased cytoplasmic basophilia, abnormal granulation (i.e., dark blue to purple granules or granules with abnormal shapes and staining),

and cytoplasmic vacuolation (Figure 21.24). Degranulated heterophils may be associated with artifacts of blood-film preparation or represent toxic changes. Nuclear lobation in species that normally do not lobate their heterophil nuclei also is an abnormal finding and suggests severe inflammation.

The presence of immature heterophils (left shift) in the blood film of reptiles exhibiting a heterophilia is indicative of an inflammatory disease. A left shift in the presence of a heteropenia is indicative of an overwhelming inflammatory response that is likely associated with an infectious etiology. Reptiles often develop a marked leukocytosis and heterophilia with the presence of many immature heterophils, often as early as progranulocytes or myeloblasts, with severe inflammatory diseases, especially those with a bacterial etiology.

Disease and exposure to environmental or chemical toxins can affect the leukogram of reptiles. Tortoises affected with herpesvirus infection often demonstrate heteropenia and lymphocytosis, toxic heterophils, and lymphocytes with pale blue, eccentric intracytoplasmic inclusions. Abnormal heterophil: lymphocyte ratios appear to be related to the circulating blood concentration of organochlorine exposure in sea turtles.

The number of circulating eosinophils in normal reptiles is variable. In general, lizards tend to have low numbers of eosinophils compared with some species of turtles, which can have as much as 20% eosinophils. Like heterophils, the number of eosinophils present in the peripheral blood is influenced by environmental factors, such as seasonal changes. The number of eosinophils generally is lower during the summer months and highest during hibernation in some species. Eosinophilia may be associated with parasitic infections and stimulation of the immune system.

The percentage of basophils in the differential leukocyte count of normal reptiles can range from 0 to 40%. Seasonal variation in basophil concentration is minimal compared to the heterophil and eosinophil concentrations. Some species of reptiles normally have high numbers of circulating basophils. For example, some species of turtles typically have circulating basophil numbers that represent as much as 40% of the leukocyte differential, although the reason for this is unknown. Based on the results of cytochemical and ultrastructural studies, reptilian basophils most likely function in a manner similar to that of mammalian basophils. They appear to process surface immunoglobulins and to release histamine on degranulation. Basophilia has been associated with parasitic and viral infections.

The lymphocyte concentration in reptilian blood also varies. Many healthy reptiles have a higher lymphocyte count than heterophil count and they can represent more than 80% of the normal leukocyte differential in some species. Lymphocyte numbers are influenced by several intrinsic and extrinsic factors. Like heterophils and eosinophils, lymphocytes also are influenced by seasonal change; lymphocyte counts tend to be lowest during the winter months and highest during the summer months. Temperate reptiles have a decreased concentration of lymphocytes during hibernation, after which the lymphocyte concentration increases. Tropical reptiles also demonstrate decreased numbers of circulating lymphocytes during the winter months despite their lack of hibernation. Lymphocyte concentrations also are affected by gender, with the female members of some species having significantly higher lymphocyte concentrations than males of the same species. Reptilian lymphocytes function in a manner similar to those of birds and mammals. They have the same major classes of lymphocytes, B and T lymphocytes that are involved with a variety of immunologic functions. Unlike those in birds and mammals, however, the immunologic responses of ectothermic reptiles are influenced greatly by the environment. For example, low temperatures may suppress or even inhibit the immune response in reptiles.

Lymphopenia often is associated with malnutrition or is secondary to a number of diseases because of stress and immunosuppression. Lymphocytosis occurs during wound healing, inflammatory disease, parasitic infection (e.g., anasakiasis and spirorchidiasis), and viral infections. Lymphocytosis also occurs during ecdysis. The presence of reactive lymphocytes and, less commonly, of plasma cells suggests stimulation of the immune system (Figure 21.22). These cells resemble those of birds and mammals. Reactive lymphocytes have more abundant, deeply basophilic cytoplasm compared with normal lymphocytes, and their nuclear chromatin may appear to be less condensed. Plasma cells have abundant, intensely basophilic cytoplasm that contains a distinct Golgi zone and an eccentrically positioned nucleus.

Monocytes generally occur in low numbers in the blood films of normal reptiles, ranging between 0 and 10% of the leukocyte differential. Snakes typically have monocytes with an azurophilic appearance to the cytoplasm, which frequently is referred to as azurophils in the literature (Figure 21.23a). The monocyte concentration changes little with seasonal variation. Monocytosis suggests inflammatory diseases, especially granulomatous inflammation. For example, chameleons with dystocia often demonstrate a monocytosis in the absence of peritonitis and a progressive increase in monocyte numbers along with the total leukocyte count and heterophil numbers have been associated with an increase in the tumor score of green turtles (*Chelonia mydas*) with fibropapillomastosis. Significant increases in monocytes (azurophils) have been noted in lizards with *Karyolysus* and snakes with *Hepatozoon* parasitemia. The cause of this was not determined but could be related to an inflammatory response to the parasites.

Monocytes in the peripheral blood of reptiles often reveal phagocytic activity. Erythrophagocytosis and leukophagocytosis by can be associated with anemia and infectious diseases. Circulating siderophagocytes and erythrophagocytes can be transiently found to be part of the postsurgical removal of extravasated blood in reptiles recovering from intracoelomic surgery, during which time the PCV remains relatively stable. Circulating siderophagocytes in the blood may reflect differences in the circulation of macrophages in snakes compared with mammals. In mammals, intraperitoneal macrophages are drained via lymphatics to lymph nodes, where they accumulate in the sinuses resulting in posthemorrhagic lymph nodes that contain large numbers of hemosiderin-laden macrophages. Because reptiles have no lymph nodes to filter out these cells, it is likely the coelomic macrophages reenter circulating blood from the lymphatic system to be transported either directly to bone marrow or to the spleen. Therefore, circulating siderophagocytes in postoperative blood films in reptiles can be interpreted as recirculating macrophages involved in the removal of blood from the coelomic cavity following mild postsurgical hemorrhage. Macrophages containing melanin (melanomacrophages) are common in lower vertebrates. These cells can be found in peripheral blood films of reptiles with inflammatory diseases.

Leukemia has been reported rarely in reptiles. Myeloproliferative diseases of reptiles are classified in the same

manner as in mammals. Special cytochemical studies may be required to identify the abnormal cells. Lymphoid leukemia and other hematopoietic neoplasia have been reported in reptiles. Affected animals frequently present with a marked to severe leukocytosis due to high numbers of atypical cells, usually blasts. Lymphoid leukemia is indicated by the presence of large number of immature and abnormal lymphocytes. The lymphocytes can be medium-sized cells with round to pleomorphic nuclei, slightly clumped chromatin, indistinct nucleoli, and scant moderate-to-dark blue cytoplasm with occasional red-to-purple cytoplasmic granulation. Advanced diagnostic tools, such as cytochemical and immunochemical staining and transmission electron microscopy, are needed to further evaluate and differentiate the neoplastic hemic cell population of hematopoietic neoplasms of reptiles. For example, the diagnosis of T-cell lymphoid leukemia can be based on positive cytochemical staining with α-naphthyl butyrate esterase using mammalian controls.

Considerations in the interpretation of the reptilian hemogram

Hematology is a valuable diagnostic tool that can be used to assess the response of a reptilian patient to disease or therapy. An example of a favorable response in the leukogram would be a shift from a leukocytosis or leukopenia to a normal leukocyte concentration. A normal heterophil, eosinophil, or monocyte count following a heterophilia, eosinophilia, or monocytosis, respectively, would usually indicate improvement as well. The disappearance of toxic heterophils, reactive lymphocytes, and plasma cells from a blood film during or after therapy indicates improvement and a favorable response to therapy. Anemic reptiles that exhibit an erythrocytic regenerative response have a better prognosis compared to those with little or no response. Similarly, a normal thrombocyte concentration following thrombocytopenia indicates a favorable response.

When evaluating the hematologic responses of reptiles, the effects that intrinsic and extrinsic factors may have on the animal's response to disease cannot be overlooked. The cellular responses in reptilian blood are less predictable than those of endothermic mammals and birds whose cellular microenvironments are more stable. Reptilian hemogram values may be affected by a number of sample-handling factors as well. The blood collection site, type of anticoagulant used, method of cell counting, type of stain used, and experience of the technician add to the variability of reptilian hemogram values. All of these factors can complicate the establishment and validation of normal reference intervals in reptiles. Because of this variability, total and differential leukocyte concentrations must be increased or decreased at least twofold from normal reference intervals in order to be considered significant.

Thrombocytes and hemostasis

Morphology

Thrombocytes of reptiles appear as small (generally smaller than erythrocytes), elliptical to fusiform, nucleated cells (Figure 21.25). The round to oval centrally positioned nucleus has dense nuclear chromatin that stains purple, whereas the cytoplasm typically is colorless to pale blue and may contain a few azurophilic granules. Some nuclei may contain a pale line that extends across the width of the nucleus. Activated thrombocytes are common and appear as clusters of cells with irregular cytoplasmic margins and vacuoles. Thrombocytes appear to be devoid of cytoplasm when aggregated. Indistinct cytoplasmic margins may be noted on some individual thrombocytes, and are probably a product of age, artifact, or function.

Laboratory evaluation

The actual thrombocyte concentration may be difficult to determine, because thrombocytes tend to clump especially when exposed to heparin, which is a commonly used anticoagulant in reptilian hematology. The thrombocyte concentration can be measured using the Natt and Herrick

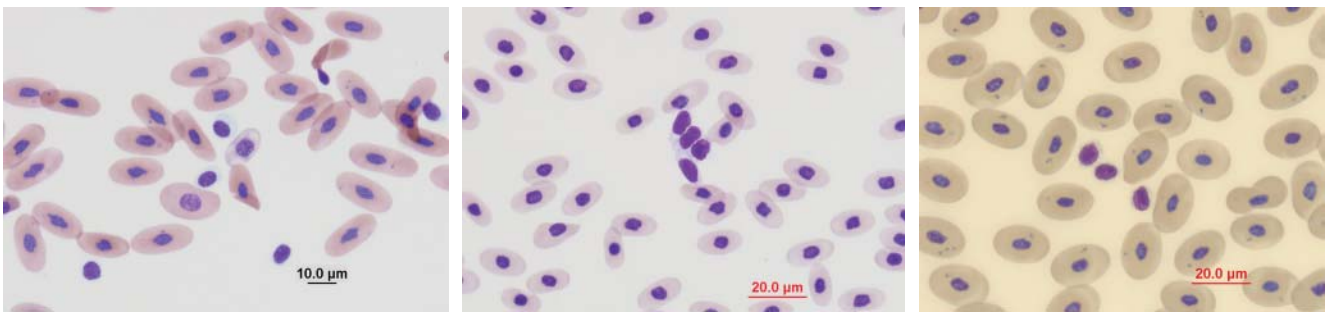

Figure 21.25 (a) Thrombocytes in the blood film of a snake (*Boa constrictor*). Wright-Giemsa stain. (b) Thrombocytes in the blood film of a lizard (*Iguana iguana*). Wright-Giemsa stain. (c) Thrombocytes in the blood film of a chelonian (*Chelonia mydas*). Wright-Giemsa stain.

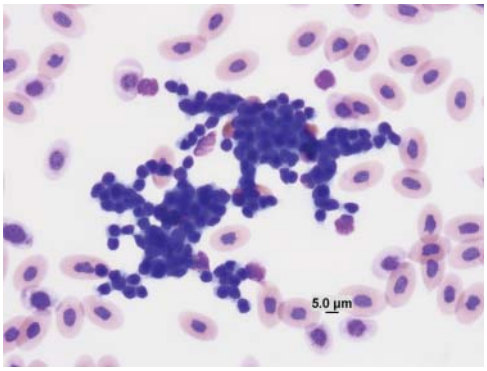

Figure 21.26 Clusters of activated thrombocytes in the blood film of a lizard (*Pogona vitticeps*). Wright-Giemsa stain.

method for obtained erythrocyte and leukocyte counts. After preparing the 1 : 200 dilution of the blood with Natt-Herrick solution and charging a Neubauer-ruled hemocytometer, the number of thrombocytes in the entire central ruled area (i.e., the central, large square) are counted on both sides of the hemocytometer. The number of thrombocytes per microliter of blood is obtained by multiplying that number by 1000. A subjective thrombocyte concentration can be determined based on the number of thrombocytes that appear in a stained blood film and it can be reported as either reduced, normal, or increased. Thrombocyte concentration typically ranges between 25 and 35 thrombocytes per 100 leukocytes in the blood film of normal reptiles (Figure 21.26).

Responses to disease

Reptilian thrombocyte numbers vary with species and seasons. For example, the mean absolute thrombocyte count of the argentine lizard (*Tupinambis merianae*) is $7.2 \times 10^3/\mu L$ during the winter months but $9.1 \times 10^3/\mu L$ during the summer. Reptilian thrombocytes have a significant role in thrombus formation, and they function similarly to avian thrombocytes and mammalian platelets. The ultrastructural features of activated reptilian thrombocytes include pseudopodia with fine, granular material and many fibrin-like filaments radiating both between and around the cells. Immature thrombocytes of reptiles resemble the immature thrombocytes of birds and, when present in blood films, represent a regenerative response. Thrombocytopenias of reptiles most likely result from excessive peripheral utilization of thrombocytes or decreased thrombocyte production. Thrombocytes with polymorphic nuclei are considered to be abnormal, and may be associated with severe inflammatory disease.

Blood parasites

Blood parasites are common in reptiles. Their presence usually is considered to be an incidental finding; however, some have the potential of causing disease, such as hemolytic anemia.

Common hemoprotozoa include the hemogregarines, trypanosomes, and *Plasmodium*. Less commonly encountered hemoprotozoans include *Leishmania*, *Saurocytozoon*, *Haemoproteus*, and *Schellackia*, and the piroplasmids. Microfilaria are commonly found in the peripheral blood films of some reptiles.

Hemogregarines

Hemogregarines are the most common group of sporozoan hemoparasites affecting reptiles, especially snakes. The three genera of hemogregarines that are common in reptiles are *Hemogregarina*, *Hepatozoon*, and *Karyolysus*. Accurate classification of the hemogregarines into their appropriate genus cannot be accomplished based on their appearance in the blood film alone. Therefore, the general term "hemogregarine" is used when reporting their presence in blood films during hematologic examinations.

Hemogregarines are identified by the presence of intracytoplasmic gametocytes in erythrocytes (Figure 21.27). The sausage-shaped gametocytes have a colorless to pale purple cytoplasm that lacks the refractile pigment granules found in the gametocytes of *Plasmodium* and *Haemoproteus*, and they distort the host cell by creating a bulge in the cytoplasm. Typically, only one gametocyte is found per erythrocyte; however, in heavy infections, two gametocytes may be found in one cell.

Hemogregarines have a lifecycle that involves sexual reproduction (sporogony) in an invertebrate host and asexual multiplication (merogony) in a reptilian host. The parasite infects the reptilian host when the sporozoites are transmitted from the invertebrate host as it feeds on the blood of the reptile or is ingested by the reptile. Several biting, invertebrate hosts (i.e., mites, ticks, mosquitoes, flies, and true bugs) can transmit the parasite to terrestrial reptiles, whereas leeches appear to be the primary intermediate host for the hemogregarines of aquatic reptiles. Reptilian

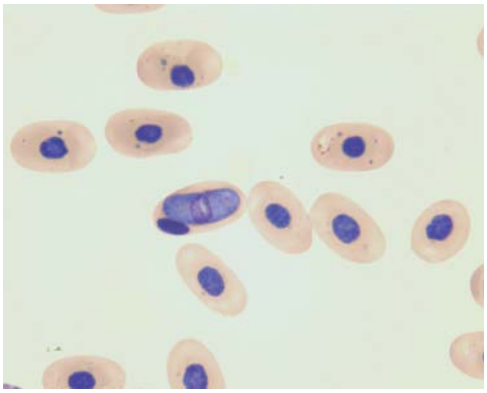

Figure 21.27 A hemogregarine gametocyte within an erythrocyte in the blood film of a chelonian (*Trachemys scripta elegans*). Wright-Giemsa stain. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 123.

hemogregarines are well adapted to their natural host and do not cause clinical disease; however, because they are relatively not host-specific, they can cause significant clinical disease in unnatural or aberrant host species. Such infections result in severe inflammatory lesions associated with schizonts in a variety of organs.

Intraleukocytic (i.e., heterophils) forms of hemogregarines appear to be parasites phagocytized by leukocytes as part of an immune response in the vertebrate host. A high level of intraleukocytic hemogregarines may represent a stage in the infection cycle where the reptilian host is clearing the parasite infection from its blood cells. The increased number of intraleukocytic forms has a seasonal appearance that may represent a more efficient immune response during warmer months. Infection intensity varies with fluctuations in vector abundance; both seasonally and spatially, whereas patterns of infection within exposed populations can vary with host body size and perhaps reproductive status. For example, the hemogregarine parasitemia has been shown to decline with increasing host body size.

Snakes are more commonly infected with hemogregarine parasites compared to other reptile species. The hemogregarines found in snakes are typically of the genus *Hepatozoon*. Hemogregarines may be found in semiaquatic freshwater turtles and are usually of the genus *Hemogregarina*. *Karyolysus* typically occurs in old world lizards and possibly tree snakes. There are no reported cases of hemogregariniasis in sea turtles, and the parasites are rare in tortoises. Hemogregarine parasites have been noted in the peripheral blood films of American alligators (*Alligator mississippiensis*) and are considered to be an incidental finding.

Trypanosomes

The trypanosomes found in reptiles resemble those found in mammals and birds. They are large, extracellular, flagellate protozoa with a bladelike shape, a single flagellum, and a prominent, undulating membrane. For transmission, they require a bloodsucking invertebrate host, such as biting flies for terrestrial reptiles or leeches for aquatic reptiles. Trypanosomes have been found in all orders of reptiles, have a worldwide distribution, rarely cause clinical disease, and often are associated with lifelong infections.

Plasmodium

More than 60 species of *Plasmodium* have been described in reptiles; most have been identified in lizards and a few in snakes. *Plasmodium* in reptiles resembles those found in birds (see Chapter 20 on avian hematology). The gametocytes have refractile pigment granules that aid in differentiation between *Plasmodium* and hemogregarines. Also, unlike hemogregarines, *Plasmodium* schizogony (packets of merozoites) can occur in blood cells. The trophozoites are small, signet-ring structures in the cytoplasm of erythrocytes. The lifecycle of *Plasmodium* involves a sporogony stage in an insect host (e.g., mosquito) and schizogony and gametogony in a reptile host. Infections with *Plasmodium* can result in a severe hemolytic anemia.

Leishmania or *Sauroleishmania*

Leishmania or *Sauroleishmania* rarely are seen in blood films of reptiles. The organism is related to trypanosomes, and it primarily infects lizards. When present, the organism (i.e., amastigote or leishmanial stage) appears as a round to oval inclusion of 2–4 μm with blue cytoplasm and an oval, red nucleus in the cytoplasm of thrombocytes or mononuclear leukocytes.

Saurocytozoon

Saurocytozoon produce large, round gametocytes that lack pigment granules in the cytoplasm of leukocytes in peripheral blood films. Only the gametocyte stage is found in the peripheral blood, and schizogony occurs in the tissues. The organism resembles *Leukocytozoon* of birds, because it grossly distorts the host cell that it parasitizes (see Chapter 20). As indicated by its name, this is a parasite of lizards and, most likely, is transmitted by mosquitoes.

Lainsonia and *Schellackia*

Lainsonia and *Schellackia* are coccidian parasites of lizards and snakes. They produce schizonts that can be found in the intestinal epithelium and sporozoites that can be found in the peripheral blood. The sporozoites are intracytoplasmic inclusions that are seen in erythrocytes and mononuclear leukocytes, primarily lymphocytes; they resemble *Atoxoplasma* in birds (see Chapter 20). The parasite is identified by the round to oval, pale-staining, nonpigmented inclusions that deform the host-cell nucleus into a crescent shape. *Schellackia* and *Lainsonia* are transmitted by mites or, possibly, by ingestion of oocysts from feces. *Lainsonia iguanae* is frequently found in the blood of normal green iguanas (*I. iguana*) housed outdoors and is not associated with health problems.

Piroplasmids

The piroplasmids of reptiles include *Babesia*, *Aegyptianella* (*Tunetella*), and *Sauroplasma* or *Serpentoplasma*. They have been reported in chelonians, lizards, and snakes and appear as small, nonpigmented inclusions in the cytoplasm of erythrocytes. The inclusions are small, round to piriform, nonpigmented, and signet ring–like vacuoles measuring from 1 to 2 μm in diameter. Piroplasmids commonly found in the peripheral blood erythrocytes of lizards are referred to as *Sauroplasma*, whereas the same organisms in the blood of snakes are called *Serpentoplasma*. The piroplasmids are transmitted by biting insects or arthropods. They reproduce by either schizogony or binary fission.

Pirohemocyton

Pirhemocytonosis is characterized as the presence of red, punctate to oval, erythrocytic inclusions that increase in size (0.5–1.5 µm) as infection develops. Pirhemocytonosis is typically reported in lizards, although similar inclusions have been reported in snakes and turtles as well. Inclusions may be associated with vacuoles or irregular pale-staining areas in the cytoplasm of erythrocytes in Giemsa-stained blood films. A single inclusion per erythrocyte is typical; however, two inclusions per cell may occur on occasion. These intraerythrocytic inclusions were previously considered to be piroplasmids and were referred to as *Pirhemocyton*, until ultrastructural studies revealed the presence of a virus consistent with members of the Iridoviridae family. Natural infections with this erythrocytic virus appear to be nonfatal, even when high viremia is present (i.e., greater than 85% of the erythrocytes are infected). Erythrocytes may appear spindle-shaped or thin and elongated. One report of pirhemocytonosis in snakes was suggestive of an oncornavirus based upon ultrastructural studies. Square to rectangular, pale, crystalline-like cytoplasmic inclusions are commonly found in the erythrocyte cytoplasm of green iguanas (*I. iguana*) (Figure 21.28). One report determined that 20% of iguanas examined had these inclusions in 1–5% of their erythrocytes. Although some consider these to be viral or *Pirhemocyton* inclusions, the exact cause for these is unknown and they do not appear to be associated with hematologic abnormalities or disease.

Hemoproteus

Hemoproteus (*Haemocystidium*) has been reported in lizards, turtles, and snakes. They resemble the *Hemoproteus* found in birds; only the gametocytes with refractile pigment granules are found in the peripheral blood films (see Chapter 20).

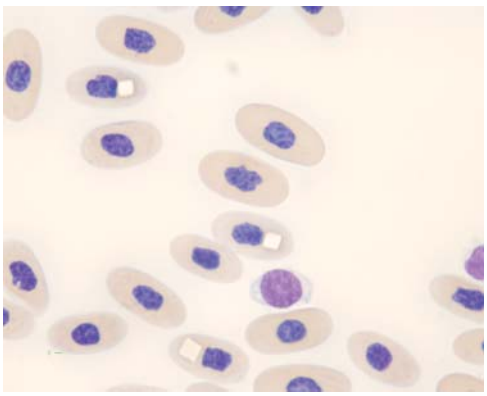

Figure 21.28 Clear, square, vacuole-like cytoplasmic inclusion in the erythrocyte in the blood film of a lizard (*Iguana iguana*). Wright-Giemsa stain. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 125.

Microfilaria

Microfilaremia in reptiles typically is not associated with clinical signs of illness or changes in the hemogram or blood biochemical profile. The reptile typically survives for years with these parasites, and microfilaria are detected as an incidental finding on examination of routine Romanowsky-stained blood films. Microfilarias are produced by adult female filarid nematodes, which can live in various locations in the body of a reptile. Microfilarias are ingested by a suitable bloodsucking arthropod (i.e., tick or mite) or insect (i.e., mosquito), in which they develop into the infective, third-stage larval form. The lifecycle is complete when the infective form enters a new reptilian host during intermediate-host feeding.

Hematopoiesis

The bone marrow appears to be the primary site for erythropoiesis, granulopoiesis, and thrombopoiesis in adult reptiles. The bone marrow of some reptiles, especially turtles and tortoises, is not gelatinous, and hematopoietic cells may be difficult to sample for study. A saline-soak technique can be used for turtles in which a 2 mm thickness of bone is allowed to soak for 18–24 hours at 4 °C and then agitated for 30 minutes, and the solution centrifuged to obtain the hematopoietic cells.

Erythropoiesis in the bone marrow occurs within the vascular space of the reticular stroma. Foci of extramedullary erythropoiesis, in the liver and spleen, are common. The stages of reptilian erythrocyte maturation appear to be similar to those of birds and mammals; however, during the final stages of maturation, the mature reptilian erythrocytes are often larger than the immature erythrocytes – a distinctive difference compared to mammals. In general, seven recognizable stages are involved in erythrocyte development: rubriblasts, prorubricytes, basophilic rubricytes, early polychromatic rubricytes, late polychromatic rubricytes, polychromatic erythrocytes, and mature erythrocytes. The morphologic features of these cells are similar to those described in birds (see Chapter 20).

The rubriblast (proerythroblast, pronormoblast) is the first progenitor cell that can be visually identified and appears as a round cell with a large round nucleus, delicate uncondensed chromatin, and one or two nucleoli. The cytoplasm is basophilic and agranular and typically appears as a narrow band surrounding the nucleus. Pinocytotic vesicles may be found along the cell margin and are a characteristic feature of early reptilian erythroid cells. These vesicles make up the process for ferritin incorporation used in hemoglobin synthesis.

The prorubricyte (basophilic erythroblast) is similar to the rubriblast. The cell is round, and the nucleus lacks nucleoli

and contains a slightly more condensed chromatin network. The cytoplasm of the prorubricyte stains basophilic.

The rubricyte (polychromatic erythroblasts) is the third stage in erythrocyte maturation. During this stage of development, the cell is smaller in size and is still spherical or just beginning to develop an oval shape. The size of the nucleus is reduced, and the chromatin appears more condensed and clumped. The cytoplasm of the rubricyte is scant and lighter in color due to hemoglobin synthesis and may be classified as basophilic, early polychromatic, or late polychromatic. Reptilian erythrocytes are typically released into the peripheral circulation in the rubricyte stage.

Reticulocytes (polychromatic erythrocyte, acidophilic or orthochromatic erythroblast, proerythrocyte) make up the next stage of erythrocyte maturation and resemble mature erythrocytes. The cell is larger in size, and the shape resembles a flattened ellipsoid. Reticulocytes may be differentiated from the mature erythrocyte based on the presence of abundant slightly basophilic cytoplasm and nuclear chromatin that is not fully condensed. The presence of reticulocytes in peripheral blood may vary with species. Some authors describe them as a common finding, and others describe them as rare.

Mature erythrocytes (normocytes) are morphologically similar among most reptiles. The mature erythrocyte is a flattened oval and has a centrally positioned nucleus with condensed nuclear chromatin. The nuclear margins may be irregular. The nucleus is ellipsoid in many species of reptile; however, in some species (turtles, tortoises), the nucleus may appear round. The cytoplasm stains light red to yellowish in color. As erythrocytes age, the nucleus becomes more condensed and darker staining. In summary, as the reptilian erythrocyte matures, the cell becomes larger and the cytoplasm increasingly eosinophilic because of increased hemoglobin synthesis. A clear, size-related progression in erythrocyte development may not be evident in some species, but the shape of the cell changes from spherical to a flattened ellipsoid with maturation. The erythrocyte nucleus also decreases in size, with its shape changing from round to ellipsoid, and the nuclear chromatin becomes increasingly condensed as the cell matures. Sudan black B stain can be used as an erythrocyte marker that stains the cytoplasm of erythrocyte precursors and mature erythrocytes dark gray to black.

Developing granulocytes are morphologically similar to mammalian granulocytes and are associated with the extravascular spaces of the bone marrow reticular stroma. The maturing granulocytes migrate through the endothelial cells of the sinusoids to enter the bloodstream. The maturation stages of the granulocytes of reptiles also resemble those of birds (see Chapter 20 on avian hematology). As the granulocyte matures, the cell decreases in size, and the cytoplasm becomes less basophilic. Specific, characteristic granules appear in the myelocyte and metamyelocyte stages of development, and these increase in number with maturation. The nuclear chromatin becomes increasingly condensed with maturity, and in those species that lobate their nuclei, the nucleus changes from round to segmented. Mature and immature heterophils from some species stain positive with chloroacetate esterase, α-naphthyl butyrate esterase, α-naphthyl acetate esterase, and leukocyte alkaline phosphatase chemical stains. The cytoplasmic granules of the eosinophils of some reptiles typically are large, round, and pink with Romanowsky stains and golden brown with benzedrine peroxidase, which helps in the differentiation of eosinophil precursors from heterophil precursors.

Granulopoiesis begins with the myeloblast. Myeloblasts have a moderate amount of agranular, slightly basophilic cytoplasm and a large, central to slightly eccentric ovoid, vesicular nucleus with a large nucleolus or prominent nucleoli. As maturation takes place, the cells decrease in size, the cytoplasm becomes less basophilic, the nuclear chromatin becomes increasingly condensed, and the nucleus changes shape from round to segmented in those reptile species that lobate their nuclei. The acidophils (heterophils and eosinophils) are derived from separate cell lines, and their specific characteristic cytoplasmic granules appear in the myelocyte and metamyelocyte stages of development. These granules increase in number as maturation continues.

The cytoplasmic granules of the eosinophils of some reptiles are typically large, round, and pink with Romanowsky stains and golden brown with benzidine peroxidase to help in the differentiation of eosinophil precursors from those of heterophils. Mature and immature heterophils from some reptile species stain positive with chloroacetate esterase, a-naphthyl butyrate esterase, a-naphthyl acetate esterase, and leukocyte alkaline phosphatase chemical stains.

Thrombopoiesis in reptiles is similar to that in birds (see Chapter 20 on avian hematology). The elliptical, mature thrombocytes are derived from round precursor cells. The thrombocyte series consists of thromboblasts, immature thrombocytes, and mature thrombocytes. Reptilian thrombocytes are derived from a distinct line of mononuclear cells found in the bone marrow or other hematopoietic tissue. Thromboblasts appear as small, round to oval cells that resemble rubriblasts and contain round nuclei with fine to punctate nuclear chromatin and one or more nucleoli. Immature thrombocytes may be divided into three groups: early, mid-, and late-immature thrombocytes, based upon their degree of maturity. As thrombocytes develop, they decrease in size, the cytoplasm becomes less basophilic, and the shape of the cell changes from round to elliptical. The nucleus changes from round to oval in shape as well. In later stages of maturation, the nuclear chromatin becomes densely packed, and specific cytoplasmic granules may appear. It often is difficult to differentiate thrombocytes from lymphocytes in hematopoietic specimens. Special chemical stains may be used to differentiate the two in some

species, in which thrombocytes stain positive with periodic acid–Schiff, acid phosphatase, and α-naphthyl butyrate esterase and lymphocytes do not.

Lymphopoiesis of reptiles resembles that of mammals and birds. Reptilian lymphoblasts, prolymphocytes, and mature lymphocytes appear identical to those found in birds and mammals and can be found in lymphopoietic tissues such as the spleen and liver. The lymphocytes are derived from blood-borne stem cells, which most likely originated from the embryonic yolk sac. Lymphoid precursors originating from the yolk sac or bone marrow colonize the thymus during embryonic development. The thymus is the first lymphoid organ to develop in reptiles, and it is likely that T lymphocytes are the predominant lymphoid cells of the spleen and peripheral blood of posthatched reptiles. T cells that originate in the thymus spread to spleen, liver, intestines, and other tissues containing lymphoid aggregates. The origin of the immunoglobulin-producing cells (B lymphocytes) is unknown since a reptilian equivalent to the avian bursa of Fabricius has not been found. The spleen functions as an organ of leukopoiesis in reptiles. During early stages of splenic development, large numbers of granulocytes are found, indicating that the organ is involved in granulopoiesis. During later development, the spleen becomes primarily involved with lymphopoiesis.

22 Hematology of Fish

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado, USA

Published hematologic reference intervals for fish and the interpretation of piscine blood test results are limited when compared to what is available for mammals and birds. This is expected given the diversity of fish, a group of animals represented by approximately 27,300 species; a number that exceeds that of all other vertebrates combined. Regardless of these limitations, hematologic evaluation of the piscine patient can be useful in the detection of diseases affecting the cellular components of blood. Certain diseases of fish result in anemia, leukopenia, leukocytosis, thrombocytopenia, and other abnormal changes of the blood cells. Evaluation of the hemogram also may be useful in following the progress of the disease or the response to therapy.

Blood collection and handling

Blood for diagnostic sampling can be collected safely from fish that are greater than 3 in. (8 cm) in length. The collection procedure itself should be accomplished in less than 30 seconds, however, because fish that are held out of water for longer periods suffer from respiratory distress and electrolyte imbalance. Blood collection from fish may be accomplished with either physical or chemical restraint. Physical restraint is used if the patient is cooperative or severely debilitated and when the procedure can be performed without causing added stress to the animal. Because their integument has many important metabolic functions, fish should be handled cautiously, and every attempt should be made to protect the skin and mucous coating. Therefore, examination or surgical gloves that contain no powder should be worn to protect the skin and mucous layer of the fish as well as the hands of the handler from zoonotic disease and the physical and chemical defense mechanisms of the fish. In general, small fish can be restrained by using one hand to grasp near the base of the tail while supporting the body with the other hand. Larger fish may require the use of ancillary equipment, such as nets or stretchers, for restraint and handling. Some elasmobranchs may enter a hypnotic state referred to as tonic immobility when placed in dorsal recumbency. Tonic immobility has been noted in several species and offers a short duration of decreased activity allowing for minor procedures such as physical or ultrasonographic examination, venipuncture, or administration of medications. When physical restraint cannot be safely accomplished, then chemical restraint is commonly used. A number of chemical agents can be used to provide sedation or anesthesia in fish; however, the most commonly used Food and Drug Administration–approved agent is tricaine methanesulfonate (Tricaine-S, previously Finquel; also referred to as tricaine or MS-222). Tricaine methanesulfonate requires buffering with two parts sodium bicarbonate and is used as an immersion bath to create sedation and anesthesia. Factors such as physical characteristics of the fish and environmental conditions may affect the outcome of a chemical agent used for sedation or anesthesia. Suggested sedation and anesthetic doses for tricaine methanesulfonate range from 50 to 400 mg/L; however, the commonly used induction dose for most fish ranges between 50 and 150 mg/L – it is recommended to begin conservatively.

The amount of blood that can be safely obtained from a healthy fish has been reported at 30–50% of total blood volume; however, a sample representing 1% of the body weight is typically collected in most clinical situations. Blood for hematologic evaluation should be collected in either heparin or ethylenediaminetetraacetic acid (EDTA) as an anticoagulant. Disadvantages of heparin include the tendency for leukocytes and thrombocytes to clump and the creation of a blue tinge to blood films with Romanowsky stains. In addition, if the blood sample contains a small clot, heparin may not prevent coagulation once it has started. Disadvantages of EDTA include the hemolysis of erythrocytes in some fish species, such as elasmobranchs. For elasmobranch blood, although heparin can be used, a combination of heparin and EDTA or use of another modified anticoagulant solution is ideal to match the osmolarity of the blood. Hemolysis also

can occur with the use of tricaine sedation or anesthesia, but cooling the blood sample to 25 °C and rapidly preparing the film can minimize the hemolysis associated with tricaine. To avoid staining artifacts caused by an anticoagulant, a freshly prepared blood film should be made at the time of blood collection.

Blood can be collected from fish via the caudal vertebral vein or artery. Venipuncture of these vessels can be accomplished with or without sedation or anesthesia, and the caudal vertebral vein or artery can be approached either ventrally or laterally. The ventral approach used for teleosts (bony fish) and small elasmobranchs begins with the fish in dorsal recumbency followed by the insertion of the needle under a scale (teleost fish) along the ventral midline near the base of the caudal peduncle (Figure 22.1). The needle is then directed toward the vertebral bodies. Slight aspiration of the plunger is applied once the needle has penetrated the skin, and advanced deeper into the tissue until blood enters the syringe. After reaching the vertebral bodies and no blood has been obtained, the needle is withdrawn slightly; both ventrally and laterally, with continued negative pressure applied to the syringe. Once the vessels have been entered, blood will begin to enter the syringe. The needle may need to be rotated slightly to properly position the needle hub in the vessel to facilitate collection of the blood.

The lateral approach in teleosts begins with the fish in lateral recumbency and identification of the lateral line. The needle is inserted into the skin between the scales, if applicable, a few millimeters below the lateral line near the base of the caudal peduncle. As the needle penetrates through the skin, mild negative pressure can be applied to the syringe as the needle is advanced deeper into the tissue toward the midline and under the vertebral bodies until blood enters the syringe (Figure 22.2). If bone is detected with the needle, the needle should be repositioned ventrally (below the spine).

Figure 22.1 Venipuncture of the caudal vein using the ventral approach in an elasmobranch fish (*Dasyatis americana*) using the ventral approach.

Figure 22.2 Venipuncture of the caudal vein using the lateral approach in a teleost fish (*Carassius auratus*) using the lateral approach.

Blood can be collected from the heart or bulbous arteriosus using a ventral approach. The needle is inserted slightly caudal to the apex of the V-shaped notch formed by the gill covers (opercula) and isthmus, and it is then advanced toward the heart while a slight vacuum is applied to the syringe. Blood will enter the syringe once the heart is penetrated. An anterolateral approach through an opened gill opercular cover also can be used to reach the heart. In this approach, the needle is directed caudally, from a point one-third of the distance between the ventral limit of the cavity (gill chamber) and medial to the bony support of the caudal wall of the opercular cavity. The needle is then advanced toward the heart using a slight vacuum. Cardiocentesis carries a greater risk of damage to the fish than use of the caudal vertebral vessels for blood collection.

Blood can be collected from large sharks using the dorsal venous sinus that courses caudal and slightly ventral to the dorsal fins. With the shark restrained in ventral recumbency or in a sling with its back exposed, a needle is inserted through the soft skin just under the caudal aspect of a dorsal fin (caudal flap) as it is lifted dorsally (Figure 22.3). The needle is then directed under the dorsal fin but is kept to the back and slightly off the midline. Use of a needle with an extension tube is often helpful for keeping the needle in position should the shark move during the procedure. Advantages of this method compared with venipuncture of the caudal vertebral vessels in large sharks include ease of access to the vessel and restraint of large sharks when using the dorsal fin approach.

Erythrocytes

Morphology

The transportation of oxygen is the primary function of fish erythrocytes, the extent of which depends on the

Figure 22.3 Blood collection from a shark (*Carcharhinus plumbeus*) using the blood vessel under the dorsal fin. Source: Image from Campbell TW. *Exotic Animal Hematology and Cytology*, 4th ed. Ames, IA: Wiley Blackwell, 2015, p. 185.

amount of hemoglobin concentration within the cell and the gas-exchange mechanism. Normal, mature erythrocytes of the majority of fish species are oval to ellipsoidal, have abundant pale eosinophilic cytoplasm, and include a centrally positioned, oval to ellipsoidal basophilic nucleus in Romanowsky-stained blood films (Figure 22.4). The long axis of the nucleus is parallel to that of the cell, except in a few species with round erythrocyte nuclei. The nuclei of fish erythrocytes can be large, occupying as much as one-fourth (or more) of the cell volume. The nuclear chromatin is densely clumped and stains dark purple. A few species of fish (e.g., certain species in the Gonostomidae family) have anucleated erythrocytes. The cytoplasm of fish erythrocytes when viewed on the stained blood film is typically homogeneous, but it may contain variable amounts of rarefied or pale-staining areas or vacuoles associated with the degeneration of organelles.

Both the size and number of erythrocytes vary between species of fish and, depending on the physiologic conditions, even within a single species. For example, the erythrocytes of fish belonging to the class Chondrichthyes (sharks and rays) generally are larger and more rounded than those of the class Osteichthyes (bony fish). Mature erythrocytes of some fish are biconvex, with a central swelling that corresponds to the position of the nucleus, whereas those of other species are flattened and biconcave.

Slight to moderate anisocytosis and polychromasia are normal in many species of fish. Polychromatic erythrocytes have a pale blue cytoplasm compared with that of mature erythrocytes (Figure 22.5). They also may appear to be more rounded and to have a less condensed nuclear chromatin.

Because erythropoiesis occurs in the peripheral blood of normal fish, immature erythrocytes may be found in blood films. An estimated 1% of the erythrocytes in peripheral blood are derived from circulatory erythropoiesis. Immature erythrocytes contribute to the degree of polychromasia and anisocytosis. As in the blood films of birds and reptiles, immature erythrocytes of fish have larger, less condensed nuclei and less cytoplasm than mature erythrocytes. Immature erythrocytes (i.e., rubriblasts, prorubricytes, and rubricytes) are round cells with centrally positioned, round nuclei. Depending on the stage of development, the cytoplasmic volume varies in both the amount and intensity of basophilic staining with Romanowsky stains. Erythroid cells in mitosis also may be present in the peripheral blood films from normal fish. Although erythropoiesis occurs in peripheral blood, the primary site of hematopoiesis in general is the

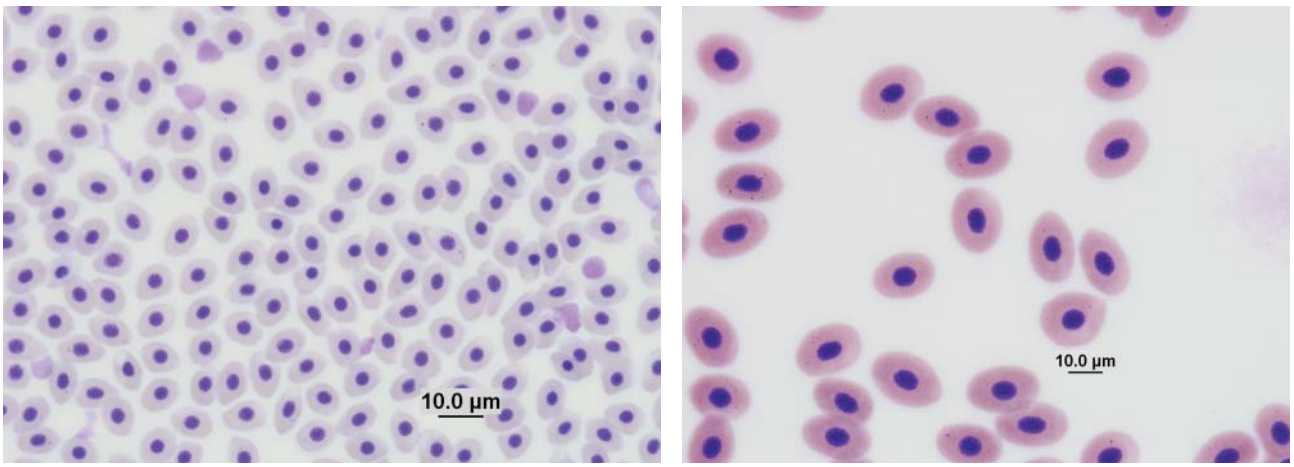

Figure 22.4 (a) Normal mature erythrocytes in the blood film of a bony fish (*Roncador stearnsii*). Wright-Giemsa stain. (b) Normal mature erythrocytes in the blood film of a cartilaginous fish (*Rhinoptera bonasus*). Wright-Giemsa stain.

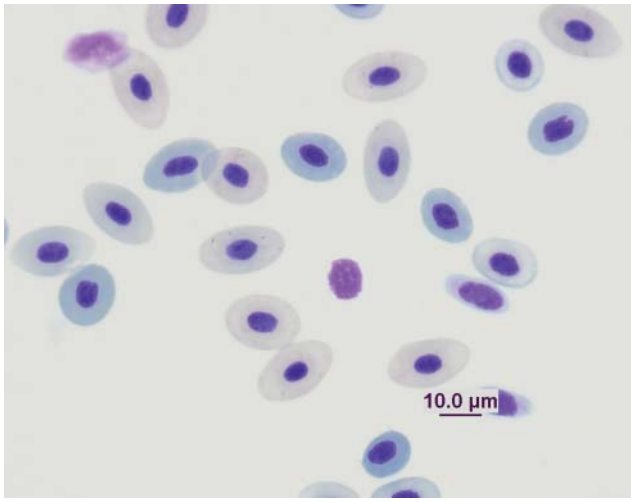

Figure 22.5 Increased polychromasia in the blood film of a bony fish (*Opsanus tau*). Wright-Giemsa stain.

kidney in teleosts and the Leydig organ, epigonal organ, thymus, and spleen in the elasmobranch.

Ultrastructurally, mature fish erythrocytes have a finely granular cytoplasm with no inclusions, whereas immature erythrocytes have a cytoplasm with mitochondria, Golgi complex, and small vacuoles.

Laboratory evaluation

Determination of packed cell volume (PCV) is the most commonly used method for evaluating the red cell mass of fish. The microhematocrit method is used for obtaining a PCV of fish blood. The normal range in bony fish is between 20 and 45%. The normal range in elasmobranchs may be similar; however, results vary based on venipuncture site. The PCV tends to be lower in samples collected from the venous sinus near the dorsal fin than from those collected from the caudal vein of the tail. Other factors that may contribute to PCV variation in healthy animals include stress (handling, anesthesia, water intake), physical characteristics (size, species), sex, environmental factors (water temperature, dissolved oxygen, population density, photoperiod), activity level (thermodynamics), reproductive status, life stage, and diet.

Although a variety of methods have been used to determine the hemoglobin concentration in fish blood, the cyanmethemoglobin method provides the most consistent results. As with avian and reptilian hemoglobin determinations, this procedure requires centrifugation of the blood–cyanmethemoglobin reagent mixture to remove the free erythrocyte nuclei before measurement of optical density. Most teleost hemoglobin concentrations range from 5 to 10 g/dL.

A total erythrocyte count (TRBC) in fish can be determined by a manual counting method using a hemocytometer or by an electronic cell counter. Three manual methods that can be used to obtain TRBCs in fish blood use the Erythro-pette™ system (Exotic Animal Solutions, Inc. Hueytown, AL, USA), Natt-Herricks solution (see Chapter 20 on avian hematology), or modified Dacie's solution (Table 22.1). The Erythro-pette™ method is the easiest of the three, because the 1 : 200 dilution of whole anticoagulated blood is made

Table 22.1 Erythrocyte parameters for selected teleost fish.

using the diluent, pipette, and mixing vial provided with the kit. The Natt-Herricks method is also easy and practical as total leukocyte and thrombocyte counts can also be obtained on the same charged hemocytometer. The modified Dacie's staining methods require preparation of the diluent/stain solution and use of the red blood cell–diluting pipette. Blood is drawn to the 0.5 mark on the pipette, and either Natt-Herricks or modified Dacie's stain is drawn to the 101 mark to prepare the 1 : 200 dilution. Commercially prepared Natt-Herricks solution kit (Natt-Pette) makes the procedure easier and more accurate. The kit contains prefilled Natt-Herricks stain reservoirs, a pipette calibrated for 5 µL (to make the 1 : 200 dilution), and tips for the pipette. The diluted blood is then discharged onto the hemocytometer counting chamber and is allowed to settle for a minimum of 5 minutes before counting. With these stains, the oval erythrocytes show a small, dark blue nucleus that is surrounded by a colorless to faint pink cytoplasm. The total number of erythrocytes in the four corner and central squares in the central, large square of a Neubauer-ruled hemocytometer chamber is obtained using ×40 (high dry) magnification. The TRBC is calculated by multiplying the numbers of erythrocytes by 10,000.

The red blood cell indices (i.e., mean erythrocyte volume [MCV], mean corpuscular hemoglobin concentration [MCHC], and mean cell hemoglobin [MCH]) can be calculated using standard formulas. However, the direct, electronic measurement of MCV appears to be more sensitive for detecting changes in the erythrocyte size in fish and is more reproducible than the calculated MCV. Table 22.1 offers erythrocyte reference values for selected teleost fish. The intervals shown are merely an estimate, as many factors may contribute to slight variation. For example, active fish will have a higher demand for oxygen and, therefore, a smaller red cell concentration (RBC) count and a lower MCV. Elasmobranchs, in general, have larger and fewer erythrocytes that contain more hemoglobin in comparison with bony fish, which translates into increased MCV, MCHC, and MCH but decreased PCV, hemoglobin concentration, and total RBCs. Similar to PCV, other factors that may contribute to changes in these values are cell maturity (the more mature, the larger the cell, thereby increasing values), species, season, and diet.

Responses in disease

In general, a PCV less than 20% indicates anemia in fish. Anemia may be due to blood loss (hemorrhagic anemia), cell destruction (hemolytic anemia), or decreased production (hypoplastic anemia). Polycythemia is classified as hematocrit greater than 45% and may due to dehydration, sexually mature males, hypoxia, stress, splenic contraction, or erythrocyte swelling.

The standard practices for collecting, handling, and analyzing blood from mammals and birds can be misleading when applied to fish. Emersion and handling of fish for venipuncture or cardiocentesis can have a marked effect on the hemogram, significantly increasing the hematocrit by as much as 25%. The magnitude of this effect relates directly to the handling and analytic time. Handling of fish for as little as 20 seconds results in the release of catecholamines, which tend to cause hemoconcentration and swelling of the erythrocytes. Therefore, the hematocrit increases, but the hemoglobin concentration remains the same, thereby resulting in a decreased MCHC. The increase in blood catecholamines causes ion exchanges (Na^+/H^+ and Cl^-/ HCO^-) across the erythrocyte membrane; thus, as Na^+ and Cl^- enter the cell, water follows osmotically, causing the cell to swell. Cannulation methods have been developed for use in research fish to minimize these effects; however, these methods are impractical for use in clinical studies.

In general, the PCV of fish is lower than that of mammals and birds. Hematocrits vary both between and within fish species, and they appear to correlate with the normal activity of the fish, with less active fish having lower hematocrits than active, fast-swimming fish. Hematocrits also vary during the life cycle of fish. For example, during prespawning conditions, Atlantic salmon (*Salmo salar*) have high hematocrits compared with those during spawning. Age, sex, water temperature, photoperiod, and seasonal variation also may influence the PCV of fish. In fact, the PCV in some species of male fish are large enough to require two reference intervals.

Cartilaginous fish (sharks and rays) and bony fish appear to have different gas transport systems, which affect their erythrocyte parameters. Bony fish exhibit a high cardiac workload and blood pressure, which are associated with a higher PCV and smaller erythrocytes. Sharks and rays, however, exhibit relatively modest cardiac work load, higher cardiac output, higher blood volumes, and increased flow rates, which are associated with lower concentrations of larger cells.

In general, fish with PCVs less than 20% are considered to be anemic and associated with blood loss (hemorrhagic anemia), cell destruction (hemolytic anemia), or decreased production (hypoplastic anemia). However, for some species, such as the Port Jackson shark (*Heterodontus portusjacksoni*), a normal PCVs may be as low as 20%.

Polycythemia is classified as hematocrit greater than 45% and may due to dehydration, sexually mature males, hypoxia, stress, splenic contraction, or erythrocyte swelling. A high PCV associated with dehydration is supported by increased serum osmolality or total protein.

Fish with regenerative anemia often have an increased concentration of polychromatic and immature erythrocytes in their blood films. Anemic fish that exhibit little or no polychromasia have nonresponsive anemia. A microcytic normochromic anemia has been associated with environmental stresses, such as increased population densities. A microcytic hypochromic anemia with marked poikilocytosis

has been reported in trout (*Salmo gairdneri*) that were fed diets containing yeast, thereby resulting in oxidative damage to erythrocytes. Anemias associated with erythrocytes having pyknotic nuclei, erythroplastids (i.e., erythrocytes without nuclei), and red-blood-cell fragmentation have been associated with conditions that interfere with the splenic removal of senescent red blood cells from the peripheral circulation. Abnormal erythrocyte nuclei (i.e., amitosis, segmentation, and fragmentation) as well as formation of erythroplastids may relate to nutritional disorders, such as deficiency of folic acid or vitamin E and toxicosis from rancid oils and environmental pollutants.

Because the immature erythrocytes of fish are smaller than the mature erythrocytes, microcytosis often is associated with marked hemorrhagic or hemolytic anemias, in which the regenerating, immature erythrocytes represent the majority of the peripheral blood erythrocytes. Hemorrhagic anemias of fish are associated with trauma, bloodsucking parasites, vitamin K deficiency, and septicemia (bacteria or viral). For example, enteric red mouth disease (yersiniosis) of fish produces a hemorrhagic septicemia and a hemogram that is characterized by leukocytosis, low PCV, and reticulocytosis. Hemolytic anemias of fish may be associated with toxins (bacterial or environmental), viral infections (erythrocytic necrosis virus), certain nutritional deficiencies, and hemoparasites. Cadmium is a calcium channel blocker that impedes normal membrane function in erythrocytes resulting in hemolytic anemia in freshwater teleost fish exposed to toxic levels of cadmium in the water. Nitrite poisoning (brown blood disease or new tank syndrome) of fish also results in severe hemolytic anemia. Nitrite is readily absorbed from the gills and enters into the blood, where it then oxidizes hemoglobin to methemoglobin, which in turn gradually changes the blood from red to brown in color. A hemolytic anemia results as splenic macrophages remove the affected erythrocytes from the circulation.

Several nutritional deficiencies have been produced experimentally in fish. For example, folic acid deficiencies result in normochromic macrocytic anemias, and vitamin B_{12} deficiencies result in hypochromic anemias. Folate deficiency has been suggested as being a cause of the chronic hemolytic anemia that occurs in channel catfish (*Ictalurus punctatus*).

Leukocytes

Fish have granulocytic and agranulocytic leukocytes, with the latter represented by lymphocytes and monocytes. Leukocytes (especially the granulocytes) exhibit a wide variation in appearance among fish species. This has led to controversy and confusion when applying the nomenclature and classification of piscine leukocytes on the basis of such descriptions from avian and mammalian Romanowsky-stained blood films. Some fish granulocytes have an appearance similar to that of the avian heterophil, while others to the mammalian neutrophil, hence the adoption of those terms in some cases. Evaluation of the cellular ultrastructure, differential cytochemical staining, immunofluorescence, and function testing of fish leukocytes, however, has helped to alleviate some of this controversy in some species.

Leukocytes of commonly studied bony fish

Channel catfish (*Ictalurus punctatus*)

One study identified these fish as having neutrophils, basophils, lymphocytes, and monocytes using both electron microscopy and cytochemical staining while another declared heterophils as the primary granulocyte, using electron microscopy only. Ultrastructural and cytochemical studies have identified heterophils, basophils, lymphocytes, and monocytes in the peripheral blood of channel catfish. These results support the general classification of these cells in Romanowsky-stained blood films of this species.

Goldfish (*Carassius auratus*) and koi (*Carassius carpio*)

On the basis of electron microscopy, leukocytes found in the peripheral blood of goldfish can be classified as lymphocytes, monocytes, heterophils, eosinophils, and rarely, basophils. On the basis of cytochemical reaction, goldfish leukocytes can be classified as lymphocytes, heterophils, monocytes, and an atypical, segmented granulocyte. Electron microscopy and cytochemical staining indicate that koi, *Cyprinus carpio*, possess neutrophils, eosinophils, basophils, lymphocytes, and monocytes. It has been suggested that cell identification might be more effectively accomplished by using more than one evaluation method.

Red pacu (*Colossoma brachypomum*)

Six types of cells are classified as leukocytes in blood films from red pacu (*Colossoma brachypomum*). The four common types are classified as heterophils, eosinophils, lymphocytes, and monocytes. Nonstaining granulocytes are reported to occur in a frequency similar to that of eosinophils and are considered to be heterophils that failed to stain properly. The sixth cell type is referred to as a "granular-lymphocytoid cell" because it resembles a medium-sized lymphocyte containing one or more dull, fusiform eosinophilic granules. This cell type represents a significant population of the blood leukocytes of red pacu.

Salmonids (trout and salmon, *Salmo* spp.)

On the basis of cytochemical staining, salmonids appear to have three types of leukocytes: lymphocytes, neutrophils, and monocytes.

Striped bass (*Morone saxatulis*)

Striped bass leukocytes are classified as lymphocytes, neutrophils, and monocytes.

Tilapia (*Oreochromis spp.*)

The leukocytes of tilapia (*Oreochromis spp.*) are classified as neutrophils, eosinophils, lymphocytes, and monocytes.

White sturgeon (*Acipenser transmontanus*)

Four types of leukocytes – lymphocytes, monocytes, neutrophils, and eosinophils – have been described in white sturgeon.

Summary

Cytochemical studies of piscine leukocytes appear to support the use of mammalian leukocyte terminology as a classification scheme because they are considered to be analogous to mammalian leukocytes based upon cytochemical and ultrastructural studies. In general, neutrophils or heterophils, lymphocytes, and monocytes commonly are reported in the peripheral blood films of fish belonging to the class Osteichthyes (teleost or bony fish). Myeloperoxidase stain is used to differentiate neutrophils from true heterophils, because neutrophils stain positive and heterophils stain negative. In general, fish heterophils are neutrophils, based on myeloperoxidase staining, but are called heterophils because of the presence of prominent eosinophilic cytoplasmic granules with Romanowsky stains. Eosinophils and basophils are rare in the peripheral blood of bony fish.

Leukocytes of sharks and rays

The peripheral blood of fish belonging to the class Chondrichthyes (cartilaginous fish, such as sharks and rays) contain leukocytes that can be classified as granulocytes, lymphocytes, or monocytes. The granulocytes exhibit marked variation in both numbers and types between species, and the granulocyte classification scheme is based on the results of ultrastructural and cytochemical studies performed in blood samples from the lesser spotted dogfish (*Scliorrhinus canicula*), which has been used as a model for cartilaginous fish. The granulocytes are classified as either G_1 (type I), G_2 (type II), or G_3 (type III). To simplify the identification of these cells using familiar terminology, the G_1 granulocytes resemble the avian or reptilian heterophil, the G_2 granulocyte resembles the mammalian neutrophil, and the G_3 granulocyte resembles the eosinophil based upon the cell's appearance on Romanowsky-stained blood films. Basophils also can be found in the peripheral blood of cartilaginous fish.

Morphology

Neutrophils of bony fish

The neutrophils of bony fish tend to be round to slightly oval cells with eccentric nuclei (Figure 22.6). The nucleus of mature neutrophils vary in shape, being round, oval, indented (metamyelocyte type), elongated (band cell type), or segmented, and usually with two to three lobes. Nonsegmented nuclei are the most common in the granulocytes of bony fish. The nuclear chromatin is coarsely clumped, and it stains deeply basophilic in Romanowsky-stained blood films. The neutrophils of bony fish have abundant colorless, grayish, or slightly acidophilic-staining (light pink) cytoplasm; small cytoplasmic granules and vacuoles also may be present. The staining of the granules varies, however, and depends on the species or the maturity of the cell. The small, cytoplasmic granules of the neutrophils vary from gray to pale blue or red. Interspecies differences in the cytochemical reactions of bony fish neutrophils are observed; however, in general, they resemble the neutrophils of mammals.

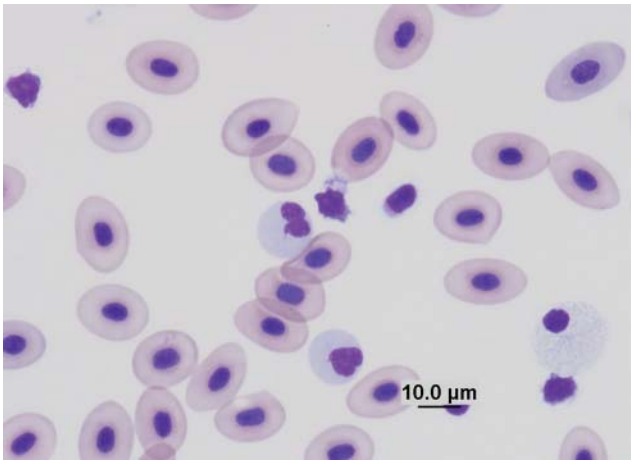

Figure 22.6 Neutrophils in the blood film of a bony fish (*Opsanus tau*). Wright-Giemsa stain.

Piscine neutrophils that exhibit distinct, rod-shaped cytoplasmic granules on Romanowsky stains often are classified in the literature as heterophils. Some species, such as goldfish and carp (*C. carpio*), have granulocytes with distinct and slightly acidophilic cytoplasmic granules, colorless cytoplasm, and eccentric, partially lobed nuclei on Romanowsky stains. These cells often are classified as heterophils rather than neutrophils, although they do have cytochemical properties similar to those of neutrophils in other fish. They measure approximately 9–10 in. diameter (some as large as 20 µm). These heterophils are peroxidase and Sudan black B positive when the granules are immature, but they are peroxidase negative in mature granules. Neutrophils from channel catfish and certain species of eel also contain prominent eosinophilic, rod-shaped cytoplasmic granules resembling those of avian heterophils on the basis of Romanowsky stains. The granules of these cells are strongly peroxidase positive. Similar cells have been found in a number of other bony fish as well. In salmonids, such as rainbow trout (*Onchorhynchus mykiss*) and coho salmon (*Onchorhynchus kisutch*), these neutrophils are the predominant granulocyte, as in most bony fish. Piscine neutrophils often reveal artifacts of blood film preparation, causing the cells to appear large and with swollen, pale nuclear chromatin (karyolysis).

Eosinophils of bony fish

Eosinophils rarely are reported in the blood films from bony fish, and some investigators doubt whether they exist at all in some species. When present, however, they appear as intermediate to large granulocytes, with distinct eosinophilic granules and pale blue cytoplasm. The nucleus varies from round (more common) to segmented. They can be distinguished from heterophils on the basis of cytochemistry and ultrastructural findings, although the absence of crystalloids (used as a fingerprint for mammalian eosinophils) often is the rule with piscine eosinophils. Eosinophils have been reported in goldfish, white sturgeon, and channel catfish. Piscine eosinophils tend to be round, with round to rod-shaped eosinophilic-stained cytoplasmic granules with Romanowsky stain (Figures 22.7 and 22.11b). The granules of piscine eosinophils often are less distinct compared with those of birds and mammals. These granules also have a tinctorial quality that differs from those of heterophils with distinct eosinophilic granules.

Fish eosinophils generally measure 9–14 μm in diameter, for example eosinophils of carp are approximately 7.5 in. diameter and have an eccentric nucleus that is indented, sausage-shaped, or bilobate as well as eosinophilic, cytoplasmic granules that are larger than those of the heterophils (neutrophils).

Basophils of bony fish

Basophils are rare in the peripheral blood of bony fish and have been reported only in a few species. Basophils are identified as round cells that have round, basophilic cytoplasmic granules that often obscure the cell nucleus. The nucleus is large, eccentric, and round. The nuclear chromatin is homogeneous. The basophils of carp measure between 10 and 20 μm. When present, basophils occur in low numbers.

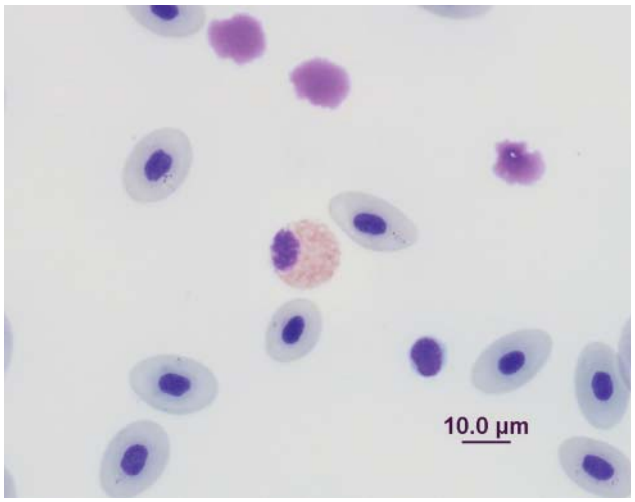

Figure 22.7 An eosinophil in the blood film of a bony fish (*Opsanus tau*). Wright-Giemsa stain.

Granulocytes of elasmobranchs (sharks and rays)

The elasmobranchs (or cartilaginous fish) appear to have the same types of leukocytes as described for other vertebrates; however, there is often disagreement associated with terms used for their granulocytes. The granulocytic leukocytes of elasmobranchs have been determined to be G_1 (also referred to as type I, heterophil, and fine eosinophilic granulocyte or FEG), G_2 (also referred to as type II and neutrophil), and G_3 (also referred to as type III, eosinophil, and coarse eosinophilic granulocyte or CEG). These cells tend to be similar in size. Some species of elasmobranchs may contain G_1, G_2, and G_3 granulocytes in their blood film. The G_1 granulocytes are typically round cells with an eccentric, irregular, nonlobed nucleus; colorless cytoplasm; and fine round to oval, eosinophilic cytoplasmic granules (Figures 22.8–22.10, 22.11a, and 22.16). The nucleus may be lobed in some species. These cells resemble avian heterophils, and they often are the most common form of the granulocytes. The G_2 granulocytes are typically round cells with a lobed nucleus and a colorless cytoplasm that lacks distinct granules (Figure 22.9). The granules and margin of the cell are often difficult to view and can be easily overlooked. These cells resemble mammalian neutrophils. The G_3 granulocytes are round cells characterized by a round to lobed nucleus (in some species), pale blue cytoplasm, and strongly eosinophilic, round to rod-shaped cytoplasmic granules (Figures 22.10 and 22.14). The cytoplasmic granules in the G_3 granulocytes have tinctorial qualities that differ from those of the G_1 granulocytes in the same blood film. The G_3 granulocytes of cartilaginous fish resemble avian eosinophils.

The granulocytes of sharks and rays tend to stain negatively for peroxidase, β-glucuronidase, and Sudan black B but positive for acid phosphatase, arylsulfatase, and acid naphthyl AS-D chloroacetate esterase. The eosinophilic granulocytes (G_1 and G_3) of the elasmobranchs share few morphologic and cytochemical characteristics with mammalian eosinophils. The function and interrelationships of the granulocytes in cartilaginous fish are not known; however, they appear to be separate cell types rather than intermediate stages of one cell type. Not all species of cartilaginous fish exhibit all of the granulocytes described for the lesser spotted dogfish (*S. canicula*). For example, only G_1 and G_3 granulocytes have been found in the rays *Raja clavata* and *Raja microcellata*. Basophils occasionally are found in peripheral blood films of some species of cartilaginous fish.

Basophils may occasionally be found in the peripheral blood of elasmobranchs, appearing as round cells with dark purple–stained granules. The amount of granules varies from sparse to obliterating the nucleus.

Lymphocytes of fish (bony and cartilaginous)

Lymphocytes frequently are the most abundant leukocyte in peripheral blood films of fish, and they resemble

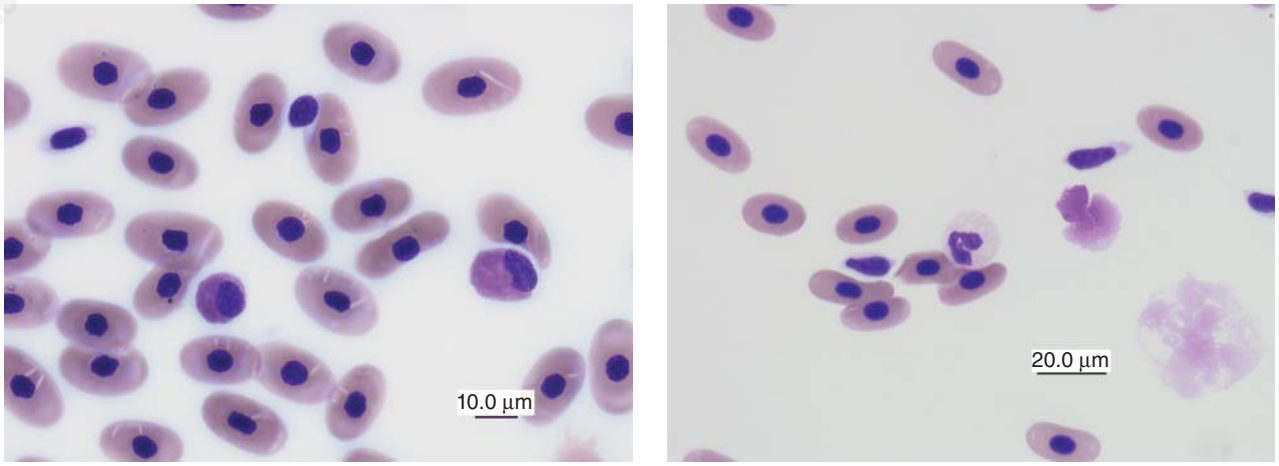

Figure 22.8 (a) G_1 granulocytes (heterophils) in the blood film of a cartilaginous fish (*Ginglymostoma cirratum*). Wright-Giemsa stain. (b) A G_1 granulocyte (heterophil) in the blood film of a cartilaginous fish (*Chiloscyllium plagiosum*). Wright-Giemsa stain.

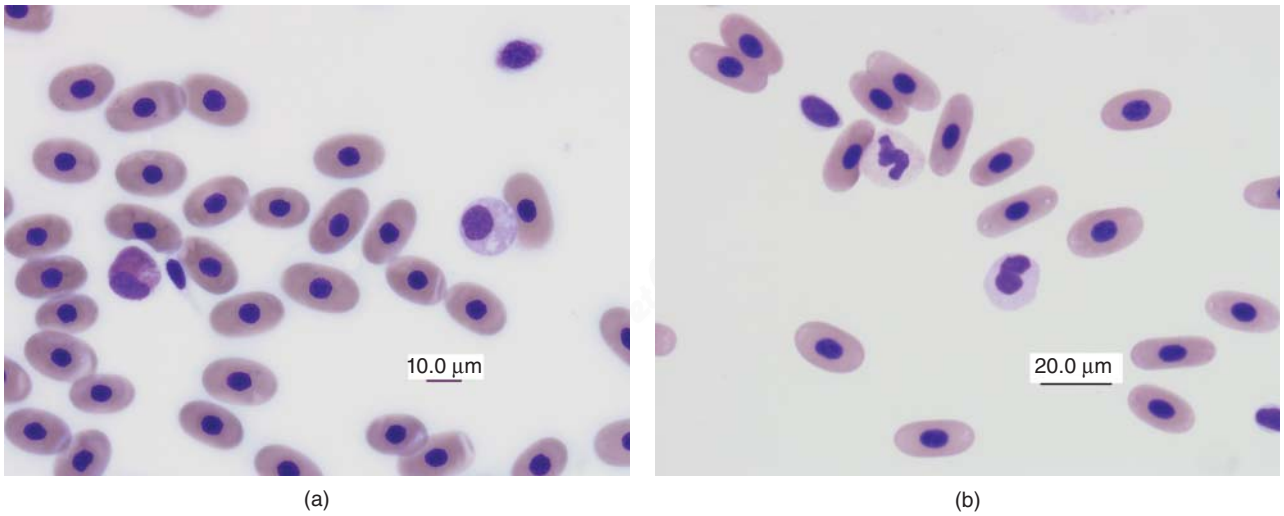

Figure 22.9 (a) A G_2 granulocyte or neutrophil (granulocyte on the right) and a G_1 granulocyte (heterophil) in the blood film of a cartilaginous fish (*Ginglymostoma cirratum)*. Wright-Giemsa stain. (b) A G_2 granulocyte or neutrophil (granulocyte near the center) and a G_1 granulocyte or heterophil (granulocyte nearest the top) in the blood film of a cartilaginous fish (*Chiloscyllium plagiosum*). Wright-Giemsa stain.

their counterparts in avian and mammalian blood films (Figures 22.11). Lymphocytes are often described by size – small, medium, and large. The small lymphocytes are considered to be more mature. Combinations of different sizes may appear in one sample. Fish lymphocytes typically measure between 5 and 10 µm in diameter. Lymphocytes tend to be round, but they may mold around adjacent cells in the blood film. They have a high nucleus:cytoplasm (N:C) ratio, with coarsely clumped, deeply basophilic nuclear chromatin. The scant cytoplasm of small mature lymphocytes stains a homogenous pale blue. An occasional lymphocyte possesses azurophilic cytoplasmic granules. Reactive lymphocytes in blood films from fish resemble those of birds and mammals, with abundant, deeply basophilic cytoplasm and an occasional, distinct Golgi complex (Figure 22.12). Plasma cells also may be seen in small numbers on the peripheral blood films of many species of fish.

Monocytes of fish (bony and cartilaginous)

Monocytes occasionally are reported in the blood films of most species of fish, and they resemble monocytes of birds and mammals. They are large, mononuclear leukocytes, with abundant blue-gray to blue agranular cytoplasm, which may contain vacuoles. Fish monocytes generally measure 10–20 µm in diameter. The cytoplasmic margins may be indistinct or ragged because of the presence of pseudopodia. The nucleus varies in shape (round to kidney-shaped to bilobate) and generally occupies less than 50% of the

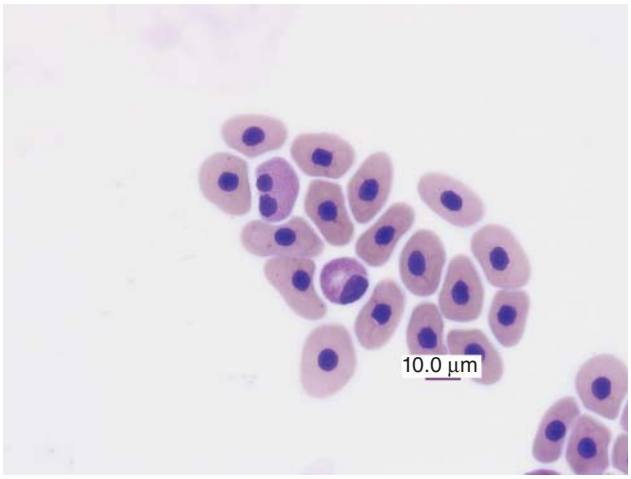

Figure 22.10 A G_3 granulocyte or eosinophil (granulocyte nearest the top) and a G_1 granulocyte or heterophil (granulocyte near the middle) in the blood film of a cartilaginous fish (*Ginglymostoma cirratum*). Wright-Giemsa stain.

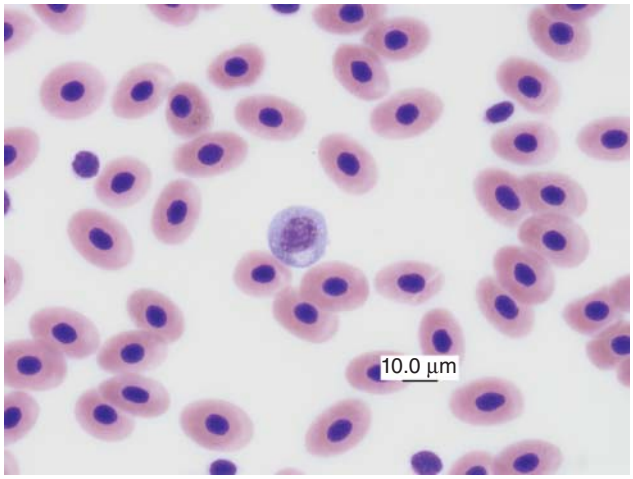

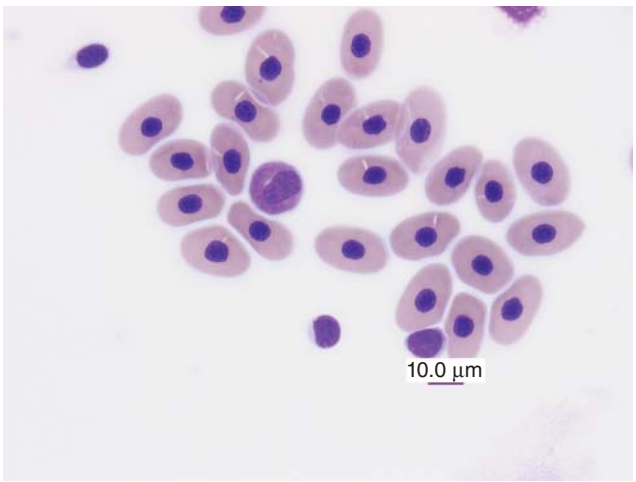

Figure 22.12 A reactive lymphocyte in the blood of a cartilaginous fish (*Rhinoptera bonasus*). Wright-Giemsa stain.

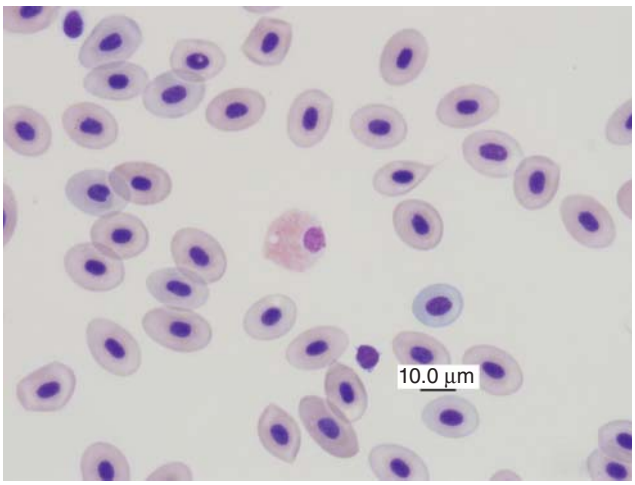

cytoplasmic volume. The nuclear chromatin of monocytes generally is more granular and less clumped compared with that of lymphocyte nuclei. Results of ultrastructural studies indicate that monocytes in all species of fish are similar to those in other vertebrates. The term monocyte/macrophage frequently is used to classify piscine monocytes, because cells resembling transformational forms between monocytes and macrophages often are found in peripheral blood films (Figure 22.13). The term monocyte, however, is reserved for those found in peripheral blood, and the term macrophage is reserved for those found elsewhere. Fish monocytes can be differentiated from immature granulocytes and lymphocytes by the positive, nonspecific esterase reaction in monocytes.

Laboratory evaluation

The same problems associated with obtaining total leukocyte counts in birds and reptiles also apply in fish. Because fish have nucleated erythrocytes and thrombocytes, manual counting methods are used. Direct leukocyte counting methods using a Neubauer-ruled hemocytometer and a variety of staining and diluting solutions have been used. Natt and Herricks method commonly is used, and the procedure is the same as that described for obtaining total leukocyte counts in avian and reptilian blood (see Chapters 20, on avian hematology, and 21, on reptilian hematology). The leukocytes appear blue and stain darker than erythrocytes stained with Natt-Herricks. It may be difficult to distinguish small, mature lymphocytes from thrombocytes if the counts are made using a ×10 objective; cells are more accurately

identified at higher magnifications. Staining for 60 minutes in Natt-Herricks solution also may improve the differentiation between small lymphocytes and thrombocytes. Alternatively, thrombocytes can be included in the hemocytometer count and the differential count from the blood film. The total thrombocyte count can then be subtracted from the total cell count to obtain the WBC. Advantages of the Natt and Herricks procedure include the ability to obtain a total erythrocyte, leukocyte, and thrombocyte count using the same charged hemocytometer. In addition, the technique can be applied to blood samples obtained from all lower vertebrates.

A leukocyte differential is obtained from a Romanowsky-stained blood film. Applying a drop of albumin to the slide during preparation of the blood film often is advantageous to minimize smudging of the cells. Quickly drying the blood film using a hair dryer also may help to alleviate cellular artifacts associated with blood film preparation.

Responses in disease

The leukocyte response of fish is affected by stress, inflammatory and infectious diseases, and nutritional disorders as well as other intrinsic and extrinsic factors. Total leukocyte counts vary with species, physiologic age, sex, season, and methods of rearing and nutrition. Normal physiological factors and various other stressors such as environmental factors and handling can cause leukocyte concentrations to range into or slightly above the upper limits of normal. Normal physiological factors include age, population densities, water quality, and other factors. For example, age-related changes in the total leukocyte and lymphocyte counts of fish are similar to those described in mammals. Juvenile fish have notably higher total leukocyte counts and lymphocyte concentrations compared to adults. High Total leukocyte counts and lymphocyte concentrations are also associated with fish kept in high-density production systems where there is constant exposure to high concentrations of bacteria in the water and poor water quality parameters.

Stress factors can cause a response similar to that of higher vertebrates in which a rapid increase in the release of catecholamines occurs followed by the release of corticosteroids. In general, the effect of stress on the leukogram of fish is manifested as a leukopenia with a lymphopenia and a relative granulocytosis (heterophilia or neutrophilia) because lymphocytes are the predominate leukocyte in the peripheral blood of most fish. Hematologic changes associated with stress may persist for several days after the removal of the stressor.

Interpretation of changes in granulocyte concentrations in the peripheral blood of fish can be, at times, challenging. Piscine neutrophils and heterophils participate in inflammatory responses; however, it would be inappropriate to view them as homologous to the granulocytes of higher vertebrates because the exact function of fish granulocytes is not known. Fish granulocytes are not always phagocytic, and little is known about their methods of intracellular killing, digestion of phagocytized organisms, and other functions. Until further studies are performed that determine the function and responses of piscine granulocytes to disease, only broad generalizations about changes in the leukocyte counts of fish can be made.

In general, increases in the concentration of fish neutrophils or heterophils are often associated with inflammatory diseases, especially those associated with infectious agents. They are known to phagocytize bacteria and yeast and their methods of intracellular killing and digestion of phagocytized organisms appear to be similar to mammals in some species. Fish neutrophils migrate to inflammatory sites to kill bacteria by producing a series of reactive oxygen species where the respiratory burst and the peroxidase contained in the neutrophils contribute to microbial killing activity during phagocytosis. A granulocytosis (neutrophilia) can also occur with inflammation associated with parasitic and viral diseases. A relative neutrophilia or heterophilia often is associated with lymphopenias, which can be interpreted as a stress response in fish.

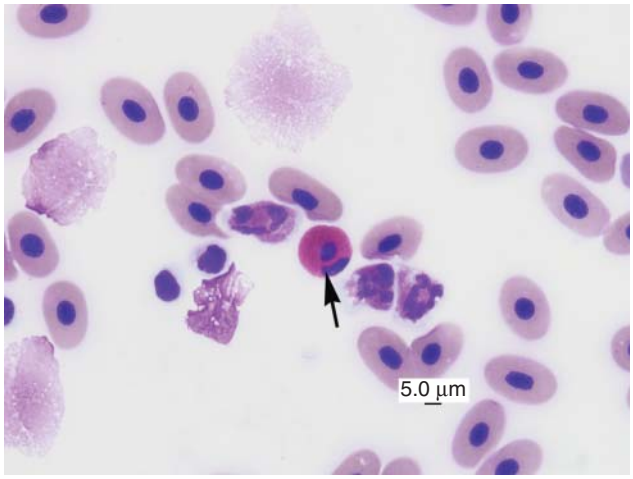

Figure 22.14 Toxic G_1 granulocytes (heterophils), a G_3 granulocyte or eosinophil (arrow), and two thrombocytes in the blood film of an elasmobranch fish (*Dasyatis americana*). Wright-Giemsa stain.

In response to severe systemic illness, piscine neutrophils and heterophils exhibit toxic changes similar to those in mammalian neutrophils and avian and reptilian heterophils. Toxic neutrophils and heterophils of fish have increased cytoplasmic basophilia, vacuolization, abnormal granulation (degranulation of heterophils, granules that appear deeply basophilic, and heterophils granules that appear to coalesce into large, round granules), and degeneration of the cell nucleus (Figure 22.14). Toxic neutrophils and heterophils in fish are associated with severe, systemic illness such as septicemia, mycotic infections, and severe tissue necrosis. The degree of toxicity usually indicates the severity of the fish's condition, and a marked number of neutrophils or heterophils exhibiting marked (4+) toxicity indicates a grave prognosis.

Eosinophils are found in low concentrations (0–3% of the leukocyte differential) in the peripheral blood of normal fish. Piscine eosinophils participate in inflammatory responses along with neutrophils (heterophils) and macrophages, and they appear to have a limited phagocytic capability. Piscine eosinophils apparently are involved in the control of infections with metazoan parasites, and they participate in the immune responses to antigenic stimulation. Therefore, an increased eosinophil concentration in the peripheral blood of fish suggests an inflammatory response associated with parasitic infections or antigenic stimulation.

The granulocytes of cartilaginous fish do appear to participate in inflammatory responses. It is important to note that because the granulocytes make up 20%–30% of the total leukocyte population in sharks and rays, the normal granulocyte to lymphocyte (G:L) ratio is typically low (i.e.,

less than 0.5). An increase in granulocyte concentration is indicative of an inflammatory response. A decrease in the lymphocyte concentration typically results from conditions that reduce the number of circulating lymphocytes, such as stress responses, for example. In sharks, increases in granulocyte concentrations and decreases in lymphocyte concentrations can be associated with bacterial septicemias. The presence of toxicity in the granulocytes as indicated by increased cytoplasmic basophilia and vacuolation is indicative of a severe inflammatory leukogram regardless of the cell count.

The functions of the granulocytes of cartilaginous fish are not known; however, they appear to participate in inflammatory responses. Because the granulocytes account for 20–30% of the leukocytes in sharks and rays, the normal granulocyte: lymphocyte ratio typically is low (<0.5). An increase in the granulocyte concentration is indicative of an inflammatory response. A decrease in the lymphocyte concentration results from conditions that reduce the number of circulating lymphocytes, such as stress responses. Both increases in the granulocyte concentrations and decreases in the lymphocyte concentrations of sharks can be associated with bacterial septicemias. The presence of toxicity in the granulocytes as indicated by increased cytoplasmic basophilia and vacuolation is indicative of a severe inflammatory leukogram regardless of the cell count. The leukogram of cartilaginous fish can be used to follow the progress of these fish during the course of the disease or in response to therapy. For example, an initial increase in the granulocyte concentration or decrease in the lymphocyte concentration that has returned to normal indicates a favorable response to therapy and prognosis.

In one study, male White-spotted bamboo sharks (*Chiloscyllium plagiosum*) with traumatic clasper wounds developed a marked anemia, leukocytosis, and heterophilia (increase in G_1 granulocytes). Surgical removal of the affected claspers as a treatment option resulted in a return of the abnormal hemogram results to normal values indicating that the hematologic differences present in males with clasper wounds were capable of mounting a significant inflammatory hemic response.

Monocytes occur in low numbers (i.e., less than 5%) in the leukocyte differential of normal bony and cartilaginous fish. Piscine monocytes are actively phagocytic cells, and they participate in acute inflammatory responses in fish. Morphologic, cytochemical, and functional studies indicate that teleost monocytes resemble those of mammals. Monocytes and macrophages appear to be the primary phagocytic cells of fish. Fish monocytes can also phagocytize melanosomes when released, suggesting a relationship to melanomacrophages. A monocytosis is suggestive of an inflammatory response in fish, perhaps associated with an infectious agent, although monocyte numbers will also increase following injections of foreign material.

Lymphocytes are the most commonly observed leukocytes in the peripheral blood of most normal fish, in which they typically represent greater than 60% (and as much as 85% in some species) of the leukocyte differential. Lymphocytes play a major role in the humoral and cell-mediated immunity of fish. Monocyte or lymphocyte have been shown to have cytotoxic reactions similar to those described as mediated by mammalian cytotoxic cells. B lymphocytes in teleost fish function in the same manner as mammalian B-1 cells and produce immunoglobulin M (IgM). Therefore, lymphocytosis is suggestive of immunogenic stimulation, whereas lymphopenia is suggestive of immunosuppressive conditions, such as stress or excess exogenous glucocorticosteroids. Interestingly, B lymphocytes from teleost fish also demonstrate phagocytic and microbicidal activity. Bacterial septicemias commonly affect fish and result in marked leukopenias and lymphopenias. Environmental conditions, such as prolonged photoperiod and elevated water temperature that cause a stress response in fish will also result in a leukopenia associated with a lymphopenia.

Thrombocytes and hemostasis

The blood of fish clots in response to injury, as it does in other vertebrates. The speed and effectiveness in fish, however, are variable. Clotting is much more rapid in bony fish compared with sharks and rays. Sharks and rays appear to rely primarily on the extrinsic pathways of coagulation; the addition of skin, high calcium solutions, sea water, or other extrinsic factors enhances clotting. Clot formation in bony fish usually occurs within 5 minutes, whereas clotting in samples taken from sharks and rays can take 20 minutes or longer.

Morphology

Fish thrombocytes are smaller than erythrocytes, vary in shape, and can be round, elongate, or spindle-shaped. In addition, the shape may vary with the stage of maturity or the degree of reactivity. The oval and elongated forms tend to be nonreactive, mature thrombocytes (Figure 22.15) (Thrombocytes can also be found in Figures 22.5, 22.8, 22.9, 22.11a, and 22.13). Immature thrombocytes are round in some species, whereas spindle-shaped thrombocytes appear to be reactive forms and often are found in clumps. The cytoplasm of the piscine thrombocyte is colorless to faint blue; the nucleus is condensed and follows the shape of the cell. Fish thrombocytes also may contain a variable amount of eosinophilic cytoplasmic granules (Figure 22.16).

Like those in birds and reptiles, thrombocytes in fish often are confused with small, mature lymphocytes. Lymphocytes, however, have slightly more abundant, mildly basophilic cytoplasm compared with thrombocytes (Figure 22.17). The nucleus of the lymphocyte also usually is larger and less

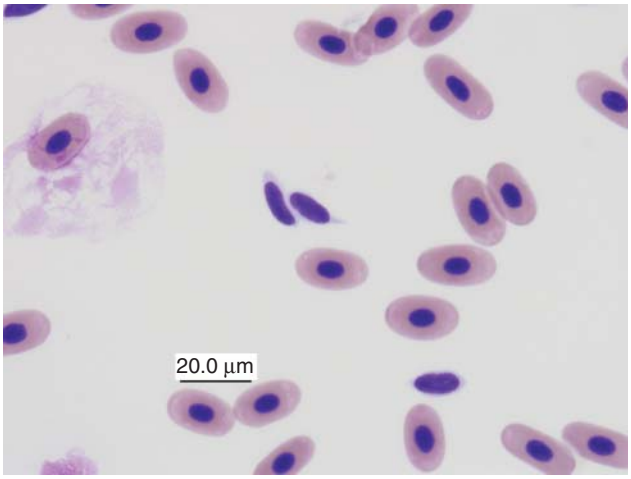

Figure 22.15 Thrombocytes in the blood film of a cartilaginous fish (*Chiloscyllium plagiosum*). Wright-Giemsa stain.

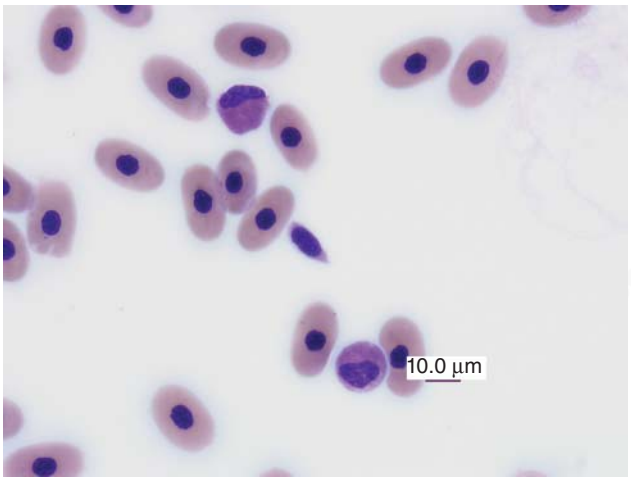

Figure 22.16 G_1 granulocytes (heterophils) and a thrombocyte with eosinophilic cytoplasmic granules (cell in the center) in the blood of a cartilaginous fish (*Ginglymostoma cirratum*). Wright-Giemsa stain.

condensed compared with that of the thrombocyte. Fish thrombocytes usually stain weakly positive with periodic acid–Schiff and positive for acid phosphatase.

Laboratory evaluation

The total thrombocyte count can be obtained via the same hemocytometer charged with diluting solutions (i.e., Natt-Herricks solution) used to obtain a total erythrocyte and leukocyte count. The thrombocytes resemble erythrocytes in the hemocytometer, but they are much smaller and appear to be round to oval, with a greater nucleus:cytoplasm (N:C) ratio compared to erythrocytes. All squares in the central, large square of a Neubauer hemocytometer are counted on both sides. The average number of thrombocytes in one large hemocytometer square is calculated and then multiplied by 2000 to obtain the total thrombocyte count per microliter. Because thrombocytes tend to clump, however, accurate counts may be difficult to achieve.

Responses in disease

During the clotting process in fish, fibrinopeptides are formed after the cleavage of fibrinogen, which is under the control of thrombin. These fibrinopeptides differ from those produced by mammals; however, the basic structure of fibrin in fish, though much larger than its mammalian counterpart, is the same as that in mammals. Fish thrombocyte aggregation differs from mammalian platelet aggregation. For example, fish thrombocytes convert arachidonic acid to prostaglandins with little, if any, thromboxane formation, whereas thromboxane is a potent inducer of platelet aggregation in mammals. Thrombocyte aggregation in sharks is temperature reversible, which is a feature not seen with mammalian platelet aggregation. Shark thrombocyte aggregation also is independent of thrombin and adenosine diphosphate. Therefore, both the control and the outcome of thrombocyte aggregation in fish may not be the same as mammals.

Glucocorticoid excess in fish tends to decrease the thrombocyte concentration and increase the clotting time. Environmental stressors, such as a prolonged photoperiod and elevated water temperature will result in a thrombopenia. Prolonged clotting times also occur with vitamin K deficiency; dietary requirements for vitamin K have been determined for salmonids and channel catfish.

Thrombocytosis and hypercoagulability of whole blood has been associated with exposure to toxic levels of cadmium (126 mg/L) in freshwater teleosts.

Blood parasites

Hemogregarina

Hemogregarina sp. affecting fish resemble those described in the blood films of reptiles, and they are identified by characteristic gametocytes in the cytoplasm of erythrocytes (see Chapter 21 on reptilian hematology). The gametocytes lack refractile pigment granules and may create a bulge in the cytoplasmic membrane. Little is known regarding the life cycle of fish hemogregarines, but they most likely require a blood-feeding, intermediate host, such as leeches, copepods, and isopods. Therefore, they more frequently are found in wild-caught fish. Often, the *Hemogregarina* sp. gametocytes in the peripheral blood of fish are considered to be an incidental finding; however, some species can cause anemia, leukocytosis with a marked left shift, and large granulomas in internal organs.

Trypanosomes

Trypanosomes occasionally may be found in blood films of fish, especially wild-caught, cold-water species. They can

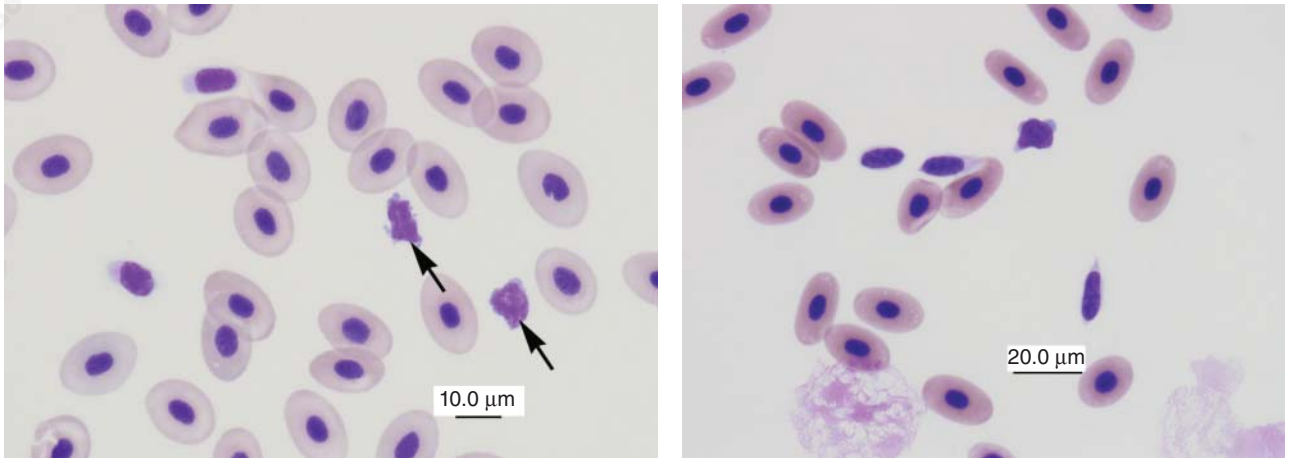

Figure 22.17 (a) Thrombocytes and lymphocytes in the blood film of a bony fish (*Opsanus tau*). Wright-Giemsa stain. (b) Thrombocytes and a lymphocyte in the blood film of a cartilaginous fish (*Chiloscyllium plagiosum*). Wright-Giemsa stain.

occur in high concentration (1,000,000 organisms/mL) and are especially prevalent in the imprints of kidney tissue. Infections with trypanosomes can result in fatal anemias. Leeches act as the intermediate host for the trypanosomes, and the infective trypomastigotes develop and then enter the fish host when the leech takes a blood meal. Trypanosomes are identified by their slender and serpentine shape, single anterior flagellum, prominent and undulating membrane, nucleus, and kinetoplast. On wet-mount preparations, the trypanosomes exhibit rapid, wriggling movements but have no forward motion.

Trypanoplasms

Trypanoplasms are hemoparasites that resemble trypanosomes morphologically, except that they are more pleomorphic (a slender, serpentine shape is most common), have two flagella (one directed anteriorly and one posteriorly), and kinetosomes. Their life cycle is similar to that of the trypanosomes. A prepatent period occurs after infection followed by a parasitemia (i.e., cryptobiasis) resulting in either death of the fish or disappearance of the trypanoplasms from the blood. *Trypanoplasma borreli* causes a severe anemia in cyprinids (i.e., koi, goldfish, and carp), and the disease is referred to as sleeping sickness. Anemia, exophthalmia, ascites, and splenomegaly occur in freshwater salmonids (i.e., trout) with *T. salmositica*; *T. bullocki* infects marine fish, especially flatfish species along the western Atlantic and Gulf of Mexico. On wet-mount preparations, trypanoplasms exhibit flowing, ameboid motility, which aids in their identification.

Piroplasmids

Babesiosoma, *Haemohormidium*, *Haematractidium*, and *Mesnilium* are genera of piroplasmids that have been described in fish. As with the hemogregarines, little is known regarding their life cycle, which most likely requires a blood-feeding, intermediate host. Piroplasmids are identified by their intracytoplasmic inclusions in circulating erythrocytes, which can vary from small, ringlike forms to anaplasma-like inclusions. Piroplasmids may cause hemolytic anemia in fish.

Microsporidians

Enterocytozoon salmonis is an intranuclear microsporidium that primarily infects hematopoietic cells of salmonids. The infected cells exhibit intranuclear inclusions. This organism was once considered to be the causative agent of plasmacytoid leukemia of Chinook salmon (*Onchorhynchus tshawytscha*). The presence of high reverse-transcriptase activity in the affected tissues from these fish, however, suggests that an oncogenic retrovirus may be the causative agent for that disease.

Viral inclusions

Intracytoplasmic inclusions occur in the erythrocytes of fish with viral erythrocytic necrosis (i.e., piscine erythrocytic necrosis), erythrocytic inclusion body syndrome, and coho anemia. Viral erythrocytic necrosis occurs in a variety of marine fish, including salmon, cod, and herring. The disease is characterized by marked poikilocytosis, a single intracytoplasmic inclusion (0.3–4.0 µm) within the erythrocytes, and karyolysis of the red-blood-cell nuclei. Erythrocytic inclusion body syndrome of young salmonids is characterized by progressive, severe anemia, which is caused by a viral agent that creates 0.8–3.0 µm intracytoplasmic inclusions within the erythrocytes. A Leishman-Giemsa stain provides the best results for demonstrating the inclusions. An anemia that occurs in seawater-reared coho salmon (*O. kisutch*) results

from 0.1 to 2.0 μm intracytoplasmic inclusions, which often are rod-shaped within the erythrocytes.

Hematopoiesis

Cartilaginous fish (Chondrichthyes) lack bone marrow and lymph nodes, but they do have a lymphoid thymus, spleen, and other lymphomyeloid tissues. Significant hematopoietic activity occurs in the sinusoids of the red pulp area of the spleen, where erythrocytes, thrombocytes, and lymphocytes develop. Little evidence, however, suggests that granulopoiesis occurs in the spleen of these fish. Development of erythrocytes in these fish appears to occur in the same manner as that in mammals. The peripheral blood may be an important component of erythropoiesis, because several stages of erythrocyte development can be found in the routine blood films from cartilaginous fish. The epigonal organ, which is associated with the gonad, and Leydig's organ, which is situated in the submucosa of the alimentary tract, are the major sites for granulopoiesis in cartilaginous fish. Myeloblasts, progranulocytes, myelocytes, metamyelocytes, and mature granulocytes have been described in these unique lymphomyeloid tissues.

The principal lymphomyeloid tissues of bony fish (Osteichthyes) are the thymus, spleen, and kidney. The thymus, which is the first lymphoid organ to develop, seeds the spleen and kidney with lymphocytes. The kidney is a major blood-forming organ in bony fish; the pronephric (anterior or head) and opisthonephric (main or trunk) kidneys are the sites of hematopoiesis in these fish. The opisthonephric kidney also functions as an excretory organ. Therefore, the kidney (primarily the pronephros) is the principal site for the differentiation and development of erythrocytes, granulocytes, lymphocytes, monocytes, and, possibly, thrombocytes in most bony fish. The typical stages of granulocyte development have been identified for each type of granulocyte in the kidney of bony fish. The spleen of teleost fish is similar to that of elasmobranchs, but it typically has a secondary role in hematopoiesis, except in some species in which it is the only hematopoietic organ.

23 Hematology of Amphibians

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Compared with other vertebrates seen in veterinary practices, amphibians are unique because their normal life cycle includes a metamorphosis from a larval to an adult form. Amphibians have adapted to aquatic, terrestrial, fossorial, and alpine environments, and their normal hematologic parameters vary accordingly. Amphibians are grouped into three orders: Caudata (Urodela), which includes salamanders and newts; Anura (Salientia), which includes frogs and toads; and Apoda (Gymnophiona), which includes the caecilians. Amphibians, especially frogs of the Ranidae family, are often used in research, but hematologic evaluation of amphibians is not routinely used in establishing the diagnosis of amphibian diseases. Hematologic evaluation may be used to monitor the health status of an amphibian as long as the reported reference intervals and interpretations account for the intrinsic and extrinsic factors that affect the hemic response. Extrinsic factors, such as environmental temperature, photoperiod, season, water-quality parameters, diet, and population density, should be noted whenever reference values are reported. Adaptation to a specific environment also influences the hematologic parameters. Important intrinsic factors include gender and age; larval and adult stages should be considered as separate entities, each with their own reference interval. Hematology can be useful in the detection of diseases that affect the cellular components of blood, such as anemia, leukopenia, leukocytosis, thrombocytopenia, and other abnormal changes of blood cells, and may also be useful in following the progression of a disease or a response to therapy.

Collection and handling of blood

The approximate blood volume of many species of aquatic amphibians ranges between 13% and 25% of the body weight and between 7% and 10% of the body weight for most terrestrial amphibians. In general, it is considered "safe" to draw a blood sample equaling 1% of the total body weight of an individual amphibian at one time. Sites for blood collection include the heart, ventral abdominal vein, ventral caudal vein, and lingual vein. Some amphibians may be manually restrained for blood collection, and others may require sedation or anesthesia. Submersion of the amphibian in a 0.05% solution of tricaine methanesulfonate is one method of restraint that may be considered for use in blood sample collection of amphibian patients. Moistened powder-free latex gloves should be worn when handling amphibians for examination, restraint, or blood collection in order to protect their skin. Small-gauge needles and small syringes are typically used to collect blood samples from amphibians. Consequently, blood flow into the syringe is usually slow. Many amphibian patients are small, making it necessary to use microhematocrit tubes with inner diameters that are smaller than regular hematocrit tubes in order to obtain a packed cell volume (PCV). Use of these small microhematocrit tubes will also help maximize the amount of hematologic testing that can be performed on small blood samples.

Blood can be collected from frogs, toads, salamanders and newts by venipuncture of the ventral abdominal or lingual vein. This vein lies under the linea alba along the ventral midline of the coelomic cavity. Venipuncture is performed by inserting a 25-gauge needle in a craniodorsal direction midway along a line of sight extending from the sternum and pelvis (Figure 23.1). Use of a Doppler probe to locate this vein may be required in species where the vein is not clearly visible. Blood may then be collected by the drip method or by aspiration of blood into a small syringe. Because lymphatic vessels accompany blood vessels in amphibians, a mixture of blood and lymph frequently occurs with venipuncture of the ventral abdominal vein. This mixing of lymphatic fluid with the blood sample is variable, but it will dilute the cellular components of the blood, thereby resulting in lower PCV, hemoglobin concentration, and erythrocyte and leukocyte concentrations.

Blood can be collected from frogs and toads by venipuncture of the lingual vein. Venipuncture of the lingual vein may be performed after gently opening the patient's mouth and

moving the tongue forward and upward using a cotton tip applicator to expose the lingual venous plexus that lies on the ventral aspect of the tongue on the floor of the mouth. Care must be taken to avoid breaking the fragile mandibular bones while holding the mouth open to collect blood from the lingual vein. Excess saliva is swabbed from below the tongue, after which a large vein of the lingual venous plexus on the ventral aspect of the tongue is punctured with a 25-G needle or smaller. Blood should be collected by the drip method into a microcollection tube or microhematocrit tube instead of by aspiration into a syringe in order to minimize the potential for hematoma formation.

Cardiocentesis is performed by placing the frog, toad, salamander, or newt in dorsal recumbency and locating the heart either by visualizing the pulsing heart, by use of a Doppler scan, or by transillumination. Cardiocentesis in amphibians often requires sedation or general anesthesia using tricaine methanesulfonate to prevent movement and potential damage to the heart and great vessels. Visualization of the heart can also be accomplished in some species via transillumination by use of the cool light from a rigid arthroscope inserted into the stomach. Once the heart is located, a 25-G needle is inserted into the ventricle, and blood is aspirated into a syringe.

Venipuncture of the ventral caudal vein (ventral coccygeal vein, tail vein) may be used for blood collection from some species of salamanders and newts and is performed in the same manner described for venipuncture of the ventral caudal vein in reptiles. This technique should not be performed in salamanders and newts that have tail autotomy (a natural ability to lose their tails) because their tails may break off during the procedure. The salamander or newt is held in dorsal recumbency to perform a venipuncture of the ventral coccygeal vein. A 25-gauge needle is inserted into the ventral midline of the tail and directed to a point just below the coccygeal vertebrae. The needle is then advanced while applying negative pressure to the syringe until blood can be aspirated into the syringe barrel.

Blood for hematologic studies in amphibians should be collected using lithium heparin as an anticoagulant. In general, ethylenediaminetetraacetic acid (EDTA) usually causes lysis of erythrocytes in the blood of amphibians and should be avoided; however, a 3% EDTA solution with distilled water may be used as an anticoagulant in some species to avoid the erythrocyte lysis effect. Syringes may be pretreated with lithium heparin or blood can be allowed to drip from the needle hub into a microcollection tube containing lithium heparin.

Erythrocytes

Morphology

Erythrocytes of amphibians are large nucleated, elliptic discs (Figure 23.2). The cells usually have a distinct nuclear bulge, and the nuclear margins often are irregular. Some amphibians, such as the slender salamander (*Batrachoceps attenuatus*), do not have nucleated red blood cells. Amphibian erythrocytes are large compared with those of other vertebrates with sizes that vary from 10 to 70 µm in diameter and typically have mean cell volume (MCV) values ranging from 390 and 14,000. The cytoplasm of frog and toad erythrocytes is homogenous and packed with hemoglobin. Ultrastructural analysis reveals rare organelles. Because the erythrocytes of salamanders and newts complete their maturation in the peripheral circulation, the cytoplasm is not homogenous, and ultrastructural examination demonstrates clusters of granular and vacuolar bodies.

There is considerable interspecies variation in the erythrocyte parameters of amphibians and they can be dramatically different from other vertebrates, especially mammals (Table 23.1). Normal amphibian erythrocytes do exhibit slight anisocytosis; however, increased anisocytosis suggests an increased concentration of large red cells due to erythroid regeneration or erythroid dyscrasia. This may be seen in association with a regenerative response to a hemolytic or hemorrhagic anemia. Conditions that result in erythroid dyscrasia may indicate a nutritional deficiency or toxicity; however, these have not been documented in the literature.

Two forms of erythrocytes differentiated by size and morphology appear to occur in amphibians. One form, a larger elongated form is considered to be the larval form, whereas a smaller, rounded form is considered to be the adult form. The transition from the larval form to the adult form begins at the onset of metamorphosis, and by day 12 a complete transformation to all adult forms occurs. There is a positive relationship between body size and erythrocyte width in salamanders. As salamanders grow, their erythrocytes become more rounded. This morphological change does not affect the overall area, however.

The appearance of the nucleus of the amphibian erythrocyte also changes as the cell matures. The nuclear chromatin of immature erythrocytes lacks the dense chromatin clumping of the mature cell (Figure 23.3). Older senescent cells have pyknotic nuclei.

The cytoplasm of the immature cells also stains more basophilic compared to mature cells with Wright's stain (Figure 23.4). The blue staining of the amphibian erythrocyte cytoplasm may also be associated, in part, with the effects of heparin on Wright's-stained blood films as heparin is a commonly used anticoagulant during blood collection in amphibians. The staining effects caused by heparin can be prevented if a blood film is made from a drop of blood remaining in the needle that does not contain heparin after blood collection.

Increased numbers of immature erythrocytes may be indicative of a disease such as iridovirus infection, or may indicate the presence of a regenerative response. Iridovirus infections have been associated with disease outbreaks associated with high mortalities in wild frogs and salamanders. Intranuclear inclusions of the iridovirus are found in the erythrocytes on histologic specimens. Irregular immature erythrocytes with characteristics reminiscent of cells in mammalian erythroid leukemia or exuberant responses can be found in blood films of clinically healthy frogs and may be indicative of rapid cell turnover or a result of environmental stressors.

Laboratory evaluation

The microhematocrit method is used for obtaining a PCV, which is the most common method for evaluating the red

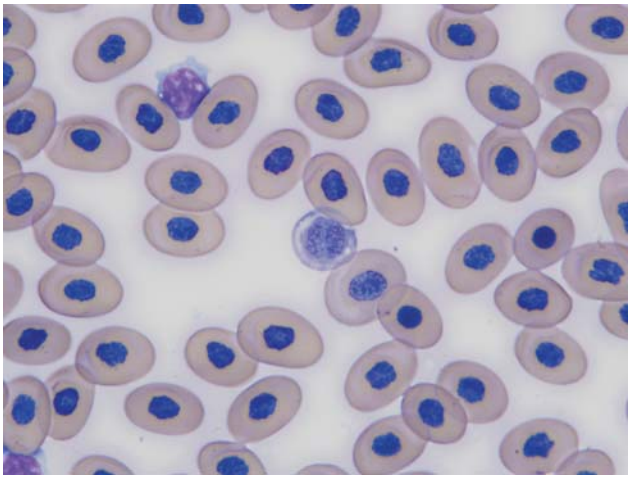

Figure 23.3 A polychromatic erythrocyte and lymphocyte in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain.

cell mass of amphibians. The cyanmethemoglobin method commonly is used to determine the hemoglobin concentration in amphibian blood. As with blood hemoglobin determinations in birds, reptiles, and fish, this procedure requires centrifugation of the blood–cyanmethemoglobin mixture to remove the free erythrocyte nuclei before the optical density is measured. The total erythrocyte count in amphibians can be determined either by manual counting with a hemocytometer or by an electronic cell counter. Manual counting methods to obtain red cell concentrations in amphibian blood use of the Erythro-pette™ system (Exotic Animal Solutions, Inc. Hueytown, AL, USA) and Natt and Herricks method. These methods are the same as those described for use in avian blood (see Chapter 20).

Responses in disease

The average amphibian erythrocyte life span is considered to be greater than 100 days, which may have an impact on the erythrocytic response. Because newts and salamanders generally are more fishlike than toads and frogs, interpretation of their hemograms may be more like those of fish, whereas hematologic changes in toads and frogs may be more like those of reptiles. In general, amphibian PCVs are lower than those of mammals and birds, and these values vary with species, age, gender, environmental temperature, photoperiod, and husbandry of the amphibian (Table 23.1). The peripheral erythrocyte count of amphibians is affected by seasonal activity. An increase in bone marrow erythropoiesis occurs during the spring and following hibernation; therefore, the highest number of circulating erythrocytes occurs at this time. In some studies, males have higher erythrocyte counts than females. Also, numbers of immature erythrocytes (as early as rubriblasts) in the peripheral blood tend to be greater in males where they can represent as high as 2% of the erythrocyte population (Figure 23.4). Captive amphibians may have more stable erythrocyte parameters than their wild counterparts due to the stability of the environment in which most captive amphibians reside. Because amphibians are ectothermic, the rapidity of their hematologic responses can be manipulated by changes in the environment, such as temperature fluctuation.

Leukocytes

Morphology

In general, amphibian leukocytes resemble those of mammals but are larger (10 and 25 µm in diameter for most

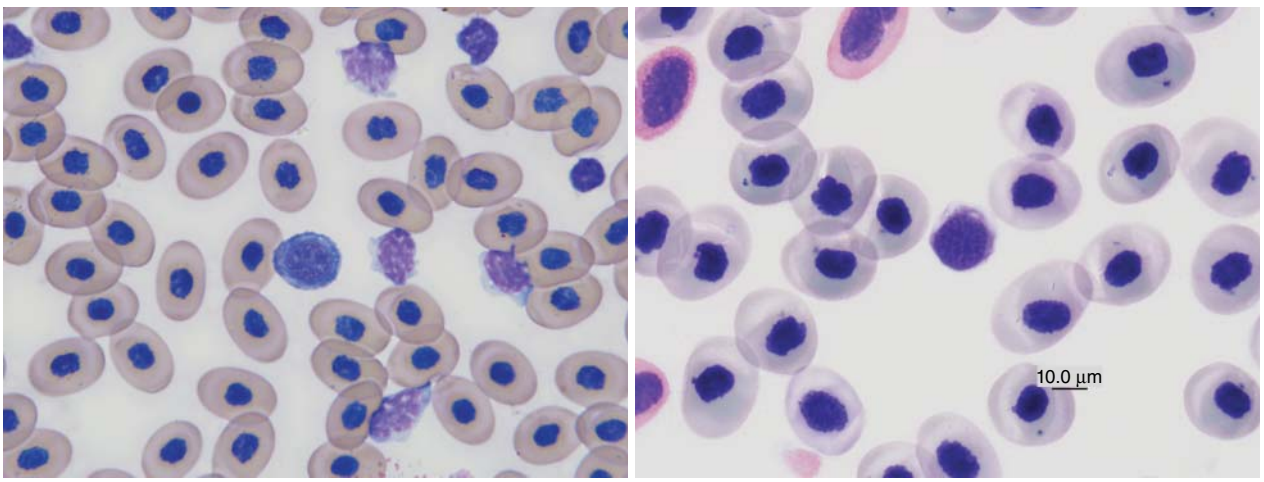

Figure 23.4 (a) An immature erythrocyte (basophilic rubricyte) and lymphocytes in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain. (b) An immature erythrocyte (early basophilic rubricyte) in the blood film of a salamander (*Ambystoma tigrunum*). Wright-Giemsa stain.

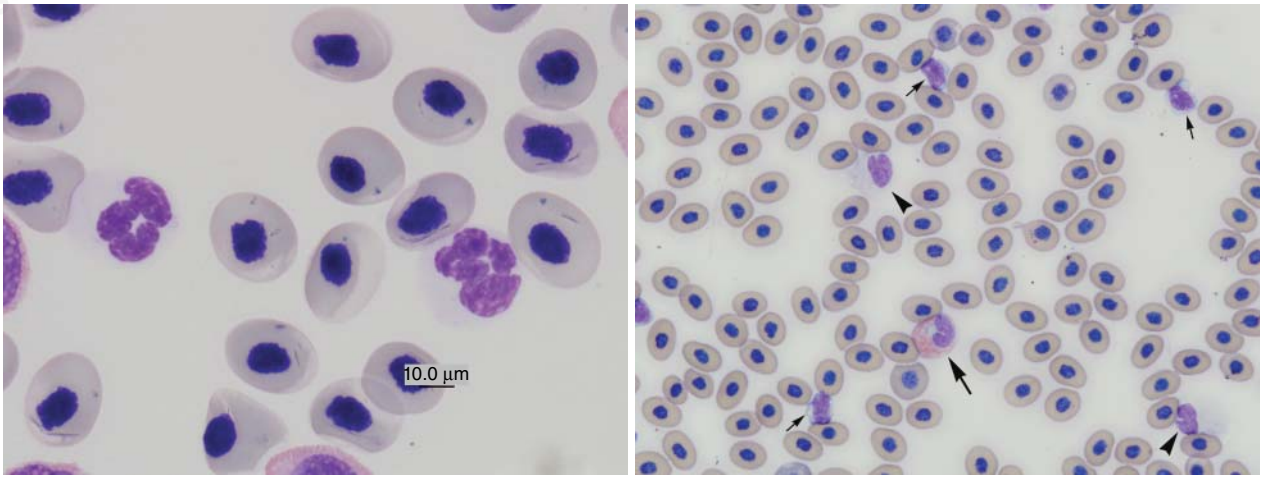

Figure 23.5 (a) Neutrophils in the blood film of a salamander (*Ambystoma tigrunum*). Wright-Giemsa stain. (b) Two neutrophils (arrowheads), an eosinophil (large arrow), and three lymphocytes (small arrows) in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain, ×500.

species) comparatively. Amphibian leukocytes are typically classified based upon their appearance in blood smears stained with Wright-Giemsa stain and their resemblance to mammalian leukocytes; therefore, they have been classified as neutrophils, eosinophils, basophils, lymphocytes, and monocytes. Other classification schemes present in the literature use heterophils instead of neutrophils and identify some cells as azurophils instead of or in addition to monocytes. Some references also include different combinations of heterophil, azurophil, and neutrophil to describe the granulocytic cells present. Amphibian granulocytes (neutrophils or heterophils, eosinophils, and basophils) have multilobed nuclei with small cytoplasmic granules that are variable in size, shape, and ultrastructure depending on the species.

Amphibian neutrophils resemble those of mammals, and they range from 10 to 25 µm in diameter for most species (Figure 23.5). When stained with Romanowsky stains, they are generally round cells with a lobed nucleus and neutral (colorless) staining cytoplasm. The small cytoplasmic granules vary in size, shape, and ultrastructure between species. Cells with small eosinophilic cytoplasmic granules often are referred to as heterophils, whereas those cells that do not are referred to as neutrophils. Some species of amphibians may exhibit neutrophils with large irregular cytoplasmic granules that stain slightly eosinophilic (light pink). These cells resemble the neutrophils found in humans and other mammals with Chediak-Higashi syndrome but are considered to be normal in amphibians. Amphibian neutrophils typically are peroxidase positive, but phosphatase activity varies with the species.

Amphibian eosinophils are similar in size to or slightly larger than the neutrophils found in the same blood film. Eosinophils have a slightly basophilic cytoplasm compared to neutrophils and have small to moderate-sized round to oval eosinophilic cytoplasmic granules (Figures 23.5b and 23.6). The nuclei of eosinophils are often less lobed than those of neutrophils; however, this may not be true of all species. Eosinophils are peroxidase negative, and the phosphatase activity varies with species. The eosinophils of some species are negative for aryl sulfatase and β-glucuronidase activity. Some amphibian eosinophil granules have a crystalloid ultrastructure, but others lack the crystalloid structures that are typical of the ultrastructural morphology of eosinophils from higher vertebrates.

The size of amphibian basophils varies between species. Typically, these basophils have nonsegmented nuclei and large, metachromatic granules (Figure 23.7). The nucleus is often obscured by the granules but when visible is nonlobed and slightly eccentric in position. Alcohol fixation and use of Romanowsky stains provide the best staining for amphibian basophils because basophil granules are frequently affected by water-based stains and will partially dissolve. The granules contain acid mucopolysaccharides (i.e., glycosaminoglycans) that are less sulfated than those of mammals, and the histamine content is lower than that of mammals. Ultrastructural analysis demonstrates large numbers of membrane-bound cytoplasmic granules with small numbers of organelles.

The lymphocytes of amphibians resemble those of other vertebrates morphologically. Small lymphocytes are more abundant than larger forms in the blood films of normal amphibians. The lymphocytes are round with round nuclei containing densely clumped chromatin and a scant amount of pale-blue cytoplasm (Figures 23.3, 23.4a, 23.5b, 23.7b, 23.8, and 23.9). Many of the lymphocytes from frogs of the family Ranidae have distinct azurophilic granules. Amphibian lymphocytes, like mammalian lymphocytes, are nonspecific esterase positive and peroxidase negative

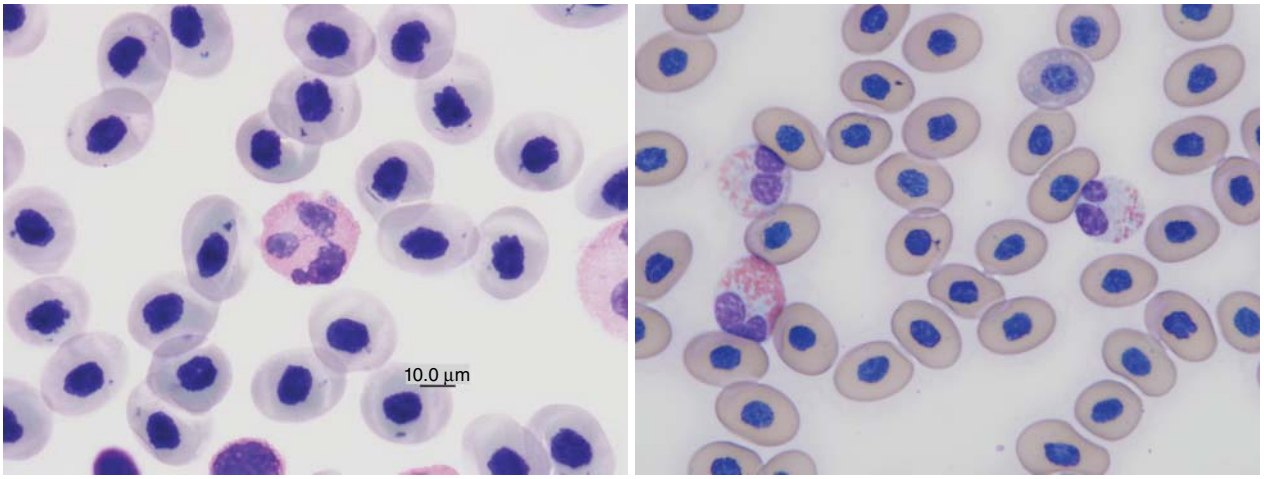

Figure 23.6 (a) An eosinophil in the blood film of a salamander (*Ambystoma tigrunum*). Wright-Giemsa stain. (b) Eosinophils in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain.

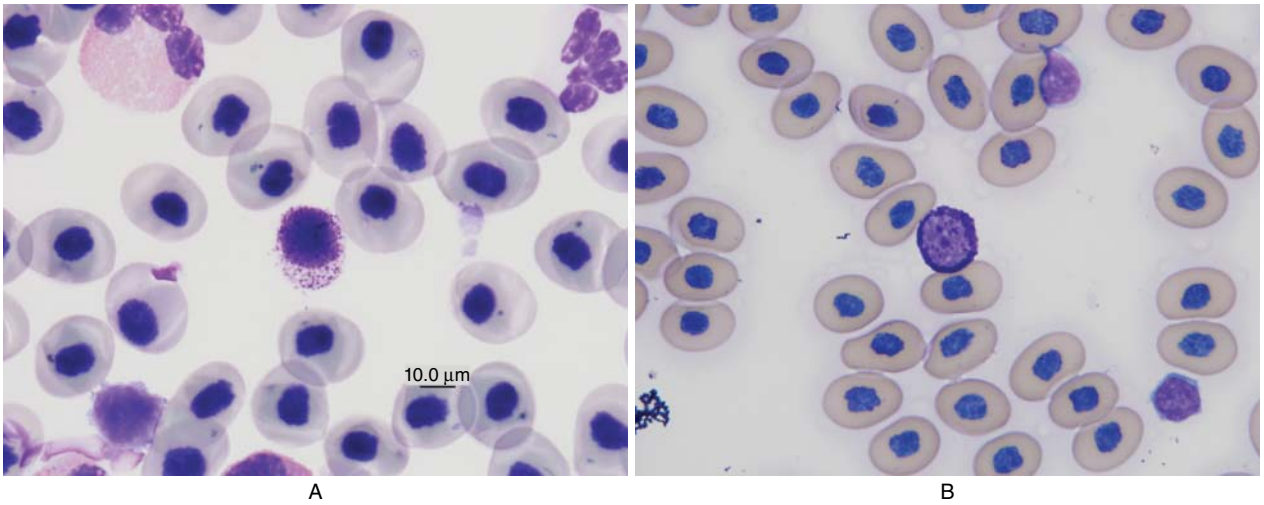

Figure 23.7 (a) A basophil in the blood film of a salamander (*Ambystoma tigrunum*). Wright-Giemsa stain. (b) A basophil and lymphocyte in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain.

but, unlike mammalian lymphocytes, are negative for β-glucuronidase and aryl sulfatase.

Monocytes in amphibian blood films are similar to those of other vertebrates. They are characterized by their large size, abundant, blue-gray cytoplasm that may be foamy or vacuolated, and a variably shaped nucleus with less chromatin clumping than seen in lymphocyte nuclei (Figure 23.9). The cytoplasm of amphibian monocytes may contain fine, azurophilic granulation and pseudopodia. Amphibian monocytes are peroxidase positive and contain some of the same hydrolytic enzymes found in mammalian monocytes.

Some amphibian leukocytes have been classified as azurophils. These cells have features commonly associated with monocytes and are considered to be monocytes by some authors. Other authors hypothesize that the amphibian azurophil is either an immature or senescent granulocyte or monocyte. There is little advantage in classifying these cells as separate cells from the monocyte population in the blood when interpreting the hemogram of amphibians. Therefore, they should be classified as monocytes until further evidence justifies classifying them as a different cell type.

Cytochemical characteristics have been applied to amphibian blood cells in an effort to characterize the cells as an aid for interpretation of cellular responses. Frog leukocytes have been described using a number of Romanowsky–type stains and cytochemical stains, including peroxidase, acid phosphatase, alkaline phosphatase, nonspecific esterase, basic protein, periodic acid–Schiff (PAS), Alcian blue, and toluidine blue, and evaluating serotonin fluorescence. For example, in the bullfrog (*Rana* (Aquarana) *catesbeiana*) and

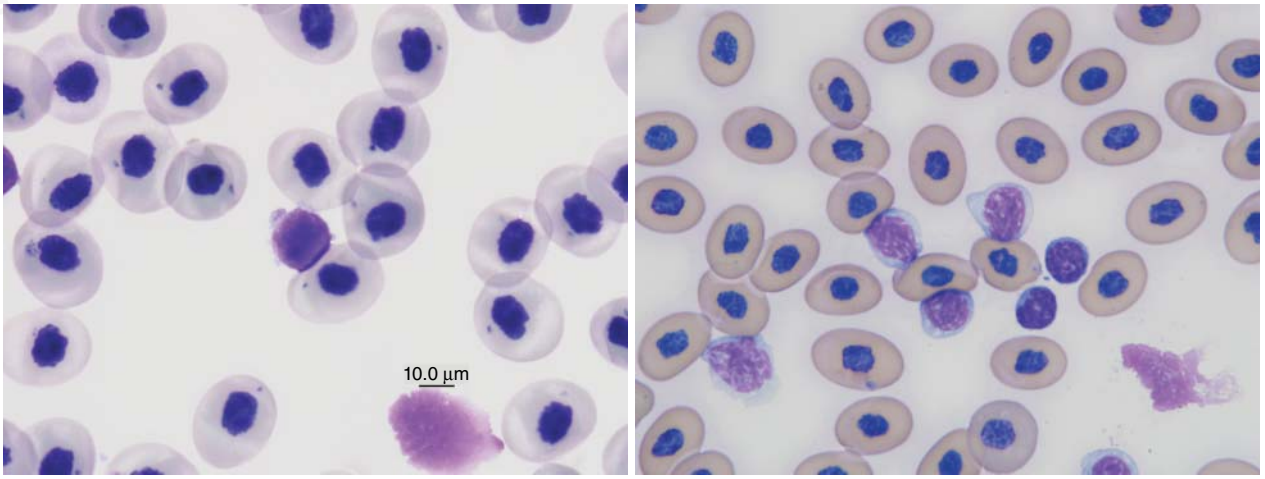

Figure 23.8 (a) A lymphocyte in the blood film of a salamander (*Ambystoma tigrunum*). Wright-Giemsa stain. (b) Lymphocytes (small, medium, and large) in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain.

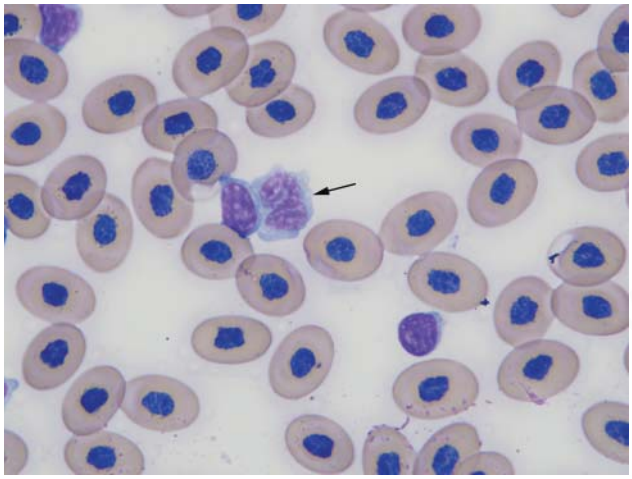

Figure 23.9 A monocyte (arrow) and lymphocytes in the blood film of a toad (*Incillius alvarius*). Wright-Giemsa stain, ×1000.

clawed frog (*Xenopus laevis*), neutrophils, eosinophils, and monocytes were positive for some or all of the following: α-naphthyl butyrate esterase (NBE), chloroacetate esterase (CAE), myeloperoxidase (PER), and Sudan black B (SBB). Lymphocytes occasionally were positive for CAE. Lymphocytes in these species were negative for all cytochemical stains and leukocyte alkaline phosphatase (LAP) was not a useful marker for any leukocyte type. Peripheral blood lymphocytes in these frogs were strongly immunoreactive for CD3ε, CD79a, and BLA.36. Also, basophils from the African clawed frog had different enzymatic activity than basophils of the bullfrog, which may suggest different functions for the basophils of these two species. Some cytochemical reactions, including PER and SBB in neutrophils, CAE in monocytes, and PER in eosinophils, were consistent across the species, suggesting they may be helpful in characterizing leukocytes from a variety of frog species. Some leukocytes were only noted occasionally in frogs, including azurophils, large granular lymphocytes, and, in the case of clawed frogs, eosinophils.

Granulopoiesis occurs in the liver, kidney, and bone marrow of amphibians; however, some species lack bone marrow. Myeloblasts and progranulocytes have not been positively described in amphibians. Immature neutrophils have small granules of various shapes that increase in both size and density with maturation until the larger, definitive peroxidase-positive granules are formed. Some species do not develop primary granules; rather, they produce a different population of granules. Evidence suggests that in some species, eosinophils begin as round cells with a round nucleus and scant cytoplasm that contains large, dense, and round primary granules. Further development of eosinophils results in a mixture of the larger primary granules and the smaller secondary granules. The monocyte is the first leukocyte to appear in the peripheral blood of bullfrog (*Rana catesbeiana*) larvae, in which immature monocytes with linear nuclear chromatin appear 15 days after hatching and mature monocytes with round nuclei, which develop into kidney-shaped or lobed nuclei, appear 22 days after hatching. Definitive neutrophils, eosinophils, and basophils in larval bullfrogs appear in the peripheral blood at the same time, late during development of the frog. Lymphopoiesis in amphibians resembles that in other vertebrates. Small lymphocytes are the most common, but larger lymphocytes also may be seen.

Laboratory evaluation

As in other nonmammalian vertebrates, amphibians have nucleated erythrocytes and thrombocytes that interfere with automated methods for counting leukocytes; therefore,

manual counting methods are used. The Natt and Herricks or phloxine B method, as described for birds in Chapter 20, can be used to obtain a total leukocyte concentration in amphibian blood.

The leukocyte differential is performed manually using Romanowsky-stained blood films (Tables 23.2 and 23.3). Because most blood samples from amphibians are collected into heparin, making blood films either with blood containing no anticoagulant or immediately after mixing of the blood with the heparin (to decrease cell clumping and improve staining) is best.

Responses in disease

Hematologic evaluation is not used routinely in veterinary medicine as a means of evaluating the health or diseased state of amphibian patients. Reasons for this include the difficulty in obtaining amphibian blood samples without affecting the hemogram results, the challenges involved in obtaining cell counts, and the lack of meaningful reference intervals. Absolute numbers of each cell type are expected to vary considerably with season, temperature, species, habitat, and a number of other extrinsic considerations. Many published reference intervals fail to include information involving intrinsic (i.e., gender and age) and extrinsic (i.e., environmental temperature, photoperiod, water quality parameters, diet, population density, and season) factors, which may influence the hematology values. Some publications do include some of this information, and whenever possible these sources should be used when interpreting amphibian hematological results. Normal total leukocyte counts exhibit inter- and intraspecies variation. The lymphocyte is generally the most numerous leukocyte and the neutrophil is the most numerous granulocyte in the peripheral blood of most amphibian species studied.

Little is known regarding the function of the various amphibian leukocytes. The process of interpreting the amphibian leukogram is extrapolated from that used with other vertebrates. Amphibian neutrophils have both migratory and phagocytic activity, and they participate in inflammation. Likewise, amphibian monocytes are phagocytic and, most likely, function in a manner similar to those of other vertebrates. Therefore, increases in the neutrophil and monocyte counts likely suggest an inflammatory response. More studies that evaluate the types of blood cells that increase or decrease during different disease states are needed to better determine the function of each cell type and their clinical importance.

The presence of a peripheral eosinophilia may be suggestive of parasitic infections. Amphibian eosinophils appear to have an inferior ability to phagocytize particles or microorganisms compared to neutrophils but do respond to metazoan parasitic infections. Increased frequency of eosinophils

has also been documented in frogs from polluted areas, perhaps a reflection of stimulation of the immune system.

Amphibian basophils may function in a manner similar to those of mammals. They rarely are found in the peripheral blood of some species but are abundant in others. For example, they occur in high numbers in the blood of the African clawed frog (*X. laevis*), an aquatic species, compared to their absence or low numbers in the semiaquatic bullfrog (*Rana* [*Aquarana*]) and Colorado River toad (*Incilius alvarus*). The difference may be reflective of their environment, as has been suggested for aquatic reptiles, such as aquatic turtles that are noted for their high numbers of circulating basophils. Another example is the aquatic Japanese newt (*Cynops pyrrhogaster*), which normally has a differential leukocyte count that includes up to 60% basophils. Basophils of this species are considered to play a significant role in immunosurveillance.

Lymphocytes of frogs and toads demonstrate an immunologic sophistication similar to those of higher vertebrates. The lymphocytes can be classified as B cells that produce immunoglobulins or as T cells with populations of functional diversity, such as helpers and different effectors. Contrast, the lymphocytes of newts and salamanders appear to lack such refinement. A lymphocytosis is suggestive of an excitement response, stimulation of the immune system, or possibly lymphoid leukemia. A transitory lymphocytosis following tail amputation for blood collection has been demonstrated in the Japanese newt (*C. pyrrhogaster*), suggesting either an excitement response or recruitment of lymphocytes.

Thrombocytes

Morphology

Amphibian thrombocytes are nucleated cells that resemble those described for birds, reptiles, and fish, although anucleated thrombocytes that resemble mammalian platelets have been described in certain species. Amphibian thrombocytes typically vary in shape from oval to spindle-shaped (Figure 23.8). When the cells are in a nonreactive state, they tend to be oval in shape. Once activated, the cells become spindle-shaped. The nucleus is dense and round to oval. Thrombocyte cytoplasm is abundant and colorless; however, when they become reactive the cytoplasm may contain numerous eosinophilic granules. Amphibian thrombocytes are often confused with small lymphocytes but may be differentiated based on the appearance of the cytoplasm. The cytoplasmic volume of small lymphocytes tends to be small and the cytoplasm stains blue. Ultrastructurally, the thrombocytes of some amphibian species, such as *Xenops* and *Rana*, are alkaline phosphatase positive, whereas the lymphocytes are negative.

Laboratory evaluation

The total thrombocyte count can be obtained from the same charged hemocytometer used to obtain the total erythrocyte and leukocyte count. The thrombocytes resemble the erythrocytes in the hemocytometer, but they are smaller and appear to be round to oval with a greater nucleus:cytoplasm (N:C) ratio compared to the erythrocytes. All squares in the central large square of a Neubauer-ruled hemocytometer are counted on both sides, and the average number of thrombocytes in one large square is calculated and multiplied by 2000 to obtain the total thrombocyte count per microliter. Accurate counts may be difficult to achieve, however, because thrombocytes tend to clump (Table 23.4).

Responses in disease

Functionally, thrombocytes are equivalent to mammalian platelets and they participate in coagulation. Immature forms of thrombocytes (round cells with round nuclei) are not normally found in the peripheral blood of amphibians; therefore, their presence suggests either a regenerative response or dyscrasia. Developing thrombocytes include thromboblasts, prothrombocytes, and immature thrombocytes. Thromboblasts are round to oval with weakly basophilic cytoplasm and a round to oval nucleus that contains fine nuclear chromatin and a large, irregular, eccentric nucleolus. Prothrombocytes have elongate nuclei and vacuolated cytoplasm with pale blue granules. Immature thrombocytes resemble those described in avian hematology. They are intermediate in size between thromboblasts and mature thrombocytes and appear as round to oval cells containing more abundant cytoplasm than the thromboblasts. The color of the cytoplasm of immature thrombocytes varies with cell development, and changes from a basophilic color in the early developing cells to a pale blue or colorless cytoplasm in the later stages. These cells may contain cytoplasmic vacuoles. The nuclear chromatin of the earlier immature thrombocytes is aggregated into irregular clumps that become more densely packed as the cell matures. Low and high thrombocyte counts are interpreted in the same manner as those described for other nonmammalian vertebrates, such as birds (see Chapter 20).

Blood parasites

Wet-mount evaluation of a whole blood sample may be utilized as a means to detect the movement of common extracellular blood parasites such as trypanosomes and microfilaria in amphibian blood. Common differentials for amphibian intraerythrocytic inclusions found on Romanowsky-stained blood films include hemogregarines, such as those described in reptiles (see Chapter 21on hematology of reptiles), *Aegyptianella* spp., and a *Pirohemocyton*-like

virus. *Lankesterella* spp. may also be found within the cytoplasm of lymphocytes. *Toxoplasma*, *Isospora*, and *Leptotheca* are also found on occasion. In general, these organisms are considered to be an incidental finding; however, they may be pathogenic when they are found in the blood of anemic patients, suggesting a possible etiology for the anemia.

Hematopoiesis

Development of the amphibian erythrocyte is similar to that described for other vertebrates with nucleated erythrocytes. Maturation of the rubriblast to the mature erythrocyte involves a progressive change of cytoplasmic basophilia to eosinophilia, a change from round to an elongated shape, a decrease in the nuclear and nucleolar size, and an increased chromatin density.

The liver is the predominant erythropoietic tissue of both larval and adult frogs. Larval amphibians may have two populations of morphologically different erythrocytes, which have different origins. One population, originating in the liver, has a centrally positioned nucleus; the other, originating in the kidney, has a peripherally located nucleus. The different erythrocyte populations also have different larval hemoglobins. During metamorphosis, a third population of erythrocytes appears, and this population persists in adults. Dark-field illumination can be used to differentiate larval erythrocytes, which have a white to gray, granular luminescence, from adult erythrocytes, which lack luminescence.

The metamorphosis from larval to adult amphibians is accompanied by the synthesis of hemoglobins with different oxygen affinities and various intracellular modulators of hemoglobin–oxygen affinity. Gilled larval amphibians have blood with a higher affinity for oxygen than that of air-breathing adults. The tetrameric hemoglobin of amphibians consists of two α-like and two β-like globin chains, thereby creating four larval-type and four adult-type hemoglobins. No globin chains are shared between larval and adult amphibians. Adult hemoglobin begins to appear in frogs during tail regression, and it is the only hemoglobin found 3 weeks after metamorphosis. Adult amphibians have higher hemoglobin concentrations and PCVs compared with the larval forms. Metamorphosis results in decreases in adenosine triphosphate (ATP) and guanosine triphosphate concentrations in the erythrocytes, thus suggesting a change in the phosphate regulation of hemoglobin in adults compared with larval forms.

Metamorphosis in newts and salamanders is not always associated with a transition in hemoglobin such as that occurring in frogs and toads. When newts and salamanders change from aquatic to aerobic respiration at metamorphosis, the larval and adult hemoglobins have the same affinity for oxygen. The reduced oxygen affinity of the blood in adults, however, frequently is achieved by an increased erythrocyte concentration of ATP. Even so, some species, such as the tiger salamander (*Ambystoma tigrinum*), experience no decrease in the oxygen affinity of blood at metamorphosis, and the hemoglobin and total erythrocytic organic phosphate concentrations remain unchanged.

Toads, which primarily rely on aerobic respiration, tend to have higher hemoglobin and erythrocyte phosphate concentrations and a lower blood oxygen affinity compared with frogs, which primarily rely on anaerobic respiration. Aquatic amphibians do not have the same association between high erythrocyte phosphate concentrations and dependence on aerobic production of energy for activity as terrestrial amphibians do. The exchange of gases from the blood to the surrounding water occurs through the skin of aquatic amphibians.

Laboratory Evaluation and Interpretation of the Urinary System

Donald Meuten[1] and Saundra Sample[2]

[1]North Carolina State University, Raleigh, NC, USA
[2]University of Missouri College of Veterinary Medicine, Columbia, MO, USA

Introduction

Diseases of the urinary system are common in all animal species, and clinical pathology is an essential tool for evaluation of the urinary system. The primary reasons for assessing the urinary system are to recognize renal failure or diseases in the urinary bladder, or as part of an annual health check. Laboratory abnormalities that indicate renal failure will not appear until so many nephrons are damaged that the remaining nephrons can no longer compensate for the damaged ones. Once identified, renal failure is then categorized as acute or chronic. This identification is further narrowed down to the renal structure that is diseased, and sometimes a specific diagnosis. For example, the disease may be centered on the glomeruli (glomerulonephritis or amyloidosis), tubules (nephrosis), interstitium (interstitial nephritis), renal pelvis (pyelonephritis), or excretory system (cystitis, obstruction, or rupture). Chronic kidney disease (CKD) is further classified into stages defined by the International Renal Interest Society (IRIS) that are based on severity of disease. There are multiple causes of CKD, and it is difficult to identify the initiating insult. Identification of a cause is not needed for patient management. A relatively common and somewhat confusing term is "acute on chronic kidney disease." This implies a disease process where underlying CKD has acutely exacerbated. Often this is due to acute dehydration. Occasionally acute on CKD occurs when the chronic disease has progressed or a second disease process is superimposed on the first (e.g., an ascending infection from the lower urinary tract damages an already diseased kidney).

The most accurate way to identify or monitor renal failure is to directly measure glomerular filtration rate (GFR); however, in veterinary medicine this is rarely done. Instead, we use indirect evidence to estimate reductions in GFR, and from this to imply that renal failure is present. Laboratory analyses of the serum biochemical profile, complete blood count (CBC), and complete urinalysis (UA) are more practical means to assess renal function and are performed daily in veterinary hospitals. If a more precise assessment of renal function is desired, then GFR can be measured by clearance studies.

There are many ways to recognize failure of the urinary system based on the history, biochemical profile, and evaluation of urine. These include identification of anuria, polyuria, azotemia, uremia, electrolyte abnormalities, hypoalbuminemia, inappropriate urine specific gravity (USG), casts, cystitis, and hematuria, to list a few (see definitions). When renal failure is severe, the clinical recognition is easy. When failure is mild and/or the disease is in the earliest stages, then recognition can be difficult and may require ancillary diagnostic tests such as creatinine clearance, fractional excretion of sodium, assessment of proteinuria, or ultrasonography. These ancillary tests are also useful to monitor the patient's response to treatments.

Understanding the physiology of the kidney makes the understanding of clinical pathology simple. If structures are damaged, then functions are lost, and if the remaining nephrons cannot compensate a clinical laboratory or physical examination finding will generally be obvious. For example, glomeruli exclude albumin from the ultrafiltrate; if glomerulonephritis is present, then this exclusionary function is lost. If the disease is severe enough and the remaining nephrons cannot compensate, there will be proteinuria, hypoalbuminemia, and, potentially, ascites and dependent edema (nephrotic syndrome; Table 24.1).

Laboratory abnormalities may be nonexistent, mild, moderate, or marked depending on severity and chronicity of disease as well as any treatments that have been undertaken to slow disease progression. Guidelines for the staging and management of chronic renal disease have been developed by IRIS and are based on severity of clinical signs, physical examination findings, and laboratory

Table 24.1 The concentration of certain substances measured in serum or plasma is affected by renal function.

Substance	Function lost	Abnormality
UN Ct	Excretion	Azotemia
Water	Balance	Polyuria, anuria, oliguria
P	Excrete	Hyperphosphatemia
Na Cl	Conserve	Normo- to hyponatremia, hypochloremia
K	Excrete	Hyperkalemia
Ca	Conserve	Hypocalcemia
Acid base	Balance	Acidosis metabolic; alkalosis cow
Albumin	Conserve	Proteinuria, hypoalbuminemia, ascites
Erythropoietin	Produce	Anemia, nonregenerative
Vitamin D	Produce	Hypocalcemia, osteodystrophy
Lipase, amylase	Excrete	Increased one- to threefold
Antithrombin III	Conserve	Decreased AT III, thrombi

Damage to specific renal structures results in damage to renal function. The abnormalities listed are generalizations and not constants. Their presence will depend on the severity of the lesion, chronicity, treatments, and compensatory ability of surviving nephrons.

abnormalities. The stage of the renal disease correlates with the severity of the renal lesions and reflects prognosis. As the stage of the renal disease progresses, so does the severity of the laboratory abnormalities. Laboratory abnormalities will not appear until enough nephrons are impaired and the remaining nephrons cannot compensate. Two classic examples are isosthenuria and azotemia. Isosthenuria occurs when approximately 66% of nephrons are not functioning properly. Azotemia is not seen until approximately 75% of nephrons are compromised. Bear in mind that analytes are not meant to be interpreted in isolation but rather must be carefully considered with the patient's clinical signs, physical exam findings, and complete laboratory data.

This chapter will follow the functions of the urinary system, predict clinical pathology results and diagnoses, and provide case examples. The emphasis is on interpretation of laboratory data with less focus on methodology, which is covered exhaustively in other excellent resources. The chapter is organized by evaluation of renal function, urinalysis, diseases of the urinary system, definitions, and glossary of terms. Students learning this body of information for the first time should consider reading the definitions and glossary first. A glossary of terms is at the end of chapter.

Laboratory evaluation of renal function: bloodwork

GFR is the volume of plasma filtered at the glomerular capillaries into Bowman's space per unit of time. It is the best predictor of renal function because it is directly related to total functional renal mass or, in other words, to the number of functioning nephrons. It is dependent on adequate blood flow to the kidneys, blood pressure, interstitial, and intratubular pressures, as well as number of functioning nephrons. A GFR of 3–6 mL/min/kg is normal for a dog and 2–4 mL/min/kg is normal for a cat. A decrease in GFR indicates decreased renal function. GFR can be used to stage renal disease and monitor the progression of renal disease. It is not easy to measure GFR directly, but it can be measured by studies that use substances that are freely filtered by the glomerulus and that are neither secreted nor reabsorbed, such as inulin, iohexol, mannitol, *p*-amminohippuric acid, and exogenous creatinine. GFR can also be estimated by endogenous creatinine clearance studies. The methodologies of these and other tests can be found in many other resources.

Because of the complexity of direct GFR measurement studies, it is seldom measured in veterinary medicine. Instead, indirect evidence of decreased GFR is derived from serum urea nitrogen concentration (UN), creatinine concentration (Ct), symmetric dimethylarginine concentration (SDMA), and phosphorus concentration (P). Additional data are derived from serum calcium concentration (Ca), electrolytes (sodium, potassium, chloride), the complete urinalysis, and/or urinary protein and creatinine clearance, as well as the fractional excretion of sodium.

A decreasing GFR is the best indicator of renal insufficiency, and because UN and Ct are freely filtered by the glomerulus, they are the analytes traditionally used to estimate GFR (Figure 24.1). As the GFR decreases, plasma UN and Ct concentrations increase; however, renal mass must be reduced 75% before UN and Ct concentrations increase in blood plasma. Because azotemia is not evident until 75% of nephrons are no longer functioning adequately, and because the ability to concentrate urine is lost after 66% of nephrons are compromised, azotemia and dilute urine or polyuria caused by renal failure are not detected until a large portion of the total renal mass is compromised. Therefore, they are not early indicators of renal failure. These percentages indicate the tremendous reserve of renal function, because only 25% of total renal mass is needed to excrete sufficient nitrogenous waste to prevent azotemia, and only 33% is needed to concentrate urine and preserve the body's fluid volume.

It should be noted that no serum biochemical abnormalities indicate irreversibility of renal damage, for, while glomeruli have no regenerative capabilities, tubules have tremendous regenerative capacity if basement membranes are preserved. If glomeruli and tubules sustain severe damage, the remaining nephrons compensate by hypertrophy, especially in CKD. Therefore, when azotemia is detected, the total nephron mass not functioning adequately may actually be greater than 75%. The remaining nephrons compensate

and maintain the overall GFR such that serum UN and Ct stay within the reference interval (WRI), delaying azotemia until more nephrons are lost. For example, if a dog with normal serum Ct of 0.5 mg/dL developed renal disease such that serum Ct increased to 1.0 mg/dL, then theoretically 50% of its nephrons are now not functioning properly. However, because that value of serum Ct concentration is still WRI, that 50% loss of function would not be detected by measuring Ct or UN concentrations because the renal reserve, or compensation via hypertrophy of remaining nephrons, would work to maintain serum Ct WRI of a "normal" dog. However, and very importantly, once Ct is increased above the upper reference interval, then every doubling of serum Ct indicates a loss of function of 50% of the remaining renal mass. Conversely, the recovery of nephrons from an insult can be monitored, for every 50% reduction in serum Ct or UN indicates that 50% of the nephrons have returned to function. This is because there is a logarithmic relationship of serum Ct to GFR (Figure 24.1). It is this principle that allows us to monitor progression of renal disease through measurement of serum Ct, once the upper limit of the reference interval has been surpassed. The great amount of renal functional reserve sometimes requires more sophisticated methods to determine if renal disease is present when serum Ct is not increased, e.g., the tests of endogenous or exogenous creatinine clearance, inulin clearance, clearance of radioisotopes, SDMA, and assessment of fractional excretion of electrolytes, etc.

It should be noted that serum Ct is a better indicator of GFR than serum UN because its rates of production and excretion are fairly constant, and extrarenal or renal processes do not metabolize it. In contrast, serum UN is influenced by more nonrenal factors than is Ct, and a significant proportion of UN excreted into the glomerular filtrate is reabsorbed (approximately 66%). Furthermore, the rate of reabsorption of UN varies with the hydration status of the animal as well as the speed of flow of the glomerular filtrate within the tubules.

Serum Ct WRI does not mean the kidneys are normal, it means that 25% of the renal mass is functioning adequately enough to excrete creatinine and keep it WRI. An endogenous creatinine clearance study is a better indicator of renal function than serum Ct or UN. Endogenous Ct clearance can be used to estimate GFR because the production of Ct is relatively constant, and essentially 100% is excreted via the kidneys (the small amount that is secreted by proximal tubules is negligible for this estimation). Creatinine clearance is useful when renal disease is suspected but the serum concentrations of Ct and UN are not increased. Creatinine clearance can be calculated from the Ct, urine Ct, the volume of urine produced in a defined period, and the weight of the patient.

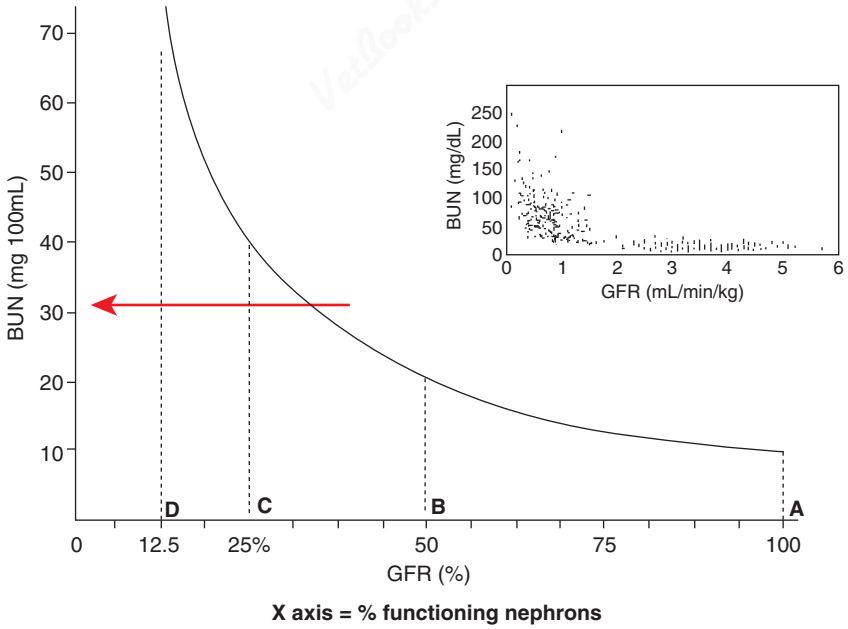

Figure 24.1 Glomerular filtration rate (GFR) as mL/min/kg body weight (inset) and as % functioning nephron units. A GFR of 3–6 mL/min/kg is normal for dogs and the BUN is less than 30 mg/dL, and as GFR decreases the BUN increases (inset). In the example provided, (A) correlates with 100% functional nephron units and a BUN of approximately 12 mg/dL. When 50% of the nephron units are compromised (GFR decreased 50%) the BUN has doubled to approximately 24 mg/dL, but it is still in reference interval (occult renal issues). Not until approximately 75% of the nephron units are compromised (GFR is now 25% of normal) is the dog azotemic (C). Therefore, BUN and serum creatinine (Ct) are poor indicators of early renal insufficiency. If the GFR is decreased by half again (D) by advancing renal disease, then a rule of thumb is the BUN and Ct will double. Likewise, a decrease in BUN and Ct by half indicates the GFR has doubled, meaning there is improvement in renal function, e.g., more nephrons are functioning. Monitoring BUN or Ct to assess deterioration or improvement of renal function can be done only after they are increased, but GFR can be used to monitor patients with renal insufficiency at any time.

Case Example 24.1. 40 kg dog with normal serum Ct and reduced Ct clearance

Canine creatinine clearance reference interval is 3–6 mL/min/kg. Serum Ct 1.0 mg/dL; over 1 hour, patient produces 30 mLs of urine with a urine Ct of 200 mg/dL.

The dog has reduced Ct clearance not reflected by the serum Ct, which is WRI. This may be seen in post-treatment of renal failure when serum Ct has returned to the reference interval. The patient feels better but there is still compromised renal function (e.g., some renal lesions may persist, such as interstitial fibrosis). These patients will benefit from dietary changes and ad libitum access to water. This might be predicted from clinical experience, but it would not be known without assessment of urinary creatinine clearance. In a 24-hour study of endogenous creatinine clearance, the urinary bladder is emptied of urine at the start of the study, the volume of urine produced in 24 hours is measured, and a serum sample is collected usually in the middle or at the end of the study.

The urinary bladder is completely emptied of urine at the start of the study, and the volume of urine produced in the duration of the study is measured.

Endogenous creatinine clearance can also be used in the diagnostic evaluation of a patient in which occult renal disease is suspected. This patient is not azotemic but has polyuria, polydipsia, and dilute urine. This situation may be observed when functional renal mass is reduced to between 66% and 75%. If more accurate assessment of renal function is desired, then clearance of exogenous creatinine, inulin, or iohexol can be performed as well as injected radioisotopes or renal scintigraphy. These studies are usually only performed in specialty hospitals and when the clinician and owner want the patient monitored closely.

Biological markers of the glomerular filtration rate

Urea nitrogen (UN)

The serum urea nitrogen and creatinine concentrations should always be correlated with the urine specific gravity and clinical findings; calculate the UN/Ct ratio.

The term "blood urea nitrogen" (BUN) is no longer a relevant term because of changes in measurement methodology. Originally, a urease method released nitrogen from urea and the amount of nitrogen was measured, i.e., BUN. Now urea is measured from the release of ammonium ions via urease. "Urea" is not a substance defined by the International Clinical Chemistry Federation, rather they use the term "carbamide." It has been difficult to switch clinicians from BUN to UN, and impossible to force the acceptance of carbamide, so throughout this chapter, the term UN will be used.

Urea is a 60 Da molecule produced in the liver. It is derived from proteins (amino acids) absorbed through the intestines and catabolized by the liver into ammonium. Likewise, the rate of urea production is dependent upon two factors, liver function and the amount of protein in the diet. Urea is the main method of nitrogen excretion in animals. UN is freely filtered by glomeruli, and approximately 50% is reabsorbed passively by the proximal tubules, with ~10% being actively reabsorbed by the collecting tubules. The amount of urea reabsorbed varies with the rate of flow through the tubules. For example, during dehydration, the tubular flow rate slows, and more UN is reabsorbed through the tubules, increasing serum UN. A portion of urea is also excreted via salivary glands into the gastrointestinal (GI) tract, where it is degraded by bacteria into ammonium. Ammonium is then absorbed and converted back into urea by the liver. Thus, there is no net excretion of UN via the gastrointestinal system in most species.

All species can excrete UN through their salivary glands. However, only ruminants and horses have unique microflora that convert the UN into amino acids. The amino acids are then reabsorbed, leading to a net excretion of UN. This is the logic of feeding cattle liquid urea as a source of protein. Cattle are so efficient with this mechanism that it may take up to 1 week post–bilateral nephrectomy before serum UN increases. Cattle on a nitrogen-deficient diet or those that are severely anorectic will excrete the majority of their UN via the GI tract. This makes it is especially critical in ruminants to rely on Ct and USG to predict renal disease. Horses are not as efficient at converting UN into amino acids with the microflora in their cecum and colon but can accomplish some net excretion of UN (case examples are found later in this chapter). Thus, in horses, serum UN is used in the assessment of renal function along with Ct and USG.

Because serum UN is dependent upon both production and excretion of UN, there are multiple factors that may contribute to changes in serum UN besides renal disease. Increases in serum UN may be due to increased dietary protein; intestinal hemorrhage (hemoglobin in blood is a very high concentration of protein); sepsis and fasting, which increase protein catabolism; decreased renal perfusion (favors increased tubular reabsorption); and most importantly, renal disease. For example, normal dogs fed a high-protein meal may have a slight increase in their serum UN peaking at 6 hours and lasting up to 18 hours. The protein is broken down in the GI tract and the ammonium produced is reabsorbed and converted into UN by the liver. This is the principle of feeding reduced-protein diets to patients in renal failure. These patients may benefit from a low-protein diet that results in less UN production and therefore reduces some of the work performed by the kidneys. All nonrenal causes of increased serum UN cause only a mild increase, usually less than 30–35 mg/dL.

Decreased serum UN is uncommon. A decreased serum UN implies decreased production of urea. Conditions that may decrease UN production are intra- or extrahepatic

shunts, chronic liver failure, malnutrition, hyperthyroidism (increased catabolism and increased GFR; hyperthyroidism may also decrease Ct due to cachexia), and diuresis. Hepatic shunts are probably the most common cause of decreased serum UN. If a shunt or chronic liver failure causes a decrease in serum UN, there will be other clinical and laboratory abnormalities suggestive of these problems, e.g., decreased mean cell volume, albumin, glucose, cholesterol, ammonium biurate crystals in the urine, to name a few.

Serum reagent strips that use urease to estimate serum UN are less accurate than strips that assay the release of ammonia, which is a semiquantitative determination. These methods are somewhat useful for broadly estimating "normal" or "increased" serum UN in after-hours situations but are not reliable for patient monitoring over time. They are good at identifying low or normal values and are not adequate to quantify abnormally high values. If the strip indicates that a patient is azotemic, then it would be preferable to determine serum UN via quantitative chemical methodology prior to fluid therapy. If serum strips are used to assess uroabdomen, then the measurement difference between abdominal fluid and serum should be definitive, and it is recommended that results be confirmed with quantitation of UN or Ct in fluid and serum (refer to the "Uroabdomen" section). As in any case, all of the pieces of data should be integrated. Reagent strips are a benefit for after-hours estimations but should not replace chemical measurement of urea, UN.

Creatinine (Ct)

Creatinine (from the Greek word for flesh *kreas*) is a waste product of creatine and creatine phosphate found in muscle. It is a ring structure with a molecular weight of 113 Da. Creatine is produced in the liver with a minor role from the pancreas, transported to skeletal muscle, where 95% of the total body creatine is located. In skeletal muscle, creatine is converted into creatine phosphate via the enzyme creatine kinase. Creatine phosphate serves as an energy store for production of adenosine triphophate (ATP) and, along with creatine, is spontaneously degraded in muscles to creatinine. Creatinine production is relatively constant (1–2%/d) and is roughly proportional to muscle mass. Creatinine has no charge and freely passes out of muscle cells. The majority of circulating Ct is filtered freely through the glomeruli and not resorbed by the tubules. It is generally considered a reliable marker of GFR. As an aside, a small amount of Ct is secreted by the proximal tubules of male dogs, but this is clinically inconsequential; cats and ponies do not secrete or reabsorb Ct in their kidneys.

Increases in serum Ct may be due to either physiologic or pathologic etiologies, and the most important is renal disease. Physiologic minimal increases are frequently associated with heavily muscled animals. For example, greyhounds have a higher serum Ct than the average dog. Factors that increase endogenous muscle catabolism such as sepsis, developing cachexia, can increase the release of creatine and, hence, the quantity of creatinine that is produced. However, these increases are mild and rarely interfere with clinical interpretation. Increases in serum Ct may also be observed in neonatal foals born to dams with dysfunctional placentas. The excess Ct typically resolves the first few days after birth. Pathologic causes of increased serum Ct are almost exclusively associated with decreased GFR. These differentials are discussed in detail below (see "Azotemia").

Decreased serum Ct or at least decreased synthesis of Ct is seen with conditions that decrease muscle mass such as chronic cachexia. It is occasionally observed in feline hyperthyroidism as patients with this condition develop an increased GFR. Hyperthyroidism may mask the development of azotemia in geriatric cats with concurrent chronic renal disease [1]. A decrease is observed rarely with chronic liver failure. Otherwise, decreased serum Ct is not considered clinically significant and has no meaningful interpretation.

Creatinine is measured spectrophotometrically, and any chromogenic substance (or noncreatinine chromogen) will also be measured, resulting in a false increase in the measured serum Ct. The most common noncreatinine chromogens are ketones, glucose, carotenes, and vitamin A (substances that tend to be higher in herbivores) as well as pyruvate, ascorbic acid, and uric acid (Table 24.2). The Jaffé reagent is used most frequently in veterinary laboratories to measure creatinine, and it reacts with many noncreatinine chromogens. At normal concentrations of serum Ct, noncreatinine chromogens can contribute up to 50% of the measured serum Ct. There are several situations where these noncreatinine chromogens contribute to the measured Ct such that they will interfere with clinical interpretation. Cattle and horses occasionally have disproportionate increases in serum Ct as compared to UN, and this may be due to an increase in noncreatinine chromogens that falsely increase serum Ct.

Table 24.2 Nonrenal factors that increase serum UN and Ct.

Both	UN	Ct
Dehydration Hypovolemia Shock	GI hemorrhage	Noncreatinine chromogens Oxyglobin Glucose Ketones Carotenes Uric acid Vitamins A and C

Protein-rich meals, fever, sepsis, and anorexia are listed as factors that will increase serum UN. While sepsis and developing cachexia can lead to increased release of creatine and increased creatinine production, these increases tend to be mild and do not interfere with clinical interpretation.

This is seen with some regularity in horses with colic. In horses, when Ct is disproportionately higher than UN, such that the serum UN:Ct ratio is 5 or less, then noncreatinine chromogens are a likely cause. This is particularly likely if UN is within or only mildly increased, above the RI, but Ct is clearly increased (3–6 mg/dL). The easiest way to determine if the increase in Ct is due to renal or nonrenal causes is to compare the USG and the serum UN. If the USG and the serum Ct are increased but UN is within the RI, then the horse has noncreatinine chromogens artifactually increasing the serum Ct. If the USG is increased and UN is increased, but Ct is disproportionately higher than the increase in UN, then the horse has prerenal azotemia and noncreatinine chromogens are contributing to the Ct measurement. If USG is isosthenuric and there is azotemia, then the animal has renal azotemia. This presents a clinical dilemma, which is compounded when the UN is not increased as much as the Ct due to the enteric excretion of UN in horses and cattle.

In small animals, false-high Ct is seen almost exclusively with artificial transfusates such as oxyglobin products. The serum Ct can be increased as high as 20 mg/dL, but serum UN will remain WRI. In addition to other analytes, these animals will have falsely increased serum hepatic enzymes, and the serum may be yellow-orange, depending on the dose of artificial transfusate administered as well as the cause of the anemia.

Azotemia

A major function of the urinary system is to excrete UN and Ct. When this function is lost, serum concentrations of UN and Ct increase – a condition termed azotemia. Traditionally, azotemia is the single best laboratory abnormality that indicates problems in the urinary system. When UN and Ct are not excreted in adequate amounts, their concentration increases in serum (azotemia), and this may lead to the clinical signs of urinary toxin accumulation in the patient, known as uremia. Both UN and Ct are reported in the biochemical profile, and an increased concentration of either implies a decreased GFR. Neither substance increases until approximately 75% of nephrons are nonfunctional. In fact, this percentage is probably closer to 80–90%. The remaining nephrons compensate by hypertrophy, especially in CKD. Therefore, when azotemia is detected, the total nephron mass not functioning adequately may actually be greater than 75%. The remaining nephrons compensate and maintain the overall GFR such that serum UN and Ct stay WRI, delaying azotemia until more nephrons are lost. Because serum UN and Ct do not increase until 75% of the nephrons are compromised, they are not useful in the detection of early renal failure, i.e., they are insensitive indicators of lower levels of renal dysfunction. However, they are fairly specific as relatively few nonrenal factors cause their increase. Table 24.2 lists nonrenal factors that increase these substances. The most common causes are dehydration (hypovolemia) and GI hemorrhage.

Once azotemia is identified, the next step is to determine if the cause is prerenal, renal, or postrenal. It is important to remember that categorizing the azotemia should not be done in isolation. Rather, findings from the urinalysis (USG, urine volume) and clinical presentation (dehydrated?) are important considerations in obtaining an accurate diagnosis. The magnitude of azotemia also factors in to the clinical assessment. Mild azotemia is characterized by a serum Ct (in mg/dL) of 1.5–2.0 in the dog, 1.6–3.0 in the cat; moderate azotemia, 2.1–5.0 dogs, 3.0–5.0 cats; and severe azotemia is >5.0 in both the dog and cat. Extreme values >10.0 may be observed when hypovolemia (e.g., dehydration) is superimposed on renal or postrenal causes of azotemia. The magnitude of serum UN or Ct does not predict a prerenal, renal, or postrenal cause of azotemia. In general, if serum Ct is your shoe size or greater, your patient has marked azotemia, but it could be reversible.

The UN:Ct Ratio

Urine Ct:serum Ct ratios can be used to distinguish renal and prerenal azotemias. The ratio of serum UN:Ct in small animals is approximately 20 : 1 and in large animals 10 : 1. An increased ratio is associated with dehydration or intestinal bleeding. A decreased ratio is associated with fluid diuresis, the presence of noncreatinine chromogens, or the unique ability of cows and horses to metabolize and excrete UN through their gastrointestinal tracts. Ratios >50 : 1 indicate prerenal azotemia and ratios <37 : 1 indicate renal azotemia.

Prerenal Azotemia

Prerenal azotemia describes etiologies that contribute to a decreased GFR that occurs outside of the urinary tract. The primary mechanism of prerenal azotemia is failure to deliver blood to the kidneys. This is most commonly associated with dehydration, shock, and cardiac insufficiency of which dehydration is the most common cause. Azotemia occurs because there is continual basal production of UN and Ct in the face of a decreased GFR. The decreased GFR results from the decreased blood volume causing inadequate blood flow to glomeruli. Characteristic findings in bloodwork and urinalysis include an increased serum UN and Ct, concentrated USG, decreased urine volume, increased packed cell volume (PCV) and serum albumin, and clinical signs of dehydration (Figure 24.2).

In cases of prerenal azotemia (e.g., dehydration) urine production should decrease as the body attempts to conserve serum volume (water), thereby increasing the USG. Increases in the PCV and albumin further support a diagnosis of prerenal azotemia. The increases in UN and Ct observed with dehydration are usually mild to moderate (e.g., serum UN 35–120 mg/dL and Ct 2–5 mg/dL). UN to creatinine ratios of >50 : 1 usually indicate a prerenal azotemia. In cases of

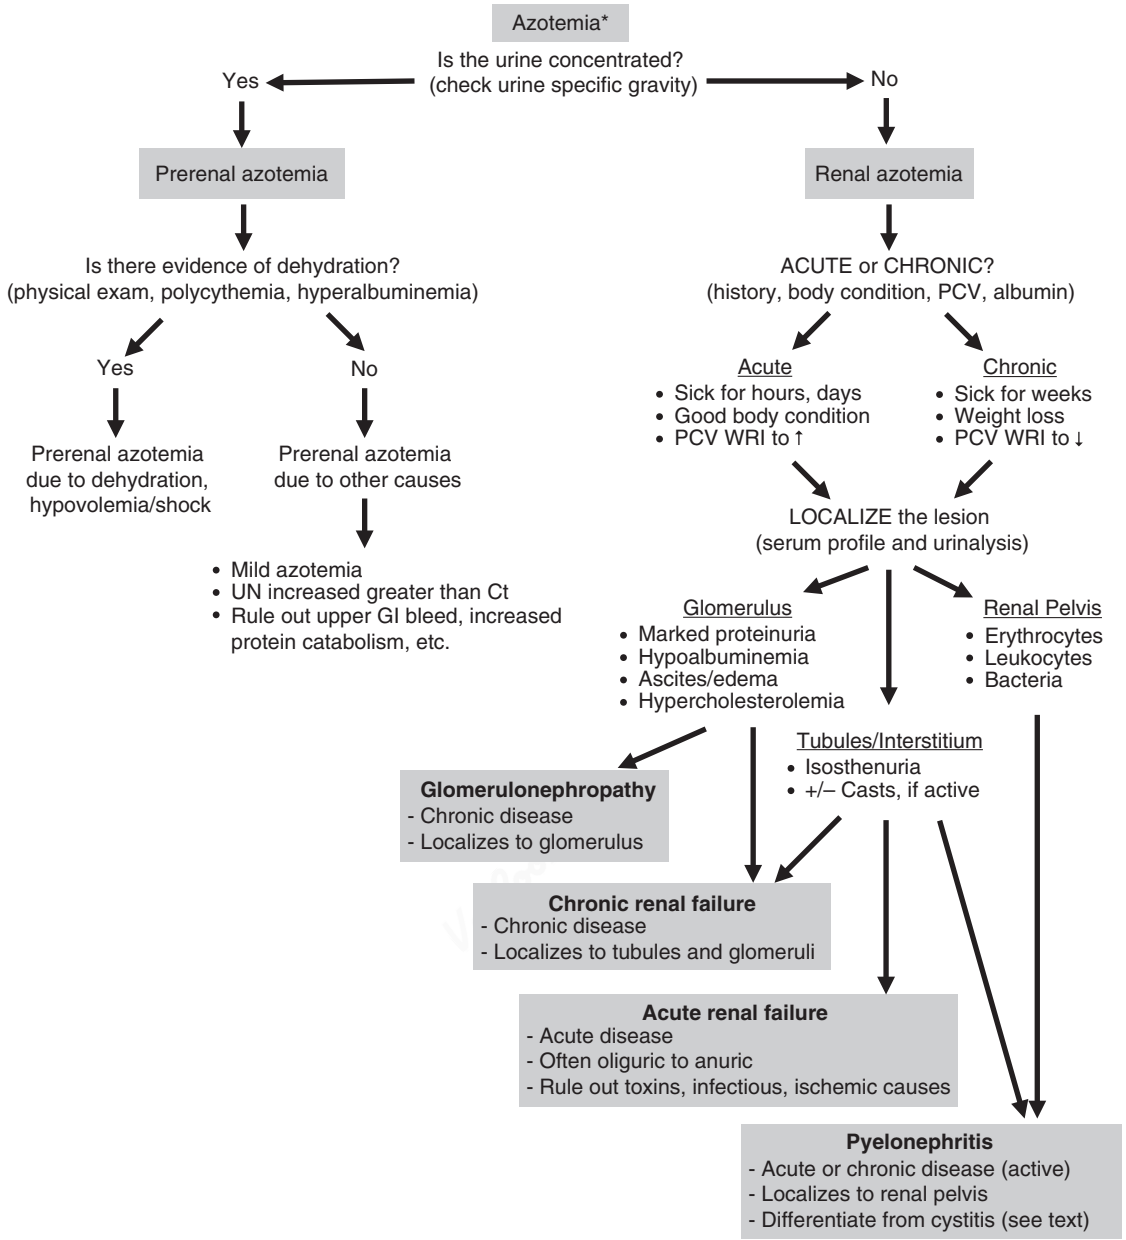

Figure 24.2 General approaches to azotemia in kidney disease. Correlate azotemia with USG, PCV, albumin, and hydration status to determine if azotemia is prerenal, renal, or a combination. Azotemia with concentrated urine is indicative of a prerenal azotemia. Urine is considered concentrated when the USG is >1.030 for a dog and >1.040 for a cat. As the USG increases, confidence in the kidney's ability to concentrate urine increases. Postrenal azotemia is due to obstruction of outflow (calculi) or rupture of the urinary bladder and is not part of this algorithm. Azotemia with urine that is not adequately concentrated (≤1.030 for a dog, ≤1.040 for a cat) suggests renal disease. It should be noted that azotemia is often exacerbated in clinically dehydrated patients, leading to a prerenal azotemia superimposed on a renal azotemia. Sometimes this is referred to as acute on chronic renal disease. In these cases, kidney disease is the primary differential. Once azotemia is identified to be caused by kidney disease, a patient's history, body condition, urine volume, PCV, and albumin are used to determine chronicity (acute injury vs. chronic disease). The lesion is then localized within the kidney (glomeruli, tubules, interstitium, pelvis) using the urinalysis and serum chemistry. There are other differentials for a patient with azotemia and unconcentrated urine. Differentials include decreased ADH (diabetes insipidus), substances that interfere with renal ADH receptors (hypercalcemia, glucocorticoids, bacterial endotoxin, etc.), medullary washout (hyponatremia secondary to hypoadrenocorticism, decreased UN in liver insufficiency, prolonged IV fluids therapy), or osmotic diuresis due to substances excreted in the urine with strong osmotic pull (glucose, ketones, mannitol, etc.). In these cases, the classical presentation is a mild azotemia with a USG <1.013. If there is no concurrent renal disease the azotemia is prerenal in origin, as patients are unable to keep up with water losses. Each of these differentials may also present with USG <1.013 and no azotemia (they are not dehydrated).

prerenal azotemia, the fractional excretion of sodium is <1% as the kidney attempts to retain sodium and thereby water.

Diagnosing a prerenal azotemia may be complicated as the classic pattern of a mild to moderate azotemia with decreased urine production and concentrated urine can vary with underlying disease. For example, the severity of the azotemia may be exaggerated if the dehydration is superimposed on a case of true renal failure. In these cases, the azotemia can be severe (e.g., UN >200 mg/dL, Ct >10 mg/dL). Fluid therapy may remove the prerenal contribution and decrease serum UN and Ct. The point at which these values plateau is the degree of azotemia that is due to the true renal insufficiency.

Additionally, a prerenal azotemia may be present in a disease process that prevents the concentration of urine. These include primary and secondary diabetes insipidus, hypercalcemia, steroids, pyometra, and medullary washout. Despite clinical dehydration, the kidneys cannot concentrate urine adequately because there is inadequate antidiuretic hormone (ADH), or a substance is interfering with ADH, or the renal medullary interstitium is no longer saturated with sodium and urea. Calcium interferes with the action of ADH and when hypercalcemia is present urine is often dilute, even if the animal is dehydrated and azotemic. Azotemia is present in 90% of dogs with hypoadrenocorticism (Addison's disease) due to dehydration, and a small percentage of these may have dilute urine because of chronic hyponatremia and resultant medullary washout. Because the constellation of laboratory and clinical signs associated with hypoadrenocorticism are similar to those caused by renal failure (namely, azotemia, inadequately concentrated urine [e.g., USG <1.020], anorexia, and vomiting), Addisonian dogs may be initially misdiagnosed. Fluid therapy will rapidly correct the azotemia in these dogs, and when fluid therapy reverses azotemia overnight or in hours, then true renal failure was not present.

Utilizing physical exam findings consistent with dehydration (tacky mucus membranes, skin tents, etc.) as well as other hematology and chemistry analytes (PCV, albumin) can assist in diagnosing prerenal azotemia in complicated cases. Bear in mind that if the PCV was decreased prior to onset of dehydration then the PCV may shift upward to WRI during dehydration, which may mask an underlying anemia.

GI hemorrhage will increase UN without increasing Ct. Blood in the GI tract is broken down, reabsorbed as amino acids and ammonia, delivered to the liver, and converted into UN for excretion by the kidneys. Hemorrhage does not have to be so severe as to cause anemia, and in fact, hemorrhage may be mild enough that it requires an occult blood test on feces to be certain it is present. Other "high-protein meals" may increase UN production postprandially, but they do not cause azotemia in healthy patients. The increase in UN is offset by a concurrent increase in GFR stimulated by the meal. The increase in Ct from the meat is so mild that the postprandial increase in GFR actually decreases the serum concentration of Ct within 2 hours of the meal. Excess muscle catabolism (e.g., starvation or fever) could increase the production of UN, but it rarely produces azotemia. If there is an increase it will be mild and will not interfere with clinical interpretation.

Case Example 24.2. 1-year-old small breed dog, poor growth, thin, and bizarre behavior (snapping at objects, not playful)

UN 5 mg/dL (RI 10–30), Ct 1.1 mg/dL (RI <1.5), UN:Ct ratio 45 : 1, USG 1.012, Serum albumin 1.8 g/dL (RI 2.6–3.9); liver enzymes are WRI (RI = reference interval, WRI = within reference interval)

Interpretation: Decreased UN and albumin in a young dog with possible central nervous system (CNS) disturbances (snapping at objects) and dilute urine is likely caused by congenital hepatic shunt and decreased synthesis of UN and albumin by the liver. Inability to concentrate urine is due to a renal medullary interstitium that never developed a high UN, resulting in an inability to produce concentrated urine (medullary washout). It would be a classical sign of congenital hepatic shunt if ammonium biurate crystals were observed in the urine. These crystals and ammonium biurate uroliths (green, green-brown [Figures 24.A.18 and 24.A.19]) are caused by the markedly elevated ammonia concentration in plasma, which, because it is freely filtered at the glomerulus, contributes to an ultrafiltrate that is both supersaturated with ammonia and alkaline in pH and leads to ammonia crystallization. Most cases of congenital liver shunts have no to only mild increases in serum liver enzymes and are not bilirubinemic. This is in contrast to most cases of acquired liver shunts, which have moderate to marked increases in liver enzymes and bilirubinemia because the severe liver lesion precedes the development of the shunt.

Renal azotemia

Renal azotemia describes failure within the kidneys and is caused by lesions in one of five locations: glomeruli, tubules, interstitium, renal pelvis, or blood vessels. Any renal disease that causes damage to greater than 75% of the nephrons and reduces GFR below 25% will decrease the excretion of UN and Ct. Azotemia with unconcentrated urine is of renal origin (Figure 24.2). The azotemia may be mild, moderate, or severe azotemia depending on the severity and distribution of the underlying pathology. Urine volume may also be variable (polyuria, oliguria, anuria). For example, in cases of acute severe renal failure, urine volume will be decreased (oliguria or anuria). In cases of CKD, urine production will be increased (polyuria). Patients with renal azotemia will have isosthenuric or possibly hyposthenuric urine.

Case Example 24.3. 11-year-old Labrador Retriever treated with NSAIDs for chronic arthritis

UN 78 mg/dL (RI 10–30), Ct 1.2 mg/dL (RI <1.5), UN:Ct ratio 65 : 1, USG 1.034

First interpretation: A disproportionate increase in UN relative to Ct coupled with a concentrated urine is most likely due to GI hemorrhage secondary to gastric erosions and ulcerations, related to NSAID use.

Further tests: Occult blood test on feces and/or suspension of NSAIDs and evaluation of hydration status.

Second interpretation: Dehydration resulting in increased renal retention of UN. However, because UN is increased and Ct is WRI, GI hemorrhage is more likely than dehydration. Evaluate hydration status.

Dehydration can increase UN without a commensurate increase in Ct, and the UN:Ct ratio may be high, i.e., >20 : 1. One hundred percent of creatinine excreted in the glomerular filtrate passes out in the urine. However, approximately 50% of UN excreted in glomerular filtrate is reabsorbed via the tubules. The amount reabsorbed is a function of health of the tubules and the flow rate of filtrate through the tubules. The slower the flow rate (dehydration), the greater the reabsorption of UN; up to 70% of urea may be reabsorbed versus the expected 50%. The faster the flow rate (diuresis), the lower the amount of UN reabsorption; perhaps only 40% or less is reabsorbed. Therefore, with dehydration UN increases more than Ct, and with diuresis UN decreases faster than Ct, and both of these situations may be seen clinically. The faster decrease in UN during fluid therapy is due to increased production of glomerular filtrate, leading to a faster transit time of fluid in tubules, and therefore reduced time to reabsorb UN.

Case Example 24.4. 9-year-old dog, 6% clinically dehydrated

UN 88 mg/dL (RI 10–30), Ct 2.8 mg/dL (RI <1.5), UN:Ct ratio 31 : 1, USG 1.058

Interpretation: Prerenal azotemia, as evidenced by a disproportionate increase of UN compared to Ct, with a highly concentrated urine and clinical signs of dehydration. Urea reabsorption is increased secondary to decreased flow of glomerular filtrate caused by the hypovolemia of dehydration. The PCV and albumin may also be increased if dehydration is severe enough and if neither PCV nor albumin were decreased below the lower reference interval prior to the onset of dehydration. If the dog was not anemic, then PCV may be increased; however, if the dog was anemic prior to the onset of dehydration, then the decrease in plasma volume may cause an increase in the PCV to WRI, thus masking the anemia.

Once renal failure is recognized, the next steps are to determine which region of the kidney is diseased and to determine whether the renal failure is acute or chronic (Table 24.3). This distinction is critical, because acute kidney injury (AKI) may be reversible whereas CKD is not.

Table 24.3 Expected results in acute versus chronic kidney disease.

	Acute	Chronic
PCV	WRI	Decreased
Albumin	WRI	Decreased
K	Increased, variable	Decreased
Urine volume	Anuria, oliguria	Polyuria, polydipsia
Body condition	Good	Poor
History	Sudden onset	Gradual deterioration
Size of kidneys	Normal to enlarged	Small, irregular contours

These are generalizations and there is a range of actual results and species variations. WRI, within the reference interval.

Characteristic features of AKI are variable but generally include a good body condition, sudden onset (the animal often being reported as "fine yesterday"), depression, lethargy, and decreased to absent urine output. Laboratory data will include PCV and albumin concentration WRI (or increased if dehydration is present) and increased potassium concentration.

The most common cause of AKI is nephrosis, meaning tubular degeneration and necrosis, which is most commonly caused by a nephrotoxin. Acute nephrosis will be reflected in the urinalysis by isosthenuria, numerous casts, mild proteinuria, mild glucosuria in the face of normal blood glucose concentration, and variable cellular abnormalities in the sediment. If the kidneys can be imaged or palpated, they will be normal sized or enlarged and have regular contours.

CKD can be the result of glomerular diseases as well as chronic interstitial nephritis, pyelonephritis, progressive familial nephropathy, and even bilateral staghorn calculi. In short, anything that can cause enough tissue damage may result in end-stage renal failure. Characteristic features of CKD are steady weight loss, mediocre to poor body

Case Example 24.5. Mixed-breed dog, 6% clinically dehydrated

Initial results: UN 120 mg/dL (RI 10–30), Ct 4.5 mg/dL (RI <1.5), UN:Ct ratio 26 : 1, USG 1.062

Post-IV fluids: UN 34 mg/dL (RI 10–30), Ct 4.5 mg/dL (RI <1.5), UN:Ct ratio 12 : 1, USG 1.008

Interpretation: Prerenal azotemia; disproportionate increase of UN to Ct with concentrated urine and clinical dehydration. Dog is still mildly azotemic post–fluid therapy and the decrease in UN is of greater magnitude (70% less) than the decrease in Ct (33%). Serum UN is almost WRI, and Ct is nearly twice the upper reference interval value. This is due to the increased flow of filtrate through the tubules caused by the fluid therapy, which allowed less time for UN and water to be reabsorbed, and, therefore, more UN and fluid remained in the plasma ultrafiltrate, allowing more to be excreted (polyuria). This led to a faster decrease in UN than Ct. During fluid diuresis the increased flow of fluid through the kidneys decreases the reabsorption of UN to <40%, and therefore BUN decreases faster than creatinine during fluid therapy.

Approximately 40–60% of the UN excreted in the glomerular filtrate is reabsorbed via the tubules by passive (proximal tubules) and active mechanisms (via ADH in collecting ducts). There are urea transporters (UT1, UT2, UT3) that are active in different regions of the tubules to accomplish urea reabsorption. The amount reabsorbed is a function of the health of tubules and the rate of flow in the glomerular filtrate. A portion of the UN remains in the interstitium, along with sodium and chloride, and contributes to the hypertonicity of medulla that is part of the countercurrent multiplier system. The degree of saturation in the interstitium is proportional to the concentration of UN, sodium, and chloride in the medulla, which makes it hypertonic compared to the fluid in the tubules, and this gradient is needed to help concentrate the glomerular filtrate as it is processed into urine. Urea and sodium are the two substances primarily responsible for the passive reabsorption of water from tubules in the descending limb of the loop of Henle. If a patient has prolonged decreases in plasma sodium or UN, it may result in decreased concentrations of either substance in the interstitium, leading to a decreased ability to reabsorb water passively and, therefore, to a decreased ability to concentrate urine. Hence, a dilute urine results that is noted clinically as polyuria. This combination of events that leads to decreased medullary tonicity is referred to as medullary washout. It is seen with hypoadrenocorticism (prolonged hyponatremia) and with prolonged decreased production of UN due to hepatic shunts (congenital or acquired) as well as severe chronic liver failure. Urea is synthesized in the liver, and chronic liver failure can result in decreased production and therefore decreased plasma UN. Single-digit UN combined with hypoalbuminemia and microcytosis may be subtle clues that indicate hepatic shunts.

Psychogenic polydipsia will wash out the medullary interstitium of UN and sodium via marked diuresis. resulting in hyposthenuria and polyuria/polydipsia (PU/PD).

condition, lethargy, polyuria, polydipsia, and laboratory data that include nonregenerative anemia, hypoalbuminemia, and hypocalcemia (the latter is uncommon in horses). Hypokalemia is often seen in cattle and cats. If the kidneys can be imaged, they will be small and have irregular contours, especially when the disease is fully developed.

To monitor these patients over time, practical parameters would include patient weight, water intake, urine volume, USG, and serum UN and Ct. If closer monitoring was desired, or if you wanted to more accurately determine the functional renal mass, then specialized studies such as exogenous or endogenous creatinine clearance, fractional excretion of sodium, microproteinuria, or ultrasonography could be offered or performed.

Postrenal azotemia

Postrenal azotemia is due to either obstruction of outflow occurring after the nephron or a rupture in the urinary outflow tract. Azotemia is present due to the continued production of UN and Ct and an inability to excrete UN and Ct from the body. In cases of urinary bladder or urethral rupture, there is additional reabsorption of UN and Ct from the abdomen or the subcutis. Postrenal azotemia is generally considered to produce the greatest and most rapid increases in serum creatinine but is not diagnostic. Urine production is decreased (oliguria) or absent (anuria), and the USG may be variable. The diagnosis of postrenal azotemia is made more from historical and physical examination findings than through laboratory evaluation and is dependent on determining that urine is not being excreted.

Most cases of postrenal azotemia are associated with urolithiasis in males due to their narrow urethra. On physical examination, the bladder will be enlarged on palpation if the obstruction is distal to the bladder. Urine obtained via cystocentesis in an obstructed animal is often red, and examination of the sediment reveals many red blood cells (RBCs) and inflammatory cells. Hyperkalemia can be severe (>8 mEq/L) and life-threatening, especially in male cats with a complete urethral obstruction. Blocked intact male cats can have rapid and marked increases of UN and Ct with Ct >15 mg/dL. The azotemia decreases rapidly following relief of the obstruction.

In cats, sheep, goats, and cattle, uroabdomen is classically a disease of males due to their narrow urethra that is more easily obstructed than wider female urethra. As urine accumulates in the bladder, it distends and eventually

ruptures. In horses, uroabdomen occurs in male foals <7 days old when the urinary bladder is ruptured during birth. In dogs, uroabdomen is frequently associated with trauma (e.g., hit by car), especially in males. On physical examination, the bladder is small and/or difficult to palpate, and a palpable abdominal fluid wave may be present. Azotemia is variable and is often associated with electrolyte derangements. Uroabdomen is confirmed by an abdominal fluid Ct > serum Ct and is discussed under diseases in this chapter.

In large animals, a disproportionate increase in serum Ct is seen most frequently in cases of equine colic and is attributed to an increase in chromogens other than creatinine. When Ct is disproportionately higher than UN, such that the serum UN:Ct ratio is 5 or less, then noncreatinine chromogens are a likely cause, especially in horses. This is particularly likely if UN is within or only mildly increased, above the RI, but Ct is clearly increased (3–6 mg/dL). The easiest way to determine if the increase in Ct is due to renal or nonrenal causes is to compare the USG and the serum UN. If the USG and the serum Ct are increased but UN is within the RI, then the horse has noncreatinine chromogens artifactually increasing the serum Ct. If the USG is increased and UN is increased but Ct is disproportionately higher than the increase in UN, then the horse has prerenal azotemia and noncreatinine chromogens are contributing to the Ct measurement. If USG is isosthenuric and there is azotemia, then the animal has renal azotemia. This presents a clinical dilemma, which is compounded when the UN is not increased as much as the Ct due to the enteric excretion of UN in horses and cattle.

Symmetric dimethylarginine (SDMA)

SDMA is a natural byproduct of intranuclear protein metabolism that is continually produced in the nucleus of cells and excreted in urine via GFR. Its small molecular weight (202 g/mmol) and positive electrical charge allow the molecule to be freely filtered by the glomerulus (net negative charge). SDMA is a strong marker of kidney function in humans [2] and is a component of a chemistry panel offered by IDEXX Laboratories. Approximately 90% of SDMA is eliminated by the kidneys [3]. SDMA serum concentration is inversely proportional to GFR [4–6] and is positively correlated to serum creatinine concentration [4–7]. SDMA has been shown to increase earlier in kidney disease than creatinine in both cats [4] and dogs [6], increasing as early as 40% reduction in GFR. It is considered a more specific indicator of renal disease because it is not affected by extrarenal factors such as lean body mass or GI bleeding [3, 8]. Thus, it is a useful marker for identifying renal disease in patients with muscle loss (e.g., hyperthyroid cats). SDMA is measured by liquid chromatography-mass spectroscopy [4] and has been validated as a clinically relevant and reliable indicator of kidney disease in dogs and cats using propriety technology [6].

Case Example 24.6. 10-year-old horse with colic, clinical signs of dehydration are equivocal

UN 35 mg/dL, Ct 5.1 mg/dL, UN:Ct ratio 7 : 1, urine not obtained

Interpretation: Disproportionate increase of Ct to UN due to noncreatinine chromogens and/or possible excretion of UN in gastrointestinal tract. A UN of 35 mg/dL is mild to insignificant; however, a Ct of 5.1 mg/dL is a moderate increase and is of concern. This is especially true if banamine and/or phenylbutazone are to be administered to alleviate pain and aid in the prevention of laminitis. NSAIDs are contraindicated if the horse is dehydrated, not drinking, or azotemic as the propensity for NSAIDs to cause medullary crest necrosis in the kidneys is enhanced in these situations. This is a practical clinical dilemma. If the increase in Ct is due to noncreatinine chromogens, then the horse would benefit from NSAIDs. However, prerenal azotemia may be present in this horse, so obtaining the USG *before* fluid therapy is the best means to determine if there is a renal contribution to the azotemia. Fractional excretion of sodium <1% would be definitive evidence of no renal involvement, whereas fractional excretion of sodium >1% indicates renal disease. In the latter case NSAIDs are contraindicated. If they occur, the renal lesions induced by NSAIDs in horses are usually mild. From a practical view, colic is much more common than renal failure in horses, and therefore odds are that the increase in Ct is due to noncreatinine chromogens.

As with all renal analytes, SDMA is not a standalone test. It needs to be interpreted with clinical findings, PCV, UN, Ct, and USG. If UN and Ct are increased in a patient with isosthenuria, there is no need to request SDMA. Serial Ct and USG can be monitored to follow the progression of renal disease or GFR clearance studies can be offered. If the concentration of SDMA (reported in µg/dL) is increased in the absence of definitive clinical signs or other laboratory evidence of kidney disease, rechecking SDMA and other clinical chemistry results in 2–4 weeks is suggested. At that time, if values are still increased, pursuing a full renal workup including urinalysis and culture, diagnostic imaging, etc. is warranted (Figure 24.3). Consider SDMA as a screening test for annual wellness checks, especially in geriatric patients or breeds that have familial renal diseases. Measurement of SDMA can be helpful in the evaluation of patients with PU/PD and concentrations of UN and Ct WRI. An increased SDMA at this time suggests that occult renal disease is likely. However, if SDMA is not increased, then other causes of inadequately concentrated urine are more likely (Table 24.4).

SDMA is still in the early stages of evaluation as a renal marker in veterinary medicine. It has been shown to successfully diagnose CKD in dogs and cats; however, it is

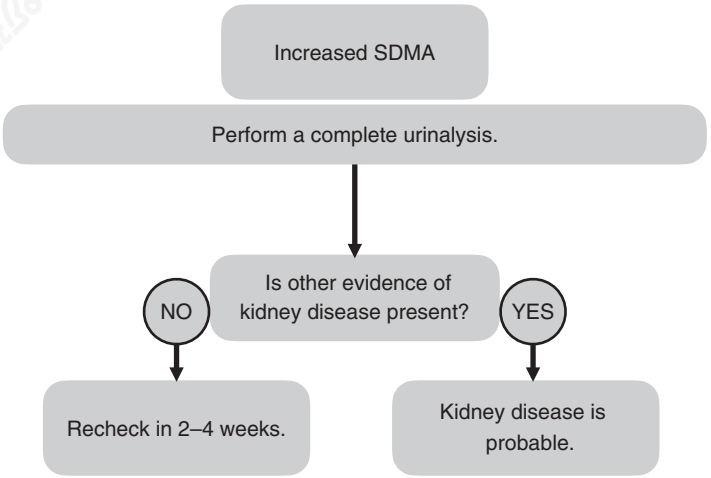

Figure 24.3 Algorithm for increased SDMA. SDMA is a relatively new test for the detection of occult renal disease; it increases in serum concentration earlier than traditional renal markers (isosthenuria, increased serum UN, Ct). SDMA is used as a screening test in animals at risk for renal disease (e.g., geriatric patients) or if early renal disease is suspected. It is a redundant test in azotemic patients.

Table 24.4 Causes of polyuria (polydipsia) and dilute urine.

Decreased ADH – central diabetes insipidus (DI)
Pituitary (hypothalamic rare) tumor, abscess, idiopathic, congenital
Inadequate response of tubular cells to adequate ADH – nephrogenic DI
Hypercalcemia, steroids, hypokalemia, pyometra, *E. coli* endotoxin, congenital lack of response of tubular cells to ADH
Decreased renal mass = lesions in kidneys, loss of tubular cells
With azotemia = >75% involvement; especially if lesions in medulla and pelvis
Without azotemia = 66–75% involvement of total renal mass
Excess fluid intake
Psychogenic polydipsia
Fluid overload diuresis
Medullary washout – medullary interstitium not saturated with sodium and urea
Addison's – prolonged hyponatremia
Liver failure – decreased urea nitrogen (other laboratory data will also support); congenital and acquired shunts; end-stage liver disease
Psychogenic polydipsia
Fluid overload diuresis
Solute overload
Diabetes mellitus, acromegaly, Fanconi syndrome, salt toxicity
Diuretics – many with actions at different regions of the tubules
Others/incompletely understood mechanisms
Hypoparathyroidism, hyperthyroidism, polycythemia, myeloma without hypercalcemia

unable to differentiate between CKD and AKI [9]. Similar to serum UN and Ct concentrations, SDMA will increase with a reduction of GFR caused by prerenal, renal (acute or chronic), and postrenal etiologies. Increases in SDMA do not help differentiate between these mechanisms. Identification of renal disease using SDMA requires the same steps as used for distinguishing causes of increased serum UN and Ct. Likewise, an increase in SDMA does not imply permanent loss of renal function. SDMA has not been correlated with specific diseases other than chronic and acute kidney disease. Nevertheless, it appears to be a promising analyte and will gain value as it continues to be evaluated by independent investigators.

Electrolyte abnormalities

There is a tremendous amount of information on how and where in the tubules electrolytes, ions, and other substances are reabsorbed and excreted. This section focuses on the abnormalities seen with renal failure and related diseases more than the physiology. Electrolyte abnormalities are common in renal failure and generalizations are predictable; however, the severity of the renal failure and the stage of compensation make accurate predictions difficult and therefore serum electrolytes must be measured. Hyperphosphatemia is expected anytime GFR is reduced. If CKD is in a compensatory state then sodium, potassium, and chloride will likely be within reference intervals. If chronic or AKI

Case Example 24.7. Categorize the azotemia: normal, prerenal, renal

Patient	A	B	C	D	E	F
Serum UN (10–30)	28	85	190	110	60	63
Serum Ct (<1.5)	1.1	4	9.2	3.2	3	3.1
Serum UN: Ct ratio	28 : 1	21 : 1	21 : 1	34 : 1	20 : 1	21 : 1
USG	1.034	1.006	1.010	1.058	1.014	1.044

(reference intervals are provided in parentheses; serum UN, Ct mg/dL)

A. "Normal": all results are within reference intervals, and USG indicates adequate concentrating capacity.
B. Renal azotemia: serum UN and Ct increased, and USG dilute.
C. Renal azotemia: UN and Ct increased and USG indicates isosthenuria; repeat USG to see if concentration increases out of the 1.007–1.013 range.
D. Prerenal azotemia: UN and Ct increased and USG elevated (concentrated); UN/Ct ratio increased to 34, which also suggests prerenal; dehydration likely, evaluate hydration status.
E. Renal azotemia: UN and Ct increased and USG close to isosthenuric range, need repeat USG to see if patient can concentrate its urine.
F. Prerenal azotemia: UN and Ct increased and USG concentrated; nearly identical values to example "E" but different causes based on results of USG; there are no values for UN and Ct that are too high for prerenal azotemia; however, often the greatest increases are seen when there is a combination of prerenal and renal azotemia.

Case Example 24.8. Match the patient to the diagnosis

Patient	A	B	C	D	E
Serum UN (10–30)	22	5	180	90	55
Serum Ct (<1.5)	1.5	1	9	2	10.2
Serum UN: Ct ratio	16:1	5 : 1	20 : 1	45 : 1	5.5 : 1
USG	1.024	1.005	1.010	1.055	Not performed

(reference intervals are provided in parentheses; serum UN, Ct mg/dL)
Possible diagnoses: normal, prerenal azotemia, renal azotemia, azotemia in a horse, hepatic shunt
Interpretation:

A. "Normal": at least all results are within reference intervals, and USG indicates some concentrating capacity. Recall that any USG is possible on a random urine sample.
B. Hepatic shunt: UN is decreased and urine is hyposthenuric, implying renal ability to dilute urine, but it may not be able to concentrate, need more USG to identify a pattern. The decreased UN is attributable to decreased hepatic production; recommend evaluation of liver function.
C. Renal azotemia: UN and Ct are increased and USG indicates isosthenuria. The USG should be repeated to determine whether it will rise out of the 1.007–1.013 range. Dilute urine suggests tubular lesions, but we need to know the rapidity of onset, body condition of the animal, serum albumin, and PCV to differentiate acute from chronic renal disease.
D. Prerenal azotemia: UN and Ct increased and high UN/Ct ratio suggestive of prerenal cause (e.g., dehydration leading to decreased GFR) with high USG (concentrated urine). One could observe similar values with GI hemorrhage, increased substrate delivery to liver for increased UN production (e.g., bleeding ulcer, hookworm infection, NSAIDs, etc.).
E. Horse: disproportionate increase in Ct relative to UN resulting in low UN/Ct ratio. Differential diagnoses include an increase in noncreatinine chromogens combined with dehydration (e.g., noted with colic). Similar results are expected in cattle with renal failure coupled with GI excretion of UN, a urinalysis and especially USG would help differentiate these possibilities. If isosthenuric urine is observed, then the results are consistent with renal failure. If urine is adequately concentrated, then the results are consistent with prerenal azotemia and the presence of noncreatinine chromogens.

is not compensated then there will be disturbances of these electrolytes that run the gamut of increased to decreased.

Phosphorus and calcium

Evaluate these two electrolytes together. Most dogs and cats with renal failure will have normocalcemia and hyperphosphatemia, next most frequent is hypocalcemia and hyperphosphatemia. Hyperphosphatemia is a nearly constant association with CKD in all species except the horse. Horses tend to have hypercalcemia and hypophosphatemia. As renal failure progresses from stage 1 to stage 4, the serum concentrations of UN, creatinine, and phosphorus

Case Example 24.9. Categorize the azotemia (normal, prerenal, renal) and list differentials

1. Categorize the Azotemia: normal, prerenal, renal
2. What are your differentials?

Patient	A	B	C	D	E-1	E-2 with fluid therapy
Serum UN (10–30)	20	98	121	220	225	68
Serum Ct (<1.5)	1.0	2	6	11	12	6.2
Serum UN:Ct ratio	20 : 1	50 : 1	20 : 1	20 : 1	20 : 1	10 : 1
PCV (30–50)	42	59	48	21	62	41
Albumin (2.8–4.0)	3.0	4.8	5.1	1.9	4.9	3.0
USG	1.022	1.044	1.059	1.009	1.006	1.010

(reference intervals are provided in parentheses; serum UN, Ct mg/dL, PCV %, albumin g/dL)

Interpretations:

A. Normal.

B. Azotemia with concentrated USG, increased UN/Ct ratio, polycythemia, and increased serum albumin all attributable to dehydration causing a prerenal azotemia. GI hemorrhage could produce similar results, the PCV does not need to be decreased for GI hemorrhage to cause an increase in UN but an increased PCV fits better with dehydration, and an increase in albumin confirms dehydration.

C. Prerenal azotemia, there is not an increase in the UN/Ct ratio in this example; the *only* cause of increased serum albumin is dehydration (bisalbuminemia or a hepatocellular carcinoma causing increased albumin either through increased production by neoplastic hepatocytes or due to reduced negative feedback on production; both conditions are incredibly rare).

D. Azotemia with isosthenuric urine indicates renal failure. The low PCV and low albumin indicate CKD. Correlate laboratory results with body condition of patient, physical exam results, and history. Ultrasonography of kidneys may reveal small, fibrotic kidneys.

E-1. Azotemia with unconcentrated urine indicates there is renal disease but that the kidneys are functional to some degree because they are able to produce urine more dilute than plasma. The increases in albumin concentration and PCV indicate a prerenal component and indicate the renal failure is probably acute and therefore tubular lesions are likely, possibly a nephrosis; this is an example of renal and prerenal azotemia, but it cannot be determined what portion of the azotemia is due to each of these factors. These data warrant performing serial urinalyses to monitor USG.

E-2. IV fluid therapy resulted in decreased azotemia supporting the interpretation that part of the azotemia was of prerenal azotemia. There is a greater decrease in UN relative to Ct, which is typical of fluid diuresis and is caused by the increased rate of flow of filtrate leading to decreased reabsorption of UN in tubules. The decrease in PCV and albumin is due to fluid therapy; the second USG is isosthenuric and is expected following fluid therapy (i.e., it cannot be interpreted). A large portion of the azotemia before fluid therapy was due to dehydration. Fluid therapy should continue to determine if fluids and other treatments can lower the azotemia further. The point at which fluid therapy cannot decrease the azotemia further is the UN and Ct concentrations that are due to the true renal lesions. The patient can be further treated and monitored. Azotemia is not a death sentence. Many dogs and especially cats can be maintained with a low degree of azotemia and inability to concentrate urine for months or years with periodic treatments and monitoring the progression or improvement of their renal disease.

increase accordingly as well as the Ca × P product. At stage 1 (mild renal disease), hyperphosphatemia is observed in approximately 20% of dogs and the magnitude is mild, e.g., 6–8 mg/dL. Hyperphosphatemia progresses to 100% of dogs in stage 4 (severe end stage) and increases are severe, 17–25 mg/dL. Similarly, parathyroid hormone (PTH) increases over time. About 33% of dogs will have increased values at stage 1 and 100% at stage 4.

Phosphorus

Approximately 80% of phosphorus entering the glomerular filtrate is reabsorbed in the proximal tubules and 20% is excreted. The most common cause of hyperphosphatemia in veterinary medicine is decreased GFR. Pre-, renal, and postrenal causes, acute, and CKD all do this. In dogs with CKD increases in serum phosphorus (P) are roughly parallel to increases in UN. In a ruptured urinary bladder, phosphorus increases in the serum because it is reabsorbed along its concentration gradient from a high concentration in the urine/abdominal fluid across the peritoneum and into the blood. Serum phosphorus may increase before azotemia in some patients with ethylene glycol toxicity if the antifreeze product ingested also contains a phosphate rust inhibitor.

Case Example 24.10. What is your diagnosis? Acute vs. chronic kidney disease

Patient	A	B	C
History	Fine yesterday	Week's weight loss	Week's weight loss
Body condition	Good	Poor	Poor, dehydrated 5%
Serum UN (10–30)	200	221	120
Serum Ct (<1.5)	10	11	5
Serum UN:Ct ratio	20 : 1	20 : 1	22 : 1
PCV (30–50)	42	19	32
Albumin (2.8–4.0)	3.0	2.2	2.8
USG	1.012	1.009	1.006
Urine volume	Small amount	Increased	Increased

(reference intervals are provided in parentheses; serum UN, Ct mg/dL, PCV %, albumin g/dL)

Interpretation:

A. Azotemia, isosthenuric urine, history, and all other data point to acute tubular disease; therefore, suspect toxic or infectious nephrosis.

B. Azotemia, isosthenuric urine, history, and all other data point to chronic renal disease/failure.

C. Azotemia, lack of concentrated urine, history, urine volume, and body condition all point to chronic renal disease/failure but PCV and albumin do not support this interpretation; suspect concurrent dehydration detected on physical exam has raised these analytes into reference interval and after fluid therapy both will be decreased; seems likely given they are at low end of reference interval and dehydration is 5%.

Hyperphosphatemia greater than 10 mg/dL is common; it can be as severe as >15 mg/dL. At these concentrations, phosphorus may amplify renal failure via mineralization of tubular cells and cellular organelles, direct nephrotoxicity, and vasoconstriction. When the serum Ca × P product is >70, soft-tissue mineralization is possible, and if it is >100, soft-tissue mineralization is occurring. Soft-tissue mineralization is enhanced in renal failure due to underlying vasculitis that damages tissues. Phosphorus is more important in mineralization than is Ca; therefore, mineralization of soft tissues will be occurring even if there is hypocalcemia as long as there is hyperphosphatemia. For example, a patient with a serum total Ca of 7.8 mg/dL and serum P of 16 mg/dL has a Ca × P product of 125. Soft-tissue mineralization is occurring even though there is hypocalcemia. Mineralization occurs outside the kidneys as well and predisposed sites are blood vessels throughout the body, mid-zonal gastric mucosa, lungs, and heart. On rare occasions, the mineralization in blood vessels is severe enough to be seen in radiographs. This metastatic calcification is very harmful and contributes to mortality in animals with renal failure. Treatment of renal failure includes dietary changes and medicinal products to bind phosphorus and decrease GI absorption in an attempt to lower serum phosphorus.

A normal serum P concentration in an azotemic patient is unusual and should prompt consideration that there is another disease lowering the serum P such as primary hyperparathyroidism or, more likely, hypercalcemia of malignancy.

Hypophosphatemia occurs in some horses with renal failure but does not occur in small animals unless it is caused by treatment. It is estimated that approximately 66% of horses in renal failure will be hypercalcemic and 50% will have hypophosphatemia. The mechanism is not clear. It is relatively easy to hypothesize on the hypercalcemia, but hypophosphatemia is problematic; there may be increased P excretion in the intestines. Some horses may adapt to the high calcium diet in alfalfa by excreting calcium and reabsorbing phosphorus in their kidneys. These horses may then retain calcium and excrete phosphorus during renal failure. This is the opposite of normal renal physiology. Hypercalcemia and hypophosphatemia in a horse is most likely due to renal failure, but in a dog hypercalcemia of malignancy is the most likely diagnosis.

PTH inhibits P reabsorption in the proximal tubules and therefore promotes phosphaturia. Increased concentrations of PTH help prevent hyperphosphatemia in renal failure for some time, but when the GFR is decreased below 20% of normal, this compensatory adaptation is overwhelmed and hyperphosphatemia develops. Hyperphosphatemia and hypocalcemia are the major stimulatory factors for renal secondary hyperparathyroidism.

Calcium

Normocalcemia is seen most frequently in animals with renal failure (50–75%); hypocalcemia is relatively common (up to 40%). Hypercalcemia is sometimes seen and is dependent upon species, stage of compensation of the renal failure, and methodology for calcium measurement.

Hypocalcemia can be explained via six mechanisms: decreased tubular cells to reabsorb the Ca, decreased concentrations of vitamin D, decreased albumin, soft-tissue mineralization, reciprocal decrease in serum due to increased P, and if renal failure is due to ethylene glycol toxicity, the chelating effect of oxalate on calcium. The hypocalcemia seen with AKI caused by ethylene glycol can be severe, <6 mg/dL. Hypocalcemia is more common with chronic than AKI and usually is mild to moderate, 7–8 mg/dL, and

asymptomatic. The rate-limiting step in the synthesis of vitamin D is in the kidney, hence CKD is associated with decreased production of vitamin D. Prolonged hypocalcemia stimulates parathyroid hyperplasia, which may lead to metabolic bone demineralization disease, osteopenia, or renal fibrous osteodystrophy, or "rubber jaw." Although the bone lesions are generalized, they are best seen radiographically in the mandible and maxillae.

The changes seen in total serum calcium are usually the same for ionized calcium, but some cases of renal failure in dogs may have decreased ionized calcium while total serum calcium is normal or increased. Rarely are there clinical signs in these patients referable to this change in calcium. If measurement of ionized calcium is available, it is the best fraction to measure to predict biologic action of calcium. If fluid therapy corrects the metabolic acidosis rapidly, then these patients may develop tremors, tetany, and neuromuscular signs that could be due to the shift of calcium from ionized (acidosis) to protein or complexed compartments (alkalosis). Use of calcium products to correct this possible effect is probably contraindicated as the administered calcium would combine with the existing hyperphosphatemia to speed soft-tissue mineralization. Hypocalcemia is expected in cows with renal failure due to the mechanisms listed above as well as the tendency for cattle to develop alkalosis with renal failure and the observations that many sick cattle with a variety of diseases will have mild hypocalcemia.

Hypercalcemia is seen in cases of canine and feline renal failure (10–20%) and equine renal failure (66%). The mechanism is not clear. It is hypothesized that there is an acquired defect in the calcium-sensing protein receptor. This protein is critical for the parathyroid gland to recognize the concentration of calcium and adjust synthesis and secretion of PTH appropriately to normalize serum calcium. If the molecule is abnormal, as in congenital and acquired disorders in humans, the parathyroid cells do not decrease their secretion of PTH. Continued secretion of PTH stimulates calcium reabsorption in the proximal convoluted tubules and osteoclastic osteolysis, further contributing to the hypercalcemia. Hypercalcemia with canine renal failure is seen most frequently in young dogs with progressive familial renal nephropathy. It is seen with other types of renal failure as well. Dogs and cats with renal failure–associated hypercalcemia will have hyperphosphatemia, and the threat of soft-tissue mineralization is high.

Renal failure is the second to third most common cause of hypercalcemia in dogs regardless of whether total serum calcium or ionized calcium is used to assess the calcium status. Several studies have highlighted that total serum calcium does not correlate with the ionized calcium in up to one-third of the cases of CKD in dogs. Approximately 4–10% of dogs with renal failure will have increased ionized calcium, and 5–15% will have increased total serum calcium.

Total serum calcium also may not reflect the ionized calcium in cats with CKD. Ionized calcium increased in 6% vs. 20% via total calcium and ionized calcium decreased in 25% vs. 8% with total calcium. The measurement of ionized calcium is preferred to accurately assess calcium biologic status. However, it is recommended to use the total serum calcium for calculating the Ca × P product.

Hypercalcemia is associated with dilute urine and PU/PD. There are multiple mechanisms for this including interference with the action of ADH, decreasing the movement of AQP2 to the apical membrane and effectively preventing water reabsorption, blocking receptors on renal epithelial cells, and mineralization of cells. Biochemical steps may be reversed, but structural lesions induced by mineralization may not. Basement membranes and cellular organelles will become mineralized and lead to death of cells, further contributing to both concentrating defects and renal azotemia.

Hypercalcemia, steroids (hyperadrenocorticism), and pyometra (*Escherichia coli* endotoxin) are examples of diseases or substances that interfere with the action of ADH and frequently result in dilute urine and PU/PD. If these patients are also azotemic, it can be difficult to differentiate prerenal from renal azotemia. This is because they will have dilute urine due to the inhibitory substance, but the azotemia may actually be due to concurrent dehydration and the kidneys are fine.

Calcium-oxalate urolithiasis or crystalluria are clues to look for hypercalcemia in small animals. Usually they are dihydrate oxalate crystals, but both dihydrate and monohydrate forms have been seen in dogs and cats with hypercalcemia, e.g., primary hyperparathyroidism and idiopathic hypercalcemia of cats. Hyperparathyroidism is often asymptomatic, and it is the presence of hypercalcemia found on a routine chemistry panel or calcium crystalluria that is the first clue that this disease is present. Calcium-oxalate monohydrate and dihydrate crystals can also be normal findings. They are also highly associated with ethylene glycol toxicity in dogs and cats, therefore their presence must be correlated with all of the clinical and lab data. Calcium-oxalate monohydrate and dihydrate crystals are seen in normal horses, rabbits, and guinea pigs. Horses and rabbits have cloudy urine and excessive mucus in their urine and have reference interval serum calcium values greater than other species, up to 13 mg/dL depending on the lab and methodology.

Calcium in complicated renal failure cases

Deciding if renal failure is the cause or the result of the hypercalcemia is problematic. The easiest way to decide is to look at all of the data and see if a primary diagnosis is evident. For example, if CKD can be established based on laboratory data, breed disposition, biopsy, etc., then that is the most likely cause of hypercalcemia. However, if a dog has lymphoma,

azotemia, and hypercalcemia then hypercalcemia is probably due to lymphoma. The marked hypercalcemia can cause renal impairment. In lymphoma, hypercalcemia is a paraneoplastic syndrome associated with parathyroid hormone related protein (PTH-rp) that stimulates urinary phosphorus excretion and calcium reabsorption. The ionized calcium may be markedly increased. The azotemia is secondary to possible dehydration, soft-tissue mineralization, and/or lymphoma in the kidneys. The serum P in these dogs will not be markedly increased despite azotemia due to the phosphaturic effect of PTH-rp. Inability to concentrate urine can be due to hypercalcemia or renal failure so USG is not a distinguishing feature.

If a primary diagnosis is not evident, then the greater the serum Ca the more likely there is a primary calcium disease, and the greater the serum P the more likely it is primary renal failure. The lower the serum P, the more likely there is a primary disease causing the hypercalcemia such as primary hyperparathyroidism or hypercalcemia of malignancy, both of which stimulate phosphaturia and a decrease in serum phosphorus. However, only 5% of dogs with primary hyperparathyroidism have azotemia so it is much more likely they have hypercalcemia of malignancy as azotemia is fairly common in these dogs. If serum phosphorus is WRI in an azotemic patient with hypercalcemia, then there is a primary calcium disease and a hormone that is stimulating phosphaturia. If the total serum calcium is increased but the ionized calcium is normal or decreased, then renal failure is the more likely cause of the hypercalcemia.

Sodium and chloride

Essentially 100% of sodium in the glomerular filtrate is reabsorbed: 65% in proximal convoluted tubules, 25% in the ascending loop of Henle, 5% in each distal tubule and collecting ducts. Most cases of renal failure have normal concentrations of serum sodium and chloride; however, CKD is associated with hyponatremia and hypochloremia, especially in horses and cattle. Hyponatremia and hypochloremia can be seen in dogs and cats with CKD. If the fractional excretion of sodium exceeds 1%, it indicates renal tubular failure. Additionally, hyponatremia and hypochloremia are characteristic electrolyte abnormalities of uroabdomen in all species.

Potassium and magnesium

Most potassium entering the filtrate is reabsorbed in the proximal tubules, and potassium is excreted in collecting tubules via aldosterone stimulation of cellular channels. Potassium increases in the serum with postrenal azotemia and in some cases of AKI, especially if oliguria/anuria are present because of inability to excrete potassium. This is often exacerbated by a concurrent inorganic acidosis that shifts intracellular potassium to the extracellular space, in an exchange for hydrogen ions to maintain intracellular electroneutrality. Potassium may increase to life-threatening concentrations (>8 mEq/L) in obstructed male cats.

Potassium decreases with CKD especially if polyuria is present (increased tubular flow). It may also decrease during the diuretic phase of AKI if dietary intake does not match renal loss. Cattle with renal failure have hypokalemia from renal loss, salivary loss, anorexia, and metabolic alkalosis. Alkalosis shifts potassium into cells in exchange for a hydrogen ion to buffer excess serum bicarbonate. Alkalosis is due to ileus and forestomach atony secondary to uremia.

Historically, approximately 30% of cats with CKD developed hypokalemia with an increased fractional excretion of potassium. When severe, the hypokalemia caused myopathy, generalized muscle weakness, and cervical ventroflexion. The mechanisms are not clear and likely multifactorial. Treatment of this syndrome has been somewhat addressed with current feline renal foods that are supplemented with potassium. Hypokalemia may also contribute to renal failure by causing degeneration of tubular cells, and it also interferes with ability to concentrate urine by decreasing the responsiveness of tubular epithelial cells to ADH. The condition is known as feline kaliopenic polymyopathy-nephropathy syndrome.

Magnesium entering the glomerular filtrate is reabsorbed via active and passive routes in the proximal tubule and in the thick ascending loop of Henle. The primary route of magnesium excretion is via the kidney and therefore serum magnesium concentrations increase with renal failure in most species, although it is seldom measured. Horses with blister beetle intoxication tend to have severe hypocalcemia and hypomagnesemia. These horses have hemorrhages in numerous tissues including the urinary bladder that result in hematuria.

Blood gas

Metabolic acidosis is expected with renal failure in all species. It is dependent upon the severity of the renal failure, the presence of concurrent diseases, and compensatory mechanisms. Compensated renal failure patients have normal blood gas values and uncompensated renal failure patients may have severe acidosis. Acidosis is usually associated with hyperkalemia. In renal failure, hydrogen ion excretion is decreased in the tubules, leading to acidemia. Hydrogen ions will shift into cells in exchange for potassium ions, a mechanism used to maintain intracellular electroneutrality. This will increase the serum potassium. Total CO_2 concentration <15 mEq/L and an increased anion gap indicated a titrational metabolic acidosis due to retention of uremic acids; these patients will have acidic urine as well.

Vomiting uremic dogs and cats will develop a hypochloremic metabolic alkalosis. This results from the loss of hydrogen and chloride ions in the vomitus, and the retention of their counterparts, bicarbonate and sodium ions, respectively, within the body. This is often a subtle finding

in the chemistry panel identified by a disproportionate hypochloremia (with respect to hyponatremia), as the alkalosis is frequently masked by the acidosis developed from renal failure. Some cattle develop metabolic alkalosis due to ileus and forestomach atony secondary to uremia. The result is sequestration of acid-rich secretions in the abomasum and rumen. These cows will also have hypochloremia, hyponatremia, hypokalemia, and an increased anion gap due to retained uremic acids.

If patients with hypochloremic metabolic alkalosis are also severely dehydrated, they may develop paradoxical aciduria. Paradoxical aciduria is an uncommon event that happens most commonly in dairy cattle with displaced abomasum, especially right-sided. These cows have severe metabolic alkalosis and severe hypochloremia due to trapping of chloride-rich fluid in the displaced abomasum. They are also dehydrated, hypokalemic, and hyponatremic, and this combination leads to paradoxical aciduria. Dehydration drives the process through activation of the renin-angiotensin-aldosterone system. Aldosterone stimulates sodium and water resorption in the renal tubules. In health, the kidney resorbs chloride with the sodium to maintain electroneutrality. However, in the face of hypochloremia, the kidney uses a back-up plan of excreting a cation. As potassium is depleted, the kidney excretes hydrogen ions, leading to the acidification of urine. The excretion of hydrogen ions potentiates tubular formation of bicarbonate, which is reabsorbed. The reabsorption of bicarbonate ion further exacerbates the alkalosis, and the hydrogen ion excretion results in acidic urine. Until the displaced abomasum is replaced and the severe hypochloremia is corrected, the paradoxical aciduria with metabolic alkalosis will persist.

Protein abnormalities

Albumin

An increased concentration of serum albumin is seen only with dehydration. There is no specific correlation of hyperalbuminemia with renal diseases, but dehydration is often present in patients with renal failure. These patients will have multiple mechanisms characterizing their azotemia including both prerenal and renal etiologies. The distinction of prerenal and renal azotemia is made by measuring the USG while assessing skin turgidity, PCV, and serum albumin to assess hydration. Decreased serum albumin is seen with glomerular diseases and end-stage renal disease. It may also be seen with diseases in the gastrointestinal, liver, and cardiovascular systems. Hypoalbuminemia due to glomerular disease is discussed in detail in the "Glomerular Proteinuria" section later in this chapter.

Antithrombin

Antithrombin (AT) (also known as antithrombin III) is a small alpha globulin synthesized in the liver and lost in the urine of patients with glomerular diseases. AT has a molecular weight just lower than albumin; hence both proteins are lost in the filtrate of patients with glomerular diseases. Antithrombin is the most potent inhibitor of the coagulation cascade. When AT is decreased, a prothrombotic state exists. The most common location of thrombi is in the pulmonary artery, but thrombi are also located in the aortic quadrification and in many other vessels if they are examined. The hypoalbuminemia also stimulates platelet hypersensitivity that further contributes to the formation of thrombi. In contrast, many cases of severe renal failure tend to bleed due to several mechanisms: concurrent disseminated intravascular coagulation (DIC), as uremia alters platelet function leading to prolonged bleeding times, and increased clotting associated with uremia-induced vasculitis.

Fibrinogen

Small animals tend to have increased fibrinogen associated with chronic renal disease. Cattle in renal failure tend to have marked increases in fibrinogen, 1000–2000 mg/dL.

Other abnormalities

Generally, as the renal disease progresses from stage 1 to stage 4 (mild to severe), the laboratory abnormalities worsen in their magnitude and/or the percentage of patients with each abnormality increases.

Packed cell volume; erythroid

CKD is characterized by nonregenerative anemia in all species. Horses will have an anemia due to CKD, but distinction of regenerative versus nonregenerative is not practical in horses. Decreased production of erythropoietin in the kidneys is the main cause; however, other factors that contribute to anemia are decreased life span of erythrocytes, blood loss due to tendency of uremic patients to bleed, anemia of chronic inflammatory disease, bone marrow suppression, hyperphosphatemia, and increased serum PTH concentration. The anemia of CKD is usually mild to moderate; a PCV in high teens to twenties is typical. If the anemia is severe, such as low teens or single digits, then search for an additional cause and/or gastrointestinal bleeding.

Rarely a renal tumor produces erythropoietin and increases the PCV. Any tumor in the kidney can produce this paraneoplastic syndrome. The result is an absolute polycythemia, and it has been reported with non-neoplastic renal masses as well.

Cholesterol

Increased cholesterol is seen with the nephrotic syndrome. The mechanism is not known, but there are numerous publications that make the association and attempt to explain hypercholesterolemia: increased hepatic production of lipoproteins, defective lipolysis of lipoproteins, and decreased conversion of cholesterol into bile acids are some of the hypotheses.

Parathyroid hormone

CKD patients will have parathyroid hyperplasia and hypertrophy secondary to hypocalcemia and hyperphosphatemia. This may result in clinically detectable fibrous osteodystrophy and osteopenia due to increased bone resorption triggered by increased serum concentrations of PTH. PTH will be increased due to decreased renal clearance and concurrent production and release in the hyperplastic parathyroid glands. These mechanisms result in increased PTH no matter what assay is used. As renal failure progresses from stage 1 to stage 4, PTH concentrations increase (along with increases in serum UN, creatinine, and phosphorus). About 33% of dogs will have increased serum PTH at stage 1 and 100% at stage 4. There is ample evidence that increased serum PTH concentrations are one of the uremic toxins that contribute to the vasculitis and suppress bone marrow function.

Vitamin D

Vitamin D concentrations will eventually decrease in patients with renal failure as the rate-limiting step in the synthesis of vitamin D is in the kidneys. The decreased serum concentration of vitamin D contributes to hypocalcemia and hyperparathyroidism. It is not necessary to measure serum vitamin D concentration in patients with renal failure, but knowledge of the possible consequences of reduced vitamin D may be useful.

Lipase and amylase in serum

These enzymes are inactivated or excreted through the urinary system, and any cause of azotemia (decreased GFR) may result in increased serum concentrations of one or both. The magnitude of increase is usually one to threefold. If the increase in lipase is greater than threefold, then a purely renal contribution is unlikely and pancreatitis should be considered. An increase of fivefold or greater is usually indicative of pancreatitis. Prerenal azotemia can produce as great an increase in lipase or amylase as renal azotemia. Expect amylase or lipase or both to increase in 70% of patients with spontaneous renal failure. Approximately 33% of azotemic patients will have an increase in both; 33% will have increased lipase only and 33% increased amylase only.

Urinalysis

No other body system has an excretory product that is produced regularly, is easy to obtain, and that informs us so vividly on the health of the parent organ. A UA is an essential component of the evaluation of the urinary system. Urinalyses have an excellent benefit-cost ratio as a screening test in all species. It is an absolute requirement for the diagnosis or to rule out urinary diseases. It is excellent as a follow-up test to determine the progression or improvement of urinary diseases. It is very useful in the diagnosis of some nonurinary diseases. It should be part of all geriatric exams, is performed in-practice, and costs almost nothing. Some of the nonurinary diseases a UA helps diagnose are hyperadrenocorticism (Cushing's disease), diabetes mellitus, hepatic diseases, hemolytic diseases, rhabdomyolysis, psychogenic polydipsia, and central diabetes insipidus. It is essential in distinguishing prerenal from renal azotemia.

Early detection of disease

In renal disease, changes in the urinalysis frequently precede changes in the serum biochemistry profile. For example, in glomerular disease proteinuria is the first abnormality and precedes hypoalbuminemia, nephrotic syndrome, and azotemia. Persistent proteinuria found in a symptomatic or asymptomatic patient should prompt evaluation for glomerulonephritis, amyloidosis, and multiple myeloma. Renal disease, especially in geriatric patients, is typified by the inability to concentrate urine adequately, often before there is azotemia (exception: some cats). Hematuria is a common clinical pathology abnormality and is detected with uroliths, transitional cell carcinoma (TCC), and several other diseases.

Monitoring of renal patients

Urinalysis and especially USG are excellent inexpensive tests for following patients post-treatment to assess the progression or improvement of disease, especially if the patient is no longer azotemic. Persistent inability to concentrate urine in a previously azotemic patient suggests that the disease is still present or that over 66% of the nephrons are still not functioning adequately. It is likely that the disease process has destroyed nephrons and fibrosis has replaced much of the renal mass. Return of concentrating ability indicates that the disease has improved and at least less than 66% of the nephrons are still damaged. The presence of waxy casts in the urine sediment suggests persistence and chronicity of the disease.

Gross, microscopic, and chemical determinations are the key components of a UA. Table 24.5 summarizes expected results in normal animals. Table 24.6 provides guidelines for urinalysis findings to predict renal site of pathology that may be present. Urine composition is determined by the serum constituents and the quantity of serum presented to the kidneys, renal function, and material added to the glomerular filtrate as it passes through the kidneys, bladder, urethra, and lower urinary tract. Urine examination should be done in-practice; there is no reason to send it out. Urinalyses should be performed on fresh urine (< $^1/_2$-hour old), and if the macroscopic and reagent strip evaluations have no abnormalities, then performing the microscopic examination is optional because the sediment is rarely abnormal if the macroscopic exam and reagent strips are normal. This is especially true if the UA is being used to screen an apparently healthy patient.

Table 24.5 "Normal"/expected findings in UA.

Urinalysis parameter	Dog	Cat	Horse	Cow
Color	Yellow	Yellow	Yellow	Yellow
Clarity	Clear	Clear	Cloudy	Clear
SG	1.020–1.045	1.020–1.050	1.020–1.045	1.020–1.045

[a]Small to trace amount with cystocentesis or catheterization collections.

Summary

- Excellent benefit-cost ratio, low costs.
- Essential to distinguish prerenal from renal-origin azotemia.
- Detects diseases in early stages.
- Detects nonrenal diseases.
- Useful for monitoring patients.
- If the macroscopic and reagent strips have no abnormalities, then performing the microscopic examination is optional; UA should be performed in-house.

Collection

- *Voided, free catch* – morning sample preferred when urine is usually at maximal concentration; may add contamination of cells and bacteria from lower urogenital tract. Lower urethra has resident bacterial population, but upper urethra and bladder are sterile. Bacteria and leukocytes are common in the prepuce. Epithelial cells are added from genital tract and distal urethra.
- *Catheterization* – may induce a small amount of hemorrhage and introduces epithelial cells from urethra.
- *Cystocentesis* – preferred for culture, commonly introduces small amount of hemorrhage especially in cats.

Urinalyses are often not performed in large animals simply due to difficulty in collecting a sample. Horses often require catheterization, but placing a horse in a stall and whistling is a commonly used technique for racehorses. Gentle rubbing below the ventral commissure of the vulva causes micturition in dairy cattle. Manually occluding the nares will cause sheep to urinate.

Timing

Perform on fresh urine, ideally less than ½ hour after collection, otherwise refrigerate (do not freeze) in an opaque airtight container to avoid deterioration of cellular components and metabolism or escape of analytes. If left at room temperature, cells and casts will lyse; glucose is metabolized; ketones and bilirubin decrease; pH increases as urea is converted into ammonia; CO_2 escapes; bacteria proliferate. Refrigeration can encourage crystal formation, so samples must be rewarmed for 20 minutes on the benchtop and mixed gently to resuspend any settled particles. Rewarm refrigerated urine to room temperature before performing a urinalysis – cold temperatures will lower USG and may influence dipstick results.

Expected volume in healthy dogs and cats

Dogs = 20–40 mL/kg/d; Cats = 10–20 mL/kg/d

Physical examination of urine

Color and clarity

Normal urine is yellow and clear, concentrated urine is deep amber, and dilute urine is clear to pale yellow. Red, brown, and various shades in between are seen commonly with hematuria, hemoglobinuria, and myoglobinuria. Uncommon differential diagnoses for red or brown urine include porphyria and administration of phenothiazine anthelmintics or aminopyrine (uncommon, given as urinary analgesic). See Table 24.7 for the differentiation of hematuria, hemoglobinuria, and myoglobinuria, and the specific diseases that cause them. Horse and rabbit urine may be cloudy in normal animals due to normal urinary

Table 24.6 Renal azotemia and predicting location of lesion.[a]

	Glomerular	Tubular (interstitial)	Tubular (interstitial)	Pelvis

[a]This is assuming the diseases are behaving in a characteristic manner. Glomerular diseases usually present when chronic; tubular diseases are commonly acute, but if they survive they can end up as chronic PU/PD patients. Pyelonephritis is in an active phase when the infection is present. All of these diseases will change over time and depending on severity (mild, moderate, severe) and treatments. All of these diseases may have acute kidney injury superimposed on a chronic disease, e.g., patient becomes dehydrated, a second renal disease develops, the primary chronic problem progresses, and the patient goes into what appears to be acute kidney injury.

tract mucus production and numerous calcium carbonate crystals. Guinea pigs may also have abundant calcium carbonate crystalluria. Cloudiness is caused by suspended solids (crystals, mucus, casts, cells, etc.) that do not change the specific gravity (SG) but may interfere with reading of the refractometric SG line. Cloudy urine in species other than those listed here is abnormal and should be assessed microscopically for the presence of cells, bacteria, casts, crystals, sperm, powder, contaminants, etc. If urine is so turbid that it is difficult to see the calibrations in an optical refractometer, then use the supernatant from a centrifuged sample to determine USG.

Hematuria, hemoglobinuria, myoglobinuria – red, red-brown urine

The main differential diagnoses for urine discolored red to red-brown are hematuria, hemoglobinuria, and myoglobinuria. Uncommon causes are aminopyrine (urinary

Table 24.7 Differentiating hematuria, hemoglobinuria, and myoglobinuria.

	Hematuria	Hemoglobinuria	Myoglobinuria

RI, reference interval.

analgesic), porphyria, and phenothiazine anthelmintics. When all of the data are considered, distinguishing the common causes of red urine is straightforward (Table 24.7). One of the easiest procedures is to simply look at the urine before and after centrifugation. If the color is cleared or greatly reduced by centrifugation, then the diagnosis is hematuria; if the color persists after centrifugation, then hemoglobinuria or myoglobinuria is present. If the color remains postcentrifugation, look at all of the data to distinguish these two differentials and if it is still not obvious, then ask a lab to perform an ammonium sulfate precipitation test on the supernatant. This will precipitate hemoglobin such that after centrifugation a red pellet forms and all or the majority of the supernatant is cleared and is now yellow or semiclear to light pink. An 80% saturated solution of ammonium sulfate will not precipitate myoglobin and the supernatant remains red-brown. If there is still doubt there are additional tests that can be requested: electrophoresis, spectroscopic, immunoprecipitation, and ultrafiltration. Hematuria, hemoglobinuria, and myoglobinuria will all produce positive reactions to blood and protein on urine strips.

Hematuria will have numerous RBCs in the urine (too numerous to count [TNTC]) and will likely have numerous white blood cells (WBCs) due to inflammation triggered by the cause of the hematuria: infection, cystitis, urolithiasis, trauma, neoplasia, etc. Depending on the amount of hemorrhage, the PCV will be normal or decreased; a normal or reference interval PCV is most likely. If the urine has a pink hue postcentrifugation, it is due to hemolysis *in vitro*, which can be due to alkaline urine, USG <1.008, prolonged storage, and/or rough handling.

Hemoglobinuria is due to intravascular hemolysis (not extravascular) of such magnitude that the buffering mechanisms are overloaded and free hemoglobin spills into the glomerular filtrate. Plasma during the hemolytic event will be pink to red, the mean corpuscular hemoglobin concentration (MCHC) will be increased (artifact of free hemoglobin), and gradually the plasma and the patient will become icteric. Heinz bodies should be searched for in all species with this problem. The PCV is decreased to variable degrees depending on the severity of the hemolysis. Etiologies to consider are those that cause intravascular hemolysis: most cases of immune-mediated hemolytic anemia (IHA) are actually extravascular, but intravascular hemolysis can occur; parasites that are in the RBCs (*Babesia*) as opposed to on the surface (*Mycoplasma*); metals such as zinc or copper; water intoxication in cattle (osmotic lysis); *Clostridium hemolyticum*; postparturient hemoglobinuria in cattle; Heinz body anemias; and acetaminophen, onions, garlic, baby food, and red maple toxicity in horses.

Myoglobinuria is rarely seen in dogs (racing, crush injuries), cats (aortic thrombus, crush injury), or cattle. It is relatively common in horses and captured wild animals.

Of the many types of equine myopathies, the most common form associated with myoglobinuria is exertional rhabdomyolysis, which has various common names: azoturia, Monday morning disease, tying up syndrome, and capture myopathy. In these situations, there is massive muscle necrosis and release of myoglobin. Myoglobin is of a small molecular weight compared to hemoglobin (18,000 vs. 68,000 Da) such that it readily passes into the glomerular filtrate, discoloring the urine. The plasma may remain clear. In horses the plasma and the patient may turn icteric due to concurrent anorexia. The PCV will be in reference interval or increased due to concurrent dehydration and/or splenic contraction secondary to pain. Muscle enzymes will be markedly increased. The serum CPK can be as high as 1,000,000 IU/mL in horses with this disease. An increased CPK means the muscle necrosis is still active. CPK increases first; it is cleared rapidly once the muscle necrosis stops and is followed by increases in AST within hours to days of the onset of the disease. This disease can be lethal and requires immediate treatment. It is typically seen in horses that are over-exercised following periods of rest and full feed ("couch potatoes"), large-breed horses undergoing prolonged anesthetic procedures (pressure necrosis and ischemia of muscles), and wild animals that are chased for prolonged periods, equidae, ruminants, etc. It is rarely seen in domestic ruminants even with severe vitamin E Se responsive disease but can be seen in young ruminants chased excessively, similar to capture myopathy of exotics.

Hematuria is not associated with azotemia unless the cause of the hematuria is obstruction of urine outflow. Azotemia is expected with myoglobinuria and often occurs with severe cases of hemoglobinuria. Neither hemoglobin nor myoglobin is the nephrotoxin; apparently small molecular weight substances released concurrently are the toxic substances. Regardless, azotemia is possible and intravenous fluid therapy to help prevent "hemoglobinuric and myoglobinuric nephrosis" is warranted. Interestingly, some cases of severe myoglobinuria do not develop azotemia even when the muscle enzymes are markedly increased (>500,000 IU/mL) and the urine is brown-black. These cases have a better prognosis, and the absence of azotemia may be due to the absence of the nephrotoxic substance in the muscles of these horses. Casts are anticipated with hemoglobinuria and myoglobinuria and should not be present with hematuria. The casts may be of any type due to concurrent nephrosis or they may be characteristic for the diseases: myoglobin or hemoglobin casts.

Urine concentration and urine specific gravity

Correlate the urine specific gravity with serum UN and Ct, as well as all of the other case data. Measuring USG is a simple and effective test to assess renal function. Generalizations: azotemia and concentrated urine = prerenal cause; azotemia and unconcentrated urine = renal tubular disease/involvement.

See "Urine Concentration" and Tables 24.7 and 24.8 for the range of possible values.

Urine concentration

Kidneys reabsorb more than 99% of the water that enters the tubules. Water is reabsorbed in the proximal tubules passively, in the descending loop of Henle passively due to the osmotic pull of the saturated medullary interstitium (countercurrent multiplier system), passively in the distal tubules, and actively in the collecting ducts through the actions of ADH. Failure in one or more of these locations may result in polyuria. Interference with of one or more of these mechanisms is used by different diuretics to stimulate water excretion.

The ability to produce concentrated urine is dependent on several factors. At least one-third of the renal mass must be functional, adequate amounts of ADH must be produced, the medullary interstitium must be saturated, the hydration status must be conducive, and there must be an absence of concurrent diseases. Therefore, animals with impaired urine concentration will have one or more of the following: lesions in two-thirds of the renal mass (tubules or interstitium), decreased ADH production (central diabetes insipidus), refractoriness to ADH (nephrogenic diabetes insipidus, hypercalcemia, excess glucocorticoids, pyometra, or hypokalemia), decreased medullary hypertonicity

Table 24.8 USG – expected, maximal, adequate, isosthenuric, and hyposthenuric concentration ranges.

	Dog	Cat[a]	Horse	Cow
Expected	1.020–1.045	1.020–1.050	1.020–1.045	1.020–1.045

Hyposthenuria	<1.007	<1.007	<1.007	<1.007
With 5% dehydration	1.040–1.075	1.045–1.088		

[a]Some cats with renal azotemia can concentrate urine.

(medullary washout), over-hydration, or solute overload (diabetes mellitus, diuretic administration).

Kidneys concentrate and dilute the glomerular filtrate as it passes through tubules by removing solutes and water in different segments of the nephron. Glomerular filtrate is plasma minus albumin, and it starts with an SG approximately 1.010 (300 mOsm/kg), and in an animal with normal hydration, it finishes with a concentrated SG.

Urine specific gravity

Measuring osmolality via freezing point depression is the gold standard for evaluating urine concentration. This methodology is generally confined to reference laboratories, as the equipment is either too expensive, or used too infrequently to make it practical for use in private practice. Instead, urine concentration is determined by measuring USG with a refractometer.

Measurement of specific gravity

SG is a ratio of the density of urine to the density of pure water (1.000) at a given temperature [10, 11]. This differs from urine osmolality for, in addition to the number of particles, SG is also affected by the size (molecular mass) of the particles. As a result, the presence of heavy molecules like glucose, proteins, and radiocontrast may cause a disproportionate increase in USG compared with urine osmolality [10]. Nonetheless, there is a linear relationship between USG and urine osmolality [10], which makes clinical decisions based on SG generally acceptable.

Refractometry measures the SG indirectly by using the urine's refractive index to estimate USG. The refractive index is the ratio of the velocity of light in air to the velocity of light in a solution [10] and is proportional to the number and type of particles in solution. Particles not in solution will not alter USG, even when the urine is turbid (cloudy). Substances in solution are dependent on temperature and pressure, therefore SG is determined at constant temperature (room temperature) and pressure (atmospheric).

There are two types of refractometers commonly used, an optical refractometer ("Goldberg-type") and digital refractometers. The scales in refractometers are calibrated to estimate SG and/or proteins. There is a maximum reading, e.g., 1.060. Urine can be diluted to determine the exact reading if clinically required. The scales are different for dogs, cats, and horses (and humans). The differences are minor and, ideally, the scale for one species should not be used for another; however, this is not always practical in the clinical setting. In a recent study, dog and cat urine were measured on five different currently available refractometers and compared to the weight of the dry matter in the urine samples. The findings showed a single sample of urine will have a small range of USG results, and thus refractometers are imprecise tools [11]. This lack of precision reduces the usefulness of strict cutoff values (e.g., 1.008, 1.012, 1.035, etc.) when classifying the concentrating ability of the kidneys [11]. Additionally, the study showed that refractometers designed specifically for cats underestimate the USG [11]. Nonetheless, refractometers are useful in all species to measure USG and estimate concentrating ability. However, their precision is such that strict cutoffs of USG should not be used to classify a disease state. Integrate the hydration status of the patient with several values of USG to determine if the urine is appropriately or inappropriately concentrated.

Refractometers require only a drop of urine, results can predict clinical problems, and it is a low-cost test that should be used in sick patients and annual wellness checks. USG is usually determined from a well-mixed sample of urine that has not been centrifuged. If the urine is too cloudy to see lines in the refractometer, then use the supernatant to determine USG. Usually, the USG values of the uncentrifuged urine and supernatant will be similar; any differences are typically minor and do not interfere with clinical interpretation.

Reagent strip tests estimate the SG indirectly based on pKa that uses a shift in the pH to produce a color change. Maximum concentration detected is 1.030, and this is inadequate to detect the concentration ranges in cats and dogs. Additionally, reagent strips do not correlate well with refractometer results; false positives and negatives are common. For these reasons, reagent strips are considered unreliable.

Interpretation of urine specific gravity

There is a wide range of reference values for USG (1.001–1.070), and depending on the patient's hydration status, any of these values can be considered "normal." The most important task is to determine the pattern of concentrating ability by correlating USG with hydration status, serum UN and Ct, urine volume, and the clinical data. In a healthy, euhydrated animal, there is an "expected range" of USG that varies slightly by species (Table 24.8). Knowing the "expected range" is important when attempting to determine if the kidneys are functioning and concentrating urine appropriately. Concentrated urine indicates good renal tubular function, as it implies removal of more water than solutes. The savvy clinical practitioner will interpret USG with respect to the patient's hydration status. For example, in a dehydrated dog with healthy kidneys, the USG is expected to be hypersthenuric (well-concentrated).

As a generality, only dilute urine is considered "abnormal"; however, dilute urine can be expected in an over-hydrated individual as the kidneys attempt to excrete the excess body water. For instance, dilute urine is expected in psychogenic polydipsia, during fluid therapy, and while patients are receiving diuretics. In contrast, isosthenuria in a dehydrated or azotemic patient is abnormal and suggests the renal lesion involves the tubules.

If a USG is dilute, the measurement should be repeated/confirmed at different times of the day to determine if urine

can be concentrated and if there is a pattern. The first urine excreted in the morning is typically the urine with the highest USG. Additionally, if findings are nebulous or unclear, repeating USG on a fresh sample is an easy and inexpensive option. Persistently dilute urine in a nonazotemic patient is abnormal and could involve renal or nonrenal causes (Table 24.8).

When serial urinalyses reveal urine with an SG of 1.007–1.013, it indicates that the kidney neither concentrated nor diluted the glomerular filtrate. In other words, urine is isosthenuric with respect to blood plasma, which has an SG of approximately 1.007–1.013 and an osmolality of 295–300 mOsmo. This is the least favorable range of urine specific gravities to detect over time as it is strong evidence of renal disease that involves >66% functional loss of both kidneys. Urine specific gravities that are <1.007 or >1.013 imply some renal function. However, cutoffs should be used cautiously as refractometers are not precise measurements [11]. USGs 1.014–1.020 are "gray zone," meaning that USG could be abnormal, and repeating USG may be warranted based on the rest of the data. A USG of 1.014 is so close to the isosthenuric range that several additional USGs should be obtained to help determine if concentrating ability is present. Likewise, a single USG in the range of 1.006–1.008 is not clear evidence of a disease process. Repeating USG at different times of the day to determine the range for that patient usually clarifies these gray-zone cases. Repeated USGs on urine samples supplied by the owner can be done for no or minimal cost. Correlate USG with the other data in cases like this to help determine a course of action.

When dilute urine is attributed to renal disease, it implies that the lesion involves the tubules. Glomerular diseases may be associated with dilute urine because 90% of the vascular supply to tubules passes through glomerular capillaries. Therefore, if the glomerular lesion is severe enough it may eventually compromise tubular function. Interstitial diseases are often associated with dilute urine because tubules and interstitium are anatomically adjacent to each other, and eventually lesions in one area involve the other. These examples illustrate the nephron concept. That is, injury to one part of the nephron may eventually lead to injury of the rest of the nephron. When renal injury is suspected, following a patient's USG over time is a practical, affordable laboratory test to monitor the progression or improvement of renal function. Fractional excretion studies or creatinine clearance studies are other more discerning methods for evaluating renal injury.

Consistently hyposthenuric USG measurements (e.g., <1.007) are probably not due to renal lesions, especially if the animal is not azotemic. Dilute urine indicates that the kidney has enough function to remove more solutes than water, because dilution is an active process. Mechanisms for the production of hyposthenuric urine include excess fluid intake (IV fluids, psychogenic polydipsia), decreased ADH production (diabetes insipidus), tubules refractory to ADH (steroids, calcium, caffeine), decreased medullary hypertonicity, plasma solute overload, combinations of the foregoing, and other unknown mechanisms (Table 24.4).

Additionally, substances in solution influence SG measurements. For example, in cases of marked proteinuria or glucosuria, every 1 g/dL of protein or glucose that is added to urine will increase the USG approximately 0.004, yet these solutes have little effect on the osmolality. The increased USG caused by proteinuria or glucosuria could lead to an overestimation of the USG and, therefore, an overestimation of the concentrating ability of the kidneys. Additionally, adding the following substances to 1 mL of water will increase the SG by 0.001 units: NaCl 1.5 mg; urea 3.6 mg; glucose 2.7 mg; albumin 4.0 mg. Each time the urine glucose increases by 1 g/dL (1+ on the dipstick) the USG increases by 0.004. A 4+ urine glucose would increase USG by approximately 0.010 units. These estimates and the principles are nice to know, but they are not used to calculate or estimate a USG. It is best to simply measure USG and realize the magnitude of change that may occur with organic solutes such as protein and glucose.

An example of a potential clinical problem would be in a dog treated intravenously with an artificial colloid substance such as hetastarch (HES). This artificial volume-expanding solution contains molecules of various sizes, some of which can pass through the glomerulus. In normal dogs 20 mL/kg of HES will increase the USG without a concurrent increase in the urine osmolality. This is because the number of molecules per kg of water determines urine osmolality. In contrast, the USG is dependent upon the density of the urine, and density is dependent upon both the size and number of particles. If USG were increased by HES therapy, it could lead to an overestimation of renal concentrating ability and mask an inadequate renal concentrating ability [12].

Suspended particles, such as hemoglobin, mucus, crystals, and cells, do not affect USG because they are not dissolved; however, they can make the urine cloudy and may make reading the line on the refractometer difficult.

Urine specific gravity in puppies

Approximately 4 weeks of age is when pups are able to concentrate urine comparable to other canine age groups. USG is significantly lower in pups younger than 4 weeks of age as compared to pups 4–24 weeks of age, but there are no differences in protein, blood, glucose, ketones, or bilirubin.

Chemical examination of urine

There are numerous products to help analyze urine, but it is beyond the scope of this writing to list them all and their associated false-negative and false-positive results. This chapter will focus on semiquantitative reagent strips that are

Case Example 24.11. 12-year-old FS Boston terrier cross named "Poppy"

The patient presents for "urinating and drinking a lot." The physical exam is unremarkable. Owners approved CBC, chemistry panel, and complete urinalysis; only abnormality detected was a USG of 1.006. What are the next steps in working up this case?

1. "Urinating a lot" is a common owner concern and may suggest either pollakiuria or polyuria. Owners should be questioned carefully regarding the frequency and quantity of urine produced. Additionally, absence of abnormalities in cellular and sediment examination of urine makes cystitis unlikely (more common in female than male dogs).
2. The USG is at the cutoff between isosthenuria and hyposthenuria. Differentiating between this is important because the differential diagnoses for isosthenuria are quite different from hyposthenuria (Table 24.4). To determine which is more likely, ask the owners to collect a clean sample of urine when the dog first wakes in the morning. Measure USG in that sample and preferably in a sample from another time of the day and determine if Poppy can concentrate urine and if not, is there a pattern. A second complete UA is a good idea, and a urine culture should also be considered. There is no need to repeat CBC or chemistry panel.
3. Consider offering the owners SDMA. The prior results of UN, Ct, and P were WRI, if SDMA is WRI then renal disease is less likely and consider differentials for low USG (Table 24.8). If SDMA is increased then offer full "renal workup" and monitor dog periodically for progression of possible renal disease.

Cushing's is unlikely as alkaline phosphatase (ALP) was WRI (no chemistry abnormalities detected) and there were no PE abnormalities suggestive of hyperadrenocorticism (HAC). Ninety-five percent of HAC dogs will have an increase in ALP. Diabetes mellitus is unlikely because of absence of glucose in urine or hyperglycemia. Hypercalcemia was not detected. Pyometra is ruled out, FS. The results of basic laboratory tests and PE are practical means to distinguish the more common causes of PU/PD.

commonly used in veterinary practice. These provide a semiquantitative analysis of the concentration of most substances of interest in urine. The strips contain pads impregnated with various chemicals that, rather than detecting a specific compound, detect the product of a chemical reaction involving the specific analyte. Formation of the product leads to a color change, and the degree of color change is proportional to the concentration of the analyte (Figure 24.4).

Product expiration dates should be adhered to because outdated strips can give false-negative results. During storage, containers must be kept tightly closed, as the reagent pads are sensitive to air and humidity. Additionally, reagent strips are designed for human urine and some of the reactions are not valid in animal urine. For example, these strips should not be used to determine WBCs, SG, urobilinogen, or nitrite concentration in animals.

After the urine sample is examined grossly for color and clarity, the reagent strip is immersed in a well-mixed sample of urine for the prescribed period (no longer or false increases will occur) and then removed with excess urine being drained while holding the stick laterally on a paper towel. Depending on the solute evaluated, the instructions will state how long after immersion that pad should be graded. Hold the reagent strip horizontally to prevent intermixing of reagents. The next step is to determine if a solute is present – a qualitative assessment. Proceeding by the time indicated on the container with the color grading scheme, the pads are read and graded, usually 1+ to 4+.

Results should be interpreted with USG because the concentration of the urine will affect the quantity of solutes. To illustrate this point, a 2+ protein in urine with an SG of 1.020 would be 1+ protein if that urine sample were diluted to 1.010 (i.e., diluted by half). A dog with a urine protein of 50 mg/dL and a USG of 1.010 is losing as much protein per day as a dog with a urine protein of 100 mg/dL and a USG of 1.020. In dogs, a 1+ proteinuria in urine with an inactive sediment and a USG of 1.060 is less significant than trace or 1+ proteinuria in urine with an SG of 1.008 and an inactive sediment. These reagent strips should be interpreted cautiously, as the various reagents are prone to false-negative and false-positive results (e.g., see "Glucose" below). If results on a strip are equivocal, there are chemical tablets available that are generally more sensitive for each substance on the strip and that can be used to clarify results.

pH

Dogs and cats have urine that is neutral to acidic, and herbivores, neutral to alkaline. The pH reagent pads contain dyes that change color based on the pH: red in acidic, yellow in neutral, and blue-green in alkaline urine. The range detected is approximately 5.0–9.0. Because urine is produced from filtration of blood plasma, urine pH reflects plasma pH. Additionally, it is a crude index of blood gas status. Urine pH may be compared with TCO_2 (bicarbonate) to determine if they correlate, and usually they do. Paradoxical aciduria is a unique situation seen most frequently in dairy cattle with a left or right displaced abomasum (described earlier). Alkaline urine in a dog with acidosis may be an indicator of "renal tubular acidosis," which indicates the inability to acidy urine in the face of metabolic acidosis. Urease splitting bacteria can cause alkalinization of urine, as will prolonged storage at room temperature and the presence of certain disinfectants (contamination of urine collection container).

Normal dog and cat urine has a pH of approximately 5–7. If urine pH is below 5 or above 7.5, the cause should be investigated. Alkaline urine with a pH >8 may result in lysis of RBCs, WBCs, and dissolution of casts. It has been reported

Figure 24.4 Two containers of representative urinalysis reagent strips. Container on left is oriented to show text labeling with storage and use directions and expiration date. Container on right is oriented to show a chart of reagent test pad color reactions. The patient urinalysis test strip must be read within the stated times for each reagent and is then compared to the color chart for recording results. Alternatively, an optical color reflectance reader device is used to determine the urinalysis test strip results.

that a pH >8 will falsely result in a 1+ protein on the reagent pad; however, recent studies suggest that this is no longer the case.

Protein

Proteinuria is a term used to describe the presence of any protein in urine, such as albumin, globulins, and Bence Jones proteins. Proteinuria has preglomerular, glomerular, and postglomerular causes (Table 24.9). However, it is used clinically to recognize renal disease, especially diseases affecting glomeruli. Quantification of renal proteinuria is a practical means to identify renal disease, predict glomerular disease, monitor renal disease, and formulate treatment plans. Colorimetric dipsticks, sulfosalicylic acid (SSA) turbidity testing, or other chemical assays detect excess protein in the urine.

Reagent pads

Most proteins produce a positive color change on the reagent strip pad, and the concentration of protein is assigned a trace to 4+. Chemical methods for protein determination are best at detecting albumin. Reagent pads on strips detect albumin up to 50 times better than globulins but are able to detect other globulins, Bence Jones proteins (if present in sufficient concentration), hemoglobin, and myoglobin relatively well. Bence Jones proteins are associated with multiple myeloma. Reagent strips do not easily recognize Bence Jones protein because light chain immunoglobulins have fewer free amino groups available to react with reagents. In general, approximately 25–50 mg/dL of Bence Jones proteins are required for a trace to 1+ reaction on the reagent pad. If concentrations are insufficient, a false-negative result will ensue.

Sulfosalicylic acid turbidity test

Protein is also determined and scored via SSA turbidity (1+ to 4+). SSA also detects albumin the best but does detect all proteins provided they are present in sufficient concentrations and is considered better than the reagent pad on the dipstick. If urine is cloudy, it should be centrifuged prior to performing the SSA turbidity test, because suspended solids can cause a false-positive result. False-positive results are also possible with certain drugs (penicillin and sulfonamides) and radiology contrast media. False-negative protein results are associated with the inability to read through very turbid

Table 24.9 Differentiating proteinuria.

Preglomerular	Glomerular	Postglomerular
• Physiologic • Fever • Exercise • Seizures • Hypertension • Pigments • Hemoglobinemia/-uria • Myoglobinemia/-uria • Neoplasia (Bence Jones proteins) • Multiple myeloma • Lymphoma	• Glomerulonephritis • Amyloidosis	• Hematuria • Cystitis (e.g., inflammation) • Tubular disease • Fanconi syndrome

Hyperadrenocorticism and exogenous steroids cause proteinuria with and without cystitis. The mechanisms when the urine sediment is inactive are not as clear; however, glucocorticoid therapy given to healthy dogs resulted in a mild increase in UPC (slightly greater than 1) and glomerular lesions. Others have shown that hydrocortisone will increase the blood pressure of dogs and cause proteinuria, both of which are reversible within 1 month of stopping the steroid. Microproteinuria, microalbuminuria: <30 mg/dL, and albuminuria is >30 mg/dL.

urine and in markedly alkaline urine. If Bence Jones proteinuria and/or multiple myeloma are suspected, then consider sending urine to a reference laboratory to request SSA, and possibly urine and serum electrophoresis to determine if immunoglobulin light chains or a monoclonal gammopathy are present.

Spectrophotometry

Protein can be quantified by a spectrophotometer in a spot urine sample or in a 24-hour collection. The latter is not recommended as it is too labor-intensive, and there is good correlation between 24-hour collections and urine protein:Ct ratios from spot urine samples. For further information, see the section on "Protein Abnormalities" in this chapter.

Interpreting a positive protein

A positive protein reaction should always be correlated with USG, presence of blood in the urine, results of the serum biochemical profile, and results of the microscopic examination of urine sediment. Hemorrhage causes a positive pad result due to hemoglobin (a protein) being released from lysed RBCs, as well as any plasma proteins that may be exuded along with RBCs. If blood is positive on the strip and RBCs are seen microscopically, then it complicates interpretation of a proteinuria. If glomerular disease is suspected, the proteinuria will need to be assessed when the hemorrhage has resolved. In general, reagent pads are generally considered poorly reactive with proteins from WBCs and epithelial cells. In dogs, a trace protein reading is ≤0.1 g/dL (10 mg/dL; 0.1 g/L) and a 1+ result indicates the renal loss of 0.03 g/dL (30 mg/dL; 0.3 g/L). Both are considered normal if urine is concentrated but abnormal if urine is dilute and/or if there is a positive blood reaction or urine sediment abnormalities. False-positive dipstick protein results have been associated with excessive urine contact time, specific antibiotics, contamination of sample with disinfectants, and historically with highly alkaline urine.

Preglomerular proteinuria

Preglomerular diseases that result in marked hyperproteinemia may damage the filtration barrier, overload the proximal tubular capacity for reabsorption, and result in persistent proteinuria, referred to as "overload proteinuria." This is most commonly associated with hemoglobinemia, myoglobinemia, and paraproteins of small molecular weight (<45,000 Da) as seen in multiple myeloma, and recognition of one of these three problems is critical to the diagnosis of preglomerular proteinuria. Serum proteins in patients with multiple myeloma may exceed 9 g/dL, and this may induce preglomerular, overload proteinuria that is persistent. If hemoglobinemia is so severe it overwhelms carrying proteins such as haptoglobin, then excess hemoglobin will enter the glomerular filtrate. Myoglobin does not have carrier proteins, and it readily passes into the glomerular filtrate producing dipstick results that are positive for protein and blood. Mild, clinically insignificant preglomerular proteinuria is also associated with excess exercise, seizures, fever, stress, etc., and is referred to as functional proteinuria. This type of proteinuria is transient and is not significant. Historical and physical exam data and UA will identify these causes. One study demonstrated that exercise did not increase the urinary excretion of albumin in dogs.

Glomerular proteinuria

Glomeruli retain proteins larger than approximately 68,000 Da and that are negatively charged, thereby conserving albumin at the level of the glomerulus. In health, the small amounts of albumin that leak through are reabsorbed by tubular epithelium and degraded by cellular lysosomes. Although albuminuria may be due to tubular lesions, the amount of protein in the urine is small and this mechanism never results in hypoalbuminemia. In glomerular disease, glomeruli lose their negative charge because immunoglobulins (positively charged) are deposited in glomerular basement membranes as part of the pathogenesis of glomerulonephritis and amyloidosis. Albumin, with its small molecular size (66,000) and negative charge, leaks through the glomerular membrane. This occurs to such an

extent that a patient will develop hypoalbuminemia, and the correlation of hypoalbuminemia with proteinuria is a cornerstone toward developing a diagnosis of glomerular disease. Furthermore, if glomerulonephritis and amyloidosis are severe enough, nephrotic syndrome may develop. Nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, edema, ascites, thrombi, and hypercholesterolemia. Diagnosis of glomerular proteinuria requires persistent proteinuria with inactive urine sediment (free of RBCs, WBCs, etc.).

The distinction of glomerulonephritis and amyloidosis could have different treatment and prognostic implications, and therefore the differentiation of these two diseases is sometimes desired. The correlation of renal biopsy results with histologic sections taken at necropsy is 98%. This is because the lesions of glomerulonephritis and amyloidosis are diffuse. Essentially 100% of glomeruli have lesions to some degree, so biopsy, even if only one to three small pieces are obtained, will adequately sample the disease process as long as the cortex is sampled. The most common complication is minor hemorrhage, resulting in hematuria; but rarely, the complications are severe and life-threatening. Results of biopsy that indicate severe end-stage renal disease may influence the decision to treat.

The majority of dogs 9 years of age and older will have some form of microscopic glomerulonephritis. The majority of these cases are subclinical. The recognition of these animals with newer screening tests that detect microproteinuria (urine albumin <30 mg/dL, correlating to 1+ on the urine dipstick) may prove beneficial for long-term care. It is reported that 2% of clinically healthy dogs have proteinuria and 20% have microalbuminuria. Proteins that are leaking through diseased glomeruli may cause damage to tubules via cytokines, direct toxicity, and overload of lysosomal degradation mechanisms. Therefore, recognizing persistent proteinuria and preventing its progression may have beneficial effects for the health of the kidney and therefore the animal.

Postglomerular proteinuria

Postglomerular proteinuria is due to inflammation in the urogenital tract and is the most common cause of proteinuria. Postglomerular proteinuria should be considered when the urine sediment reveals evidence of inflammation, such as erythrocytes and/or leukocytes (i.e., "active sediment"). When an active sediment is seen, investigation into the underlying inflammatory cause should be sought. If the cause of the proteinuria is due to postglomerular inflammation, when the underlying cause has been managed, the proteinuria should also resolve. For example, cystitis is a common cause of postglomerular proteinuria. Attention is focused on the diagnosis and treatment of cystitis, not proteinuria. In most cases, the proteinuria is gone once the cystitis and associated inflammation is resolved. If proteinuria persists, then consideration is given to causes of persistent proteinuria. In rare occasions, postglomerular proteinuria may be due to in-tubular resorptive defects as seen in familial or acquired Fanconi syndrome.

Quantifying proteinuria

Once proteinuria has been diagnosed, and causes of prerenal and postrenal proteinuria have been ruled out, the next critical step is to determine if the proteinuria is persistent. A persistent proteinuria should be quantified, as this helps determine the severity of renal lesions and serves as a means of monitoring disease progression or response to treatment. This is most commonly done via urine protein to creatinine ratio (UPC). Determination of UPC is accomplished by collecting urine and serum simultaneously and chemically measuring the protein and creatinine in both samples. The amount of protein in the urine is divided by the amount of creatinine in the urine and a ratio is derived, Prot:Ct. Determining UPC ratios on several samples taken 24 hours or more apart is recommended for even more reliable results because there can be random variation in the amounts of albumin loss in any one sample. However, measuring serial UPC may be cost-prohibitive. In these situations, pooling one mL aliquots taken from three urine samples collected 24–48 hours apart yields results that are clinically useful and more cost-effective. The IRIS has proposed reference values for dogs and cats. A UPC <0.2 is considered normal in both species. In dogs a borderline proteinuria is 0.2–0.5 and is 0.2–0.4 in cats. A UPC of >0.5 in dogs and >0.4 in cats is indicative of glomerular disease or CKD, and UPCs of >2.0 are strongly suggestive of glomerular disease. To determine if the disease is progressing or improving, a change of at least 35% in UPC should be observed in high values, and 80% at low UPC values (near 0.5) is required.

Microproteinuria

Microproteinuria, microalbuminuria is an extension of proteinuria and refers to situations where the amount of protein in the urine is small or below the limit of detectability of most qualitative and some routine quantitative assays. A trace or 1+ protein in concentrated urine is considered insignificant; however, it can imply early or occult renal disease (minimal change nephropathy). The primary protein in the urine of these patients is albumin, and assays are now available to measure microalbuminuria. Microalbuminuria is albumin <30 mg/dL and albuminuria ("overt albuminuria") is urine albumin >30 mg/dL in urine normalized to SG of 1.010. The limit of detectability of dipstick colorimetric pads is approximately 6–10 mg/dL and SSA 5 mg/dL. If these trace amounts are detected in urine with an SG of 1.020, then the concentrations would double if the USG was 1.040. Similarly, trace amounts in urine with an SG of 1.020 would be undetectable with these qualitative methods in urine with an SG of 1.010

or less, yet this may be significant. The detection of microproteinuria may be of value in geriatric patients, patients with suspected occult renal disease, monitoring chronic renal patients, breeds with known familial nephropathies, or sick patients with an unknown diagnosis. Recognizing occult renal disease opens avenues for patient management such as restricted diets and angiotensin-converting enzyme (ACE) inhibitors. It is not known if these treatments can change the progress of the disease or are beneficial to these patients but it may prove helpful, and the first step is to recognize the problem exists. Although its use is implied to recognize occult glomerular or chronic renal disease, any cause of proteinuria, pre-, glomerular, and postglomerular, will be positive with these microalbumin assays. Therefore, these other causes must be ruled out before steps are taken to recognize occult renal disease. There are qualitative (reagent pad) and semiquantitative immunologic test strips (ELISA) available to estimate Prot:Ct ratios, but their clinical utility has not been proven.

The other methodologies, protein electrophoresis and immunoturbidimetric tests, are quantitative and are performed in reference labs. Semiquantitative immunologic test strips and protein electrophoresis are less accurate than automated immunoturbidimetric assays. Semiquantitative immunologic test strips are easy to use. Urine is diluted to an SG of 1.010 by adding distilled water, and the strip is immersed for 3 minutes and the color intensity compared to various categories. The sensitivity and specificity of the test strips are 91% and 92%, respectively. They have a false-positive rate of 8%, false-negative rate of 9%, and at the high and very high positive categories are detecting overt proteinuria that can be assessed with routine dipsticks.

Blood (occult blood, heme)

The reagent pad has a chromogen that changes to various shades of blue-green after oxidation of the enzyme. Anything that causes oxidation of the enzyme is detected and it implies blood is present only because that is how the pad is labeled and because iron in RBCs is the most common substance that will stimulate this oxidation reaction. However, a positive blue color change is also seen with iron in free hemoglobin, iron in myoglobin, peroxidase in plants and bacteria, and cleaning agents. The reaction is sensitive and the color intensity varies with the amount of "heme" detected; it is more sensitive to free hemoglobin than intact RBCs.

Method

Immerse the stick in well-mixed, noncentrifuged urine. A "speckled" pattern of green dots is due to individual RBCs that contact the pad and then lyse; this pattern is associated with microscopic hematuria. A uniform color change is due to a greater amount of hemorrhage, free hemoglobin, myoglobin, or contaminants. False negatives are uncommon but are associated with bacteria that produce nitrites and treatments with vitamin C. Ascorbic acid is a reducing substance that counteracts the oxidation reaction.

Correlate the results with microscopic enumeration of RBCs in urine, PCV, muscle enzymes, USG, and urine pH. Very dilute urine, less than 1.007, and alkaline urine may lyse RBCs and mask hematuria. Distinction of hematuria, hemoglobinuria, and myoglobinuria is clinically important and is described in the section on diseases.

Degrees of sensitivity of various tests to detect blood

Method	Positive	RBC/hpf
Hemastix, Labstix; hemolytic reagents in the stick lyse RBCs	1/8000	200 RBC/hpf
Occult test tablet	1/32,000	20 RBC/hpf
Microscope		<10 RBC/hpf

Glucose

There should be no glucose in the urine of healthy animals. Reagent strips are sensitive, and detect glucose via an oxidation reaction that produces a color change. False negatives are due to vitamin C and outdated strips. False negatives can occur if the glucose in urine is in low concentrations and one of these substances is present: vitamin C, formaldehyde, ketones, bilirubin (large amount), salicylates, or tetracyclines. False-positive results are observed when samples are contaminated with oxidizing cleaning agents and hydrogen peroxide. Cats with urethral obstruction reportedly have an unknown substance that reacts with the color indicator to produce false-positive results. In an animal (most commonly cat) with a positive urine glucose, it is important to correlate the dipstick result with serum glucose as stress can cause a transient hyperglycemia that results in a transient glucosuria.

Urine dipsticks are accurate to rule in glucosuria (high specificity) but not rule it out (low sensitivity). Therefore, if glucosuria is suspected but the dipstick is negative consider assessing for glucosuria with a different method. For example, submit a urine sample for analysis on a clinical chemical analyzer or request urine glucose to creatinine ratio (UGCR). Visual readings of urine dipsticks were more accurate than automated readings in this study that included more than 500 dog and cat urine samples. Automated reading of glucosuria was more accurate for cat than dog urine. This same study sought to establish a UCGR measurement as an additional clinical diagnostic test. Although the UCGR correlated well with the absolute measurement of urine glucose, it did not add any clinically useful information in these patients [13].

Tablets are available to detect glucose and do so through copper reduction. False negatives are due to outdated product and low glucose concentration in urine. False positives are fairly common as any reducing substance can cause the color change.

Always correlate results of urine glucose with serum glucose. The main clinical differential is transient (epinephrine, corticosteroids) versus persistent hyperglycemic disorders (diabetes mellitus, hyperadrenocorticism). When plasma glucose exceeds certain concentrations, the ability of the proximal tubules to reabsorb glucose is surpassed and glucose escapes into the urine. The renal threshold for glucose in dogs is approximately 200 mg/dL (range: 180–220 mg/dL), cats 300 mg/dL (range: 250–350 mg/dL), horses 150 mg/dL (range: 120–200 mg/dL), and cattle 100 mg/dL (range: 80–120 mg/dL). Positive urine glucose results coupled with serum glucose concentrations below the renal thresholds suggest a defect in tubular reabsorption mechanisms, and may be seen with nephrosis (toxic insults), tubular injury, primary or familial glucosuria, and Fanconi syndrome. Fanconi syndrome is a heritable or acquired disease characterized by defects in proximal tubular reabsorption of various substrates that include one or more of glucose, sodium, calcium, bicarbonate, amino acids, and phosphate. Primary glucosuria is seen in Scottish terriers, Norwegian elkhounds, and dogs of mixed breeding and is marked by glucosuria in the absence of hyperglycemia. Glucosuria without hyperglycemia may also be seen due to a time delay of urine collection relative to serum collection. The urine in the bladder may be several hours old relative to the serum and therefore a transient hyperglycemia may have occurred, while the serum glucose has meanwhile normalized. This can be seen with stress, postprandially, and after fluid therapy with glucose-enriched fluids. Glucosuria is common in cattle due to their low renal threshold for glucose and the ease of which cattle develop stress hyperglycemia. Cattle with CNS disease may have serum glucose values of 300 mg/dL or greater; pyloric obstruction can produce serum glucose values up to 500 mg/dL or greater.

Serum fructosamine is formed when sugar moieties become attached to plasma proteins, and its concentration can be used to distinguish transient from persistent hyperglycemia. The longer blood sugar has been elevated, the higher the serum fructosamine concentration. Serum fructosamine concentration reflects the average serum glucose concentration over the past 1–3 weeks (roughly the half-life of albumin and globulins), and will not be increased by transient hyperglycemia.

Postprandial glucosuria lasts for approximately 1.5 hours; glucosuria beyond 2 hours is abnormal and should prompt examination of serum glucose. Persistent hyperglycemia and glucosuria is seen commonly with diabetes mellitus and hyperadrenocorticism (Cushing's disease), and less frequently with pheochromocytoma, pancreatitis, acromegaly, progesterone administration, and some cases of sepsis. A urinalysis used to screen for glucosuria is an acceptable screening test for diabetes mellitus and in monitoring the effect of treatment for diabetes. Marked hyperglycemia, glucosuria, and ketonuria are diagnostic for diabetes mellitus.

Glucose increases the USG by approximately 0.004 units for each 1 g/dL of glucose in the urine. A 4+ urine glucose would increase USG by approximately 0.010 units. Glucosuria promotes bacterial and fungal growth.

Ketones

There should be no ketones in the urine of healthy animals. Reagent strips detect ketones via a reaction with nitroprusside that produces a purple color change proportional to the concentration of ketones present. Ketones enter the circulation first and then spill into the glomerular filtrate. Ketonuria can be detected in the absence of ketonemia. Ketogenesis produces three kinds of ketone bodies, but only two have the form of a true ketone and are detected by the nitroprusside reaction. The proportions of ketones excreted in the urine are approximately 78% beta-hydroxybutyrate, 20% acetoacetic acid and 2% acetone. The reaction mainly detects acetoacetic acid (approximately 90%), and reacts less efficiently with acetone (volatile). Beta-hydroxybutyrate, the most abundant product of ketogenesis, does not have the structure of a ketone and therefore is not detected. The most sensitive test for ketones in cattle is Ketostix™. Tablets are available but are less sensitive than Ketostix. Tablets rely on the same nitroprusside reaction as the urine reagent pads. Place one drop of urine (or blood, serum, plasma, or milk) on the tablet and read the color change in thirty seconds. Lavender to deep purple is positive and the intensity is proportional to the concentration of ketones present in the urine or blood. Tablets are more sensitive than strips and can detect ketones in the urine at 5 mg/dL, as opposed to 10 mg/dL for strips, and 10 mg/dL in blood.

If there is a trace ketone reaction on the dipstick consider confirming their presence with Ketostix, or the tablet method. A positive test result can be due to: excessive fat catabolism, as with negative energy balance, inadequate carbohydrate content in the diet, cachexia, starvation, anorexia, hyperthyroidism, pregnancy toxemia, and diabetes mellitus. Ketonuria occurs most commonly in high production dairy cattle, which enter a state of negative energy balance that promotes formation of ketones. Diabetes mellitus is the most common cause of ketonuria in dogs and cats. Ketones are negatively charged and force the excretion of a cation (sodium or potassium) when the kidney filters them. This may lead to hyponatremia and hypokalemia.

The chemicals used in the pads to detect ketones are light, humidity, heat, and date sensitive; therefore, do not use expired strips and keep the lid secured tightly.

Blood glucose	Urine glucose	Urine ketones	Diagnosis
High	Positive	Positive	Diabetes mellitus
High	Positive	Negative	Diabetes mellitus, hyperadrenocorticism; uncommon causes
High	Negative	Negative	Epinephrine or corticosteroids
Low	Negative	Positive	Starvation, pregnancy toxemia, etc.
Normal	Positive	Negative	Transient hyperglycemia, time delay, nephrosis, other tubular diseases, Fanconi

Bilirubin

Use fresh noncentrifuged urine for analysis. Reagent strips detect only conjugated bilirubin using a diazo methodology similar to Ictotest tablets. Since the color reaction is beige to pink to red, any substance that imparts a red color to urine may interfere with interpretation. Large quantities of vitamin C may cause false-negative results. As with all substances, correlate results with the USG. The sensitivity of strips is approximately 0.2–0.4 mg/dL, and tablets approximately 0.05–0.1 mg/dL. Tablet testing is recommended if interference is suspected (e.g., hemoglobinuria or myoglobinuria).

The reaction does not detect biliverdin, and conjugated bilirubin will hydrolyze to biliverdin in urine exposed to light, so analyze fresh urine. Conjugated bilirubin is water soluble and readily enters the glomerular filtrate in most species (cats have a higher threshold). Unconjugated bilirubin is bound to albumin and therefore should not pass through glomeruli.

Bilirubinuria indicates possible liver disease or hemolysis rather than disease in the kidneys. It is most commonly associated with cholestasis. Any positive reaction in a cat is considered abnormal and warrants further investigation. Dogs have a low renal threshold for bilirubin, and additionally, it can be conjugated in small quantities in tubular epithelial cells of normal dogs. In dogs, up to 1+ bilirubin in concentrated urine is considered normal and is common, especially in male dogs but the finding must correlate with other clinical abnormalities. Approximately 20–25% of normal dogs will have positive reaction for bilirubin in urine via reagent strips, and up to 60% with tablets. Bilirubinuria precedes bilirubinemia and icterus, and may therefore be an early indicator of hepatic disease.

Urobilinogen

Urobilinogen is present on reagent strips used for human patients but it is not present on reagent strips designed for animals as it has no value. The detection of urobilinogen indicates a patent bile duct and a fresh urine sample, and is ignored.

Nitrites

Detection of nitrites is indirect evidence of bacteriuria as some bacteria produce nitrite, however, the results are unreliable so do not use in animals. Determination of bacteriuria should be done by microscopic examination and culture of the urine.

Leukocytes

Reagent strips for WBCs recognize a specific leukocyte esterase that is found in human neutrophils, eosinophils, basophils, and monocytes but is not reliable for dogs and cats. Determination of leukocytes in the urine of animals should be done by microscopic examination.

Urine specific gravity

The reagent strip tests are considered unreliable in veterinary medicine. The strips indirectly estimate the SG based on pKa, the shift in the pH produces a color change. Maximum concentration detected is 1.030, and is inadequate for determination of concentration ranges in dogs and cats. Furthermore, results do not correlate well with refractometry measurements, and false positives and negatives are common. (See earlier discussion in the "Urine Specific Gravity" portion of this chapter.)

Microscopic sediment examination

It is standard to centrifuge 5–10 ml of well mixed fresh urine at 1500–2500 rpm for 5 minutes; however, the exact volume is not critical. It is recommended to use a consistent amount or whatever is available when collection volume is small. Pour off or aspirate and save the supernatant (for possible chemistry analysis) and resuspend the sediment in the urine that remains (0.5 ml is ideal and the amount left should be consistent) by flicking the tube several times with your finger until the pellet and its contents are well mixed. Place one unstained drop on a slide, add a coverslip and examine at low-power field (10× objective) for casts and crystals and at a high-power field (40× objective) for cells and bacteria. Reduce the light in the field by closing the iris diaphragm (preferable to lowering the condenser) until the material in the field is refractory. Scan the slide with the 10× objective and then record the results as number seen per low- or high-power field (#/lpf; #/hpf) by counting 10 fields and averaging the results. There also are manufactured systems that aid in these steps and results will be based on number seen per microliter. Change the focus during examination to better see the materials present as not all material is in the same plane of focus in wet-mount preparations. If the sample of urine is excessively turbid dilute it with additional supernatant or physiologic saline (but results per magnification are now reduced) and if RBCs are so numerous that

it is difficult to see other structures then lyse the RBCs with 2% acetic acid (vinegar). All abnormalities can be seen in unstained preparations however if unusual structures are seen consider a wet-mount stain (follow directions) and/or prepare an air-dried film and stain it with a Diff-Quik type stain just like a cytology specimen; the latter is preferable. If neoplasia is suspected you may want a fresh sample of urine obtained with a wash as urine is harsh on cellular features and cells sitting in urine for several hours in the bladder will be visibly altered. Better yet is an ultrasound-guided aspirate from the mass. These slides should be air dried and stained with Diff-Quik type stains or Wright stains. Do not diagnose neoplasia on wet-mount preparations, use air-dried, monolayer preparations.

Always correlate results with mode of collection, USG, chemical results, and clinical findings. Examples: 2 casts/lpf in urine with a USG of 1.004 in an azotemic animal is very significant, whereas 2 casts/lpf in urine with a USG of 1.044 in a wellness check is probably normal. Leukocytes in a voided sample may be from the genital tract. Normal findings or results expected in normal patients are in Table 24.5.

Casts and heavier structures tend to aggregate along the edges of the coverslip so be sure to examine all regions of the cover slipped area. Count in a low-power field but proceed to high-power fields to better see their morphology and for more accurate identification.

Sources of technical error

Inexperience, open iris diaphragm, dirty objectives, old urine, poorly mixed urine, contamination, variable amounts of urine centrifuged, too much stain added, organisms growing in contaminated stain jars, random rather than systematic examination of 10 fields, and confusion of Brownian movement of small material with bacteria are all contributors to error.

Refer to Appendix 24.A for color imagery related to microscopic examination of urine; Figures 24.A.1–24.A.37.

Red blood cells

Hematuria occurs when there is greater than 5 RBCs per high-power field (/hpf). As with all cellular events in urine, correlate results with collection technique, SG, pH, reagent pad findings, and mode of collection. For example, cystocentesis and catheterization may induce minor hemorrhage; and RBCs lyse in urine with a USG of <1.008 and in alkaline urine. At USG >1.025 they tend to crenate (shrink and have irregular contours). At a USG in mid-ranges, erythrocytes are uniform, discoid, smoothly contoured, clear to light-yellow or rust-red, refractile, and have no internal detail. Results are recorded as number seen/hpf. Normal is considered <5/hpf, and the phrase "too numerous to count" (TNTC) is used when the field is crowded with RBCs.

There are too many causes of hematuria to produce a practical list. However, the common denominator is trauma: cystocentesis, catheterization, calculi, hit by car, obstruction, cancer, biopsy of kidney or bladder; and nonphysical traumatic events such as infection, estrus, nephrosis, feline lower urinary tract disease (formerly known as feline urologic syndrome), parasites, and bleeding disorders. RBC casts are rare but localize the hemorrhage to the renal tubules. RBC casts are very fragile and often disintegrate with handling of urine. RBCs may be confused with fat droplets, but fat droplets are not uniform in size, are more refractile, and some will be out of the plane of focus.

Leukocytes

Greater than five WBCs per high-power field (#/hpf) is abnormal and is termed pyuria. The magnitude of WBCs/hpf is the key and as always, the results should be correlated with USG, the rest of the data in the UA, other data in the case (steroids will decrease the number of WBCs in urine), mode of collection, urine pH, etc. WBCs lyse easily in alkaline urine and hypotonic urine (as do RBCs). Voided urine could have inflammation anywhere in the urogenital tract. Cystocentesis localizes the source of the inflammation to the kidneys or more likely the urinary bladder; however, reflux is possible, e.g., prostatitis.

WBCs are slightly larger than RBCs (1.5–2× larger), are spherical, granular, have internal structures, a nucleus, and appear singular, in clumps, or in casts. WBC casts localize their source to renal tubules and indicate pyelonephritis. Although any WBC could be seen they are almost always neutrophils and differentiation of the types of WBCs is not necessary but if desired will require examination of a stained film. Neutrophils indicate inflammation in the urogenital tract. They are usually accompanied by RBCs and bacteria should be searched for microscopically and via culture. Inflammation is also seen with cancer, calculi, cystitis, prostatitis, and pyelonephritis. Eosinophils are rarely seen, can be associated with parasitic diseases and in dogs consider eosinophilic polypoid cystitis. The latter is a common histologic diagnosis that causes persistent hematuria and produces a mass in the urinary bladder that resembles a tumor. The mass is infiltrated with eosinophils and there is eosinophilpoiesis within the mass. It requires surgical removal.

Epithelial cells

These cells may be squamous (urethra, genital, or skin), transitional (bladder), renal (tubules), or neoplastic (usually TCC). Squamous cells are huge (5× larger than WBCs, 10× larger than RBCs), have lined or sharp edges, with nuclei often not visible, and usually are in low numbers. If numerous squamous epithelial cells are seen in a free catch sample from a female dog in estrus. They are genital in origin and if numerous squamous epithelial cells are seen in a male dog

consider a Sertoli cell neoplasm that is secreting estrogen and inducing squamous metaplasia of the prostate.

Transitional epithelial cells are from the bladder, ureter, or renal pelvis and most are from the bladder. Supposedly the depth of location in the urothelium changes their morphology enough to recognize the different sources, but this is difficult to discern and does not aid a diagnosis. In normal urine there are only a few epithelial cells: <5/hpf. When in large numbers they are usually accompanied by RBCs and WBCs and are associated with cystitis. If numerous and in rafts they may be due to catheterization. Their appearance has a wide range; they are approximately 2× larger than WBCs, round to polygonal, have a round nucleus, and are granular to homogenous appearing. These are the most common epithelial cell seen in urine.

Renal tubular epithelial cells are the least common or the least commonly recognized. They are approximately the size of WBCs and look like WBCs. They are round, granular, and have a central round nucleus. Different shapes and sizes may be localized to different regions of the kidneys but too little is known in veterinary medicine for this to be clinically useful.

Neoplastic transitional epithelial cells may be found in this chapter, under "Diagnoses."

Bacteria

The kidneys, ureters, bladder, and proximal urethra are sterile therefore urine should be sterile, at least until it passes through the distal urethra where normal flora can be added as a contaminant. Centrifugation at speeds used for urinalysis will not take bacteria out of suspension so the supernatant or the pellet is equally satisfactory for microscopic detection. Use the pellet as that is what is used for everything else in the microscopic examination and it will permit visualization of cells and therefore the possibility of seeing bacteria inside neutrophils. This will be seen best if a film is prepared and stained, rather than a wet mount. The key to seeing bacteria is the number present, the type of bacteria, and the observer's ability to see them. *Reduce the light considerably* to help outline them (decrease the iris diaphragm or lower the condenser to increase wet-mount contrast). The greater the numbers the more likely they will be seen. They are usually reported as few, moderate or many. Counting the number/field is impractical.

A bacterial infection should be confirmed with culture and preferably sensitivity. Bacteria can be seen in wet mounts with the 40× objective; however, Brownian movement of particulate matter is easily confused with bacteria and single cocci are easy to confuse with debris. If bacteria are seen but culture results are negative consider misinterpretation of particulate material and Brownian movement as a possible explanation. These "false-positive" observations are relatively common in clinical practice. Additional explanations for visualization of bacteria but culture negative include inhibition of growth by cold or frozen storage, or the patient has received antibiotics. It is not due to decreased sensitivity of culture technique, as culture is better to identify bacteria than is visualization. It takes about 10,000 rods/mL urine to see them and up to 100,000 cocci/mL to see them as opposed to only 1–10 bacteria/mL to produce a positive culture.

Localization of the infection is critical as they could be from kidney, bladder, urethra, prostate, uterus, prepuce, external genitalia, or the environment. If bacteria are detected in urine that was collected aseptically via cystocentesis an infection in the kidneys or bladder is the diagnosis. Correlate results with the rest of the urinalysis and if WBC casts are present (tubules involved), especially with concurrent azotemia, then pyelonephritis is the source. These patients may also have concurrent cystitis as an ascending infection from the bladder is the most common cause of pyelonephritis. Catheterized and voided samples that are positive for bacteria because of contamination will be culture positive, but bacteria are usually in too low a number to visualize. If cystocentesis is not possible then use a sterile catheter and take as many precautions as possible to reduce contamination from the catheter. If a voided sample is used for culture, clean the genitalia and catch a midstream sample. Voided samples are to be avoided to rule in an infection, but they can be used to rule out an infection. Most contaminants and normal flora are Gram positive. Bacteria can replicate in urine readily therefore examine and culture soon after collection. Refrigeration, and especially freezing, will inhibit growth and/or kill bacteria and therefore may result in false negatives. If samples are to be shipped to a lab, refrigerate and strive to have cultures prepared in <24 hours from collection; do not store at room temperature or freeze. Storage of canine urine at four degrees centigrade for 24 hours will not affect results of culture and susceptibility tests.

Bacterial infections should be accompanied by pyuria, hematuria, proteinuria and various clinical signs including dysuria, stranguria, etc., so correlate all of the data available. The presence of intracellular bacteria in neutrophils is good evidence for *in vivo* infection but can happen *in vitro* if samples are allowed to sit at room temperature. Results of urinalysis may look similar for cystitis and pyelonephritis. Cystitis will not have azotemia or casts in the urine. Pyelonephritis may be associated with azotemia and casts, especially if the disease is active and widely disseminated (>75% involvement of kidneys). Infectious cystitis is more common in females due to their wider urethra and predisposition to ascending infection. It should be treated aggressively as it may lead to an ascending pyelonephritis. Sterile cystitis can occur with uroliths and neoplasia but all cases of cystitis/pyuria should be cultured before they are determined to have a nonbacterial etiology. Bacterial infection may also be a secondary event. Regardless of cause, bactiuria requires therapy. Bacteriuria without neutrophils is a paradox but is associated with contamination,

Cushing's disease or exogenous steroids that inhibit the influx of neutrophils, dilute or alkaline urine that may lyse the neutrophils, and antibiotic therapy that inhibits growth but bacteria are still seen. Cushing's disease is associated with increased prevalence of urinary tract infection due to dilute urine and decreased urinary bladder immunity.

Microscopic absence of bacteria does not rule out an infection. Rule out requires negative cultures to be certain. Aerobic Gram-negative rods account for most infections in the urinary tract, and *E. coli* is the most common pathogen cultured. Commercial products are available to culture urine and/or enumerate colonies in practice but they will require an incubator. Results obtained can be correlated with results of UA and this is a rapid way to identify a urinary tract infection and/or differentiate the discrepancy of Brownian movement versus true bacteria. If bacteria are seen in practice and culture results from a commercial laboratory are negative, the likely explanations are (i) the purported "bacteria" were actually Brownian movement of small particles; or (ii) the patient is receiving antibiotics. Urine should be placed in the culture system as soon after collection as possible for best results. Some systems use select media that turn different colors around different bacterial colonies. If numerous different colors are identified consider contamination. In these systems, the colonies are enumerated or the entire Culturette can be sent to a referral lab for enumeration, culture, and identification. Positive results determined in practice should be confirmed, bacteria classified, and an antibiotic sensitivity recommended. In samples obtained by cystocentesis and enumerated with these products >1000 cfu/mL is significant, 100–1000 is suspect and <100 is probably contamination or unimportant. For samples obtained by catheterization these guidelines are increased by 10-fold. Point-of-care commercial systems are an alternative to sending out urine to a commercial laboratory [14]. A positive culture result is reliable; a negative result should be interpreted with caution, as the bacteria may not have been identified. Susceptibility results are part of these systems; however, they may be limited to five antimicrobials and results may not correlate with those from the commercial laboratory.

Quantitative bacterial culture results from a commercial laboratory are still the best means of determining if a bacterial infection is present. The number of colonies is reported as "colony forming units per milliliter of urine" (cfu/mL). The gold standard for documenting urinary tract infection is ≥10 [5] cfus/mL. Susceptibility testing is provided if requested. Most commercial laboratories provide interpretation and consultation of their results. Generally, bacterial growth from urine collected via sterile cystocentesis technique is interpreted as clinically significant. Approximately 20% of normal female dogs will have >100,000 cfu/mL urine via catheterization but normal male dogs rarely have >1000 cfu/mL via catheterization. The following numbers can be used as guidelines to diagnose true infection via collection technique when correlated with all of the other data:

- Catheterization female dog >100,000 cfu/mL.
- Catheterization male dog >1000 cfu/mL.
- Catheterization female and male cat >1000 cfu/mL.
- Cystocentesis cat or dog either sex >100 cfu/mL.

Voided urine is not reliable to rule in but can be used to rule out an infection.

Yeast and fungi

Fungal hyphae and yeast forms in urine sediment are most commonly due to overgrowth of contaminants in old samples, or from the skin, litter box, etc.; however, if they are seen in a fresh sample/cystocentesis collected, then a fungal infection of the kidneys and/or bladder should be suspected. They are colorless, often plentiful when present; appear as long hyphae or budding ovals and spheres when in yeast forms. They tend to occur in immune-suppressed patients or patients on long-term antibiotic therapy. If noted in a feline, the feline immunodeficiency virus and feline leukemia virus status should be determined.

Parasites

Capillaria plica or *felis, Dioctophyma renale*, and *D. immitis* are seen rarely in urine of dogs and cats. *Klosiella* spp. in horse urine has been seen but is exceedingly rare. Capillaria ova look like whipworm ova, with oval shape, bipolar plugs, rough surface, and colorless to light yellow-tan. Check a fecal float for *Trichuris* and differentiate fecal contamination from dual infection. Microfilaria of heartworm may be seen due to hematuria, and a heartworm check should be performed if the status is not already known. Adult *D. renale*, or the kidney worm, is sometimes seen during a laparotomy and the ova are rarely seen in urine as large oval-shaped structures with an internal structure and a pitted tan to light brown surface.

Debris

Spermatozoa, talc crystals from gloves, pollen, fibers, and hair are some of the more common large "debris" seen with the 10 or 20× objectives. Brownian movement that can be confused with bacteria is seen with 40, 50, or 100× objectives.

Lipid

Lipid droplets are clear, variable in size, refractile, round, in different planes of focus, and common in cat urine. They may appear gray to black at low magnification and rarely can be seen grossly in urine from cats. Cat kidneys have considerable amounts of lipid in tubular epithelium and presumably this is the source of the lipid. There is no correlation between lipiduria and lipemia in these individuals.

Casts

Casts are molds of tubular lumens. Their primary component is the Tamm-Horsfall mucoprotein that is secreted by tubular epithelial cells. Casts may contain variable amounts of cells, lipid, and debris. When present in significant numbers they reflect active disease in renal tubules, nephrosis, which usually has an acute toxic etiology. Casts are not a reliable marker of onset, severity, or reversibility of the tubular disease, but they do imply that the disease is still active and is in the kidneys. Tubules have excellent regenerative capabilities if the basement membrane remains intact. Casts form in the loops of Henle, distal tubules and the collecting ducts. Absence of casts does not rule out tubular involvement. If they are not reported but tubular disease is suspected then repeat the UA as they may be shed intermittently or in showers. If casts continue to be shed post-treatment, they indicate the disease is still active. Waxy casts are often seen in chronic progressive tubulointerstitial renal disease.

Casts are classified based on their microscopic appearance and an attempt is made to correlate their appearance with a pathologic process, which has variable success. They are reported as the number seen/lpf (10× objective) and they are seen more easily if contrast is increased by closing the iris diaphragm. Normal urine should have no casts or only a few casts, and 1–2 hyaline or fine granular casts/lpf in concentrated urine is considered acceptable. Correlate number of casts with the USG as 1–2 casts in dilute urine, especially if other abnormalities are present, is abnormal. Increased number of casts is termed cylindruria.

Hyaline casts

These are the most difficult to see, are clear, have rounded or blunt ends, tend to dissolve in dilute or alkaline urine, and are composed almost entirely of mucoprotein and albumin with no cells or granularity. In elevated numbers, they imply glomerular disease or, less likely, a preglomerular proteinuria. The albumin that leaks through glomeruli apparently stimulates excess secretion and precipitation of tubular Tamm-Horsfall mucoprotein leading to formation of these casts. A few hyaline casts in concentrated urine are normal, a few in dilute urine and many in urine of any SG are abnormal. When they are observed, the possibility of glomerular disease or, less likely, multiple myeloma (Bence Jones proteinuria) should be pursued.

Granular casts

These are clear to tan-brown, easy to see, and consist of cells and mucoprotein. They are from epithelial cells that recently sloughed, became entrapped in the mucoprotein, and formed a cast. They indicate possible nephrosis, pyelonephritis, or infarction. The longer the casts are in the tubules before they are released, the more their granular appearance changes from rough and coarse to fine and then waxy, which is the final stage of degeneration of granular casts. Differentiation of coarse and fine granular casts is not necessary. One to two fine granular casts per lpf in concentrated urine are considered normal, but the presence of coarse granular and elevated numbers of fine granular casts is abnormal.

Waxy casts

Waxy casts are clear, with no internal structure, and they have sharply defined margins and squared-off ends as they are brittle and break. To the novice, they may resemble hyaline casts that are smoother and the ends are more rounded. Waxy casts imply chronicity and indicate a pathologic process when found in large numbers.

Cellular casts

These can be composed of epithelial, red, or WBCs, and all can have a granular appearance (granular casts). If RBCs are recognized in the cast it indicates hemorrhage in the tubules and if WBCs are recognized in the cast it indicates pyelonephritis. It can be difficult to recognize the type of cells in casts as the cells are degenerating and they are not stained well; RBC casts tend to be fragile.

Lipid casts

These are composed of lipid and are seen in cats; one may see refractile droplets in the casts. These casts are associated with tubular disease (degeneration) and diabetes mellitus. Confirmation of lipid content may require use of fat stains such as Sudan black B or Oil-red-O.

Hemoglobin and myoglobin casts

These are seen rarely and indicate intravascular hemolysis or myoglobinuria, respectively. They are yellow to pink-red to brown, homogeneous and smooth or may be granular if tubular cells are dying and sloughing into the lumens of the tubules. Correlate their presence with the rest of the case data.

Crystalluria (see Appendix 24.A for visual examples)

Crystalluria is the term used to describe the presence of crystals in the urine. Crystals may be found in normal patients (incidental finding, no treatment needed) or sick patients wherein the crystals may correlate with a known disease or they may indicate a primary disease that was formerly unidentified. For example, calcium oxalate dihydrate may indicate a hypercalcemic disorder; calcium oxalate monohydrate may indicate ethylene glycol toxicity; and ammonium biurate may indicate liver failure. Crystals in urine are often incidental and of no diagnostic significance; struvite, carbonate, and oxalate crystals can be present in urine from normal patients. The observation of crystalluria should be correlated with clinical and other clinical pathology data. Crystals are only one of several risk factors for urolithiasis. For crystals to form, the urine must be supersaturated and therefore the

potential for nephrolith or urolith formation is present but not guaranteed. Stones must be analyzed to identify them properly as urinary crystals may or may not be the same as the urolith. Analyses of uroliths always require a send out test. Urethral obstruction in most species is due to a urolith and is almost exclusive to males. However, obstructions in male cats are usually due to a plug of mucoid material and phosphate crystals rather than a stone.

Crystals should be identified in fresh urine, as storage, refrigeration, and preservatives may influence their formation or dissolution. Delaying examination for 6–24 hours can induce crystal formation especially in refrigerated samples. The formation of crystals depends on multiple factors including, species, breed, pH, hydration, diet, and underlying diseases. Urine pH influences precipitation of some crystals and changing urinary pH through diet modification can lead to crystal dissolution.

There are general guidelines for expected pH ranges for different crystals. However, urinary pH does not establish identification of the crystal. Identification is done visually by matching photos with what is seen in the urine; shape, color, and size of crystal are all used. Rarely, chemical analyses or X-ray diffraction are used for crystal identification.

Ammonium biurate

These are brown, tan, yellow, or greenish spiky spheres. They often have protrusions giving a "mite-like" or "thorn-apple" appearance. These can be seen in normal animals, especially in Dalmatians and English bulldogs. They may also be suggestive of liver failure, congenital or acquired shunts, in which there is decreased conversion of ammonia to urea. In these cases the serum UN may be decreased while serum ammonia is increased and excreted in urine where it forms urate crystals, and may lead to nephrolith or urolith formation (tan to green in color). Their formation is generally favored in lower pH urine, but they can form in any pH. Patients in liver failure may have concurrent hypoalbuminemia, microcytosis, decreased serum cholesterol, and variable liver-derived serum enzyme activity.

Bilirubin

These are yellow, yellow-red, or red and usually needle-shaped or granules. They are associated with bilirubinemia and bilirubinuria but these abnormalities do not have to be present to form bilirubin crystals. They are common in canine urine, especially in concentrated specimens. They are abnormal in urine of other species. They typically are associated with a pH <7 and may resemble tyrosine crystals.

Calcium carbonate

These are colorless, tan, or brown. They are large and may have radial striations. Shape may include spheres and dumbbell-shapes. They are commonly seen in herbivores, such as horses, rabbits, and guinea pigs. They are not seen in the dog or cat. Dumbbell-shaped crystals in a dog or cat are more likely to be calcium oxalate monohydrate.

Calcium oxalate dihydrate

These are colorless with an "x" pattern through the crystal that imparts a "Maltese cross" or "envelope" pattern in square to rectangular shape. These are common in horses and cows and associated with ingestion of oxalate-rich plants. They may be seen in normal dogs and cats but also suggest hypercalcemia and hypercalciuria. If numerous, their presence should prompt investigation of a potential hypercalcemic disorder, such as hyperparathyroidism or idiopathic hypercalcemia. These crystals are seen in conjunction with calcium oxalate monohydrate crystals in ethylene glycol toxicity.

Calcium oxalate monohydrate

These are colorless with shapes including "Washington monument," "double-ended picket fence" (may look like double-ended hippuric acid crystals), dumbbell (may look like calcium carbonate), spindle, sheaths, and hemp seed-like. They can be normal in herbivores, dogs, and cats. However, their presence in prominent numbers suggests ethylene glycol toxicity (correlate with signs and laboratory data). When observed in dilute urine in any number from a dog or cat with AKI they indicate the possibility of ethylene glycol toxicity. One should also consider hypercalcemic diseases in dogs and cats, especially if dihydrate forms are also present.

Calcium phosphate

These are colorless to tan with shapes including amorphous aggregates, spheres, elongated prisms, and needles that may aggregate into sheaths or rosettes. They can be normal in dogs but may form uroliths. They are typically associated with alkaline urine.

Cholesterol

These are colorless and transparent large flat plates occurring in rectangles, often with a notch in one corner. They may stack on top of each other. They are birefringent and colorful with polarized light. They may be present in normal dogs but also may suggest hypercholesterolemic syndromes and protein losing nephropathy.

Cystine

These are colorless with hexagonal shape with a tendency to stack on top of each other. They are rare and not always abnormal. They may be seen with the rare inherited metabolic disorder cystinuria. This may occur in both male and female dogs, but clinical signs are observed almost exclusively in male dogs. This has occurred in Newfoundland, Australian cattle dogs, Mastiffs, Scottish deerhounds, English bulldogs, and Dachshunds.

Drug-associated

These are dark to light brown in color and typically form needles arranged in sheaves, bundles, fans, and radiating spokes. They are occasionally seen with sulfa family drugs, ampicillin, allopurinol, xanthine crystals, radiographic contrast media, and others. Correlate this finding with history of drug administration.

Hippuric acid

These are distinguished from calcium oxalate monohydrate by noting single-ended points, but distinction is difficult.

Leucine

These are yellow or brown spheres with concentrically radiating circles. They are rarely identified in animals but are suggestive of liver disease.

Magnesium ammonium phosphate – struvite – triple phosphate (a misnomer)

These are colorless with variable shapes including a "coffin-shaped" pattern, prisms, and plates. They are variably three-dimensional with have to six sides and oblique ends. They are a very common crystal in dogs and cats and tend to occur in alkaline urine. Urease splitting bacteria that produce free ammonia and alkaline urine enhance their formation. They can be numerous in normal dogs and cats, especially in concentrated urine. They commonly form uroliths.

Struvite

See "Magnesium Ammonium Phosphate" (above).

Tyrosine

These are colorless or yellow with needle-like shape and can resemble bilirubin crystals. They are rare and suggest liver disease.

Urate ammonium

See "Ammonium Biurate" (above).

Uric acid

These are yellow, yellow-brown; diamonds, rhomboid, rosettes; imply the same as urates. Uric acid is produced during purine degradation. Dalmatian dogs have a genetic defect in the gene for a uric acid transporter resulting in failure to metabolize uric acid and leads to increased plasma and urine concentrations of uric acid. These dogs have adequate uricase in hepatocytes as compared to an absence of this enzyme in people but Dalmatians cannot transport uric acid into hepatocytes for uricase to convert uric acid to allantoin. Increased uric acid is excreted in the urine. Their importance should be correlated with clinical signs. These crystals may also be seen in dogs with primary hepatic disease in which there is failure to convert uric acid to allantoin and ammonia to urea.

Xanthine

These are brown or tan. They appear similar to ammonium biurate crystals, but xanthine crystals usually form after treatment with allopurinol, a xanthine oxidase inhibitor to prevent formation of uric acid in dogs with urate calculi. They may be familial in Cavalier King Charles spaniels and dachshunds.

Fractional excretion of electrolytes

Fractional excretion of all of the electrolytes can be calculated, but sodium, potassium, and phosphorus are most clinically useful. Fractional excretion of electrolytes is performed to determine whether there is renal tubular failure in an animal that is hyponatremic or hypokalemic. They are used to determine the contribution of the kidney to the respective electrolyte decrease. Fractional excretion of phosphorus is examined to determine the likelihood of increased PTH in a nonazotemic animal. Single-spot urine and serum samples are adequate and are preferred over 24-hour urine collections for clinical assessment. Collect a serum sample close to the time of the urine sample and submit both for measurement of the electrolyte(s) desired and creatinine in serum and urine. The reference laboratory should calculate the result or use this formula:

$$\text{Fx exc of electrolyte} = \frac{\text{Serum Ct}}{\text{Urine Ct}} \times \frac{\text{Urine electrolyte}}{\text{Serum electrolyte}} \times 100$$

About 99% of the sodium entering the filtrate is normally reabsorbed. Increased FE_{Na} >1% is consistent with tubular failure or decreased aldosterone activity. The result should correlated with all other data. FE_{Na} in an azotemic patient <1% is consistent with prerenal azotemia, and if hyponatremia is observed, is consistent with sodium loss via the GI.

FE_P > reference interval indicates increased serum PTH or PTH-rp.

Reference intervals

Fx excretion, %	Dog	Cat
Sodium	<1	<1
Potassium	<6–20	<6–20
Chloride	<1	<1.5
Phosphorus	<20	<73

Fractional excretion of sodium in normal horses is 0.01–0.70; 0.80–10.10 in horses with renal failure, and 0.02–0.50 in horses with prerenal azotemia. It can also be used to determine if renal failure is present in nonazotemic patients and to follow recovery post-treatment of an azotemic patient.

PTH and PTH-rp stimulate phosphorus excretion. Animals with hypercalcemia and primary hyperparathyroidism or humoral hypercalcemia of malignancy (if mediated by PTH-rp) will both have increased fractional excretion of phosphorus and, therefore, measuring the fractional excretion of phosphorus does not help distinguish these two diseases. Physical examination to locate the cancer is the best means to distinguish these differential diagnoses. If that is inconclusive then concurrent measurement of PTH, PTH-rp and serum calcium usually is definitive with or without imaging techniques of the parathyroid-thyroid region of the neck.

Enzymes in urine

Gamma glutamyltransferase (GGT) and N-acetyl-glucosaminidase (NAG).

Enzymes found in urine have two sources, filtered at glomeruli or released from tubular epithelium. Enzymes that are too large to be filtered at glomeruli but that are released from damaged tubular epithelial cells can be a useful adjunct to determine if there is an acute tubular lesion before azotemia develops. Two such enzymes are GGT and NAG. GGT is a membrane-bound enzyme and NAG is a lysosomal enzyme. Although both enzymes are produced in other tissues neither is filtered at the glomerulus, and therefore, any amount in the urine reflects a tubular source. Proximal tubular epithelium contains more of these enzymes than other tubular cells, and most toxins affect the proximal convoluted tubules preferentially due to their high metabolic rate. These enzymes are measured in a random urine sample along with urine Ct, and the ratio of enzyme to Ct is reported. Samples should be refrigerated but not frozen as freeze thawing destroys the activity of enzymes. Enzymes cannot accumulate in the urine because they are voided from the bladder on urination. Therefore, the amount measured indicates the amount released since the last urination, and an increased amount implies that the lesion is active or ongoing. These enzymes are not absorbed into the circulation. GGT and NAG have proven useful in dogs, cats, horses, sheep, and cattle, particularly in cases of drug-induced tubular injury (e.g., gentamicin, neomycin, NSAIDs). Urinary NAG varies with sex, being twofold greater in male dogs.

Reference values should be obtained from the laboratory and not the literature due to analytical variation in how the enzymes are measured. Despite the early detection of renal tubular disease afforded by urinary enzymes, they are seldom measured. This may be because the by the time animals with spontaneous renal diseases present the diagnosis of AKI is easily made and use of urinary enzymes is unnecessary. A potential use would be to monitor an animal placed on a nephrotoxic drug such as an NSAID or gentamicin, where an increase in these enzymes would warrant discontinuing drug therapy. In experimental gentamicin nephrotoxicity, increased tubular enzymes occurs before increased fractional excretion of electrolytes, and precedes azotemia by 7–8 days and decreased creatinine clearance by 4–6 days (Figure 24.5). Increases in C-reactive protein and retinol binding protein also occur with tubular disease and may be future useful disease markers.

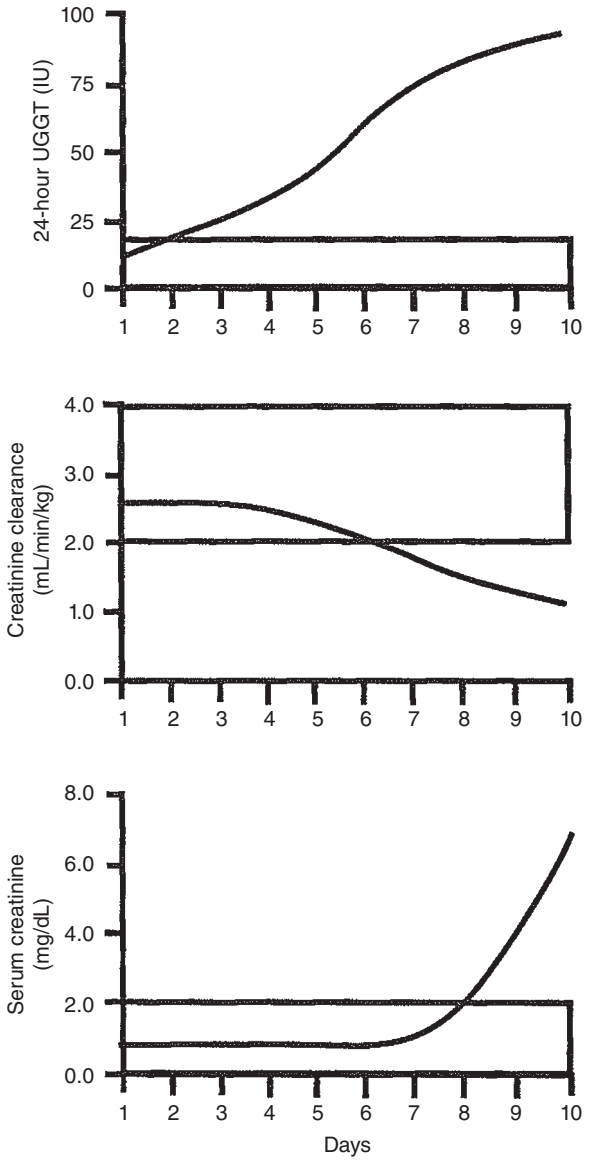

Figure 24.5 Serum creatinine, 24-hour endogenous creatinine clearance, and 24-hour urine GGT activity in experimental gentamicin nephrotoxicosis.

Diseases/syndromes

Chronic kidney disease

CKD is a common problem in older cats and dogs, and is the most common cause of renal failure in cats [15]. In cats, this disease most commonly manifests in the adult to

geriatric patient [16]. It is a clinical term for animals with the following chronic renal diseases: chronic glomerulonephritis, amyloidosis, chronic interstitial nephritis, chronic pyelonephritis, progressive familial renal nephropathy, and even staghorn calculi. If none of these are confirmed then generic terms applied are CKD, chronic nephrosclerosis, or, if severe, end-stage kidney disease. If the kidney is biopsied or an autopsy is performed one of those diseases may be recognized. However, the lesions may be so chronic that the primary disease process can no longer be recognized. At the late stage, it may not matter as the kidneys contain fibrous connective tissue and chronic inflammation with an overall irreversible reduction in tubules and glomeruli (loss of renal mass). The underlying etiology is seldom known. A large number of potential etiologies have been proposed ranging from toxic insults, tissue hypoxia, infectious etiologies, neoplasms, polycystic kidney disease, and some congenital disorders have been implicated [17]. Dogs progress more rapidly, and once clinical signs and lab data worsen they will only live months or less, but the lives of cats may be extended for years. The diagnosis is usually easy. Patients present with weight loss, inappetence, and poor body condition score, PU/PD, dehydration, and hypertension. Clinicopathologic findings include a nonregenerative anemia, increased Ct and UN concentrations, and inappropriately low USG measurements (isosthenuric) [17, 18]. Kidneys are small with irregular renal contours. All of these signs range from mild to marked depending on the severity of the disease and when the patient is seen. Once baseline clinical signs and laboratory data are documented they can be used to monitor the progression of the disease.

The IRIS has published guidelines for the staging of CKD in both cats and dogs (Table 24.10). The stages presently used range from asymptomatic but at risk for development of CKD through degrees of severity based on increasing serum Ct concentration and increased clinical abnormalities. Staging of CKD is done following diagnosis to facilitate appropriate treatment and monitoring of the patient. It is based on fasting serum Ct evaluated at least twice in the stable patient (see Table 24.10). Once a stage is determined, the patient may be sub-staged based on proteinuria and blood pressure. Early data derived from the use of SDMA in veterinary patients is being considered for IRIS staging. Currently, if patients are diagnosed with CKD using SDMA before azotemia develops, patients are considered to be IRIS stage 1.

The International Society of Feline Medicine (ISFM) recently published consensus guidelines for the diagnosis and management of feline CKD in the *Journal of Feline Medicine and Surgery* [17]. In patients with suspected CKD, recommendations include a minimum routine database starting with a complete history and physical examination. A routine urinalysis, serum biochemistry, and hematology, along with a systolic blood pressure, and renal diagnostic imaging are considered ideal in the workup process. Monitoring of CKD should include clinical signs, patient's condition, and regular monitoring of blood pressure, azotemia, proteinuria, hypokalemia, hyperphosphatemia, anemia, and urinary tract infections. Following diagnosis, initial reevaluations should be done every 1–4 weeks based on clinical needs. Patient's undergoing long-term management should be reevaluated at least every 3–6 months. Management of CKD is centered around supportive care and increasing the patient's quality of life. Many think some aspects of management slows disease progression, aside from diet modification. However, the veterinary literature lacks data to support this assumption. Therapy predominately involves maintaining hydration and diet modification. Additional therapeutics targeted at various other disease manifestations (nausea, electrolyte and mineral imbalances, hypertension, proteinuria, anemia, etc.) are commonly utilized. Therapeutic plans are developed around each individual patient's needs and are frequently correlated with the IRIS stage [17].

Table 24.10 IRIS staging of chronic kidney disease.

Stage	Blood creatinine (mg/dL)		Comments
	Dogs	Cats	
At risk	<1.4	<1.6	History suggests the animal is at increased risk of developing CKD in the future because of a number of factors (e.g., exposure to nephrotoxic drugs, breed, high prevalence of infectious diseases in the area, old age).
1	<1.4	<1.6	Nonazotemic. Some other renal abnormality present (e.g., lower than anticipated USG).
2	1.4–2.0	1.6–2.8	Mild renal azotemia. Clinical signs usually mild or absent.
3	2.1–5.0	2.9–5.0	Moderate renal azotemia. Many extrarenal clinical signs may be present.
4	>5.0	>5.0	Increasing risk of systemic clinical signs and uremic crises.

Ethylene glycol intoxication

Ethylene glycol (EG) is sweet tasting and is one of the most common lethal toxins in veterinary medicine. First it causes vomiting, ataxia, and CNS depression such that owners might think their pet is "drunk." At this stage, a UV light may reveal fluorescence in the oral cavity, in vomitus, and in

urine. Fluorescent dye is commonly present in commercial antifreeze preparations (the dye helps detect radiator leaks). Negative fluorescence does not rule out EG ingestion as not all antifreeze products add this dye. EG itself is not nephrotoxic, but alcohol dehydrogenase converts EG to toxic metabolites, principally oxalic acid. Competitive inhibition of alcohol dehydrogenase by ethanol is the treatment of choice for cats as 4-methylpyrazole (fomepizole) does not work well in cats. 4-Methylpyrazole directly inhibits alcohol dehydrogenase in dogs and is therefore recommended to treat dogs exposed to antifreeze.

Key to successful treatment is to confirm the diagnosis before the patient becomes azotemic. Azotemia is usually not present until about 24 hours postexposure, and therefore the goal is to diagnose AKI in a patient that is not azotemic. Five ways to accomplish this are: UV fluorescence, visualize calcium oxalate monohydrate crystals in urine (present in 3 hours postexposure in cats and 6 hours postexposure in dogs), increased serum osmolality and increased serum osmole gap (both occur in first hour postingestion), increased anion gap (3–6 hours postingestion), and perhaps the easiest way is a test kit that can be used in-house. Additionally, the FE_{Na} will be increased in the first 3 hours postexposure prior to the onset of azotemia.

The commercial diagnostic kit detects serum EG via a color change. The test takes 15 minutes to perform. The test is designed for serum and packet directions state it is useful only in the first 12 hours postexposure as it recognizes the parent compound, but not metabolites. We have used the kit on aqueous humor, serum, and urine up to 2 days postexposure with positive results achieved along with the diagnosis confirmed by histology. However, this is too late for effective therapy to be implemented. Commercial kits: Ethylene glycol test kits (Allelic Biosystems, Kearneysville, WV, and PRN Pharmacal, Pensacola, FL).

Serum phosphorus may increase before azotemia if the antifreeze product ingested also contains a phosphate rust inhibitor. Calcium oxalate monohydrate crystals are more plentiful in EG toxicity than are dihydrate crystals. Both types can be seen in urinalyses but they require careful searching with increased contrast as there may only be low numbers.

Osmole gap

Markedly increased osmole gap is diagnostic for EG. The increased osmolality and the gap are due to the parent compound ethylene glycol. Both are increased within one hour of ingestion. Osmolality is measured in serum by freezing-point depression. Serum osmolarity is calculated using the following formula, and osmole gap is calculated by subtracting the calculated osmolarity from the measured osmolality:

$$\text{Calculated osmolarity} = 1.86\,(\text{Na} + \text{K} + \text{Glucose}/18 + \text{UN}/2.8)$$

$$\text{Osmole gap} = \text{measured osmolality} - \text{calculated osmolarity}$$

Osmole gap interpretive guideline is: > 20 suggestive, > 30 diagnostic

Serum osmolality is rarely measured in private practices and the blood sample must be kept cool in transit to the referral laboratory. The technique to measure serum osmolality is based on the freezing point depression of a fluid. Ethylene glycol (antifreeze) is a small molecular weight molecule that lowers the freezing point of serum and therefore increases the measured osmolality and does so within an hour of ingestion.

The increased anion gap (AG) is due to the metabolites of EG and therefore an increased AG is seen after the increased osmole gap, usually around 3–6 hours postingestion. Most laboratories now report the AG in a chemistry panel, but it can be calculated via the following equation:

$$\text{Anion gap} = \text{Na} + \text{K} - \text{CL} - \text{HCO}_3$$

An AG >35 is suggestive of EG toxicity and >45 is highly suggestive. However, it is important to correlate the results with all of the other data in the case. Diagnosis of ethylene glycol toxicity should not be diagnosed by an increased anion gap alone.

Hypocalcemia often develops because the toxic metabolite, oxalate, will chelate calcium in the serum. This may produce marked hypocalcemia, in the range of 4–5 mg/dL total serum calcium. Many of the other laboratory and clinical abnormalities present in patients with antifreeze toxicity are not unique to this toxicity but are part of AKI. These include oliguria to anuria, dilute urine, casts in UA, and hyperphosphatemia. Azotemia does not develop for almost 24 hours postingestion of EG.

Diethylene glycol

This compound is related to ethylene glycol; however, it is less nephrotoxic. It is found in a variety of industrial products such as brake fluid, dyes, oils, ink, glue, lubricants, and heating/cooking fuel, as well as personal care products such as skin creams, deodorants, and toothpastes, and as an adulterant to create sweet wine or sweeten cough syrups. It is metabolized in the liver into various aldehydes and the acid 2-hydroxyethoxyacetic acid (HEAA) that is believed to be the nephrotoxic metabolite. Much like EG toxicity, the first phases of diethylene glycol (DEG) toxicity affect the GI and central nervous systems, producing an inebriation-like state that is followed by renal failure. Similar to EG toxicity both ethanol and fomepizole are used in the treatment (to prevent the formation of HEAA), but unlike EG there are no calcium oxalate crystals in the kidneys. Scattered cases in pets have been observed. The LD 50 for small mammals is between 2 and 25 g/kg.

Uroabdomen

Abdominal fluid Ct > serum Ct in concurrent samples; hyponatremia, hyperkalemia, hypochloremia, hyperphosphatemia; hole is usually located dorsally in the bladder; some animals can urinate and retain contrast dye; more common in males.

The best method to confirm uroabdomen is to measure creatinine in the abdominal fluid and serum concurrently. Abdominal fluid creatinine greater than serum creatinine is diagnostic. The slower diffusion of creatinine as opposed to UN (4 hours vs. 90 minutes) is why creatinine is measured preferential to UN in the diagnosis of uroabdomen, but either can be used. This difference in diffusion rates may be due to the difference in sizes of these molecules (UN is 60 Da and creatinine 113 Da) or their shape (urea is a simple chain and creatinine a ring structure). If the serum creatinine is increased in a patient with uroabdomen then the abdominal fluid creatinine will always be greater than the serum Ct concentration. The greater the difference between the serum and abdominal Ct values the greater the level of confidence of the diagnosis. The abdominal fluid creatinine does not have to be twice as high as the serum creatinine to confirm the diagnosis. Do not wait for a threefold or greater difference as the patient will benefit from surgical correction as early as possible. Because the hole in the bladder is almost always located dorsally the patient may still be able to urinate and retain radiopaque dye in the bladder. Cytologic examination of the abdominal fluid is not useful to establish the diagnosis. On rare occasions, urinary crystals and/or sperm may be seen in the abdominal fluid. These findings also confirm the diagnosis of uroabdomen. Classically uroabdomen is a disease of males due to their narrow urethra that is more easily obstructed than the wider urethra of females. In horses uroabdomen occurs most frequently in male foals less than 7 days old that were fine for several days postbirth and now are lethargic and anorectic. The urinary bladder ruptured during birth and there are no calculi. Uroabdomen in sheep, goats, cattle, and cats occur in males that have a calculus or mucus plug (cats) lodged in the most narrow portion of the urethra. The narrow portion in sheep and goats is the urethral appendage; in cattle it is the sigmoid flexure. In steers the rupture may also occur in the urethra. The bladder is intact and these individuals tend to have less severe clinical pathology abnormalities and a better surgical prognosis. In dogs uroabdomen is most typically seen post-trauma, e.g., hit by car. The characteristic serum electrolyte abnormalities include hyponatremia, hyperkalemia, and hypochloremia, along with hyperphosphatemia. In the experimental induction of uroabdomen in dogs these electrolyte abnormalities develop slowly over a 48-hour period.

Substances that are excreted into the urine in high concentration are now greater in the abdominal fluid than the blood and diffuse from the abdominal fluid into the blood, following their concentration gradient and gradually increase the serum concentration of UN, Ct, K, and P. Substances such as Na and Cl that are excreted into the urine in low concentration are lower in the abdominal fluid than the blood and therefore diffuse from the blood into the abdominal fluid gradually decreasing their serum concentrations. This is most notable for Na and Cl. Additionally fluid will flow into the abdominal cavity due to the irritation and increased osmolality from the urine mixing with the peritoneal fluid producing a third space and dilution effect on multiple analytes.

Differential diagnoses for hyponatremia, hyperkalemia, and hypochloremia are uroabdomen, Addison's disease, renal failure, GI disease (whipworms, salmonella, colibacillosis), Akita and other dog and sheep breeds with potassium-rich RBCs, chylothorax with repetitive drainage, and others (see Addison's disease in this book).

Patients in renal failure and with an intact urinary bladder will have increased concentrations of Ct and UN in all body fluids due to diffusion of Ct and UN from the blood. Therefore, Ct is increased in comparable amounts in abdominal fluid, thoracic fluid, cerebrospinal fluid, aqueous, and blood; however, the increase in these fluids will be less or nearly the same as the increased serum Ct concentration. The diffusion of Ct into other fluids is the basis of peritoneal dialysis in patients with renal failure.

Examples:

	Uroabdomen			Renal failure		Healthy
	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6
Serum Ct mg/dL	8.1	4.5	5	6.3	11	1.2
Abdominal Ct mg/dL	13.4	6.2	15	6.1	10	0.9

The first three examples are all characteristic of uroabdomen. The next two examples are azotemia with an intact bladder and the last example is a "normal" or at least nonazotemic patient. The patients with an intact bladder and azotemia may benefit from peritoneal dialysis. The procedure involves abdominal fluid removal, injection of warm saline into the abdomen, allow time for Ct to diffuse from the blood into the saline and remove the fluid. This cycle is repeated until serum creatinine is reduced to an acceptable concentration. In AKI, peritoneal dialysis may, along with other treatments, permit the patient to survive long enough for tubules to regenerate.

Azostick determination of abdominal versus blood UN has been used to diagnose uroabdomen and may be beneficial if after-hour chemical measurements are not available. However, the color differences should be obvious and the qualitative results confirmed with chemical measurements and/or all of the data should correlate superbly. This includes a male

animal that cannot urinate or does so in small volumes, a bladder that is small or collapsed, excess fluid in abdomen, azotemia, and characteristic electrolyte abnormalities.

Medullary washout

Primary diseases: Psychogenic polydipsia, liver failure, and hypoadrenocorticism.

Urea and sodium chloride are the main solutes that saturate the renal medullary interstitium. This hypertonic medullary intersitium combined with the vasa recta form the *counter current multiplier system*. This system is responsible for the passive absorption of water from the proximal convoluted tubules and is the first step in the process of concentrating the glomerular filtrate. If either urea or sodium, or both, are decreased in the interstitium of the medulla then passive absorption of water from the tubules is compromised and the filtrate concentration is impaired. Two syndromes that do this are chronic liver failure, such as acquired and congenital shunts (decreased urea) and hypoadrenocorticism (chronic hyponatremia). Liver failure caused by congenital shunts will have decreased serum concentrations of other substances produced by the liver such as albumin and cholesterol, and may have microcytosis as clues that this disease is present. Addison's patients will have azotemia, a Na: K ratio <23, and basal cortisol <2 μg/dL.

Psychogenic polydipsia will "wash out" the medullary interstitium via marked diuresis that provides insufficient time for urea and sodium reabsorption.

Fanconi syndrome

This is a heritable or acquired disease characterized by defects in proximal tubular reabsorption of various solutes that include one or more of glucose, sodium, calcium, bicarbonate, amino acids, and phosphate. Abnormal lab data includes dilute urine, inappropriate glucosuria, and proteinuria, increased fractional excretion of electrolytes, cystinuria, and aminoaciduria. Clinical signs range from asymptomatic to marked clinical alterations and death from renal failure. The disease is heritable and is present in 10–33% of Basenjis and is seen in Norwegian elkhounds, Shetland sheepdogs, and Schnauzers. It is recognized by breed susceptibility, clinical signs, and UA.

Nephrotic syndrome

Proteinuria, hypoproteinemia, hypoalbuminemia, ascites, and hypercholesterolemia, with or without azotemia, define this syndrome.

The combination of proteinuria, hypoalbuminemia, edema, ascites, and hypercholesterolemia are the classical features of the nephrotic syndrome but not all are present in every case, or are not detected. Ascites and edema may not always be present, but if the rest of the features are present, that is adequate to use this term (see section on "Protein Abnormalities" and tables and figures in this chapter). The nephrotic syndrome implies a lesion is present in glomeruli, either amyloidosis or glomerulonephritis. End-stage kidneys from any cause could present with similar features. Dogs with severe and chronic lesion pathology usually have peripheral edema and some develop thrombi due to a decrease in antithrombin III (AT III). This is a common syndrome in veterinary medicine because glomerulonephritis is so common in older dogs.

Proteinuria will precede azotemia in most cases. The more severe the lesions the more likely azotemia will be present. Approximately half of the dogs with glomerulonephritis will be azotemic and 75% of the dogs with amyloidosis will be azotemic. Dogs that are azotemic at initial diagnosis have the shortest survivals. Dilute urine will be seen in 50–60% of the cases. Casts are often present and they can be hyaline (protein-rich) or of other types. Amyloidosis may account for more cases simply because the glomerular lesions are more severe and therefore there is greater proteinuria. There is no effective treatment for amyloidosis. Glomeruli cannot regenerate, but if the lesions are mild and the underlying cause of inflammation predisposing to glomerulonephritis can be removed it is possible glomerulonephritis patients can survive for several years.

Progressive familial renal nephropathy/dysplasia

Chronic progressive familial nephropathy (renal dysplasia) is one of the most common causes of renal failure in young dogs, with some presenting as early as eight weeks of age. This is not hypoplasia as the kidneys start with a normal number of nephrons and then progressively lose nephrons over time. In severe cases the kidneys are shrunken and fibrotic, but there often are regions of embryonic glomeruli, tubules, and interstitium. There also are other familial glomerulopathies that look similar clinically and histologically. Regardless of nomenclature there are several diseases of high prevalence in many purebred animals that present at a young age. Amyolidosis has breed predilections as well. The lesions vary in severity, as do the laboratory findings. Clinical pathology results look like CKD. The kidneys appear shrunken on imaging, but the patient is a young or middle-aged purebred dog. Of all of the causes of renal failure, these diseases probably have the highest incidence of concurrent hypercalcemia. Hyperphosphatemia will accompany the azotemia, and therefore soft-tissue mineralization is prominent. Some breed-specific anomalies include the following:

- Progressive familial renal nephropathy is observed in the Lhasa Apso, Shih Tzu, soft-coated Wheaten terrier, standard poodle, miniature schnauzer, Alaskan malamute, golden retriever, Norwegian elkhound, and Doberman breeds.
- Inherited glomerulopathies have been documented in the Samoyed, Bernese mountain dog, bull terrier, chow chow, English cocker spaniel, and Rottweiler breeds.

- Amyloidosis is noted in Abyssinian, Siamese, and Oriental shorthair cats and in Shar Pei, beagle, and English foxhound dogs.
- Polycystic kidney disease is observed in the Persian cat, West Highland white and Cairn terrier, and bull terrier.

Neoplasms

Lymphoma is the most common tumor in the kidneys of animals but is a secondary tumor, metastatic to this site. Primary tumors are uncommon and split approximately equally between mesenchymal and epithelial. Primary renal tumors are tubular adenomas and carcinomas, nephroblastomas in young animals, fibromas, and hemangiosarcomas. Other neoplasms of the kidneys are infrequent and detailed descriptions can be found in other resources [19].

Bladder tumors account for approximately 1.0% of all canine neoplasms. Approximately 90% of urinary bladder neoplasms in dogs, cats, and horses are epithelial and malignant. Urothelial carcinoma (UC) or transitional cell carcinoma (TCC) is the most common tumor of the bladder in all species. Tumors in the kidney and bladder are difficult to diagnose clinically. Clinical signs and laboratory data are not specific. Urinalysis abnormalities are seen in 90% of dogs with tumors of the urinary bladder, but these abnormalities are also nonspecific. The most common UA abnormalities are hematuria (>75%), pyuria (50%), proteinuria (30%), and bacteriuria (30%). Cystitis or uroliths are much more likely to cause these abnormalities than is neoplasia. Hypertrophic osteopathy occurs with several different bladder tumors. There are numerous reports of hypertrophic osteopathy with bladder rhabdomyosarcomas in young dogs, but this is an uncommon tumor.

Renal lymphoma

Rarely is a renal tumor diagnosed from examination of cells in the urine; most cases will be diagnosed from ultrasound-guided fine needle aspiration into the focal renal mass. Lymphoma, however, can cause marked bilateral renomegaly and aspirational cytology of an enlarged kidney without ultrasound guidance can be performed to diagnose lymphoma in these cases. Neoplastic lymphoid cells appear as they do in lymph nodes and other organs infiltrated with lymphoma. Sometimes renal tubules are aspirated concurrently (Figure 24.A.7). If lymphoma is in the kidneys it will also be located elsewhere. An unusual feature of lymphoma in the kidneys is the occasional tumor that stimulates erythropoietin production resulting in polycythemia. This is not unique to lymphoma and has been seen with other neoplasms and non-neoplastic renal masses. A nonregenerative anemia due to decreased erythropoietin production combined with anemia of chronic inflammatory disease is much more likely than polycythemia.

Transitional cell carcinoma

TCC of the urinary tract is synonymous with UC. It is the most common tumor in the urinary system from the renal pelvis to the distal urethra. Clinical signs are similar across species. In dogs they include weight loss, weakness, dysuria (85%), pollakiuria (40%), and incontinence (10%). The Scottish terrier has 20-fold greater likelihood of developing UC than mixed breeds. Etiology is multifactorial and likely involves interactions of susceptible genes and environmental factors. Interestingly, consumption of cruciferous vegetables may help reduce the risk of bladder cancer in humans and dogs [20].

Activation of BRAF mutation is present in canine UC tissue and was detectable in the urine of dogs with UC [21]. The mutation was found on chromosome 16 in canine UC cell lines and in >80% of 62 naturally occurring canine UC cases [21]. BRAF mutation is rare (<1%) in human UC, which also tends to be much less invasive than canine UC. A genomic test is available for early and noninvasive diagnosis of canine UC in patients with this mutation. The test requires a urine sample with a low number of neoplastic cells [22]. Approximately 80% of dogs with TCC have a single point mutation in the BRAF gene; likewise, the test has a high specificity and moderate sensitivity. The test is not affected by the presence of blood or bacteria in the urine sample [22]. Fluorescence in situ hybridization (FISH) is used to detect chromosomal aneuploidy in cells present in the urine of humans with suspected bladder cancer and has been developed for use in dogs [23]. If molecular changes precede morphologic changes, then these tests could be used to screen or detect bladder cancer early and monitor recurrence. Molecular tests do not replace traditional diagnostic methods but can be used in tandem to help establish a diagnosis or to determine if further testing is warranted. Other molecular based tests include a PCR based assay, *BRAF* mutation, calgranulins, microRNAs, and peptide cancer-binding ligands. If tests can be developed that use urine samples to differentiate dogs with TCC/UC from dogs with diseases that have similar clinical problems such as cystitis or urolithiasis than we may be able to recognize the tumor early in its course when treatments are more effective. Presently, by the time we recognize TCC/UC the tumor has already invaded the bladder wall or has metastasized. Screening tests are useful in annual wellness exams, especially for breeds with high a prevalence of TCC/UC such as the Scottish terrier.

We need tests that can recognize UC earlier because 20% of dogs have clinically detectable metastases at the time of clinical diagnosis. Of these, 50% actually have metastases and 90% are expected to develop metastases if the tumor is allowed to progress. This is likely due to the combination of a highly malignant tumor, which remains occult and for which early diagnostic tests are not performed. Most cases of bladder cancer are recognized when the tumor is advanced, and therefore the prognosis is uniformly poor.

TCC can be diagnosed by finding neoplastic cells in the urine (Figures 24.A.4–24.A.6). Approximately 30% of UC/TCC can be diagnosed via urine cytology, 75% via urethral or prostatic washes, and 90% via aspiration cytology of the mass. Cytological diagnosis of neoplastic cells in the urine seems a logical diagnostic aid but must be interpreted cautiously as inflammation of the urinary tract stimulates hyperplasia and dysplasia of transitional epithelium, making the distinction of hyperplasia from dysplasia or neoplasia difficult. Furthermore, urine is caustic to cells and will cause cellular deterioration if preparations are not made promptly.

The best method to diagnose TCC in urine is to collect a fresh sample, centrifuge the urine to prepare a concentrated preparation, pour off the supernatant, make a film of the sediment, and stain with a Romanowsky stain (do not diagnose from a wet-mount, sedi-stain preparation). Additionally, a diagnostic laboratory can prepare a cellblock of the sediment and prepare a histologic section. Tumor cells will be in clusters or individual, neoplastic cells will be extremely large (>40 μm diameter), and will have marked cytologic and nuclear atypia (various sizes and shapes of cells, nuclei, and nucleoli). Some cells will contain Melamed-Wolinska bodies, which are large cytoplasmic vacuoles diagnostic for UC (Figures 24.A.5 and 24.A.6). The more numerous these abnormalities and the less inflammation present, the more likely the cells are neoplastic. If only a few of these cytologic abnormalities are identified and there is inflammation, then the cellular atypia is more likely due to dysplasia or hyperplasia than to neoplasia. Correlate results with other data, such as a mass in the trigone region of the bladder, unresponsive hematuria, and age of patient. TCC can seed and grow in the abdominal incision site used for surgical removal of the tumor. This occurs in approximately 10% of cystotomies performed on dogs with UC [24]. A few reports exist of seeding from fine needle aspiration cytology, but this should not prevent attempts to diagnose the tumor via this means. Other means of confirming the diagnosis (catheterization, wash) can be tried first. Seeding of TCC/UC in the abdominal wall from FNA is unlikely but owners should be made aware of this possibility and that it could complicate treatments. There are also reported cases of abdominal wall TCC/UC in dogs in which a contributing cause could not be found [24].

Basic fibroblast growth factor (bFGF) is a pro-angiogenic peptide used as a marker for urologic and nonurologic tumors in humans and has been detected in high concentrations in the urine of dogs with bladder cancer. Although the numbers of dogs were small, one study demonstrated significantly higher concentrations of bFGF in dogs with bladder cancer than in normal dogs or dogs with urinary tract infection (UTI). Results are expressed as ng/g creatinine, and the median concentration of bFGF was 2.23 in normal dogs, 2.45 in dogs with UTI, and 9.86 in dogs with bladder cancer. Of dogs with cancer 86% could be correctly identified by increased concentrations of bFGF, and 90% of dogs with UTI did not have increased concentrations. The commercially available ELISA test kit uses a monoclonal antibody to recognize natural and recombinant human bFGF.

Another commercially available test is the bladder tumor-associated antigen (BTA). The assay detects a glycoprotein antigen complex that is of host basement membrane origin and partly of tumor origin. The dipstick test was used on 65 dogs, 20 with TCC, 19 healthy controls, and 26 controls. Test sensitivity (dogs with cancer have positive results) was reported to be 78% and the specificity (dogs without cancer have negative results) 90%. Results are not quantified, they are either positive or negative. False-positive results can be seen with pyuria, hematuria, proteinuria, and glucosuria. When these abnormalities are present the utility of the dipstick test is greatly limited, and if used, the test should be performed in conjunction with cytology and other ancillary tests. The dipstick test may be more appropriately applied as a screening test in older dogs for bladder cancer; however, cost and index of suspicion may limit utility.

Second-generation BTA statistical tests use a monoclonal antibody to recognize a human complement complex that is secreted into the urine of humans with bladder cancer. When applied to dogs with TCC the results have been negative, and they were attributed to the lack of cross-reactivity of the monoclonal antibody to canine TCC generated antigens.

Definitions, glossary, and principles

Definitions

Urea nitrogen (UN)

This is produced in the liver from ammonium and bicarbonate, and is excreted from the body via glomerular filtration through the kidneys. The most common cause for an increase in serum UN is decreased GFR, less common causes, and to lesser magnitudes include high-protein diet, hemorrhage into the GI tract, increased catabolism, and fever. An increase in UN due to a decrease in GFR will not be detected until approximately 75% of both kidneys are not filtering adequately. A decrease in UN is usually due to chronic liver disease. The units of serum or plasma UN are reported in mg/dL, and as μmol/L, internationally. The conversion factor between these units is: 1 mg/dL × 0.7140 = μmol/L (e.g., 10 mg/dL UN is 7.1 μmol/L). The atomic weight of urea is 60 Da. Approximately half of the UN excreted into the tubules is reabsorbed passively in the proximal tubule and actively by the cells of the collecting ducts. Urea is held in the medullary interstitium and in combination with Na make the necessary concentration gradient for the "counter current multiplier" system (CCM). If UN and/or Na are not in sufficient concentration in the interstitium the CCM is compromised and dilute urine is produced. Renal, prerenal and postrenal diseases can increase serum UN and the increase is comparable for all three causes.

Creatinine (Ct)

Creatinine is a breakdown product of muscle creatine and creatine phosphate. It is excreted via glomerular filtration in the kidneys. It is produced at a fairly constant rate dependent on muscle mass; 1–2% of muscle creatine is converted to creatinine/day (human). The most common cause for an increase in serum Ct is decreased GFR. Less common minimal causes include increase breakdown of muscle, increased catabolism, and fever. An increase in Ct due to a decrease in GFR will not be detected until approximately 75% of both kidneys are not filtering adequately. Creatinine concentration is reported in mg/dL and as μmol/L internationally. The conversion factor between these units is: 1 mg/dL × 88.4 = μmol/L (e.g., 1 mg/dL Ct is 88.4 μmol/L). Minimal to no creatinine is reabsorbed in tubules and therefore endogenous Ct clearance can be measured to indicate GFR. Noncreatinine chromogens, such as glucose, ketones, vitamins A and C, carotenes, oxyglobin, pyruvate, and uric acid, may falsely increase measured creatinine. This occurs most frequently in cows and horses. Approximately 50% of measured serum creatinine consists of noncreatinine chromogens. If creatinine is increased due to renal failure then the majority of the increased serum Ct is from decreased GFR and not noncreatinine chromogens. Renal, prerenal and postrenal diseases can increase serum Ct and the increase is comparable for all three causes.

Azotemia

This is the most commonly used laboratory indicator of decreased GFR (renal dysfunction) and occurs when the serum concentration of UN and/or Ct concentrations are increased, to any degree. An increase in UN or Ct due to a decrease in GFR will not be detected until approximately 75% of both kidneys are not filtering adequately. Azotemia indicates the kidneys are not functioning adequately. However, this may be due to diseases that are in front of kidneys (prerenal), in the kidneys (renal: glomerular, tubular, interstitial, pelvis), or after the kidneys (postrenal), or due to combinations of each. The greater the concentration of UN/Ct the more likely the disease is severe, but there are no concentrations that indicate irreversibility or that distinguish prerenal, renal, postrenal, or combinations. Patients may be azotemic but are not yet necessarily uremic (see below). Although azotemia means UN/Ct are increased in the blood both substances are also increased in "all" bodily fluids (CSF, aqueous, peritoneum, joint, etc.). This occurs because both UN and Ct have small molecular weights and they diffuse freely across membranes.

Uremia

This is the term used when clinical signs are attributed to azotemia. Uremia results in anorexia, weight loss, depression, stupor, vomiting, oral ulcers, anemia, mineralization, electrolyte and fluid imbalances, and hormone deficits and/or increases. This is caused by accumulation of nitrogenous waste products and uremic toxins in blood. Uremic toxins is an umbrella term for the retention of all solutes, many of which are unmeasured, normally excreted by a healthy kidney that contribute to "uremia."

Prerenal azotemia

This is recognized when azotemia is present and USG is concentrated. To be considered concentrated, USG should be greater than 1.030 in dogs, 1.035 in cats, and 1.025 in horses and cattle. The urine s.g. is often >1.050 when the azotemia is due to dehydration. Causes of prerenal azotemia include any state that results in a decreased renal blood flow, including hypovolemia due to dehydration, shock, and cardiac insufficiency. Prerenal conditions are the most common cause of azotemia. If these conditions persist, they can lead to kidney damage and renal azotemia. Prerenal azotemia is often superimposed on either renal or postrenal, usually due to concurrent dehydration. If the azotemia is only due to prerenal causes it is usually mild e.g., <100 mg/dL. However, there are no concentrations of UN/Ct that rule out prerenal as the cause. Dehydration will cause a more rapid increase in serum UN than Ct and a disproportionate increase in UN to Ct (increased UN/Ct ratio). Ratio of UN/Ct is now reported by some clinical laboratories to help identify prerenal azotemia.

Renal azotemia

This is recognized when azotemia is coupled with inability to concentrate urine, especially isosthenuric urine, as indicated by a USG between 1.007 and 1.013 (do not use strict cutoffs of a single USG to define isosthenuria). Isosthenuria implies that the kidneys are damaged to such an extent that they are no longer able to concentrate or dilute the plasma ultra-filtrate (urine). An SG of 1.007–1.013 is approximately the SG of plasma (295–300 mOsm/L). Renal azotemia can be due to acute or CKD. The defect in renal function may arise from many different diseases of the glomeruli, tubules, interstitium, renal pelvis, and, least likely, from renal blood vessels. Renal azotemia identifies the lesion is in the kidneys, but it does not localize the disease to a structure, type of disease, or etiology.

Postrenal azotemia

This is associated with any obstruction to the outflow of urine or rupture of urinary bladder or urethra. Oliguria or anuria will be observed, and any USG is possible. In theory, the nephrons (kidneys) are excreting UN and Ct adequately into the ultra-filtrate, but UN and Ct are not excreted from the body. If the cause is obstruction then some UN/Ct can be

reabsorbed through the bladder wall but more importantly backpressure from the obstruction causes structural lesions (hydronephrosis) and/or functional lesions in all renal structures. A ruptured bladder or urethra cause azotemia when UN and Ct are reabsorbed through the peritoneum (ruptured bladder) or subcutaneous tissues (ruptured urethra). Both molecules are small (low atomic weight) and are passively reabsorbed easily from regions of high concentration gradient (peritoneum) to lower concentration gradient (blood).

Nephrons

These are the smallest individual anatomic units in the kidney, and are composed of a glomerulus, tubule, and collecting tubule. There are approximately one million glomeruli per kidney.

Renal disease

This is classified as a structural or biochemical lesion in kidney. If the lesion is focal, it may never produce clinical problems (such as with the interstitial nephritis caused by ascarid migration). Renal disease is a continuum that begins with renal insufficiency and finishes with end-stage renal disease.

Renal insufficiency

This is a state in which nephrons are functionally impaired but not yet sufficiently damaged as to result in clinically apparent disease. Unaffected individual nephrons compensate for these losses by hypertrophy, but with progression of disease, enough nephrons become impaired so that they are unable to maintain the health of the animal.

Renal failure

This exists when roughly at least two-thirds of functional renal mass is impaired. Urine cannot be concentrated adequately and polyuria, oliguria, or anuria results. When three-quarters of nephrons are dysfunctional, remaining nephrons cannot compensate and azotemia is detected.

Clinical signs associated with renal failure are attributable to a loss of functional renal tissue, and accumulation of nitrogenous and other waste products in blood. Signs may include anemia, vomiting, lethargy, anorexia, weight loss, vasculitis, glossal, and/oral ulcers, gastric erosions or ulcers, bleeding diatheses, petechiae, thrombosis, gastrointestinal tract bleeding, parathyroid hyperplasia, mineralization of soft tissues, and fibrous osteodystrophy.

Glossary

Anuria: Refers to a state wherein there is no urine output.

Dysuria: Describes painful or difficult urination.

Glomerular filtration rate (GFR): The volume of plasma filtered by the glomerular capillaries into Bowman's space per unit of time. A GFR of 3–6 mL/min/kg is normal for dogs and 2–4 mL/min/kg is considered normal in cats. A decrease in GFR can occur due to prerenal, renal or postrenal causes.

Microalbuminuria: Describes a state in which small quantities of protein are lost in urine but are below the limit of detection of reagent sticks. Microalbuminuria is urinary albumin 1–30 mg/dL and albuminuria ("overt albuminuria") is urine albumin >30 mg/dL in urine normalized to a USG of 1.010. Persistent microalbuminuria may indicate early or mild renal disease.

Oliguria: Indicates reduced urine output.

Pollakiuria: A term indicating an increased frequency of urination. However, the total volume of urine produced may not be increased. Pollakiuria is associated with diseases of the urinary bladder, urethra, and vaginal canal.

Polydipsia (PD): A term denoting an increased volume of water is consumed within a 24-hour period. It is associated with renal failure and multiple other causes. This usually occurs secondary to polyuria caused by the loss of urinary concentrating ability. In dogs, polydipsia is considered as drinking >90 mL/kg/d, and in cats >45 mL/kg/d.

Polyuria (PU): A term denoting an increased total volume of urine produced within 24 hours. The normal range in dogs is 20–40 mL/kg/d (1 mL/kg/hr), and in cats, 10–20 mL/kg/d.

Proteinuria: Refers to protein in the urine as detected by reagent sticks or SSA protein precipitation methods. It is caused by preglomerular, glomerular, or postglomerular causes. Persistent proteinuria coupled with a quiescent urine analysis suggests a glomerular lesion, such as amyloidosis or glomerulonephritis.

Stranguria: Refers to straining to urinate.

Principles

The ability of the kidneys to concentrate urine is a good indicator of renal function. Loss of this capability is one of the earliest signs of renal failure, preceding azotemia in all species except cats.

Expected urine specific gravity: The expected USG of a random urine sample from a healthy domestic animals 1.020–1.045 for dog, horse, cattle, and 1.025–1.050 for cat. The USG must always be considered in conjunction with the hydration status. On any random urine sample, an adequate USG is considered to be >1.030 in the dog; >1.035 in cat; and >1.025 in horse and bovine. Dogs are not born with an adult's level of concentrating capacity, and dilute urine is expected up to four weeks of age. There are no differences in protein, blood, glucose, ketones, or bilirubin based on age.

Dilute urine specific gravity: For the purposes of this chapter, dilute urine refers to urine that is inappropriately concentrated for the patient's hydration status. In many instances this will match with hyposthenuria. However, there are clinical situations in which the USG is >1.020, and yet this is inappropriately concentrated. For example, in the clinical setting adequate renal function in a healthy cat is generally associated with a USG of >1.035. If a dehydrated cat presents, the USG is expected to be >1.035 (and often >1.060). However, if this same patient presents with a USG 1.025, the urine is considered inappropriately concentrated (i.e., dilute for this cat). The next step is to verify this clinical finding (as described above) and begin an investigation to determine the underlying cause (e.g., osmotic diuresis/glucosuria, pyelonephritis, CKD, etc.) by evaluating clinical signs, complete bloodwork, diagnostic imaging, urine culture and sensitivity.

Hyposthenuria occurs when the kidneys actively produce urine with a USG <1.007, or with an osmolality less than that of plasma, e.g., <300 mOsm/kg. Hyposthenuria has several renal and nonrenal causes, and indicates that the kidneys are healthy enough to actively dilute the plasma ultrafiltrate.

Isosthenuria indicates a USG similar to the SG of plasma, i.e., 1.008–1.012 and 1.007–1.013 are reported in different sources. This USG implies that the nephrons were unable to either concentrate or dilute the plasma ultrafiltrate. Isosthenuric urine with concurrent azotemia indicate renal failure and the lesion involves the tubules or the medulla. If the disease was confined to the glomeruli then tubules should be able to concentrate urine, in principle. However, 90% of blood supply to the tubules passes through glomeruli therefore glomerular diseases will secondarily affect tubules and ability to concentrate urine is compromised.

Hypersthenuria, or baruria, are two rarely used terms that describe urine with an SG greater than 1.013. These terms imply that urine has been concentrated to greater than the isosthenuric range.

Differential diagnoses for polyuria and polydipsia (PU/PD) include renal failure (with or without azotemia), diabetes mellitus, primary or secondary diabetes insipidus, hyperadrenocorticism, hypercalcemia, pyometra, psychogenic polydipsia, and medullary washout (associated with hypoadrenocorticism or liver failure). A complete list is in Table 24.4.

Water reabsorption occurs passively/osmotically in the proximal convoluted tubules and descending loop of Henle. It is actively reabsorbed in the collecting tubules through the actions of antidiuretic hormone (ADH).

Medullary washout occurs when the solutes urea and sodium chloride, located in the interstitium of the renal medulla, are decreased. This loss of hypertonicity in the medulla results in production of a dilute urine, and the clinical signs of PU/PD. Decreased urea happens with hepatic shunts and severe chronic liver disease. Decreased sodium happens with hypoadrenocorticism.

Creatinine clearance is the volume of plasma that is cleared of creatinine per unit time and can be used to estimate GFR. In dogs essentially 100% of creatinine entering the filtrate is excreted (male dogs also secrete a small amount of Ct via the proximal tubules). However, 40–60% of UN is reabsorbed from the filtrate and the amount reabsorbed varies with hydration status. Therefore, creatinine clearance is an acceptable means to estimate GFR and UN clearance is not acceptable.

Acute kidney injury (AKI): The onset of AKI is swift. It is commonly due to a nephrotoxin that causes necrosis of tubules (nephrosis), and less commonly due to an infectious etiology (e.g., leptospirosis), or ischemic injury. AKI is typified by azotemia and inability to concentrate urine coupled with hyperphosphatemia, variable changes in potassium, a normal to increased PCV, and good body condition. Potassium >8 mEq/L can be life-threatening. It is generally accompanied by anuria or oliguria. This term is used interchangeably with acute renal injury, acute renal failure, acute kidney failure, acute renal insufficiency, acute kidney insufficiency.

Chronic kidney disease (CKD) can be due to chronic glomerulonephritis, amyloidosis, chronic interstitial nephritis, chronic pyelonephritis, progressive familial renal dysplasia, etc. Lab data include azotemia, inability to concentrate urine, and mild nonregenerative anemia. If the disease process involves the glomeruli, there may be hypoalbuminemia. The onset of CKD is chronic, progressing over months to years. As a result, the patient has poor to thin body condition. The etiology is often unknown as the primary event was months to years previous to diagnosis. This term is used interchangeably with chronic renal disease, renal failure, and chronic kidney failure.

Acute on chronic renal failure implies there is underlying CKD and now something else has acutely made the renal failure "worse." There are multiple potential etiologies for the acute exacerbation, including dehydration, progression of the chronic primary disease and/or a second disease process superimposed on the first (e.g., pylenonephritis occurring in a cat with CKD).

Formed elements in urine: Casts may be observed during microscopic examination of urine, and suggest tubular disease. They are formed in the loop of Henle and in the distal and convoluted tubules. Rare hyaline and fine granular casts (1–2/low-power field) may be observed in concentrated urine and are considered normal; however, casts found in dilute urine are considered abnormal.

Crystalluria refers to crystals in urine. *Nephroliths* are stones found in the kidney, while the term *urolith* indicates the presence of stones in the bladder or urethra.

Staging renal disease: The severity of renal disease is graded as 1, 2, 3, or 4 based on severity of clinical signs, physical examination results, and laboratory abnormalities. As the stage of renal disease progresses so do the severity of the laboratory abnormalities and the percentage of animals that have an abnormality. For example, 20% of azotemic dogs also have mild hyperphosphatemia (~6 mg/dL) in stage 1. This percentage increases to 100% of dogs in stage 4 renal failure, where the serum phosphorus will be markedly increased (>20 mg/dL).

The *nephrotic syndrome* is due to chronic glomerular disease. It is characterized by proteinuria, hypoproteinemia, hypercholesterolemia, ascites, and edema. There may or may not be an azotemia. With nephrotic syndrome, the lesion is in glomeruli, e.g., amyloidosis or glomerulonephritis.

Other terms, disease conditions, and methods of analyzing renal function

Chronic progressive familial nephropathy (renal dysplasia) is one of the most common causes of renal failure in young dogs, and it has a high prevalence in many purebred breeds. In severe cases, kidneys are shrunken and fibrotic and look like any end-stage kidney disease. They retain regions of embryonic glomeruli, tubules, and interstitium.

Uroabdomen or uroperitoneum is typified by hyponatremia, hypochloremia, and hyperkalemia. Serum Ct and UN are variable, but abdominal fluid Ct:serum Ct is ≥ 1.5–2 : 1. This commonly occurs in males due to their narrow urethra that becomes obstructed, or in male foals in which the dorsal bladder wall ruptures during birth or from being stepped on.

Paradoxical aciduria is a unique situation seen in dairy cattle with displaced abomasums, or other animals with proximal duodenal blockage, and is typified by profound hypochloremia, severe metabolic alkalosis, and acidic urine.

Transitional cell carcinoma (TCC) is a highly malignant tumor of transitional epithelium and is the most common tumor of the urinary bladder and the urinary excretory system.

Monitoring renal disease patients over time is advisable for purposes of prognostication and for monitoring response to therapy. Practical methods include accurate weight of the patient, water intake and urine volume measurement, USG, and periodic serum UN and Ct. If closer monitoring is desired, then specialized studies such as ultrasonography, endogenous or exogenous creatinine clearance, fractional excretion of sodium, monitoring of microproteinuria, clearance studies of inulin, iohexol, radioisotopes, and renal scintigraphy can be undertaken.

Essentially 100% of sodium is reabsorbed from the glomerular ultrafiltrate and therefore less than 1% is excreted in the urine of animals with normal renal function. If there is increased renal loss of sodium as measured by an increase in the urinary fractional excretion of sodium (>1%) it indicates renal insufficiency or failure. A fractional excretion of sodium is <1% indicates prerenal azotemia.

Urinary protein:Ct ratio (UPC): The concentration of protein and creatinine are measured in a random urine sample, and urine protein concentration is divided by urine Ct concentration. This is used to quantify the degree of proteinuria, and to identify what the most likely disease process affecting the kidneys is.

In dogs, a UPC <0.5 is considered normal, 0.5–1 is inconclusive, and >1 is considered abnormal.

Urine cortisol:Ct ratio (UCCR): Urinary cortisol concentration is a good estimate of cortisol production over the preceding 24 hours, and the UCCR is used to rule out hyperadrenocorticism (Cushing's disease). Of dogs with normal UCCR 90% do not have hyperadrenocorticism. About 95% of dogs with hyperadrenocorticism have increased UCCR, but 80% of dogs with nonadrenal disease have increased UCCR. The latter animals are generally sick and stressed, and the finding of an increased UCCR in these individuals is considered a false-positive result. Creatinine and cortisol are measured in a sample of urine collected at home first thing in the morning.

Urine bile acid:Ct ratio: With increased production, bile acids are excreted in the urine. Increased urine bile acid:Ct ratios have the same diagnostic value as measuring serum bile acid. Creatinine and total bile acids, or bile acid components, are measured in a random urine sample from a nonfasted dog or cat, a ratio is calculated and compared to published data or the reference laboratory's reference interval.

Appendix 24.1

A Urinalysis and Urinary System Imagery

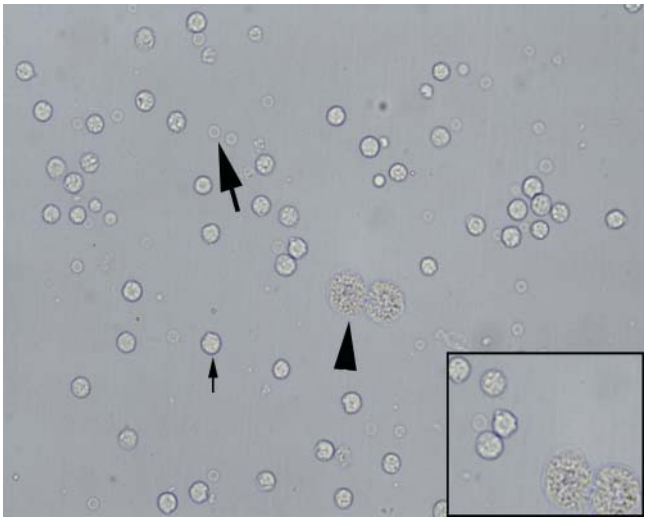

Figure 24.A.1 Urine sediment, unstained. There are numerous leukocytes (small arrow), fewer erythrocytes (large arrow), and two epithelial cells (arrowhead). Despite the number of white cells, there are no bacteria visible. A culture of the urine is required to verify there are no bacteria. ×400.

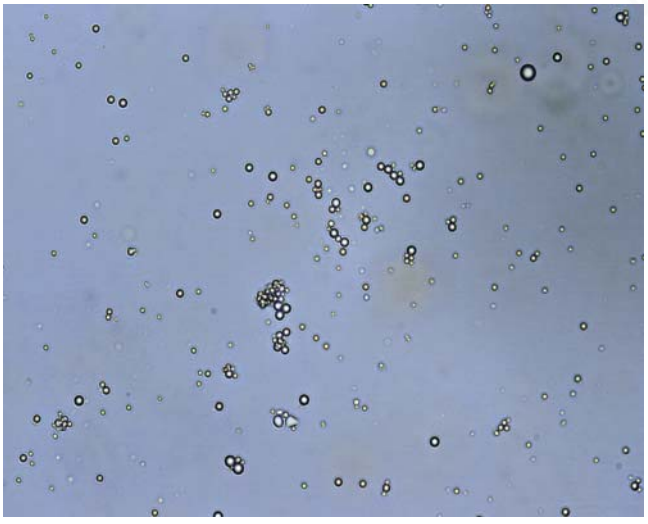

Figure 24.A.2 The numerous lipid droplets present are frequently noted in feline urine and are suspected to come from renal tubular epithelium but have unknown significance. They may be mistaken for red blood cells, but lipid droplets are variably sized and are in a different plane of focus from cellular elements in the urine due to their lower density. ×100.

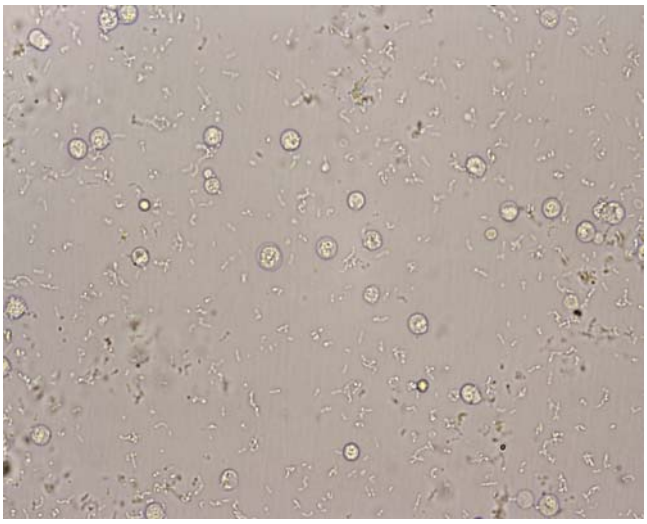

Figure 24.A.3 Urine sediment, unstained. There are numerous leukocytes and rod-shaped bacteria present, indicating bacterial urinary tract infection. ×400.

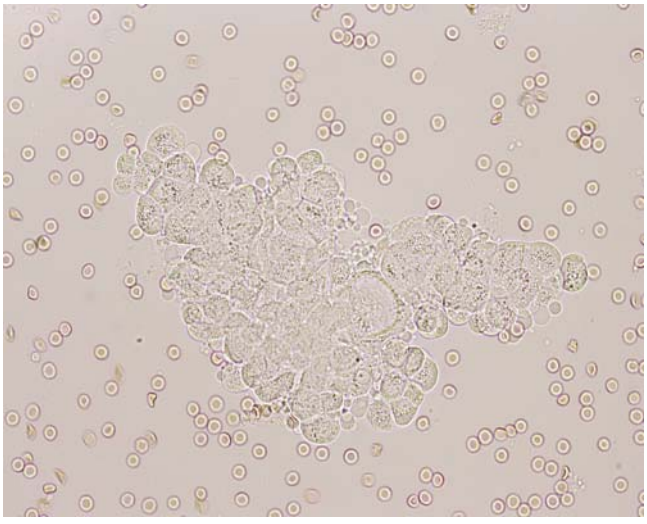

Figure 24.A.4 Urine sediment, unstained. Note the large cluster of many pleomorphic epithelial cells on a background of erythrocytes. This dog had a lesion in the trigone of the urinary bladder confirmed as transitional cell carcinoma. ×400.

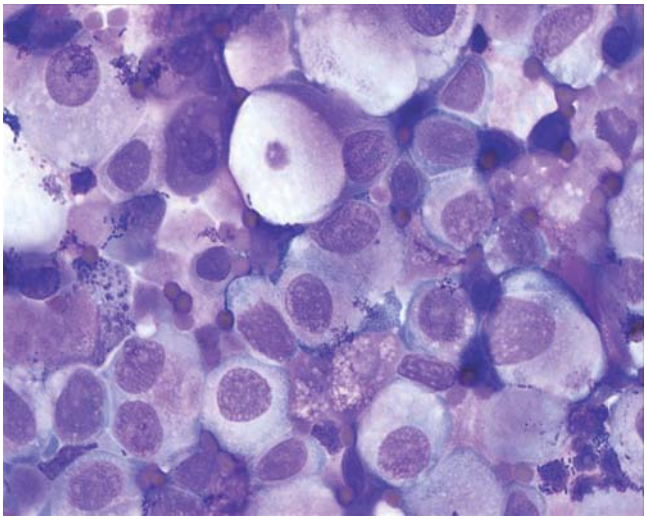

Figure 24.A.5 Urine sediment, Wright-Giemsa stain. There are many pleomorphic epithelial cells without any inflammation consistent with transitional cell carcinoma. Key to the diagnosis is the overall number of epithelial cells, the variability in sizes and shapes of these cells, and the absence of inflammation. ×1000.

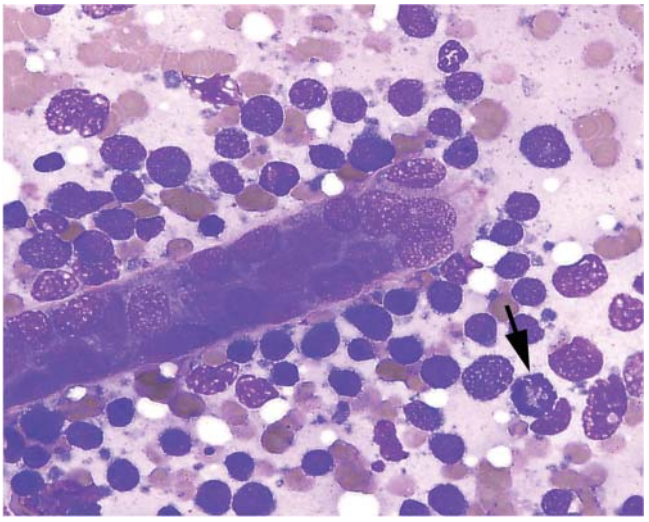

Figure 24.A.7 Kidney aspirate, Wright-Giemsa stain. A renal tubule is surrounded by numerous intermediate to large lymphoid cells with one mitotic figure (arrow); diagnosis is renal lymphoma. ×500.

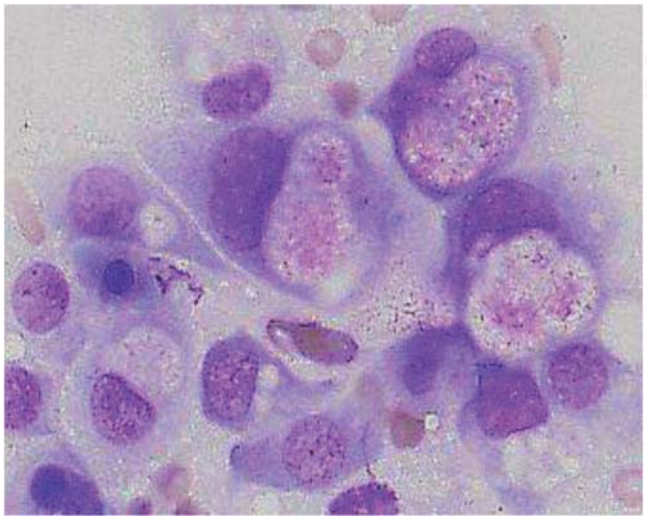

Figure 24.A.6 Urine sediment, Wright-Giemsa stain. These pleomorphic epithelial cells, seen in the absence of inflammation, occasionally have large cytoplasmic vacuoles containing pink material characteristic of transitional cell carcinomas. ×1000.

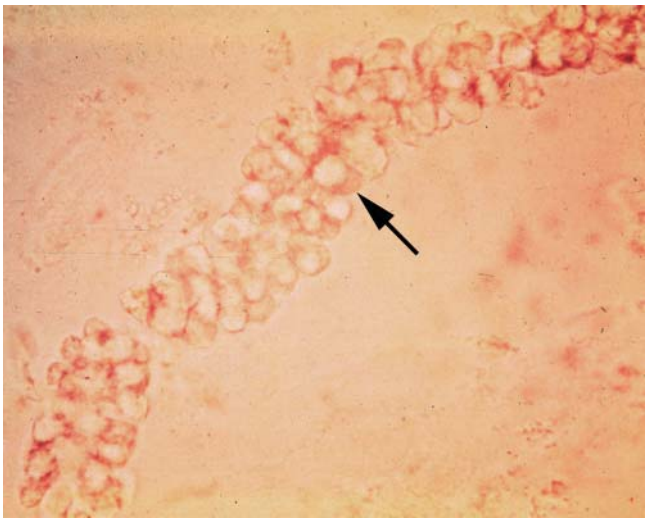

Figure 24.A.8 Urine sediment, unstained. Leukocyte casts (arrow) are quite fragile, seen infrequently, indicate inflammation is in renal tubules and therefore suggests pyelonephritis. ×400.

Figure 24.A.9 Urine sediment, unstained. Erythrocyte casts (arrow) are fragile and infrequently seen. When present, they indicate hemorrhage within the renal tubules. ×400.

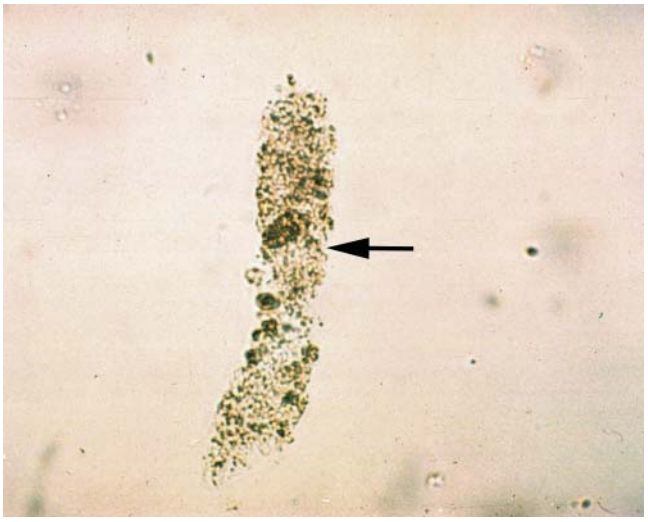

Figure 24.A.11 Urine sediment, unstained. The coarse granular cast (arrow) shown here is seen most frequently with a toxic insult (nephrosis) and can be caused by renal ischemia. ×400.

Figure 24.A.10 Urine sediment, unstained. Note the cellular casts and bilirubin crystal (arrow) present. ×400.

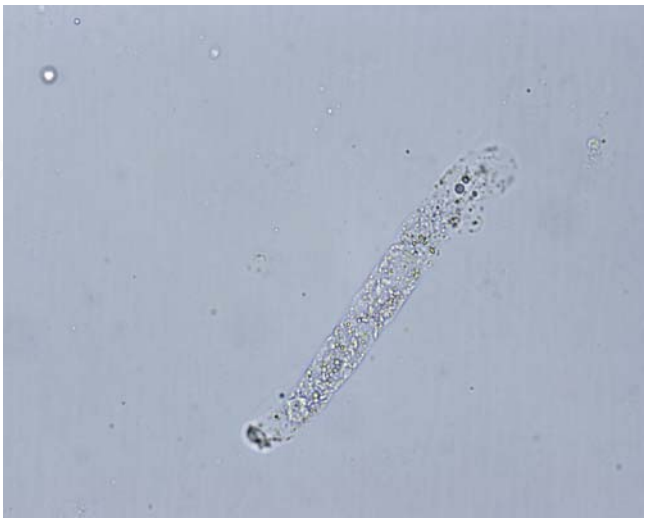

Figure 24.A.12 Urine sediment, unstained. The granular cast is progressing from coarse to finely granular; the distinction is not important, the critical factor is that these type of casts indicate an active tubular lesion when they are numerous and if urine is not concentrated. ×400.

Figure 24.A.13 Urine sediment, unstained. These fine granular casts (arrows) occur under the same circumstances as coarse granular casts. ×100.

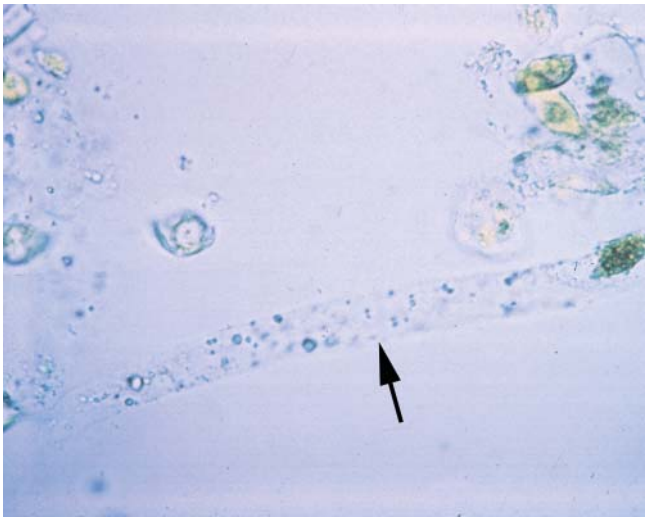

Figure 24.A.15 Unstained urine sediment with a hyaline cast (arrow). These casts can be seen in low numbers in healthy patients that have concentrated urine; they also are associated with proteinuria (particularly the nephrotic syndrome). ×400.

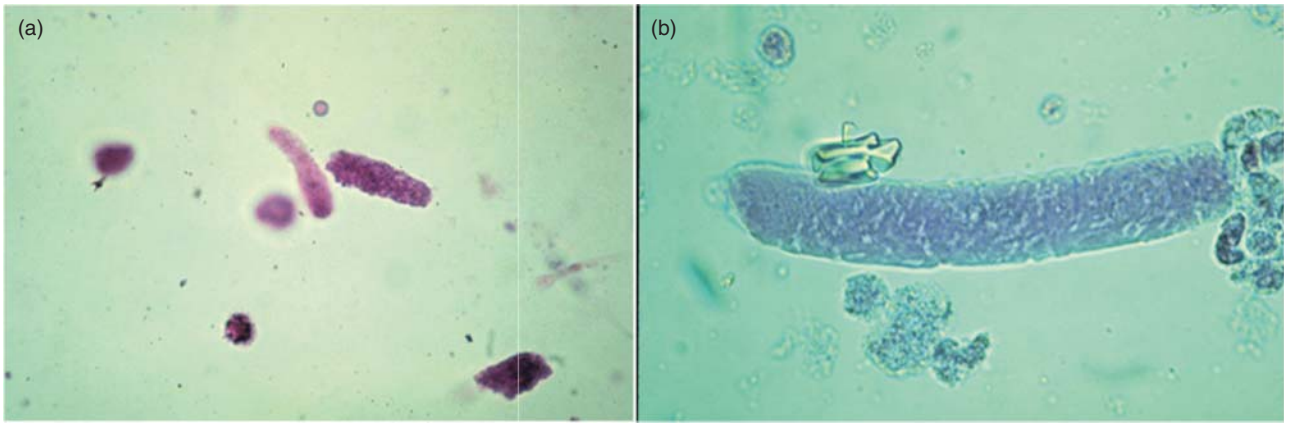

Figure 24.A.14 Urine sediment, sedi-stain. The multiple granular casts present at (a) low power (×100) and (b) at high power (×400) were found in urine with an SG of 1.008, indicating hyposthenuria and active tubular disease (nephrosis).

Figure 24.A.16 Urine sediment, unstained. Note the lipid (fatty) cast. ×400.

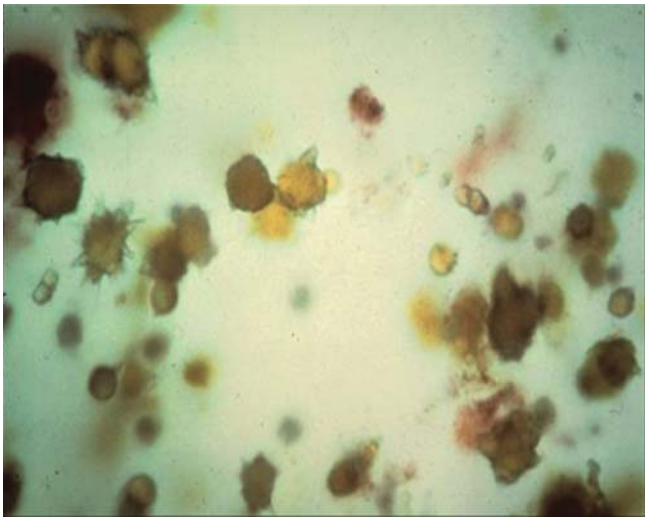

Figure 24.A.18 Note the many crystals with a thorn-apple appearance typical of ammonium biurate, which can be seen in health in English bulldogs and Dalmatians and are also associated with portosystemic shunts and severe liver failure. Clinical chemistry should be performed to identify low BUN, glucose, cholesterol, and albumin confirming decreased synthesis of these substances by the liver.

Figure 24.A.17 Urine sediment, unstained. The waxy cast (arrow) depicted here has sharp, linear edges with blunt ends and has a brittle appearance. When seen, waxy casts indicate prolonged periods of decreased tubular flow, most likely due to chronic renal lesions. ×400.

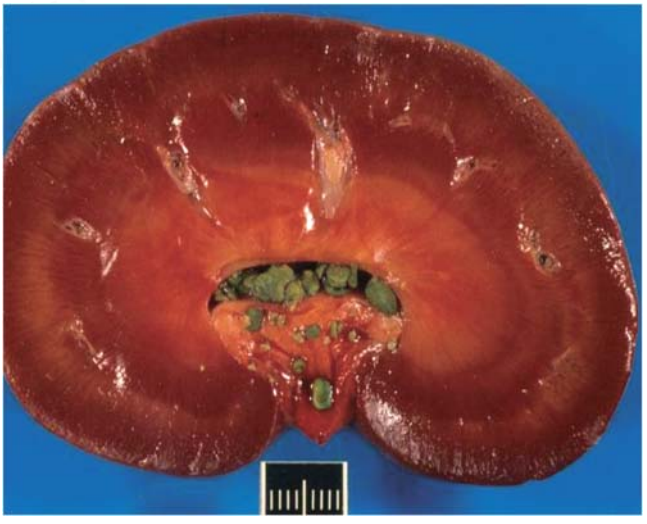

Figure 24.A.19 These variably sized green calculi located in the renal pelvis are nephroliths. This dog had a portosystemic shunt as well as the ammonium biurate crystals seen on sediment analysis in Figure 24.A.18.

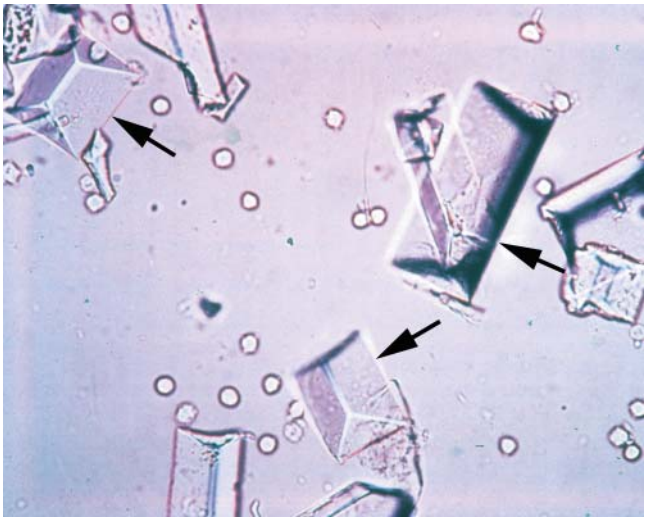

Figure 24.A.20 Urine sediment, unstained. Note the magnesium ammonium phosphate crystals (arrows) and the prism-like appearance. These are the most common crystals seen in cats and dogs. In dogs, they are associated with bacterial urinary tract infection. ×400.

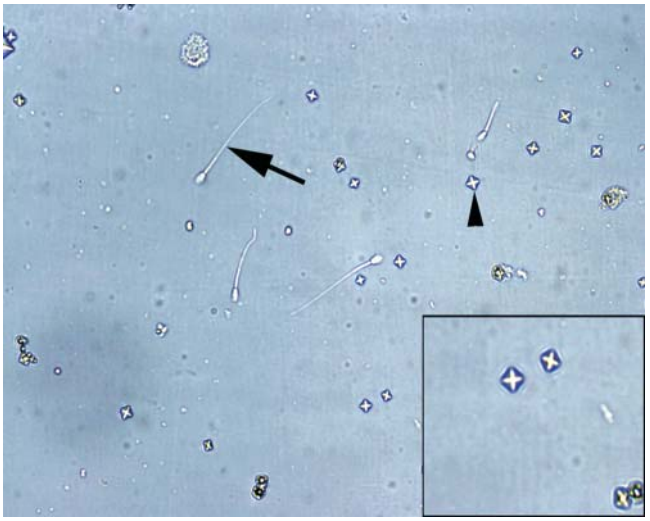

Figure 24.A.22 Urine sediment, unstained. The many crystals (arrowhead) depicted here have a Maltese cross appearance typical of calcium oxalate dihydrate. These crystals are seen in neutral to acidic urine. They can occasionally be seen in normal urine although when seen persistently are a clue to investigate hypercalcemic disorders. These crystals can be seen alone or with calcium oxalate monohydrate in ethylene glycol toxicity. There are also occasional sperm (arrow) present. ×100.

Figure 24.A.21 These multiple struvite crystals present on a background of many rod bacteria indicate bacterial overgrowth, as evidenced by the lack of leukocytes. ×400.

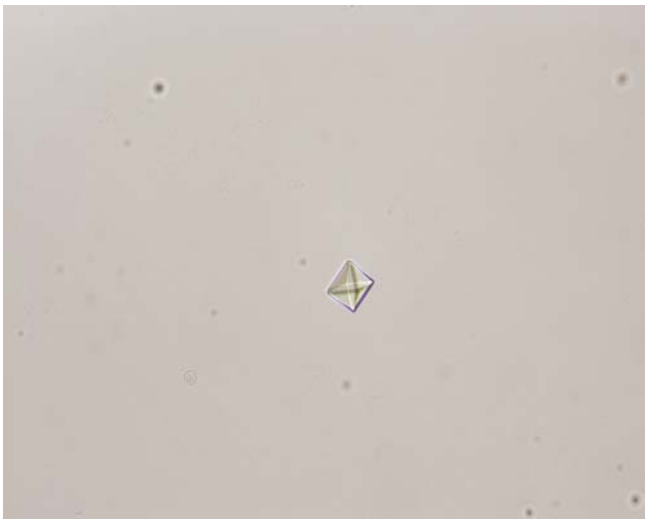

Figure 24.A.23 Urine sediment, unstained. Note the calcium oxalate dihydrate crystal at high power. ×400.

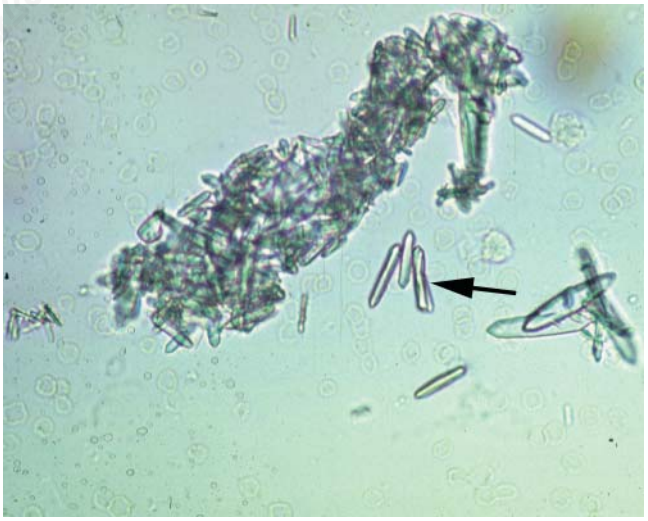

Figure 24.A.24 Urine sediment, unstained. These calcium oxalate monohydrate crystals shown here are present individually and in aggregate. If these crystals are found in a patient with acute kidney injury, they are diagnostic for ethylene glycol intoxication. Intoxication can be confirmed with the ethylene glycol test kit, or a marked osmolar and anion gap. ×400.

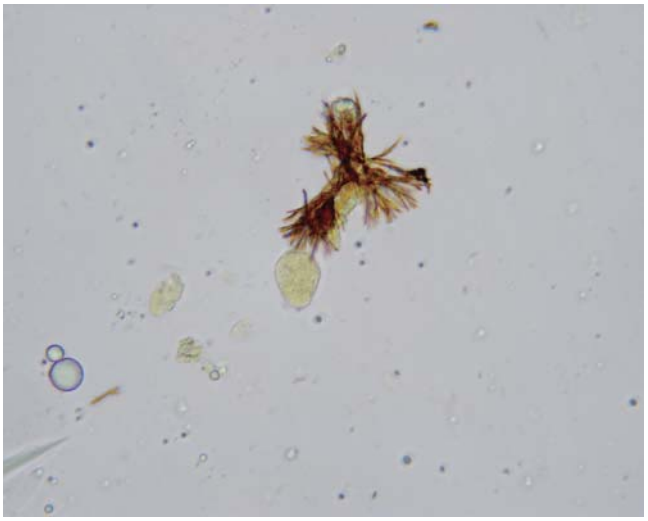

Figure 24.A.26 Urine sediment, unstained. This cluster of crystals is bilirubin, which can be seen with hemolysis, hepatocellular disease, or intra or extrahepatic cholestasis. The cellular elements present are also stained with bilirubin. ×400.

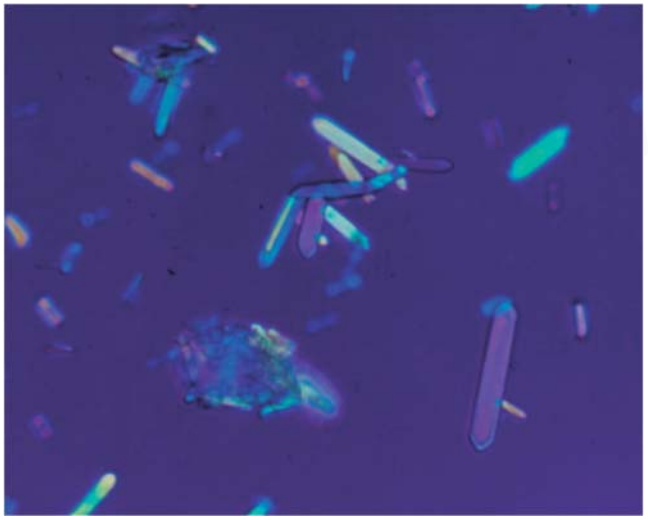

Figure 24.A.25 Urine sediment, unstained under polarized light. Note the many "picket-fence" calcium oxalate monohydrate crystals seen with ethylene glycol toxicity.

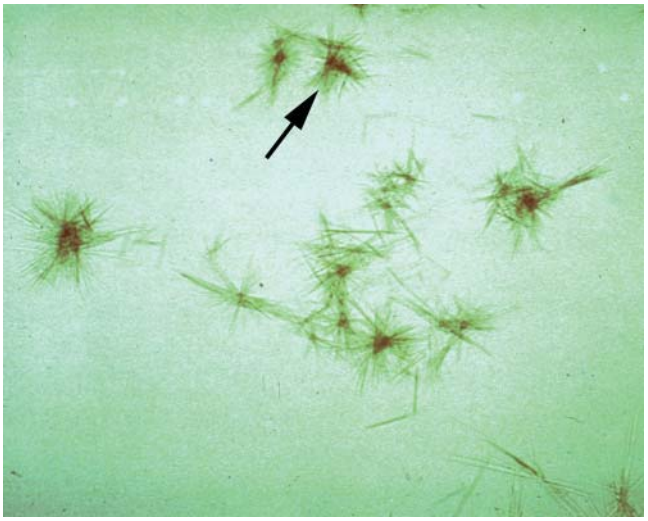

Figure 24.A.27 Urine sediment, unstained. Numerous tyrosine crystals (arrow) are present. These crystals are associated with hepatic disease, resemble bilirubin crystals, and occur under similar circumstances. ×400.

Figure 24.A.28 Urine sediment, unstained. Note the radiographic contrast crystal. These can be seen after intravenous contrast studies are performed. ×400.

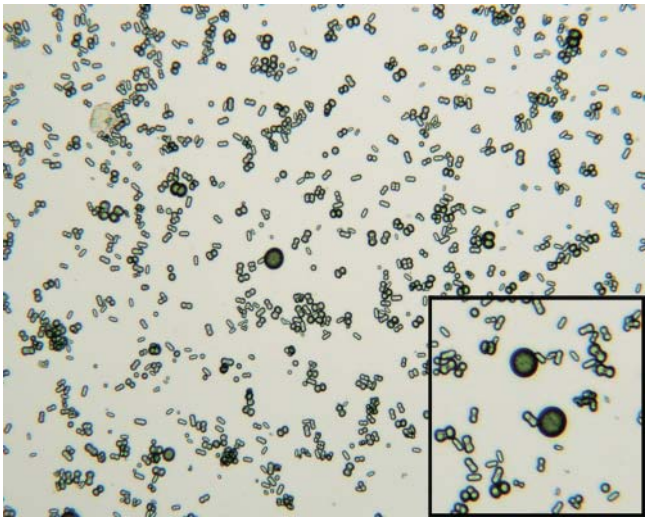

Figure 24.A.30 Urine sediment, unstained. Note the calcium carbonate crystals seen commonly in horses, rabbits, and guinea pigs, predominantly in the spherical forms. ×400.

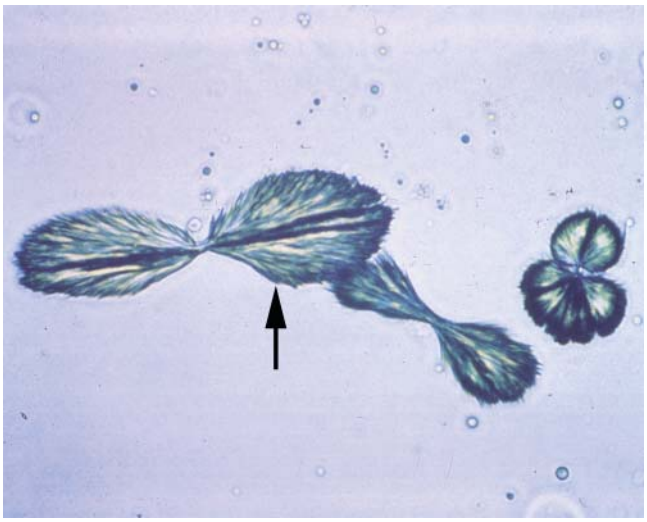

Figure 24.A.29 Urine sediment, unstained. Note the sulfonamide crystals (arrow). Nephrotoxic drugs may lead to the appearance of bizarre crystals in urine. ×400.

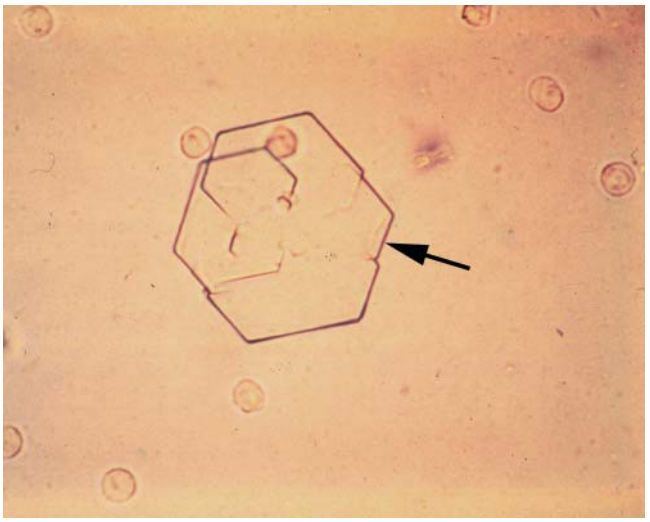

Figure 24.A.31 Urine sediment, unstained. The cystine crystals (arrow) seen here are always an abnormal finding and indicate cystinuria, which is due to a tubular defect heritable in English bulldogs, mastiffs, Chihuahuas, dachshunds, Newfoundlands, Australian cattle dogs, and American Staffordshire terriers. ×400.

Figure 24.A.32 Urine sediment, unstained. The large, cylindrical-shaped budding yeast structure here is typical of *Cyniclomyces guttulatus*. The *Cyniclomyces* yeast can be seen in urine due to fecal contamination. This yeast is seen uncommonly, is regarded as nonpathogenic, and can be seen due to ingestion of rabbit feces. Many rod bacteria are also present within the background. ×1000.

Figure 24.A.34 Urine sediment, unstained. Note the pseudohyphae and budding yeast forms in a young golden retriever with an incompetent urethral sphincter treated chronically with antibiotics and subsequently diagnosed with *Candida albicans* cystitis. ×500.

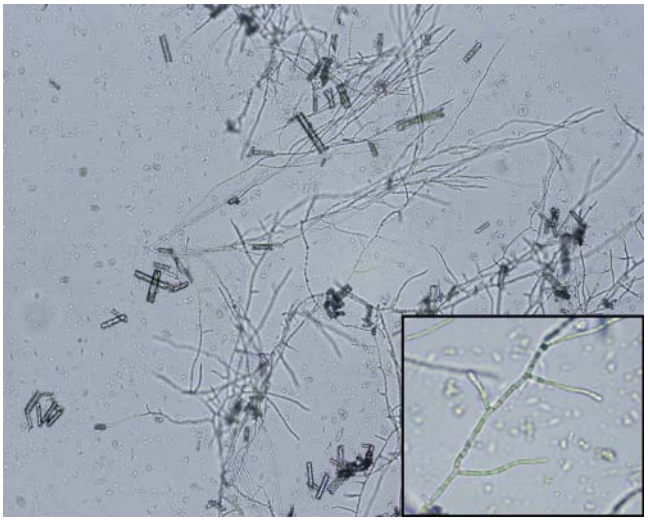

Figure 24.A.33 Urine sediment, unstained. Note the pseudohyphae and budding yeast forms in a pet with confirmed *Candida albicans* cystitis. These can also be contaminants; therefore, correlate presence of organisms with presence or absence of inflammation and clinical findings. ×500.

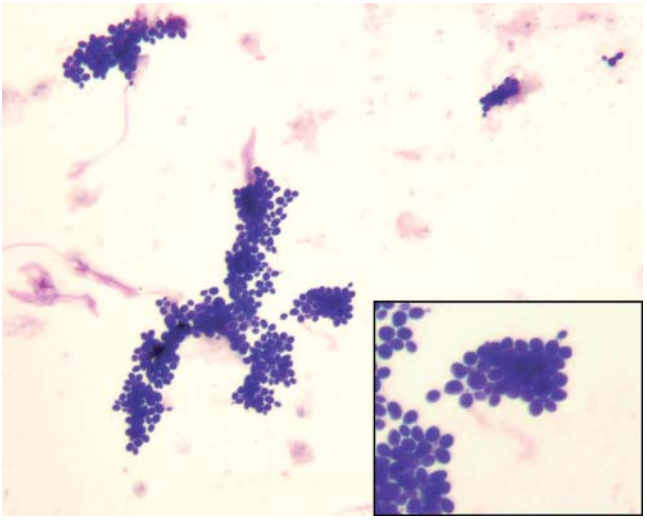

Figure 24.A.35 Urine sediment, Wright-Giemsa stain. There are numerous budding yeast present confirmed on culture as *Candida albicans*. These organisms are larger than bacteria and smaller than red blood cells, despite the lack of cells in this field for size comparison. This feline patient was a newly diagnosed diabetic with a history of multiple urinary tract infections and was chronically treated with antibiotics. ×500.

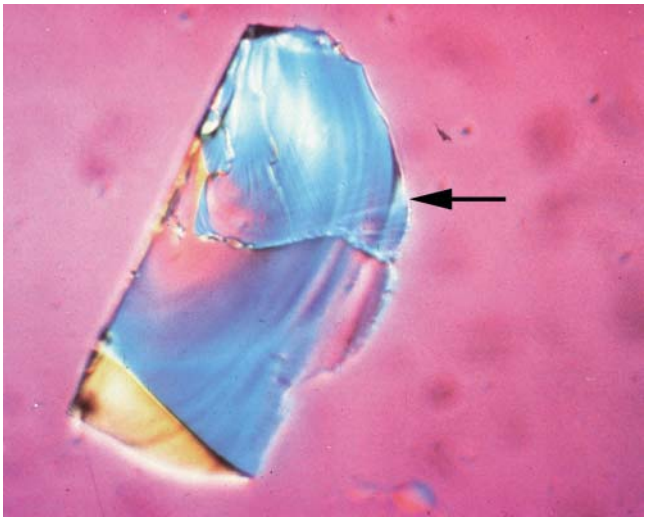

Figure 24.A.36 Urine sediment, unstained. The glass fragment (arrow) seen here may be from urine specimen containers or environmental contamination. It is important that this and other debris not be mistaken for crystals of pathologic significance. ×400.

Figure 24.A.37 Urine sediment, unstained. The pine pollen (arrow) shown here can be commonly seen in free-catch urine specimens. ×400.

25 Laboratory Evaluation of Electrolytes

Andrea A. Bohn
Department of Microbiology, Immunology and Pathology, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Evaluation of electrolyte concentrations is often used to assess severity of disease and guide treatment but can also aid in the diagnosis of disorders. Electrolytes are present in all intracellular and extracellular body fluids, but we typically measure their concentration in blood, plasma, or serum. The serum electrolyte concentration may not accurately reflect the balance of that particular electrolyte within the whole body, especially for electrolytes that are predominantly intracellular. Sodium and chloride are the electrolytes whose concentrations are greatest in extracellular fluid (ECF). The concentration of potassium, calcium, phosphorus, and magnesium are highest in intracellular fluid (ICF). Maintaining the intra- and extracellular concentration of each electrolyte within narrow limits is essential to life.

Intake of all of the electrolytes is via the oral route. The common organs that are important in maintaining all serum electrolyte levels are the gastrointestinal (GI) system and the kidneys. Additional regulatory mechanisms as well as the consequences and causes of imbalances for each individual electrolyte will be covered when each electrolyte is discussed in more detail.

Sodium

Sodium has many important functions, including maintaining normal blood pressure and volume and maintaining normal function of muscles and nerves. These functions are dependent on keeping plasma sodium concentrations within a narrow range. The concentration of sodium in the blood is predominantly a balance between what is consumed in food and drink and what is excreted in urine. Only a small amount is normally lost through stool and sweat, but these routes can become more important in certain disease or physiological states, depending on species.

The regulation of sodium cannot be discussed without also discussing water balance since these substances are intricately tied together. Water comprises approximately 60% of body weight, with about two-thirds in ICF and one-third in ECF. Approximately one quarter of ECF is within the vasculature while three quarters is present in the interstitium. Water balance between different compartments is dependent on osmotic pressures. As the most abundant cation of plasma, sodium, along with its associated anions, is the major determinant of extracellular osmolality. (For further information on osmolality, see Box 25.1) Sodium pumps maintain concentration differences across cell membranes, but sodium can freely cross vascular walls, equilibrating between interstitial and vascular spaces. Serum concentration of sodium reflects its ratio with water and does not necessarily reflect whole body sodium content. Abnormalities in serum sodium concentration are more likely due to abnormalities in water than sodium content.

Water and sodium regulation is associated with maintaining normal blood volume and osmolality. Sensors of osmolality and vascular pressure, including hypothalamic osmoreceptors, arterial, and atrial baroreceptors, and the juxtaglomerular apparatus, result in changes of sodium and/or water handling by the kidney. As little as a 1–2% increase in plasma osmolality will be detected by osmoreceptors in the hypothalamus, resulting in vasopressin (antidiuretic hormone or ADH) secretion from the posterior pituitary. By contrast, baroreceptors must perceive rather large deficits of blood volume (≥10%) to result in vasopressin release; in these instances maintaining blood volume is prioritized over maintaining osmolality. Vasopressin enhances water reabsorption in the renal collecting duct to replenish vascular water. Osmoreceptor cell are also involved in the sensation of thirst as an additional mechanism to replenish body water. Atrial baroreceptors that sense elevated blood pressure or blood volume signal the hypothalamus to inhibit

Box 25.1 Osmolality

Solutes = Substances that are dissolved in plasma (electrolytes, proteins, etc).
Osmolality = The concentration of solutes in plasma (only the number matters, not size or weight).
- In plasma, osmolality and osmolarity are nearly equal and can be used interchangeably.
- Definitions are: the concentration of osmotically active particles *per kilogram solvent* (osmolality) vs. *in one liter of solution* (osmolarity).

Effect = Water will flow from low to high osmolar solutions.
Measurement = Osmolality is measured by determining either the freezing point depression or vapor-point elevation of a solution compared to water.
Calculated estimate =
- 2[Na] + [glucose (mg/dL)]/18 + [urea (mg/dL)]/2.8
- Calculated osmolality is typically about 300–310 mOsm/L.

Osmolar gap = Measured mOsm - Calculated mOsm
- In a healthy state, calculated mOsm is ~10 mOsm/L less than the measured value.
- Increased osmolar gap indicates an increase in or presence of osmolar substances not included in the calculation (mannitol, ethylene glycol, etc.)

vasopressin release and decrease sodium reabsorption in the distal nephron.

While osmolality is regulated by water intake and excretion, sodium balance is regulated by sodium excretion, largely by the renal system. The juxtaglomerular cells of the kidney act as baroreceptors that detect low blood pressure. These cells activate the renin-angiotensin-aldosterone system (RAAS) by secreting renin. Renin cleaves angiotensinogen to angiotensin I, which is then converted to angiotensin II by angiotensin-converting enzyme. Angiotensin II causes the release of aldosterone from the adrenal glands, increases secretion of vasopressin, and stimulates thirst centers. Aldosterone acts on the renal cortical collecting tubules to reabsorb sodium. The reabsorption of sodium is coupled with either the secretion of potassium (another very important function of aldosterone) or the absorption of chloride to maintain electroneutrality.

When evaluating serum sodium concentration, the animal's total body water must be taken into consideration. Is there clinical or biochemical evidence of low body water (dehydration; Boxes 25.2 and 25.3) or does it appear normal or, possibly, increased? An increase in serum sodium concentration can be due to more sodium, less water, or a combination of causes. A decrease in serum sodium concentration can be due to less sodium, more water, or a combination of causes.

Box 25.2 Physical and biochemical parameters used in the assessment of hydration status

Assessment of body water content:
Physical exam
- Skin turgor = interstitial tissue consistency
- Capillary refill time = peripheral vascular blood flow
- Change in body weight

Biochemical analysis
- PCV and plasma protein concentration
- Serum urea concentration
- Serum sodium concentration

Hypernatremia

Hypernatremia (Figure 25.1) is most commonly associated with an imbalance in body water; it is usually easy to prevent with normal vasopressin and thirst responses, but there are conditions in which it occurs. Hypernatremia can happen with either decreased water intake or loss of water that exceeds the loss of electrolytes. Decreased intake can be due to water deprivation, defective thirst response, or a physical inability to drink. Loss of water can occur through insensible losses (respiratory or skin losses) or loss from the kidney or gastrointestinal systems.

For hypernatremia to develop, more water needs to be lost than electrolytes. Pure water loss occurs when there is an increase in insensible fluid losses, fever, and heat stroke are examples, or when the kidney cannot conserve water, as with diabetes insipidus. Whether vasopressin is deficient, as with central diabetes insipidus, or ineffective, as with congenital or acquired nephrogenic diabetes insipidus, a concurrent decrease in water intake is typically required for hypernatremia to occur. In many instances of water loss, electrolytes are also lost, as with vomiting, diarrhea (osmotic diarrhea, ruminal acidosis), osmotic diuresis, chronic or acute nonoliguric renal disease, or burns. Animals that lose electrolytes with water will become hypovolemic. With pure water loss or inadequate intake of water, the total body sodium content is normal, and intracellular water is drawn into the extracellular spaces, maintaining plasma volume (isovolemic hypernatremia).

Sodium excess is an uncommon cause of hypernatremia; either concurrent fresh water restriction or lack of urine concentration is usually necessary for hypernatremia to occur. Hypernatremia can occur either by ingesting excess salt (salt licks, sea water) or iatrogenically with the administration of hypertonic fluids. Decreased excretion of sodium can also lead to sodium excess; this can occur with the rare condition of hyperaldosteronism. These animals will become hypervolemic. If excess sodium is present in ECF, intracellular water will shift to the ECF and cells will become dehydrated.

Box 25.3 Manifestations and underlying processes of the various states of dehydration

Isotonic dehydration: proportional loss of NaCl and water
Some diarrheas and renal diseases
[Na] and [Cl] do not change.
PCV and [plasma protein] increase.
No change in osmolality; water does not shift between ICF and ECF, therefore ECF volume decreases.

Hypertonic dehydration: (ECF becomes hypertonic)
Water loss > NaCl loss.
- Diabetes insipidus
- Water deprivation/hypodipsia
- Respiratory loss with high temperature/panting
- Osmotic diuresis
- Diarrhea

[Na] and [Cl] increase.
PCV and [plasma protein] increase.
Osmolality increases; water shifts from ICF to ECF to maintain ECF volume.

Hypotonic dehydration: (ECF is hypotonic)
NaCl loss > water loss.
- Secretory diarrhea
- Vomiting
- Third-space loss
- Equine sweat

[Na] and [Cl] decrease.
PCV and [plasma protein] increase.
Osmolality decreases; water shifts from ECF to ICF, leading to volume depletion.

Protein and/or PCV may not appear increased if there is concurrent protein loss and/or anemia.

In a retrospective study that looked at hypernatremia in dogs and cats, disease processes and pathophysiologic factors were described for animals with moderate to severe hypernatremia (>10 mEq/L above reference interval) [1]. Over half of the cats had urological disease processes. Neurological disease was common in both dogs and cats and dogs had a higher incidence of neoplasia. Some of the other disease processes associated with cases of hypernatremia involved the respiratory, hepatobiliary, and gastrointestinal systems. Underlying pathophysiologic factors were commonly related to the renal system in cats. Gastrointestinal loss was common in both dogs and cats; in many instances, vomiting and diarrhea were likely secondary to another disease process rather than a primary gastrointestinal disorder. Central diabetes insipidus and fever/hyperthermia were also common factors in dogs. Osmotic diuresis and nephrogenic diabetes insipidus were among other causes. Common clinical signs in animals with hypernatremia were obtundation, vomiting, lethargy, weakness, and ataxia; it is not clear whether these signs were more likely due to the underlying disease process or the electrolyte imbalance.

When considering differentials for hypernatremia, along with other biochemical data, urinalysis and history are also important to consider [2, 3]. Concentrated urine indicates that extrarenal water loss is present and very dilute urine (hyposthenuric) is an indication of free water loss from the kidney. It is also important to know if the animal is polyuric and polydipsic, has had adequate access to water, has demonstrated any changes in mentation or shown neurological signs, or has had any recent significant events (burns, urinary obstruction, etc.) or therapies (fluid administration, etc.).

Hyponatremia

Hyponatremia (Figure 25.2) may be either due to sodium loss that exceeds water loss or an increase in body water. Hyponatremia is associated with hypo-osmolality except in cases of pseudohyponatremia or in translocational hyponatremia, in which large numbers of alternative osmoles are present.

Pseudohyponatremia can occur when sodium concentration is measured in whole plasma and not just plasma water because sodium is only dissolved in the water component of plasma. Marked hyperlipidemia or hyperproteinemia cause volume displacement and decrease the percent of serum or plasma that is water (known as the electrolyte exclusion effect). If the method used to measure sodium dilutes the sample (as with the majority of large chemistry analyzers), an artifactually low sodium concentration may be obtained, although measured plasma osmolality is normal. Direct ion-specific electrode potentiometry (the method used by most point of care and blood gas analyzers) uses undiluted samples and measures sodium concentration in just the water component of plasma so that pseudohyponatremia will not occur.

Translocational hyponatremia is due to the presence of other substances in the plasma causing hyperosmolality. Substances that readily cross cell membranes, like urea, will not cause translocational hyponatremia. Tonic substances,

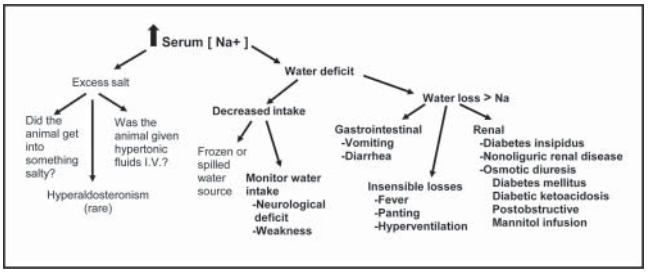

Figure 25.1 Algorithm for causes of hypernatremia (the more common causes are bolded).

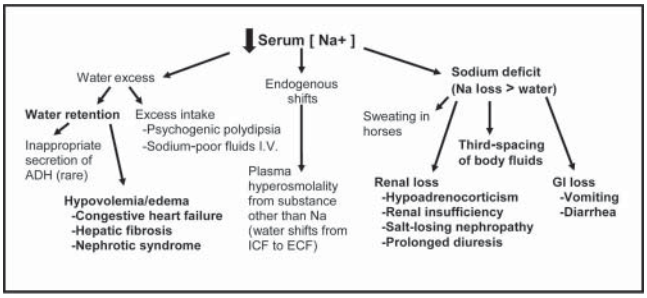

Figure 25.2 Algorithm for causes of hyponatremia (the more common causes are bolded).

osmolar substances that cannot easily cross cell membranes, will draw water from the ICF to the higher osmolality of the ECF, diluting out the sodium that is present. If glucose cannot enter cells due to the lack of insulin or its actions, hyperglycemia can result in translocational hyponatremia. In this case, measured and calculated osmolality will be similar. Exogenous substances (mannitol, ethylene glycol) that cause translocational hyponatremia will result in an increase in osmolar gap.

Hypo-osmolar hyponatremia occurs because of either increased water content or decreased sodium content. Increased water content occurs if there is impaired renal excretion of either dilute urine or free water or if water intake exceeds the maximal renal excretory capacity. Excess water intake is rare but can occur with psychogenic polydipsia. With excess intake, urine osmolality as well as plasma osmolality will be low.

Decreased renal excretion of free water in response to perceived hypovolemia can lead to an increase in total body water. This occurs due to third-spacing of fluid (accumulation within body cavities) associated with congestive heart failure, cirrhosis of the liver, or nephrotic syndrome. Vasopressin is released in response to perceived hypovolemia, resulting in increased reabsorption of water. Impaired renal excretion of water due to renal failure can also lead to hyponatremia with hypervolemia.

Hypovolemia typically accompanies loss of sodium from the body. Sodium is rarely lost from the body without some water, but to become hyponatremic there either has to be loss of hypertonic fluid (more sodium lost than water) or isotonic or hypotonic fluid loss resulting in volume depletion, which stimulates drinking and renal water retention, diluting the remaining body fluids. Hypovolemic, hypo-osmolar hyponatremia can result from gastrointestinal loss (vomiting, diarrhea), renal loss (hypoadrenocorticism, prolonged diuresis), third-space loss (body cavity effusions), or sweating in horses. Primary hypoadrenocorticism (Addison's disease) is associated with aldosterone deficiency, resulting in decreased renal reabsorption of sodium, increased retention of potassium in cortical collecting tubules, and a decreased sodium potassium ratio (Box 25.4).

It is important to keep in mind that an animal may be normonatremic in many of the conditions listed above despite being dehydrated or hypervolemic if there is a net loss or gain of isotonic fluids or if an equilibrium has been reached. Hypovolemia not only stimulates vasopressin release but triggers the RAAS, which leads to sodium retention.

Hyponatremia is more common than hypernatremia and was present in 49.4% of hospitalized cats and 25.5% of hospitalized dogs in a recent study [4]. In that study, disease processes and pathophysiologic factors were described for animals with moderate to severe hyponatremia (>10 mEq/L below reference interval), which comprised 4% of dogs and 8% of cats. The most common disease processes in this subset of cats were urological and cardiovascular and, in dogs, gastrointestinal and urological. Some of the other disease processes associated with hyponatremia were neoplasia, diabetes mellitus, hypoadrenocorticism, and respiratory, hepatobiliary, and pancreatic disorders. The most common pathophysiologic factors were gastrointestinal loss from vomiting and diarrhea, third space loss ± decreased effective circulating blood volume, and factors associated with urological diseases. Common clinical signs in animals with hyponatremia, were obtundation, vomiting, lethargy, and weakness; it is not clear whether these signs were more likely due to the underlying disease process or the electrolyte imbalance.

Determining the cause of hyponatremia is often achieved after considering history, physical exam findings (ECF volume status, presence of body cavity effusions, jaundice, heart murmur, etc.), the rest of the serum biochemical panel and urinalysis. For challenging cases, one may wish to measure urine fractional excretion (see the "Fractional Excretion of Electrolytes" section in Chapter 24) to differentiate appropriate from inappropriate vasopressin secretion or to determine if there is an inappropriate amount of sodium getting excreted by the kidneys. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a syndrome where urine is inappropriately being concentrated without the kidneys being in a state of sodium retention (which would be an appropriate response if the animal was hypovolemic). Urine electrolyte and osmolality measurements are necessary for the diagnosis of SIADH [5].

Chloride

Chloride is the major anion in the ECF and, similar to sodium, chloride is important in the regulation of body fluids. Chloride also plays an important role in digestion and muscular activity and serves as a conjugate anion in acid base metabolism. To maintain electroneutrality, chloride either moves in the same direction of the positively charged sodium or exchanges with the negatively charged bicarbonate ions. When evaluating an abnormality in serum

Box 25.4 Sodium potassium ratio

Reference interval ~ 27 : 1 to 40 : 1

Ratios <27 : 1 can be due to either an absolute or relative increase in potassium, decrease in sodium, or a combination of these changes; increased potassium is the most common reason.

Low ratios are commonly associated with hypoadrenocorticism.

Hypoadrenocorticism should always be a differential with a decreased Na:K ratio BUT not the only one.

Other diseases/conditions commonly associated with low Na:K ratios include

- Renal/urinary tract disease.
- Gastrointestinal disease; parasitism in dogs.
- Body cavity effusions.

Low Na:K ratios have also been reported with:

- Diabetes mellitus, pancreatitis, cardiorespiratory disease, pyometra, disseminated neoplasia, grade III patellar luxation, mushroom poisoning, behavior problem, ocular disease, skin disease.

Na:K ratios <15 are more commonly associated with hypoadrenocorticism in dogs.

A small percent of dogs with primary hypoadrenocorticism have a normal ratio.

The ratio is often normal in dogs with secondary hypoadrenocorticism (low ACTH).

Box 25.5 Using sodium to correct chloride concentration in the analysis of chloride abnormalities

Correction of chloride for water imbalance

Can the abnormality in chloride be attributed to the water imbalance that is affecting sodium concentration?

This can be estimated by proportionally correcting chloride using the sodium concentration. The middle of the reference interval (RI) can be used as the "normal" sodium value. Divide this value by the measured sodium concentration to arrive at the factor with which to multiply the measured chloride concentration. The corrected chloride concentration can then be compared to the RI for chloride.

Normal sodium/Measured sodium × Measured chloride = Corrected chloride

Example 1: Na = 164 mEq/L (RI 134–144 mEq/L; middle = 139)
Cl = 136 mEq/L (RI 105–125 mEq/L)
Corrected chloride = 139/164 × 136 = 115
Therefore, Cl shifts are due to same process as Na shifts.

Example 2: Na = 124 mEq/L (RI 134–144 mEq/L; middle = 139)
Cl = 75 mEq/L (RI 105–125 mEq/L)
Corrected chloride = 139/124 × 75 = 84
The corrected chloride concentration is still markedly outside of the RI. Bicarbonate is expected to be increased.

CHAPTER 25

chloride concentration, it is important to compare chloride levels with sodium levels and to the animal's acid base status. If abnormalities in chloride concentration appear to be in proportion to abnormalities in sodium concentration (Box 25.5), differentials to consider are similar to those given for hyponatremia or hypernatremia above. If the change in chloride concentration appears greater than a change in sodium concentration, bicarbonate concentration should be evaluated and a blood gas analysis may be indicated (Chapter 26).

Hyperchloremia

If the degree of hyperchloremia is proportional to concurrent hypernatremia (Box 25.5), consider the same differentials as hypernatremia. Hyperchloremia is usually associated with a water deficit.

Alternatively, hyperchloremia can be related to hypobicarbonatemia (Figure 25.3). Loss of bicarbonate can occur from the gastrointestinal tract with diarrhea, loss of saliva in cattle that contains a high bicarbonate concentration, or vomiting intestinal contents as can occur with intestinal obstruction. Biliary, pancreatic, and duodenal secretions contain high concentrations of bicarbonate, the addition of which requires exchange with chloride at the luminal cell membrane. The secreted bicarbonate is normally resorbed in the jejunum, but when resorption does not occur, hyperchloremia will result. Additional regulation of bicarbonate occurs in enterocytes of the ileum and distal colon, where secretion of bicarbonate is, again, dependent on exchange with chloride; hypersecretory states result in hypobicarbonatemia and hyperchloremia, most commonly seen with secretory diarrhea in calves.

Renal loss of bicarbonate (and therefore chloride retention) occurs with proximal or distal renal tubular acidosis (RTA), which can be primary or acquired. Proximal RTA is due to a lack of bicarbonate absorption in the proximal tubules and subsequent loss. Distal RTA is due to decreased ability to secrete an acid load in the distal tubules, which would otherwise be accompanied by bicarbonate absorption and concurrent chloride excretion. Some of the diverse disease processes that result in RTA are congenital tubular defects, hypoadrenocorticism, and renal tubular disease.

In a physiologic compensatory response to chronic respiratory alkalosis, the kidneys decrease acid secretion and bicarbonate resorption, resulting in retention of chloride. Mild alkalosis associated with hypoalbuminemia may also lead to mild hyperchloremia [13].

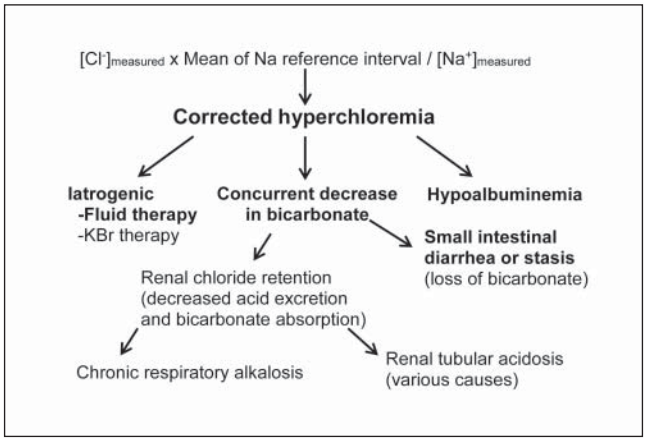

Figure 25.3 Algorithm for causes of corrected hyperchloremia (the more common causes are bolded).

Hyperchloremia can occur iatrogenically if administered solutions contain proportionally greater amounts of chloride than sodium: 0.9% sodium chloride (chloride is proportionally higher in saline than ECF), hypertonic saline, ammonium chloride, potassium chloride, and cationic amino acids (e.g., total parenteral nutrition). Administration of halides (e.g., bromide, iodide, fluoride) can result in artifactual hyperchloremia because ion selective electrodes are not specific and these substances are measured as chloride. A false elevation in chloride is often seen in animals receiving potassium bromide as an anticonvulsant.

Hypochloremia

If the degree of hypochloremia is proportional to the degree of hyponatremia (Box 25.5), the same differentials listed for hyponatremia apply.

If chloride is decreased to a greater degree than sodium, differentials related to metabolic alkalosis must be considered (Figure 25.4). In the process of secreting HCl into the stomach, serum chloride is decreased and serum bicarbonate is increased. These changes are normally reversed when hydrogen and chloride ions and water are reabsorbed in the intestines. If gastric fluid is lost due to vomiting or sequestered due to a displaced abomasum, pyloric obstruction, or functional obstruction, serum chloride will remain low and bicarbonate will remain elevated.

In a physiologic compensatory response to chronic respiratory acidosis, the kidneys increase acid secretion and bicarbonate resorption, resulting in chloride secretion and hypochloremia.

The chloride concentration in equine sweat is up to twice as much as in plasma and it is higher than sodium concentration. After sweat loss, hypochloremia can be present even after correcting for hyponatremia. Bicarbonate will be elevated.

Iatrogenic hypochloremia is fairly common. Loop diuretics (furosemide) and thiazides cause a proportionally greater

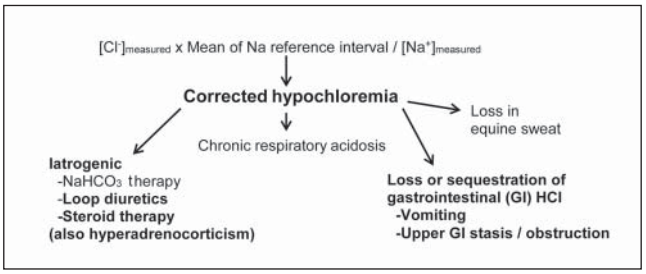

Figure 25.4 Algorithm for causes of corrected hypochloremia (the more common causes are bolded).

loss of chloride than sodium. Glucocorticoids have been associated with mild hypochloremia, likely an effect on cortical collecting ducts. Administration of solutions containing sodium and without chloride (e.g., sodium bicarbonate) may also result in corrected hypochloremia.

Potassium

Potassium is a major intracellular cation that plays an important role in resting cell membrane potential. Clinical signs associated with abnormal serum potassium concentrations manifest as cardiac and skeletal muscle dysfunction, and hyperkalemia can have life-threatening effects on cardiac conduction. Therefore, it is important to maintain serum potassium concentrations within narrow limits. Total body potassium is a balance between what is ingested (100%) and what is excreted from the kidneys (normally ~90–95%) and colon (normally ~5–10%). The concentration of ECF (serum) potassium is also reliant on the translocation of potassium between the ECF and ICF. Less than 5% of total body potassium is present in the ECF; therefore serum potassium concentration is an unpredictable representation of total body potassium content.

Hyperkalemia

Hyperkalemia (Figure 25.5) occurs if there is an increased potassium load, a decrease in potassium excretion, or a shift of potassium from ICF to ECF. Increased ingestion of potassium is unlikely to result in hyperkalemia unless there is a concurrent decrease in renal excretion. An increase in potassium load can occur iatrogenically and may result in death when fluids containing high concentrations of potassium are mistakenly given.

Decreased renal excretion of potassium is a common cause of hyperkalemia and can result from renal or postrenal diseases of the urinary tract. In anuric or oliguric renal failure the kidney itself does not have the capacity to remove excess potassium from the body. Postrenal processes that result in decreased removal of urine from the body, such as urethral obstruction or ruptured urinary bladder, can also result in hyperkalemia.

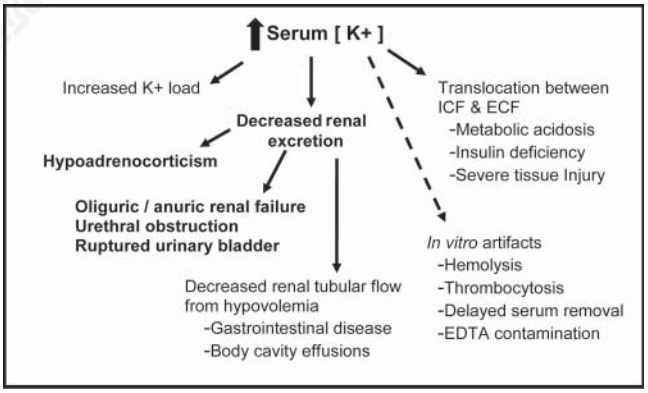

Figure 25.5 Algorithm for causes of hyperkalemia (the more common causes are bolded).

Aldosterone acts to increase serum sodium and decrease serum potassium concentrations by reabsorbing sodium and excreting potassium in the renal cortical collecting tubules and, to a lesser extent, in the colon. Aldosterone deficiency results in decreased excretion of potassium, thus hypoadrenocorticism is commonly associated with hyperkalemia, hyponatremia, and decreased sodium potassium ratio (Box 25.4).

Potassium renal excretion is decreased with a decrease in tubular flow rate, which can occur with hypovolemia. This is thought to be the reason for increased serum potassium concentrations associated with body cavity effusions and gastrointestinal disease. Hypovolemia and hyponatremia become more severe with repeated drainage of body cavity effusions, and hyperkalemia is more commonly seen with effusions that have been repeatedly drained. The gastrointestinal disease that is most commonly associated with hyperkalemia in dogs is severe whipworm infestation. The hyperkalemia seen with neonatal calf diarrhea is predominantly attributed to the degree of dehydration and prerenal azotemia in the calves [14].

Translocation between ECF and ICF plays a large role in maintaining serum potassium concentrations. A condition that moves potassium from the ICF to ECF causing hyperkalemia is the movement of acid (H^+) into cells with metabolic acidosis. Experimentally, this has been reproduced only with non–anion gap metabolic acidosis. Since insulin is important in normal movement of potassium from the ECF to ICF, insulin deficiency can result in hyperkalemia. Given the high concentration of intracellular potassium, potassium released from injured cells can increase its concentration in the ECF, especially if there is also decreased renal excretion. A large degree of tissue injury is typically necessary to result in hyperkalemia, which can occur with tumor lysis syndrome, rhabdomyolysis, or severe trauma. Potassium can also be released from muscle during exercise and transient hyperkalemia may be seen during and shortly after exercise in horses [15].

Pseudohyperkalemia occurs if large amounts of potassium leak out of cells during or after blood is drawn. Platelets contain abundant intracellular potassium that is released upon activation. Blood clotting, therefore, can result in an elevation in serum potassium concentration, especially if a thrombocytosis is present. Reference intervals for serum potassium are typically about 0.5 mEq/L higher than for plasma. Hemolysis causes potassium to leak from erythrocytes. The amount of potassium in erythrocytes varies with species and even breed. Horses, pigs, and cattle have high erythrocyte potassium concentrations. Cats and dogs typically have lower erythrocyte potassium except for the Akita and other Japanese dog breeds.

False increases in potassium also occur if a sample has been contamination with potassium ethylenediaminetetraacetic acid (EDTA). In this case, calcium and magnesium should be very low.

Hypokalemia

Hypokalemia (Figure 25.6) is one of the more common electrolyte disturbances in critically ill veterinary patients, although a definitive cause cannot always be identified. Hypokalemia may be due to decreased intake, increased excretion or loss, shifts between the ECF and ICF, or (often) a combination of these. Decreased intake from diet can contribute to hypokalemia. This is usually not a cause on its own, although it may play a larger role in ruminants where potassium absorption is reliant on ruminal potassium concentration. A significant decrease in plasma potassium concentration was shown in as little as 18 hours of food withholding from steers [16]. Hypokalemia can also be caused iatrogenically with potassium-poor fluids.

Loss of potassium occurs from the gastrointestinal or renal systems. Vomiting and small intestinal diarrhea can result in hypokalemia. Renal losses can occur for a variety of reasons. Hypokalemia associated with chronic renal failure occurs more commonly in cats. Distal RTA, postobstructive diuresis, diabetic ketoacidosis, acquired or congenital Fanconi syndrome, and diuretic administration all can lead to increased

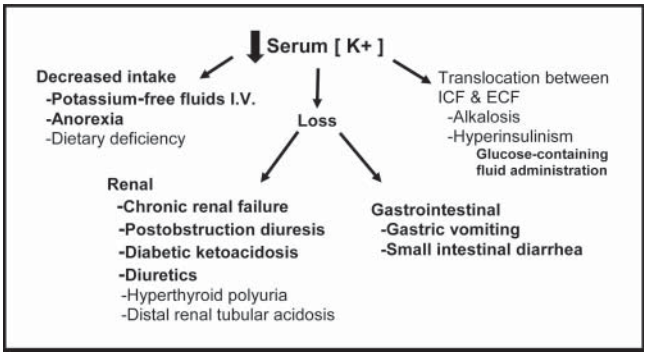

Figure 25.6 Algorithm for causes of hypokalemia (the more common causes are bolded).

Box 25.6 Calculation of the anion gap

Na^+ and K^+ are the major cations; all other cations are classified as unmeasured cations (UC^+).

Cl^- and HCO_3^- are the major anions; all other anions are classified as unmeasured anions (UA^-).

Given the law of electoneutrality:

$$Na^+ + K^+ + UC^+ = Cl^- + HCO_3^- + UA^-$$

Subtracting UC^+ and Cl^- and HCO_3^- from both sides:

$$\mathbf{Na^+ + K^+ - Cl^- - HCO_3^- = UA^- - UC^+ = Anion\ gap}$$

potassium excretion and hypokalemia. Hyperaldosteronism is a rare cause of hypokalemia, but repeated administration of isoflupredone acetate is a potential cause of hypokalemia syndrome in cattle [17].

Increased movement of potassium from the ECF to ICF can cause hypokalemia. This can be due to an excess of insulin, a glucose infusion, or alkalosis. Hypokalemia due to xylitol toxicity in dogs is because of insulin release and its effect of moving potassium into cells along with glucose. Alkalosis is thought to play a large role in the frequent occurrence of hypokalemia in cattle with displaced abomasums [16]. Catecholamines can also cause a shift of potassium from ECF to ICF secondary to pain, sepsis, or trauma.

Anion gap

We measure several anions and cations in the blood, but there are many others that are not routinely measured. The predominant cations of ECF are sodium, potassium, calcium, and magnesium, and the predominant anions are chloride, bicarbonate, plasma proteins, organic acid ions, phosphate, and sulfate. The number of unmeasured anions is greater than the number of unmeasured cations, and the difference between these is called the anion gap. The greatest change in the anion gap is when an increase occurs owing to an increase of organic acids in the circulation. The anion gap, therefore, is important in determination of the acid-base status of an animal (Chapter 26). The anion gap is essentially used to determine the cause of decreased blood bicarbonate concentrations (metabolic acidosis) or to detect metabolic acidosis during a mixed acid-base disorder in which bicarbonate may be normal or increased.

An indirect method is used to calculate the anion gap (Box 25.6). The calculation is based on the law of electroneutrality (i.e., the number of positive charges need to equal the number of negative charges in the body). The cations and anions that are considered "measured" are sodium & potassium and chloride & bicarbonate, respectively. The anion gap is the difference between these anions and cations as illustrated in Figure 25.7.

Because cations rarely change enough to affect the anion gap, a decrease in bicarbonate has to be accompanied by either an increase in unmeasured anions or a decrease in chloride to keep the equation equal and to maintain electroneutrality. (Figure 25.7) Unmeasured anions that have the most effect on anion gap are the endogenous products lactate, ketones, and uremic acids, as well as the exogenous substances salicylate and the metabolites of ethylene glycol toxicity. Lactic acidosis is produced during hypoxia and anaerobic metabolism. Keto acids are produced when there is a negative energy balance and metabolism switches from primarily glycolysis to lipolysis. Uremic acids are phosphates, sulfates, and organic acids that are no longer adequately filtered because of decreased glomerular filtration rate (GFR). Decreases in anion gap are typically due to hypoalbuminemia, as the predominant unmeasured anion in health is albumin. For further utilization of the anion gap, see Chapter 26.

Calcium, phosphorus, and magnesium

Calcium, phosphate, and magnesium are required for vital extra- and intracellular functions. Like potassium and in contrast to sodium and chloride, intracellular concentrations of calcium, phosphate, and magnesium are higher than extracellular concentrations. As with the other electrolytes, their intake is by ingestion and the regulation of their blood concentration involves the kidneys and gastrointestinal tract. Bone is another essential player in regulation, as the majority of total body calcium, phosphate, and magnesium are stored in bone. Maintaining appropriate circulating concentrations of these electrolytes is largely dependent on hormonal control. Regulatory hormones are shared by these electrolytes, with magnesium regulation being less well understood. The main hormones that function to maintain normal calcium and phosphate levels are calcitonin, parathyroid hormone (PTH), and 1,25-dihydroxyvitamin D (calcitriol or vitamin D).

Calcitonin is produced by thyroid parafollicular cells (C-cells). It is released in response to hypercalcemia and its release is inhibited by hypocalcemia. The main function of calcitonin is to limit postprandial hypercalcemia by inhibiting osteoclastic bone resorption and decreasing reabsorption of calcium and phosphate by the kidney tubules. Its overall effect is to decrease serum calcium and phosphate concentrations (Figure 25.8).

PTH is produced by chief cells in the parathyroid gland and is the principle hormone in fine, minute-to-minute blood calcium regulation. It is released in response to hypocalcemia and its release is inhibited by elevated calcium levels and vitamin D. PTH acts to increase the activity of vitamin D, increase calcium and phosphate reabsorption from bone, and increase

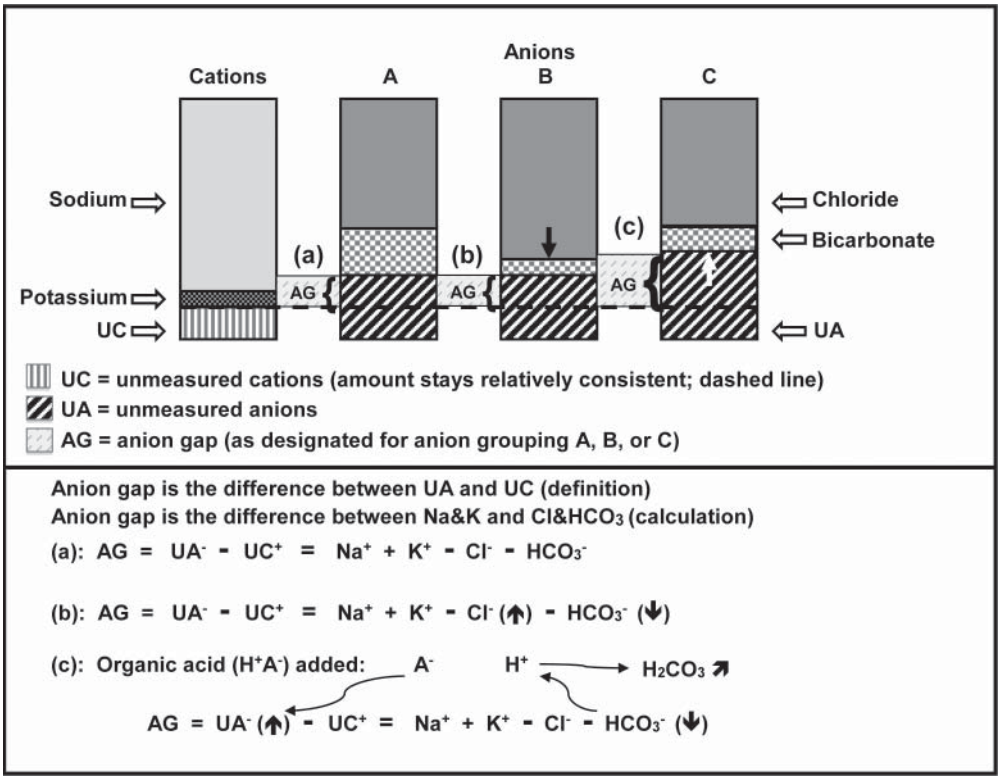

Figure 25.7 Demonstration of how anion gap is affected in different situations resulting in metabolic acidosis. Anions A: normal acid base status; normal anion gap (a). Anions B: Nonanion gap (secretional) metabolic acidosis. Bicarbonate is exchanged for chloride (solid black arrow); anion gap is not affected (b). Anions C: Anion gap (titrational) metabolic acidosis. As organic acids are introduced, bicarbonate is utilized to buffer the hydrogen ion while the leftover anion adds to the unmeasured anion pool (solid white arrow); anion gap is increased (c).

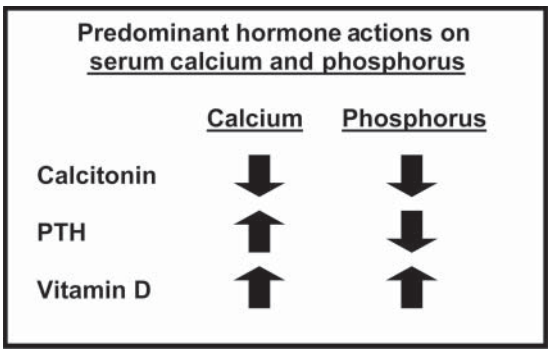

Figure 25.8 The effect of hormones on blood calcium and phosphorus concentrations.

calcium while decreasing phosphate reabsorption by the kidneys. Because of its potent phosphaturic action, the overall effect of PTH is to increase serum calcium and decrease serum phosphate concentrations (Figure 25.8).

Vitamin D comes from diet or is synthesized in the skin from sunlight exposure. In dogs and cats, diet is the only significant source. The dietary or synthesized form of vitamin D is inactive and must be metabolized in the liver and kidney for activation. Cholecalciferol is metabolized to calcidiol in the liver under fairly loose regulation. Renal metabolism of calcidiol is more tightly regulated and generates active calcitriol under the influence of PTH. The activation of calcitriol is influenced by serum calcium, phosphate, PTH, and calcitriol concentrations and the effects of calcium and calcitriol concentrations on PTH release. Vitamin D predominantly acts to increase the absorption of calcium and phosphate from the gastrointestinal tract. Its overall action is to increase both serum calcium and phosphate concentrations (Figure 25.8).

Calcium

Why is calcium measured? One reason is that alterations in blood calcium concentrations can result in severe clinical problems, including death. Another reason is that recognizing and pursuing the cause of calcium abnormalities often aids in diagnosing the underlying disease process.

When measuring serum concentrations of calcium, it is important to understand the difference between the measurement of total calcium (tCa) and free, ionized calcium (iCa). Free (unbound) iCa is the biologically active, hormonally regulated fraction that comprises approximately 50% of tCa. Measuring the concentration of iCa is necessary to confirm if abnormalities in tCa concentrations are significant or

if calcitonin, PTH, and vitamin D concentrations are appropriate. Ionized calcium is not routinely included in serum chemistry panels because it is measured by an ion-selective electrode methodology that is not typically used in the large chemistry analyzers. Total calcium is what is routinely reported on a serum biochemical panel; it is measured via a colorimetric technique. The tCa measurement includes all calcium, whether bound or unbound. The bound fractions of tCa are those that are bound to protein (~40–45% of tCa) and complexed with nonprotein ions such as phosphates, citrate, lactate, etc. (5–10% of tCa). Changes in the amount of calcium bound to proteins or other ions will affect tCa but will not affect the concentration of iCa. Bound calcium is essentially removed from the biologically active pool of calcium. Therefore, as long as regulatory mechanisms are functioning properly, the iCa concentration typically remains within a narrow range, even if tCa concentrations decrease or increase because of changes in the amount of substances that bind calcium in the blood (Figure 25.9).

Ionized calcium is required for vital intracellular and extracellular functions, including muscle tone and contraction, nerve conduction, hormone secretion, enzymatic reactions, blood coagulation, and cell growth, division, and function. It is also required for skeletal support. Some of the more common sequelae to marked hypercalcemia include polyuria, constipation, acute renal failure, and cardiac arrhythmias. The majority of signs related to hypocalcemia are due to the importance of calcium in muscle function. Signs may include muscle fasciculations, tetany, seizures, paresis, tachycardia, hypotension, and respiratory arrest.

Box 25.7 An acronym to help remember the differentials for hypercalcemia

Acronym for most hypercalcemia differentials (tCa):

- **G** ranulomatous inflammation
- **O** steolytic lesions
- **S** purious results
- **H** yperparathyroidism (primary)
- **D** vitamin toxicity
- **A** ddison's disease
- **R** enal disease (chronic)
- **N** eoplasia
- **I** diopathic
- **T** ransient

Abnormalities in blood calcium concentration result from an imbalance in hormonal regulation, altered absorption from the gastrointestinal tract, pathologic excretion from the kidneys, or altered distribution involving bone or other tissues. This chapter will briefly cover differentials for calcium and phosphate abnormalities. For more in-depth discussion of regulation and pathophysiologic mechanisms, see Chapter 34.

Hypercalcemia

Hypercalcemia (Box 25.7), if ignored, can lead to serious consequences such as acute renal injury and failure. Therefore,

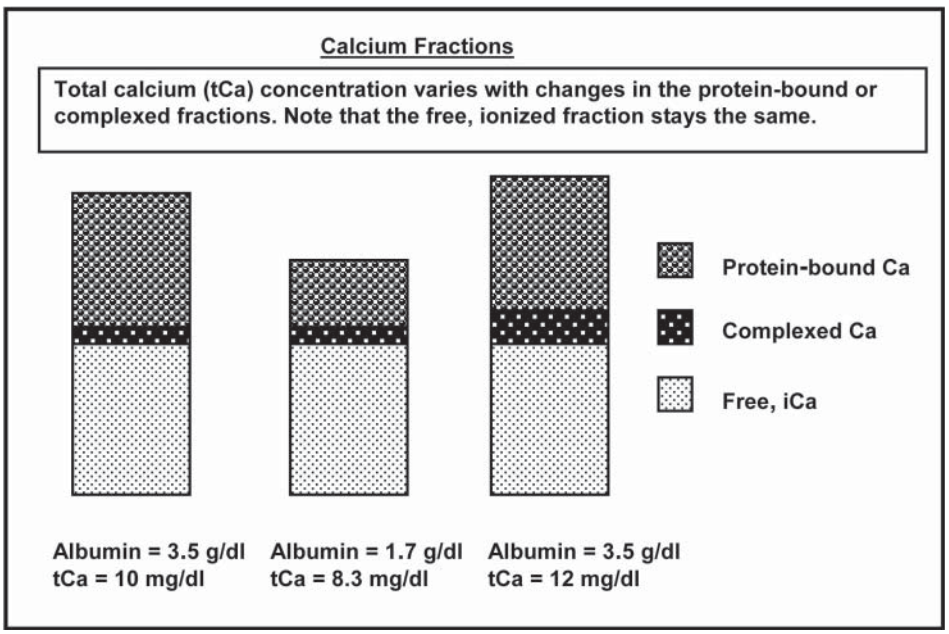

Figure 25.9 Ionized calcium, the biologically active fraction, normally stays within a very narrow range while total calcium concentration is affected by calcium that is bound or complexed and, therefore, inactive.

depending on the situation, if hypercalcemia is not immediately investigated, it is a good idea to at least determine persistence by rechecking or, ideally, to measure the iCa concentration when tCa is elevated. More routine measurement of iCa may be indicated when potential for a calcium disorder exists because concordance of tCa and iCa concentrations is poor; >60% of cats with elevated iCa had tCa concentration within reference intervals [18]. If the iCa concentration is normal, this suggests that abnormalities in tCa are due to changes in the amount of bound calcium and, therefore, an increase in the concentration of complexing or binding substances. If the iCa concentration is increased there is a problem with calcium regulation.

Hypercalcemia can occur due to an increase in PTH or PTH-like substances. High concentrations of calcium normally feed back to decrease PTH secretion. If PTH concentrations are higher than they should be in the face of hypercalcemia, the cells producing PTH are not responding to feedback signals, as occurs with parathyroid tumors. Primary hyperparathyroidism is most commonly associated with parathyroid adenomas; in this disease, the thyroid gland itself is inappropriately over-producing PTH. Along with increased iCa and PTH levels, hypophosphatemia is typically present, unless there is a concurrent decrease in GFR, with which normal or increased phosphate concentrations may be seen.

A substance that has similar actions to PTH is PTH-related protein (PTHrP). While this substance has normal functions, it becomes a problem when produced by neoplastic cells. One of the most common causes of hypercalcemia is neoplasia, and PTHrP is associated with many of these cases of humoral hypercalcemia of malignancy (also called pseudohyperparathyroidism). The more common neoplasms associated with humoral hypercalcemia of malignancy are lymphoid neoplasms (e.g., lymphoma) and apocrine gland adenocarcinoma of the anal sac, although many different tumors have been associated with hypercalcemia, including thymoma and various carcinomas. An assay to measure the concentration of PTHrP is available for dogs and cats. In cases of humoral hypercalcemia of malignancy, PTHrP is often increased, iCa concentrations are increased, and PTH is appropriately low. Phosphate levels are typically decreased, unless there is a concurrent decrease in GFR.

Vitamin D toxicity results in increased absorption of calcium from the gastrointestinal tract. Toxicity can occur with cholecalciferol rodenticide poisoning, ingestion of plants containing vitamin D glycosides (*Cestrum diurnum*, *Solanum malacoxylon*, and *Trisetum flavescens*), ingestion of calcipotriene, an analog of calcitriol found in a topical preparation used to treat psoriasis in people, or over-supplementation. Some granulomatous diseases as well as some neoplasms activate vitamin D precursors in an unregulated manner, resulting in hypercalcemia. Hypervitaminosis D results in increased iCa and phosphate and low PTH concentrations.

Renal disease can be associated with hypercalcemia but should only be attributed as the cause after other differentials are ruled out because hypercalcemia can induce renal failure.

Hypercalcemia is a common finding in chronic renal failure in horses, as the horse kidney plays a more important role in excreting excess calcium than in other species. In equine chronic renal failure, iCa is often high, phosphate low, and PTH appropriately low. Only approximately 10% of dogs with chronic renal failure are hypercalcemic; within this population, dogs with hereditary disease are more common. Hypercalcemia is also a common finding in dogs with grape or raisin-induced renal failure [19]. Hypercalcemia is more common in cats with chronic renal failure than in dogs. In cats and dogs, although tCa may be increased in chronic renal failure, iCa is usually normal or low, consistent with increased complexing of calcium, and PTH may be increased.

Hypoadrenocorticism (Addison's disease) is a common cause of hypercalcemia in dogs. Approximately 1/3 of dogs with hypoadrenocorticism are hypercalcemic. The mechanism of hypercalcemia is unclear and the concentration of iCa is variable [20, 21].

Because bone contains high amounts of calcium, osteolytic lesions occurring from inflammatory conditions or from metastatic neoplasia can result in hypercalcemia.

Idiopathic hypercalcemia is diagnosed if all other potential causes have been ruled out. This has become one of the most common causes of hypercalcemia in cats [18]. As the name implies, the underlying mechanism is unknown. Hypercalcemia is typically mild to moderate, with increased iCa, low to normal PTH, and normal vitamin D concentrations [22].

There can be nonpathological reasons for hypercalcemia. Mild, transient increases may occur postprandially. Dehydration concentrates proteins within the blood, which can result in mild increases in tCa concentration. Acidosis decreases calcium binding of serum proteins, which can result in increased iCa concentrations. Young, growing animals normally have higher calcium concentrations; consequently, if adult reference intervals are used, they will appear hypercalcemic when, in fact, their calcium concentrations are normal for their age. Depending on method of analysis, lipemia or marked hemolysis may interfere with the colorimetric measurement of tCa. If there is significant lipemia or hemolysis present in the sample, a new sample should be collected and measured or iCa determined.

Diagnostic tools for further working up the cause of a persistent hypercalcemia include laboratory techniques as well as other diagnostic modalities. If hypercalcemia was

detected by measuring tCa, determining the iCa concentration is important in order to interpret the importance of the abnormality as well as helping differentiate between causes. A complete blood count (CBC), serum chemistry panel, and urinalysis are critical for the assessment of underlying disease processes. A thorough physical exam, including careful palpation of lymph nodes and the perianal area as well as radiographs and/or ultrasonography are valuable in the detection of masses or osteolyic lesions. Cytologic or histologic examination of mass lesions provides additional diagnostic information. It is possible to measure PTH and vitamin D concentrations as well as, in dogs and cats, PTHrP for assessment of hormonal status.

Hypocalcemia

It is uncommon for hypocalcemia (Box 25.8) to be severe enough to cause clinical signs, but mild hypocalcemia is often detected on a serum biochemistry panel when tCa is measured. The most common reason for hypocalcemia is a decrease in the protein-bound fraction when hypoalbuminemia is present. When this is the cause, the iCa concentration is normal. A simple correction factor is frequently used to correct for the decreased protein-bound fraction of calcium (3.5 – patient albumin + patient calcium = corrected calcium), but it must be kept in mind that this equation was determined only for dogs and is only a rough estimate that tends to underestimate the incidence of deficient iCa concentrations. While it serves as a reminder of the importance of albumin in tCa content, the use of the equation is no longer recommended since it does not accurately predict iCa concentrations [18]. It is more important to measure iCa in order to determine the significance of decreased tCa concentrations and if iCa is also low, especially in critically ill animals.

Primary hypoparathyroidism is an uncommon cause of hypocalcemia. It should be considered after other causes are ruled out. Iatrogenic hypoparathyroidism is more common and occurs if the parathyroid glands are mistakenly removed during thyroidectomy. With hypoparathyroidism, PTH is inappropriately low in the face of a low iCa concentration. Phosphate concentration is typically increased.

Dietary deficiency of calcium seldom leads to hypocalcemia because of the regulatory mechanisms in place to maintain normal blood calcium, but a severe decrease in absorption from the gastrointestinal tract caused by a malabsorption or maldigestion disease process or by cantharidiasis (blister beetle toxicity in horses) can result in hypocalcemia. Decreased absorption associated with vitamin D deficiency can also result in hypocalcemia along with hypophosphatemia.

Imbalances of other electrolytes can lead to hypocalcemia. Hypomagnesemia decreases PTH secretion and action, resulting in hypocalcemia. This is a common occurrence in bovine grass tetany but also occurs in other species. Hyperphosphatemia can also lead to hypocalcemia because high levels of phosphate decrease the activation of vitamin D and decrease the action of PTH on bone. This pattern of events is most commonly associated with renal disease (increased phosphate with decreased GFR) or nutritional imbalances (excess phosphate or low calcium:phosphate ratio) and is termed secondary hyperparathyroidism because PTH levels become increased secondarily to the persistent hypocalcemia.

During late pregnancy or lactation, the demand for calcium may be greater than the bearer's body can maintain. Puerperal hypocalcemia most commonly occurs a few weeks post-whelping in dogs and is rare in cats. Parturient paresis most commonly occurs within 3 days on either side of calving in cattle but can occur several weeks before or after parturition in sheep and goats. In horses, hypocalcemic tetany usually occurs 1–2 weeks after foaling (lactation tetany). Hypocalcemic tetany can also occur with increased calcium loss caused by excessive sweating in horses.

Transport tetany has occurred in cattle, small ruminants, and horses. Pregnancy or lactation can be a contributing factor, but the primary cause of the hypocalcemia is thought to be due to stress and decreased intake.

Altered distribution of calcium results in hypocalcemia when there is deposition of calcium in tissues as can occur with saponification of fat with pancreatitis or in massive tissue injury, including acute tumor lysis. Precipitation of calcium with oxalates occurs with ethylene glycol toxicity.

Although the mechanism is not completely understood, inflammatory mediators appear to influence calcium regulation. Hypocalcemia associated with sepsis and critical illness is well recognized in human medicine and has been reported in dogs with sepsis, [23–25] in cats with septic peritonitis [26], and with equine colic [27–30]. Total calcium concentrations and calcium concentrations corrected for albumin are not reliable indicators of iCa in these cases. Free, iCa

Box 25.8 An acronym to help remember the differentials for hypocalcemia

should be measured in critically ill patients, especially if signs of hypocalcemia are evident.

Alkalosis promotes calcium binding to serum proteins and can cause a decrease in iCa concentrations.

Calcium chelators can result in decreased calcium measurements. Contamination of a sample with EDTA will result in a falsely low calcium value; magnesium is also low and potassium is typically increased.

Phosphorus

Phosphorus is required for energy metabolism, nucleic acid synthesis, and cell signaling. In the body, phosphorus is in the form of phosphate, a molecular anion that is in higher concentrations in ICF than ECF. It is an important buffer in blood and urine and an important component of bone and structural plasma membrane phospholipids and phosphoproteins. Abnormalities in serum phosphate concentrations can be due to abnormalities in hormonal balance, intestinal absorption, renal excretion, or tissue or cell distribution. Serum concentrations of phosphate may not reflect total body levels.

If there is a concurrent abnormality in serum calcium, pursuing and determining the cause of the calcium abnormality will often provide explanation for an abnormality in phosphate. Examining the pattern of change between calcium and phosphate can provide important clues.

Hyperphosphatemia

Hyperphosphatemia (Box 25.9) typically occurs when the phosphate load (from GI absorption, cellular release, or exogenous administration) exceeds excretion and tissue uptake. In most species, the primary route of phosphate excretion is via the kidneys, but in ruminants, it is via the gastrointestinal tract. The most common cause of hyperphosphatemia is decreased renal excretion associated with a decrease in GFR. Chronic renal failure is the most common cause of hyperphosphatemia in adult dogs and cats. In ruminants, upper GI obstruction can lead to hyperphosphatemia because of decreased gastrointestinal excretion.

Phosphate enters the body via the gastrointestinal tract, dependent on diet and hormonal regulation. The amount of phosphate absorbed in the small intestine is linearly related to its concentration in the intestinal lumen. Therefore, an excess phosphate load from high phosphate diets or ingestion of nondietary substances containing high concentrations of phosphate, such as ethylene glycol that contains phosphate rust inhibitors, will increase intestinal absorption. Hypervitaminosis D increases the amount of phosphate absorbed from the gastrointestinal tract, leading to hyperphosphatemia and hypercalcemia. Phosphate enemas can also lead to severe hyperphosphatemia.

Given that the majority of total body phosphate is stored in bone and that the concentration of intracellular phosphate is more than 10 times that of ECF, the redistribution of phosphate from bone or from the intracellular space can

Box 25.9 An outline for working through the differentials for hypophosphatemia and hyperphosphatemia

Working through phosphorus abnormalities

1. What is the serum calcium concentration?
- Is there a pattern consistent with hormonal imbalance?

Hypophosphatemia	Hyperphosphatemia
Hypercalcemia • Primary hyperparathyroidism? • Hypercalcemia of malignancy? Hypocalcemia • Vitamin D deficiency?	Hypercalcemia • Vitamin D toxicosis? Hypocalcemia • Hypoparathyroidism?

2. What do renal parameters look like?
- Is there evidence for decreased excretion or resorption?

Hypophosphatemia	Hyperphosphatemia
Prolonged diuresis? • Treatments? • Hyperglycemia? • Polyuria? • Dilute urine? Possible tubular defects? • Glucosuria? Horse with hypercalcemia and azotemia?	Is there evidence for decreased GFR?? • Elevated serum BUN and creatinine? **Most common cause of hyperphosphatemia.**

3. Is there any evidence of dietary or gastrointestinal problems?

Hypophosphatemia	Hyperphosphatemia
Prolonged anorexia? Diarrhea? Vomiting? Low phosphorus diet?	High phosphorous diet? Phosphate enema use? Ingestion of ethylene glycol with phosphate rust inhibitors? Ruminant with upper GI obstruction?

4. Could there be redistribution; a shift between the ICF and ECF?

Hypophosphatemia	Hyperphosphatemia
Insulin therapy? Carbohydrate loading? Alkalosis?	Evidence of extensive tissue damage? Presence of osteolytic bone lesion? Acidosis?

result in hyperphosphatemia. Release from bone can occur with osteolytic lesions. Release from cells occurs with injury, which must be extensive in order to significantly affect the serum concentration of phosphate; this can occur with acute tumor lysis or acute myopathies. Acidosis decreases the cellular uptake of phosphate and can contribute to hyperphosphatemia.

Improper sample handling may cause falsely increased serum phosphate concentrations. This includes hemolysis of the sample or a delay in the removal of serum from erythrocytes after collection. Mild, transient increases in serum phosphate concentration may occur postprandially. Young, growing animals have higher concentrations of serum phosphate; consequently, if adult reference intervals are used, they will appear hyperphosphatemic when, in fact, their phosphate concentrations are normal for their age.

Hypophosphatemia

Hypophosphatemia (Box 25.9) occurs from hormonal imbalances, decreased renal reabsorption, decreased intestinal absorption, or redistribution from ECF to ICF. Hormonal imbalances typically include concurrent calcium abnormalities, the pattern of which can aid diagnosis. A low phosphate with increased calcium concentration is the pattern seen with pseudo- or primary hyperparathyroidism. A decrease in both phosphate and calcium is the pattern seen with hypovitaminosis D. Hypophosphatemia can also occur due to elevated PTH in response to periparturient hypocalcemia (physiologic hyperparathyroidism).

Decreased renal phosphate reabsorption (increased phosphate excretion) leads to hypophosphatemia. This can occur because of congenital or acquired defects in the proximal tubules where the majority of reabsorption normally occurs, often called Fanconi's syndrome. Diuresis results in decreased renal phosphate reabsorption, which, when prolonged, can lead to hypophosphatemia. Diabetic ketoacidosis leads to hypophosphatemia because of osmotic diuresis, as well as phosphate's role as a buffer for excreted acid. Although the mechanism is poorly understood, hypophosphatemia is often seen with the hypercalcemia associated with chronic renal failure in horses. Increased phosphate excretion is also the mechanism of hypophosphatemia associated with hyperparathyroidism as PTH decreases reabsorption of phosphate in proximal renal tubules.

Decreased intestinal absorption of phosphate is an uncommon cause of hypophosphatemia as the body typically can maintain normal blood levels even with decreased intake, although anorexia or a low phosphate diet, if prolonged, may lead to hypophosphatemia. Impaired absorption because of vomiting, diarrhea, or an intestinal malabsorption disease can also lead to hypophosphatemia. Decreased intestinal absorption is the mechanism of hypophosphatemia with hypovitaminosis D.

Redistribution of phosphate from ECF to ICF can result in hypophosphatemia. Insulin causes phosphate to move into cells. Hypophosphatemia can occur with administration of insulin or with insulin-producing tumors. It can also occur with carbohydrate loading or intravenously administered glucose, which induces the secretion of insulin. Respiratory alkalosis has been associated with hypophosphatemia because phosphate shifts to the intracellular space when CO_2 moves out of the cell. Because phosphate is required for energy metabolism, accelerated metabolism, in general, will result in intracellular shifts of phosphate, decreasing extracellular concentrations.

Magnesium

Magnesium is primarily an intracellular ion and is a cofactor of many enzymatic reactions, including all reactions involving the formation and utilization of ATP and many mitochondrial reactions. It is also required for protein and nucleic acid synthesis. Vitamin D and PTH influence, but do not regulate, magnesium metabolism [31]. Homeostasis is primarily a balance between intestinal absorption and renal excretion. Magnesium has a similar charge as calcium and, as does calcium, exists in free ionized, protein-bound (approximately 30%), and complexed forms in serum. Serum magnesium contains only approximately 1% of total body magnesium and therefore is not necessarily an accurate representation of total body magnesium.

Hypomagnesemia

Hypomagnesemia is more commonly associated with morbidity than hypermagnesemia. Neuromuscular signs occur with hypomagnesemia, including hyperexcitability, muscle tremors, spasms, and fasciculations, and ataxia. Other complications associated with hypomagnesemia include the development of hypokalemia or hypocalcemia. These deficiencies may not be able to be corrected unless hypomagnesemia is corrected first.

Hypomagnesemia is typically associated with either increased loss or decreased intake. Losses, the most common cause of hypomagnesemia in small animals, are through the renal or gastrointestinal systems. Renal loss occurs due to lack of renal conservation of magnesium, typically associated with diuresis or tubular dysfunction. Causes of urinary magnesium loss include: diuretics, osmotic diuresis, diabetic ketoacidosis, postobstructive diuresis, polyuric renal failure, RTA, hyperthyroidism, hypercalcemia, and nephrotoxic drugs [32]. Malabsorption and diarrhea are causes of gastrointestinal magnesium loss.

Decreased intake is a common cause of hypomagnesemia in ruminants. Grass tetany is a disease that is associated with ruminants eating lush green pastures that are high in potassium and low in magnesium content. Increased potassium ingestion blocks normal magnesium absorption in the rumen. Milk tetany is a disease that is associated with

older calves being fed milk-only diets. Prolonged anorexia or poor diet can lead to hypomagnesemia, especially if an animal is lactating. Prolonged intravenous fluids or parenteral nutrition can also lead to hypomagnesemia if magnesium supplementation is not included.

Other causes of hypomagnesemia include redistribution and hypoalbuminemia (if total magnesium is measured instead of free, ionized magnesium). Redistribution of magnesium is not well understood but may be influenced by administration of insulin or glucose, sepsis, trauma, or pancreatitis.

Hypermagnesemia

Hypermagnesemia is typically a less significant clinical problem, unless it develops acutely. It can result in cardiac or neurological problems and cause nausea and vomiting.

Hypermagnesemia can occur iatrogenically or due to decreased renal excretion, primarily associated with acute renal failure or urethral obstruction.

26 Laboratory Evaluation of Acid-Base Disorders

Glade Weiser
Loveland, CO, USA

Introduction

Acid-base analysis, also known as blood-gas analysis, has been a growing point-of-care diagnostic application established for complicated medical cases and in critical care settings. Assessment of acid-base status is typically done in conjunction with electrolyte evaluation to determine the presence and severity of fluid and electrolyte derangement attributable to the animal's underlying disease process. Advances in technology have made acid-base evaluation possible and even routine within the in-clinic laboratory. These determinations allow for correction of such clinical abnormalities, which in turn aids recovery time and may improve mortality outcome.

Blood-gas analysis has historically been regarded as complex and intimidating for many clinicians. This is likely because measurement and interpretation of partial pressures of gases in blood solution are less conceptually intuitive than concentration measurements dealt with in hematology and conventional clinical chemistry. The subject also is complicated by many derivative specialty calculations that may appear on laboratory reports. Sample transportation to a central laboratory, perceived complex sample handling, and a perception that blood-gas analysis necessitates arterial blood collection are factors that have contributed to adoption reluctance. However, the clinician is encouraged to embrace this capability made possible by the availability of simplified point-of-care analysis systems that eliminate most of these barriers.

Recommendations to facilitate use include the following. It may help to think of blood-gas analysis more simply as analysis of acid-base balance. This approach may be more intuitive. Today's point-of-care electrochemical analyzers make capability to evaluate acid-base status routine. Incorporation of this capability into the practice routine provides the use frequency needed to build and maintain interpretive skills. Users should focus on a few key values and not be overwhelmed by the various possible derivative calculations that may appear on laboratory reports. Most of the calculations may be ignored while initial interpretive skill is acquired. Users may then adopt a few selected calculations as skill is accumulated.

The purposes of this chapter are to present a background of the technical aspects of acid-base analysis and an introductory approach to interpretation of basic acid-base laboratory data. The introductory approach is designed to help the reader recognize and interpret basic, common acid-base abnormalities; there is no intention to discuss advanced concepts used by various specialties. The latter is left to literature and advanced training that exists for specialty applications.

Technical considerations

Measurement of acid-base parameters

Acid-base laboratory data are generated on electrochemical analyzers (Chapter 1). These typically use the same sample to simultaneously determine both electrolyte and acid-base determinations. Venous blood collection is adequate for evaluation of the metabolic complications of disease that result in acid-base and electrolyte disturbances. Arterial blood is typically only required when it is necessary to critically evaluate blood oxygenation.

While a number of parameters may appear on an acid-base report, there are very few direct measurements and calculations that are important for interpretation of acid-base balance. A systematic focus on this small number of parameters will simplify interpretation. These include the following.

pH

The primary measurement of blood acidity is pH. It is directly measured by an ion specific electrode (see Chapter 1). pH is the negative log of hydrogen ion concentration. Therefore, a decrease in pH value indicates an increase in free hydrogen ion concentration (relatively acidic) and an increase in

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.
© 2022 John Wiley & Sons, Inc. Published 2022 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/thrall/veterinary

pH indicates a decrease in free hydrogen ion concentration (relatively alkaline). pH is very tightly regulated in the body by a number of buffering systems.

PCO_2

The partial pressure of carbon dioxide (CO_2) gas dissolved in blood, measured in mm of mercury (mmHg). This may be measured in either venous or arterial blood.

HCO_3 or bicarbonate concentration

Using the pH and pCO_2 values, bicarbonate concentration is calculated by the instrumentation software. It is expressed in mmol/L. The pH and bicarbonate values are the most useful for interpretation of acid-base disturbances when venous blood is the sample.

PO_2

The partial pressure of oxygen (O_2) gas dissolved in blood, measured in mm of mercury (mmHg). This measurement is typically only useful for analysis of blood oxygenation and therefore is only of interpretive value when arterial blood is sampled specifically to evaluate the patient for oxygenation pathology.

Other calculated values

There are a number of possible calculated indices. The presentation of these on reports varies by the manufacturer. Their use is somewhat optional, and most are typically adopted by critical care specialists. Some relate to arterial human applications that are rarely used in animals.

Sample handling requirements

Proper sample handling instructions are available and are simplified by the capability provided by point-of-care analysis. pH may be affected by changes in pCO_2. Both CO_2 and O_2 may move toward ambient equilibrium in blood removed from the body if not properly handled. The following are proper sample handling guidelines for electrochemical analyses that should be supplemented by instructions accompanying point-of-care analyzers:

- Avoid manual heparinization of syringes. This can cause gross over-heparinization of the sample, leading to errors in any of the acid-base and electrolyte results.
- It is recommended to use a balanced heparin-containing syringe produced specifically for electrochemical analysis samples (see Chapter 2).
- Any gas bubbles in the collection syringe should be expelled.
- Unless the sample is introduced for analysis immediately after collection, the syringe should be capped to prevent sample contact with air. Recommended collection devices have a cap for this purpose.

Physiologic considerations

Regulation of blood pH

It is critical for most physiologic functions that acid-base balance be maintained within a narrow range of pH, typically 7.35–7.45, with some minor species variations indicated in reference interval tables. A number of pathologic conditions may add or subtract acid in blood and body fluids. The blood contains considerable buffering capacity to aid regulation of blood pH. Major buffers include hemoglobin and the bicarbonate buffer systems. Minor contributory buffers include inorganic phosphate and plasma proteins. Through equilibrium reactions, these molecules may incorporate or release hydrogen ions in the effort to maintain pH. The bicarbonate buffer system is important because of its rapid buffering capacity and because its components are readily measured for assessment blood pH and associated therapeutic monitoring. In addition, the bicarbonate system interacts with the mass quantity of hemoglobin in both pH regulation and gas exchange between tissues and respiration. The equilibria within the bicarbonate buffer system are shown in Figure 26.1.

The relationship of the bicarbonate buffer system to pH is described as:

$$\text{pH} = \text{pK} + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

where pK is the pH at which 50% of an acid is dissociated; this is ~6.1 for carbonic acid.

Because pCO_2 can be measured and the dissolved CO_2 in blood is proportional to the carbonic acid concentration, this relationship may be simplified to:

$$\text{Blood pH} = 6.1 + \log \frac{[HCO_3^-]}{\alpha pCO_2}$$

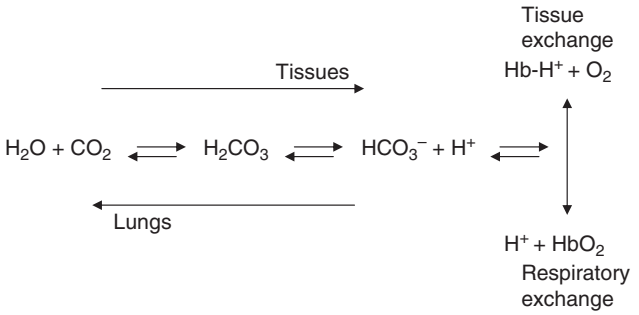

Figure 26.1 Bicarbonate buffer system interactions. At the lung level, hemoglobin binds oxygen; this creates a molecular change that favors dissociation of H^+ from hemoglobin. This will push the equilibrium to the left, yielding CO_2 and water that is expired. At the tissue level, metabolism yields CO_2 and considerable acid. Hemoglobin releases O_2 to tissues and deoxygenated hemoglobin then binds H^+. Thus, equilibrium is driven to the right.

where α pCO_2 is pCO_2 multiplied by its solubility constant to yield the amount of CO_2 gas dissolved in blood. Using the solubility constant, the above formula may be rearranged to:

$$\text{Blood pH} = 6.1 + \log \frac{[HCO_3^-]}{0.03 \times pCO_2}$$

Normally, the ratio of bicarbonate to CO_2 is 20 : 1. At this ratio, the log of 20 plus 6.1 yields the desired blood pH of 7.4. For interpretation purposes it is helpful to think of bicarbonate as being the metabolic component of blood pH regulation and pCO_2 as being the respiratory component of blood pH regulation. For example, if bicarbonate is utilized to buffer an increase in metabolic acid (H^+), a decrease in bicarbonate in the above equation results in a decrease in pH, or acidosis. In response, respiration may increase CO_2 expiration to partially normalize the ratio and is known as compensation. The compensation response attempts to normalize the ratio, which in turn helps normalize or regulate pH. This framework of metabolic and respiratory components in the above equation will be very helpful for identifying and interpreting acid-base abnormalities.

Acid-base balance pathology

General processes that may result in life-threatening abnormalities in acid-base balance are classified in the following four primary categories. Common disease entities that may result in these categories are outlined in Table 26.1. Metabolic acid-base disturbances develop relatively slowly, usually over a period of days, whereas respiratory acid-base disturbances may develop very acutely.

Bicarbonate (HCO_3^-) depletion – metabolic acidosis

This is due to pathologic metabolic production of acid in the form of hydrogen ions. The increased hydrogen ions are buffered by combining with bicarbonate to form carbonic acid that then dissociates to CO_2 gas and water. The CO_2 is then rapidly eliminated from the system via respiration. Common examples of pathologic metabolism resulting in metabolic acidosis include lactic acidosis, ketoacidosis, renal failure, and acid toxicities (e.g., ethylene glycol toxicity). Alternatively, bicarbonate may be lost from the system such as may occur with severe diarrhea. By any of these mechanisms, depletion of bicarbonate establishes metabolic acidosis.

Metabolic acidosis is the most common acid-base disturbance. This is attributed to the fact that dehydration and poor tissue perfusion leading to lactic acid production is a process common to many primary internal medical disorders. Renal failure and diabetes mellitus, relatively common disorders in veterinary patients, also contribute to the incidence of metabolic acidosis.

CO_2 retention due to hypoventilation – respiratory acidosis

This is due to acute respiratory failure with accumulation of CO_2. Causes include hypoventilation during anesthesia or any pathologic cause of acute spontaneous hypoventilation or severe impairment of gas exchange at the blood – lung interface.

Bicarbonate excess – metabolic alkalosis

This is due to metabolic production and accumulation of excess bicarbonate. Gastric parietal cells produce hydrogen

Table 26.1 Acid-base disturbances resulting in abnormal blood pH.

Acid-base disturbance	Metabolic acidosis decreased pH	Metabolic alkalosis increased pH	Respiratory acidosis decreased pH	Respiratory alkalosis increased pH
Primary bicarbonate buffer alteration	Decreased bicarbonate	Increased bicarbonate	Increased CO_2	Decreased CO_2
Causes	Any cause of generalized poor perfusion leading to lactate production	Loss of acid due to vomiting or functional upper gastrointestinal obstruction	Any cause of respiratory failure, e.g.:	Pulmonary pathology resulting in impaired O_2 alveolar diffusion
	Diabetic ketoacidosis Lactic acidosis	Excess bicarbonate therapy	Severe pneumonia Pneumothorax Severe pleural fluid	Excess positive pressure ventilation during anesthesia
	Renal failure Ethylene glycol toxicity	Excess diuretic therapy	Airway obstruction Hypoventilation due to anesthetic overdose	
	Diarrhea			

For each disturbance category, the major abnormality in the bicarbonate buffer system is indicated. Also, common causes or processes that may cause a given disturbance are listed.

ions by combining CO_2 and water to form carbonic acid, which then dissociates to H^+ and bicarbonate. Bicarbonate is exchanged to the plasma for chloride ions. H^+ and Cl^- are then excreted into the gastric lumen as part of the gastric acid (H^+Cl^-) digestive response. The most common cause of metabolic alkalosis is upper gastrointestinal obstruction. The hydrogen ions are secreted into the stomach and are lost in the obstructive process, while bicarbonate is retained.

CO_2 loss due to hyperventilation – respiratory alkalosis

This may occur when there is hypoxemia that stimulates hyperventilation, as seen with some forms of pneumonia. With inflammatory or fluid pneumonia, the gas diffusion barrier is increased. Oxygen diffuses more slowly than CO_2 across such barriers. Increased ventilation due to poor oxygenation can result in loss of CO_2 since it diffuses more freely across the barrier. More severe pneumonia that impairs even CO_2 diffusion is more likely to lead to respiratory acidosis as a result of CO_2 retention. Excess positive pressure ventilation during anesthesia may also cause respiratory alkalosis.

Relationship of acid-base pathology to anion gap

The anion gap is discussed in Chapter 25. The anion gap is useful in classifying metabolic acidosis into one of two categories, which may help determine the cause of the acid-base disturbance. The most common pathway to metabolic acidosis is accumulation of acid due to either production of organic acid or the presence of an acid toxicity. The accumulation of a dissociable acid yields H^+ and the respective anion. As the H^+ is buffered by bicarbonate, the bicarbonate concentration decreases. The anion is unmeasured in calculation of anion gap and its accumulation results in the increased anion gap. Representative unmeasured anions associated with metabolic acidosis disorders are listed in Table 26.2.

The alternative cause of metabolic acidosis is due to a primary process of bicarbonate loss. This may be due to severe diarrhea or, less commonly, renal tubular acidosis in which there is pathologic renal loss of bicarbonate. In this situation, the anion gap will be normal because there is no accumulation of unmeasured anions. Increased serum chloride may develop with this type of acidosis. The kidneys will continue to reabsorb the vast majority of filtered sodium. Because active renal sodium reabsorption requires either bicarbonate or chloride as a counterion, more chloride may be retrieved when there is relatively severe deficit of bicarbonate. As a result, hyperchloremia may develop.

Table 26.2 Causes of metabolic acidosis with increased anion gap, with associated pathologic acids.

Disease with unmeasured anions	Pathologic acid(s)
Diabetes, unregulated	Ketoacids: acetoacetate, beta-hydroxybuterate
Renal failure	Sulfates, phosphates, and lactate when dehydrated
Hypoxemia and/or poor perfusion	Lactic acid
Acid toxicity, e.g., ethylene glycol toxicity	Metabolism to form oxalic and glycolic acids

Approach to interpretation of acid-base data

Evaluation of acid-base status begins with analysis of blood pH, bicarbonate concentration, and the partial pressure of carbon dioxide. It is desirable to develop a stepwise approach to interpretation of the acid-base data. A recommended stepwise approach is described below and diagrammed in Figure 26.2.

Step 1 – Evaluate pH. The pH is abnormal if either decreased or increased beyond the reference interval limits. If the pH is decreased, the animal by definition has acidemia. This is due to some process that is causing acidosis or accumulation of acid in the system. If the pH is increased, the animal by definition has alkalemia. This is due to some process that is causing alkalosis or accumulation of base in the system.

If the pH is within the reference interval, a major acid-base disturbance is unlikely. However, there is still merit in checking the bicarbonate buffer pair for abnormality. If the pH is near the lower or upper limit it should still be evaluated as a possible indicator of acidosis or alkalosis. Borderline pH values may be an indication that a process causing acidosis or alkalosis is present, but there has been compensation in an attempt to normalize the pH. Alternatively, a mixed acid-base disturbance may be due to severe disease but result in a relatively normal pH value. A mixed acid-base disturbance is due to two or more processes affecting acid and/or base addition to the system.

Because of the relationship between pH and HCO_3^- and pCO_2 described above, the bicarbonate buffer system should next be evaluated to determine the cause of the acid-base disturbance defined by the pH. This involves a determination of whether the metabolic component (HCO_3^-) or respiratory component (pCO_2) of the buffer system is responsible for the primary acid-base disturbance.

Step 2 – Evaluate bicarbonate (HCO_3^-) concentration. Interpret if the HCO_3^- value is below the reference interval limit, indicating increased metabolic acid (acidosis), or above the reference interval limit, indicating increased metabolic base (alkalosis).

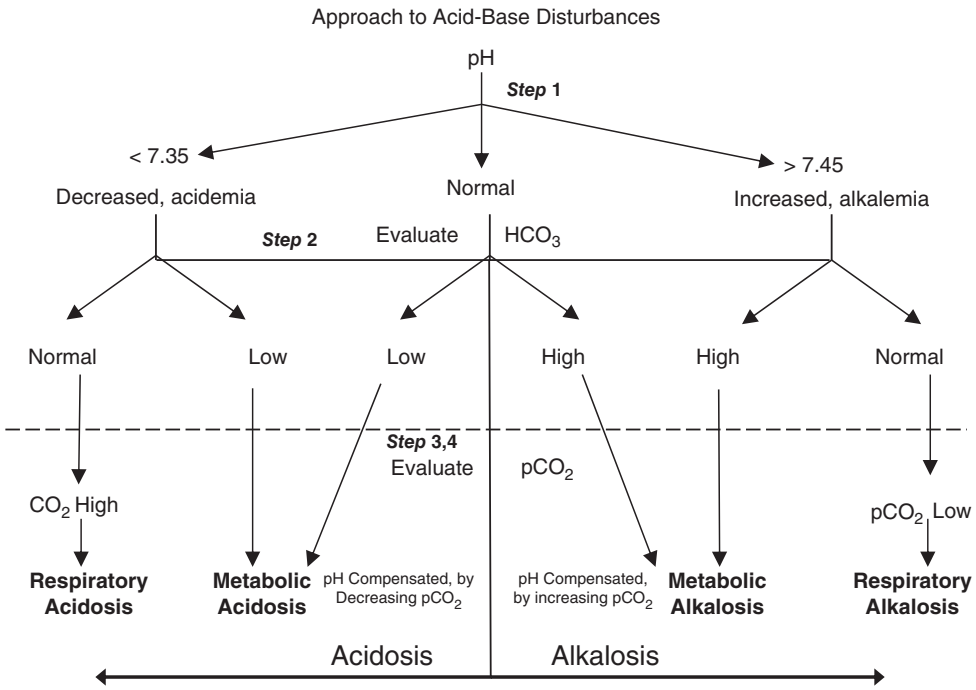

Figure 26.2 Stepwise approach to interpretation of acid-base disturbances. See text for narrative discussion.

Note that some references may suggest evaluation of pCO_2 first. However, because most acid-base disturbances identified in animals are due to metabolic disorders, evaluation of HCO_3^- first usually will readily define the acid-base disturbance.

Step 3 – Evaluate the pCO_2. If the pCO_2 value is normal, the acid-base disturbance is defined by the bicarbonate concentration abnormality. Interpret if the pCO_2 value is above the reference interval limit, indicating increased respiratory acid (acidosis), or below the reference interval limit, indicating increased respiratory base (alkalosis).

Step 4 – If needed, evaluate any combined abnormalities between HCO_3^- and pCO_2. If both the HCO_3^- and pCO_2 values are abnormal, the primary acid-base base disturbance is almost always due to the most abnormal value in the pair. The change in the least abnormal value is almost always due to a compensation response in an attempt to normalize the pH. In addition, the compensating value is either abnormal or moving toward abnormal in a direction *opposite* what would be required to cause the pH abnormality. This step may also aid in identification of acid-base disturbances due to more than one process, known as a mixed acid-base disturbance.

This approach may be illustrated in the following example of a common patient acid-base data, with comparison reference intervals (RI):

pH 7.21 RI = 7.35–7.45

decreased—indicates a primary acid disorder (acidemia)

HCO_3^- 12 mmol/L RI = 15–23 mmol/L

decreased—indicates acid response,

metabolic component of buffer system

pCO_2 30 mmHg RI = 35–40 mm Hg

decreased—indicates base response,

respiratory component of buffer system

Both determinants of the bicarbonate buffer system are abnormally decreased. The determinant abnormality that adds acid or base consistent with the pH change is the primary cause of the acid base disturbance. In this example, a decrease in HCO_3^- is interpreted as an addition of acid. The decrease in pCO_2 cannot explain the pH because this change would add base to the system, increasing the pH. Therefore, the concluding interpretation is metabolic acidosis with some respiratory compensation. The decrease in pCO_2 is a compensation response. Increased respiratory elimination of CO_2 tends to compensate to normalize the pH to some degree. Some will find it useful to utilize the formula of this relationship when making these interpretations:

$$\text{Blood pH} = 6.1 + \log \frac{[HCO_3^-]}{0.03 \times pCO_2}$$

Looking at this equation, it is apparent that either a decrease in HCO_3^- or an increase in pCO_2 would be required to decrease blood pH.

Table 26.3 Expected values for pH, HCO_3, and pCO_2 in various acid-base disturbances, including expected compensation responses.

Disturbance	pH	HCO_3	pCO_2
Metabolic acidosis	Dec	Dec	N
Metabolic acidosis, compensating	Dec or low N	Dec	Dec or low N
Metabolic alkalosis	Inc	Inc	N
Metabolic alkalosis, compensating	Inc or high N	Inc	Inc or high N
Respiratory acidosis	Dec	N	Inc
Respiratory acidosis, compensating	Dec	Inc or high N	Inc
Respiratory alkalosis	Inc	N	Dec
Respiratory alkalosis, compensating	Inc or high N	Dec or high N	Dec

N, normal value, within reference interval; Dec, decreased; Inc, increased.
Note that acute respiratory acidosis may not effectively compensate.

Compensation is a normal, active physiologic action to attempt pH correction in response to the primary acid-base disturbance. Unless the acid-base disturbance is very acute, a compensation response is expected. Typically, respiratory compensation for metabolic disorders occurs faster than metabolic compensation for respiratory disorders. Table 26.3 shows abnormalities in the bicarbonate buffer system for various acid-base disturbances and the expected respective compensation responses. It is important to note that compensation will move the pH toward normal but may at best only partially normalize the pH. For certain, mechanisms involved in compensation will not overcompensate pH normalization. This perspective is helpful for recognizing the presence of mixed acid-base disturbances.

More advanced considerations

Mixed acid-base disturbances

As mentioned above, a mixed acid-base disturbance is composed of two or more pathologic processes that affect pH. The pH value will reflect a balance of the contributing processes. An example of a mixed acid-base disturbance might be recognized in a dog with severe pancreatitis. In this situation, there may be dehydration with poor tissue perfusion and prerenal azotemia. These processes lead to metabolic acidosis. If there is also protracted or disproportionate vomiting, there is a superimposed process of metabolic alkalosis as a result of loss of gastric H^+Cl^-. The latter process may be suspected if there is a disproportionately decreased serum chloride concentration.

Recognition of a mixed acid-base disturbance should start with suspecting it based on diagnosis of the existing clinical problem or problems. Some example clinical scenarios that may result in mixed acid-base disorders include

- Hypoadrenocorticism with disproportionate vomiting – metabolic acidosis and alkalosis.
- Protracted vomiting and aspiration pneumonia – metabolic alkalosis and respiratory acidosis.
- Heart failure with severe pulmonary edema – metabolic and respiratory acidosis.
- Renal failure with disproportionate vomiting – metabolic acidosis and alkalosis.
- Gastric dilatation/volvulus – variable, depending on manifestations.
- Anesthesia in excess, with preexisting disorder – variable, depending on disorder.

The acid-base data may aid in confirming the presence of a mixed disturbance. Using the clinical findings and the most likely primary acid-base data abnormality, identify the primary acid-base disturbance. Then, predict the expected compensation response to the primary disturbance. Guidelines for magnitude of compensation changes in Table 26.4 may aid this determination. If the expected compensation response is either not present, excessive, or in the opposite direction of what is expected, then a second primary disturbance should be suspected, indicating a mixed acid-base disturbance. These guidelines should be used with considerable latitude and only large deviation from the expectation should be interpreted as inappropriate. By way of example, consider the following case data.

pH 6.99 RI = 7.35 – 7.45

severely decreased—indicates

a primary acid disorder (acidemia)

HCO_3^- 12 mmol/L RI = 15 – 23 mmol/L

decreased—indicates acid response,

metabolic component of buffer system

pCO_2 50 mm Hg RI = 35 – 40 mm Hg

increased—indicates acid response,

respiratory component of buffer system

At first glance, this may appear confusing if one is suspecting a single primary disturbance. If it is initially assumed that metabolic acidosis is the primary abnormality, one would expect a compensatory decrease in pCO_2 of about 2 mmHg below the lower RI limit, or ~33 mmHg (Table 26.4). However, the pCO_2 result is grossly different from the

Table 26.4 Guidelines for expected magnitude of compensation of primary acid-base disturbances.

Acid-base disturbance	Metabolic acidosis decreased pH	Metabolic alkalosis increased pH	Respiratory acidosis decreased pH	Respiratory alkalosis increased pH
Primary bicarbonate buffer alteration	Decreased bicarbonate	Increased bicarbonate	Increased CO_2	Decreased CO_2
Expected compensation	Decrease pCO_2 by respiration change	Increase pCO_2 by respiration change	Increase HCO_3^- by metabolism	Decrease HCO_3^- by metabolism
Expected magnitude of compensation	0.7 mmHg per 1.0 mmol/L^{-1} decrease in HCO_3^-	0.7 mmHg per 1.0 mmol/L^{-1} increase in HCO_3^-	Acute: 1.5 mmol/L HCO_3^- per 10 mmHg increase in pCO_2 Chronic: may approximately double	Acute: 2.5 mmol/L HCO_3^- per 10 mmHg decrease in pCO_2 Chronic: may approximately double

For each acid-base disturbance, the table shows the associated primary alteration, action for compensation, and expected magnitude of change in the compensation response.

compensation expectation. If it is initially assumed that respiratory acidosis is the primary abnormality, one would expect an increase in HCO_3^- of about 1.5–3.0 mmol/L, or ~ 25 mmol/L. Again, the result is grossly different than the compensation expectation. This should prompt consideration of a mixed acid-base disturbance. In this case there are two acid responses consisting of both respiratory acidosis and metabolic acidosis. The two primary acid-base disturbances are recognized as a mixed disturbance. Therefore, both the pulmonary function and potential causes of metabolic acidosis should be investigated (Table 26.1).

Arterial blood oxygenation

A conventional blood-gas analyzer measures pO_2 along with other values discussed above. It then calculates or predicts the percent hemoglobin saturation with oxygen (SO_2) based on the expected behavior of hemoglobin affinity at a given pH, body temperature, and pO_2. The relationship between percentage saturation and these variables is characterized by the hemoglobin-oxygen dissociation curve. These values are present on all blood-gas analyzer reports but are typically only useful for arterial samples performed specifically to evaluate oxygenation. As an initial alternative to arterial sampling, a simpler approach is to use a pulse oximeter to measure hemoglobin percentage saturation as a screening measurement to rule out oxygenation defects.

When breathing ambient air and blood oxygenation is normal, the animal will have an arterial pO_2 in the range of 85–100 mmHg. At this level, the SO_2 is typically 95% or higher. Generally, a large pathologic change in pO_2, e.g., <60–70 mmHg, is required to result in clinically important changes in SO_2. The calculation of percentage saturation is reasonably accurate when hemoglobin is normal. However, it is not accurate in the presence of the toxicities such as methemoglobinemia and carboxyhemoglobinemia (below) and in some hemoglobin abnormalities present only in humans.

Base excess calculation

The base excess (BE) value is typically included on the acid-base data report. This value is calculated to account for the combined bicarbonate and hemoglobin buffering capacity of blood. This is a complex calculation that utilizes information from a nomogram built on the relationship between pH, pCO_2, and HCO_3^- in blood. This relationship is similar for human and dog but may vary with other species. Instrument software typically uses the human calculation to derive BE. The normal range of BE is slight positive and negative deviation around zero. A positive abnormal value indicates an excess of base, or alkalosis. A negative value indicates the magnitude of HCO_3^- deficit in mmol/L in metabolic acidosis. The amount of deficit may be useful in planning fluid and bicarbonate therapy in treatment of metabolic acidosis in conjunction with hydration.

The BE utility is for calculation of the amount of bicarbonate replacement in fluid therapy formulae. These calculations result in the target amount of bicarbonate that would be administered with fluids to normalize the bicarbonate concentration and pH. The calculation is based on body weight and the goal to deliver bicarbonate to the extracellular fluid space, which is approximately 30% of body weight. A representative formula using the absolute value of BE is:

$$\text{Bicarbonate dosage (mmol)} = 0.3 \times \text{Body weight (kg)} \times \text{BE (mmol/L)}$$

One may encounter variations of the above formula, but the general principle is unchanged. The user must realize that bicarbonate replacement in acidosis is a moving target. The administration of bicarbonate is initially distributed to

the extracellular fluid space, but there is movement intracellularly over time. Furthermore, the process(es) causing acid-base disturbance may change or continue to affect bicarbonate balance. As a result, the acid-base status should be monitored during replacement therapy and ongoing bicarbonate administration should be adjusted accordingly.

Co-oximetry

In contrast to measurement of pO_2, co-oximetry is the measurement of hemoglobin (HGB) spectrophotometrically using multiple wavelengths of light. HGB will absorb light maximally at different wavelengths depending on its configuration. The four common absorption maximum wavelengths used in these devices are to provide measurement of:

- Oxygenated hemoglobin (oxy-HGB or O_2-HGB), which is expressed as true, measured oxygen saturation percent.
- Unoxygenated hemoglobin (deoxy-HGB).
- Carboxyhemoglobin (CO-HGB) – used to detect the presence and severity of carbon monoxide poisoning.
- Methemoglobin (Met-HGB) – used to detect the presence and severity of methemoglobinemia.

Because co-oximetry is used to characterize HGB oxygenation, it is typically useful only for arterial blood analysis.

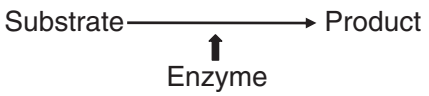
27 Laboratory Evaluation of the Liver

Robin W. Allison
Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

The liver functions in an amazing variety of biologic processes that are essential to life. These functions include metabolism of carbohydrates, lipids, proteins, hormones, and vitamins; detoxification and excretion of waste products and other toxic substances; digestion (especially of fats); and production of most clotting factors. The liver is highly vascular and uniquely situated to receive not only arterial blood via the hepatic artery but also venous blood via the portal vein. In fact, the majority (70–75%) of blood flow to the liver arrives from the portal circulation, and the liver's capacity to remove various solutes from portal blood is central to many of its functions [1]. Because of the liver's remarkable diversity, liver dysfunction may result in a variety of laboratory abnormalities.

Liver disease versus liver failure

Liver disease includes any process that results in hepatocyte injury, cholestasis, or both. These include hypoxia, metabolic diseases, toxicoses, inflammation, neoplasia, mechanical trauma, and intra-hepatic or extrahepatic bile duct blockage. It is important to realize that the liver is frequently secondarily affected by primary disease processes occurring in other tissues, such as inflammatory bowel disease and pancreatitis. Liver failure may result from liver disease, and is recognized both by failure to clear the blood of those substances normally eliminated by the liver and by failure to synthesize those substances normally produced by the liver. Liver disease, however, does not always result in liver failure. The liver has a marked reserve capacity, and 70–80% of the functional hepatic mass must be lost before liver failure occurs. Tests for liver disease or failure fall into three main categories:



- Serum enzyme assays that detect hepatocyte injury.
- Serum enzyme assays that detect cholestasis.
- Tests that evaluate liver function.

Introduction to enzymology

A basic understanding of diagnostic enzymology is necessary to interpret the results of serum enzyme assays used to detect liver disease. Principles of diagnostic enzymology include:

- Different organs, tissues, or cells contain different enzymes. In some cases, only a few organs or tissues contain a given enzyme; these "tissue-specific" enzymes tend to be the most diagnostically useful.
- Increased serum enzyme activity results when an increased quantity of the enzyme passes into the blood, either because of leakage from injured cells or because of increased production.
- Detection of increased serum enzyme activity, therefore, suggests either injury to the cells of origin or stimulation of the cells to produce increased quantities of the enzyme.
- Diagnostic enzymology is a means of locating where tissue injury or stimulation of increased enzyme production has occurred.
- Results of diagnostic enzymology, in combination with other clinical and laboratory data, are helpful in understanding the disease process and in making a diagnosis.
- Diagnostic enzymology does **NOT** provide information about tissue *function*.

In the body, enzymes catalyze biochemical reactions by converting a substrate into a product. For example,

To measure enzyme activity, a standard quantity of serum containing the enzyme to be measured is mixed with a solution containing the substrate for that enzyme. The reaction is then allowed to occur, and the enzyme's activity is measured by the rate of either substrate disappearance or product formation. The more rapidly that either one occurs, the greater

the patient's serum enzyme activity. Frequently, the product is not measured directly; rather, it is incorporated into a second reaction, which often involves the conversion of NAD^+ (or $NADP^+$) to NADH (or NADPH), or vice versa. This second reaction results in a change in the sample's light absorbance, which can be measured using a spectrophotometer [2].

Enzyme concentrations are not measured directly, but the serum activity of an enzyme is considered to be directly proportional to its concentration. Currently, enzyme activities are reported in terms of units per liter (U/L), with a unit defined as the quantity of enzyme that catalyzes the reaction of 1 µmol of substrate per minute [2]. Although this unit was historically referred to as an international unit (IU), the actual SI unit (Système International, for international uniformity) is the katal, which describes enzyme activity in moles per second. The SI system enzyme activity is reported in terms of katals per liter (kat/L) [2]. For conversion of units, IU/L × 0.01667 = µkat/L [3].

Basic concepts and information that must be considered to properly interpret the results of serum enzyme assays include:

- The difference between leakage enzymes and induced enzymes.
- The duration of enzyme activity after passage into the blood (i.e., the enzyme's biologic half-life in the blood).
- The tissue specificity of enzymes.
- The proper handling and storage of serum for enzyme assays.

Leakage versus induced enzymes

Increased serum enzyme activities can result from either leakage or induction. Enzymes can be released when cell injury alters cell membranes; enzymes that pass into the extracellular space and then into the serum by this mechanism are termed *leakage enzymes* (Figure 27.1). The term is somewhat misleading, however. Although membranes of fatally injured cells can certainly leak enzymes as they degrade, sublethally injured cells may release membrane blebs that later rupture, resulting in increased serum enzyme activity [4]. Nevertheless, it is useful to think of the process in terms of leakage. By contrast, induction involves the increased production of an enzyme by cells that normally produce the enzyme in smaller quantities. This increased production is induced by some type of stimulus, and it results in increased release of the enzyme from the cells and subsequent increased activity of the enzyme in serum. Enzymes that pass into the serum by this mechanism are termed *induced enzymes* (Figure 27.2).

Leakage enzymes are present in the cytosol, organelles, or both, and escape following sub-lethal or lethal (i.e., necrosis) cell injury. Increased serum enzyme activities can be detected within hours of the injury [5]. By contrast, induced enzymes are attached to cell membranes. Increased serum activity of these enzymes depends primarily on increased production and develops more slowly (i.e., days rather than hours) [5].

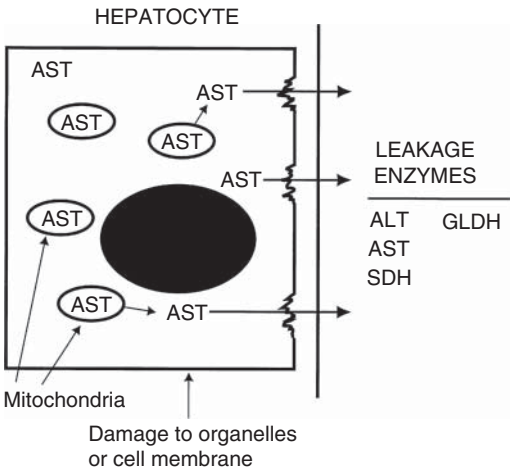

Figure 27.1 Leakage enzymes escape from the cell because of altered plasma membranes. Some leakage enzymes, such as AST, are also present in the organelles. More severe damage is required to cause leakage from these organelles.

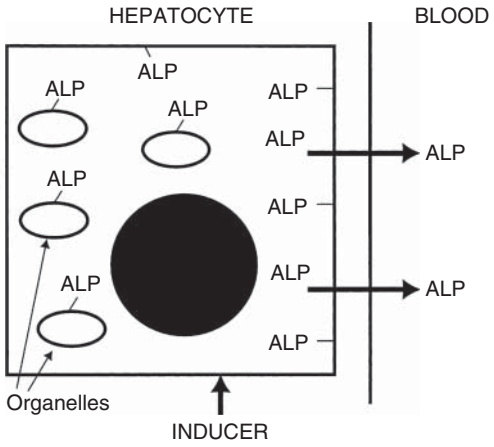

Figure 27.2 Increased serum activities of induced enzymes result, in part, from increased production of these enzymes, with a subsequent increase in secretion. This increased production is caused by some type of inducer.

The concept of leakage versus induced enzymes is important, but the difference is not entirely clear-cut in clinical situations. For example, acute hepatocyte injury can result in loss of leakage enzymes, but enzyme production may be upregulated in the subsequent reparative process of hepatic regeneration, resulting in a slower decline of serum enzyme activity than expected based on the enzyme half-life [6]. In addition, the release of membrane blebs containing membrane-bound enzymes may cause rapid but generally mild increases in serum activity of those "inducible" enzymes [5]. Release of induced enzymes can also occur secondary to less acute membrane alterations. The increased serum activities of alkaline phosphatase (ALP) and gamma

glutamyltransferase (GGT) that occur as a result of cholestasis are examples. A portion of the increase in the serum activities of these enzymes probably results from increased enzyme production, but the bile acids sequestered in bile canaliculi and ducts can solubilize membranes of hepatocytes and bile duct epithelial cells, resulting in increased release of these enzymes [7, 8].

Although activities of both leakage and induced enzymes often increase during most types of liver disease, the relative magnitudes of the increases can provide a hint about the underlying liver lesions. In diseases characterized primarily by hepatocyte injury, the activities of leakage enzymes tend to be increased to a greater degree than are the activities of induced enzymes. Similarly, in diseases characterized primarily by cholestasis, the activities of induced enzymes tend to be increased to a greater degree than are the activities of leakage enzymes. However, many liver diseases (particularly chronic diseases) result in both hepatocyte injury and cholestasis, so these distinctions are not always useful.

Enzyme half-life

After leakage or secretion from cells, the enzymes eventually are degraded and/or excreted from the body. Some enzyme molecules also lose their activity in the serum over time. The rate at which the loss of activity, degradation, or excretion occurs determines the length of time during which the enzyme activity is detectable in the serum after leakage or secretion. The disappearance rate of enzyme activity typically is measured as the biologic half-life of the enzyme, which is the time required for one-half of that enzyme's activity to disappear from the serum. Knowledge of the average biologic half-life of an enzyme is helpful when assessing how recently leakage or increased production has occurred and whether these processes are continuing. The biologic half-lives of various diagnostic enzymes and the use of enzyme half-lives in assessing tissue injury are discussed later.

Tissue specificity

It is important to know from which tissue the enzyme most likely originated. Knowledge of tissue specificity allows the diagnostician to narrow the list of possible tissues that are involved in a disease process. Tissue specificity is a function of:

- The presence or absence of the enzyme in the tissue. When increased serum activity of an enzyme is detected, only the tissues in which that enzyme is normally present are considered potential sites of injury.
- The concentration of the enzyme in tissues. An enzyme can be present in many tissues but have high concentrations in only one or a few. When increased serum activity of an enzyme is detected, the tissues in which that enzyme is found at the highest concentrations are the most likely sites of injury.
- Where the enzyme goes after leakage or secretion. Enzymes that are detected in serum have either leaked or been secreted into the extracellular spaces and then passed into the serum. Some tissues may have high enzyme concentrations, but leaked or secreted enzymes are not readily accessible to blood. For example, injury to renal epithelial cells results in leakage of the enzyme GGT [9]. This enzyme leaks from the brush border of the cell into the lumens of the renal tubules, rather than into the extracellular space. Thus, increased GGT activity can be detected in the urine, but the serum activity does not increase.
- The half-life of different isoenzymes. Enzymes with the same catalytic activity might be produced in several different tissues, but these enzymes can vary regarding other properties. These different forms of enzymes are termed isoenzymes or isoforms (see later discussion of ALP isoenzymes versus isoforms), and they may have different half-lives in serum. If an isoenzyme has a very short half-life (e.g., minutes to a few hours), it is less likely to accumulate in the serum after leakage or secretion and, therefore, is less likely to be detected. If an enzyme originates from two different tissues but the half-life of the isoenzyme from one tissue is minutes and that of the isoenzyme from the second tissue is days, then the increased serum enzyme activity is more likely to have originated from the second tissue. For example, the placenta of dogs contains large quantities of the enzyme ALP, but the half-life of the placental isoenzyme is minutes. Therefore, the placenta is not considered to be a likely source when an increased serum ALP activity is detected [5].

The ideal diagnostic enzyme would be specific for only one tissue. Increased serum activities of such an enzyme would direct the diagnostician to that tissue as the site of a disease process. Almost no diagnostic enzymes are found in only one tissue; however, some are found in only a few tissues.

Diagnosticians sometimes attempt to relate the magnitude of increased serum enzyme activities with the type or degree of injury in a tissue. It is tempting to assume that higher enzyme activities are indicative of more severe tissue injury (especially in the case of leakage enzymes), but this assumption is not always true (Figure 27.3). Dead cells release all of their enzymes, and they produce no additional enzymes. Sublethally injured cells, however, lose only a portion of their enzyme content and continue to produce enzymes (possibly at an increased rate). Such cells can ultimately release more enzyme than can dead cells. In other words, necrosis can result in increased enzyme activity, but diffuse, sublethal injury to the same tissue can result in even greater serum enzyme activity. Thus, the magnitude of the serum enzyme activity is not a reliable indicator of the type or degree of tissue injury. The relative magnitude of increased serum enzyme activity is often referred to in terms of the fold increase above the upper reference limit (URL); for example, 3× URL signifies a threefold increase above the upper reference limit.

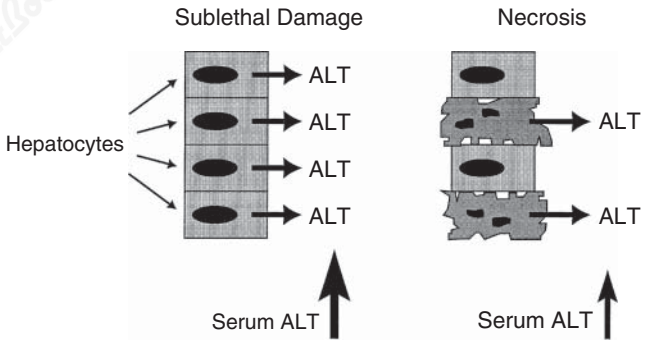

Figure 27.3 The magnitude of serum enzyme activity is not necessarily related to the severity of tissue injury. Serum ALT leaks from hepatocytes when their plasma membranes are injured. The resultant serum ALT activity can be greater after sublethal injury to many hepatocytes than after necrosis of a few hepatocytes.

Sample handling

Unlike substances in serum that are directly measured (e.g., urea, creatinine, electrolytes), serum enzyme concentrations are determined by measuring serum activity and assuming that the activity is proportional to the serum concentrations. If serum samples are not properly handled the enzyme activity can be altered leading to erroneous results. It is important to realize that serum enzymes are proteins that are subject to degradation or denaturation by heat, changes in pH, and exposure to various chemicals, any of which can result in loss of enzyme activity [2].

Regardless of whether serum enzyme activities are assayed in an in-clinic laboratory or a reference laboratory, some delay usually occurs between sample acquisition and testing, making proper sample handling essential. While serum to be used in these assays should be harvested and assayed as soon as possible, most enzymes are stable in refrigerated, separated serum for 24 hours. The degree of degradation that occurs after 24 hours varies considerably depending upon the particular enzyme [10]. Lipemia and *in vitro* hemolysis should be avoided because of the potential to interfere with spectrophotometric assays (increased serum bilirubin may also interfere but is not preventable). Some enzymes are present in erythrocytes, and hemolysis can also directly contribute to the increased enzyme activity (see Chapter 3).

Hepatocyte injury

Hepatocyte injury is detected by measuring the serum activities of hepatocellular leakage enzymes. The three serum enzymes that are commonly measured to provide information about hepatocyte injury include alanine aminotransferase (ALT), aspartate aminotransferase (AST), and sorbitol dehydrogenase (SDH). An additional enzyme, glutamate dehydrogenase (GLDH), is available but is primarily utilized in countries other than the United States. However, numerous other enzymes are utilized in laboratory animals as biomarkers of hepatic toxicity [11].

Alanine aminotransferase

ALT, previously referred to as serum glutamic pyruvic transaminase (SGPT), is a leakage enzyme that is free in the cytoplasm. In dogs and cats, the highest concentrations of ALT occur in hepatocytes (especially those in periportal regions), and the ALT assay is commonly included in the serum biochemical profiles of these species [12]. ALT activity is sometimes the only test used to detect hepatocyte injury in dogs and cats because ALT is much more liver specific than AST (discussed below). However, ALT is not totally liver specific; severe muscle damage or disease can cause increases in serum ALT activity [13]. ALT activity of muscle is less than that of the liver (in dogs, activities in skeletal and cardiac muscle are approximately 5% and 25% that of liver activity, respectively) [12]. Because the total mass of muscle is much greater than that of the liver, muscle can be a significant source of ALT leakage. While increased serum ALT activity in dogs and cats is usually indicative of either hepatocyte death or sublethal hepatocyte injury, necrosis or sublethal damage to muscle cells must be considered as well. When ALT activity is increased, measurement of a serum enzyme activity that is more muscle specific (e.g., creatine kinase [CK]) is helpful in order to determine if muscle damage is a possible source of the increased ALT.

Horses and ruminants have low ALT concentration in hepatocytes; consequently, serum ALT activity is not useful for detecting liver disease in these species [12]. Moderate amounts of ALT are present in the muscle of horses and ruminants, and moderate increases in the serum ALT activity occur with muscle injury in these species [12]; however, ALT is not usually included in large animal biochemical profiles. Other muscle-specific enzymes (e.g., CK) are more commonly used for detecting muscle injury in these species.

In dogs and cats, a wide variety of liver diseases can produce increased serum ALT activity. Hypoxia, metabolic alterations resulting in hepatocyte lipid accumulation, bacterial toxins, inflammation, hepatic neoplasia, and a multitude of toxic chemicals and drugs can cause hepatocyte injury, thereby resulting in ALT leakage. Acutely, the serum activity of ALT is proportional to the number of cells that are injured, but as illustrated in Figure 27.3, the magnitude of ALT activity is not indicative of the *cause* of the injury or of the *type* of damage to the hepatocytes (sublethal damage versus necrosis). After acute severe injury, such as from a toxin, serum ALT activity can increase markedly within a day or two [5]. If the injury is not ongoing, ALT activity slowly decreases over several weeks. Serum ALT activity can also be increased during recovery from liver injury when active hepatocyte regeneration is occurring; this may explain why ALT activity does not always return to normal as quickly as expected based on its serum half-life, which has been estimated at

17–60 hours in dogs and 3.5 hours in cats [12]. More chronic inflammatory liver diseases can result in periodic "flares" of increased ALT activity. Thus, repeated measurement of serum enzyme activity may give insight about the underlying disease process. However, it is important to recognize that in certain situations significant liver disease can occur with normal or only slightly increased serum ALT activity. For example, if liver disease is severe and the hepatic mass is markedly decreased there may be too few remaining hepatocytes to result in markedly increased serum activity, even if the remaining cells are injured and leaking ALT. Some chronic diseases may have little active hepatocyte injury taking place, resulting in little enzyme leakage. Also, a few toxins (aflatoxin, microcystin) seem to interfere with transaminase production; massive acute hepatic necrosis may occur with minimal increases in ALT (or AST) [5, 14].

Increases in serum ALT activity can also be observed in dogs with hyperadrenocorticism or that have been administered corticosteroids [15]. These increases are generally mild (two- to fivefold), but ALT activity increases can vary widely among dogs receiving corticosteroid therapy, depending on the dose and duration of treatment [16–18]. It is not entirely clear whether these increases in ALT activity are due to induction of enzyme production by steroids (as is well-documented for the induction enzymes ALP and GGT) or due to actual hepatocyte membrane injury; morphologic changes in hepatocytes develop within days after steroid therapy begins and resolve slowly after therapy ceases [16, 17, 19].

Anticonvulsant drugs (e.g., phenobarbital, primidone, phenytoin) also cause mildly increased serum ALT activity in dogs [20, 21]. Because most dogs remain clinically healthy and liver biopsies have not shown morphologic evidence of liver damage these increases have been attributed to induction (up-regulation of enzyme production); however, *in vitro* studies have not supported that hypothesis [22, 23]. In addition, some dogs receiving anticonvulsants will develop a toxic hepatopathy, in which case ALT activity may be markedly increased due to hepatocyte injury [24].

Aspartate aminotransferase

AST, previously termed serum glutamic oxaloacetic transaminase (SGOT), is present at highest concentrations in hepatocytes and muscle cells (both skeletal and cardiac) of all species [12]. Therefore, AST is not a liver-specific enzyme. AST is a leakage enzyme that is found predominantly in the cytoplasm with about 20% located within mitochondria [25]. In contrast to ALT, hepatocyte AST is in highest concentration in cells of the periacinar region, surrounding central veins (zone 3) [5]. Increased serum AST activity can result from lethal or sublethal injury to either hepatocytes or muscle cells.

In dogs and cats, serum AST activity will increase as a result of the same liver diseases previously listed for ALT and generally parallels ALT activity, but the magnitude of the increase may be less than that of ALT [5]. The serum AST activity may return to baseline faster than ALT following acute liver injury in some animals, making repeated measurements useful for monitoring disease resolution. Although AST is less liver specific than ALT, it may be more sensitive than ALT for detecting some liver diseases in dogs and cats [5]. For example, one study reported 89% of cats with hepatic lipidosis had increased AST activity compared to 72% for increased ALT activity [26].

Similar to ALT, mild increases in AST activity may be seen in dogs as a result of enzyme induction due to corticosteroids and possibly phenobarbital, although there is some controversy in the literature [21, 23, 27]. Because muscle is a possible source of serum AST activity, measurement of an enzyme specific for muscle injury (i.e., CK) is useful to determine if the increase in AST activity is due to muscle injury.

In horses and ruminants, AST is often used for the routine detection of hepatocyte injury since it is included in most large animal biochemical profiles and because of low hepatocyte ALT concentrations. In these species, an increased serum AST activity can result from the same spectrum of liver diseases (both sublethal and necrotic) as listed for ALT. The major problem with AST in detecting hepatocyte injury is its lack of liver specificity. As in dogs and cats, increased serum AST activity in horses and ruminants can result not only from hepatocyte injury but also from muscle injury. This problem can be mitigated to a certain extent by assaying a muscle-specific enzyme such as CK along with AST. Increased AST activity with normal CK activity may be seen if the source of the AST is the liver, suggesting hepatocyte injury has occurred. Uncertainty remains in such a case, however, because the half-life of CK is shorter than that of AST (Figure 27.4). Serum activities of both enzymes may increase as a result of muscle injury, but the CK activity may return to normal earlier than the AST activity [28]. These problems with use of AST in detecting hepatocyte injury in horses and ruminants have led to use of more liver-specific enzymes (such as SDH) in these species.

As discussed for ALT, the serum activity of AST may be normal or only slightly increased with significant liver diseases that are chronic and low-grade, that have resulted in markedly decreased hepatic mass, or that are due to toxins that inhibit transaminase activity. In dogs and cats, the half-life of AST is shorter than that of ALT and has been estimated between 4 and 12 hours in dogs and 77 minutes in cats [12, 29]. In horses, the half-life of AST has been estimated at 7–8 days [28].

Sorbitol dehydrogenase (iditol dehydrogenase)

SDH, also called iditol dehydrogenase (ID), is a leakage enzyme that is free in the cytoplasm. It is present at high concentrations in the hepatocytes of dogs, cats, horses, and ruminants, but its concentration in other tissues in

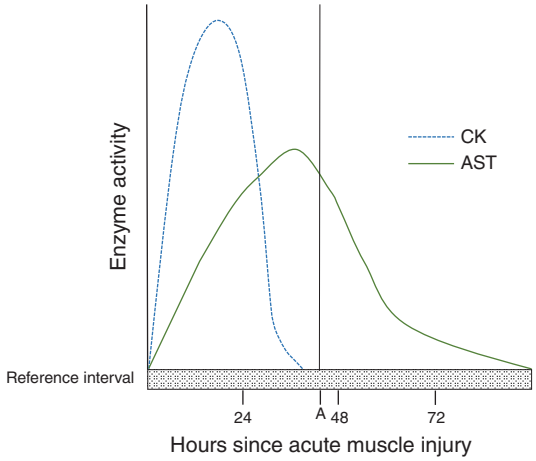

Figure 27.4 Serum activities of both AST and CK increase because of muscle injury. As illustrated here, these activities increase and decrease at different rates. Depending on when a blood sample is analyzed after muscle injury, it is possible to detect increased serum AST activity and normal serum CK activity (note time A) and to erroneously interpret this as being an indication of hepatic injury.

these species is low [12]. Therefore, SDH is a liver-specific enzyme. Increased serum SDH activity is suggestive of either hepatocyte death or sublethal hepatocyte injury. SDH is not superior to ALT for detecting hepatocyte injury in dogs and cats, and it is not commonly used in these species. In horses and ruminants, however, SDH is much more specific than AST for detecting hepatocyte injury. The half-life of SDH is very short (<2 days); serum activities may return to normal within 4–5 days after acute hepatocyte injury [30]. The main disadvantage to SDH is that it is less stable *in vitro* than most other diagnostic enzymes, and the stability varies by species. In both horses and cattle, however, SDH is stable in room temperature or refrigerated serum for as long as 5 hours (24 hours refrigerated in cattle), and for as long as 48 hours (72 hours in cattle) when frozen [31]. In llamas, SDH is stable in serum for 8 hours, and in refrigerated or frozen serum for up to 1 week [32]. In dogs, SDH is stable in serum for 4 hours at room temperature, 48 hours refrigerated, 1 week frozen at −20 °C, and one month frozen at −70 °C [33]. In most cases, these time periods should be sufficient to allow the delivery of serum to a laboratory for an SDH assay. Because SDH is preferable to AST for detecting hepatocyte injury in horses and ruminants, one should identify a laboratory that can perform this assay within the appropriate time frame.

Glutamate dehydrogenase

GLDH is a leakage enzyme present in highest concentrations within mitochondria of hepatocytes, predominantly in periportal regions [12]. The same types of reversible and nonreversible hepatocyte injury that cause increased serum activity of ALT will cause increased serum activity of GLDH. Increased serum concentration of this enzyme is reported to have excellent sensitivity for the detection of canine hepatic disease [10, 34]. The sensitivity for equine hepatic disease is reported to be good but slightly less than that of GGT [35]. GLDH activity is stable in canine serum for 2 days at room temperature, 7 days refrigerated at 4 °C, and 6 months frozen at −20 °C [34]. Serum activity of GLDH increased in dogs with hyperadrenocorticism; increases have also been documented in dogs receiving anticonvulsants [36]. Assays for this enzyme have not been routinely available in the United States but are used more commonly in other countries.

Cholestasis

Cholestasis (impaired bile flow) can be detected by measuring the serum activities of enzymes whose increased production is induced by cholestasis or by measuring the serum concentrations of substances (either endogenous or exogenous) that normally are considered tests of liver function and are discussed later. The two serum enzymes used to detect cholestasis are ALP and GGT.

Alkaline phosphatase

ALP is an induced enzyme that is attached to cell membranes and synthesized by many tissues such as liver, bone, kidney, intestine, pancreas, and placenta [12, 25, 37]. In domestic animals two ALP isoenzymes are produced from two different genes; these are referred to as the intestinal isoenzyme and the tissue-nonspecific isoenzyme [37]. The tissue-nonspecific isoenzyme undergoes further post-translational modification in different tissues resulting in different isoforms from liver (LALP), bone (BALP), kidney, and placenta. The intestinal isoenzyme can also undergo further modification to produce the unique corticosteroid induced isoform (CALP) in dogs. These different isoforms are often mistakenly referred to as different isoenzymes, but isoenzymes must be produced from different genes. Most of the normal serum ALP activity originates from the liver. The half-life of intestinal, renal, and placental ALP in dogs is approximately 6 minutes, and the half-life of intestinal ALP in cats is approximately 2 minutes, thus they are unlikely to cause increased serum ALP activity [37]. Increased ALP production and increased serum ALP activity commonly occur with cholestasis, increased osteoblastic activity, induction by certain drugs (primarily in dogs), and a variety of chronic diseases.

Increased serum alkaline phosphatase activity

Hepatobiliary disease

ALP in the liver is associated with biliary epithelial cells and canalicular membranes of hepatocytes [5]. A variety of hepatobiliary diseases can result in increased serum ALP activity due to increased enzyme production, solubilization of membranes by the action of bile salts, and release of

membrane blebs after cell injury [4, 7, 8, 37]. Cholestatic diseases can result in marked increases in serum ALP activity in dogs (greater than 10-fold URL) but increases are more variable in other species [5, 37–39]. Disorders that impair bile flow in focal areas of the liver may result in variable increases in ALP activity. For example, dogs with hepatic nodular hyperplasia, which is a relatively common benign condition in older dogs, were reported to have ALP activities that were 2.5–14× URL [40]. Impaired bile flow induces increased ALP production, and sequestration of bile salts in the biliary system causes solubilization of ALP molecules attached to cell membranes, which are then released into the blood [7, 8, 41, 42]. The half-life of the cholestasis-induced LALP is approximately 3 days in dogs but only 6 hours in cats [5]. In cats, this short half-life, in addition to lower liver ALP concentration per gram of tissue, contribute to the relatively smaller magnitude of serum ALP activity increases seen with liver disease in cats compared to dogs [5]. However, ALP is still a useful enzyme to evaluate feline cholestatic liver disease if one keeps in mind that even mild increases (2–3× URL) can be significant [5]. The utility of ALP for detection of cholestasis in horses and ruminants is generally considered inferior to that of GGT (discussed later) [37, 39]. Wide reference intervals for ALP in horses and ruminants contribute to the reduced sensitivity of the serum ALP assay for the detection of liver disease in these species.

When cholestasis is the cause of increased serum ALP activity, serum total bilirubin and bile acid concentrations may be increased concurrently. In dogs with cholestasis, serum ALP activity often increases prior to increases in serum bilirubin concentration; thus ALP is a more sensitive indicator of cholestasis in dogs [10, 43]. However, even if the serum bilirubin concentration is normal, bilirubinuria may accompany cholestasis-induced increases in ALP. Whereas lesions primarily involving the intra- or extrahepatic biliary system are common causes of cholestasis, hepatic diseases resulting in significant hepatocyte swelling (e.g., lipidosis or inflammation of the hepatic parenchyma) can obstruct small bile canaliculi and also induce increased ALP production and release [44]. It is also important to realize that pancreatic and intestinal lesions can sometimes be the primary cause of cholestasis due to extrahepatic bile duct obstruction.

Osteoblastic activity

Increased serum ALP activity associated with increased osteoblastic activity occurs in all species. These increases are most often are detected in young, growing animals when the results of ALP assays are compared with adult reference intervals for ALP. For instance, the mean serum activity of alkaline phosphatase of bone origin (BALP) in immature cats in one study was more than 10 times that of adult cats, resulting in a mean total ALP activity more than twice that of the adults [45]. Another study found reference intervals for total ALP activity in 4-week old kittens was 97–274 U/L compared to 10–80 U/L for adult cats [46]. Puppies up to 8 weeks of age have been found to have total ALP activities greater than the adult reference interval [47, 48]. Since age-specific reference intervals are seldom provided, one must remember that young animals commonly have serum ALP activities greater than adult reference intervals. In puppies, kittens, and calves, ALP activity increases attributed to bone growth are generally mild (<4–5× URL), but foals may have increases up to 20× URL in the first 3 weeks of life [37, 49].

A few causes of increased osteoblastic activity in mature animals may result in mildly increased serum ALP activity due to production of BALP. Osteosarcoma and other bone neoplasms (both primary and secondary) inconsistently result in increased serum ALP activity because of osteoblast proliferation in these processes, and dogs with osteosarcoma and increased serum ALP activity appear to have a worse prognosis than those with normal ALP activity [37, 50, 51]. Fracture healing usually results in localized increases in osteoblastic activity and mild increases in serum ALP that may be useful for monitoring the progression of healing. In one study dogs with uncomplicated fracture healing had mild increases in serum ALP activity that returned to normal with bone union, while dogs with failure of bone union had no changes in serum ALP activity [52]. Canine hyperparathyroidism (primary or secondary) and feline hyperthyroidism may result in increased bone turnover and increased osteoblastic activity; mild increases in serum ALP may be detected in patients with these diseases [37].

Induction by drugs (dogs)

Serum ALP activity can be markedly increased when enzyme production is induced by certain drugs. Drug-induced ALP production is well documented in dogs but not in other species, thus the following discussion pertains to dogs only. Corticosteroids (exogenous or endogenous) and anticonvulsants (e.g., phenobarbitol, phenytoin, primidone) induce increased ALP production by canine hepatocytes. Exogenous corticosteroids in any form (oral, parenteral, topical, ophthalmic, and otic) have been implicated [53, 54]. Serum ALP activity increases induced by corticosteroids vary depending on dose and duration of exposure but can be marked (>20× URL) [5, 16]. Anticonvulsants generally cause somewhat milder increases (<10× URL) [5, 24, 55].

Corticosteroids induce production of a unique isoform (CALP) that is distinct from that produced by hepatocytes in response to cholestasis (LALP). Although it is possible to distinguish LALP from CALP with special laboratory tests, the clinical utility of such distinction is uncertain. In dogs given corticosteroids the initial rise in serum ALP activity is due to LALP, while CALP increases after a 10-day lag period, and there appears to be considerable individual variation in the degree of ALP induction caused by corticosteroids [17, 18, 56–58]. Although not specific, increased CALP activity is common in dogs with naturally occurring

hyperadrenocorticism, and a *lack* of increased CALP argues against hyperadrenocorticism in suspect cases [57, 59]. Although many dogs with increased blood corticosteroid concentrations will have increased serum ALP activity due to induction, some will develop a steroid hepatopathy with swelling of hepatocytes due to glycogen deposition. Evidence of decreased hepatic function (increased total bilirubin or bile acids) is uncommon in these dogs but can occur, depending on severity of disease [5]. Chronic stress resulting in increased blood concentrations of endogenous steroids may also cause increases in CALP activity [5, 37].

To help distinguish cholestasis-induced from corticosteroid-induced increases in serum ALP in dogs, other tests can be performed. These tests include serum and urinary bilirubin concentrations, serum bile acid concentration, and tests to detect hyperadrenocorticism. A suggested approach is presented in Figure 27.5. The concurrent presence of increased ALP activity and hyperbilirubinemia is strongly suggestive of cholestasis, but the serum bilirubin concentration may be normal in some cases of cholestatic disease (e.g., early in the disease process or if only a portion of the biliary tree is obstructed). In the latter situation, the unobstructed portion of the biliary system excretes enough bilirubin that serum concentrations remain within the reference interval.

Dogs receiving anticonvulsant drugs (e.g., phenobarbitol, phenytoin, primidone) often have increased serum ALP activity, which may be due to LALP, CALP, or both [5, 55]. Most of these dogs remain clinically healthy, but anticonvulsants are also known to cause a toxic hepatopathy in some dogs. In healthy dogs the serum ALP increases have been attributed to induction, but this has not been confirmed by *in vitro* studies and remains controversial [22, 23]. Animals that develop a toxic hepatopathy will usually have other indications of decreased hepatic function (increased total bilirubin or serum bile acids), as well as histologic abnormalities [24].

Miscellaneous other causes

Neonates of several species have high serum ALP activity following ingestion of colostrum. During the first few days of life puppies, kittens, and lambs have transient marked increases in serum ALP activity (up to or >30× URL for adult animals) [46, 60, 61]. Foals and calves do not have such marked increases following colostrum ingestion, although serum ALP activity is increased compared to adults due to BALP, as discussed earlier [49, 62, 63].

A variety of endocrine diseases have been associated with increased serum ALP activity. Hyperadrenocorticism has already been discussed as a cause of often marked corticosteroid-induced ALP activity increases in dogs. The precise mechanisms for the generally mild increases seen with other endocrine diseases are not clearly defined but are likely multifactorial; remember that stress associated with any chronic disease may increase endogenous corticosteroids

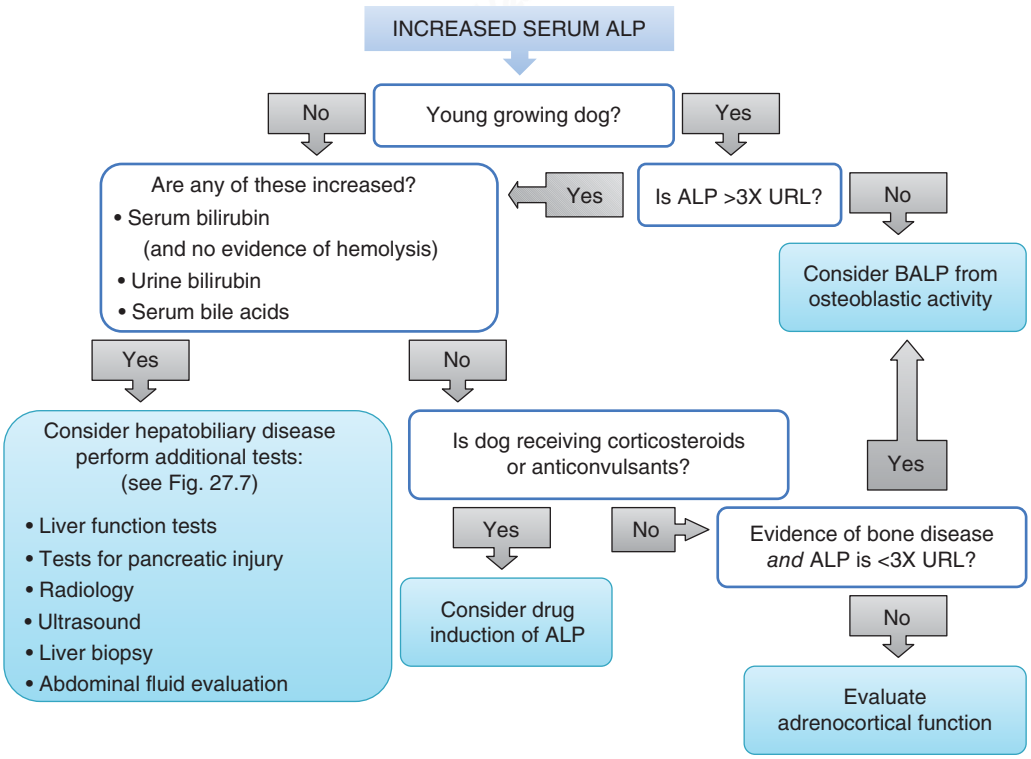

Figure 27.5 Flow chart for evaluating the possible causes of increased serum ALP activities in dogs.

and result in induction of CALP (at least in dogs). Such diseases include diabetes mellitus, canine hypothyroidism and hyperparathyroidism, and feline hyperthyroidism; as many as 80% of hyperthyroid cats are reported to have increased serum ALP activity (generally <4× URL, due to both BALP and LALP) [37, 64–67].

Neoplasia may be associated with increased serum ALP activity; hepatic neoplasia may directly cause cholestasis, and bone neoplasia may be associated with increased osteoblastic activity (both discussed earlier). In addition, mammary gland neoplasia, without metastases to bone or liver, has been identified as a cause of increased serum ALP activity in dogs. Serum ALP activity increases may be seen with benign or malignant mammary gland tumors, are generally mild (<8× URL), and do not appear to have prognostic value [68, 69].

In cattle, there are mild increases in ALP activity associated with pregnancy (mid to late gestation) and early lactation [70, 71]. In dogs, serum ALP activity increases slightly during pregnancy but remains within reference intervals [37].

Breed-related increases in serum ALP activity have been identified in Siberian husky and Scottish terrier dogs. ALP activity (characterized as BALP) in some Siberian huskies was >5× that of siblings in eight related litters; no underlying cause was identified and the condition was described as benign familial hyperphosphatasemia [72]. Increased serum ALP activity in comparison to other breeds has been reported in Scottish terriers, with ALP activity as high as 15× URL [73]. A study of 34 apparently healthy Scottish terriers found that CALP activity was significantly increased in 14 dogs with hyperphosphatasemia compared to 14 dogs with normal ALP activities [74]. The authors attributed these findings to hyperadrenocorticism based on exaggerated cortisol responses to ACTH administration. Histologic changes consistent with hyperadrenocorticism were observed in liver biopsies from both groups of dogs, but no dogs had clinical signs suggestive of hyperadrenocorticism.

γ-Glutamyltransferase

GGT is considered an induced enzyme. Acute hepatic injury, however, can produce rapid increases in serum GGT activity, likely due to release of membrane fragments to which GGT is attached [4]. Most body tissues synthesize GGT, with the highest concentrations occurring in the pancreas and kidney [12, 25, 75, 76]. It also is present at lower concentrations in the hepatocytes, bile duct epithelium, and intestinal mucosa and at high concentrations in the mammary glands of cattle, sheep, and dogs. Most of the serum GGT activity originates in the liver (except for neonates of some species, discussed later). Release from renal epithelial cells results in increased urinary GGT activity but not increased serum GGT activity (see Chapter 24). Similarly, GGT is released into pancreatic ducts by pancreatic cells, rather than into the blood.

Increased GGT production, release, and subsequent increased serum GGT activity occur with cholestasis and biliary hyperplasia [77, 78]. The increased serum GGT activity that occurs with cholestasis may result from both increased production and solubilization of GGT attached to cell membranes [5]. In dogs, increased GGT activity also occurs as a result of drug induction, similar to that described for ALP [5].

Experimentally, extrahepatic bile duct obstruction in dogs results in increases in GGT activity up to 50-fold within 2 weeks; similar studies in cats found increases up to 16-fold [5, 79, 80]. For the detection of liver disease in dogs, GGT is more specific, but less sensitive, than ALP [38]. For the detection of liver disease in cats, GGT is more sensitive, but less specific, than ALP (the exception is hepatic lipidosis, discussed below) [81]. In both dogs and cats, results of serum ALP and GGT assays performed in combination to detect hepatobiliary disease are more diagnostically valid than those of either enzyme assay used alone [38, 81]. Cats with hepatic lipidosis usually have greater relative increases in serum ALP activity compared to GGT, which may be within the reference interval or only minimally increased [5, 82]. However, if there is an underlying necroinflammatory disease present that is the primary cause of the hepatic lipidosis, GGT activity may be increased to a greater degree than is ALP activity [26, 81].

Similar to ALP, increases in serum GGT activity are seen in dogs receiving corticosteroids, but it is not clear whether these increases are due to increased GGT production or are secondary to steroid hepatopathy [19, 56]. When the increase in GGT activity is induced by corticosteroids, GGT activity increases more slowly and to a lesser degree than does ALP activity [16]. Drug induction of GGT activity has also been reported in dogs receiving anticonvulsant medication, but resulting increases are minimal (2–3× URL) and may not even exceed reference intervals [5, 23, 83]. If increases of greater magnitude are seen in dogs receiving such medications, they are more likely the result of cholestasis. Marked increases in the serum GGT activity of a dog being treated with anticonvulsant medication may be indicative of a drug-associated toxic hepatopathy with life-threatening implications [5, 84].

In horses and cattle, GGT is generally considered more sensitive than ALP for detection of cholestasis. In horses with experimental cholestasis induced by bile duct ligation, serum GGT activity increased to a greater degree than did ALP activity [39]. Cattle and horses with pyrrolizidine alkaloid toxicity, which causes marked biliary hyperplasia and eventual liver failure, consistently have early increases in serum GGT activity [85, 86]. However, ALP activity may be increased to a greater degree than GGT activity in more chronic cases [86]. Cattle with moderate to severe hepatic lipidosis have only mild increases in serum GGT activity (2–3× URL) [87].

High serum GGT activity in the colostrum of dogs, cattle and sheep can result in extremely high activities in the

serum of young puppies, calves and lambs that have consumed colostrum [61, 88, 89]. In calves, the GGT activity can be >50× URL for adult animals during the first few days after birth [62, 63, 89]. Typically, the GGT activity declines over a period of weeks to reach normal adult levels by about 5 weeks of age. Lambs also have markedly increased serum GGT activity after colostrum consumption, with this activity falling to within the adult reference intervals by approximately 30 days of age [88]. In puppies, marked increases in GGT activity (up to 100× URL for adults) following colostrum ingestion return to normal adult levels more quickly, by about 10 days of age [61]. Increased serum GGT activity also occurs in foals and is typically 1.5–3× URL during the first month of life, but this enzyme activity is apparently not of colostral origin [90, 91].

Liver function

Tests of liver function include measurement of the serum concentrations of substances that normally are removed from the blood by the liver and then metabolized or excreted via the biliary system (e.g., bilirubin, bile acids, ammonia, cholesterol), and substances that normally are synthesized by the liver (e.g., albumin, globulins, urea, cholesterol, coagulation factors). Although abnormal blood concentrations of these substances can result from nonhepatic factors, the detection of abnormal concentrations *in addition to evidence of liver injury* (as detected by changes in leakage or induced enzyme activities) can supply further evidence of significant liver disease or liver failure. Often, however, liver biopsy is required for a definitive diagnosis.

Bilirubin

Normal bilirubin metabolism

Bilirubin is formed primarily from the degradation of hemoglobin (Figure 27.6), with a small contribution from other hemoproteins (e.g., myoglobin, cytochromes, peroxidase, catalase) [92]. Erythrocytes normally are destroyed at a constant rate because of aging, but they also can be destroyed at an increased rate because of hemolytic processes (discussed later). Senescent erythrocytes, which have reached the end of their normal life span, are phagocytized by mononuclear phagocytes primarily in the spleen but also in the liver and the bone marrow. These phagocytized erythrocytes are broken down, and their hemoglobin is dismantled. The globin portion is converted to amino acids, and the heme portion is split into iron and protoporphyrin. The iron is recycled, but the protoporphyrin is converted first to biliverdin and then to bilirubin. The newly formed unconjugated bilirubin (U-bilirubin, also called indirect bilirubin) is released from macrophages, noncovalently bound to albumin, and transported in blood to the liver sinusoids, where it is released from albumin and enters

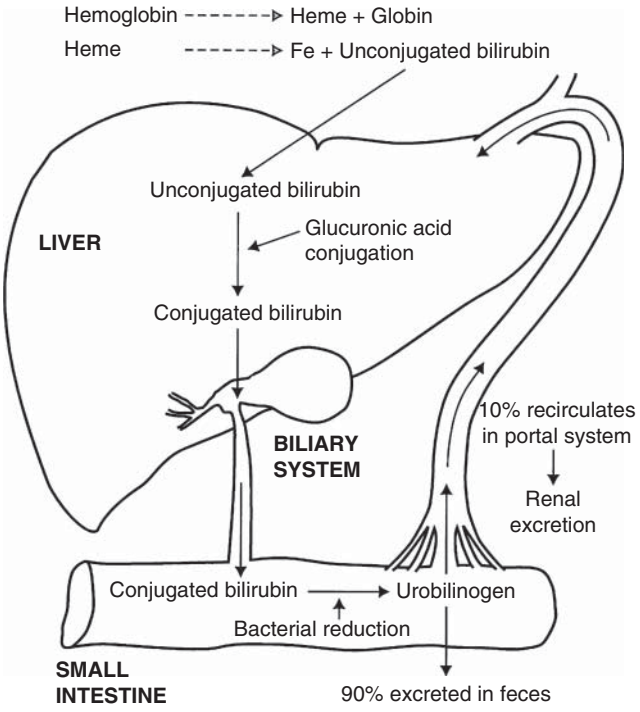

Figure 27.6 Normal bilirubin metabolism.

hepatocytes. Passage through the hepatocyte membrane is facilitated by a carrier, the capacity of which can be saturated if too much bilirubin is presented to the liver (as occurs with increased erythrocyte destruction).

Once inside the hepatocyte, U-bilirubin is bound by proteins (Y protein or ligandin, and Z protein), which limit efflux of U-bilirubin back into the plasma [93]. In the hepatocyte, U-bilirubin is conjugated to sugar groups forming conjugated bilirubin (C-bilirubin, also called direct bilirubin). In many mammals, the major sugar group to which bilirubin is conjugated is glucuronic acid, resulting in the formation of bilirubin glucuronide. This reaction is catalyzed by membrane-associated enzymes of the UDP-glucuronosyltransferase superfamily [94]. Both monoglucuronides and diglucuronides are formed in mammals, with the latter being the predominant form of conjugated bilirubin in bile. In addition to glucuronides, alternate conjugates (e.g., glucosides, glucoside-glucuronide mixed conjugates, xylosides) are produced in some species, with glucosides predominating in horses [95, 96]. Conjugated bilirubin is not tightly protein bound, and is more water soluble than the protein-bound, unconjugated bilirubin. Most C-bilirubin is actively transported against the concentration gradient into bile canaliculi and then excreted in the bile. A small amount of C-bilirubin normally passes through the sinusoidal side of the hepatocyte membrane and back into the blood. If this C-bilirubin remains unbound to protein, it is quickly excreted by the kidney via glomerular filtration. A portion of the C-bilirubin in the blood may

become covalently bound to albumin and is termed biliprotein or delta bilirubin [97]. This form of C-bilirubin does not pass through the glomerulus and remains in the blood for a longer period of time. (The implications of delta bilirubin in the assessment of cholestatic disease are discussed later.)

Conjugated bilirubin that is secreted into bile canaliculi passes with the bile into the small intestine where it is converted to urobilinogen by bacterial reduction. Approximately 90% of the urobilinogen is excreted with the feces as stercobilinogen. The remaining 10% of urobilinogen is reabsorbed and enters the blood. A portion of this urobilinogen then is removed from the blood by the hepatocytes and is re-excreted. Another portion of the urobilinogen circulates to the kidneys, where it passes through the glomerulus and is excreted in the urine.

Abnormalities of bilirubin metabolism

Increased serum bilirubin concentrations (hyperbilirubinemia) can be caused by three main pathologic processes: increased bilirubin production (due to increased erythrocyte destruction), decreased bilirubin uptake or conjugation by hepatocytes, and decreased bilirubin excretion (cholestasis).

Increased production of bilirubin most often occurs due to hemolytic disease (extra- or intravascular hemolysis) but can also result from massive internal hemorrhage and subsequent breakdown of erythrocytes in the area of that hemorrhage. During the process of extravascular hemolysis, macrophages remove and destroy erythrocytes just as they do senescent erythrocytes but at an accelerated rate. Hemoglobin breakdown and bilirubin delivery to the liver then occurs in the normal way. During the process of intravascular hemolysis, the free hemoglobin that is released into the blood forms complexes with haptoglobin. These complexes are removed from the circulation by mononuclear phagocytes with subsequent breakdown of hemoglobin and U-bilirubin production. Whatever the specific underlying cause, increased erythrocyte destruction and production of increased amounts of U-bilirubin may overwhelm the liver's capacity for U-bilirubin uptake or C-bilirubin excretion, resulting in an increased serum bilirubin concentration. This is often referred to as prehepatic hyperbilirubinemia.

By contrast, hepatic hyperbilirubinemia may result from decreased uptake or conjugation of bilirubin by hepatocytes. (Intrahepatic cholestasis, discussed later, is also a cause of hepatic hyperbilirubinemia.) Decreased functional hepatic mass due to acute or chronic hepatic disease can cause both decreased bilirubin uptake and decreased bilirubin conjugation. Hereditary defects in conjugation due to enzyme deficiencies occur in people but have not been confirmed in domestic animals. There has been one report of persistent hyperbilirubinemia in a horse that appeared to have a congenital defect in an enzyme required for bilirubin conjugation, similar to Crigler-Najjar Syndrome in people; the exact enzymatic defect was not characterized [98]. Two forms of inherited hyperbilirubinemias have been identified in sheep. Mutant Southdown sheep can have hyperbilirubinemia associated with defective hepatocyte up take of bilirubin from the serum producing increased serum U-bilirubin concentrations; this is similar to Gilbert syndrome in humans [99]. Mutant Corriedale sheep can have hyperbilirubinemia associated with defective hepatic excretion of conjugated bilirubin producing increased serum C-bilirubin concentrations; this is similar to Dubin-Johnson syndrome in humans [100].

Decreased uptake of bilirubin occurs in some species secondary to fasting. This type of hyperbilirubinemia is most marked in horses and can result in serum bilirubin concentrations that plateau at 5–6 mg/dL by 64–136 hours after initial food deprivation; bilirubin concentrations up to 8.5 mg/dL have been reported due to fasting alone [101, 102]. Fasted cattle develop milder hyperbilirubinemia (<1.4 mg/dL) [103]. Small increases in the serum bilirubin concentration occur in other species when deprived of food. These increases result from an increased serum concentration of U-bilirubin, but they do not appear to relate to increased bilirubin production. The mechanisms responsible for fasting hyperbilirubinemia have not been determined, but increased blood fatty acid concentrations correlate with hyperbilirubinemia. Increased fatty acids in the blood may compete for binding to Y and Z proteins in hepatocytes, or may compete with membrane protein transport proteins [101, 102, 104].

Decreased bilirubin excretion (cholestasis) can be either hepatic or posthepatic in origin, and usually results from a blockage (partial or complete) in the biliary system that causes accumulation of bile. Blockage of bile flow results in regurgitation of C-bilirubin into the blood. Blockages are often caused by processes directly affecting the biliary tree, such as infections or neoplasms that compress or damage bile ducts, or biliary calculi. However, diseases that primarily affect the hepatic parenchyma can also result in cholestasis by causing hepatocyte swelling that blocks small bile canaliculi and prevents the normal flow of bile. Extrahepatic bile duct obstruction can also occur secondary to small intestinal or pancreatic lesions, which may cause severe cholestasis and hyperbilirubinemia. Leakage of bile into the abdominal cavity resulting from rupture of the gall bladder or bile duct can also result in hyperbilirubinemia.

Another type of intrahepatic cholestasis results not from obstruction but from impaired excretion of C-bilirubin secondary to extrahepatic bacterial infection, and has been termed functional or sepsis-associated cholestasis. Functional cholestasis has been well described in people but is likely under-recognized in animals. The pathogenesis involves the production of inflammatory cytokines (TNF, IL-6, IL-1β) that reduce bile flow by inhibiting hepatocellular transport mechanisms [105].

Whenever there is increased serum C-bilirubin concentration, a portion of the C-bilirubin may become tightly (covalently) bound to serum protein (biliprotein or delta bilirubin). Delta bilirubin is removed from circulation relatively slowly; it is eliminated at a rate approximately equal to the half-life of albumin (8–20 days) [106]. Delta bilirubin is included in the serum total bilirubin as measured by routine wet chemistry methods. Therefore, total bilirubin concentrations can occasionally be misleading since delta bilirubin may persist for a period of weeks in the serum of animals with resolved cholestatic disease. Such animals may have increased serum total bilirubin concentrations but normal urinary bilirubin concentrations, since tightly protein-bound delta bilirubin does not easily cross the glomerulus. Practical laboratory methods for the measurement of delta bilirubin concentration exist; dry chemical methods allow calculation of delta bilirubin concentrations. However, delta bilirubin is not currently routinely measured.

Historically, the measurement of serum bilirubin involved not only the measurement of total bilirubin but also the determination of the concentrations of both conjugated and unconjugated bilirubin. In theory, hyperbilirubinemia associated with hemolysis or reduced hepatic uptake of bilirubin should produce marked increases in U-bilirubin and smaller, if any, increases in C-bilirubin. Similarly, cholestasis or leakage of bile should produce marked increases in C-bilirubin and smaller, if any, increases in U-bilirubin. Such determinations, however, have proved unreliable in differentiating between causes of hyperbilirubinemia [97, 107]. If hyperbilirubinemia is detected, the patient history, physical findings, and results of other laboratory tests can be helpful in differentiating the potential causes. A flow chart for the evaluation of hyperbilirubinemic animals is presented in Figure 27.7.

Species differences should be considered when evaluating serum bilirubin concentrations. If cholestasis is the cause of hyperbilirubinemia, the serum ALP and GGT activities will likely also be increased and are considered more sensitive than serum bilirubin concentrations for cholestasis in dogs and cattle, but not cats and horses [10, 43]. Most species have a relatively low renal threshold for bilirubin, and because C-bilirubin is efficiently excreted by the kidney, bilirubinuria often precedes hyperbilirubinemia [108]. Healthy dogs, however, frequently exhibit mild bilirubinuria, likely due to the ability of the canine renal tubules to form and conjugate bilirubin [109]. Bilirubinuria in dogs should be interpreted in conjunction with the urine specific gravity; concentrated urine (specific gravity >1.025) may normally contain a small amount of bilirubin [108].

Serum total bilirubin concentrations in healthy horses tend to be greater than in other domestic species, so it is important to use species-specific reference intervals when

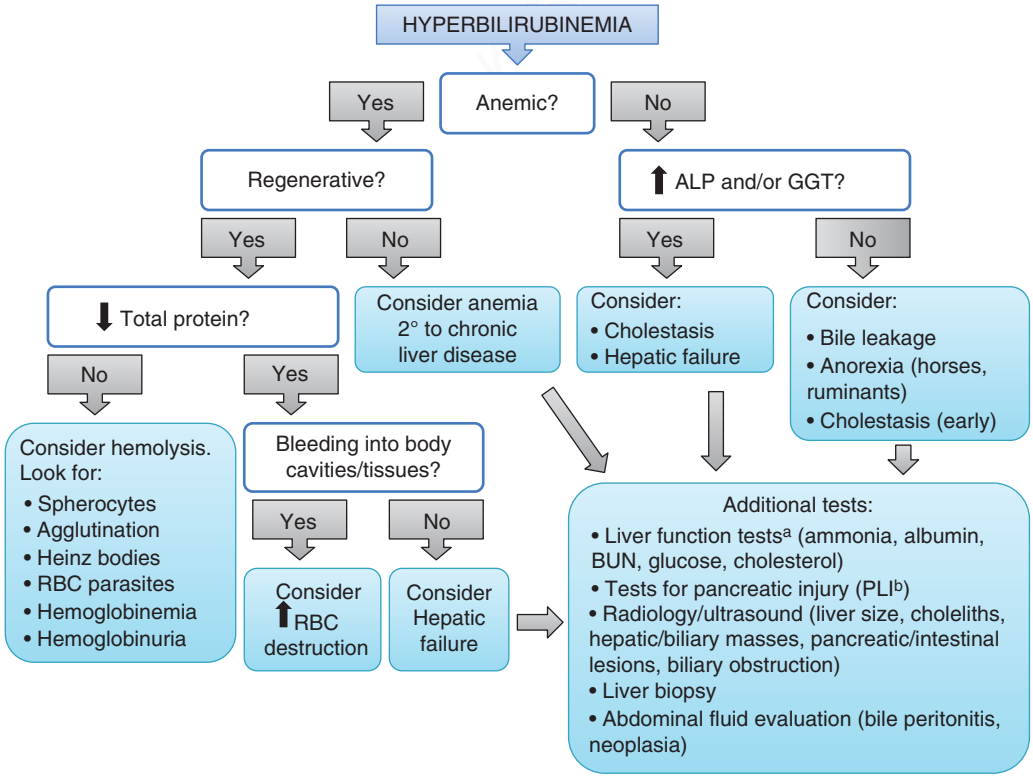

Figure 27.7 Flow chart for the evaluation of hyperbilirubinemic animals. [a]Serum bile acids are not usually useful in hyperbilirubinemic animals but may be helpful in anorexic horses or anemic animals (see text for details). [b]PLI, pancreatic lipase immunoreactivity.

interpreting test results. Hepatic necrosis, neoplasia, cirrhosis, lipidosis, fasting, and hemolysis are reported to cause hyperbilirubinemia in horses; biliary obstruction is a relatively uncommon cause [110]. Hyperbilirubinemia in horses with hemolysis can be marked; serum bilirubin concentrations approaching 50 mg/dL have been reported in foals with neonatal isoerythrolysis [111]. As noted earlier, anorexia or starvation can result in increased serum bilirubin concentrations in horses. Regardless of the cause of hyperbilirubinemia in horses, most of the bilirubin in the blood is unconjugated [112].

Hyperbilirubinemia is not consistent in ruminants with liver disease. Diffuse hepatic diseases such as hepatic lipidosis or chronic liver failure are most likely to cause hyberbilirubinemia [87, 113]. Primary diseases of the biliary tract and gallbladder are uncommon in ruminants. Significant hyperbilirubinemia most often results from hemolysis. Cattle that are ill with a variety of nonhemolytic, nonhepatic diseases may have hyperbilirubinemia associated with rumen stasis and anorexia [114].

Bile acids

Serum bile acids

Measurement of serum bile acid (SBA) concentrations is a routine diagnostic test for hepatic function, cholestasis, and abnormalities of portal circulation, and has replaced the more difficult to perform dye excretion tests (BSP, ICG). Bile acids are synthesized in hepatocytes from cholesterol (Figure 27.8). Cholic acid and chenodeoxycholic acid are the primary bile acids in most animals. After their synthesis, bile acids are conjugated to amino acids (primarily taurine in most animals) before secretion into bile. Bile acids are stored and concentrated in the gallbladder (in those species that have one). At the time of a meal, hormonal and neurohormonal factors stimulate gallbladder contraction and passage of bile acids into the small intestine, where dehydroxylation by anaerobic microorganisms results in the conversion of the primary bile acids to secondary bile acids. Thus, cholic acid is converted to deoxycholic acid, and chenodeoxycholic acid is converted to lithocholic acid. Bile acids emulsify fat and, therefore, promote both the digestion and absorption of fat as well as of fat-soluble vitamins. Most of the bile acids are reabsorbed from the ileum into the portal circulation (<5% of the bile acid pool is lost in the feces each day) [115]. Normally, bile acids are efficiently cleared from the portal circulation on their first pass through the liver; as a result, only a slight postprandial increase in SBA concentrations is seen in healthy animals. Bile acids that are cleared by hepatocytes are secreted into the biliary system and recirculate; a bile acid molecule recirculates several times after a meal.

There are three main pathologic processes involving the liver that result in increased SBA concentrations. Decreased SBA concentrations do not occur with hepatic disease but may occur with some intestinal disorders [115].

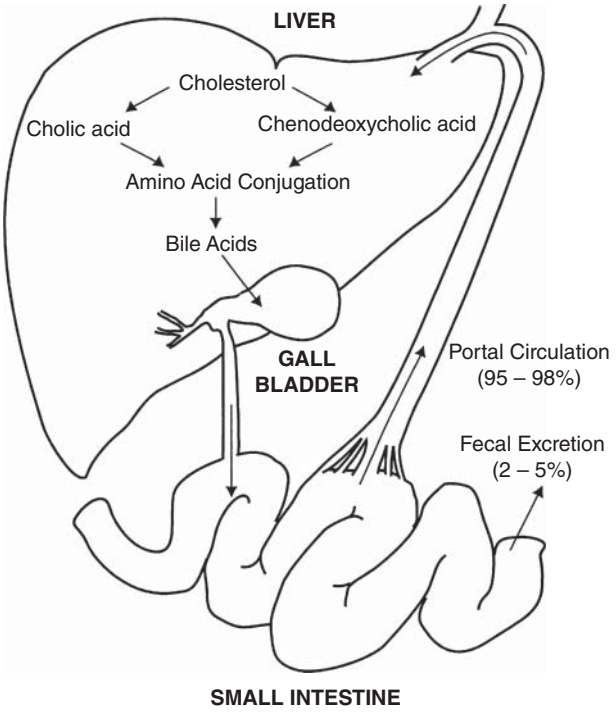

Figure 27.8 Normal production and circulation of bile acid.

1. Abnormalities of portal circulation (e.g., congenital portosystemic shunts, hepatoportal microvascular dysplasia, acquired shunts due to severe cirrhosis). In these situations, blood is shunted away from hepatocytes impairing first-pass clearing of bile acids from portal circulation; bile acids then enter the systemic circulation.

2. Decreased functional hepatic mass. This is a major factor in many diffuse liver diseases (e.g., hepatitis, necrosis, glucocorticoid hepatopathy) that result in sufficient hepatocyte damage that uptake of bile acids from portal blood is impaired.

3. Decreased bile acid excretion in bile. This can result from hepatic or posthepatic cholestasis from any cause (obstruction, hepatocyte swelling, neoplasia, inflammation), functional or sepsis-associated cholestasis, or leakage from the bile duct or gallbladder.

Bile acid assays are most useful for animals in which liver disease is suspected but not unequivocally proven on the basis of routine biochemical profile tests; for example, when serum liver enzyme activities are increased but serum total bilirubin concentrations are normal. SBA concentrations are a sensitive indicator of cholestasis, and it is important to recognize that patients already icteric due to cholestasis will always have increased SBA concentrations as well. However, measuring SBA concentrations may be helpful in differentiating hemolytic hyperbilirubinemia from hepatic or cholestatic hyperbilirubinemia in anemic patients for which a hemolytic cause is not obvious and liver enzyme activities are equivocal. Bile acids do not compete with

bilirubin for uptake or metabolism by hepatocytes; therefore, a hemolytic hyperbilirubinemia can occur without a concurrent increase in SBA concentrations [115]. However, severe anemia can cause hepatocellular hypoxia leading to hepatic dysfunction, with subsequent increases in SBA concentrations [115]. In horses, SBA concentrations may also be helpful in discriminating fasting hyperbilirubinemia from hepatic or cholestatic hyperbilirubinemia. Bile acid concentrations do increase twofold to threefold after 3 days of fasting but generally stays below 25 μmol/L, and so may be only slightly outside of laboratory reference intervals [39, 116]. By contrast, horses with experimental bile duct obstruction or diffuse hepatic necrosis have SBA concentration increases exceeding 8- to 10-fold (50–100 μmol/L) after 3 days [39].

Bile acid assays are readily available. Bile acids are stable in serum at room temperature for several days, and serum for bile acid assays can be frozen. Depending upon the test method, hemolysis may cause false decreases and lipemia false increases in SBA concentrations [115]. Administration of ursodeoxycholic acid to dogs for the treatment of hepatobiliary disease has been shown to minimally increase SBA concentrations, usually still within the reference interval [117].

In dogs and cats, both fasting (preprandial) and postprandial samples are recommended for bile acid assays in order to provide the most reliable information. A standard procedure is the following:

1. The patient is fasted for 12 hours before collection of the first (fasting) serum sample.

2. A fat-containing diet of adequate volume and containing adequate fat to stimulate cholecystokinin secretion by the small intestine and subsequent gallbladder contraction is fed. Growth diets with higher fat content are recommended. In animals with potential hepatic encephalopathy, a restricted-protein diet can be used but should be supplemented with corn oil to increase the fat content to approximately 5%.

3. A serum sample is collected at 2 hours after feeding (postprandial sample).

4. Both fasting and postprandial bile acid concentrations are measured.

Fasting bile acid concentrations of >20 μmol/L and postprandial bile acid concentrations of >25 μmol/L are very specific for liver disease in dogs and cats [115]. A fasting bile acid concentration of <5 μmol/L is normal in dogs and cats, and concentrations between 5 and 20 μmol/L are suggestive of hepatic disease. However, fasting bile acid concentrations as great as 20 μmol/L occasionally occur in normal dogs and cats. Fasting bile acid concentrations between 5 and 20 μmol/L in dogs and cats should be interpreted in light of the patient history, clinical signs, and results of diagnostic imaging as well as other laboratory tests for hepatic disease or function.

In dogs, increased SBA concentrations can occur with a variety of liver diseases, including portosystemic shunts, hepatic microvascular dysplasia, cholestasis, cirrhosis, necrosis, hepatitis, hepatic lipidosis, glucocorticoid hepatopathy, and neoplasia [118, 119]. Exaggerated increases in postprandial bile acid concentrations are most consistent and marked in animals with portosystemic shunts [115]. However, defining the type of liver disease on the basis of the bile acid concentrations alone is not possible. Abnormal bile acid concentrations are an indication for further testing (e.g., liver biopsy, radiologic studies, ultrasound) aimed at identifying the specific type of liver disease that is present. Dogs with hepatic microvascular dysplasia may have subtle clinical signs and normal portograms but do have increases in SBAs; liver biopsy and histopathology is required for diagnosis [120]. Slight increases in SBA concentrations with an increased percentage of unconjugated bile acids have been reported in some dogs with small intestinal bacterial overgrowth [121]. Additionally, there is one report of increased SBA concentrations in healthy Maltese dogs [122]. The sometimes-marked increases were found with the routine enzymatic assay but not by an HPLC assay, suggesting presence of a cross-reacting substance or unusual bile acid.

In cats, increased SBA occurs with portosystemic shunts, cholestasis, cirrhosis, necrosis, hepatitis, hepatic lipidosis, and neoplasia [123, 124]. Fasting bile acid concentrations in cats with these diseases are less consistently increased than are postprandial concentrations, and measuring both is desirable.

Postprandial bile acid concentrations are occasionally lower than fasting bile acid concentrations in dogs and cats. This may result from spontaneous emptying of the gallbladder during the fasting period or to differences in gastrointestinal variables (gastric emptying time, intestinal transit time, intestinal flora) or the release of/response to cholecystokinin [115].

In horses, ruminants, and llamas, a single sample is usually collected for a bile acid assay. Reference intervals in these species tend to be wider than those in dogs and cats. Interpretation of SBA concentrations in cattle is hampered by the periodically interrupted flow of ingesta into the duodenum, which results in considerable hourly variation (differences up to 60 μmol/L) in SBA concentrations [125]. Differences also occur between dairy and beef breeds, and among age groups and stages of lactation [126]. However, despite relatively wide reference intervals SBA concentrations are still the most sensitive test for hepatobiliary diseases in cattle [113]. Fluctuations in SBA concentrations are less in llamas than in cattle, and increased SBA concentrations have been reported in llamas with hepatic lipidosis and portosystemic shunt [127–129]. Reported reference intervals for llamas ≤1 year of age are 2–50 μmol/L, and those for llamas >1 year of age are 1–23 μmol/L [127].

In horses, the SBA reference interval has varied in different studies, but the upper limit of this interval is <20 μmol/L [39, 130]. Horses continuously secrete bile into the intestinal tract because of their lack of a gallbladder and apparent weakness of the sphincter of the common bile duct. Increased SBA concentrations are sensitive indicators of hepatobiliary disease in horses with a variety of disorders including hepatic necrosis, hepatic lipidosis, neoplasia, and cirrhosis [110, 130]. The increases in SBA concentrations observed with these diseases are often marked (40 to >100 μmol/L).

Urine bile acids

Because the liver efficiently removes bile acids from portal circulation, in health only small amounts of bile acids enter systemic circulation to be eliminated in the urine. However, when SBA concentrations are increased there are increased amounts of bile acids excreted in urine. In theory, a one-time measurement of urine bile acid (UBA) concentration compared to urine creatinine concentration (UBA:creatinine ratio) might provide information similar to assays measuring SBA without the need for fasting and postprandial blood samples. Preliminary investigations of urine sulfated and nonsulfated bile acid:creatinine ratios have been performed in dogs and cats [131, 132]. In dogs, the ratio of unsulfated UBA:creatinine had excellent specificity (100%) but relatively poor sensitivity (63%) for liver disease [131]. In cats, the ratio of unsulfated UBA:creatinine had good specificity (88%) and sensitivity (87%) for liver disease [132]. The clinical utility of these ratios for diagnosis of various hepatic disorders awaits further study.

Plasma ammonia

Ammonia (predominantly ammonium, NH_4^+) is produced largely by bacteria in the GI tract during normal digestion and absorbed from the intestinal tract into the blood. It is removed from portal circulation by the liver, where it is used for urea and protein synthesis. Alterations in blood flow to the liver or markedly decreased numbers of functional hepatocytes can result in increased blood ammonia concentrations. Blood ammonia measurement or the ammonia tolerance test may be used to assess liver function. One advantage of measuring ammonia concentrations over SBA concentrations is that blood ammonia levels are not altered by cholestasis. Additionally, increased blood ammonia concentration is considered evidence for hepatic encephalopathy, although this is not a consistent finding. Increased blood ammonia concentrations are considered fairly specific but relatively insensitive for serious hepatic disease. Increased plasma ammonia concentrations are most common in animals with portosystemic shunting of blood (either congenital shunts or shunting secondary to severe cirrhosis). Increased blood ammonia concentrations also can occur with the loss of 60% or more of the hepatic functional mass [44].

In addition to decreased clearance of ammonia from portal circulation, as occurs with portosystemic shunting or decreased functional hepatic mass, there are additional situations in which blood ammonia concentrations may be increased. Increased ammonia intake and/or production have been documented in cattle with urea toxicosis or ingestion of contaminated feed [133, 134]. Strenuous exercise has been shown to increase ammonia levels in dogs and horses [135–137]. Intestinal disease in horses has occasionally been associated with increased ammonia concentrations and signs of hepatic encephalopathy [138–140]. Irish wolfhound puppies may have transient hyperammonemia that disappears in adulthood; however, Irish wolfhounds also have an increased incidence of inherited portosystemic shunts [141]. Finally, there are rare instances of inherited or acquired urea cycle defects that may cause hyperammonemia [108].

Ammonia concentrations are typically measured in plasma using an enzymatic method available in commercial laboratories. Ammonia concentrations in blood are very unstable after collection, however, which has been a deterrent to routine use of this test [142]. A procedure for the collection and storage of plasma for an ammonia assay is as follows [108]:

1. Simple-stomached animals are fasted for at least 8 hours before sampling.

2. Blood is collected and placed into EDTA or ammonia-free heparin anticoagulant, placed in an ice bath, and the plasma separated immediately (within 10 minutes). There should be minimal exposure to air. Delayed separation of plasma or storage at room temperature will cause falsely increased ammonia concentrations.

3. Plasma is refrigerated (4°C) and assayed within 30–60 minutes.

Point-of-care analyzers that utilize whole blood samples have increased the usefulness of blood ammonia assays in clinical situations by eliminating the issues related to proper sample handling for timely delivery of plasma to a commercial laboratory [143, 144]. However, reference intervals for these point-of-care methods may need to be adjusted in order to minimize false-negative test results [143].

Assaying blood ammonia concentrations following administration of ammonium chloride (ammonia tolerance test) increases the diagnostic accuracy of the test [44, 145]. The ammonia tolerance test is usually performed on animals in which portosystemic shunt or decreased hepatic function are suspected but other tests are equivocal and fasting ammonia concentrations are normal. Ammonia tolerance tests should never be performed on animals with fasting hyperammonemia, as dangerously high blood ammonia concentrations may result causing acute ammonia toxicity. Ammonia tolerance tests involving both oral and rectal administration of ammonium chloride have been described.

A suggested procedure for the oral ammonia tolerance tests is as follows [44]:

1. A fasting (preadministration) heparinized (ammonia-free heparin) blood sample is obtained and processed as previously described.

2. Ammonium chloride solution (20 mg/mL) at a dosage of 100 mg/kg body weight is administered via a stomach tube.
3. A total dose of 3 g should not be exceeded.
4. A 30-minute postadministration heparinized blood sample is collected and processed.

The preadministration to postadministration increase of blood ammonia in normal dogs is from 2.0- to 2.5-fold. Most dogs with portosystemic shunts or severe hepatic insufficiency have postadministration increases of 3- to 10-fold.

A postprandial ammonia tolerance test has also been described for dogs, in which food instead of ammonium chloride is used as the challenge material [146]. This test had a sensitivity of 91% for detection of portosystemic shunts in dogs when the postadministration sample was collected 6 hours after feeding. However, it was not useful for detecting other liver diseases.

Albumin

Liver is the site of all albumin synthesis. Hypoalbuminemia usually is not noted until 60–80% of hepatic function is lost. There appear to be some species differences, however, in the incidence of hypoalbuminemia accompanying liver disease. Hypoalbuminemia is quite common in dogs with chronic liver diseases (>60% have hypoalbuminemia), but it does not appear to be as common in horses with chronic liver diseases (~20% have hypoalbuminemia) [35, 147, 148]. Many nonhepatic factors can influence blood albumin concentrations (see Chapter 30).

Globulins

Liver is the site of synthesis for the majority of globulins, with the exception of immunoglobulins synthesized in lymphoid tissue. Hepatic failure can result in decreased synthesis and, therefore, decreased serum concentrations of these globulins. However, globulin concentration usually does not decrease as much as the albumin concentration, and so the albumin: globulin ratio commonly decreases in hepatic failure. In many cases, globulin concentrations may increase with chronic liver disease, either as a result of increased acute phase protein production or immunoglobulin production [149]. This has been especially well documented for horses, in which more than 50% of those with chronic hepatic disease also have increased globulin concentrations [147]. In animals with severe liver disease, the clearance of foreign proteins by the Kupffer cells of the liver is theorized to be decreased. Such foreign proteins are thought to be absorbed from the intestine and carried to the liver by the portal circulation. Thus, when Kupffer cells fail to efficiently clear these proteins on their first passage through the liver, they come in contact with the immune system in other parts of the body resulting in an immune response and hyperglobulinemia.

Glucose

The liver plays a key role in glucose metabolism. Glucose that has been absorbed by the small intestine is transported to the liver via the portal circulation and then enters hepatocytes. The hepatocytes convert glucose to glycogen, which helps to regulate the blood glucose concentration. Hepatocytes also synthesize glucose via gluconeogenesis and release stored glucose via glycogenolysis. In animals with hepatic failure, glucose concentrations can vary from decreased to increased. Increased glucose concentrations may occur because of decreased hepatic glucose uptake, resulting in prolonged postprandial hyperglycemia. Conversely, decreased glucose concentrations may occur because of reduced hepatocytic gluconeogenesis or glycogenolysis. The liver has tremendous reserve capacity for maintaining normal blood glucose levels; 70% hepatectomy does not result in hypoglycemia [149].

Urea

Urea is synthesized by hepatocytes from ammonia. In animals with liver failure, the decrease in functional hepatic mass results in decreased conversion of ammonia to urea. Consequently, the blood ammonia concentration increases, and the blood urea (also known as BUN) concentration decreases. However, blood urea concentrations also may decrease because of numerous other disorders (see Chapter 24).

Cholesterol

Bile is a major route of cholesterol excretion from the body. Therefore, interference with bile flow (cholestasis) can result in increased serum cholesterol concentrations (hypercholesterolemia). Many other nonhepatic disorders, however, also can result in hypercholesterolemia (see Chapter 32).

The liver is also a major site of cholesterol synthesis. In some forms of hepatic failure, decreased cholesterol synthesis can lead to decreased blood cholesterol concentrations (hypocholesterolemia). The balance between decreased cholesterol synthesis and decreased cholesterol excretion varies with different types of liver disease. If decreased synthesis of cholesterol is the major alteration in hepatic failure, hypocholesterolemia can result; if cholestasis is the major alteration, hypercholesterolemia may occur. Many dogs and cats with portosystemic shunts (60–70%) have hypocholesterolemia [150]. However, many animals with liver failure have normal serum cholesterol concentrations.

Coagulation factors

The liver plays a central role in the regulation of coagulation as the sole source of synthesis for the majority of coagulation factors; it also produces anticoagulants such as antithrombin, protein C and protein S [33]. In addition, the blockage of bile flow can result in decreased absorption of vitamin K leading to decreased function of the vitamin K–dependent coagulation factors (factors II, VII, IX, and X) and anticoagulants (proteins C and S). Therefore, defects in both hemostasis and finbrinolysis may occur in animals with liver

disease [149]. Accordingly, animals with liver disease may have abnormalities in a variety of coagulation tests including prothrombin time, activated partial thromboplastin time, antithrombin activity, protein C activity, and fibrinogen concentrations [151–156]. Although coagulation test abnormalities are frequent, clinical bleeding tendencies are recognized less often [153, 155, 157]. Platelet abnormalities including thrombocytopenia and decreased platelet function may also be associated with liver disease [33, 149]. Animals with evidence of liver disease and coagulation abnormalities have the potential for serious complications such as disseminated intravascular coagulation (DIC), and should be fully evaluated using the tests discussed in Chapter 17.

Patterns of laboratory abnormalities for specific diseases

The spectrum and potential magnitude of changes in laboratory test results for selected liver diseases are summarized in Table 27.1. The most common changes in different types of liver diseases are listed but one should be aware that there is a great deal of overlap.

Portosystemic shunt

Portosystemic shunting of blood can be acquired because of severe cirrhosis, and if this is the case, test results similar to those described for end-stage liver disease are expected. Early congenital portosystemic shunts usually do not produce much active hepatocyte damage. Consequently, leakage enzyme activities often are normal or only slightly increased. Cholestasis is not a feature of congenital portosystemic shunts; consequently increased production of ALP and GGT does not occur. However, because congenital shunts most commonly occur in young animals with growing bones, mildly increased serum ALP activity (due to BALP) is common. Because portal circulation to the liver is impaired, increased fasting or postprandial bile acid concentrations and increased blood ammonia concentrations are common. While fasting SBA increases may be marginal, postprandial SBA increases are often marked. The decreased hepatic blood flow can cause hepatic atrophy and decreased functional hepatic mass. Therefore, other tests of hepatic function may become abnormal in more chronic cases. Microcytosis, with or without mild anemia, is a relatively common hematologic finding in dogs with portosystemic shunts. The pathogenesis is uncertain, but abnormal iron metabolism associated with altered iron transport has been implicated [158–160].

Hepatic necrosis

Hepatic necrosis can vary from focal to multifocal to diffuse. Focal to multifocal hepatic necrosis can result in increased activities of leakage enzymes, but these increases are less frequent and of lesser magnitude than those resulting from diffuse necrosis. Focal necrosis usually does not cause significant cholestasis, and induced enzyme activities usually remain normal. Diffuse necrosis is more likely to compromise the flow of bile and cause cholestasis, resulting in induced enzyme activity increases. Bile acid concentrations usually are not affected by focal necrosis, but diffuse necrosis can produce increases in SBA concentrations because of decreased hepatocyte removal of bile acids from the portal circulation as well as cholestasis. Similarly, other tests of hepatic function are not affected by focal necrosis, but if more than 60–80% of the hepatic mass is lost because of diffuse necrosis, results of liver function tests (i.e., albumin, BUN, glucose, cholesterol, coagulation) may be abnormal.

Infiltrative disease, such as lymphoma or other hematopoietic cell neoplasia, can cause laboratory changes similar to those seen with diffuse necrosis. Modest increases in leakage enzyme activities may occur, with variable increases in induced enzyme activities depending on the degree of cholestasis. Liver function may eventually become impaired in advanced cases of infiltrative disease.

Hypoxia or mild toxic damage

Hypoxia (due to conditions such as anemia, hepatic congestion, heart or lung disease, and chronic tracheal collapse [161]) or mild toxic damage (possibly secondary to endotoxins, mycotoxins, or other toxicants) can result in mild injury to many hepatocytes. As a result, leakage enzyme activities can be mildly to moderately increased. Generally cholestasis does not occur, and the activities of induced enzymes usually are normal. However, cell swelling may occur and if it is severe enough, swollen hepatocytes can impinge on bile canaliculi and cause cholestasis as well as increased activities of induced enzymes. This cholestasis usually is not severe enough to result in increased serum bilirubin concentrations but may cause mild increases of SBA concentrations.

Focal lesions

Focal lesions such as abscesses, infarcts, or localized neoplasms may only cause local hepatocyte damage, in which case the activities of leakage enzymes are normal or mildly increased. The activities of these enzymes depend on the time and the extent of hepatocyte damage. Expansion of abscesses or neoplasms into the surrounding tissue may be slow and result in only a few hepatocytes being damaged during any given period of time. Activities of induced enzymes usually are normal but may be increased if the focal lesion causes significant cholestasis. Serum bilirubin or SBA concentrations occasionally are increased, however, the pathogenesis is not clear; focal lesions seldom occlude bile ducts that are large enough to interfere significantly with bile flow. Other tests of hepatic function usually are normal, because 60–80% of the hepatic mass is not lost with focal lesions.

Table 27.1 Common laboratory findings for various hepatic diseases.

Disorder	Leakage enzymes (ALT, AST)	Induced enzymes (ALP, GGT)	Bilirubin	Serum bile acids	Other function tests	Miscellaneous
Congenital portosystemic shunt	N to ↑	ALP = N to ↑ (due to BALP in young animals)	N	Fasting = N to ↑↑ Postprandial = ↑↑ to ↑↑↑	Ammonia = N to ↑ Albumin = N to ↓ BUN = N to ↓ Glucose = N to ↓ Cholesterol = N to ↓ Protein C = ↓ PT = N to prolonged	RBC microcytosis (60–70% of dogs) Ammonium biurate crystalluria

Hepatic lipidosis

Hepatic lipidosis occurs in many species, but the syndrome has been documented best in cats [26]. Serum activities of leakage enzymes (ALT, AST) are mildly to markedly increased in 70–90% of cats with hepatic lipidosis, likely from marked lipid accumulation in hepatocytes. More than 80% of cats with hepatic lipidosis have increased serum ALP activity, varying from mild to marked, whereas only approximately 16% have increased serum GGT activity [82]. However, cats with underlying necroinflammatory disorders may have relatively greater GGT activity compared to ALP activity [26]. Serum activities of these induced enzymes are most likely increased because lipid-laden hepatocytes impinge on bile canaliculi, with resultant cholestasis. The serum bilirubin concentrations are increased to some degree in the majority of cats (75–95%), probably because of cholestasis, and most cats have increased SBA concentrations. Other tests of hepatic function are inconsistently abnormal. If diabetes mellitus is the underlying problem in cats with hepatic lipidosis, blood glucose concentrations may be very high. Coagulation abnormalities (prolonged prothrombin time or activated partial thromboplastin time) occur in 25–40% of cats with hepatic lipidosis.

Steroid hepatopathy

Steroid hepatopathy is most common in dogs and can produce moderate damage to hepatocytes, largely due to distention of hepatocytes from glycogen accumulation. The serum activities of leakage enzymes usually are mildly increased in dogs with steroid hepatopathy, while serum activities of induced enzymes may be markedly increased because of corticosteroid-mediated induction of their synthesis. Serum bile acids may be modestly increased but total bilirubin concentration is rarely increased, and other tests of hepatic function are usually normal.

Biliary abnormalities

Cholangitis, cholangiohepatitis, and extrahepatic bile duct obstruction can occur in many different species. Because lesions usually are centered in the portal areas of the liver or outside of the liver, increased serum activities of leakage enzymes usually are mild and result from secondary damage to hepatocytes caused by increased intrabiliary pressure. The serum activities of induced enzymes are markedly increased and become progressively higher as the disease becomes more severe. Increased intrabiliary pressure induces hepatocytes and biliary epithelial cells to produce increased amounts of these enzymes. Serum bilirubin concentrations are moderately to markedly increased because of the blockage of bile flow. Both fasting and postprandial serum bile acid concentrations are usually increased and sometimes markedly so, resulting from the blockage of bile flow. Other tests of hepatic function are usually normal, unless these diseases progress to end-stage liver disease.

Chronic progressive liver diseases

Chronic progressive liver diseases can occur in many species but are most common in dogs. Moderate to severe inflammation is a common feature, and variable degrees of hepatocyte necrosis, fibrosis, and cirrhosis may also occur. Some cases of chronic hepatitis are associated with abnormal copper accumulation in the liver. Bedlington terriers have a well-described hereditary disorder resulting in hepatic copper accumulation and chronic hepatitis; the molecular defect in this disorder has been characterized [162]. A variety of other dog breeds have been identified that seem to have a predisposition to hepatic copper storage and chronic hepatitis, including West Highland white terriers, Skye terriers, Doberman pinschers, Dalmatians, and Labrador retrievers [163, 164]. Certain drugs (e.g., anticonvulsants) and infectious agents also may cause chronic hepatitis in dogs. Serum activities of leakage enzymes often are mildly or moderately increased because of progressive hepatocyte damage. If progression of the disease is slow, the release of these enzymes within a given period of time may be minimal, and serum activity may not increase. Many of these diseases ultimately result in varying degrees of hepatic fibrosis that may compromise bile flow. Therefore, serum activities of induced enzymes are often mildly or moderately increased. Serum bilirubin concentrations are normal in animals with the early, less severe forms but can be increased in those with later, more advanced disease. Fasting and postprandial SBA concentrations are inconsistently increased, depending on how far the disease has advanced. These increases probably relate to impaired blood flow to the liver, impaired clearance of bile acids by hepatocytes, and cholestasis. Other tests of hepatic function are normal, unless the disease has resulted in the loss of 60–80% of functional capacity. The coagulation status of dogs with chronic liver disease can be variable, with laboratory abnormalities suggestive of both hypo- and hypercoagulability. When evaluated with thromboelastography, which measures the dynamics of clot formation, 7 of 21 and 5 of 21 dogs with chronic hepatopathy were found to be hypercoagulable and hypocoagulable, respectively [165].

End-stage liver disease

End-stage liver disease occurs when more than 60–80% of the hepatic functional mass has been lost. The serum activities of leakage enzymes are normal to moderately increased. Normal serum activities of these enzymes may result from markedly decreased numbers of hepatocytes or minimal active hepatocyte damage. Serum activities of induced enzymes are moderately to markedly increased because of cholestasis. Serum bilirubin concentrations are usually moderately to markedly increased. Fasting or postprandial SBA concentrations are increased, and sometimes markedly so, resulting from decreased hepatic blood flow, impaired hepatocyte uptake of bile acids from portal blood, and cholestasis. Many other hepatic function tests are often

abnormal, including increased blood ammonia concentrations, decreased blood glucose concentrations, decreased blood urea (BUN) concentrations, and decreased serum albumin concentrations. Serum globulin concentrations vary from mildly decreased to increased. Coagulation tests are also often abnormal in animals with end-stage liver disease.

Summary

Biochemical testing can suggest three basic categories of liver disease depending upon the pattern of abnormalities observed: hepatocellular injury, cholestasis, and decreased function. However, characterization of the specific type of liver disease usually requires additional tests (e.g., radiographic studies, ultrasound, liver fine needle aspirate, liver biopsy). If serum enzyme activity greater than 2× URL is persistently increased for more than 4–8 weeks, serum bile acids should be determined. If bile acids are increased, additional testing as previously described should be performed. Additionally, careful attention must be paid to the patient's clinical history, current medications, and physical examination findings in order to rule-out underlying conditions that could affect test results. Repeated biochemical testing is often useful for evaluating disease progression or response to therapy.

28 Laboratory Evaluation of the Pancreas and Glucose Metabolism

Robin W. Allison
Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

The pancreas is a compound organ with both exocrine and endocrine functions. The exocrine pancreas is composed of glandular epithelium that forms acinar lobules comprising about 80% of the pancreas [1], and the endocrine cells are concentrated in the islets of Langerhans.

The exocrine pancreas

The primary function of the exocrine pancreas is the synthesis and secretion of digestive enzymes. These enzymes include proteases that are stored in acinar cell zymogen granules and secreted as inactive proenzymes (e.g. trypsinogen, chymotrypsinogen, proelastase, and procarboxypeptidases), lipase, which hydrolyzes lipids; and amylase, which hydrolyzes starches [2]. The inactive proenzymes become activated by enzymatic cleavage of a small peptide (activation peptide). Normally, trypsinogen is cleaved by enterokinase in the intestine to form trypsin and trypsinogen activation peptide (TAP); trypsin then activates other proenzymes [3]. Unlike the proteases, amylase and lipase are secreted in active form [2].

Two major disorders of the exocrine pancreas can be detected by laboratory evaluation:

- Injury to the pancreatic parenchyma, usually due to pancreatitis. Inflammation may result in the premature activation and leakage of pancreatic enzymes into the pancreatic interstitium, peritoneal cavity, and vasculature. Pancreatitis is recognized most commonly in dogs and cats and may be acute or chronic. Intraperitoneal release of pancreatic enzymes causes tissue damage in the area of the pancreas, thereby increasing both the severity and the extent of the inflammation. Subsequent release of inflammatory mediators can result in a systemic inflammatory response [4].
- Exocrine pancreatic insufficiency (EPI), a disorder resulting in insufficient production and secretion of pancreatic enzymes. EPI is due to loss of pancreatic acinar cells and results in inadequate digestive function (maldigestion). The clinical signs are similar to intestinal disorders that result in inadequate absorption of adequately digested nutrients (malabsorption). Laboratory testing to differentiate maldigestion and malabsorption is discussed in Chapter 29.

Detection of pancreatic injury

The diagnosis of pancreatitis can be extremely difficult to establish, especially in cases of chronic or mild disease. Dogs with acute pancreatitis frequently exhibit vomiting and abdominal pain, but these clinical signs are less common in cats [4]. Cats seem to develop chronic pancreatitis more frequently than acute disease [5]. Necropsy studies indicate subclinical chronic pancreatitis occurs more often in both dogs and cats than previously appreciated [6–8]. Although most cases of pancreatitis are considered idiopathic, various risk factors have been identified. Some dog breeds (miniature schnauzers, Yorkshire terriers) seem to be at increased risk [8]. Idiopathic hyperlipidemia is also common in miniature schnauzers, and hyperlipidemia frequently occurs with acute canine pancreatitis; whether hyperlipidemia is a cause or effect of the pancreatitis is not clear [3]. Other risk factors in dogs include obesity, high fat diets, a wide variety of drugs, zinc toxicosis, hypercalcemia, trauma, ischemia, biliary tract obstruction, neoplasia, and infectious agents [3]. In cats, many cases of pancreatitis have been associated with inflammatory diseases of the bowel and biliary tract (often referred to as triaditis) [5, 9, 10]. Trematode infections of the liver or pancreas can cause pancreatitis [11–13]. Other risk factors in cats are similar to those in dogs [8, 14].

Because clinical signs are nonspecific and highly variable depending upon disease severity, laboratory testing, imaging studies, and sometimes pancreatic fine-needle aspiration (FNA) cytology or biopsy are employed to confirm the diagnosis. Many laboratory tests for pancreatitis have been developed, but most have significant limitations.

Historically, serum activities of enzymes such as amylase and lipase were measured, but such tests have poor sensitivity and specificity for pancreatitis (discussed later). However, immunodiagnostic methods have greater utility, as detailed below.

Pancreatic lipase immunoreactivity

Pancreatic lipase immunoreactivity (PLI) tests are species-specific immunoassays that use antibodies to measure serum concentrations of lipase originating specifically from the pancreas [15, 16]. By contrast, older tests (discussed later) used enzymatic methods to measure serum enzyme activity of lipase, which includes lipase originating from many tissue sources (i.e., not pancreas-specific lipase) [17]. Radioimmunoassays have been developed to detect canine (cPLI) and feline (fPLI) pancreatic lipase immunoreactivity, and newer versions of these assays are available commercially (Spec cPL™ and Spec fPL™, IDEXX Laboratories, Westbrook, ME) [15, 16]. There are also rapid in-clinic tests available for cPLI (SNAP® cPL, IDEXX Laboratories) and fPLI (SNAP fPL, IDEXX Laboratories). In dogs, the sensitivity of the Spec cPL assay for the detection of pancreatitis has been estimated at 72–94% with a specificity of 66–96%, depending upon the cutoff value used and disease severity [18, 19]. False-negative results are considered more likely in cases of chronic pancreatitis [19]. Using that assay, a cPL concentration >400 µg/L is considered consistent with pancreatitis and concentrations between 200 and 400 µg/L are considered a gray zone, with retesting recommended [19]. The rapid SNAP test uses a reference spot that corresponds to the upper reference limit (URL) (200 µg/L for dogs and 3.5 µg/L for cats); if the sample test spot is darker than the reference spot the result is considered abnormal and could be either in the gray zone or consistent with pancreatitis [19]. Sensitivity in dogs has ranged between 92% and 94% and specificity between 71% and 78%, thus confidence in a negative test result is reasonably high [18]. Limited studies suggest that cPLI concentrations are minimally increased with renal failure and not affected by prednisone administration, in contrast to enzymatic serum lipase assays; however further studies in this area are needed [20, 21]. In cats, the sensitivity of fPLI for the detection of pancreatitis is 54–100%, depending upon disease severity, with a specificity of 91% [22]. Sensitivity and specificity of the feline SNAP test have not been published to date. Similar to the situation in dogs, a negative (normal) test result makes pancreatitis unlikely [19, 23]. These assays are most reliable for detection of moderate to severe pancreatitis, and currently are the most useful laboratory tests for diagnosis of pancreatitis in dogs and cats [4, 19, 23].

Serum trypsin-like immunoreactivity

Trypsinogen is synthesized only by the pancreas, and it is converted to the active proteolytic enzyme, trypsin, in the small intestine. The trypsin-like immunoreactivity (TLI) assay uses species-specific antibodies to detect both trypsinogen and trypsin in serum (hence, trypsin-like immunoreactivity). Currently, TLI assays are readily available for dogs and cats, and have been used experimentally in horses [24–26]. In healthy animals, a small amount of trypsinogen leaks into the extracellular space and then diffuses via the lymphatics into the blood. Thus, a normal serum TLI concentration is a good indicator of adequate pancreatic trypsinogen production [26].

Increased serum TLI is expected with pancreatitis due to leakage from damaged acinar cells; however, trypsinogen is cleared by glomerular filtration [27]; thus any disorder causing a decreased glomerular filtration rate (GFR) can increase serum TLI concentration. Activated trypsin, on the other hand, is quickly complexed with protease inhibitors in the blood, and these complexes are removed by the mononuclear phagocyte system [3]. The sensitivity of increased serum TLI concentration for diagnosis of pancreatitis in dogs and cats is 33–36%, less than that of PLI [4, 5]. Specificity has been reported between 65% and 90%, also less than that of PLI [4]. As a result, the serum TLI concentration is now principally applied to diagnosis of pancreatic exocrine insufficiency (see Chapter 29).

Acute and chronic pancreatitis have been recognized in horses, albeit infrequently, and an assay for equine TLI has been described [24, 28]. Information on the utility of this assay for diagnosis of equine pancreatitis awaits clinical trials. In one study, five of seven horses with strangulating intestinal obstructions had increased serum TLI, with the highest values in two horses that did not survive [24]. Serum TLI was not increased in three of three horses with nonstrangulating obstructions. Pancreatic histopathology was not performed. Plasma enzymatically active trypsin (EAT) activity has also been investigated in horses. In one study, 10 horses with acute abdominal disease and histologic evidence of pancreatic injury had increased plasma trypsin activity (mean 196 ng/mL) compared to that of three control horses (mean 28.5 mg/mL) [29].

Serum lipase activity

Enzymatic assays that measure serum lipase activity detect lipase from pancreas as well as other tissues [17]. Thus, increases in serum lipase activity are not specific for pancreatic injury. The utility of measuring serum lipase activity to detect pancreatitis varies between species. Serum lipase activity is frequently normal in cats with spontaneous pancreatitis, and therefore is not considered useful for the diagnosis of pancreatitis in this species [4, 5, 30]. Similarly, it is not considered helpful in the diagnosis of pancreatitis in horses or cattle, although there are rare reports of increased serum lipase activity with acute pancreatitis in these species [31–33]. Serum lipase activity has some utility as a screening test for detection of pancreatitis in dogs, and is frequently

included on standard biochemical profiles. However, it is neither sensitive nor specific for canine pancreatitis [4, 34]. Generally, increases of serum lipase activity of greater than 3–5× the URL are interpreted as suggestive of pancreatitis in dogs, and should prompt further evaluation (cPLI, imaging, biopsy) [4]. However, in one study of dogs with fatal acute pancreatitis, serum lipase activity was increased in only 16 of 41 cases [35]. In dogs, increased serum lipase activity can result from a variety of conditions other than pancreatitis, including:

- Decreased GFR. Dogs with prerenal, renal, or postrenal azotemia can have increased serum lipase activity due to decreased renal excretion and/or inactivation of lipase [36–38]. Usually the increase is <4× URL, but increases up to 10× URL have been reported.
- Corticosteroid administration. Dexamethasone and, to a lesser extent, prednisone can cause increased serum lipase activity in dogs without pancreatitis [39, 40]. Increases are typically <2× URL but may be as much as 5× URL.
- Neoplasia. A variety of neoplasms involving the pancreas (carcinoma, adenocarcinoma), liver (hepatocellular carcinoma, bile duct carcinoma, lymphoma), gastrointestinal tract (lymphoma, adenocarcinoma), and heart (hemangiosarcoma) have been associated with increased serum lipase activity in dogs [38, 41].
- Hepatic disease. In addition to neoplasia, hepatic necrosis and fatty degeneration have been associated with increased serum lipase activity in dogs [38].
- Other. Gastrointestinal and hepatic tissues can be a source for serum lipase activity [42]. Increased serum lipase activity up to 5× URL has been reported in dogs with acute enteritis; however, pancreatitis was not ruled out in those dogs [43]. Mild transient increases in serum lipase activity (threefold baseline values) were reported in dogs following exploratory laparotomy that included manipulation of viscera; no histologic evidence of pancreatitis was present [44].

Serum amylase activity

Assays that measure serum amylase activity, similar to those for serum lipase activity, detect amylase from a variety of tissue sources in addition to the pancreas [17, 45]. Thus, increased serum amylase activity is not specific for pancreatic injury. In dogs, four amylase isoenzymes have been identified including amylase complexes bound to proteins (macroamylases), which have a longer serum half-life than uncomplexed amylase [45, 46].

Although serum amylase activity is readily available on standard biochemical profiles, its utility for the diagnosis of pancreatitis is limited. Cats with spontaneous or experimental pancreatitis typically have normal to minimally increased serum amylase activity, although decreased activity has also been reported [30, 47]. Therefore, serum amylase activity is not useful for diagnosis of pancreatitis in cats [5]. Increased serum amylase activity has rarely been reported with pancreatitis in cattle or horses [31–33], and may also occur with intestinal mucosal injury [48]. In dogs, increased serum amylase activity is neither sensitive nor specific for pancreatitis, and generally considered inferior to serum lipase activity as a screening test [4, 38, 49–51]. Increases of 3–5× URL may be interpreted as suggestive of pancreatitis, prompting further evaluation (cPLI, imaging, biopsy). However, in dogs without pancreatitis many of the same conditions that cause increased serum lipase activity (discussed earlier) can also cause increased canine serum amylase activity [4, 8, 36, 38, 44, 50]. The main exception is corticosteroid administration, which does not increase serum amylase activity and may actually decrease it [39, 40].

Peritoneal fluid amylase and lipase activities

If peritoneal fluid can be obtained from animals suspected of having pancreatic injury, measurement of amylase and lipase activities in this fluid may be diagnostically useful. With active pancreatic damage, these enzymes leak into the cavity resulting in increased fluid enzyme activity. Peritoneal fluid amylase or lipase activity that is higher than serum amylase or lipase activity is suggestive of pancreatic injury [31, 48, 52]. However, duodenal perforation can also result in increased peritoneal fluid amylase and lipase activities. The sensitivity and specificity of peritoneal fluid amylase and lipase activities for detecting pancreatic injury have not been determined.

Cytologic evaluation

Ultrasound-guided FNA of the pancreas for cytologic evaluation is becoming an accepted diagnostic tool, and a few recent studies have evaluated its usefulness in dogs and cats. In healthy dogs, pancreatic FNA did not cause significant increases in serum cPLI or TLI [53]. A study of 92 dogs that had pancreatic FNA for clinical evaluation estimated diagnostic yield of the procedure at 74% with few clinical complications; cytologic interpretations agreed with confirmatory test results in 10 of 11 cases [54]. In 73 cats with clinical evidence of pancreatic disease, pancreatic FNA was considered safe with a diagnostic yield of 67%; cytologic interpretations agreed with histopathologic diagnoses in seven of nine cases [55]. Results of these preliminary evaluations are promising, but additional studies are needed to further assess the safety and efficacy of pancreatic FNA.

Other laboratory abnormalities associated with pancreatic injury

None of the routine laboratory tests typically performed as part of the minimum database (complete blood count [CBC] and biochemical profile) are diagnostic for pancreatic injury, but the presence of several of these abnormalities in addition to physical findings suggestive of pancreatitis should prompt further evaluation using more sensitive and specific tests (cPLI, imaging, etc.). Laboratory abnormalities

that can accompany pancreatic injury are discussed here. It is important to realize that some cases of pancreatitis, particularly chronic pancreatitis in cats, may have normal CBC and biochemical profile results [5, 8].

- Leukocytosis and neutrophilia with or without a left shift may be present. Hematologic evidence of inflammation occurs more often with severe pancreatitis in dogs (~55% of cases) and less often with pancreatitis in cats [4, 5]. Because pancreatitis can be very painful, neutrophilia induced both by epinephrine (excitement) and corticosteroids (stress) may also occur. Lymphopenia may also be present, due to either inflammation or stress.
- Increased hematocrit, hemoglobin concentration, and red blood cell count may be present if the animal is significantly dehydrated, which may occur secondary to vomiting and reduced fluid intake. Mild anemia, regenerative or nonregenerative, occurs occasionally in dogs and cats with pancreatitis.
- Azotemia, usually prerenal, is common in severe cases of pancreatitis and is caused by a combination of factors, including dehydration and hypovolemia that result in decreased GFR [4, 5]. Tubular concentrating ability is usually normal, and urine specific gravity is usually high. Urine specific gravity helps to differentiate prerenal azotemia accompanying pancreatitis from renal azotemia associated with renal failure. This is an important distinction, because pancreatitis and renal failure can cause increases in serum amylase and lipase activities of similar magnitude. In addition, the clinical signs of pancreatitis and renal failure can be similar. Analysis of urine collected at the time of blood sampling is important for animals in which pancreatitis or renal failure (or both) are possibilities; keep in mind that acute renal failure can occur in severe cases of pancreatitis. Details of differentiating prerenal from renal azotemia, including other potential causes of dilute urine in azotemic animals, are discussed in Chapter 24.
- Hyperglycemia is common in animals with acute pancreatic injury and, acutely, is the result of increased serum concentrations of corticosteroids, epinephrine, and glucagon [3]. In patients with chronic or recurring pancreatitis, hyperglycemia may be caused by diabetes mellitus resulting from islet cell injury.
- Mild to moderate hypocalcemia is inconsistently present in animals with pancreatic injury and seems more common in cats than in dogs [35, 56]. The exact pathogenesis of this hypocalcemia is not known but is likely multifactorial. Proposed mechanisms include calcium binding with fatty acids in plasma or those freed from peripancreatic fat by the action of pancreatic lipase (fat saponification), hormonal imbalances involving parathyroid hormone, glucagon, or calcitonin, and intracellular translocation of calcium [57]. In dogs with marked hypoproteinemia, hypoalbuminemia resulting in decreased protein-bound calcium also may contribute to the hypocalcemia. In one study of cats with acute pancreatitis, 19 of 46 cats had low total serum calcium, but 28 of 46 had low ionized calcium, and low ionized was associated with a poorer clinical outcome [56].
- Hypercalcemia has been reported in people with pancreatitis and has been suggested as a cause of pancreatitis in people with diseases such as hyperparathyroidism and lymphoid tumors, although the pathogenesis is unclear [58–60]. Hypercalcemia has been reported occasionally in dogs with pancreatitis [35]. One study in cats demonstrated that acute hypercalcemia increases the pancreatic duct permeability to large molecules, suggesting that pancreatic enzymes could leak and contribute to pancreatitis [61].
- Increased serum activity of leakage (alanine aminotransferase, aspartate aminotransferase) or induced (alkaline phosphatase, γ-glutamyltransferase) liver enzymes occurs frequently [3, 5]. Increased serum activity of leakage enzymes results from ischemic or toxic damage to hepatocytes secondary to pancreatic damage and release of pancreatic enzymes. Increased serum activity of induced enzymes may result from blockage of the common bile duct secondary to inflammation of tissue near both the pancreas and the bile duct. Hepatic lipidosis can occur with pancreatitis in anorexic cats and contribute to hepatic enzyme activity increases. Serum bilirubin concentration may be increased in dogs and cats with pancreatitis, particularly those with acute disease; potential causes include cholestasis (intra- or extrahepatic) and secondary hepatocyte injury [30, 35].
- Hypercholesterolemia and hypertriglyceridemia, often with gross plasma lipemia, are common in dogs with pancreatitis. Although the pathogenesis is not clear, altered lipoprotein processing is suspected, and cholestasis may contribute [62]. Hypertriglyceridemia may be either a cause or an effect of pancreatitis [63]. Hypercholesterolemia and, less commonly, lipemia have been reported in cats [5].
- Serum and plasma protein concentrations are variable in patients with pancreatitis. Exudation of protein-rich fluid into the peritoneal cavity, as a component of peritonitis, can decrease the serum protein concentration, but dehydration tends to increase the serum protein concentration. In some cases, these changes counterbalance each other.
- Disseminated intravascular coagulation can be a sequela to acute pancreatitis. Alterations in hemostatic function tests that occur with disseminated intravascular coagulation are discussed in Chapter 17. Because bile flow is essential for absorption of fat-soluble vitamins in the intestine, bile duct obstruction caused by pancreatic disease occasionally leads to vitamin K deficiency, causing altered hemostasis and abnormal coagulation test results.

The endocrine pancreas

The islets of Langerhans contain the cells of the endocrine pancreas (Figure 28.1). There are a variety of specialized

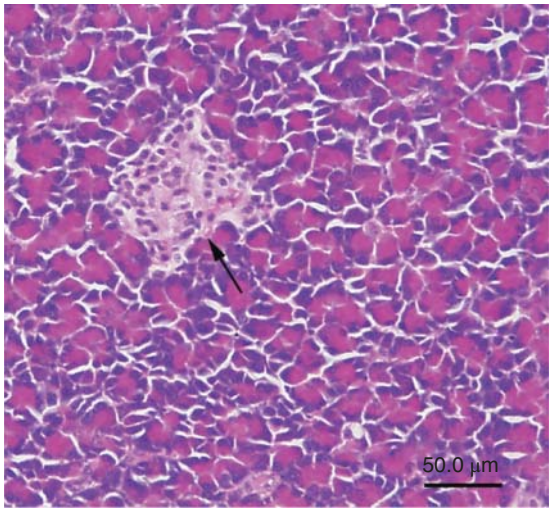

Figure 28.1 The islets of Langerhans (arrow) are the endocrine portion of the pancreas. Both deficient and excessive production of insulin by islet β cells result in abnormalities of glucose metabolism.

endocrine cells present in the islets, including α cells, which secrete glucagon, δ cells, which secrete somatostatin, and PP cells, which secrete pancreatic polypeptide. However, the most common functional abnormalities of the endocrine pancreas involve the β cells, which comprise 60–80% of all islet cells and secrete insulin [64]. Both deficient and excessive insulin production may result in serious abnormalities of glucose metabolism. Many factors in addition to the endocrine pancreas play key roles in glucose metabolism. This section reviews the major factors affecting glucose metabolism, discusses the causes of decreased blood glucose concentration (hypoglycemia) and increased blood glucose concentration (hyperglycemia), and describes tests for evaluating the status of glucose metabolism.

Glucose metabolism

Sources of blood glucose

Glucose in blood is derived from three sources:

- Intestinal absorption. Dietary carbohydrates are broken down and absorbed in the intestine. Intestinal absorption of glucose can increase blood glucose concentrations in monogastric animals for 2–4 hours after a meal.
- Hepatic production. Hepatic production of glucose results from gluconeogenesis and glycogenolysis. Gluconeogenesis is the formation of glucose from noncarbohydrate sources, primarily amino acids (from protein) and glycerol (from fat) in monogastric animals. Ruminants absorb volatile fatty acids rather than carbohydrates, and gluconeogenesis from propionic acid is a major source of blood glucose in ruminants. Glycogenolysis is the hydrolysis of glycogen to glucose.
- Kidney production. Although the liver is considered the primary source of glucose production, gluconeogenesis has also been documented in renal epithelial cells. One study in dogs demonstrated the kidney is responsible for about 30% of glucose turnover during fasting [65]. Renal gluconeogenesis occurs in the proximal tubule and is now understood to have a significant effect on glucose metabolism in both normal and abnormal physiological states [66].

Regulation of blood glucose concentration

Blood glucose concentrations are dependent on multiple interacting factors, including time since last meal, hormonal influences, and use of glucose by peripheral tissues such as skeletal muscle. Time since the last meal is important only in monogastric animals, in which food ingestion is followed by an increase in the blood glucose concentration.

Hormones affect the blood glucose concentration by regulating hepatic production and peripheral use of glucose (Table 28.1). Insulin is secreted by pancreatic islet β cells. Insulin lowers blood glucose concentrations by promoting glucose uptake by liver, skeletal muscle, and fat; by inhibiting gluconeogenesis in the liver; and by promoting the formation and storage of liver glycogen. Glucose uptake into myocytes and adipocytes is facilitated by a glucose transport protein called GLUT-4, which is translocated to plasma membranes after insulin binds to cell surface insulin receptors [64]. After a meal, approximately 1/3 of absorbed glucose is stored as glycogen within the liver, and approximately 2/3 is used as energy by other tissues [67]. Insulin also accelerates the conversion of glucose to fat, accelerates glucose oxidation, and promotes protein and glycogen synthesis in muscle. The net effect of these actions is increased hepatic and peripheral

Table 28.1 Effects of various hormones on glucose metabolism and blood glucose concentrations.

Hormone	Actions	Effect on blood [glucose]
Insulin	Promotes tissue glucose uptake Inhibits gluconeogenesis Promotes glycogen synthesis	Decrease
Glucagon	Promotes gluconeogenesis Promotes glycogenolysis Inhibits glycogen synthesis	Increase
Glucocorticoids	Promotes gluconeogenesis Promotes glucagon release Inhibits tissue glucose uptake	Increase
Catecholamines	Promotes glycogenolysis Inhibits insulin secretion Stimulates growth hormone release	Increase
Growth hormone	Inhibits tissue glucose uptake Inhibits insulin action Promotes glucose production	Increase

uptake and use of glucose, with decreased hepatic synthesis of glucose.

Glucagon is secreted by α cells of the pancreatic islets in response to insulin-induced hypoglycemia. In direct contrast to insulin, glucagon increases blood glucose concentrations by stimulating hepatic gluconeogenesis and hepatic glycogenolysis, and inhibiting hepatic glycogen synthesis [68].

Glucocorticoids increase blood glucose concentrations by promoting glucagon release, hepatic gluconeogenesis, and inducing a state of insulin resistance by affecting the ability of membrane proteins (such as GLUT-4) to transport glucose into cells [69]. The net effect of these actions is decreased peripheral use of glucose and increased hepatic synthesis of glucose.

Catecholamines (i.e., epinephrine and norepinephrine) increase blood glucose concentrations by increasing hepatic glycogenolysis, inhibiting insulin secretion, and stimulating growth hormone release [69]. The net effect of these actions is decreased peripheral use of glucose and increased hepatic synthesis and release of glucose.

Growth hormone increases blood glucose concentrations by inhibiting insulin-mediated uptake of glucose by hepatocytes, muscle cells, and adipose cells; by increasing hepatic production of glucose; and by exerting a post receptor influence within cells that inhibits the action of insulin on glucose metabolism [70, 71]. The net effect of these actions is decreased peripheral use of glucose and increased hepatic synthesis of glucose.

Extreme physical activity might result in a decreased blood glucose concentration because of increased use of glucose by tissues such as skeletal muscle. In normal animals, hormonal influences keep the blood glucose concentrations stable during most types of physical activity.

Causes of hypoglycemia

Conditions that can cause hypoglycemia are listed in Table 28.2. Additionally, delayed separation of serum from erythrocytes will result in artifactually decreased glucose concentrations (see later discussion in section on "Laboratory Evaluation of Glucose Metabolism").

• Drugs. Therapeutic insulin overdose may occur when treating an animal that has diabetes mellitus. Similarly, sulfonylurea medications such as glipizide and glyburide, which act by stimulating insulin secretion, may cause hypoglycemia. An increased insulin concentration decreases gluconeogenesis and glycogenolysis and increases cellular uptake and use of glucose.

• Extreme exertion. Hypoglycemia may occur in hunting dogs and endurance horses, if glycolysis demands more glucose than gluconeogenesis or glycogenolysis can produce [69].

• Glycogen storage diseases. These rare diseases are congenital deficiencies of the enzymes required for glycogenolysis, causing intracellular glycogen accumulation and possibly hypoglycemia. A variety of specific enzyme deficiencies have been reported in cattle, dogs, cats, and horses [72–76].

Table 28.2 Causes of hypoglycemia.

Drugs
Insulin overdose
Sulfonylurea medications
Extreme exertion
Glycogen storage diseases
Hepatic insufficiency or failure [a]

β cell tumor (insulinoma) [a]
Non-β cell tumors
Pregnancy hypoglycemia
Sepsis [a]
Starvation or malabsorption
Xylitol toxicosis
Unripe ackee fruit poisoning

[a]Relatively common.

• Hepatic insufficiency/failure. Severe hepatic insufficiency or hepatic failure resulting from the loss of >70% of functional hepatic mass may cause hypoglycemia due to decreased gluconeogenesis and glycogenolysis. Other laboratory evidence of decreased hepatic function is expected to be present, such as hypoalbuminemia, decreased blood urea nitrogen (BUN) concentration, and increased serum bile acid concentration (see Chapter 27).

• Hypoadrenocorticism. Hypoglycemia occurs inconsistently in dogs with hypoadrenocorticism, likely caused by a lack of cortisol. Hypoglycemia is usually mild and probably results from decreased gluconeogenesis and increased insulin-mediated uptake of glucose by muscle tissue [77, 78].

• Hypopituitarism. Lack of adrenocorticotropic hormone (ACTH) secretion from the pituitary results in hypocortisolemia, which may cause mild hypoglycemia. Lack of growth hormone secretion may also contribute to hypoglycemia.

• Juvenile and neonatal hypoglycemia. Neonatal hypoglycemia is especially common in pigs, but it can occur in other species. It is usually associated with poor nursing secondary to diarrhea, dehydration, or hypothermia in the piglets or agalactia in the sow [79, 80]. Hypoglycemia during periods of decreased food intake in neonates results from inadequate storage pools of glycogen and protein, which could be used for glucose production. Juvenile hypoglycemia is a syndrome that usually is seen in toy breed puppies younger than 6 months [81, 82]. Clinical signs often are triggered by stressors such as diarrhea, fasting, or

parasitism. As in neonatal hypoglycemia, inadequate storage pools of glycogen and protein probably play an important role in this syndrome. Inadequate levels of hepatic enzymes for gluconeogenesis also may contribute.

• Lactational hypoglycemia. This syndrome, also known as spontaneous bovine ketosis, occurs in cattle during periods of marked milk production [83]. Hepatic gluconeogenesis is unable to meet the demand for glucose production, and ketosis develops due to increased fat mobilization.

• Neoplasia. Neoplasms of the β cells of the pancreatic islets (insulinomas) are the most common tumors associated with hypoglycemia. Insulinomas have been reported in dogs, cats, and ferrets [84, 85]. Excess insulin production by the neoplastic β cells causes increased glucose utilization by tissues and decreased hepatic gluconeogenesis and glycogenolysis. Hypoglycemia may be sporadic but is often of sufficient magnitude to cause clinical signs of weakness and seizures. Non-β cell tumors of several types have also been associated with a paraneoplastic hypoglycemia. In dogs, many of these tumors have been mesenchymal (leiomyoma, leiomyosarcoma), but epithelial tumors (hepatic carcinoma, renal carcinoma, and others) and round cell tumors (lymphoma, plasma cell tumor) have also been reported [85]. Proposed mechanisms for the hypoglycemia include liver dysfunction, glucose utilization by neoplastic cells, and neoplastic cell production of insulin-like growth factor [86]. In horses, hypoglycemia has been reported in association with hepatic and renal neoplasia, peritoneal mesothelioma, and gastrointestinal stromal tumor [87–91].

• Pregnancy hypoglycemia. A syndrome of hypoglycemia and ketonemia may occur during late pregnancy in dogs and sheep [92, 93]. There is a decreased ability to produce glucose via gluconeogenesis, glycogenolysis, and lipolysis due to blunting of the normal responses to hypoglycemia. In sheep, this is referred to as pregnancy toxemia, which may be related to the number of fetuses and quality/quantity of feed. Pregnancy hypoglycemia appears to be uncommon in dogs.

• Sepsis. Hypoglycemia occurs inconsistently with sepsis, most often associated with endotoxemia. Experimentally, hyperglycemia occurs early, followed by hypoglycemia [94]. The causes of hypoglycemia that occurs in association with sepsis are not completely understood. Possible causes include impaired gluconeogenesis and glycogenolysis and increased use of glucose by tissues, including leukocytes. Hypoglycemia secondary to glucose consumption by large numbers of hemotropic mycoplasmas, bacteria that parasitize erythrocytes, has been reported in pigs, sheep, llamas, and calves. However, rapid bacterial glycolysis *in vitro* may also cause artifactually decreased blood glucose concentrations [95].

• Starvation or malabsorption. Decreased glucose absorption from the intestine is a rare cause of hypoglycemia. Hypoglycemia only occurs after long-term starvation or malabsorption, because gluconeogenesis helps to maintain a normal blood glucose concentration at the expense of other substances, principally protein.

• Xylitol toxicosis. Xylitol is used as a sugar substitute in various products and is a strong promoter of insulin release in dogs. Severe hypoglycemia has been reported in dogs following ingestion of xylitol-containing sugar-free products [96, 97]. Xylitol also causes marked changes in liver leakage enzymes, as described for diffuse hepatic necrosis (Chapter 27).

• Unripe ackee fruit poisoning. The ackee apple fruit is commonly found in West Africa and some islands of the Caribbean. The unripe fruit and seeds are toxic, containing hypoglycin A and B, respectively, so named for their ability to cause hypoglycemia [98, 99]. In people, consumption of the unripe fruit causes severe vomiting, marked hypoglycemia, and seizures, and may progress to coma and death. Although published reports in animals are lacking, unripe ackee fruit poisoning has been associated with hypoglycemia in dogs in the Caribbean islands (Mary Anna Thrall, personal communication).

Causes of hyperglycemia

Conditions that can cause hyperglycemia are listed in Table 28.3.

• Drugs or toxins. A variety of drugs are associated with transient mild hyperglycemia. The mechanisms of action differ. Detomidine, xylazine, propanolol, and thyroxine inhibit insulin release. Progestins and morphine stimulate growth hormone release; ketamine stimulates epinephrine release. Megestrol acetate acts as a steroid and also stimulates growth hormone release. The Somogyi effect is a paradoxical hyperglycemia that may occur in a diabetic animal in response to excess insulin administration. The actions of glucagon and glucocorticoids were described earlier (see "Regulation of Blood Glucose Concentration").

• Physiologic. Mild hyperglycemia can occur secondary to several physiologic responses. During diestrus, progesterone stimulates release of growth hormone, which decreases tissue glucose utilization. Catecholamine release (epinephrine and norepinephrine) associated with excitement, pain, or strenuous exertion stimulates growth hormone release, inhibits insulin secretion, and stimulates glycogenolyis. Cats frequently exhibit transient hyperglycemia related to struggling during blood collection; the magnitude of the hyperglycemia may reach 300 mg/dL or greater, and it may persist for 1.5–2 hours [100, 101]. A stress response, caused by endogenous corticosteroid release, stimulates gluconeogensis, glucagon release, and causes a state of insulin resistance. Corticosteroid and/or catecholamine release likely play a role in many different disease processes in which hyperglycemia occurs secondarily. Monogastric animals experience a normal postprandial increase in blood glucose concentrations that typically subsides within 4 hours.

Table 28.3 Causes of hyperglycemia.

Drugs or toxins
Detomidine
Ethylene glycol
Glucocorticoids
Glucagon
Insulin (Somogyi effect)
Intravenous glucose
Ketamine
Megestrol acetate
Morphine
Progestins
Propanolol
Thyroxine
Xylazine
Physiologic
Diestrus (progestins)
Exertion/excitement/pain (catecholamines)
Postprandial (monogastrics)
Stress (corticosteroids)
Pathologic
Diabetes mellitus
Hepatocutaneous syndrome (dogs)
Hyperammonemia (horses and cattle)
Metabolic syndrome (horses)
Milk fever (cattle)
Moribund animals
Neoplasia — acromegaly, glucagonoma, hyperadrenocorticism, pheochromocytoma, hyperthyroidism, hyperpituitarism
Pancreatitis
Proximal duodenal obstruction (cattle)

The magnitude of increase may be either constrained within the reference interval or result in an interpreted mild hyperglycemia.

• Diabetes mellitus. Diabetes mellitus is caused by a deficiency of insulin production or an interference with the action of insulin in target tissues, thereby resulting in abnormal glucose metabolism. Altered protein and lipid metabolism also occurs in diabetes mellitus. Diabetes is typically associated with the greatest degrees of hyperglycemia. Therefore, animals with diabetes mellitus usually have blood glucose concentrations greater than the renal threshold resulting in glucosuria. Glucosuria occurs less commonly with other causes of glucose intolerance. Diabetes mellitus has been classified according to the underlying cause as either type 1 or type 2, and by the dependence of the affected animal on insulin therapy as either insulin dependent (IDDM) or noninsulin dependent (NIDDM). These two classification schemes overlap, causing confusion regarding the types of diabetes mellitus occurring in animals. Type 1 diabetes mellitus results from immune-mediated destruction of pancreatic β cells, and animals with type 1 diabetes mellitus are insulin dependent. Type 1 diabetes is the most frequent cause of diabetes in dogs, but it has not been well documented in cats [102]. Insulin dependent diabetes mellitus can also occur secondary to other disease processes that destroy β cells (such as pancreatitis [102]) or cause β cell hypoplasia (genetic diabetes mellitus in keeshond dogs [103], and juvenile pancreatic atrophy in greyhounds [104].) Type 2 diabetes mellitus is characterized by a sluggish insulin response to hyperglycemia (i.e., decreased capacity to produce insulin) and a poor tissue response to insulin (i.e., insulin resistance). Animals with type 2 diabetes mellitus may be either insulin or noninsulin dependent. This is the most common type of diabetes mellitus in cats, but it can occur in dogs as well [102]. Approximately 70% of cats with type 2 diabetes mellitus are insulin dependent [105]. The pathogenesis of type 2 diabetes mellitus in cats is complex and incompletely understood. A consistent finding in more than 90% of diabetic cats is deposition of islet amyloid, derived from islet amyloid polypeptide (IAPP, or amylin) [106] (Figure 28.2). Pancreatic amyloidosis is toxic to β cells, causing cell death and decreased insulin secretion [106]. IAPP is secreted by β cells along with insulin, and states of insulin resistance (obesity, e.g.) cause increased secretion of both insulin and IAPP. In turn, circulating IAPP may contribute to peripheral insulin resistance. Obesity causes insulin resistance in several ways (downregulates insulin receptors, impairs receptor affinity for insulin, causes postreceptor defects in insulin action) and is considered a major risk factor for diabetes mellitus in cats [105, 107].

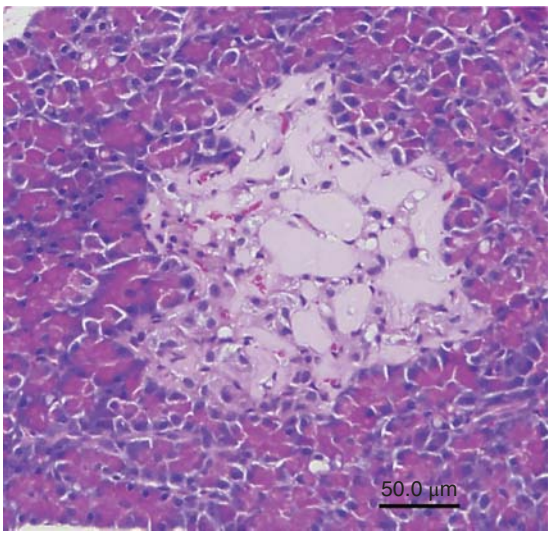

Figure 28.2 Pancreatic amyloidosis. Amyloid deposition surrounds β cells and has enlarged this islet of Langerhans. Amyloid deposition is toxic to β cells and hampers insulin secretion.

• Hepatocutaneous syndrome. This uncommon syndrome in dogs is characterized by liver disease in combination with superficial necrolytic dermatitis. Hyperglycemia is common, but the pathogenesis is not clear [108].
• Hyperammonemia. Hyperglycemia may occur in horses and cattle with hyperammonemia that is unrelated to liver disease (for example, excess ammonia production in the intestine, urea toxicosis, ammonia toxicosis). Proposed mechanisms include stimulation of gluconeogenesis and reduced tissue uptake of glucose [109, 110].
• Metabolic syndrome. Serum glucose concentrations may be increased or normal in horses with metabolic syndrome, which is a complex disorder that mimics Cushing's disease [111]. Affected horses are typically obese and insulin resistant and are prone to develop laminitis.
• Milk fever. Hyperglycemia, along with hypocalcemia and hypophosphatemia, is often present in cattle with milk fever (parturient paresis) [112]. Hypocalcemia suppresses insulin release [113]; catecholamine and/or corticosteroid release in "down" cows may also contribute to the hyperglycemia.
• Moribund animals. Hyperglycemia may occur in moribund animals, usually ruminants. Likely causes include catecholamine and/or corticosteroid release and decreased peripheral use of glucose.
• Neoplasia. A variety of neoplastic diseases can predispose to development of diabetes mellitus. Acromegaly is typically caused by a pituitary adenoma that secretes growth hormone and occurs most commonly in cats. Excess growth hormone promotes insulin resistance. Glucagonoma is a pancreatic α cell tumor that secretes glucagon, which increases hepatic glucose production. Hyperadrenocorticism, whether due to pituitary or adrenal neoplasia, results in excess cortisol production that increases hepatic gluconeogenesis and causes insulin resistance. Hyperadrenocorticism is a fairly common concurrent disorder in dogs diagnosed with diabetes mellitus [114]. Pheochromocytomas secrete catecholamines, which inhibit insulin secretion and stimulate glycogenolyis. A small percentage of cats with hyperthyroidism are persistently hyperglycemic, theorized to be due to insulin resistance; the mechanism is unknown [115]. Hyperpituitarism may be due to pituitary hyperplasia or neoplasia, with excess secretion of growth hormone or ACTH that causes insulin resistance and increased cortisol concentrations. Pituitary pars intermedia dysfunction in horses causes increased ACTH secretion and hyperglycemia [116].
• Pancreatitis. Destruction of β cells due to pancreatitis can lead to development of insulin dependent diabetes mellitus. This may be the underlying cause in up to 30% of canine IDDM cases [102].
• Proximal duodenal obstruction. Cattle with proximal duodenal obstruction may have marked hyperglycemia, up to 1000 mg/dL [117]. The proposed pathogenesis is a combination of stress and decreased peripheral glucose utilization. By contrast, cattle with abomasal volvulus have a much milder hyperglycemia, usually attributed to stress.

Laboratory evaluation of glucose metabolism

Blood glucose

Measurement of the blood glucose concentration is the initial step in evaluating glucose metabolism. After detection of either hyperglycemia or hypoglycemia, tests for more specific evaluation of glucose metabolism may be required. Analysis of blood glucose concentration can be performed by a reference laboratory and is usually part of the standard biochemical profile. Serum or plasma is the sample required by reference laboratories, and it must be separated from erythrocytes within 30 minutes of blood collection. Glycolysis in erythrocytes results in loss of 10% of glucose per hour if the serum or plasma remains in contact with erythrocytes. Sodium fluoride anticoagulant inhibits glycolysis and should be used if serum or plasma cannot be separated from cells promptly. All in-clinic clinical chemistry analyzers also have glucose methods, either as single tests or included in panels. Portable blood glucose meters (PBGMs) are also available that allow rapid and repeated measurements of whole blood glucose concentrations in clinic situations; some pet owners utilize these instruments to monitor diabetic pets at home [118–120]. Several of these instruments have been evaluated for use in animals; most of them provide results that differ to some degree from reference methods [121, 122]. In most cases (but not all), glucose concentrations determined by PBGMs are lower than those determined by reference methods. Therefore, it is important to consider test methodology when comparing results from any individual patient.

Because blood glucose concentrations in monogastric animals are increased for 2–4 hours postprandially, glucose concentrations should be measured after fasting. Dogs and cats should be fasted for 12 hours before sampling to avoid postprandial influences. Potentially hypoglycemic animals should not be fasted before sampling, however, because severe hypoglycemia may result. Horses usually are not fasted before collecting blood samples for glucose analysis; however, blood glucose concentrations might increase during a period of 2–4 hours after eating high-energy supplements. It is not necessary to fast ruminants before blood glucose analysis, because they primarily absorb volatile fatty acids rather than glucose from the gastrointestinal tract.

Artifactual hypoglycemia may occur due to *in vitro* consumption of glucose in cases of extreme leukocytosis and marked erythrocyte parasitemia with hemotropic mycoplasmas [95].

Urine glucose

Urine glucose measurement is discussed in Chapter 24. Glucosuria occurs when the blood glucose concentration exceeds the renal threshold, which varies by species. Renal thresholds are between 180 and 220 mg/dL in dogs [123],

200–300 mg/dL in cats [105], 180–200 mg/dL in horses [124], and 100 mg/dL in cattle [124]. Concurrent measurement of blood glucose is important when interpreting glucosuria; diabetic animals typically have both persistent hyperglycemia and glucosuria. Glucosuria can occur in the absence of hyperglycemia if the renal glucose threshold is decreased. Decreased renal thresholds usually result from proximal tubular abnormalities, which may be acquired or congenital. Acquired abnormalities include those caused by ischemia, nephrotoxins, and amyloidosis [125]; congenital disorders include primary renal glcosuria and Fanconi syndrome [126].

Serum insulin

Insulin concentrations can be determined in serum or heparinized plasma. These are usually immunoassays using antibodies developed to detect porcine or human insulin, but there is good cross-reactivity with canine insulin; assays should be validated for the species of interest. Serum insulin is stable for a week if kept refrigerated, and for several months if frozen [69].

Insulin concentrations are most frequently measured in hypoglycemic animals when insulinoma is suspected. Because animals with insulinoma may be euglycemic on a random blood sample, it is important to document inappropriate insulin levels at the same time that hypoglycemia is present. Normally, insulin concentrations should be very low when glucose concentrations are low. In dogs with a blood glucose <60 mg/dL, detection of insulin concentrations that are above the reference interval (usually >20 μU/mL) is strong evidence for insulinoma [85]. Insulinoma is possible in hypoglycemic dogs with insulin concentrations in the mid to upper reference interval (10–20 μU/mL). Fasting, with hourly evaluation of blood glucose concentrations, may be required to achieve the desired hypoglycemic state for accurate results. Dogs must be carefully monitored during this process to avoid life-threatening hypoglycemia. Following the test, the dog should be fed several small meals over several hours. Calculated ratios (insulin: glucose or amended insulin: glucose) are not reliable for diagnosis of insulinoma and are not recommended.

In theory, measurement of insulin levels in diabetic animals could help to classify their disease as IDDM or NIDDM. Practically, however, this has not proved to be very useful. The vast majority of dogs have IDDM with low serum insulin concentrations. Most cats with type 2 diabetes mellitus (insulin resistant) also have low serum insulin and require insulin therapy, although some only transiently. Prolonged hyperglycemia and glucose toxicity, which impairs β cell function, is thought to be responsible for this finding [105].

Fructosamine

Fructosamine is a general term that refers to any glycated protein (i.e., a protein with attached carbohydrate). Fructosamine is formed when glucose is linked irreversibly to amine groups of albumin and other proteins in the blood [127]. The serum fructosamine concentration is an indicator of blood glucose concentrations during the previous 2–3 weeks (based on the average life span of the proteins involved in this complex) [128]. Fructosamine provides more reliable information regarding the long-term state of glucose metabolism than the blood glucose concentration, which may be transiently increased in some situations. Fructosamine, therefore, has potential in establishing the diagnosis of diabetes mellitus and in monitoring therapy for diabetics.

Serum fructosamine assays are available at reference laboratories. Fructosamine appears to be quite stable in serum kept refrigerated (~10 days) or frozen (~30 days) [129, 130]. Hemolyzed samples may give erroneous results, and should be avoided. Hyperproteinemia and hyperbilirubinemia do not appear to affect test results [131].

Increased fructosamine concentrations

Increased fructosamine concentrations are indicative of persistently increased blood glucose concentrations and, in diabetic animals receiving insulin treatment, of a lack of therapeutic control of blood glucose concentrations during the previous 2–3 weeks. Because hyperglycemia is relatively common even in well-controlled diabetics, the cutoff value used for a determination of poor glycemic control is greater (typically >500 μmol/L) than the URL for nondiabetic animals (typically 365 μmol/L) [105, 123].

Fructosamine also is useful in distinguishing excitement-induced hyperglycemia from diabetic hyperglycemia in cats. Fructosamine concentrations are usually within the reference interval in cats with hyperglycemia caused by excitement, since hyperglycemia must be present for approximately 4 days before increased fructosamine concentrations are detected. The reported sensitivity of increased fructosamine concentration for detection of diabetes mellitus in cats is 93%, with a specificity of 86% [132]. The reported sensitivity and specificity of increased fructosamine concentration for detection of diabetes mellitus in dogs is 88% and 99%, respectively [133].

Mildly increased fructosamine concentrations have been reported in some dogs with hypothyroidism; however, those dogs were not hyperglycemic [134]. Prolonged albumin half-life due to decreased protein turnover is the proposed mechanism.

Decreased fructosamine concentrations

Decreased fructosamine concentrations are expected with persistent hypoglycemia, as occurs with insulinoma. However, because fructosamine is a measure of glycated proteins, hypoproteinemia may be a cause of decreased fructosamine concentrations. In one study, normoglycemic dogs had decreased fructosamine concentrations that correlated best

with the degree of hypoalbuminemia, while normoglycemic cats had decreased fructosamine concentrations that correlated best with the degree of hypoproteinemia [131]. Based on these correlations, formulae have been suggested to correct fructosamine concentrations for protein abnormalities in dogs and cats. In these formulae, the reference interval median value is used for the "normal" albumin and total protein concentrations:

- Dogs: Corrected fructosamine = fructosamine × (normal albumin ÷ patient albumin).
- Cats: Corrected fructosamine = fructosamine × (normal total protein ÷ patient total protein).

Decreased fructosamine concentrations have been reported in normoglycemic cats with hyperthyroidism, likely due to increased protein turnover [135]. Decreased fructosamine concentrations in the absence of hypoglycemia or hypoproteinemia have also been reported in some animals with parasitic infections, including dogs with *Angiostrongylus vasorum* [136] and sheep with *Teladorsagia circumcincta* [137] infections. Increased protein turnover is suspected in these cases. Decreased fructosamine concentrations were reported in normoglycemic, normoproteinemic dogs (but not cats) that were hyperlipidemic or azotemic [131].

Glycated hemoglobin

Glycated hemoglobin (GHb) is formed in erythrocytes by an irreversible reaction between carbohydrates (especially glucose) and hemoglobin. GHb forms continuously during the life span of an erythrocyte; therefore, older erythrocytes usually contain more GHb compared with younger erythrocytes. The amount of GHb that is formed is proportional to the blood glucose concentration during the life span of the erythrocyte. The blood GHb concentration reflects glucose status during a longer period of time than does the serum fructosamine concentration, because of relatively long erythrocyte life spans (approximately 110 days in dogs, 70 days in cats, 150 days in cattle and horses) [138]. Increased GHb concentrations do not immediately return to normal after reestablishing more normal blood glucose concentrations, because this requires the removal of senescent erythrocytes with high GHb concentrations. Such decreases in GHb concentrations might be delayed for several weeks. GHb can be used in the same situations as fructosamine [139, 140]. However, fructosamine concentrations change faster with changes in blood glucose concentrations, which may be an advantage in many situations.

GHb is measured in EDTA-anticoagulated whole blood, and is stable for 7 days when refrigerated [123]. GHb will be decreased in anemic animals, due to decreased hemoglobin concentrations and/or increased numbers of reticulocytes present as part of a regenerative response [140]. Conversely, GHb will be increased in polycythemic animals.

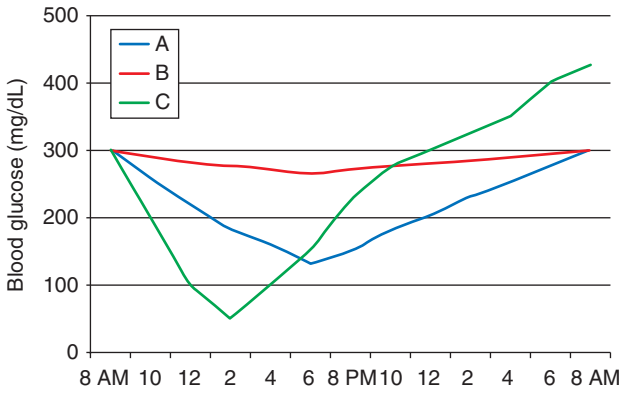

Figure 28.3 Hypothetical serial glucose curves in three diabetic cats receiving insulin at 8 AM. Cat A appears well controlled, with blood glucose concentrations reaching a nadir of about 125 mg/dL and staying between 125 and 300 mg/dL over a 24-hour period. Cat B exhibits a poor response to insulin, which may be related to insulin underdosage. Cat C becomes rapidly hypoglycemic, with rebound hyperglycemia. This is known as the Somogyi effect, which is due to hormonal responses following excess insulin administration.

Serial glucose curve

In diabetic animals receiving initial insulin therapy, measurement of blood glucose concentrations at one- to two-hour intervals throughout the day helps to assess the efficacy and appropriateness of the insulin dosage. These results, which are known as the serial glucose curve, are analyzed to ensure that the insulin therapy has lowered the blood glucose concentrations, that the lowest glucose concentration after insulin treatment (nadir) is in an appropriate range, and that the duration of the insulin effect is appropriate (Figure 28.3). Serial glucose curves are also useful when animals with previously well-controlled IDDM show clinical signs of hyperglycemia or hypoglycemia.

In diabetic dogs, the goal is to keep glucose concentrations between 100 and 250 mg/dL [123]. In diabetic cats, the goal range is 100–300 mg/dL [105]. Ideally, the blood glucose nadir should be 100–125 mg/dL for both dogs and cats. Many factors must be taken into account when interpreting serial glucose curves, including the type and duration of insulin being administered, time of feeding, and stress and/or excitement induced by hospitalization during the procedure. PBGMs are sometimes used by owners of diabetic pets to generate serial glucose curves at home, under the supervision of their veterinarian, to avoid the effects of stress or excitement [120].

Continuous glucose monitoring

New technological developments are providing advances in glucose monitoring of diabetic animals. A continuous glucose monitoring system (CGMS) utilizes a subcutaneous sensor that measures interstitial fluid glucose concentrations and stores up to 288 measurements in a 24-hour period [141]. Interstitial fluid glucose concentrations correlate well

with blood glucose concentrations. Commercially available CGMS have been tested on dogs, cats, cattle and horses [142–145]. Use of these systems avoids limitations associated with traditional serial glucose curves such as repeated blood collection, patient restraint and hospitalization, and provides more detailed information about glucose metabolism since measurements are taken every 5 minutes. Brief periods of hypoglycemia and Somogyi phenomena can be easily identified using CGMS [142, 143].

Glucose tolerance tests

Oral or intravenous glucose tolerance tests can be performed to provide more information about glucose metabolism in animals suspected of having insulin resistance. These tests are labor and time intensive and rarely used in clinical small animal practice but are occasionally performed in horses that are suspected to have metabolic syndrome [146] and are used in research settings [147]. As discussed previously (see "Serum Insulin"), it is rarely clinically useful to document insulin resistance in animals that have been diagnosed with diabetes mellitus.

Basically, these tests involve administration of a glucose solution followed by blood collection at predetermined intervals; blood samples are analyzed for glucose concentrations and sometimes insulin levels. Intravenous tests are considered superior to oral tests because gastrointestinal factors are eliminated. Decreased glucose tolerance is suggested if glucose concentrations fail to return to baseline within the expected time period or if the calculated fractional glucose turnover rate is low. Insulin response tests can also be performed [148], and a test combining glucose tolerance with insulin response (combined glucose-insulin test) has been developed for horses [149].

Other laboratory abnormalities associated with diabetes mellitus:

• CBC findings may include increased packed cell volume/hematocrit and increased plasma protein concentrations due to dehydration. The leukogram may indicate stress or inflammation.

• Azotemia and dilute urine. Glomerular lesions have been reported in diabetic dogs and cats, but the occurrence of clinical renal disease in such animals is not well documented. Urine specific gravity usually is low in animals with glucosuria, generally because of the osmotic effect of glucose rather than from a defect in the ability of the tubules to concentrate urine. If dehydration is present, there may be a prerenal azotemia in addition to dilute urine, mimicking renal failure. The serum phosphorus concentration also may be increased in azotemic animals because of the decreased glomerular clearance of phosphorus. Some diabetic animals have hyperphosphatemia, but hypophosphatemia may occur in others (discussed later).

• Pyuria, hematuria, and proteinuria. Urinary tract infection is common in diabetic animals. Such infection can result in increased numbers of leukocytes, erythrocytes, and bacteria in the urine as well as in an increased concentration of protein. Increased urine protein concentration without evidence of inflammation could result from glomerular damage, which commonly occurs in humans with diabetes but is not well documented in animals with diabetes mellitus.

• Ketonemia and ketonuria. Ketones include acetoacetate, β-hydroxybutyrate (βHB), and acetone. Deficient insulin production in diabetes mellitus results in decreased incorporation of fatty acids into triglycerides (i.e., decreased lipogenesis). Fatty acids then are converted to acetyl–coenzyme A (acetyl-CoA). Almost all acetyl-CoA is converted to acetoacetate in animals with severe diabetes mellitus. Some of this acetoacetate then is converted to βHB and acetone. Increased blood ketone concentration (i.e., ketonemia) and increased urine ketone concentration (i.e., ketonuria) can result. Ketones are acids that dissociate into hydrogen ions and respective unmeasured anions. Their metabolic production therefore results in development of acidosis and increased anion gap. Impaired peripheral use of ketones because of insulin deficiency also contributes to ketonemia and ketonuria in diabetes mellitus. The renal threshold for ketones is low, and ketonuria often precedes ketonemia. The common method of detecting ketones used by urine dipsticks (nitroprusside reaction) detects acetoacetate and acetone, but it does not detect βHB. In some ketoacidotic patients, production of βHB can predominate, thereby resulting in failure to detect ketouria. Point-of-care (POC) methods for measuring concentrations in blood have proven useful in people and have recently been investigated for use in veterinary species [150–153]. In one study of 72 diabetic dogs, blood βHB concentration measured with a POC analyzer (MediSense Optium®, Abbott Laboratories) was superior to urine dipstick tests for identification of ketoacidosis [151]. Sensitivity and specificity varied with the cutoff value used for ketonemia; a cutoff value of 2.3 mmol/L had 100% sensitivity and 70% specificity, while a cutoff value of 4.3 mmol/L had 64% sensitivity and 100% specificity. The authors concluded that if the ketone concentration is <2.8 mmol/L the risk of ketoacidosis is very low [151]. A study in 62 cats using a different POC analyzer (Precision Xceed®, Abbott Laboratories) demonstrated that the analyzer was easy to use and results were in good agreement with the reference method when values were <4.0 mmol/L; concentrations >4.0 mmol/L were underestimated with the POC method [153]. In 138 diabetic cats, a cutoff value of 2.55 mmol/L had a sensitivity of 94% and specificity of 68% for diagnosing ketoacidosis using the POC analyzer Precision Xtra® (Abbott Laboratories) [154]. Causes of ketonemia and ketonuria, in addition to diabetes mellitus, include starvation, bovine ketosis, pregnancy toxemia in sheep, and hepatic lipidosis syndrome of cattle. In cattle, a meta-analysis

of 18 different studies concluded that a POC analyzer (Precision Xtra, Abbott Laboratories) had good sensitivity (95%) and specificity (98%) for detection of hyperketonemia at a cutoff value of 1.2 mmol/L [152].

• Electrolyte abnormalities. Osmotic diuresis and ketonuria cause the loss of sodium, chloride, potassium, and phosphorus in the urine. Hyponatremia, hypochloremia, and, less commonly, hypokalemia and hypophosphatemia may result. The serum potassium concentration may be normal or increased in diabetic animals, especially if the animals are acidotic, but the whole-body potassium concentration is often depleted. Potassium depletion results from hypoinsulinemia, which allows intracellular potassium to shift out of cells and into blood; this potassium then is lost via the urine. This has an important therapeutic implication because administration of insulin in treatment of the acute stage of diabetes will drive potassium back inside cells, which may cause severe hypokalemia. Phosphorus depletion results from multiple factors, including increased renal excretion, increased tissue catabolism, and in animals treated with insulin, shifting of phosphorus from the serum into cells. Serum phosphorus concentrations of less than 1.5 mg/dL may occur in diabetic dogs and cats, especially after the initiation of insulin therapy. Severe hypophosphatemia may potentially result in hemolysis, leukocyte or platelet dysfunction, neurologic disorders, and abnormal muscle function.

• Metabolic acidosis (ketoacidosis). Ketones are acidic, and increased concentrations lead to metabolic acidosis, which can be life-threatening.

• Increased anion gap. An increased anion gap usually results from increased ketoacid concentrations in the blood. Increased blood lactate concentration also can contribute to this gap.

• Hyperosmolarity. Hyperosmolarity usually occurs in animals with extremely high blood glucose concentrations (>600 mg/dL). A serum osmolarity of >350 mOsm/L can cause neurologic and gastrointestinal abnormalities.

• Increased hepatic and pancreatic enzyme activities. Metabolic alterations in hepatocytes can lead to the leakage of enzymes. Fatty change in hepatocytes results from the increased liberation of fatty acids from adipose tissue, influx of these fatty acids into hepatocytes, and incorporation of fatty acids into triglycerides. Activities of induced enzymes also increase if these alterations result in hepatocyte swelling and cholestasis. Pancreatitis can cause diabetes mellitus as a result of islet damage, and if active pancreatitis is present, serum activities of PLI, amylase, or lipase may be increased.

• Increased serum bilirubin concentration. Cholestasis secondary to the hepatocyte swelling that is associated with fatty change may lead to hyperbilirubinemia. Moreover, hemolysis resulting from Heinz-body formation can occur in diabetic cats and result in increased serum bilirubin concentrations.

• Hyperlipidemia. Increased blood concentrations of several lipids, including triglycerides, cholesterol, and free fatty acids, result from decreased incorporation of triglycerides into fat deposits, decreased hepatic degradation of cholesterol, and increased hepatic production of very low-density lipoproteins. Increased concentrations of these proteins often result in visible lipemia.

Other laboratory abnormalities associated with hyperinsulinism

In addition to hypoglycemia, the only laboratory abnormality that is frequently associated with hyperinsulinism is hypokalemia, which may result from insulin-mediated shifting of extracellular potassium into cells.

Laboratory Evaluation of Gastrointestinal Disease, Digestion, and Intestinal Absorption

Dawn Seddon
St. George's University, Grenada

Introduction

Diarrhea, vomiting, and weight loss are clinical signs that are frequently seen with disease of the digestive system. These signs are not, however, indicative of a specific disease or cause. Laboratory tests that are specific for gastrointestinal (GI) disease are also limited, but tests that specifically evaluate the digestive system can provide important diagnostic information in these cases. Because many underlying disease processes can secondarily affect the gastrointestinal tract, basic laboratory tests such as a complete blood count (CBC), biochemical profile, urinalysis, and routine fecal examination are usually performed in animals with evidence of gastrointestinal disease prior to more specialized tests. Minimum data evaluating proteins, electrolytes, and packed cell volume (PCV) can provide significant information. Examples of some more specific laboratory tests used in small animals include trypsin-like immunoreactivity (TLI), pancreatic lipase immunoreactivity (PLI) [1], cobalamin (vitamin B_{12}) and folate, α1-proteinase inhibitor, canine microbiota dysbiosis index [2], etc.

Other modalities such as ultrasound, endoscopy, and/or biopsy of the affected area of the GI tract may be required to obtain a definitive diagnosis, but it must be borne in mind that there are a number of functions of the bowel such as motility, absorption, secretion, permeability, visceral sensitivity, and oral tolerance that may be compromised without evidence of structural or morphological anomalies [3]. The choice of laboratory tests to evaluate the digestive system depends on whether clinical signs are suggestive of acute or chronic disease. Vomition or diarrhea that persists for more than 3 weeks is regarded as chronic.

There are a number of breed-specific predispositions to various GI tract disturbances. In dogs, more than 400 inherited defects have been identified by molecular methods [4], using cheek swabs or whole blood. Only a few disorders are recognized in cats [5]. Knowledge of these diseases may help in the compilation of a differential list but should not be used in isolation to make a definitive diagnosis. Some of these are listed in Table 29.1.

Two important syndromes that cause signs of chronic gastrointestinal disease are maldigestion and malabsorption. Maldigestion is a failure to adequately digest food and usually results from extensive atrophy of exocrine pancreatic acinar cells, causing inadequate secretion of digestive enzymes. This is known as exocrine pancreatic insufficiency (EPI), which results secondarily in the inadequate absorption of nutrients. By contrast, malabsorption is failure of the intestinal tract to absorb adequately digested nutrients and results from a variety of small intestinal lesions. Clinical signs of these two syndromes can be similar, including increased fecal volume and poorly formed feces; however, the treatment for these conditions differs. This chapter describes the use of laboratory tests to differentiate maldigestion from malabsorption in animals showing signs of weight loss and to differentiate between EPI and other small intestinal disorders. In addition, several other laboratory tests to evaluate the digestive system are discussed.

Maldigestion and malabsorption in dogs and cats

The treatment and prognoses differ in maldigestion and malabsorption, thus distinguishing these two syndromes is important in small animals. Since malabsorption may result secondary to maldigestion, the clinical signs are similar regardless of which syndrome is the primary disease process.

Exocrine pancreatic insufficiency or maldigestion

Although EPI can occur at any age, it is usually recognized in young dogs (1 to 5 years of age). Dogs are thin, have a

Table 29.1 Common breed-specific predispositions to various gastrointestinal disorders found in dogs and cats.

Gastrointestinal disorder	Breed	Notes
Antibiotic-responsive diarrhea/enteropathy [6, 7] (small intestinal bacterial overgrowth [SIBO])	Young, large-breed dogs, especially German shepherds [8, 9]	Genetic inheritance unknown Secretory dysregulation or deficiency of IgA [8, 10]
Cobalamin (vitamin B_{12}) deficiency (selective) [11]	Beagles [12]	
	Border collies [13, 14]	Puppies fail to thrive, have magaloblastic anemia and methylmalonic aciduria [13]
	Giant schnauzer [11, 17]	Autosomal recessive, with proteinuria
	Chinese Shar Peis [15, 16]	
Eosinophilic enteritis [18–21]	Boxers	
	Chinese Shar Peis	
	Doberman pinschers [22]	
	German shepherds	
	Rottweilers [19, 20]	
Exocrine pancreatic insufficiency [23]		Autosomal recessive [26]
	German shepherds	Age of onset 36 mo
	Rough collies [24]	Age of onset 36 mo
	Cavalier King Charles spaniels	Age of onset 72 mo
	Chow chows	Age of onset 16 mo
	English setters [25]	Age of onset 5 mo
Gastric carcinoma [26, 27]	Belgian shepherds	
	Rough collies	
	Norwegian Lundehunds	
Gastric dilatation volvulus [26]	Great Danes	
	Irish setters	
Gluten-sensitive enteropathy [28]	Irish setters [28, 29]	Autosomal recessive clinical onset between 4 and 7 mo of age [28, 30] Weight loss with/without diarrhea [30]
Histiocytic ulcerative (granulomatous) colitis (HUC) [31]	Boxers [31–33]	Common in boxer dogs <2 yr of age [35] Genetic inheritance unknown Associated with mucosally invasive *E. coli* [31, 32, 35, 36]
	French bulldogs	
	Mastiffs	
	Alaskan malamutes	
	Doberman pinschers [34]	
Hypertrophic pyloric gastropathy [26]	Lhasa Apsos	
	Maltese	
	Pekingese	
	Shi Tzus	
	Yorkshire terriers	
Inflammatory bowel disease (IBD) [36, 37]	German shepherds	Interaction between genetic predisposition, dysbiosis [39], and dietary antigens
	Shar Peis	
	Siamese cats	Includes: antibiotic-responsive diarrhea [6, 7]/enteropathy, cobalamin deficiency [11, 40], gastric carcinoma [26], gluten sensitive enteropathy, granulomatous colitis [26], lymphangiectasia [41, 42], and PLEs [29, 41, 43]
	Soft-coated Wheaten terriers [37]	
	Basenjis [38]	Genetic inheritance unknown Including immunoproliferative small intestinal disease
Lymphangiectasia [41, 42]	Basenjis [38]	Most common causes of PLE in dogs [41, 43]
	Norwegian Lundehunds [42]	Genetic inheritance unknown
	Rottweilers	
	Soft-coated Wheaten terriers	
	Yorkshire terriers	
Lymphoplasmacytic enteritis [43, 44] and hypergammaglobulinemia	Basenjis [38]	
	Boxers	
	Chinese Shar Peis	

Table 29.1 (*continued*)

Gastrointestinal disorder	Breed	Notes
Megaesophagus [43]	German shepherds Irish setters [29] Labrador retrievers
