Protein losing enteropathies (PLEs) [29, 41, 43]	Basenjis [38] Chinese Shar Peis German shepherds Norwegian Lundehunds Rottweilers Soft-coated Wheaten terriers	Genetic inheritance unknown (the latter breed has also been documented with protein losing nephropathy [45])
Pyloric stenosis	Brachycephalic breeds [26]	

ravenous appetite, and typically have voluminous greasy, rancid, gray stools (steatorrhea), often with diarrhea. Signs of EPI generally do not occur until >90% of the functional capacity of the exocrine pancreas is lost [24]. Steiner [46] reports that lesions suggesting feline EPI have been found in 0.2% of the feline pancreata that he has examined. The most frequently reported clinical signs of EPI in cats include loss of weight, copious amounts of loose stools and oily soiling of the hair coat [46].

The serum TLI assay (discussed later) is the most common test used to diagnose EPI. There are no consistent hematological or biochemical changes with maldigestion and amylase and lipase values are usually normal in cases of EPI. Undigested fats may be found in the feces, but this is an inconsistent finding.

A number of specific conditions are recognized:

1. Idiopathic pancreatic acinar atrophy is the most common cause of EPI in dogs but has not been reported in cats [47].

2. Juvenile pancreatic acinar atrophy is thought to be caused by hereditary immune-mediated lymphocytic pancreatitis and has been reported in German shepherd dogs and rough-coated collies [48, 49].

3. EPI may be acquired in dogs and cats secondary to chronic pancreatitis due to atrophy and/or fibrosis of the pancreas. There may be subsequent development of diabetes mellitus if there is concurrent islet cell destruction [50]. Chronic pancreatitis occurs more commonly in cats than dogs [51], and chronic pancreatitis is thought to be the most common cause of EPI in cats [47].

4. Pancreatic duct obstruction can occur in dogs and cats and may impair secretion of pancreatic enzymes into the intestine. This is usually associated with acute inflammation, but animals do not necessarily develop maldigestion. However, some cases of pancreatic neoplasia that cause obstruction of the pancreatic duct may lead to pancreatic atrophy [46, 47].

Infection with the fluke *Eurytrema procyonis* has also been reported to cause EPI in cats without previous evidence of pancreatitis, although this is extremely rare [52].

Malabsorption

There are many possible underlying causes of malabsorption, including inflammatory, infectious, and neoplastic processes. Chronic disease usually results in protein losing enteropathy (PLE). A list of possible causes of malabsorption syndromes in dogs (PLE) can be seen in Table 29.2. In young dogs with chronic intermittent diarrhea and protein loss, where hookworm has been ruled out, intussusception should be a consideration [26].

Specific function testing for intestinal absorption is not always necessary as syndromes such as osmotic diarrhea can usually be recognized clinically and signs generally tend to cease when the animal is fasted. Osmotic diarrhea is associated with water retention in the GIT, which results from the presence of osmotically active solutes in the intestine that are not absorbed. TLI testing can be used to differentiate osmotic diarrhea due to malabsorption from that due to maldigestion [3] (see later). Examples of osmotic and secretory diarrheas can be found in Table 29.3.

A variety of specialized tests, discussed later in this chapter, may be useful in cases of suspected malabsorption. Diagnostic tests such as endoscopy and intestinal biopsy rather than tests for intestinal absorption are usually recommended. Intestinal absorption tests that may be useful in the diagnosis of malabsorption include the breath hydrogen test (dogs) [76–78] or vitamin B_{12}/folate levels (dogs and cats). Orocecal transit time can be measured by means of the H_2 breath test, which has been validated in cats and dogs [79]. There are no consistent hematological or biochemical changes in cases of malabsorption, but more chronic cases may have decreased serum protein concentrations (often panhypoproteinemia) due to PLE, and lowered cholesterol.

Table 29.2 Causes of malabsorption syndromes in dogs (associated with PLE).

Disease syndrome	Breeds associated with disease syndrome and comments
Antibiotic responsive diarrhea (ARD)/bacterial overgrowth [7, 9]	German shepherds [8, 9]
Chronic inflammatory small intestinal enteropathies [26, 37, 53]	Basenjis [38], Norwegian Lundehunds, Chinese Shar Peis, German shepherds, Rottweilers, soft-coated Wheaten terriers
Defective brush-border enzymes [30]	Basenjis [38], Irish setters [28–30]
Eosinophilic enteritis [18–21]	Rottweilers, soft-coated Wheaten terriers [37, 53], Yorkshire terriers
Giardiasis [54]	See Table 29.5
Granulomatous enteritis [26, 45]	Norwegian Lundehunds, Rottweilers, and Yorkshire terriers
Histoplasmosis [45, 55]	
Intestinal lymphoma [16]/adenocarcinoma [26, 27]	Occult blood may be useful to evaluate gut bleeding in these cases
Lymphangiectasia [41, 42]	Basenjis [38], Lundehunds, soft-coated Wheaten terriers, and Yorkshire terriers
Lymphocytic-plasmacytic enteritis	Soft-coated Wheaten terriers [37, 53], Yorkshire terriers
Pythiosis [16, 45]	Pythium occurs in large-breed dogs. Can be cultured, ELISA, serology
Protothecosis [45]	
Villous atrophy [26]	German shepherds
Wheat-sensitive enteropathy [29]	Hereditary in Irish setters [28, 30]

Table 29.3 Examples of osmotic and secretory diarrheas.

Osmotic diarrheas	Secretory diarrheas
Intestinal malignant lymphoma	Endotoxemia
Johne's disease	Enterotoxic colibacillosis
(Mycobacterium avium subspecies *paratuberculosis)* – cattle >18 mo of age	Salmonellosis – most commonly associated with increased sodium chloride loss induced by the enterotoxin that promotes active secretion into the gut lumen. Increased water loss follows this osmotic gradient
Lymphangiectasis	
Magnesium cathartics	
Other maldigestion/malabsorption syndromes	
Protein losing enteropathies	
Proximal enteritis (horses)	

A failure of oral tolerance may result from food allergy that can cause acute or chronic gastrointestinal disease, which is difficult to differentiate from inflammatory bowel disease (IBD) without dietary elimination-challenge tests. Dietary trials should be a routine part of all gastrointestinal workups [3], but details are beyond the scope of this text.

Maldigestion and malabsorption in horses

Maldigestion alone is a rare cause of malassimilation in horses and maldigestion syndromes are uncommon in horses as compared with other domestic species. EPI is not recognized in cattle and horses [51], but Carlson [80] reported a few cases in ponies and draft horses where horses showed chronic weight loss and intermittent colic. Definitive diagnosis of chronic pancreatic necrosis was made on necropsy.

Malabsorption is more common in horses, and many horses with malabsorptive disease develop PLE and subsequent hypoproteinemia. A list of causes of PLEs in horses can be found in Table 29.4.

Maldigestion and malabsorption in ruminants

In ruminants, maldigestion syndromes are poorly understood and are generally uncommon. Main causes of maldigestion may be associated with changes in the rumen microflora or gastric function, overgrowth of small intestinal bacteria, or lactase deficiencies [85]. Variations in bile salt concentrations may exacerbate diarrhea in milk-fed neonates, but this does not interfere with digestion in the adult ruminant.

Malabsorption syndromes in cattle are poorly documented, but villous atrophy in calves secondary to viral infection (rotavirus, coronavirus), or cryptosporidia leads to maldigestion and malabsorption. Maldigestion results from villous destruction with subsequent hydrolytic enzyme deficiency (such as lactase) [85]. Other causes of malabsorption include congestive heart failure, which may result in localized or generalized ischemia, lymphatic obstruction, parasitism (trichostrongylosis of sheep and cattle), protein malnutrition, tuberculosis, and Johne's disease (*Mycobacterium avium* subspecies *paratuberculosis,* which can be found

Table 29.4 Causes of malabsorption and PLE in horses.

Syndrome	Examples
Biochemical or genetic abnormalities	Congenital or acquired lactase deficiency (lactose intolerance) [81, 82] Monosaccharide transport defects
Cellular infiltrates	Granulomatous enteritis [83] Eosinophilic gastroenteritis enterocolitis [21, 84] Lymphocytic, plasmacytic, or monocytic
Fungal (may be secondary to antibiotic [61] or corticosteroid therapy [85])	*Aspergillus fumigatus* [85] *Histoplasma capsulatum* [61]
Immune mediated	Amyloid A-associated gastroenteropathy [86]
Metabolic	Congestive heart failure, intestinal ischemia
Microbiological	
Bacterial	Chronic infectious granulomatous enterocolitis due to tuberculosis [86] Paratuberculosis Salmonellosis *Rhodococcus hoagie* *Lawsonia intracellularis* [86–89] Multiple abscessation *Clostridium* [88]
Neoplastic	Intestinal mural lymphoma [16, 90] Leiomyoma, leiomyosarcoma [84] Squamous cell carcinoma [91] Adenocarcinoma [92]
Nutritional	Dietary-induced enteropathy Zinc deficiency
Pancreatitis	
Parasitic	*Strongylus vulgaris* larvae, [93] and small strongyles – *Strongyloides westeri* (foals) causing ischemia and damage due to migration Cryptosporidia [93]
Toxic	Heavy metal toxicity
Viral (rotavirus, coronavirus) [94]	Villous damage or atrophy [71]

in cattle more than 18 months of age and can also be seen in sheep, goats, llamas and alpacas, deer and wildlife).

Screening tests in veterinary medicine

Several tests can be performed in a veterinary practice on animals with clinical signs and histories that are suggestive of digestive system disease. The results of these tests can be supportive of but are not always definitive for a specific diagnosis or etiology. Further confirmatory tests may need to be performed at a reference laboratory (discussed later).

Fecal assessment

Optimal fecal assessment involves systematic formulation of a differential list based on signalment, history, and clinical signs. The options for fecal testing surpass simple flotation for parasite ova, and it is essential to select appropriate tests for specific etiologies and to interpret them based on their relative sensitivity and specificity for the specific disease process [71]. Basic methods for the detection of parasitic ova, larvae, oocysts, cysts, and trophozoites are discussed here, but a parasitology textbook should be consulted for more detailed descriptions and interpretations of these techniques.

In small animals with vomition, fecal sedimentation or smears help in the detection of the stomach worm *Physaloptera rara,* and in cats examination of vomitus is useful for detection of feline stomach worm *Ollulanus tricuspis* [26]. In dogs and cats with diarrhea, fecal examination should include assessment for intestinal parasites (including coccidia, *Cryptosporidium, Giardia*, *Tritrichomonas*, hookworms [*Ancylostoma* and *Uncinaria*] and whipworms [*Trichuris vulpis, Trichuris campanula* in dogs and *Trichuris serrate* – rare in cats]) and culture for potentially pathogenic bacteria (including *Salmonella* and *Campylobacter*) [55]. In dogs, *Trichuris vulpis* is the most common cause of acute and chronic large intestinal diarrhea [34, 62, 95, 96]. Other infectious causes of diarrhea in cats include *Anerobiospirillum, Candida, Histoplasma, Pythium,* and viral (corona, feline leukemia virus [FeLV] or feline immunodeficiency virus [FIV]) associated diarrhea [62]. In young ruminants, *Yersinia* should also be considered in addition to the previously mentioned bacterial pathogens. There are numerous other nematodes and pathogens that are more species and age specific but these are beyond the scope of this text.

Feces starts deteriorating from the time a stool is passed and cells undergo degenerative changes, which makes identification difficult. Organisms such as *Giardia* and trichomonads are fragile and undergo rapid deterioration with time, refrigeration, or processing, and fecal samples that are more than 5 minutes old are inadequate for the detection of these organisms [67, 71, 97, 98]. Marks [67] suggests that feces should be less than 2 hours old, and if there is a delay in examination, the sample should be refrigerated at 4 °C [67, 68]. Nematode eggs undergo development or hatch, which makes identification difficult. Hookworm eggs tend to hatch within 24 hours in warm humid weather, giving rise to motile larvae. *Toxascaris* eggs embryonate within a few days in older fecal samples [98]. Variations in bacterial flora lead to overgrowth and sporulation of some species [71].

Fecal collection methods

The preferred collection method for fecal cytology is by means of digital rectal examination, but fecal loops are more practical for smaller animals where digital collection is inappropriate [71]. Rectal lavage may be useful for cytology,

but the technique results in less fecal material with relatively more mucous secretion from the mucosal surface, and thus the amount of fecal material may be insufficient for some techniques. Flush samples have high yields of motile protozoa and bacteria as these organisms are usually more ubiquitous at the mucosal surface, whereas eggs and cysts are more common in fecal material [68].

Rectal wall scrapes [16] may be useful in cases with suspected infectious diseases of the gastrointestinal tract (e.g., *Aspergillus, Balantidium, Candida, Cryptococcus, Entamoeba, Histoplasma, Leishmania, Pentatrichomonas, Prototheca*, and *Pythium* [16]) or infiltrative disease such as inflammation or neoplasia [45]. Cell harvest from the rectal wall can be obtained by means of moistened cotton swabs, a gloved fingernail, or spatula (similar to those used for conjunctival scrapes). Slides are made by gently rolling the harvested material onto glass slides [16], which are subsequently stained with Diff-Quik® or Wright-Giemsa stains.

Voided fecal samples provide larger samples, which are required for fecal flotation, sedimentation and Baermann techniques [71]. Defecation should occur in uncontaminated areas, followed by timely collection and appropriate storage.

Adequate amounts of feces are required for various tests: 1–2 g feces is required for fecal flotation or sedimentation, 2–3 g feces are necessary for fecal culture [71], and up to 10 g of feces should be used for the evaluation of lungworm (Baermann technique) [68, 96]. Feces can be refrigerated for up to 24 hours for flotation or sedimentation techniques [71], and can be preserved in formalin for longer periods. Fecal antigen (mainly for polymerase chain reaction [PCR]) can be preserved by freezing feces [71] but culture requires transport medium [68].

Wet preparations

Wet mounts can be used to detect motile parasites (trophozoites of *Giardia* and *Tritrichomonas*). Direct smears should be carried out on fresh feces, which is ideally less than 5 minutes old [97] but not more than 2 hours old [67, 71, 97, 98].

A small sample (not larger than match head size) should be mixed with a drop of warm saline (0.9%) on a warmed glass slide with a wooden applicator stick, which is then covered with a coverslip. The smear preparation can then be examined on low power (×10) for eggs, cysts, and larvae. Other organisms may be found using higher magnification (×40). Motile organisms seen on wet mounts can also be assessed on dry mount and stained slides, but it is important not to make dry smears too thick [71], as trophozoites can be overlooked in thick smears. It should be possible to read print through the preparation. Prolonged survival of *Tritrichomonas* is facilitated by adding 3 mL of warmed 0.9% saline to 2–5 g feces. *Tritrichomonas* can be confused with *Giardia* and this misdiagnosis may often explain the lack of response to treatment. Direct smear examination for *Tritrichomonas* has low sensitivity (14%) [26].

Giardia cysts can also be mistaken for pollen grains or yeasts. Cysts are shed intermittently and numbers can vary significantly (from 1 or 2 to thousands) even in samples taken over 4 consecutive days, although the recommendations suggest higher sensitivity for examination of feces from three [16] non-consecutive stools over a period of 6–10 days [65–67]. The sensitivity for fecal flotation and examination for cysts has been quoted in a study as 85.3% in cats [72].

A list of potential fecal pathogens identifiable on wet and dry fecal mounts, including additional selected tests available for diagnosis, as well as the brief clinical implication, is presented in Table 29.5.

Fecal flotation and sedimentation

In many cases, low concentrations of parasites preclude their detection in direct fecal smears, and fecal flotation is required for examination of parasitic ova and oocysts. Samples for these tests should be refrigerated within an hour of collection, and should be sent chilled to the laboratory. The integrity of the sample for fecal flotation and sedimentation is maintained for up to 7 days in the fridge. Fecal flotation with zinc sulfate and centrifugation [99] is the most sensitive for the detection of whipworm eggs (*Trichuris vulpis*) [96]. Centrifugal flotation techniques show an 8× higher yield of organisms than gravitational flotation techniques. In dogs with large intestinal disease, presence of *Trichuris* can only be ruled out by testing at least three fecal samples, as whipworms produce eggs sporadically and in low numbers [69], and eggs are shed intermittently [95].

Other nematodes that may be found in the gut of young pups and kittens include *Toxocara canis* and *cati*, *Toxascaris leonina* and *Ancylostoma*.

Parasites from other organ systems may also be detected by fecal flotation, such as ova of Eucoleus aerophilus (formerly known as Capillaria aerophila) (lungworm of cats), *Oslerus osleri* (tracheal worm of dogs), and *Filaroides hirthi* (lungworm of dogs).

The typical fecal flotation technique involves mixing feces with water, removing large pieces of debris by straining the mixture, centrifuging the strained feces, followed by mixing the resulting sediment with flotation solutions composed of varying concentrations of sugar or salts, including sodium chloride [68, 98], magnesium sulfate (35%) [71], zinc sulfate (33%) [71, 96], or sodium nitrate [68, 100]. Flotation solutions are commercially available. The fecal sediment/flotation solution mixture is then centrifuged for 5–10 minutes or is allowed to stand for 30 minutes. The correct specific gravity (SG) should be maintained for flotation solutions to be effective [68]. Zinc sulfate (with an SG of 1.18–1.20) is a superior flotation solution for maintenance of the morphology of *Giardia* cysts as compared with other flotation solutions [67]. Sheather's solution [71, 96] is a sugar solution with a specific gravity high enough to float any ova. It is considered superior for isolation of most eggs and oocysts as it generally causes little distortion and it does

Table 29.5 Potential fecal pathogens identifiable on wet and dry stained mounts with other selected tests available for diagnosis.

Wet and dry preparations	Parasites	Microscopic characteristics, clinical implications, location and other tests available for diagnosis
Algae	*Prototheca* spp. [45, 55] *P. wickerhamii* and *P. zopfii*	**Microscopy:** Achlorophyllous algae – oval hyaline cells 1.2–16.1 μm long, 1.3–13.4 μm wide [55] Granular basophilic to magenta internal structure containing 2–20 or more small sporangiospores (endospores or autospores) Have a thick cell wall surrounded by a clear highly refractile capsule **Location:** Large intestine **Testing:** Feces, culture
	Pythium insidiosum [16, 45] Water mold (oomycete)	**Microscopy:** Wide, poorly staining occasionally branching pseudohyphae with parallel cell walls and occasional septae [45] Cannot be differentiated cytologically from *Lagenidium* **Location:** In stomach, small intestine, ileocolic junction **Testing:** Culture, serology, PCR
Bacteria	*Campylobacter* [56]	**Microscopy:** Spiral to rod or curved shape. Gram negative **Location:** Feces **Testing:** Culture, PCR (http://www.cvm.tamu.edu/gilab)
	Clostridium perfringens [45]	**Microscopy:** Large rectangular straight or curved Gram-positive bacilli with rounded or truncated ends, 3-8 μm × 0.4-1.2 μm, encapsulated **Testing:** Fecal enterotoxin ELISA, PCR
	Helicobacter [45, 57]	**Microscopy:** Commonly curved or spiral but some can be short, tapered rod shape, Gram negative, flagellated **Location:** Stomach (gastric mucosa) **Testing:** Culture Helicobacter may be implicated as a cause of vomition in some patients.
	Sarcina ventriculi [58]	**Microscopy:** Large Gram-positive cocci in bundles Abomasal bloat in small ruminants, gastric dilitation dogs [58]
Fungi [55]	*Blastomyces dermatitidis*	**Microscopy:** Yeast 7–15 μm, refractile, basophilic yeast with thick cell wall, with single broad-based bud **Location:** Stomach, intestine or colon **Testing:** Culture and cytopathology, antigen testing, antibody immunodiffusion, antigen enzyme immunoassays and PCR [60]
	Candida spp. [45, 56]	**Microscopy:** Yeast 3–6 μm, basophilic round to oval, clear cell wall, pseudohyphae and hyphae **Location:** Stomach intestine. Opportunistic pathogen **Testing:** Fungal culture, PCR
	Cryptococcus neoformans	**Microscopy:** Yeast 3.5–7 μm, with clear nonstaining capsule, narrow based budding **Testing:** Microscopic examination and/or culture of tissue or body fluids such as blood, cerebrospinal fluid and sputum. The cryptococcal latex antigen test is a rapid test that can be performed on blood and/or on cerebrospinal fluid
	Histoplasma capsulatum	**Microscopy:** Yeast, ovoid 2-4 μm, non-refractile walls, narrow based budding **Location:** Located in macrophages, intestine **Testing:** Fungal culture, PCR, latex agglutination
	Cyniclomyces guttulatus [45, 59] *(Saccharomycopsis guttulata)*	**Microscopy:** Oval to cylindrical yeast, 5–7 × 20 μm with a clear wall [45]. Nonpathogenic in canines that have ingested rabbit feces, but large numbers may be clinically significant in chronic diarrheas [61, 62] **Location:** Large intestine, feces **Testing:** Fungal culture, PCR

Table 29.5 (*continued*)

Wet and dry preparations	Parasites	Microscopic characteristics, clinical implications, location and other tests available for diagnosis
Protozoa	*Balantidium* [63]	**Microscopy:** Trophozoite Oval pointed anterior end, 50–130 mm long by 20–70 mm wide Two nuclei – the macronucleus is long and kidney-shaped, with an adjacent spherical micronucleus A peristome is located at the pointed anterior end Covered in cilia – rotary motility Cyst stage is the infective stage – spherical 40–60 mm diam, thick, hard cyst wall with cilia Nonmotile **Testing:** IFA, PCR Infects dogs ingesting pig feces [55]
Protozoa	Coccidial oocysts [45, 63] Puppies: *Isospora canis, I. ohioensis* Kittens: *I. rivolta, I. felis*	**Microscopy:** Oocysts ovoid to ellipsoid in shape 10–40 μm long, 10–30 μm wide **Fecal flotation:** Sheather's sugar solution or wet preparations
Protozoa	*Cryptosporidium* [63] *C. parvum, C. canis & C. felis*	**Microscopy:** Spherical, red staining oocysts, 2–6 μm against a green or blue background – depends on counterstain. Difficult to see on smears Modified Ziehl-Neelsen (acid fast) stain **Testing:** **Concentration techniques:** Sheather sucrose or zinc sulfate flotation, saturated sodium [45] Sensitivity fecal flotation is as low as 21.4% in cats **Immunofluorescent antibody staining:** MeriFluor *Cryptosporidium* Direct immunofluorescence test kit: [56, 64, 65]. IFA (Texas A&M - fresh chilled feces, shipped on ice) Sensitivity of 77–91% and specificity of 94–95% in cats ProSpecT® *Cryptosporidium* Microplate Assay [66, 67] 71.4% sensitivity, 96.7% specificity in cats Coproantigen ELISA kit [63, 68] (PCR) [61, 69] **Polymerase chain reaction**: This is the most sensitive assay, detecting 100–1000 *Cryptosporidium* oocysts per gram of feces [69]. Occurs in young or immune-compromised adults. Can be asymptomatic or cause severe diarrhea and protein losing enteropathy. Shed intermittently *Cryptosporidium* can have up to a 6-month prepatent period [5]
Protozoa	*Entamoeba* sp. [54]	**Microscopy:** *Entamoeba histolytica* trophozoites 12–50 μm· Large nucleus and central karyosome Cysts 10–20 μm, one to four nuclei Trichrome or methylene blue stains **Location:** In large intestine, feces **Testing:** Specific culture media [16] Antigen ELISA [67]
	Giardia [54, 70]	**Microscopy:** **Trophozoites** pear-shaped 15–10 μm long [45, 55] (four pairs flagella: one cranial, two posterior, one caudal) Appearance of a "smiling alien face" with two anterior nuclei, divided by a longitudinal axioneme and a posterior transverse median body **Giardia cysts** oval, 8–19 μm (average 11–14 μm) [45, 55] Immature cysts – two nuclei Mature cysts – four nuclei

Table 29.5 (*continued*)

Wet and dry preparations	Parasites	Microscopic characteristics, clinical implications, location and other tests available for diagnosis
Protozoa	*Giardia* [54, 70]	**Testing: Zinc sulfate centrifugation** of feces Sensitivity 85.3% cats [70] Specificity greater than 99.4% [70] Higher sensitivity if three nonconsecutive samples evaluated over 6–10 d [65, 67] Coproantigen ELISA kit [70, 71] **SNAP *Giardia* Antigen** ELISA from IDEXX (IDEXX Laboratories, Westbrook, ME) 85.3% [72], 92% [71] Sensitivity >99.4% [65, 66, 70]/100% [73] Increased sensitivity of 97.8% for *Giardia* when tested in parallel with fecal flotation This test detects cyst wall protein 1 The ELISA tests should not be used to monitor effectiveness of treatment, as any residual antigen present in the cyst wall will give a positive result ProSpecT Giardia Microplate Antigen ELISA (Remel Microbiology Products, Lenexa, KS) [56, 66, 72] Human immunoassays utilize different genotypes of *Giardia* to those found in dogs and cats. 91.2% sensitivity, 99.4% specificity in cats [66, 72] Direct IFA, PCR [45] Cysts shed intermittently – vary in number [54] Young kittens and puppies or immune-compromised adults Acute diarrhea may be intermittent and can become chronic (>3 wk duration) May be subclinical in adult animals, usually self-limiting [72] Feces may be transiently soft Infection usually from contaminated water May occur concurrently with *Cryptosporidium* Vomition is uncommon [73]
	Pentatrichomonas hominis [45]	**Microscopy:** Spindle to pear-shaped, five anterior flagella, one posterior flagellum, undulating membrane **Testing:** Motile in feces PCR
	Tritrichomonas foetus [54, 56]	**Microscopy:** Oval to pear-shaped, 5–20 × 3–14 μm [55] Highly motile – three anterior flagella, an undulating membrane, a longitudinal axostyle, an anterior nucleus, and a single posterior flagellum **Location:** Large intestine, feces **Testing:** Wet preparations – sensitivity 14% [26]. No cyst stage InPouch™ TF culture systems [63] (Biomed Diagnostics, San Jose, CA) Sensitivity 70–80% 0.05 g fresh feces is inoculated directly into the pouch Pouches are incubated for 24 h at 37 °C, followed by room temperature (25 °C) incubation for up to 10 d, with examination of pouches every 48 h PCR for *T. fetus* antigen in feces [55] sensitivity >90% [74] Affects young cats 3–9 months but can occur in aged cats Bengals and Abyssinian cats predisposed Foul-smelling large bowel diarrhea (colitis) but can cause diarrhea in puppies [72] May/may not cause bleeding Self-limiting but can take 2 years to resolve Some animals asymptomatic
Nematodes	*Nanophyetus salmincola* ova [75]	**Testing:** Fecal flotation
	Strongyloides larvae [63, 71]	**Testing:** Fecal flotation Can cause diarrhea in animals of all ages with anemia, colitis, weight loss, or poor weight gain

A brief clinical implication for each organism is also mentioned.

not crystallize, but it does tend to distort *Giardia* and some lungworm larvae [67, 71].

A modified Sheather's solution (sugar) with a higher specific gravity (SG of 1.270) gives increased recovery of species with heavier eggs such as *Taenia* spp. [67]. Most parasitic ova and oocysts float to the surface of the mixture as they have a lower density than the flotation solution. They can be harvested by touching a coverslip to the surface. Microscopic observation of the material collected (×10 objective) reveals the presence of parasitic ova or oocysts, but the technique can be modified for counting ova and oocysts to assess their concentrations in feces.

The double centrifugation flotation technique [72, 101] (below) is regarded as the gold standard and is reported to have fewer false-negative results and allows higher recovery of more parasite eggs, cysts, and oocysts than passive (gravitational) flotation techniques (e.g., Ovassay®, Fecalyzer®, Ovatector®) [71, 101].

Double centrifugation/flotation technique [72, 101]:

1. Make a suspension of feces sample by mixing 1–5 g of feces, with 10–12 mL water in a beaker.

2. Pour the mixture through a fine sieve or tea strainer into another beaker, pressing feces in the strainer with a spatula, and discard the excess material in the strainer.

3. Pour strained solution into a 15 mL centrifuge tube and fill to the top with water.

4. The centrifuge should be balanced every time before use.

5. Centrifuge at 1200–1500 rpm for 5–10 minutes.

6. Decant the supernatant.

7. Resuspend the fecal pellet with flotation solution, stir, and fill tube with flotation solution to form a slight positive meniscus.

8. Place the tube in the centrifuge and position a coverslip on the meniscus. The coverslip will not fall off if using a free swing centrifuge. (If a fixed angle centrifuge is used, fill the tube to within 3 cm from the top of the tube, and spin without a coverslip (as it will fall off). Gently fill the tube with the flotation solution to form a positive meniscus, coverslip, and leave for 10 minutes before examination.)

9. Centrifuge at 1200–1500 rpm for 5–10 minutes.

10. Remove the tube and allow to stand for 10 minutes.

11. Remove the coverslip by lifting upwards and place on a clean slide.

12. Examine the entire coverslip at 100× magnification (10× objective).

13. A 40× objective can be used to confirm identification and measurement of parasites/eggs.

Fecal sedimentation is superior for the detection of fluke ova, even though they float in flotation solutions such as zinc sulfate. Sedimentation can also be used for detection of embryonated nematode eggs, such as *Physaloptera* spp. and *Spirocerca lupi* [71]. This method involves mixing feces with water or another appropriate flotation solution, straining off large pieces of debris, and centrifuging the strained feces at 1200 rpm (280 × g) for 5 minutes [67]. Centrifugation of the mixture sediments the fluke ova, and the presence or absence of the parasite ova can then be demonstrated by microscopic examination of a few drops of the sediment. Saline is superior for sedimentation of fluke eggs, as they hatch in water [68].

Some GI parasites (e.g., *Strongyloides* sp.) produce larvae rather than ova. These larvae are not easily detected using flotation methods, but they may be detected using sedimentation techniques. The Baermann technique is the most sensitive for the detection of fecal larvae. Samples should ideally be less than 1 hour old and should not be refrigerated [29]. The technique involves placing warm water in a glass funnel that is plugged by a stopcock or rubber hose clamped at its end. A small amount of feces is wrapped in a double layer of gauze and placed in the water for 8 hours. During this time, larvae that are present in the feces pass into the water, and descend to the bottom of the funnel. After 8 hours, a small aliquot of fluid is collected from the base of the funnel and centrifuged. The resulting sediment is then examined microscopically for the presence of larvae. This method can be used for detection of various larvae such as lungworm (i.e. *Aelurostrongylus* and *Filaroides*) and small intestinal threadworms (i.e., *Strongyloides*). Hookworm eggs (i.e., *Ancylostoma* and *Uncinaria*) can hatch in fresh feces, producing active larvae [68].

Samples for enzyme-linked immunosorbent assay (ELISA), direct fluorescent antibodies (DFAs), or PCR

Fresh feces should be refrigerated within 1 hour of collection, and sent chilled to the lab.

Dry mount fecal cytology

Fecal cytology has the potential to provide a diagnosis for some animals with signs of GI disease, although there are mixed opinions on the usefulness of fecal cytology. Thin fecal smears are preferable over thick smears and a small sample not larger than match head size should be used [71]. Thin fecal smears may be stained with routine hematology stains (e.g., Wright-Giemsa or Diff-Quik stain [Dade Diagnostics of P.R., Inc., Aquada, Puerto Rico]). Bacteria and cell morphology are best assessed with oil immersion at 500 to 1000× magnification. Single smears may not be entirely representative and there may be variation of cells or organisms seen depending on how dilute/watery the stool sample is at the time of sampling.

Bacterial flora

The initial step in fecal cytology is assessment of the bacterial flora, which should be mixed in normal small domestic animals (Figure 29.1) with bacilli predominating [45]. Cocci should be in the minority (with only low numbers detected). Occasional extracellular yeasts may be observed

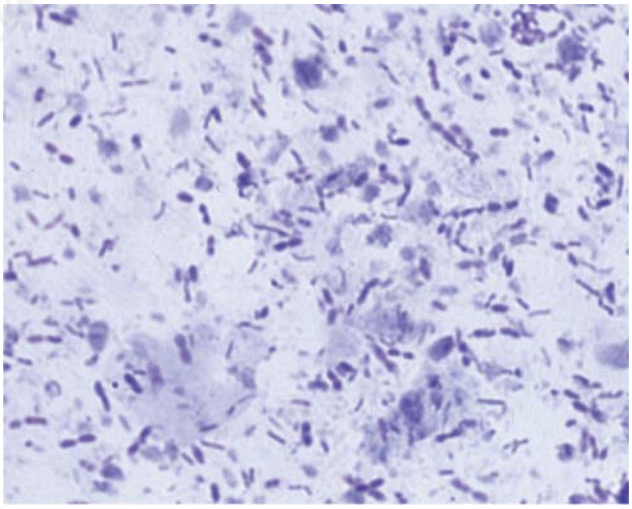

Figure 29.1 Wright-Giemsa-stained fecal smear from a dog showing a mixture of bacteria representing the mixed bacterial flora typical of normal animals. ×1000.

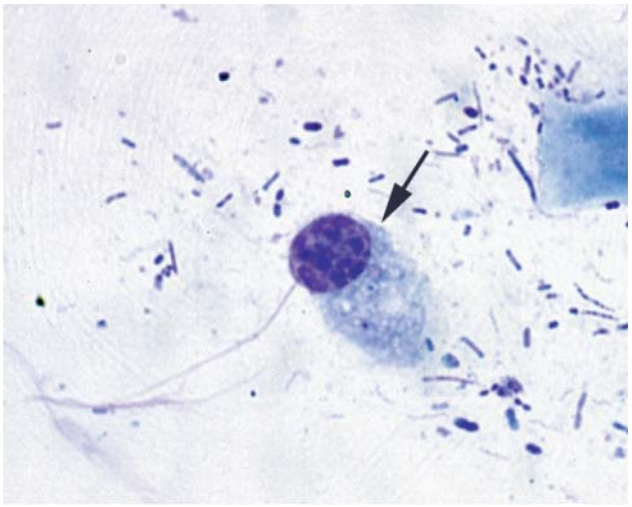

Figure 29.2 Wright-Giemsa-stained fecal smear from a dog. Epithelial cells (arrow) are interspersed with a variety of bacteria and amorphous material. Small numbers of epithelial cells are a normal finding in fecal smears. ×1000.

but it is unknown whether these are clinically significant [22]. If there is an obvious predominance of a single type of bacterium, this organism may be pathogenic, and bacterial culture is indicated. In animals with maldigestion or malabsorption, mixed flora is usually observed.

The small intestine contains primarily aerobic bacteria whereas anerobic and facultative anerobes are predominant in the large intestine and colon. *Helicobacter* colonizes the canine stomach and mucosa of the large intestine (amongst others), but very few are found in the mucosa of the small intestine.

Historically, culture of specific pathogens (such as *Campylobacter* or *Salmonella*) has been used for detection of organisms in the small animal GI tract, but more recently it has been shown to have low sensitivity [102]. Sequencing of bacterial DNA following PCR amplification of 16S rRNA can be used to identify bacteria present in the sample. At least 10^{12}–10^{14} bacteria in the GI tract constitute the intestinal microbiome [102]. Abnormal changes of the intestinal microbiome can manifest as acute hemorrhagic diarrhea, IBD and stress diarrhea. Using PCR sequencing, mucosally invasive *Escherichia coli* can be identified. This organism has been described in causing granulomatous colitis in French Bulldogs and Boxer dogs [32].

Epithelial cells

Small numbers of epithelial cells (Figure 29.2) can be found in fecal films from normal animals.

Neutrophils

The presence of neutrophils (Figure 29.3) in fecal smears is abnormal and suggestive of inflammation of the colon [71]. Neutrophils often appear degenerate as they undergo degenerative changes during their migration into the lumen

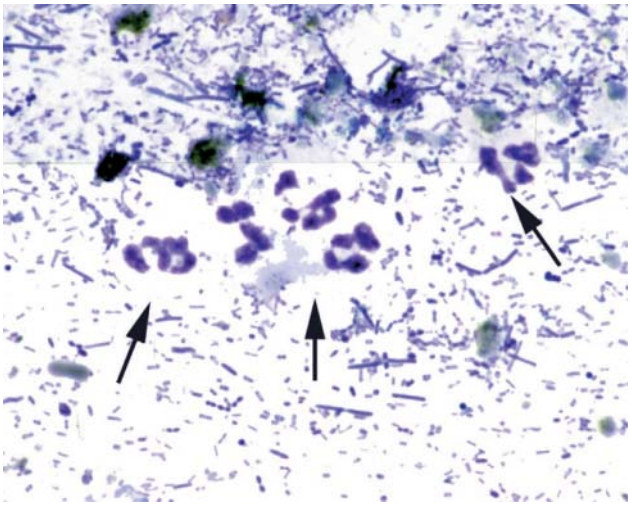

Figure 29.3 Wright-Giemsa-stained fecal smear from a dog. Large numbers of degenerate neutrophils are present (arrows). Neutrophils are abnormal in fecal smears from all species. ×1000.

of the small intestine in transit to the terminal colon. Invasive bacterial pathogens (e.g., *Salmonella*, *Campylobacter* sp., *Clostridium* and enterotoxigenic *E. coli*) should be considered as possible etiologic agents when neutrophils are present in feces, although the presence of clostridial spores is not specific for toxin-associated diarrhea [95]. Counts of clostridial endospores on smears are unreliable.

Presence of fecal neutrophils can also be associated with whipworm and IBD in small animals. Viral disease is a consideration in puppies with hemorrhagic diarrhea if fecal neutrophils are absent [71].

Eosinophils

Eosinophils are also abnormal in fecal films and, when present, are suggestive of eosinophilic colitis, chronic endoparasitism or IBD. They may also be associated with GI lymphoma and mast cell tumor (the latter more commonly in small animals). Occasionally neoplastic lymphocytes can be seen in cases of gastrointestinal tract lymphoma [16]. Refer to Table 29.1 and 29.2 for breeds associated with eosinophilic inflammation. Eosinophilic infiltrates are occasionally seen in horses and can manifest as IBD (the main clinical sign is colic), which is characterized by a number of different syndromes (see section on IBD).

Macrophages

Granulomatous inflammation (predominantly macrophages) is associated with causes of chronic inflammation such as fungal or algal disease [22].

Granulomatous enteritis in horses has been associated with mycobacteria, and PCR is used for identification.

Infectious organisms

Clostridia are bacilli, which, in the sporulated form, have a "tennis racquet" or "safety pin" appearance (Figure 29.4) and can be identified microscopically. The spore causes distension of the bacillus, which then appears swollen and clear. However, recent studies have documented a poor correlation between fecal endospore numbers and the presence of enterotoxin [103]. Only certain strains of *Clostridium perfringens* produce toxins in the gut that can be associated with acute or chronic intermittent (every 4–6 weeks) hemorrhagic diarrhea. The latter can reoccur over months or years. It is thought that up to 20% of diarrhea cases in dogs are associated with *Cl. perfringens*, but it is less commonly seen in cats [27, 104].

Healthy cats can have large numbers of *Cl. perfringens* endospores in their stools, and thus one should be aware of the possibility of over-interpreting the presence of *Cl. perfringens* endospores in fecal smears obtained from cats with diarrhea [105]. *Cl. piliforme* also causes colitis and *Anaerobiospirillum* causes ileocolitis in cats [44]. *C. difficile* also produces specific enterotoxins and is a less common cause of colitis in dogs and horses (including foals). It is most commonly seen in animals treated inappropriately with antibiotics, which causes disturbances in the microbiota (normal flora)

Campylobacter sp. are recognized by their "seagull" or "W" shape (Figure 29.5), and spiriliform bacteria are commonly *Serpulina* spp., which are associated with mucoid diarrhea [22].

Examination of stained fecal smears can be useful for the detection of numerous pathogenic protozoa such as trophozoites of *Balantidium coli* (rectum), *Entamoeba histolytica*, *Giardia* and *Leishmania* [56] (Figure 29.6). Fecal films or scrapings from the colon may also reveal other infectious agents (e.g., fungal organisms such as *Aspergillus, Candida* [56], *Cryptococcus* (intestine), *Histoplasma* (intestine, rectum), *Pythium* and *Prototheca* (rectum) [55]) (Figure 29.7). Special stains may be required for different organisms, e.g., *Cryptosporidium* stains red with a modified acid fast stain. Various stains such as iodine (for *Giardia*), methylene blue (for *E. histolytica*), or acid methyl green (for *B. coli*) help to optimize recognition of some organisms.

Birds

In birds, Gram-positive cocci and bacilli predominate in cloacal films from noncarnivorous birds, and thus stains may be useful in these species. In avian feces, occasional *Candida*-like yeasts or Gram-negative bacterial rods (or even

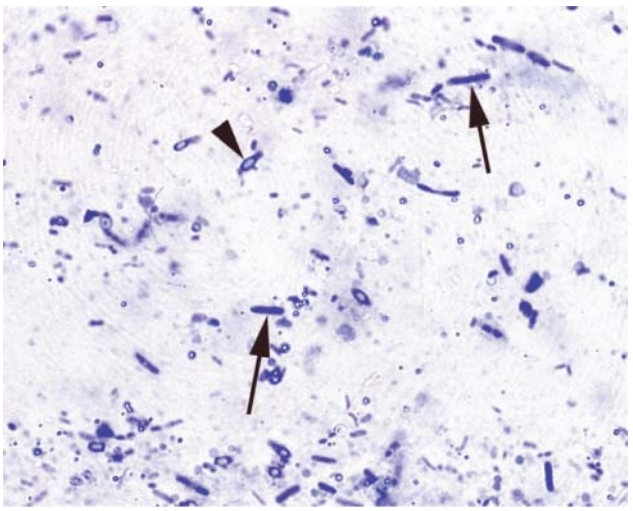

Figure 29.4 Wright-Giemsa-stained fecal smear from a dog showing an overgrowth of *Clostridium* sp. (arrows) that are recognized in the sporulated form ("safety pin" form, arrowhead). ×1000.

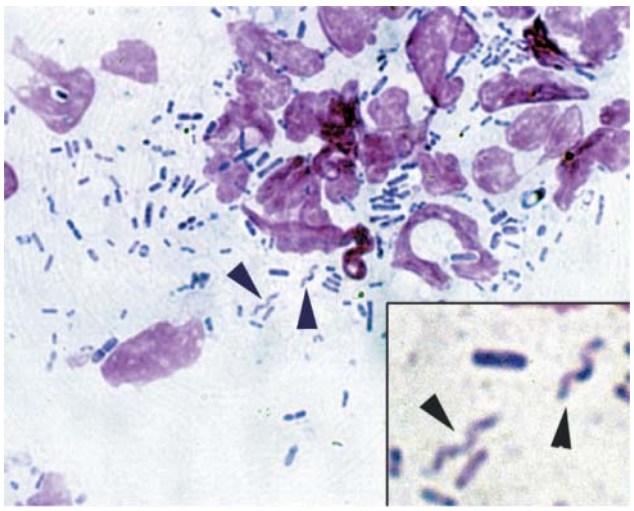

Figure 29.5 Wright-Giemsa-stained fecal smear from a dog showing an overgrowth of *Campylobacter* sp., which are recognized by a distinctive "sea gull" morphology (arrowheads). ×1000.

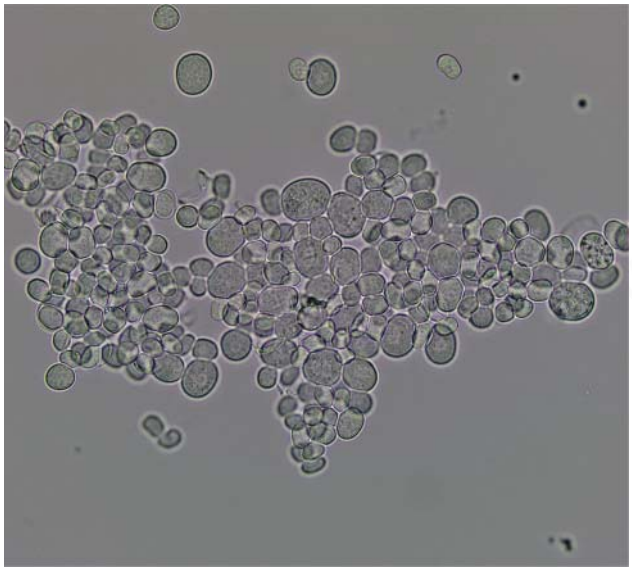

Figure 29.7 *Prototheca* organisms in a fecal wet preparation. ×500.

partial Gram-positive rods) per 1000× oil are regarded as normal. Gram-negative bacteria (bacilli) that are present in large numbers, increased numbers of filamentous Gram-positive bacteria or increased numbers of *Candida*-like yeasts, protozoa, or parasite ova are regarded as abnormal. Staining cloacal smears with carbol fuchsin or iodine may facilitate detection of *Giardia* on cytology [106].

Horses

Grindem et al. [61] suggest that fecal cytology may be of use in horses for the evaluation of variations to the GI flora or for the identification of precise etiologic agents, which may cause gastrointestinal disease. These authors prefer Romanowsky stains over Gram stains for detection of the presence of inflammatory cells or infectious agents during the initial evaluation of smears, as Romanowsky stains give better differentiation than Gram stains. With Gram stains, most cellular structures (including neutrophils) tend to stain Gram negative (red).

Fecal cytology may also be used to make a tentative diagnosis of chronic IBD in horses. These infiltrative bowel diseases include eosinophilic lymphoproliferative disorders and granulomatous gastroenteritis (the latter may be associated with mycobacteriosis, histoplasmosis, or parasitic larvae) [26]. Eosinophilic gastroenteritis may be part of a complex multisystemic epitheliotropic syndrome that may be associated with eosinophilic dermatitis and eosinophilic granulomatous pancreatitis [90, 107] (see later section on IBD).

Rectal biopsies in healthy horses may often contain eosinophils, thus making a definitive diagnosis of eosinophilic infiltrative disease difficult [92]. Ciliated protozoa such as *Tritrichomonas* and nonciliated protozoa such as *Eimeria* have been associated with chronic diarrhea in horses, but their pathogenicity is uncertain [93]. *Eimeria leuckarti* has been reported in North American horses and a study demonstrated a prevalence in foals from Kentucky, but the organism appears to be relatively harmless and clinical significance is questionable [63].

Cytology of biopsy samples

Intestinal biopsies [16] can be used to make scrape or impression smears for cytologic preparations. Ultrasound guided FNAs can be used to make rapid or tentative diagnoses of various disease syndromes such as malignant lymphoma, adenocarcinoma, mast cell tumors (cats) and adenocarcinoma and leiomyomas in dogs. Inflammatory infiltrates such as lymphoplasmacytic or eosinophilic enteritis can also be diagnosed in this manner. Impression smears of gastric mucosa or biopsies can be stained with routine methods for the evaluation of *Helicobacter* spp. [57], although this cannot be differentiated from *Gastrospirillum*-like bacteria on light microscopy [55]. Further clarification of the clinical significance of these organisms is required as they can also be seen in healthy animals [108].

Brush cytology

Brush cytology tends to exfoliate more cells as it represents deeper layers as compared with impression smears but can induce hemorrhage and inflammation [55]. Inflammation causes dysplastic change of epithelial and spindle cells, and over-interpretation of cytological changes must be avoided. Negative results do not rule out any differentials and full thickness gut biopsies for histopathology are the preferred sample in most cases for definitive diagnosis and confirmation of the cytological findings [109].

Fecal occult blood

A large amount of blood (life-threatening amounts) can be lost into the gut without evidence of external blood loss. Microcytic hypochromic, nonregenerative anemia (characteristic of iron deficiency) usually results from chronic gastrointestinal blood loss. Melena (black tarry feces) is usually due to digestion of blood when passing through the GI tract, and is most commonly due to bleeding of the proximal GI tract, but this is also dependent on the transit time. There are a number of drugs and foods (metronidazole, spinach and liver [26]) that can cause dark colored feces, which can be confused with melena. Fresh blood in feces (hematochezia) is usually associated with coagulopathies (rodenticides), colitis, foreign bodies and neoplasia.

Testing for fecal occult blood is a simple test, and is available for in-practice use. The test detects the pseudoperoxidase activity of fecal hemoglobin and picks up minute amounts of fecal blood at concentrations as low as 20× to 50× times less than those where blood is visible grossly [110]. A loss of 30–50% of the blood volume into the GI tract can occur without gross blood being visible in the feces. The test procedure involves application of the feces to the test paper, and when blood is present, the peroxidase activity results in the formation of a blue color (Figure 29.8).

There are two types of fecal occult blood tests available. The modified guaiac slide test is based on the detection of a conjugate product called quinone by chemical oxidation of guaiaconic acid, and the orthotolidine tablet test is based on the oxidation of tetramethylbenzidine. In both tests, a positive fecal blood is evidenced by the development of a blue color. In dogs, some authors report a higher threshold for peroxidase detection in the orthotolidine (o-tolidine) test [111, 112]. In a study by Rice et al. [112], the o-tolidine test was shown to be more specific as compared to the guaiac test, but these tests appear to have similar sensitivities. The clinical applications of the fecal occult blood test include testing animals with unexplained acute or chronic diarrhea, those with loose stools, or in cases of microcytic anemias, where the cause of chronic blood loss is not obvious. The test can also be used to monitor animals that are at risk of developing GI hemorrhage due of treatment with ulcerogenic drugs (e.g., nonsteroidal anti-inflammatory compounds [NSAIDs]) or those with a history of GI neoplasia [110].

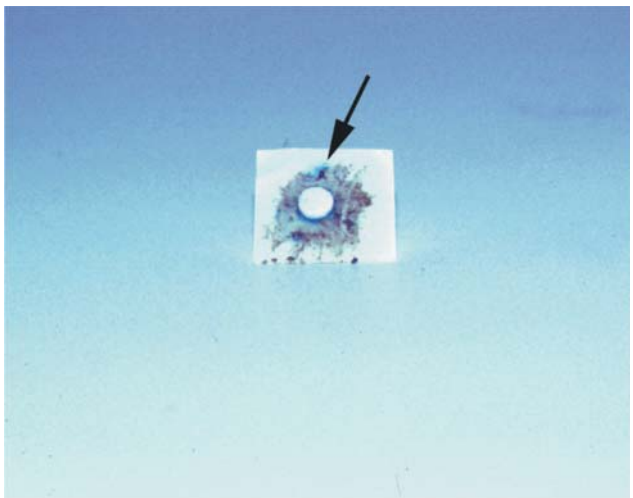

Figure 29.8 The occult blood test. This test is positive for occult blood, as indicated by the blue color on the filter pad.

The fecal occult blood test is extremely sensitive, and thus false positive results may be seen with meat or fish diets that contain myoglobin and hemoglobin, and some vegetable diets including plants such as brassicas [112] and citrus. The guaiac slide test is reported to be more likely to give false positive results than the orthotolodine tablet test, but this difference also depends on the composition of different diets [112].

It is important to observe strict dietary restriction for at least 3–5 days prior to performing the occult blood test as this decreases the number of false-positive results [16, 71]. Recommended feed restrictions include meat-free, low-peroxidase diets (e.g., rice or pasta with cottage cheese or egg as a protein source).

Cimetidine is reported to cause a false-positive hemoccult reaction in gastric juice but has not been shown to be associated with false-positive hemoccult reactions in feces [113].

Fecal immunochemical tests used for human testing detect globin in feces (rather than heme) and are human specific and do not work in veterinary species.

Positive results on the fecal occult blood test in the absence of grossly visible blood in the feces suggests the possibility of upper or lower (colon) [114] GI tract inflammation, ulceration, or neoplasia. Blood from the upper GI tract is usually digested and is not always grossly visible in the feces, but blood from the lower GI tract is undigested, and is normally evident grossly. Loss of large amounts of blood in the upper GI tract can cause rapid transit times, and occasionally, results in grossly visible blood in the feces. At least three consecutive tests for fecal occult blood should be carried out [71] to make a definitive diagnosis, as the sensitivity of the test increases when three tests are done as compared with a single test result. In a study by Smith [115], the fecal occult blood test in ruminants (Hematest, Miles Laboratories, Inc., Elkhart, IN) was reported to have a sensitivity of 77% and a specificity of 97% for abomasal ulceration, which was confirmed at surgery or necropsy [115, 116]. Serum pepsinogen is an indirect test for the detection of abomasal ulceration in young ruminants (usually <2 years of age).

Gastric ulceration in horses can result in constriction of mesenteric arteries, which can lead to necrosis of tissue supplied by these vessels, such as the pelvic flexure and distal ileum, which in turn can cause intermittent colic. Mild decreases in serum albumin can suggest GI ulceration. An Equine Fecal Blood Test™ marketed as SUCCEED® is a

lateral flow species (antibody) specific colorimetric test that measures the presence of increased levels of albumin and hemoglobin in feces. This test can be used in the field and is suggested as a marker for hind gut lesions, as enzymatic activity in the area of the common bile duct causes digestion of albumin. Grade 2 ulcerative lesions are required before hemoglobin is found in feces [117].

Digestion/absorption screening tests

Historically there have been numerous screening tests performed on feces to try to evaluate maldigestion and/or malabsorption, which included microscopic examination for fecal starch, fat, and muscle protein, and tests for fecal proteolytic activity. These tests have become obsolete as they are subjective, imprecise, and interpretation is complicated by numerous factors including the variation associated with different diets and intestinal transit times. They have low sensitivity and specificity for diagnosis of GI disease, and are regarded by current leading experts and researchers as diagnostically useless and are not recommended for clinical use [16, 26, 29, 118]. The tests for fecal proteolytic activity are fraught with numerous false positive and negative results because of the daily fluctuations in fecal protease activity and the presence of protease inhibitors in the feces, and are not recommended even as a crude screening test [119, 120].

The plasma turbidity test for fat absorption has poor sensitivity (i.e., 80% or more of ingested fat is still absorbed in dogs with EPI). There can also be marked variation in the degree of lipemia that develops and in the length of time required for lipemia to develop in normal animals.

CHAPTER 29

Tests in a reference laboratory

Serum trypsin-like immunoreactivity

Serum TLI (canine and feline specific cTLI and fTLI respectively) [121] is regarded as the most sensitive and specific laboratory test available for diagnosing EPI [121]. It should be part of any standard workup for canine small intestinal diarrhea [3]. TLI assay (GI Lab, Texas A&M University) utilizes species-specific antibody that detects cationic trypsin and trypsinogen, which are bound to protease inhibitors [51]. Immunoassays are currently available for dogs and cats. In healthy animals, trypsinogen is constantly produced by pancreatic acinar cells and small amounts leak continually into the peripheral circulation, thus most of the serum TLI measured is trypsinogen. Trypsinogen is converted in the small intestine to trypsin, which is the active form of the proteolytic enzyme, but this is not reabsorbed into circulation. In animals with EPI, TLI levels are severely decreased due to the marked depletion of functional exocrine pancreatic tissue. EPI can be treated successfully, which results in the resolution of the changes that usually occur in the small intestine, thus EPI should be ruled out as a differential before considering a diagnosis of primary intestinal disease. Commercially available Immulite® TLI testing (Siemens Medical Solutions Diagnostics) for dogs is a solid phase enzyme-labeled chemiluminescent immunometric assay but is not suitable for other species such as felines.

EPI can also cause cobalamin (vitamin B_{12}) malabsorption, which in turn, can hinder interpretation of serum cobalamin levels and thus the diagnosis of intestinal disease [122].

The following information should be considered when performing TLI:

- Animals should be fasted for a minimum of 12 hours prior to collection of a blood sample, as recent feeding may falsely increase TLI levels.
- 1 mL of nonhemolyzed serum is preferred, but EDTA or heparinized plasma may be used [51]. Severe lipemia will interfere with the radioimmunoassays commonly used for the measurement of TLI [118, 121].
- Serum TLI is stable for several days at room temperature and for several years when frozen. High temperatures will destroy TLI. Samples should be stored at 4 or −20 °C [51].
- Oral supplementation with pancreatic extracts (generally extracted from porcine pancreatic tissue) do not interfere with TLI assays or affect results [118].

Normal dogs have serum cTLI concentrations >5 μg/L (5–35 μg/L [123], 5.7–45.2 μg/L [124]). Serum TLI concentrations are dramatically decreased in dogs with EPI (<2.5 μg/L) [77]. In dogs with clinical signs of maldigestion due to EPI, the diagnostic sensitivity, specificity and accuracy of fasting serum cTLI is high (approaching 100%) [121]. Values between 2.5 and 5.0 μg/L are seldom associated with signs of EPI but may reflect subclinical pancreatic acinar cell destruction secondary to ongoing immune-mediated lymphocytic pancreatitis [125]. Dogs with reproducible subnormal results of between 2.5 and 5.0 μg/L may have subclinical disease (EPI) with partial pancreatic acinar atrophy and concurrent chronic diarrhea and weight loss.

The cTLI can decrease from the "gray" zone to a confirmatory level within a few weeks. In these cases the TLI assay should be repeated after 1 month, ensuring that food is withheld for 12–15 hours prior to blood sample collection. Other possible causes for results in this "gray" zone (2.5–5.0 μg/L) include:

- The dog is in the process of recovering pancreatic function after an episode of pancreatitis, and the results may be normal at retesting.
- The sample had a normal TLI when collected but was exposed to excessive heat during transit. Results may be normal at retesting.
- Food was not withdrawn for an adequate length of time prior to testing. Retesting may indicate that the dog has EPI.

In cats, values ≤8.0 μg/L are diagnostic for EPI [77, 121]. Values between 8.0 and 12.0 μg/L are equivocal and retesting in a month (as for dogs) is recommended [40, 126].

TLI concentrations are reported to be normal in cases where EPI is due either to obstructive pancreatic duct tumors or to congenital deficiencies of the enzymes other than trypsinogen [64]. Diseases causing decreased GFR are reported to increase TLI [124], and could potentially mask an abnormally low serum TLI concentration.

Assays for serum cobalamin (vitamin B_{12}) and folate are strongly recommended whenever serum TLI is assayed as serum vitamin abnormalities are common in dogs and especially cats with EPI.

High TLI values (>50 μg/L (dogs) and 100.0 μg/L (cats)) can be associated with pancreatitis but PLI testing is preferred for the diagnosis of pancreatitis (see Chapter 28).

Fecal elastase 1

The fecal elastase 1 (E1) is a canine monoclonal (species specific) immunoassay ELISA test (ScheBo®, BiotechUS) which claims a sensitivity of 97% and a specificity of 98% for the detection of canine pancreatic insufficiency [127]. Spillman et al. have demonstrated that fecal elastase has a lower specificity than cTLI [127]. In a recent study, Steiner quotes false positive rates up to 23.1% [26]. This test measures undegraded pancreatic elastase in feces, which reflects EPI.

The single advantage of this test over cTLI testing is that it does not require a 12-hour fast, but the disadvantages are that feces are required, it is a more cumbersome assay and may also be more expensive than TLI. Fecal elastase values <10 μg/g in dogs with appropriate clinical signs suggest severe dysfunction [123]. There are also marked daily variations in fecal elastase results, with no clear cut differentiation in results between subclinical and control dogs [125].

Fecal α_1-proteinase inhibitor concentration (α_1-PI)

Many gastrointestinal disorders can be associated with protein loss. In small animals the most common causes of GI protein loss include IBD, intestinal lymphoma, and lymphangiectasia [29].

α1-Proteinase inhibitor (PI) is a protein in feces that has a similar molecular mass to albumin but is not degraded by digestive or bacterial proteinases (as is albumin). It is lost at approximately the same rate as albumin and other plasma proteins into the GI lumen [128]. α1-Proteinase inhibitor is normally found in plasma, lymph, and interstitial fluid but is not normally present in the intestinal lumen [129]. In dogs with gastrointestinal protein loss, increases in fecal α_1PI concentrations may be seen before the protein loss becomes severe enough to observe hypoalbuminemia [130].

Confirmation of gastrointestinal protein loss in dogs, i.e., PLE, can be made by measurement of fecal α1-proteinase inhibitor by means of a validated ELISA assay [128]. The test is only valid in dogs more than one year of age. This assay is available through the Gastrointestinal Laboratory at Texas A&M University (College Station) [128, 131], and this test is no longer available for cats (http://www.cvm.tmu.edu/gilab).

There are daily fluctuations in fecal α_1-PI levels and excretion should preferably be measured over 24 hours, but a more realistic approach involves collection and evaluation of three individually voided fecal samples [71]. Fecal blood is reported to falsely increase α_1-PI [132]. Three different fecal samples (1 g) should be frozen immediately and shipped to the reference laboratory frozen [71], on dry ice for testing. They must be received in a frozen state by the testing laboratory.

Time and increased temperature decrease concentrations [128]. Samples kept at room temperature for 72 hours were shown to have only 66% of the prestorage concentrations [128].

Abnormal results in dogs are reported as a three day average of α_1-PI ≥13.9 μg/g feces or a α_1-PI in one individual sample of ≥21.0 μg/g feces [131]. When serum albumin decreases to a level of 1–2 g/dL, ascites and peripheral edema may result.

Serum vitamin B_{12} (cobalamin) and folate [40]

In dogs and cats that have unexplained weight loss or chronic small intestinal diarrhea, serum vitamin B_{12} and folate concentrations may be useful to evaluate intestinal function [16], but it must be remembered that a precise etiologic diagnosis based on these tests results is unlikely [16]. Results will be abnormal in animals with EPI, and thus animals should be evaluated for EPI prior to vitamin B_{12} or folate testing [40]. These tests are the most useful to diagnose small intestinal bacterial overgrowth (SIBO)/antibiotic responsive diarrhea, although sensitivity for B_{12} is reported as 25–55% and that of folate as 50–66% [11].

Serum is the preferred sample for both vitamin B_{12} and folate assays, but EDTA plasma may be used for folate only with some methodologies [51]. Assays should be validated for the species of interest. Vitamin B_{12} is stable in serum for 12 hours at 8 °C, and for up to 8 weeks at −20 °C. Folate is stable for 24 hours at 4 °C and for up to 8 weeks at −20 °C [51]. Exposure to light may cause false decreases in vitamin B_{12} values [16, 51, 133], whereas hemolysis falsely increases folate concentrations [16, 51, 118, 133]. Samples should preferably be frozen [40].

Texas A&M reference intervals for vitamin B_{12} (cobalamin) in dogs range from 251 to 908 ng/L and folate 7.7–24.4 μg/L. In cats the vitamin B_{12} range is from 290 to 1500 ng/L and folate 9.7–21.6 μg/L.

Deficiency of tissue cobalamin is also associated with increases of serum and urine methylmalonic acid (MMA) (produced by mitochondria) as an alternative pathway of cobalamin production [40].

Serum vitamin B_{12} (cobalamin)

Cobalamin is a large molecule that cannot pass through the intestinal epithelial barrier either by diffusion or by carrier-mediated transport, and thus vitamin B_{12} (cyanocobalamin/cobalamin) has a highly complex homeostasis, which primarily involves sequential metabolism by means of enterohepatic recirculation [29].

Secretions of pepsin and gastric acid (HCl) in the stomach mediate the release from dietary proteins. Free cobalamin then binds to specialized proteins (known as R proteins), which in turn renders cobalamin unavailable for absorption. This complex passes into the small intestine, where it subsequently becomes digested by pancreatic proteases, which in turn releases the vitamin B_{12} [77]. Intrinsic factor is produced primarily by the pancreas in dogs and cats [134], and also by the gastric mucosa in dogs [51], then binds to the free vitamin $B_{12.}$ This vitamin B_{12}-intrinsic factor complex is later absorbed in the distal small intestine, especially the ileum [18, 29].

The three main causes for decreased serum B_{12} (cobalamin) concentrations are:

- **Exocrine pancreatic insufficiency:** Either cobalamin is not released from R proteins because of insufficient secretion of bicarbonate-rich fluid into the duodenum, or there is decreased intrinsic factor production, especially in cats because they lack gastric intrinsic factor [135]. Low serum cobalamin levels are an indication for checking serum TLI.
- **Antibiotic responsive diarrhea/enteropathy – formerly known as small intestinal bacterial overgrowth (SIBO):** SIBO was defined as a specific number of colony-forming units/mL of duodenal juice [136], but further studies have shown that there is no correlation between bacterial counts and disease status [11, 16]. Bacteria involved are predominantly anerobes (*Clostridium* and *Bacteroides*). The amount of cobalamin bound to intestinal bacteria is increased, decreasing free cobalamin for absorption.

Increases in bile acids can also be seen in cases of intestinal overgrowth and EPI (without evidence of liver disease) [137]. This is due to the increased production of unconjugated bile acids by intestinal bacteria that are freely absorbed into portal circulation but fail to be cleared sufficiently [26].

- **Decreased absorption of cobalamin:** In the ileum of dogs and cats, decreased cobalamin absorption may be due to diseases damaging the ileum, such as IBD and neoplasia.

Additionally, congenital selective cobalamin malabsorption and cobalamin deficiency has been documented in cats [138], border collies [14], giant schnauzers [11, 17], Australian shepherd dogs, and beagles with defective ileal cobalamin–intrinsic factor receptor.

In a study at the GI Lab at Texas A&M, they report that approximately 70% of the serum samples tested from Shar Peis with GI disease have serum cobalamin B_{12} levels below the reference interval [15, 16], but these dogs do not appear to have abnormal pancreatic function. They also report that in nearly half of these dogs tested, the serum cobalamin could not be detected by normal methods [16].

Increased levels of serum cobalamin concentrations are relatively uncommon in dogs, but they may occur with supplementation of cobalamin, or they can also arise from hepatic parenchymal damage, as hepatocytes store cobalamin.

Low levels of cobalamin may reflect chronic malabsorption (often associated with chronic diarrheas), and should be treated appropriately. This can commonly be seen in young cats with chronic diarrhea. Cobalamin deficiency is also associated with mucosal inflammation, villous atrophy, immunodeficiency, and neuropathies [26].

Increased levels of serum cobalamin

Occasionally increased serum cobalamin concentrations are found and are generally attributed to either parenteral supplementation or dietary factors or are usually ignored. In man, hypercobalaminemia has, however, been associated with a number of diseases such as neoplasia and hepatic disease. Trehy et al. suggest that hypercobalaminemia in cats should not be ignored and that investigation to rule out hepatic disease or neoplasia should be undertaken [139].

Serum folate

Folate is ingested in the diet (green leafy plants) in the form of folate polyglutamate. It is conjugated with glutamic acid residues but is poorly absorbed. In the proximal small intestine, folate polyglutamate is deconjugated by folate deconjugase enzyme to folate monoglutamate [77], which is then absorbed by specific folate carriers in the proximal small intestine, especially the jejunum. Enteric bacteria also produce folate.

The main cause of decreased serum folate concentrations is the decrease of intestinal folate absorption due to proximal small intestinal disease. Many potential underlying causes are possible, such as IBD or infiltrative neoplasia such as lymphoma. Ingested antigens are in increased concentrations in the lumen of the proximal small intestine and this area is thus vulnerable to damage by specific diets, e.g., gluten enteropathy in Irish setters [28, 29]. Overuse of antibiotics with subsequent sterilization of the intestine can also lead to decreased serum folate levels. A functional folate deficiency may also occur in cases of cobalamin deficiency, and serum folate concentrations may be normal or be potentially increased in those animals due to the decreased utilization of folate [51].

There are several potential causes for increased serum folate concentrations, including excess supplementation or high dietary intake. Many different bacterial species synthesize folate and thus SIBO can lead to significant increases in serum folate concentrations [9]. Bacterial overgrowth may

result secondary to EPI or a variety of underlying intestinal diseases that cause defects in the mucus barrier or decreased peristalsis. IgA deficiency in German shepherds has also been associated with intestinal bacterial overgrowth [8]. Greater folate absorption occurs at lower pH, which could be caused either by excess gastric acid secretion or decreased bicarbonate secretion. The latter can be seen in cases of EPI.

Interpretation of vitamin B_{12} and folate concentrations

Results are only meaningful if pancreatic function is normal and if the condition is sufficiently chronic for body reserves of vitamin B_{12} and folate to have been depleted. Dietary intake is a consideration as prolonged anorexia can affect serum concentrations. Misleading results can occur in cats or dogs with EPI and in patients who have bacterial overgrowth or are receiving vitamin supplements. In a survey by Hall et al. [140], the authors reported that 74% of dogs with EPI had decreased vitamin B_{12} and 32% had increased folate [140].

The combination of decreased vitamin B_{12} and increased folate concentrations with normal pancreatic exocrine function suggests SIBO [16], also known as antibiotic responsive diarrhea or bacterial dysbiosis [141]. In dogs, decreased B_{12} and increased folate concentrations have a low sensitivity (5%) for detecting bacterial overgrowth but have high specificity (almost 100%) [7].

Bacterial dysbiosis [2] is not a clinical condition that is commonly seen in cats, but serum cobalamin concentrations can be decreased due to binding by intestinal bacteria. In cats, low concentrations of serum cobalamin are most frequently associated with small intestinal disease, that is, if pancreatic insufficiency (EPI) has been excluded [29].

A decrease in serum concentrations of both vitamin B_{12} and folate suggests severe, chronic diffuse disease involving the entire small intestine (generalized malabsorption).

Decreased vitamin B_{12} and folate concentrations have been reported in cats with EPI. In a study by Simpson [32], in more than 50% of the cats tested at the time they were presented with GI disease, the cobalamin concentration was below normal, and some cats with GI lymphoma were also found to have concurrently low folate levels [32]. It is hypothesized that the reduced serum vitamin B_{12} concentration results from decreased secretion of pancreatic intrinsic factor, which is necessary for vitamin B_{12} absorption in cats. Decreased folate concentrations are thought to result from concurrent intestinal disease with EPI and the resultant decrease in folate absorption. Detection of decreased vitamin B_{12} and folate concentration in cats warrants consideration of EPI in addition to intestinal disease.

A decrease in vitamin B_{12} with normal folate concentration but normal pancreatic function suggests distal small intestinal disease, whereas decreased folate with normal B_{12} concentrations suggests proximal small intestinal disease. A decrease in vitamin B_{12} with or without increased folate in dogs (due to bacterial overgrowth) suggests EPI, and TLI testing is indicated. If both vitamin B_{12} and folate concentrations are increased, vitamin supplementation prior to sampling is the most likely explanation, because there is no disease process that should give rise to this change.

A summary of the interpretation of vitamin B_{12} and folate levels is presented in Table 29.6.

Table 29.6 Summary of the interpretation of vitamin B_{12} and folate levels.

SIBO – normal or ↓ vitamin B_{12}, folate ↑ (TLI measurement indicated)
EPI – slight ↓ vitamin B_{12} folate normal/↑ (ileal mucosal disease – TLI low)
Cats EPI – most ↓ vitamin B_{12}, >50% folate ↓
Vitamin supplementation – ↑ vitamin B_{12}, folate ↑
Severe, diffuse long-standing SI disease – usually ↓ vitamin B_{12}, folate ↓ (IBD, lymphoma, or fungal disease)
Upper SI disease – usually normal or ↑ B_{12}, folate low (IBD, lymphoma or fungal disease)
Malabsorption – low folate
Hepatic disease or neoplasia - ↑Vitamin B_{12}, folate within reference interval [139]

Methylmalonic acid [142]

MMA is most often used in conjunction with vitamin B_{12}, especially in cases where equivocal results are obtained for cobalamin. It is used to detect cobalamin (vitamin B_{12}) deficiency on a cellular level, which is more physiologically important as cobalamin co-reactions are intracellular. Fasted serum samples, shipped to the lab frozen are the preferred samples. Reported reference intervals (Texas A&M) for dogs are 414–1193 nmol/L and 139–897 nmol/L for cats [142].

Cobalamin in large animals

Cobalt is required for synthesis of cobalamin by ruminal bacteria, and thus cobalt deficiencies in ruminants can result in decreased serum cobalamin (vitamin B_{12}) [143]. Cobalamin deficiencies are shown to have repercussions on production in large animals, with manifestations of diarrhea, weight loss, ill thrift, pica, etc. [144].

Other tests that may be useful in assessing gastrointestinal disease

Canine microbiota dysbiosis index [145]

The GI Lab at Texas A&M offers a PCR test that is carried out on canine feces that quantifies eight fecal groups of bacteria and is expressed as a summary of these as a single number.

The secondary interpretation uses the microbial profile to predict conversion of primary to secondary fecal bile acids. Fecal dysbiosis is indicated by a dysbiosis index >0, which can

be seen in cases of chronic enteropathies such as antibiotic responsive diarrhea, IBD, food responsive diarrhea, EPI, and dysbiosis [2] induced by antibiotic therapy.

Specificity is approximately 75% with 15% of normal dogs having false positive results within an equivocal range of 0–2. Feces is best shipped frozen.

Markers for gastric disease

Gastrin is a peptide hormone produced by the parietal cells of the stomach, G cells of the duodenum, and pancreas whose main function is to elicit the release of hydrochloric acid, and that plays a role in gastric motility.

Excessive amounts of gastrin can be associated with gastrin producing tumors (gastrinoma) of the duodenum or pancreas (Zollinger-Ellison syndrome) [146], immune mediated gastritis leading to low stomach acidity and compensatory over-secretion of gastrin, and chronic gastritis associated with *Helicobacter* infection.

Gastrin concentration in serum can be measured in dogs and cats. Gastrin is labile and serum should be separated immediately, frozen and shipped on ice. The diagnosis of gastrinoma is made on the basis of a 10× increase in gastrin levels as compared with fasting samples [26]. Chronic inflammation of the gastric lining causes damage to the gastric glands leading to atrophic gastritis and decreased secretion of gastrin, which is reported in Norwegian Lundehunds [147].

Damage and inflammation of the gastric mucosa elicits an increase in serum C-reactive protein concentrations in dogs that is highly sensitive but nonspecific [148].

Gastroscopy (beyond the scope of this text) is regarded as the gold standard for evaluation of gastric disease [77].

There are no specific markers for general gastric disease but anecdotally, gastric carcinoma is often associated with increases of ALP (usually accompanied by evidence of anemia on CBC).

Evaluation of ruminal fluid

When sampling the ruminal contents, it is important to avoid contamination with saliva, which has an alkaline pH.

Ruminal pH varies according to the type of feed, and time interval between feeding and sampling. The maximal decrease in pH occurs 5–6 hours postprandially due to production of volatile fatty acids. pH increases on exposure to air and thus should be measured immediately after sampling [149].

Normal rumen pH is reported to be between 5.5 and 7.2, with an average of 6.5–6.8 (on roughage) [149, 150]. Acidosis is evidenced by a pH less than 5.5–6.0 (usually due to grain overload or high concentrate diets) [151], although an animal with lactic acidosis with protracted anorexia may have a normal rumen fluid pH if there is persistent saliva production [144]. Alkalosis is associated with pH above 7 (8–10) and is due to high protein diets, saliva contamination of rumen content, or rumen putrefaction due to rumen stasis [149].

Microscopic examination of rumen fluid includes evaluation of the types of bacteria and types and motility of the protozoa present. It is important to mix the sample adequately prior to examination. Protozoal motility can be evaluated on wet preparations at low power that should be kept warm [152]. Numbers and morphology can be examined on wet mounts without stains (or by adding a drop of Lugol's iodine to the rumen contents) on a slide and covered with a coverslip. Normally a minimum of five to seven active protozoa should be seen per low-power field [149].

Ruminal bacteria are predominantly Gram negative but these may be replaced by Gram-positive organisms in cases of ruminal acidosis [149].

Normal rumen chloride is <30 mmol/L (10–25 mmol/L) in cattle and (<15 mmol/L) in sheep [149], and chloride concentration of the abomasum is (>90 mmol/L) [152]. Increases in rumen chloride are associated with abomasal reflux of HCl, ileus, or high salt intake [144, 149].

A list of additional tests that may be used for the evaluation of gastrointestinal disease is presented in Table 29.7.

Absorption tests

The functional assessment of small intestinal disease in small animals by measuring absorption of various substrates such as glucose, lactose, and starch are obsolete [16]. This is because concentrations of plasma glucose after dosing of these compounds depends on more than mucosal hydrolysis of starch and lactose, and absorption of glucose, making these tests unreliable [16]. Other insensitive tests that have also become outdated include vitamin A testing (previously used to assess malabsorption), D-xylose testing in small animals, and triglyceride absorption tests [16].

Some of these absorption tests however, are still used in large animals, such as xylose absorption, and are occasionally used in horses when malabsorption is suspected [162, 163]. This has largely been replaced by glucose absorption tests, which are used to assess chronic weight loss in horses [164]. An abnormal test result does not, unfortunately, provide a specific etiology for the weight loss. Both tests are influenced by the rate of gastric emptying, small intestinal transit time, diet and fasting period. Both tests require adequate fasting prior to testing, but this may be contraindicated in debilitated animals.

Xylose absorption tests depend largely on absorption of xylose whereas glucose absorption tests depend on intestinal absorption and utilization of glucose by hepatocytes and other tissues. Theoretically the xylose absorption test is preferred because xylose is not a normal metabolite, although the test has a number of disadvantages. The test is more expensive, xylose assays are less accessible, and results may be difficult to interpret [149]. Results are also affected by diet (horses on high energy diets show lower absorption curves). The glucose absorption test is more practical because glucose is readily available, less expensive, and assays are

Table 29.7 Additional tests that may be useful for the evaluation of gastrointestinal disease.

Test type	Purpose of test
Fecal antigen detection methods	Evaluation of microorganisms associated with diarrhea and/or vomition, e.g., ELISA for viruses (parvo [153], rota) Parvo ELISA is only positive during viral shedding (10–12 d postinfection) False positives seen if vaccinated with live attenuated vaccine within 10 d of testing [153] Also useful for panleukopenia in cats, along with severe leukopenia on leukogram PCR required to differentiate field from vaccinal strains
Fecal ELISA for bacterial enterotoxins	*Clostridium perfringens* [29] and *Clostridium difficile* [29, 154]
Fecal PCR or bacterial or fungal culture	Evaluation of microorganisms, associated diarrhea, and or vomition such as *Campylobacter* spp. [97, 155, 156], *Clostridium difficile* [45, 154], *Clostridium perfringens* [97, 103, 154], pathogenic strains of *Escherichia coli* [9, 32, 45, 97, 157] and *Salmonella* spp. [66, 71, 97], *Helicobacter* [57, 158], *Heterobilharzia americana* [159], *Histoplasma capsulatum* [45], *Tritrichomonas* [55, 74]
Hydrogen breath test [76–78]	Investigation of bacterial overgrowth and carbohydrate malabsorption secondary to EPI in dogs and cats [43, 160]
Intestinal biopsy	Evaluation of etiology of GI tract disease [16]/causes of malabsorption/ maldigestion [55]
Serum gastrin	Evaluation for gastrinoma (Zollinger-Ellison syndrome) [146]
Serum pepsinogen	Screening for abomasal ulceration/damage [151] in ruminants and screening test for *Teladorsagia* (ostertagiasis) [161] in young calves <2 yr of age

more accessible. Glucose absorption tests can be used in monogastrics and preruminant calves to assess intestinal absorption but cannot be used in adult ruminants as sugars are degraded in the rumen.

Oral D-xylose absorption tests in horses

Protocol:

- The animal is fasted for 12–18 hours [165].
- D-xylose is administered orally via nasogastric tube at a dosage of 0.5–1.0 g/kg (10% solution) in horses [149].
- Blood samples are collected into heparinized tubes for D-xylose determinations and are collected before D-xylose administration and at 30-minute intervals for up to 5 hours (30, 60, 90, 120, 180, 240, and 300 minutes) after administration. For routine diagnostic purposes, the 60- through 180-minute samples are the most important.

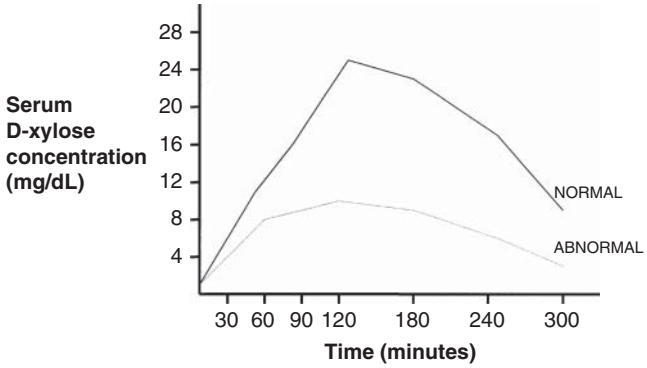

Figure 29.9 The D-xylose absorption curves from normal and abnormal horses. A normal D-xylose absorption curve in a horse peaks at greater than 20–30 mg/dL at 90–180 minutes after D-xylose administration.

D-xylose concentrations should represent a bell-shaped curve but should peak at greater than 20–30 mg/dL (1.34–2.01 mmol/L) at 90–180 minutes (Figure 29.9) [149]. In normal horses, peak values should be greater than 15 mg/dL (1.00 mmol/L) above baseline values. In normal foals the xylose peak is reached at 30–60 minutes, but peak concentrations are reported to vary with age [149]. A flattened D-xylose absorption curve is suggestive of malabsorption [149].

The D-xylose absorption test is insensitive, and thus a normal D-xylose absorption test does not rule out malabsorption. D-xylose absorption curves can be affected by many factors not directly related to malabsorption such as diet, anorexia, age, decreased renal clearance, infections, anemia, hypoxia, and in foals, the IgG concentration. D-xylose absorption can be falsely decreased (i.e., a falsely flattened curve or delay in reaching peak value) with delayed gastric emptying, bacterial overgrowth causing intraluminal bacterial breakdown of xylose, and sequestration of xylose in patients with abnormal extravascular fluid accumulation (e.g., edema, hydrothorax, or ascites).

Oral glucose absorption/tolerance test (OGTT) in horses

Protocol [164, 166–168]:

- The animal is fasted overnight (18–24 hours), and a baseline (0-hour) blood sample for glucose is drawn into a sodium fluoride oxalate tube.
- Glucose (20% solution) is administered at 1 g/kg body weight via nasogastric tube.
- Blood samples for glucose determination are collected into sodium fluoride tubes at 30, 60, 90, 120, and 180 minutes after glucose administration.

Normal horses should show increases in blood glucose concentrations of greater than 85–100% above the baseline concentration at 120 minutes [51, 83]. Results may be affected by a number of factors such as age and diet [166, 169], bacterial overgrowth, delayed gastric emptying (excitement) [164, 167, 168], small intestinal obstruction, reduced intestinal circulation, and sequestration in ascitic fluid. Anorexia or prolonged fasting may delay or decrease peak glucose concentrations, causing flatter curves due to decreased peristalsis.

The specificity of the oral glucose tolerance test was assessed in 42 cases of horses with chronic weight loss [167]. Specificity was found to be very good; normal OGTT results correlated well with normal histopathological findings of the small bowel, but severe infiltrative disease of the small intestine (such as lymphoma or granulomatous enteritis) was associated with a complete malabsorptive response [167]. Histopathological findings correlated poorly with a partial malabsorption response.

Tests for maldigestion in horses

Oral lactose tolerance test in horses

Maldigestion syndromes are infrequently observed in horses as compared with other species. In foals and young adults less than 3 years of age, lactase enzyme (found in the brush border of the small-intestinal enterocytes) hydrolyzes lactose into its two component sugars d-glucose and galactose before absorption occurs. Acquired lactase deficiency can be seen in foals and preruminant calves secondary to a number of causes of intestinal mucosal damage. These include viral (rotavirus), protozoal, or bacterial enteritis (*C. difficile* enterocolitis in foals) [82, 83] or other less specific causes of small intestinal disease [51]. Preruminant calves and lactose-deficient foals may develop osmotic diarrhea due to the presence of osmotically active particles (lactose) and subsequent retention of water and electrolytes in the small intestine. These two types of diarrhea may be difficult to differentiate clinially [88].

The lactose tolerance test does not distinguish maldigestion from malabsorption but is used principally in foals to identify lactase deficiency and for young foals and calves with diarrhea or poor growth. The test is inappropriate for adult ruminants and horses (the latter greater than 3 years of age as they are lactose-intolerant).

Protocol [51, 81, 164, 167]:

- Grain and hay should be withdrawn from the dam and foal for 18 hours and water removed 2 hours prior to testing. Muzzling of the foal is recommended 4 hours prior to testing, and the foal should remain muzzled for the duration of the test. A baseline (0-hour) blood sample for glucose is taken.
- Lactose monohydrate (20% solution) is dosed at 1 g/kg body weight via nasogastic tube [149].
- Blood samples for glucose assay are collected into sodium fluoride tubes at 30-, 60-, and 90-minute (120 minutes optional) intervals after lactose administration.

In healthy foals, the glucose concentration is reported to be 150–250% of baseline concentration at 60 or 90 minutes [81, 83] or should peak at least 35 mg/dL (1.94 mmol/L) greater than the baseline concentration [81]. Maldigestion or malabsorption will usually result in an inappropriate increase in the blood glucose concentrations after the administration of lactose. If the lactose tolerance test is abnormal, then either a glucose or D-xylose absorption test is recommended to evaluate for possible malabsorption. Casein hypersensitivity and lactose intolerance can be differentiated by evaluation of the foal's response to enzymatically treated and untreated milk. A definitive diagnosis of lactase deficiency can be confirmed by direct measurement of mucosal lactase activity in the intestinal tissue, but this is rarely performed in practice, as surgical biopsy of the mucosa is required.

Starch digestion test in horses

This is a test of small intestinal and pancreatic function.

Protocol [149]:

- The horse is fasted for 18 hours, after which a baseline sample for blood glucose is taken into a sodium fluoride tube.
- Cornstarch is dosed at 1 kg in 4 L of water or 2 g/kg body weight via nasogastric tube.
- Samples for blood glucose determinations are collected in sodium fluoride tubes at 15-, 30-, 60-, 90-, 120-minute intervals and then hourly for 6 hours.

Normal horses are reported to should show increases in blood glucose concentrations of approximately 30 mg/dL (1.67 mmol/L) with a peak at 60 minutes, and the curve should return to pretreatment levels within 3 hours. This pattern of response closely approximates results obtained by oral glucose absorption tests [170].

Other laboratory abnormalities associated with disease of the digestive system

Laboratory test abnormalities associated with gastrointestinal disease vary with the area of the system affected, the disease etiology, and the speed of onset and duration of the disease. Common abnormalities associated with acute or chronic diarrhea or vomiting are discussed here.

Other laboratory abnormalities associated with acute or chronic diarrhea (more than 3 weeks' duration) or vomiting

Dehydration and hemoconcentration

Dehydration and hemoconcentration are characterized by increased hematocrit, hemoglobin concentration, and erythrocyte count, as well as increased plasma and serum

protein concentrations. These changes can occur with acute diarrhea or vomiting, and are due to the loss of fluid via the GI tract. Increases in blood urea nitrogen or (serum urea) and creatinine can occur secondary to dehydration (i.e., prerenal azotemia).

Leukogram

Variable abnormalities in the leukocyte concentration can occur with acute diarrhea. If the diarrhea results from an infectious agent that produces toxins, (such as *Salmonella)*, then sequestration of neutrophils as well as strong tissue demand can result in marked neutropenia and leukopenia with or without a left shift and toxic change. Less severe endotoxemia or tissue demand can result in neutrophilia with a left shift.

- Eosinophilia may or may not be seen with hypersensitivity – allergy or intestinal parasitism, intestinal mast cell tumor, GI lymphoma, hypoadrenocorticism, eosinophillic enteritis, or hypereosinophilic syndrome.
- Lymphopenia may be seen with immunodeficiency, stress, or lymphangiectasia [16, 29, 34]. Severe lymphopenia in cats can also be associated with lymphoma [171] and FeLV/FIV infection.
- Thrombocytopenia, coagulopathies, and disseminated intravascular coagulation may be features of endotoxemia secondary to sepsis.

Acid-base and electrolyte abnormalities

Acid-base and electrolyte abnormalities can occur in animals with diarrhea or vomiting. These abnormalities, however, are variable and unpredictable. Assessment of acid-base and serum electrolyte status is important in such animals. In patients with secretory diarrheas, loss of Na, Cl, and occasionally K can result in decreased serum concentrations of these electrolytes. Hypokalemia is common in horses with long-standing colic with impaction of the large colon, or in horses that have been anorexic for a few days [149].

Increases in potassium with pseudohypoadrenocorticism (pseudoaddisons) is noted in some dogs with secretory diarrhea, especially with whipworm (*Trichuris*) infection [71, 172]. Bicarbonate is also lost in diarrhea, which can cause a metabolic acidosis. This in turn can result in a shift of K from intracellular to extracellular spaces as well as retention of K by the kidneys. Potassium shifts can lead to a normal or increased serum K concentration despite a loss of K in the feces. Vomiting animals may lose significant amounts of HCl in the vomitus, which often leads to hypochloremia and metabolic alkalosis. If the vomitus includes alkaline small intestinal contents, however, such animals may have normal acid-base results or metabolic acidosis.

Metabolic alkalosis in vomiting animals is associated with obstructive GI disease, and is caused by loss of HCl without loss of alkaline intestinal contents. No significant association was found by Boag et al. [173] between electrolyte or acid-base abnormalities and the site of foreign body; metabolic alkalosis with hypochloremia (disproportionate to sodium) and hypokalemia can be seen with both proximal and distal gastrointestinal foreign bodies. Linear as compared with discrete foreign bodies were more likely to be associated with lowered sodium concentrations [173].

A marked disproportionate decrease in chloride as compared to sodium may also be associated with left displacement of the abomasum (LDA) in ruminants with alkalosis and hypokalemia. This may be accompanied by paradoxic aciduria [149]. A less severely (but disproportionately) lowered chloride with low or low normal potassium and alkalosis has also been observed in cattle with ileus, vagal indigestion, or oversupplemented with magnesium.

Increased activities of hepatic leakage enzymes

Increased activities of hepatic leakage enzymes (mainly ALT [alanine aminotransferase] in dogs and cats or ALP [alkaline phosphatase] in dogs [16] and GLDH [glutamate dehydrogenase] in large animals) can occur with acute diarrhea, possibly because of hepatocyte damage resulting from toxins absorbed from the injured GI tract or seeding of the liver by bacteria from the gut or circulating inflammatory mediators and cytokines. The liver's dual blood supply and large blood flow make it sensitive to injury due to systemic disorders and diseases in organ systems drained by the portal circulation, especially the GI and pancreas.

Serum amylase and lipase

Serum amylase and lipase may be variably increased with gastrointestinal disease in dogs, including gastrointestinal space occupying lesions such as foreign body or neoplasia.

Hypocholesterolemia

Hypocholesterolemia although nonspecific, may be present in some cases of intestinal disease. Many dogs with PLE have hypocholesterolemia, which may be secondary to lymphangiectasia [16], and presumably results from fat malabsorption associated with failure of chylomicron transport.

Panhypoproteinemia

Panhypoproteinemia can be seen with PLEs [16, 34] including neoplasia. This should be differentiated from hypoalbuminemia secondary to protein losing nephropathies and liver failure [16]. Checking for urine protein with a dipstick is a simple means of looking for proteinuria (see Chapter 30). Chronic intussesception should be a consideration in young dogs with chronic diarrhea [174] and PLE that are negative for hookworm [26].

Coagulation defects

Coagulation defects can be seen in horses with severe colic and is characterized by low levels of antithrombin III and prolonged PT and APTT [175].

Other laboratory abnormalities associated with exocrine pancreatic insufficiency or malabsorption syndrome

Hematologic and serum biochemical tests usually are not helpful in establishing the diagnosis of EPI. Routine hematologic tests and biochemical profiles, however, may help to differentiate EPI from other disorders. Serum amylase and lipase activities may or may not decrease slightly with EPI, but these decreases usually are not recognized as being significant. Increased alanine aminotransferase (ALT) activities and decreased cholesterol concentrations occasionally are seen in dogs with EPI.

Other laboratory abnormalities that can occur with malabsorption syndrome include:

1. Microcytic anemia associated with iron deficiency, which commonly results from chronic blood loss via the GI tract [34]. Chronic GI blood loss can be associated with a variety of underlying conditions, including neoplasia and parasites.

2. An inflammatory leukogram, may be suggestive of significant inflammation or deep ulceration in the intestinal wall.

3. Neutropenia with or without a left shift. If neutrophils are toxic, then endotoxin absorption from the GI tract secondary to Gram-negative enteritis, intestinal stasis, septicemia, severe bacterial peritonitis secondary to intestinal perforation, or viral enteritis are possible.

4. Eosinophilia, may be associated with eosinophilic gastroenteritis or parasitism, is an inconsistent marker of eosinophilic gastroenteritis [16, 34]. Lack of eosinophilia does not rule out these differentials. Hall [16] states that in his experience, fewer than 50% of cases of biopsy-proven eosinophilic enteritis have peripheral eosinophilia and that mild eosinophilia can also be seen with other forms of IBD [16].

5. Abnormal serum protein, albumin, or globulin concentrations. Serum albumin and globulin concentrations are important in screening for protein losing enteropathies [34]. In these cases, both albumin and globulin concentrations are usually decreased. In other types of malabsorption

or maldigestion, the only decrease, if any, occurs in the albumin concentration. An exception is immunoproliferative enteropathy of basenjis [16], in which globulin concentrations increase as part of an immune response. Similar immunoproliferative enteropathies with hyperglobulinemia may occur in other breeds of dogs, especially German shepherds.

6. Prolonged coagulation times – prothrombin time (PT), prolonged activated partial thromboplastin time (APTT), and prolonged activated clotting time (ACT) caused by vitamin K deficiency may be seen in animals with malabsorption syndrome. A suspected vitamin K–deficient bleeding syndrome has been reported in cats with malabsorption syndrome. Malabsorption of vitamin K, which is a fat-soluble vitamin, probably plays an important role in this syndrome, but the vitamin K deficiency in such animals also is potentiated by secondary hepatic diseases, thereby resulting in decreased production of vitamin K–dependent clotting factors; possible antibiotic therapy, thereby altering small intestinal bacterial flora and reducing bacterially derived vitamin K_2 production; and in some cases, severe dietary fat restriction, thereby reducing vitamin K uptake still further, because it is dependent on fat absorption. Before these changes are seen, the activity of vitamin K–dependent clotting factors decrease to less than 35% of the reference interval by which time these animals are markedly deficient and should receive parenteral vitamin K supplementation [176].

Specific gastrointestinal disease syndromes

Antibiotic responsive diarrhea (ARD)/enteropathy – formerly known as small intestinal bacterial overgrowth (SIBO) [6, 7]

SIBO was a syndrome that described animals with chronic GI disease that responded to antibiotic therapy [177]. These dogs were shown to have similar numbers of bacteria in their GI tracts to dogs with EPI, response to steroids or food trials, and normal dogs [6]. These animals may show histologic evidence of lymphocytic-plasmacytic IBD, and German shepherd dogs appear to be predisposed [9]. Patients with chronic or intermittent diarrhea are retrospectively diagnosed with this syndrome if they respond to a specific antibiotic such as Tylosin [178] (dogs usually respond within 3 days), doxycycline, oxytetracycline, or metronidazole [26, 178].

Gastrointestinal disease in working dogs

The most common manifestations seen in working dogs are vomition, diarrhea, and gastric ulceration. These can be associated with metabolic disease or can be psychological. Protracted physical exertion is associated with hyperthermia and oxidative stress [179] with production of reactive oxygen species, which increases intestinal permeability [180]. The energy requirement in these dogs is high and diets are usually high in fat, which is associated with maldigestion and malabsorption. As a consequence, bacterial flora is disturbed and there is inflammation of the mucosa and liquefaction of feces [181].

Chronic diarrhea in cats

The most common causes for chronic diarrhea in cats are parasites (especially protozoal infections), lymphoma, IBD, food hypersensitivity and hyperthyroidism. Intestinal lymphoma is the most common neoplastic condition in cats [182]. FNA of thickened intestines and or histopathology with immunocytochemistry or immunohistochemistry is required for diagnosis of lymphoma. Small intestinal

lymphoma is most commonly small cell, T phenotype. Progression of the tumor can result in thickening of the gut wall, intestinal perforation and peritonitis. In the early stages of disease differentiation from IBD is necessary, but chronic IBD can progress to lymphoma in later stages of the disease. PCR for clonality is required [183].

Inflammatory bowel disease [36, 37]

IBD is defined as chronic persistent to intermittent inflammation of the GI tract, manifesting as chronic small intestinal diarrhea, and /or vomition (small animals), and/or weight loss, with accompanying alterations in the gut flora and changes in the mucosa associated bacteria (dysbiosis) [39], along with immune dysregulation and irregularities of pro- and anti-inflammatory cytokines and chemokines [39, 184, 185]. Dogs may show abnormal behavior [26].

There are canine breed predispositions to a number of IBD phenotypes [22], including antibiotic-responsive diarrhea [6, 7]/enteropathy, cobalamin deficiency [11, 40], gastric carcinoma [26], gluten sensitive enteropathy [28, 30], granulomatous colitis [26], lymphangiectasia [41, 42] and PLEs [29, 41, 43]. These are referred to in Tables 29.1 and 29.2. In cats the inflammation can extend to the liver and pancreas causing triaditis. Malabsorption may also be involved with a ravenous appetite and significant weight loss [186].

Because of the variety of potential etiologies (including idiopathic), the histopathological diagnoses should not be regarded as the diagnostic endpoint. There are a number of different breed predilections and phenotypes of IBD, and diagnosis is multifactorial (including histopathological findings that may represent the culmination of many different diseases) [36].

Infectious disease

Infectious disease should be considered in cases of a histopathological description of granulomatous or pyogranulomatous inflammation. Organisms involved include bacteria (*E. coli* [187], *Campylobacter*, *Streptococcus, Yersinia*, and *Mycobacteria*) [56], algae (*Prototheca*) [45, 55], or fungal infections (*Histopaslma*). Culture, PCR (16S rRNA amplification), or canine microbiota dysbiosis index may aid in further evaluation in these cases. *Campylobacter jejuni, C. coli,* and *C. upsaliensis* can be seen in large and small animals with diarrhea and healthy animals [155]. Shedding of *Campylobacter* is 2× higher in young dogs with diarrhea than healthy dogs [156]. Treatment with antibiotics usually prolongs shedding, as these infections are usually self- limiting.

In cats other differentials that need to be ruled out include hyperthyroidism, EPI, liver disease, lymphoma, giardiasis and other parasites, viral disease (FeLV, FIV, FIP), adenocarcinoma [26, 27] and lymphoma [16].

Eosinophilic infiltrates

Eosinophilic infiltrates are generally associated with hypersensitivity – allergic (dietary) or parasitic disease, but environmental triggers and genetics may also play a role [86]. GI tract thickening with small intestinal diarrhea, vomition, and weight loss are common manifestations, although large intestinal signs may also be seen. Animals may or may not have peripheral eosinophilia. Other disease processes with similar findings on CBC include Addison's disease (dogs), intestinal mast cell tumors (dogs and cats), lymphoma, and endoparasites.

Eosinophilic infiltrates in horses are part of the IBD syndrome [21, 84] and are characterized by several specific conditions. Eosinophilic enteritis (EE) is associated with eosinophilic and lymphocytic infiltrates. Idiopathic focal eosinophilic enteritis (IFEE), which involves the small intestine mainly in young horses <5 years of age, is associated with an eosinophilic-macrophage infiltrate with fibrous focal lesions causing obstruction. Eosinophilic colitis is also a disease of young horses with eosinophilic infiltrates into left dorsal colon, also with fibrous bands causing impaction. Carbohydrate tests may be abnormal. Multisystemic eosinophilic epitheliotropic disease (MEED) [21] is seen in horses >5 years of age, and is characterized by eosinophilic infiltrates of skin, liver, pancreas, lungs, and large intestine. Blood work and carbohydrate tests may be normal, but rectal biopsies may be diagnostic. Prognosis is poor.

Lymphoplasmacytic enteropathies

Lymphoplasmacytic enteropathies are the most commonly described PLEs (IBDs – see Tables 29.1 and 29.2) even though this diagnosis is controversial as healthy dogs [188] and cats [189] have similar numbers of lymphocytes and plasma cells as compared with affected animals. The World Small Animal Veterinary Association has made significant headway in defining this in the Gastrointestinal Standardization Group 2008 publication [109]. Dogs with chronic enteropathy that have low albumin [37] or cobalamin [190] have been shown to have a guarded prognosis, and hypokalemia in cats is also associated with a poor outcome. In horses, PLE, anemia, and abnormal carbohydrate absorption tests are inconsistent findings, and as for small animals, lymphoplasmacytic infiltrates from rectal mucosa are nonspecific and can be seen in normal or disease states of any age but are regarded as possible precursors to gastrointestinal malignant lymphoma. If biopsies are suggestive of lymphoma, PCR should be undertaken to determine clonality.

Granulomatous enteropathies [83]

Granulomatous enteropathies are seen in young horses (<4 years of age) and may be associated with mycobacteria, with accompanying skin and coronary band lesions, anemia, and PLE. Carbohydrate absorption tests are abnormal, and rectal biopsies may be diagnostic.

Lymphangiectasia [41, 42]

The majority of these animals have significant PLE, which is usually associated with chronic diarrhea and vomition,

weight loss, ascites, and chylothorax. The Norwegian Lundehund [42] and Yorkshire terrier are overrepresented, and soft-coated Wheaten terriers appear to be predisposed. Associated serum biochemical changes include hypoproteinemia (albumin and globulins), with associated hypocalcaemia (40% total calcium is albumin bound), hypocholesterolemia, hypomagnesemia (vitamin D deficiency) [191], hypokalemia and hypochloremia, (vitamin D deficiency) [191], and the leukogram may show lymphopenia.

Chronic vomition

There are numerous potential underlying causes including obstruction, inflammation, drugs, metabolic and endocrine disease, toxins, neurological and numerous miscellaneous causes. Clinical pathology workup should include a full CBC, chemistry (with electrolytes), urinalysis, fecal examination, PLI (feline or canine), paired bile acids, serum B_{12} and folate, FeLV, FIV in cats, and T4 in cats older than 4 years of age (approximately 40% of hyperthyroid cats vomit chronically) [192]. A coagulation profile is indicated if there is hematemesis.

Chronic weight loss

More than 10% loss of body mass is clinically significant and >20% constitutes emaciation [75]. The most common causes of weight loss include decreased food intake or poor quality food, and systemic disease such as the various causes of PLE, PLN, and infiltrative intestinal disease including IBD and neoplasia. Other metabolic causes include renal, liver, pancreatic disease, and some endocrine disorders such as diabetes mellitus and hypoadrenocorticism (Addison's disease). Cardiovascular disease can result in cardiac cachexia (myo-, endo-, or pericarditis), and infectious causes include *Borrelia*, *Dirofilaria*, or *Trypanosoma*. Maldigestion and malabsorption is associated with IBD, antibiotic responsive diarrhea (SIBO), EPI and endoparasitism to name a few.

Pyrexia concurrent to weight loss occurs with a number of inflammatory, infectious (viral, bacterial, ehrlichial or rickettsial, systemic fungal), immune mediated (SLE, polyarthropathy) and intestinal neoplastic diseases (adenocarcinoma, lymphoma and leiomyosarcoma) [26]. Other SI tumors reported in dogs include fibrosarcoma, mast cell tumors (Maltese predisposed) [169] extramedullary plasmacytomas, and in cats, MCT, hemangiosarcoma [193], extraskeletal osteosarcomas [194].

Acute gastritis and enteritis

These are commonly caused by dietary indiscretion or hypersensitivity [195] but can also be associated with IBD, eosinophilic (idiopathic eosinophilic gastrointestinal masses, Rottweilers predisposed [19, 20], scirrhous eosinophilic gastritis/feline GI eosinophilic sclerosing fibroplasia), [196] lymphoplasmacytic (hyperplasia, atrophy, [41] parasites) or granulomatous [45] IBD or infectious agents including *Cryptococcus, Entamoeba, Histoplasma, Heterobilharzia americana* (causes hypercalcemia) [197], *Prototheca,* pythiosis, and *Neorickettsia*. Histiocytic ulcerative colitis (granulomatous colitis) in boxers is associated with *E. coli* [35, 187]. Feline infectious peritonitis (FIP) can cause granulomatous colitis and lymphadenitis.

Gastritis in horses is associated with a number of syndromes including equine gastric ulcer, glandular, and squamous ulcer syndrome. There are no specific diagnostic clinical pathology tests for these syndromes and gastroscopy is used for diagnosis. *Gasterophilus* can also cause gastritis, and diagnosis is difficult – larvae may been seen in feces or bot eggs on the hair.

Acute enteritis in horses (including duodenitis-proximal jejunitis [198] seen in horses >1.5 years of age) can be associated with infectious causes such as bacteria (*C. difficile* and *perfringens, E. coli* [187], *Salmonella)*. *C. difficile* produces toxins A and B, which can be detected in feces. Viral enteritis is associated with rotavirus (foals) and coronavirus (adults) [94]. Acute bacterial enteritis can be associated with gastric reflux, and culture and PCR may be useful to diagnose a specific etiological agent.

Chronic enteritis is associated with equine proliferative enteropathy (*Lawsonia intracellularis* [87] (foals 4–7 months of age, affecting ileum and jejunum, with significant PLE) [89], *Rhodococcus hoagii* (young horses)), granulomatous (mycobacteria), and eosinophilic infiltrates. Abdominal effusion with a predominance of neutrophils with high protein and lactate content can be seen with strangulating lesions (higher than seen with infectious causes). Neutrophilic inflammation is usually associated with gastric ulceration that can be seen with irritation (foreign material), hormone secretions, or ulcerogenic drugs (including NSAIDs and steroids) [44].

Gastric neoplasia is relatively uncommon in small animals. Gastric lymphoma in cats and gastric carcinoma is the most common in dogs [43, 199].

Chronic gastritis

Chronic gastritis is a vague syndrome that may be associated with parasitism, metabolic or immune mediated disease or can be idiopathic, and is considered to be part of the IBD syndrome.

Colitis

In dogs and cats colitis is associated with large intestinal diarrhea, often with mucus and hematochezia [26]. Various causes of acute colitis include toxins (including drugs), foreign bodies, diet, and *Trichuris* infection (dogs). Chronic colitis is associated with IBD. *Cl. perfringens* infection with enterotoxin type A [200] is associated with both acute and chronic colitis. Diagnosis can be made using a Tox A/B II ELISA Kit (TECHLAB, Blacksburg, Virginia, USA). Diagnostic usefulness of culture and PCR are limited due

to high prevalence in normal dogs [201]. Other infectious causes of chronic colitis are less common [26].

In horses, colitis involves colon and/or cecum (typhlitis), and is seen in horses average age 2–10 years. It can be acute or chronic, infectious or noninfectious. Infectious causes include various bacteria such as *Clostridium difficile* and *perfringens* [201], *E. coli, L. intracellularis*, *Neorickettsia risticii* (Potomac horse fever), *Salmonella,* rotavirus (foals) and coronaviruses, and small strongleyes [202]. Noninfectious causes include antibiotic responsive diarrhea, dietary, IBD, neoplasia, plant and drug toxicity (including NSAIDs), and sand impaction. NSAIDs can cause ulceration throughout the gut, but a right dorsal colitis [203] has been described using appropriate doses for less than a week [204] Clinicopathological findings of anemia with hypoproteinemia and hypocalcemia are typical although nonspecific. Occult blood testing is useful if there is no overt hematochezia or melena. Diagnostic workup should include routine CBC and chemistry, serum amyloid A, fecal testing for occult blood, specific bacterial culture, fecal examination for parasites, and PCR/ELISA testing.

Intestinal neoplasia

Gastrointestinal lymphoma is the most commonly diagnosed tumor in dogs and cats [171, 182]. Neoplasia of the intestines includes lymphoma, leiomyomas and sarcomas (now known as GI stromal tumors), mast cell tumors, plasmacytomas, rectal ganglioneuromas, neurilemomas, and carcinoids [26, 205]. Large intestinal tumors in dogs include carcinoma in situ and adenomatous polyps. Adenocarcinomas predominate in cats.

Laboratory Evaluation of Plasma and Serum Proteins

Robin W. Allison

Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

Laboratory evaluation of plasma and serum protein concentrations is a part of both basic hematology and biochemistry testing in animals. Protein alterations occur commonly as secondary changes in a large number of diseases and may be the major abnormal finding in a few disease processes. Measurement of plasma or serum protein concentrations often yields important information that can be helpful in narrowing the list of diseases to be considered and, in some cases, in revealing the presence of a specific disease. This chapter discusses the types of proteins that are normally present in plasma and serum, the methods for analyzing these proteins, and the significance of abnormal protein concentrations.

Classification of plasma proteins

The two major types of proteins in plasma are albumin and the globulins. Albumin is one of the smallest of these proteins and the single most abundant, accounting for approximately 75% of the oncotic pressure (colloidal osmotic pressure) of plasma within the vasculature, which prevents water from diffusing from the blood into the tissues [1]. Albumin is an important carrier protein and plays a role in the transport of free fatty acids, bile acids, bilirubin, calcium, hormones, and drugs [2]. Albumin is synthesized by the liver, enters the blood, and is catabolized by most tissues. The half-life of a circulating albumin molecule varies in different species, ranging from approximately 8 days in dogs to approximately 20 days in horses [3, 4].

Globulins are a heterogeneous group of proteins that are variable in size but usually larger than albumin. Hundreds of different types of globulins are present in plasma, including the immunoglobulins (e.g., IgG, IgM, IgA), complement proteins, clotting factors, many different enzymes, and a variety of proteins that carry lipids, vitamins, hormones, extracellular hemoglobin, and metal ions (e.g., iron, copper) [1]. The majority of the globulins are produced in the liver, with the exception of immunoglobulins (antibodies) that are produced in lymphoid tissues. Globulins typically are classified as alpha, beta, or gamma on the basis of their electrophoretic mobility. (The separation and measurement of these globulins are discussed later.) A relatively small number of globulins are present in sufficient quantities to affect the electrophoretic pattern. Some of the major contributors to each fraction are listed below.

The alpha globulin fraction includes α_1-fetoprotein, α_1-acid glycoprotein (seromucoid), α_1-antitrypsin (protease inhibitor), α_1-antichymotrypsin (protease inhibitor), α_1-lipoprotein (HDL; transports lipid), ceruloplasmin (transports copper), haptoglobin (binds hemoglobin), α_2-macroglobulin (protease inhibitor), and serum amyloid-A [5, 6]. The beta globulin fraction includes β_2-lipoprotein (LDL; transport lipids), transferrin (transports iron), ferritin (iron storage), complement components (C3 and C4), and fibrinogen (in plasma but not serum) [5, 6]. Immunoglobulin molecules of the IgM and IgA type occasionally migrate in the beta fraction. The gamma globulin fraction is composed primarily of immunoglobulins (all types). These proteins are produced by plasma cells in the lymphoid tissues in response to antigenic stimulation. C-reactive protein migrates in this fraction in dogs but migrates between the beta and gamma fractions in horses [7, 8].

Acute phase proteins

Concentrations of a number of plasma proteins change significantly during the acute systemic response to inflammation; collectively these proteins are referred to as acute-phase proteins (APP). The acute-phase response occurs due to release of a variety of cytokines (e.g., IL-1, IL-6, and TNF-α) from the site of inflammation [9]. These cytokines affect the production of APP by the liver. The plasma concentrations of most APP increase; these proteins are called positive APP, and they generally reach maximal

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

Companion website: www.wiley.com/go/thrall/veterinary

serum concentrations within a day or two after initiation of the response. Concentrations of some APP actually decrease; these are called negative APP. The specific pattern and magnitude of protein alterations during the acute-phase response is species-specific; however, the concentration of serum albumin (a negative APP) is consistently decreased by 10–30% [10]. Transferrin, measured in serum as the total iron-binding capacity (TIBC), is another negative APP. The positive APP are globulins; important ones in veterinary species include haptoglobin, fibrinogen, C-reactive protein, serum amyloid-A, and α_1-acid glycoprotein [9, 10]. Serum amyloid-A is a major APP of dogs, cats, pigs, and horses; haptoglobin is a major APP of cattle, sheep, and pigs; C-reactive protein is a major APP of dogs, horses, and pigs.

Measurement of plasma and serum proteins

Plasma versus serum

The two types of samples commonly used for clinical biochemistry analyses are plasma and serum. Plasma is the liquid portion of blood that has not clotted, thus the blood must be collected in an anticoagulant. Plasma contains all of the proteins described earlier. Serum is the liquid portion of the blood that remains after clotting. When a blood sample is collected without use of an anticoagulant, the subsequent clotting in that sample results in the conversion of all fibrinogen to fibrin. Therefore, serum is devoid of fibrinogen but contains albumin and the remaining globulins.

Total protein concentration

The total plasma or serum protein concentration can be estimated using a refractometer. Protein molecules in plasma or serum increase the refractive index of that fluid in proportion to their concentration. However, there are other molecules potentially present in plasma or serum that can increase the refractive index and artifactually increase the estimated protein concentration. Substances most likely to cause significant interference include lipoproteins (such as in lipemic serum), cholesterol, urea, and glucose [11]. Note that marked elevations in cholesterol concentrations will not result in visible lipemia but can artifactually increase the protein estimate. Plasma protein may be falsely increased by 0.6 g/dL by serum urea concentrations of 300 mg/dL or glucose concentrations of 700 mg/dL [5]. Synthetic colloid solutions, sometimes given as volume expanders, will artifactually increase the refractometer estimate of total protein. Hyperbilirubinemia and hemolyzed serum typically do not interfere with the total protein estimate, although hemolysis may obscure the line of demarcation on the refractometer [11].

The total protein concentration of serum is measured routinely in reference laboratories by spectrophotometry, most commonly the biuret method, which detects peptide bonds and is considered very specific. The serum total protein concentration obtained by this method will be less than the plasma protein estimation from a refractometer, due in part to the absence of fibrinogen from serum. Differences in protein measurements performed by different methods (refractometry versus spectrophotometry) should be expected, even for the same type of sample. In avian species, marked differences in total protein concentrations have been found depending upon the methodology used, with lower values determined with the biuret method versus refractometry [12, 13]. Use of method and species-specific reference intervals are necessary for accurate interpretation [14].

Albumin concentration

The albumin concentration is routinely measured spectrophotometrically using dye-binding methods, usually with bromcresol green (BCG). However, BCG is not specific for albumin and may bind to some globulins. As a result, the BCG method may overestimate the albumin concentration when it is very low (<1 g/dL). Other dye-binding methods sometimes used in human laboratories (BCP, HABA methods) are unreliable for accurate measurement of albumin concentrations in animals due to species variations. Albumin concentrations measured by the BCG method may be overestimated as much as 1.2 g/dL in canine heparinized plasma samples compared to serum samples, especially when fibrinogen concentrations are increased; this interference may be eliminated by changes in the specific method protocol [15]. In avian species, albumin concentrations measured by the BCG method often correlate poorly with results obtained by electrophoretic methods (discussed later) [13, 16, 17].

Globulin concentration

Calculated globulin concentration

The serum total protein and albumin concentrations are measured routinely as part of serum biochemical profiles. The globulin concentration as reported on these profiles is not measured, however, but rather is calculated by subtracting the serum albumin concentration from the total protein concentration.

Serum protein electrophoresis

Both serum albumin and globulin concentrations can be determined by serum protein electrophoresis (see Chapter 1). Electrophoresis is performed by placing a small amount of serum near one end of a supporting substance such as cellulose acetate or agarose gel. An electrical current is applied, causing the serum proteins to migrate at variable rates as determined by the net negative charge and size of each type of protein. Staining of the gel reveals the various protein bands, which are then scanned by a densitometer to produce an electrophoretogram (i.e., a hard copy depiction of the distribution of the proteins) (Figure 30.1).

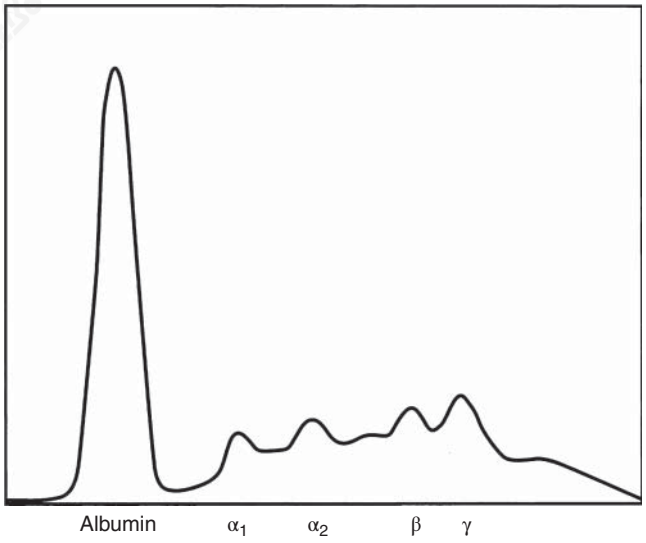

Figure 30.1 An electrophoretogram from a serum protein electrophoresis separation.

Modern scanning densitometers also calculate the concentration of protein in each fraction after the operator inputs the total protein concentration of that sample. This method separates globulins into several fractions, including alpha, beta, and gamma globulins. Albumin and globulin concentrations that are derived using this method do not necessarily match those obtained using spectrophotometric methods. The number of fractions separated by serum protein electrophoresis varies both with the species and with the type of supporting substance used; high resolution agarose gels are capable of resolving more protein fractions than low resolution agarose or cellulose acetate gels. Albumin and the alpha, beta, and gamma globulin fractions can be separated in specimens from all species with all types of support substances. In some species, the alpha, beta, and gamma globulins are separated into alpha$_1$ and alpha$_2$, beta$_1$ and beta$_2$, or gamma$_1$ and gamma$_2$ fractions, respectively. (Causes for altered concentrations of these protein fractions are discussed later.)

A relatively new type of electrophoresis, capillary zone electrophoresis, is now being used with animal sera [18–20]. In this method protein fractions are separated in solution within a narrow-bore capillary exposed to high voltage. No staining of proteins is required; protein fractions are detected and quantified by ultraviolet light absorbance. Potential advantages of capillary zone electrophoresis include smaller sample size, better resolution and reproducibility, and the ability to automate the procedure. The visual appearance of the electrophoretogram produced by this method differs from that of traditional methods, and quantitative results may also differ. In particular, peaks that appear polyclonal with agarose gel electrophoresis may appear monoclonal or biclonal with capillary zone electrophoresis [21]. Thus experience and method-specific reference intervals are necessary for proper interpretation of results [22].

Qualitative and semiquantitative estimation of immunoglobulin concentrations

Several different types of rapid screening tests for the estimation of immunoglobulin concentrations are available. These tests can be performed in clinical practice, and they can provide qualitative or semiquantitative estimates of immunoglobulin concentrations. They primarily are used to screen neonates (especially calves, foals, and crias) for possible failure to ingest colostrum or to absorb immunoglobulins from colostrum; this failure results in increased susceptibility to infection and is referred to as failure of passive transfer (FPT). These tests are not as sensitive or specific as more sophisticated tests such as radioimmunodiffusion (RID; considered the gold standard), but the results are usually available immediately and allow for treatment decisions to be made without delay. Results are most valid as indicators of adequate passive transfer or FPT when tests are performed within a few days of birth. General guidelines have been established for minimum IgG concentrations that that indicate adequate passive transfer; >800 mg/dL for foals and >1000 mg/dL for calves and crias [23–25].

Total protein measurement by refractometry

Immunoglobulins absorbed from colostrum are the major determinant of the total serum protein concentrations in neonates. Total protein concentrations in calves increase by approximately 2 g/dL after the ingestion of colostrum [26]. Measurement of the total protein concentration by refractometry, therefore, has been evaluated as an indicator of serum immunoglobulin concentration and as a gauge for the adequacy of passive transfer.

In calves, use of the serum total protein concentration as an indicator for the serum immunoglobulin concentration has been evaluated using different cutoff values or decision thresholds. A serum total protein concentration of 5.2 g/dL correlates with an IgG concentration of 1000 mg/dL and adequate passive transfer [24]. A decision threshold of either 5.0 or 5.5 g/dL classifies >80% of calves correctly, however sensitivity and specificity of these thresholds are different [24]. Sensitivity and specificity of the 5.0 g/dL threshold are 0.59 and 0.96, respectively, indicating few normal calves would be incorrectly classified as FPT (false positives). Sensitivity and specificity of the 5.5 g/dL threshold are 0.94 and 0.74, respectively, indicating few calves with FPT would be incorrectly classified as normal (false negatives). Because many sick calves with FPT are also dehydrated, which results in a relative hyperproteinemia, the higher decision threshold may be more appropriate for those individuals [27].

In crias, one study found that serum total protein concentrations of <4.5 g/dL measured by refractometer indicated FPT, and concentrations >5.5 g/dL indicated adequate

passive transfer; however, concentrations between those values could not be accurately interpreted [28].

In foals, using the serum total protein to estimate IgG concentrations appears to be unreliable and is not recommended as a sole indicator of FPT [23]. The poor performance of serum total protein might result, in part, from wide variations in precolostral protein concentrations in foals.

Turbidity and coagulation assays

These tests are based on the ability of different substances to either precipitate or form insoluble complexes with serum immunoglobulins. Solutions used in these assays can be made in the clinic or purchased in kit form from several different manufacturers. In general these are inexpensive and rapid assays that are easy to perform, but sensitivity and specificity for the diagnosis of FPT varies considerably when different cutoff values are used. Additionally, because assessment of the degree of turbidity or coagulation present is subjective, results can vary between users.

- *Sodium sulfite precipitation test* [29]. The sodium sulfite precipitation test is based on the fact that immunoglobulins can be selectively precipitated from serum using concentrations of anhydrous sodium sulfite ranging from 14% to 18%. A higher sodium sulfite concentration is required to cause precipitation in serum containing lower immunoglobulin concentrations. Sera with very low immunoglobulin concentrations do not undergo precipitation when mixed with any sodium sulfite solutions in the 14–18% range. Fibrinogen also is precipitated by these concentrations of sodium sulfite; thus serum, rather than plasma samples, should be used. This test is useful for calves and crias but does not work well for foals [24, 25, 30, 31]. A procedure for performing the sodium sulfite precipitation test in ruminants is presented in Appendix 30.1; test kits are also commercially available (Bova-S and Llama-S, VMRD, Inc. Pullman, WA). In this test, the immunoglobulin concentration is determined by judging the presence or absence of precipitation in three concentrations of sodium sulfite: 14%, 16%, and 18%. The test can distinguish three ranges of immunoglobulin concentrations: <500 mg/dL, 500–1500 mg/dL, and >1500 mg/dL. Using the <500 mg/dL limit makes the test more specific for detecting FPT (e.g., calves negative for precipitation are likely to have FPT) but less sensitive for detecting FPT (e.g., will miss some calves with FPT). Using the 1500 mg/dL limit makes the test more sensitive for detecting FPT but reduces the specificity (e.g., will indicate FPT in calves with adequate transfer of immunoglobulin). Using the <500 mg/dL limit appears to correctly predict the highest percentage of calves with FPT (~86%); thus some recommend using only the 18% sodium sulfite solution [27].
- *Zinc sulfate turbidity test* [31, 32]. Immunoglobulins are precipitated from serum by zinc sulfate over a wide range of zinc sulfate concentrations. This test is most useful in calves; a procedure is presented in Appendix 30.2. Like the sodium sulfite precipitation test, a positive reaction (i.e., turbidity) in sera with low immunoglobulin concentrations occurs when a solution with a high zinc sulfate concentration is used, but not when a solution with a low zinc sulfate concentration is used. In sera with high immunoglobulin concentrations, turbidity occurs when zinc sulfate solutions of lower concentrations are used. Thus, different sensitivities and specificities for detecting FPT result when different concentrations of zinc sulfate are used (see Appendix 30.2). The highest proportion of calves correctly classified as having FPT (i.e., true immunoglobulin concentration <1000 mg/dL) occurs when either 350 or 400 mg/L concentrations of zinc sulfate are used (83% and 88% correctly classified, respectively) [32]. The actual concentrations most appropriate for this test depend on whether high sensitivity or high specificity is most important in the specific situation. A procedure for the zinc sulfate turbidity test in foals is presented in Appendix 30.3; commercial kits are also available (Equi-Z, VMRD Inc., Pullman, WA). Observing any visible turbidity in the reaction solution after 1 hour of incubation is a good indication that the foal has a serum immunoglobulin concentration of >400 mg/dL. This procedure, however, does not distinguish foals with immunoglobulin concentrations of between 400 and 800 mg/dL, which are considered evidence for partial FPT. Correlations between zinc sulfate turbidity results and those of more specific tests for immunoglobulin concentrations in foals are not strong.
- *Glutaraldehyde coagulation test* [33, 34]. The glutaraldehyde coagulation test is based on the ability of glutaraldehyde to form insoluble complexes with immunoglobulins, resulting in coagulation of the test mixture. Glutaraldehyde also forms insoluble complexes with fibrinogen; therefore, serum rather than plasma is preferred. This test has been evaluated in neonatal calves and foals. A procedure for this test in ruminants is presented in Appendix 30.4; commercial kits previously available (Gamma-Check®-B, Plasvacc USA Inc., Templeton, CA) were unreliable when used with whole blood [35]. In neonatal calves, use of a 10% glutaraldehyde solution results in no coagulation in almost all calf sera with immunoglobulin concentrations of less than 400 mg/dL and complete or partial coagulation in almost all calf sera with immunoglobulin concentrations of greater than 600 mg/dL. Calves with immunoglobulin concentrations of between 400 and 600 mg/dL have results that vary from no coagulation to complete coagulation. However, the accepted cutoff limit for adequate passive transfer in calves is 1000 mg/dL, thus this test has poor sensitivity (FPT in calves with immunoglobulin concentrations between 400 and 1000 mg/dL will not be identified). A procedure for performing the glutaraldehyde coagulation test in foals is presented in Appendix 30.5; a commercial kit is also available (Gamma-Check-E, Plasvacc USA Inc., Templeton, CA). In horses, FPT is defined as serum IgG concentrations <200 mg/dL, and partial FPT occurs at serum IgG concentrations of 200–800 mg/dL [23].

The glutaraldehyde coagulation test distinguishes three ranges of immunoglobulin concentrations: >800 mg/dL, 400–800 mg/dL, and <400 mg/dL. Reported sensitivities and specificities for detection of IgG concentrations <400 mg/dL have ranged from 95% to 100% and 80% to 89%, respectively [23, 36]. For detection of IgG concentrations <800 mg/dL, sensitivities and specificities have ranged from 93% to 100% and 59% to 94%, respectively [36, 37]. Lower test specificity using the 800 mg/dL cutoff value indicates a greater chance of false-positive results (diagnosing FPT in a normal foal), suggesting the need for additional confirmatory tests prior to treatment.

Antibody-based detection kits

A number of manufacturers have developed commercial kits for detection of FPT in foals and calves that use antibody-based methods (e.g., latex agglutination, enzyme-linked immunoassays). Examples include the Quick Test® calf or foal IgG kits (Midland Bio-Products, Boone, IA), Foalcheck® (Centaur, Overland Park, KS), and SNAP® Foal test (IDEXX Laboratories, Westbrook, ME). Accuracy, sensitivity, and specificity of these assays vary with the individual test and cutoff values [23, 37, 38]. These commercially available tests are not necessarily superior to the screening tests described earlier. To minimize false-negative results and ensure detection of a high percentage of animals with FPT, screening tests should have high sensitivity. In foals, the glutaraldehyde coagulation test may be equal or superior to commercially available semiquantitative tests in terms of sensitivity (depending on the cutoff value used) [36, 37]. However, more specific confirmatory tests may be desired in some situations.

Measurement of immunoglobulin concentrations by reference laboratories

Reference laboratories offer more sophisticated antibody-based methods for quantitating specific immunoglobulins (e.g., radial immunodiffusion, immunochemistry). Use of these methods is indicated when a detailed examination regarding the status of the immune system is desired. These methods are more expensive, however, and the results usually are delayed (incubation periods of 18–24 hours are required) compared with those of the screening methods discussed earlier.

Fibrinogen concentration

Plasma fibrinogen concentrations can be determined by two methods. One assesses the conversion of fibrinogen to fibrin in the presence of thrombin (thrombin time, Clauss method) and requires instrumentation that is somewhat expensive for routine use in clinical practice. Such measurement of plasma fibrinogen concentrations also requires citrated plasma that has been harvested from a mixture of nine parts fresh, whole blood and one part 3.8% sodium citrate anticoagulant. Special evacuated blood collection tubes containing sodium citrate anticoagulant are available for this purpose; these tubes draw the appropriate amount of blood to ensure a 9 : 1 ratio of blood to anticoagulant. This method is not routinely used to measure plasma fibrinogen concentrations but may be included in a coagulation profile.

A point-of-care method designed to measure equine fibrinogen using the Clauss method is also available (VetScan VS*pro* fibrinogen test cartridge, Abaxis, Inc.). One study concluded that the accuracy of this test compared to standard laboratory methods was acceptable, but there was greater variability in results when fibrinogen concentrations were increased [39].

In clinical practice situations, the most common method for measuring plasma fibrinogen concentration is heat precipitation. This method is less expensive than the method described earlier and requires minimal equipment; it is summarized in Appendix 30.6. The heat precipitation method provides an estimate of the plasma fibrinogen concentration that is adequate for evaluation of hyperfibrinogenemia but lacks the analytic sensitivity needed for evaluation of hypofibrinogenemia. (The significance of abnormal fibrinogen concentrations is discussed later.)

Abnormal protein concentrations

Both decreased and increased total protein concentrations are commonly detected laboratory abnormalities in animals. These findings may result from alterations in the albumin or globulin concentrations, or both. In plasma, an increased concentration of fibrinogen, which is a globulin, can occasionally produce an increased protein concentration. Interpretation of altered protein concentrations depends on determining which major protein constituents of the serum or plasma are abnormal. A decreased or increased albumin or globulin concentration does not always result in detectable alterations of the total protein concentration. Therefore, albumin and globulin as well as total protein concentrations should be assessed. Causes of decreased or increased total protein, albumin, globulin, and fibrinogen concentrations are summarized here. It is often helpful to consider alterations in albumin and globulin concentrations together for interpretation.

Causes of decreased protein concentrations

Decreased total protein concentrations can result from decreased concentrations of albumin, globulin, or both. A diagnostic algorithm for evaluating variations in these decreases is presented in Figure 30.2.

Hypoalbuminemia with hypoglobulinemia

Concurrent hypoalbuminemia and hypoglobulinemia can result from overhydration (e.g., excessive fluid therapy,

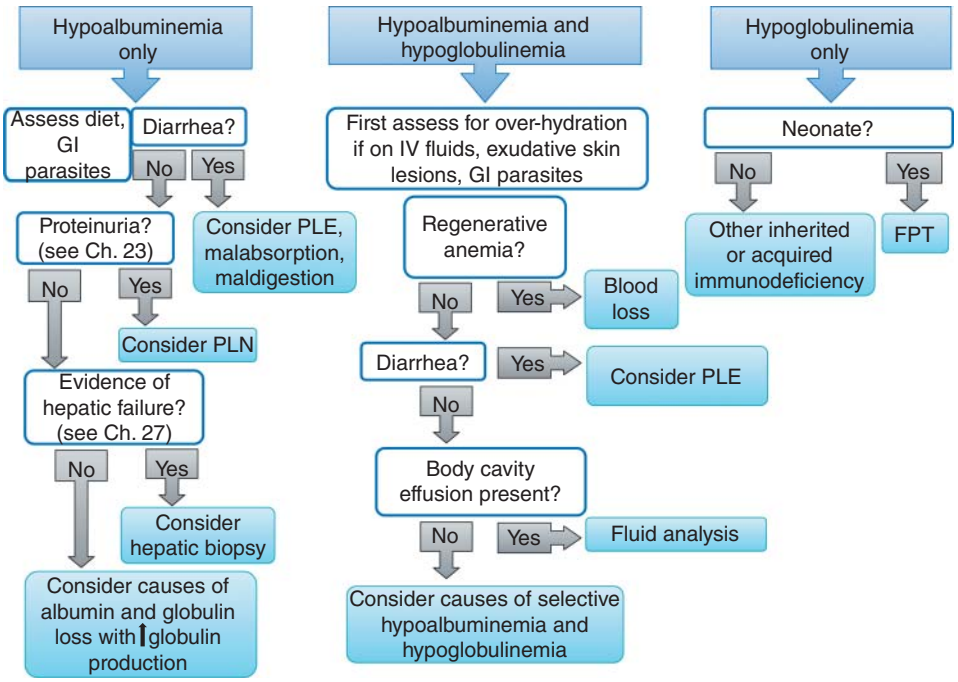

Figure 30.2 An algorithm for evaluation of decreased serum protein concentrations. FPT, failure of passive transfer; PLE, protein losing enteropathy; PLN, protein losing nephropathy. Refer to text for details.

excessive water intake) or from loss of both protein fractions. The latter occurs in the following disorders:

• Blood loss. This results in proportional loss of all blood constituents. Albumin and globulin, therefore, are lost in concentrations equal to their concentrations in the blood. After blood loss, fluid moves from the extravascular space to the intravascular space and dilutes the remaining blood constituents, including the proteins (and erythrocytes). It is important to remember that this water shift takes time to develop, and will not be evident for the first few hours following acute hemorrhage. Hypoproteinemia due to blood loss is generally caused by external (rather than internal) hemorrhage, and may also be caused by blood-sucking parasites (external or internal). Although protein concentrations may decrease with severe internal hemorrhage, such as might occur with a bleeding hemangiosarcoma, in cases of chronic internal hemorrhage the proteins are reabsorbed.

• Protein-losing enteropathy. This may result from a variety of generalized intestinal lesions, including inflammatory bowel disease, lymphangiectasia, infectious diseases, neoplasia, and gastrointestinal hemorrhage [40–42]. Hypoproteinemia can develop whenever protein leakage into the intestinal lumen exceeds the rate of protein synthesis. In some instances a concurrent immune response causes increased instead of decreased globulin concentrations; gastrointestinal lymphoma may also be associated with hyperglobulinemia [43].

• Severe skin disease. Generalized exudative skin disease or burns can result in loss of plasma proteins due to increased vascular permeability [44]. Concurrent immune responses may increase globulin concentrations.

• Effusive disease. This results in the accumulation of body-cavity fluids with high protein concentrations that can result in decreased serum albumin and globulin concentrations [5]. Such decreases depend on the degree of increased vascular permeability accompanying these disorders.

Selective hypoalbuminemia

Decreased albumin concentrations that are not accompanied by decreased globulin concentrations can result from either decreased production or increased loss of albumin. If the globulin concentration is concurrently increased, total protein concentration may be within the reference interval despite hypoalbuminemia.

Decreased production of albumin can occur in the following disorders:

• Hepatic failure. The liver is the site of albumin production. Because of the liver's reserve capacity, most types of liver damage do not result in decreased albumin production. If more than 60–80% of the functional liver mass is lost, however, decreased albumin production and hypoalbuminemia can occur. In such cases, other evidence of hepatic failure is also present (see Chapter 27). Serum globulin concentrations are not usually decreased because immunoglobulin production in lymphoid tissues is not hampered; globulin concentrations may actually be increased in patients with hepatic failure (discussed later).

• Starvation or cachexia. Marked malnutrition or starvation results in less hepatic protein production due to a deficiency of available amino acids. In cachectic states associated with neoplasia or chronic infections, a prolonged negative protein balance causes increased catabolism of body proteins that exceeds protein production. Body fat and muscle mass are lost in both cases, resulting in weight loss. Usually these conditions result in selective hypoalbuminemia; rarely there is concurrent hypoglobulinemia.
• Gastrointestinal parasitism. This can cause hypoalbuminemia by at least two mechanisms. If the parasites absorb significant amounts of nutrients, including amino acids, the animal is deprived of the amino acids needed to produce albumin. If the parasites attach to the gastric or the intestinal wall and consume the host's blood, albumin and globulin are lost. Gastrointestinal parasitism seldom results in a deficiency of amino acids that is severe enough to lead to hypoglobulinemia. Fecal examination for parasite ova is helpful in establishing the diagnosis of this potential cause of hypoalbuminemia.
• Intestinal malabsorption or maldigestion. Decreased albumin production can occur if intestinal malabsorption results in deficient absorption of amino acids. Animals with malabsorption syndrome often have a history of chronic diarrhea or loose stools. If malabsorption syndrome is considered a possible cause of hypoalbuminemia, tests to verify this syndrome should be performed (see Chapter 29).

Inadequate digestion of dietary proteins can result from exocrine pancreatic insufficiency (EPI), in which amino acids are not liberated by protein digestion in the intestine and, therefore, are not available for absorption, thus resulting in amino acid deficiency and decreased albumin production. Animals with EPI often have a history of chronic diarrhea or loose stools. If EPI is suspected, tests to verify this disease should be performed (see Chapter 29).
• Inflammation. Because albumin is a negative APP, albumin synthesis is decreased during acute inflammation. Globulin concentrations are typically mildly increased due to increased positive APP synthesis. Because albumin and globulin concentrations change in different directions, total protein concentrations may be within the reference interval.

Increased loss of albumin can occur in the following disorders:
• Glomerular disease. Because albumin molecules are small and more negatively charged than globulin molecules, they leak more readily through damaged glomerular membranes. Severe glomerular disease, therefore, can result in selective hypoalbuminemia. Both urinary protein concentrations and urinary protein:creatinine ratios will be increased in animals with glomerular disease [45, 46]. Glomerular disease may result in nephrotic syndrome, which is characterized by proteinuria, hypoalbuminemia, hypercholesterolemia, and edema and/or ascites. The combination of hypoalbuminemia and hypercholesterolemia that occurs with nephrotic syndrome (see Chapter 32) contrasts to the hypoalbuminemia and hypocholesterolemia that may be seen with liver failure and protein losing enteropathy (PLE).
• Gastrointestinal parasitism (discussed earlier).
• Diseases listed as being possible causes of hypoalbuminemia with hypoglobulinemia (discussed earlier). Loss of both albumin and globulin typically occurs with these diseases, but a concurrent immune response may cause increased production of globulins resulting in normal to increased globulin concentrations. These diseases also should be considered when hypoalbuminemia with normal to increased globulin concentrations are detected.

Selective hypoglobulinemia

Hypoglobulinemia in the absence of hypoalbuminemia usually results from a decreased beta or gamma globulin concentration. A decreased alpha globulin concentration alone does not result in a decreased globulin concentration. A selective decrease in beta or gamma globulin concentrations is usually due to a decreased immunoglobulin concentration. Such a decrease can occur in the following disorders:
• Failure of passive transfer. Ingestion of colostrum and absorption of immunoglobulins from colostrum are termed passive transfer. Because most animals are born with minimal immunoglobulin concentrations, this process plays an important role in transferring resistance to infection during the neonatal period. Failure to ingest colostrum or to absorb immunoglobulins from colostrum is termed FPT and is well documented in domestic animals [23, 25, 27]. Several screening tests are available to assess the adequacy of passive transfer (discussed earlier).
• Inherited or acquired immune deficiency. Immune deficiency involving B lymphocytes or plasma cells can result in low concentrations of immunoglobulins and, in some cases, hypoglobulinemia. Immune deficiencies resulting in low globulin concentrations have been reported in foals (e.g., severe combined immunodeficiency, selective IgM deficiency, Fell pony immunodeficiency, transient hypogammaglobulinemia, agammaglobulinemia) [23], calves (e.g., selective IgG2 deficiency, severe combined immunodeficiency, transient hypogammaglobulinemia) [5], and puppies (e.g., severe combined immune deficiency, selective IgA deficiency, selective IgM deficiency, selective IgA and IgG deficiency) [5].

Causes of increased protein concentrations

Increased total protein concentrations can result from increased concentrations of albumin, globulin, or both. An increased albumin or globulin concentration, however, does not always produce detectable increases in total protein concentrations. A diagnostic algorithm for evaluating the variations in these increases is presented in Figure 30.3. In clinical practice, serum protein electrophoresis is often

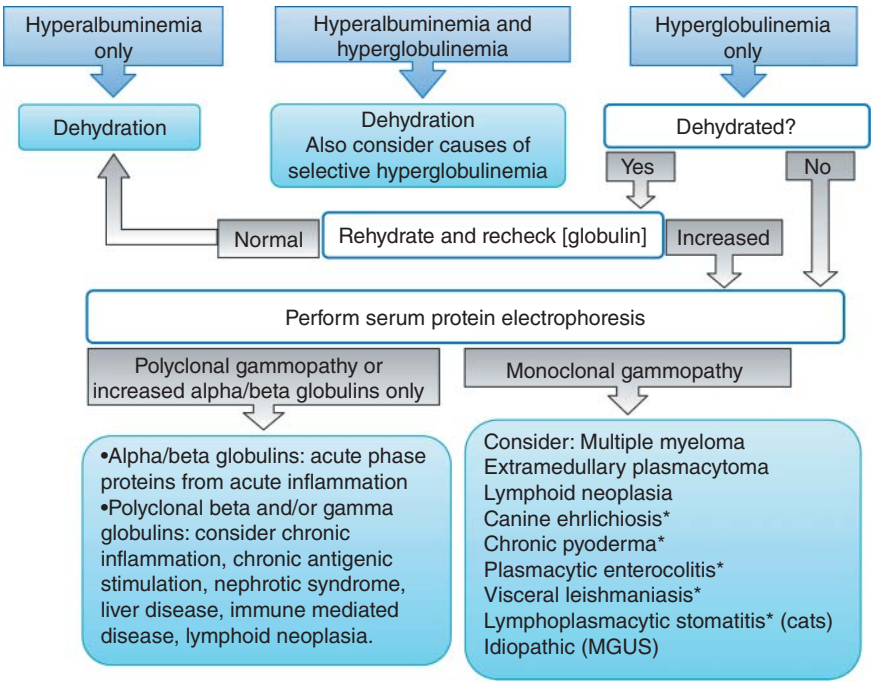

Figure 30.3 An algorithm for evaluation of increased serum protein concentrations. MGUS, monoclonal gammopathy of undetermined significance. *Typically causes polyclonal, not monoclonal, gammopathy. Refer to text for details.

reserved for patients with moderate to severe hyperglobulinemia (>5 g/dL), for which an underlying cause for inflammation or chronic antigenic stimulation has not been identified (discussed later).

Hyperalbuminemia

The primary cause of hyperalbuminemia in clinical patients is dehydration. Loss of plasma water results in a relative increase in albumin, which may be of sufficient magnitude to cause hyperproteinemia. Globulin concentrations also may be increased in some patients with dehydration (discussed later).

Rarely, administration of drugs (glucocorticoids) has been associated with mild transient hyperalbuminemia [47]. A single case report exists of hyperalbuminemia associated with hepatocellular carcinoma in a dog [48].

Hyperalbuminemia with hyperglobulinemia

Concurrent increases in albumin and globulin concentrations most commonly result from dehydration, which causes loss plasma water and a relative increase in both protein fractions. The albumin:globulin ratio is not altered, because both fractions are concentrated equally. The hematocrit is often increased as well (unless there was a preexisting anemia). Other potential causes of hyperglobulinemia should also be considered (discussed later).

Selective hyperglobulinemia

The significance of hyperglobulinemia depends on the magnitude and the type of globulin that is increased, which can be determined by serum protein electrophoresis. No matter what the underlying cause, mild to moderate hypoalbuminemia is often also present. Common disorders and typical electrophoretic patterns are discussed below.

Increased alpha/beta globulin concentrations

Acute/chronic inflammation: During acute inflammation, increased synthesis of APP causes hyperglobulinemia, which is generally mild. The APP are located in the alpha and beta globulin regions of the electrophoretogram (except for fibrinogen, which is absent from serum). There are numerous APP, and generally many of them must be increased in order to visualize an electrophoretic abnormality or result in hyperglobulinemia; however, fibrinogen or haptoglobin alone can be increased to a degree sufficient to cause hyperglobulinemia and an increase in total protein [5]. Because albumin is a negative APP, albumin concentrations usually decrease due to decreased hepatic production during acute inflammation. The magnitude of the decrease is usually <30% [10].

Increased gamma globulin concentrations

The gamma globulin fraction includes immunoglobulins of all types. Increases in gamma globulin concentrations are termed gammopathies. Gammopathies may be monoclonal or polyclonal, which may be distinguished presumptively on the basis of the width of the globulin peak in an electrophoretogram. Polyclonal gammopathies have broad-based peaks (i.e., wider than the base of the albumin peak, with a slope that is less steep than the albumin peak) on the electrophoretogram (Figure 30.4). These polyclonal peaks represent increased quantities of a mixture of immunoglobulin types

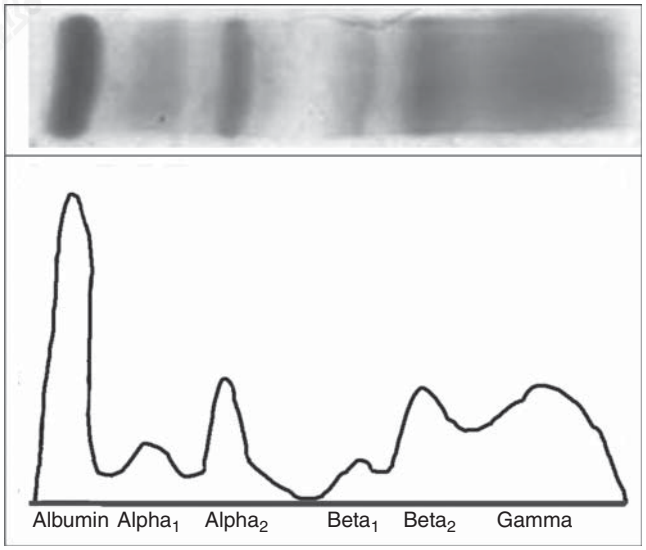

Figure 30.4 An electrophoretogram and corresponding gel from a dog with a polyclonal gammopathy. There is an increase in alpha$_2$-globulins and a broad-based peak in the beta$_2$ and gamma regions.

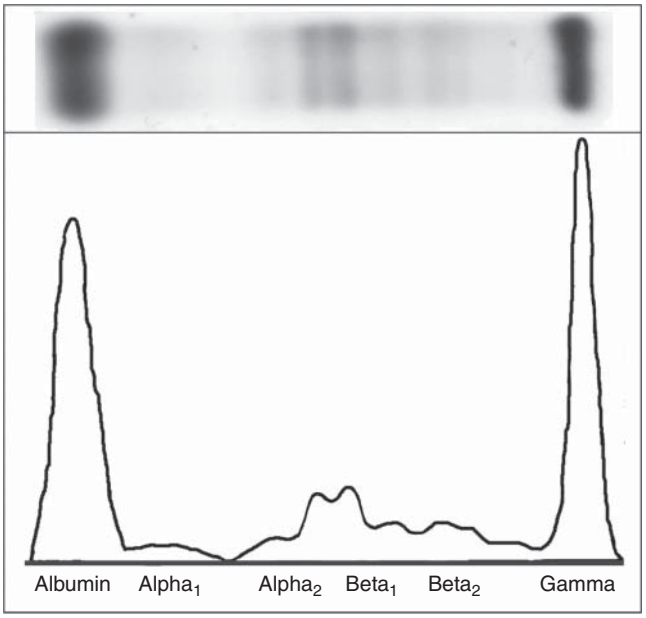

Figure 30.5 An electrophoretogram and corresponding gel from a cat with a monoclonal gammopathy due to multiple myeloma. There is a narrow-based peak in the gamma region; the corresponding monoclonal band is apparent on the gel.

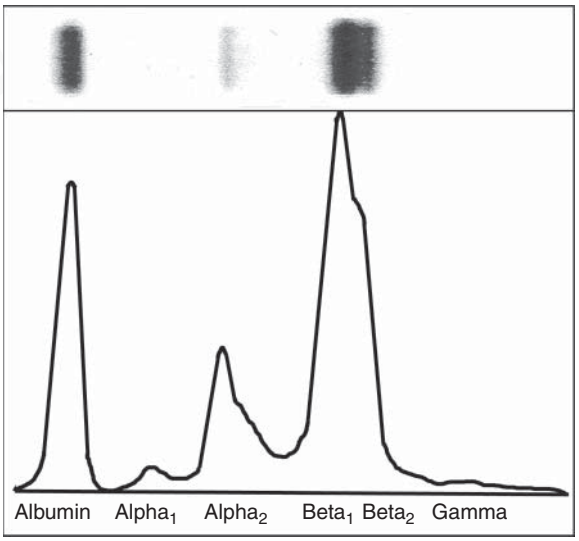

Figure 30.6 An electrophoretogram and corresponding gel from a dog with a suspect oligoclonal gammopathy. There is a steep peak with a narrow shoulder encompassing the beta$_1$ and beta$_2$ regions of the gel. The base is slightly wider than that of the albumin peak. Immunoelectrophoresis demonstrated that the majority of the immunoglobulin was IgA, most consistent with a monoclonal gammopathy caused by lymphoid neoplasia. The narrow shoulder may be caused by the presence of IgA dimers.

produced by a heterogeneous population of B lymphocytes, plasma cells, or both, each secreting its own immunoglobulin molecule specific for one particular antigen. Monoclonal gammopathies, however, have narrow-based peaks (i.e., similar in width to the base of the albumin peak, with a slope that is as steep or steeper than the albumin peak) on the electrophoretogram (Figure 30.5), and they result from increased production of a single type of immunoglobulin by a single clone of B lymphocytes or plasma cells. Proliferation of a single clone of lymphocyte results in overproduction of its specific immunoglobulin molecule.

Visually determining whether a peak is polyclonal or monoclonal is not always straightforward; peaks may be steep but slightly wider than the albumin peak (Figure 30.6). The term oligoclonal has been used to describe a polyclonal peak with a restricted migration pattern such that it appears narrow and monoclonal on an electrophoretogram [5]. Oligoclonal gammopathies may be difficult to distinguish from monoclonal gammopathies and have been recognized in animals with chronic infectious diseases [5, 20, 21]. When an oligoclonal gammopathy is suspected, characterizing the gammopathy with immunoelectrophoresis may be helpful. If the gammopathy is composed primarily of IgA or IgM, a monoclonal gammopathy due to neoplasia is most likely. If it is composed primarily of IgG, the gammopathy could be monoclonal or polyclonal.

Uncommonly, two narrow-based peaks may be seen on the electrophoretogram; this is termed a biclonal gammopathy (Figure 30.7). Biclonal gammopathies can occur when a single neoplastic clone produces immunoglobulin molecules that migrate separately. Examples include polymerization of immunoglobulin molecules (such as dimer formation), production of incomplete molecules (such as free light chains in addition to intact immunoglobulins), or production of an immunoglobulin that undergoes isotype switching [49, 50].

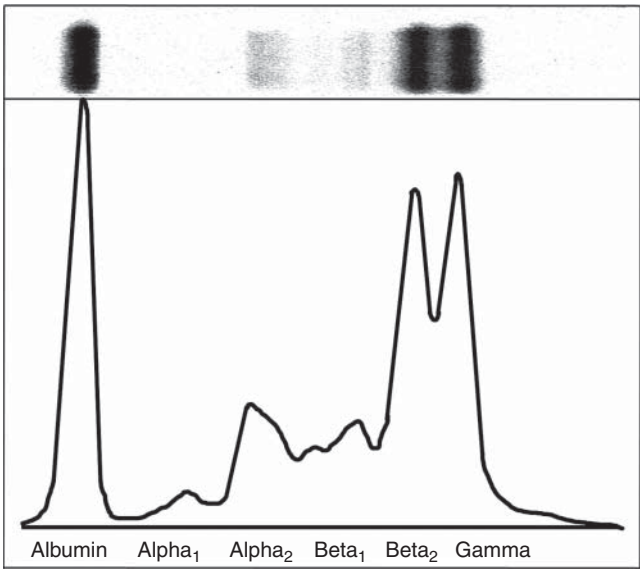

Figure 30.7 An electrophoretogram and corresponding gel from a dog with a biclonal gammopathy. Two distinct tall, sharp peaks are visible, one in the $beta_2$ region and one in the gamma region of the gel. Immunoelectrophoresis demonstrated that the immunoglobulin was predominantly IgA, consistent with lymphoid neoplasia. The second peak in the gamma region most likely resulted from IgA dimer formation.

Rarely, two clones of plasma cells or B lymphocytes may proliferate, resulting in production of two separate, but homogeneous, types of immunoglobulins [51]. It is possible for a monoclonal gammopathy to be obscured by a concurrent polyclonal peak; in these cases, visual inspection of the stained electrophoretic gel may suggest presence of a monoclonal band. More sensitive and specific techniques may be required to confirm presence of a monoclonal gammopathy (i.e., immunoelectrophoresis or immunofixation) [52, 53].

Hyperviscosity of the blood can result from high concentrations of immunoglobulins, especially in association with monoclonal gammopathies. Hyperviscosity syndrome might cause the initial clinical signs observed in animals with monoclonal gammopathies. These signs include epistaxis, ocular abnormalities (e.g., visual impairment, distension and tortuosity of retinal veins, retinal hemorrhage and detachment), cardiovascular abnormalities (e.g., gallop rhythm, left ventricular hypertrophy), and neurologic dysfunction (e.g., disorientation, seizures) [54]. Hyperviscosity syndrome is often associated with monoclonal gammopathies involving IgM (because of their large size) or IgA (because of dimer formation) but can also occur with IgG.

Monoclonal cryoglobulinemia is a rare variation of monoclonal gammopathy that has been reported in dogs, cats, and horses [55]. In this disorder, the monoclonal globulins are soluble at 37 °C but become reversibly insoluble at lower temperatures, causing formation of a gel-like precipitate. To demonstrate cryoglobulins, serum must be harvested from the blood at 37 °C. If blood samples are stored at refrigerator temperature before harvesting the serum, the cryoglobulins are not harvested, and cryoglobulinemia is not detected. Cryoglobulins are rarely associated with polyclonal disorders.

***Conditions typically associated with polyclonal gammopathies include*:**

• Chronic inflammation or antigenic stimulation. As an inflammatory response becomes chronic (>1 week), production of immunoglobulins and complement proteins may be increased; APP may remain increased as well. Chronic antigenic stimulation from any cause, including immune-mediated diseases, can cause similar abnormalities. Immunoglobulins usually migrate in the gamma globulin region, although some (IgA and IgM) occasionally migrate in beta globulin region along with complement proteins. The magnitude of the hyperglobulinemia that occurs with chronic inflammation is variable but can be marked in some cases (>10 g/dL) [56].

Gammopathies associated with chronic inflammation are usually polyclonal, exemplified by canine ehrlichiosis and feline infectious peritonitis. However, exceptions to this rule have been recognized. In particular, apparent monoclonal gammopathies have been reported in dogs with chronic ehrlichiosis, chronic pyoderma, plasmacytic enterocolitis, visceral leishmaniasis, and in cats with lymphoplasmacytic stomatitis [21, 57–61]. In some of these cases, the apparent monoclonal spike was likely oligolonal and not a true monoclonal gammopathy because it consisted of a several subclasses of IgG or heterogeneous light chains [62, 63]. Infection with *Bartonella henselae* has been reported to cause a monoclonal gammopathy (confirmed by immunofixation) in people, and a monoclonal or oligoclonal gammopathy has been described in a dog with *B. henselae* infection [64, 65].

• Liver disease. Especially when chronic, liver disease may lead to increased globulin production, which has been well-documented in horses but also occurs in other species [66]. The globulins are frequently immunoglobulins that migrate in the beta or gamma region of an electrophoretogram and can obscure the border between the beta and gamma regions, known as beta–gamma bridging. It is theorized that mononuclear phagocytes (Kupffer cells) in the diseased liver fail to clear antigens from the portal circulation. The antigens subsequently reach the general circulation, where they stimulate B lymphocytes to mount an immune response. In liver failure, albumin concentrations may be decreased concurrently due to decreased hepatic synthesis. Although historically believed to be pathognomonic for hepatic disease, recent studies have shown that beta-gamma bridging is frequently seen with infectious diseases as well [67].

• Lymphoma and lymphocytic leukemia. Polyclonal gammopathy occasionally occurs with lymphoma and lymphocytic leukemia, sometimes because of increased

production of heterogeneous immunoglobulins by multiple clones of proliferating, neoplastic lymphoid cells [1]. However, monoclonal gammopathies are more commonly associated with lymphoid neoplasia (discussed later). Secondary infectious processes may stimulate immunoglobulin production in animals with lymphoma and lymphocytic leukemia.

***Conditions typically associated with monoclonal gammopathies include*:**

• Multiple myeloma. This is a malignant, proliferative disease of plasma cells that involves the bone marrow at multiple sites and, often, other tissues (e.g., spleen, liver). Infiltration of visceral organs appears to be relatively common in cats [68]. Multiple myeloma typically results from the proliferation of a single clone of plasma cells that produce a homogeneous type of protein that is referred to as paraprotein or M-component. This protein most commonly is IgA or IgG; IgM paraproteinemias occur with lymphoma and lymphocytic leukemia but are rare with multiple myeloma [69, 70]. Primary macroglobulinemia (Waldenström macroglobulinemia) results from neoplastic proliferation of less differentiated B lymphocytes and is an uncommon cause of IgM monoclonal gammopathy; this disease may be difficult to distinguish from multiple myeloma [71]. Multiple myeloma paraproteins can be composed of entire immunoglobulin molecules or of just heavy or light chains of these molecules [50, 72–74]. Paraproteins typically are found as a monoclonal peak in the beta or gamma region and, more rarely, in the alpha region of the electrophoretogram [75]. As discussed previously, biclonal peaks are also possible but rare. Light chains also may be detected in the urine and are referred to as Bence Jones proteins. The diagnosis of this disease is usually established on the basis of finding at least three of the following four features:

1. Monoclonal gammopathy.

2. Excessive numbers of plasma cells on a bone marrow film. The percentage of plasma cells that is considered to be suggestive of myeloma varies with different authors (>5% to >20%). Chronic antigenic stimulation also can result in greater than 5% plasma cells on a bone marrow film. Other features that are suggestive of plasma cell neoplasia, such as the presence of plasma cell aggregates, poorly differentiated plasma cells, or both, are helpful in differentiating myeloma from antigenic stimulation in bone marrow films with increased numbers of plasma cells.

3. Radiographic evidence of osteolytic bone lesions.

4. Bence Jones proteinuria. Bence Jones proteins are light chains of immunoglobulins that are produced in some gammopathies. Because of their small size, these proteins readily pass the glomerulus. If the concentration of Bence Jones proteins in the urine exceeds the tubular reabsorptive capacity, they are excreted in the urine. Bence Jones proteins rarely are detected by urine dipstick tests for proteins, because dipsticks primarily detect albumin. Bence Jones proteins can be detected by several techniques, including the heat precipitation test, electrophoresis, and immunoelectrophoresis. The heat precipitation test can be performed in a practice laboratory, but this test is difficult to perform and interpret [76]. Bence Jones proteins are detectable in approximately 30% of dogs and cats with multiple myelomas and have been reported in a horse with multiple myeloma [73, 77]. Bence Jones proteins have also been detected in animals with other neoplastic and non-neoplastic monoclonal gammopathies [58, 61, 78, 79].

• Extramedullary plasmacytoma [80]. Extramedullary plasmacytomas are proliferations of plasma cells originating from a site other than bone. They are usually solitary, cutaneous, benign lesions that most commonly occur in dogs but have also been reported in cats. Plasmacytomas that occur in the digestive tract are more likely to be malignant. In cats, there is evidence that extramedullary tumors may progress to multiple myeloma [81]. Monoclonal gammopathies rarely occur in association with these tumors. A biclonal gammopathy has been reported in a cat with two extramedullary plasmacytomas [82].

• Lymphoma and lymphocytic leukemia [83–85]. Monoclonal gammopathies can occur with lymphoma and lymphocytic leukemia. Approximately 5% of dogs with lymphoma and lymphocytic leukemia have monoclonal gammopathies [85]. The incidence appears higher in dogs with chronic lymphocytic leukemia, however, with studies indicating an incidence of greater than 50% in such cases [79]. The immunoglobulin most commonly increased is IgM, especially in cases of chronic lymphocytic leukemia, but IgG and IgA monoclonal gammopathies also have been reported [79].

***Less common causes of apparent monoclonal gammopathies include*:**

• Canine ehrlichiosis [57]. Although polyclonal gammopathies are more common, monoclonal gammopathies have been reported in dogs with ehrlichiosis. Infrequently, polyclonal gammopathies progress to monoclonal gammopathies. Typically, the monoclonal gammopathies are composed of IgG and result from an unexplained proliferation of one plasma cell clone. Monoclonal spikes disappear after treatment for ehrlichiosis. The serum hyperviscosity syndrome (discussed later) has also been reported in these dogs.

• Chronic pyoderma [58]. An IgG monoclonal gammopathy with Bence Jones proteinuria has been reported in a dog with chronic pyoderma. Treatment and resolution of the pyoderma were followed by disappearance of the monoclonal gammopathy.

• Plasmacytic enterocolitis [59]. Monoclonal gammopathy has been reported in a dog with this disease. The monoclonal gammopathy disappeared after treatment and resolution of the inflammation.

• Visceral leishmaniasis (in dogs) [60]. Most dogs with visceral leishmaniasis have polyclonal gammopathies. In a few such dogs, a single clone of plasma cells may proliferate and result in IgG monoclonal gammopathy.
• Lymphoplasmacytic stomatitis (in cats) [61]. Monoclonal gammopathy with Bence Jones proteinuria occurs infrequently in cats with this disease.
• Idiopathic monoclonal gammopathy [78, 86]. Unexplained monoclonal gammopathies among animals in which known causes have been eliminated are termed idiopathic, or monoclonal gammopathy of undetermined significance (MGUS). These animals are asymptomatic and may have stable production of the monoclonal immunoglobulin for a prolonged period of time (i.e., months to years); Bence Jones proteinuria occurs in some of these cases. These gammopathies may relate to antigenic stimulation of a B lymphocyte clone. "Idiopathic" monoclonal gammopathy, however, may precede the onset of overt multiple myeloma.

Hyperfibrinogenemia

Increased plasma fibrinogen concentrations are most often associated with inflammatory conditions and dehydration but have also been recognized pregnancy and neoplasia [5, 87–89].
• Dehydration. With dehydration, fibrinogen increases in proportion to other plasma proteins. To eliminate the effect of hydration status, a plasma protein:fibrinogen ratio (PP:Fib) can be calculated as follows [5]:

$$\text{PP:Fib} = \frac{\text{Plasma protein (g/dL)} \times 1000}{\text{Plasma fibrinogen (mg/dL)}}$$

The PP:Fib should not change with changes in hydration status.

As a general rule, a PP:Fib <10 is considered consistent with hyperfibrinogenemia due to inflammation (discussed later), and a ratio >15 is considered normal or consistent with dehydration [90]. Some authors suggest slightly different cutoff values for horses; <15 for inflammation and >20 for normal or dehydration [5]. These are rough guidelines for use in adult animals, and do not take into account other factors that could influence plasma protein and fibrinogen concentrations.
• Inflammation. Fibrinogen is a positive APP, therefore plasma concentrations increase with inflammation. Although other APP may be better indicators of inflammatory disease, fibrinogen continues to be used because it is easy to measure in practice situations [10, 91, 92]. It is often included in routine equine and bovine complete blood counts. With inflammation in those species, fibrinogen concentrations may sometimes be increased in the absence of an inflammatory leukogram [93]. In dogs, it offers no advantage over leukocyte counts for evaluation of inflammation [94].

Appendix 30.1

A sodium sulfite precipitation test: application in ruminants

1. Prepare three solutions of sodium sulfite (14%, 16%, and 18%) from anhydrous sulfite and distilled water.
2. Place 1.9 mL of sodium sulfite solution into each of three 13 × 100 mm test tubes.
3. Add 0.1 mL of serum into each of the three tubes.
4. Mix immediately, and then incubate at room temperature for 1 hour.
5. After 1 hour, examine the tubes for evidence of precipitation.
6. Interpret as described in Table 30.A.1.

Table 30.A.1 Interpretation of sodium sulfite precipitation test results.

Estimated immunoglobulin concentration (mg/dL)	Sodium sulfite concentration		
	14%	16%	18%
<500	–	–	+
500–1500	–	+	+
>1500	+	+	+

– No precipitation after 1 hour (cloudiness without visible flakes is a negative test).
+ Flakes of precipitation after 1 hour (regardless of flake density).

Appendix 30.2

Zinc sulfate turbidity test: application in ruminants

1. Prepare a solution of zinc sulfate ($ZnSO_4 \cdot 7H_2O$) by mixing 350 mg of zinc sulfate in 1 L of distilled water that has been previously boiled to remove CO_2. Note that lower concentrations of zinc sulfate might be appropriate in some cases. Lower concentrations have a higher sensitivity but a lower specificity; higher concentrations (e.g., 350 mg/L) have a lower sensitivity and a higher specificity (Table 30.A.2).
2. The solution should be stored in an air-tight bottle that is connected to a CO_2 trap to prevent CO_2 absorption.
3. Add 0.1 mL of serum (hemolysis might interfere with the test) to a tube (13 × 100 mm) containing 6 mL of the zinc sulfate solution. Cap the tube to prevent absorption of CO_2, which adds to turbidity.

Table 30.A.2 Zinc sulfate turbidity test performance for detection of FPT in ruminants.

Zinc sulfate concentration (mg/L)	Sensitivity	Specificity
200	100%	25%
250	100%	42%
300	98%	65%
350	94%	76%
400	83%	91%

Source: Adapted from Hudgens KA, Tyler JW, Besser TE, Krytenberg DS (1996). Optimizing performance of a qualitative zinc sulfate turbidity test for passive transfer of immunoglobulin G in calves. *Am J Vet Res* 57: 1711–13.

4. Mix the contents of the tube and incubate at room temperature (23 °C) for 1 hour.
5. After the incubation period, mix the contents of the tube, and then hold the tube in front of newsprint.
6. Cloudiness sufficient to obscure newsprint when viewed through the tube is considered to be a positive reaction.
7. Interpret a negative reaction as being suggestive of the failure of passive transfer.

Appendix 30.3

Zinc sulfate turbidity test: application in horses

1. Prepare a solution of zinc sulfate ($ZnSO_4 \cdot 7H_2O$) by mixing 208 mg of zinc sulfate in 1 L of distilled water that has been previously boiled to remove CO_2.
2. The solution should be stored in an air-tight bottle that is connected to a CO_2 trap to prevent CO_2 absorption.
3. Add 0.1 mL of serum to a 13 × 100 mm test tube containing 6 mL of the zinc sulfate solution. Cap the tube to prevent absorption of CO_2, which adds to turbidity.
4. Mix the contents of the tube and incubate at room temperature (23 °C) for 1 hour.
5. After the incubation period, mix the contents of the tube, and then observe for turbidity.
6. Interpret as follows:
A. Visible turbidity indicates immunoglobulin concentration is at least 400 mg/dL.
B. This test can be made semiquantitative by using a spectrophotometer and reading absorbance at 600 nm, which requires the use of standards.

Appendix 30.4

Glutaraldehyde coagulation test: application in ruminants

1. Prepare a 10% solution of glutaraldehyde (usually prepared via dilution of a 25% solution to a 10% solution).
2. Place 0.5 mL of serum into a 13 × 100 mm test tube.
3. Add 50 µL (0.05 mL) of the 10% glutaraldehyde reagent to the tube.
4. Mix immediately, and then incubate at room temperature.
5. Examine the tube at intervals for as long as 1 hour, looking for evidence of coagulation.
6. Interpret as follows:
A. Complete coagulation indicates immunoglobulin concentration is more than 600 mg/dL.
B. Semisolid gel indicates immunoglobulin concentration is 400–600 mg/dL.
C. No coagulation indicates immunoglobulin concentration is less than 400 mg/dL.

Appendix 30.5

Glutaraldehyde coagulation test: application in horses

1. Perform steps 1 through 4 as outlined in Appendix 30.4.
2. Examine the tube at 5, 10, 15, 20, 30, 45, and 60 minutes.
3. A positive reaction is solid coagulation (i.e., does not move when the tube is tilted).
4. Interpret as follows:
A. Coagulation within 10 minutes indicates immunoglobulin concentration is more than 800 mg/dL.
B. Coagulation by 60 minutes indicates immunoglobulin concentration is 400– 800 mg/dL.
C. No coagulation by 60 minutes indicates immunoglobulin concentration is less than 400 mg/dL.

Appendix 30.6

Fibrinogen determination by heat precipitation

1. Fill two microhematocrit tubes with ethylenediaminetetraacetic acid (EDTA)–anticoagulated blood.
2. Sediment blood in both tubes using a microhematocrit centrifuge.

3. Break one tube at the bottom of the plasma column, apply the plasma to a refractometer, and read the protein concentration.

4. Place the second microhematocrit tube in a water bath at 56–58 °C for 3–5 minutes, which denatures and precipitates the fibrinogen in the sample. Note that hot tap water frequently is in the 56–58 °C range. If so (check with a thermometer), such tap water placed in an insulated container can replace the water bath as an incubation chamber.

5. After incubation, recentrifuge the second microhematocrit tube in the microhematocrit centrifuge to sediment the precipitated fibrinogen.

6. Measure the protein concentration in the second tube using a refractometer.

7. Subtract the protein concentration of the second tube from that of the first tube. The difference is the estimate of the plasma fibrinogen concentration. For example, if the protein concentration in the first tube is 7.1 g/dL and that in the second tube is 6.7 g/dL, then the fibrinogen concentration is 0.4 g/dL.

8. Fibrinogen concentrations usually are converted to mg/dL (e.g., 0.4 g/dL = 400 mg/dL).

31 Laboratory Detection of Muscle Injury

Robin W. Allison
Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

Routine laboratory tests that evaluate muscle are primarily aimed at detecting muscle injury. These tests include assays that measure the serum activities of enzymes and other proteins that leak from injured muscle cells and the urine concentrations of myoglobin, which also leaks from injured muscle cells and is excreted via glomerular filtration. Tests that are more specific for cardiac muscle injury measure serum concentrations of proteins or hormones released from cardiac muscle (cardiac biomarkers).

Creatine kinase

Creatine kinase (CK) is an enzyme present in highest concentrations in skeletal muscle, cardiac muscle, smooth muscle, and brain, with lesser amounts present various organs such as intestine, liver, and spleen [1, 2]. CK is found free in the cytoplasm of muscle cells and leaks from these cells when they are damaged. CK is considered a muscle-specific leakage enzyme. Although CK is present in the brain, brain injury causes increased CK activity in the cerebrospinal fluid instead of the blood because of the blood–brain barrier. Increases in CK activity following muscle injury occur rapidly (peaking in 6–12 hours) but also decline rapidly (a day or 2) because CK has a short half-life of about 2 hours (see Figure 31.1) [3]. Thus, persistent increases in CK activity indicate ongoing muscle damage. Although the specificity of CK activity for muscle injury is high, sensitivity is fairly low, likely related to its short half-life [4].

CK exists as a dimer, composed of different combinations of two subunits designated B (brain) and M (muscle). A total of four isoenzymes have been identified. There is some variation by species, but in dogs CK-BB (CK-1) predominates in brain and organs such as spleen and kidney; CK-MB (CK-2) is mainly in intestine, lung, and spleen with a small amount in myocardium; and CK-MM (CK-3) is the major form in skeletal and cardiac muscle [1]. The fourth isoenzyme, CK-Mt, exists within mitochondria of many tissues. The reported distributions of isoenzyme activities in the blood of normal dogs vary, but CK-MM and CK-BB together are responsible for the majority of the CK activity with a small contribution from CK-MB [4]. Because of the different tissue locations, CK isoenzymes have the potential to be tissue specific. In people, increased serum CK-MB activity has historically been considered a reliable marker of myocardial injury but has been replaced by other cardiac biomarkers in recent years (see discussion of cardiac biomarkers) [5]. Measurement of CK isoenzyme activities requires electrophoresis or specifies-specific antibodies, and these assays are not routinely available for animals.

CK activity can be measured in serum or plasma, but the activity is reportedly about 2.5 times greater in serum, most likely due to release of CK from platelets during clot-

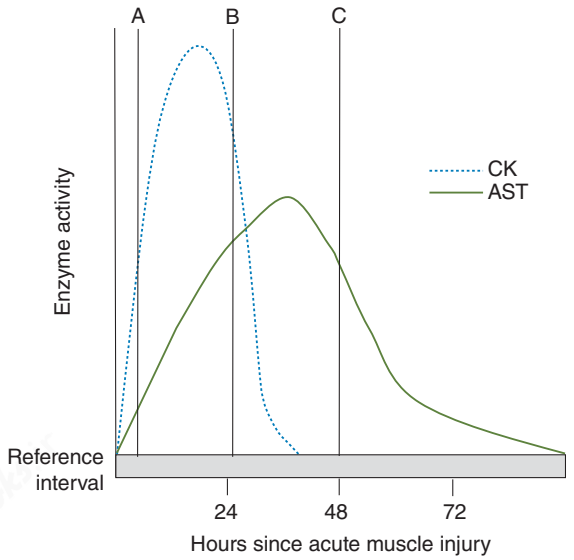

Figure 31.1 Serum activities of both AST and CK increase as a result of muscle injury but rise and fall at different rates. Evaluation of these two enzymes together can help estimate when a muscle injury occurred and indicate whether such injury is still occurring. An increase in predominantly the serum CK activity (line A) suggests very acute muscle injury. Increased serum activities of both AST and CK (line B) suggest active or recent muscle injury. An increase in only the serum AST activity (line C) suggests that muscle injury has stopped and that the serum CK activity returned to normal as a result of the short half-life of CK. An increase in only the serum AST activity may also result from liver injury.

ting. In dogs, plasma CK activity is stable for a week when refrigerated and a month when frozen at −20 °C. Serum CK activity has also been reported to be greater in young puppies compared to adult dogs, with four times adult levels found in puppies under a month of age [6]. Marked increases (>20X URL) seen in newborn puppies are suspected to be caused by normal muscle trauma during the birthing process [7]. Moderate increases in CK activity, compared to that of adult dogs, have been demonstrated in puppies up to 2 months of age [7, 8]. A falsely increased CK activity can occur as a result of hemolysis, hyperbilirubinemia and muscle fluid contamination of the blood sample during a difficult venipuncture. Extremely high serum CK activities (>100X URL) occasionally are detected in animals with muscle injuries. These markedly increased CK activities may be greater than the linearity limits for the assay. Technicians analyzing such serum for CK activity may have difficulty reaching an end point in the assay because the serum CK activity continues to increase with serial dilution. Various theories have been postulated to explain this phenomenon, including that dilution of serum CK inhibitors is responsible [9–11]. In these cases CK activity may be reported as greater than the limit of linearity for that particular assay.

Increased serum CK activity results from:

- Skeletal muscle injury. Injury to skeletal muscle is the most common cause of increased CK activity, which may result from such minor procedures as physical restraint and intramuscular injections. Muscle necrosis and ischemia, strenuous exercise or seizures, and trauma during shipping can result in an increased serum CK activity. The underlying causes for muscle injury are numerous and varied, including trauma, toxins, exertional rhabdomyolysis, inflammatory myopathies due to bacterial, viral, or parasitic diseases, and inherited conditions such as muscular dystrophy [4, 12]. So-called "downer" cattle will have increased CK activity due to ischemic muscle necrosis. Increased CK activity has also been reported in dogs with endocrine diseases (hypothyroidism and hyperadrenocorticism) [4]. Depending on the underlying cause, the magnitude of the increase may be mild to marked and correlates somewhat with the extent of muscle injury.
- Cardiac muscle injury. Increases in CK activity can occur with injury to cardiac muscle. In dogs, this is due to increases in both CK-MM and CK-MB activities [13]. Because of the relatively small volume of cardiac muscle compared to skeletal muscle, CK activity increases with cardiac muscle injury are unlikely to reach the magnitude seen with severe injury to skeletal muscle.
- Smooth muscle injury. In theory, injury to tissues containing abundant smooth muscle could cause increased serum CK activity, but this is rarely recognized in practice. However, the bovine uterus has been shown to contain relatively high concentrations of CK, and serum CK increases have been documented in cattle with endometritis [14].
- Muscle catabolism. Increased CK activity can occur in anorexic cats that have diseases not directly involving muscle. A median serum CK activity of 2529 IU/L, with some activities being greater than 10,000 IU/L (reference range = 10–100 IU/L), has been reported in such cats [15]. Muscle catabolism to supply amino acids for protein synthesis and gluconeogenesis is theorized to result in the leakage of CK from muscle cells. The CK activity in these cats decreased rapidly after nutritional support was initiated.

Aspartate aminotransferase

Aspartate aminotransferase (AST), previously known as serum glutamic oxaloacetic transaminase (SGOT), is present at highest concentrations in hepatocytes as well as in skeletal and cardiac muscle cells [1]. AST is present in both the cytoplasm and mitochondria of these cells [2]. Serum AST activity increases not only from muscle injury but also hepatocyte injury and may be mildly increased in dogs due to drug induction (see Chapter 27). Serum AST activity increases more slowly than serum CK activity after muscle injury (Figure 31.1). It peaks at approximately 24–36 hours after acute muscle injury, and it decreases more slowly than serum CK activity after the muscle injury ceases. The half-life of AST in the blood has been estimated between 4 and 12 hours in dogs, 77 minutes in cats, and 7–8 days in horses [1, 3, 16].

The relative serum activities of both CK and AST can be used to estimate when muscle injury occurred and whether active muscle injury is ongoing (Figure 31.1). An increase in only the serum CK activity (Figure 31.1, line A) suggests very acute muscle injury (i.e., there has not been sufficient time since the injury occurred for the serum AST activity to increase). Increased serum activities of both AST and CK (Figure 31.1, line B) suggest active or recent muscle injury. An increase in only the serum AST activity (Figure 31.1, line C) suggests that muscle injury stopped more than 2 days earlier and that the serum CK activity returned to normal as a result of the short half-life of CK. This latter combination of results also can occur with liver injury (i.e., if liver is the source of the AST, the CK activity would be normal).

Alanine aminotransferase

Alanine aminotransferase (ALT), previously known as serum glutamic pyruvic transaminase (SGPT), is a leakage enzyme that is free in the cytoplasm. This enzyme is primarily used to detect hepatocyte injury (see Chapter 27), but it is not totally liver specific [17]. In dogs, the ALT activities in skeletal and cardiac muscles are approximately 5% and 25%, respectively, of the liver ALT activity [1]. In cats, the ALT activities of both skeletal and cardiac muscle are approximately 5% of

the liver ALT activity [1]. The situation is different in horses, where liver contains relatively little ALT activity and the ALT activity in skeletal muscle is approximately four times that of liver [1]. Muscle should be considered as a potential source of increased serum ALT activity even in dogs and cats, because the total mass of muscle is much greater than that of liver. Measuring the serum activity of an enzyme with greater muscle specificity (CK) is preferable for detecting muscle damage.

Lactate dehydrogenase

Lactate dehydrogenase (LDH) is located in the cytoplasm of most cells in the body. [1] Injury to most tissues results in leakage of LDH into the extracellular space and the blood; therefore, LDH is a very nonspecific enzyme.

Lactate dehydrogenase isoenzymes

Five LDH isoenzymes exist, which can be identified by electrophoretic separation. Each isoenzyme is present in a limited number of tissues and, therefore is more tissue specific than the serum total LDH activity [18]. LDH molecules are composed of four components, which are either muscle (M) or heart (H) subunits. The five isoenzymes are LDH_1 (H_4), LDH_2 (MH_3), LDH_3 (M_2H_2), LDH_4 (M_3H), and LDH_5 (M_4). The designations H_4, MH_3, and so on refer to the number of each subunit (M or H) in the LDH isoenzyme molecule. Although there is considerable species variation, generally the LDH_1 (H_4) isoenzyme predominates in cardiac muscle and the LDH_5 (M_4) isoenzyme predominates in skeletal muscle [1]. The remaining three isoenzymes are found in variable quantities in several different tissues. Although measurement of specific isoenzyme activities may provide information about skeletal versus cardiac muscle injury, isoenzyme assays are not routinely performed by most veterinary laboratories and more specific serum markers are now available for evaluating myocardial injury (see discussion of cardiac biomarkers).

Cardiac biomarkers

The use of biomarkers in blood to detect cardiac disease is commonplace in human medicine and is the subject of continuing research in veterinary medicine. Two classes of cardiac biomarkers that have received the most attention for use in veterinary species are the troponins (myocardial structural proteins) and the natriuretic peptides (hormones produced by cardiomyocytes).

Cardiac troponins

Troponins are structural proteins of striated muscle. In people, antibody assays developed against cardiac troponins I (cTnI) and T (cTnT) have identified that these proteins are released from injured cardiac muscle and enter the peripheral blood [19]. Assays for cTnI and cTnT have largely replaced assays for CK-MB activity as markers for myocardial injury in people, and are being investigated for similar purposes in animals [5, 20, 21]. Because the cardiac troponins are well-conserved between species, immunoassays designed for use in people have been used to detect these proteins in plasma from a variety of species including dogs, cats, horses, and cattle [21–24]. However, not all commercially available immunoassays have been used successfully in animals [25, 26]. Additionally, values obtained with one type of assay may not be directly comparable to values obtained with another [27].

Although regarded as highly sensitive and specific markers for cardiac disease in people, how cardiac troponin concentrations will correlate with specific diseases in animals is the subject of ongoing investigations. Troponin concentrations in healthy animals are very low or undetectable with many available assays. Increases in serum troponin concentrations are relatively modest in animals with cardiac injury, prompting recent development of assays with lower limits of detection [28]. Several studies have shown that cTnI concentrations are greater in dogs with acquired cardiac diseases compared to normal healthy dogs; conditions included mitral valve disease, dilated cardiomyopathy, and acute myocardial damage secondary to gastric dilatation-volvulus or blunt chest trauma [29–31]. However, cTnI concentrations were also increased in cases of renal failure, noncardiac systemic disease, and noncardiac dyspnea [32, 33].

Breed differences also exist. Greyhound and boxer dogs were shown to have cTnI concentrations significantly greater than those of non-greyhound or non-boxer control dogs [34, 35]. The specificity of cardiac troponins for cardiac injury in animals will depend on development of appropriate decision limits for the particular assay being used. It is important to keep in mind that cardiac injury, and resulting increases in cardiac biomarkers, may occur secondarily to many noncardiac diseases [20]. Serial determinations of cTNI concentrations may provide prognostic information in dogs with known cardiac disease [36]. However, data suggest that intraindividual variability in cTNI values is high and an increase of 112% is needed to be confident that there is a changed clinical status [37].

Natriuretic peptides

Brain naturiuretic peptide (BNP) is a hormone released by cardiomyocytes in response to volume expansion and pressure overload, and has been recognized as a biomarker of systemic hypertension and congestive heart failure in people [38]. Laboratory tests are available to measure plasma concentrations of the C-terminal fragment (C-BNP) in dogs and the N-terminal fragment of proBNP (NT-proBNP) in dogs and cats [39]. A point-of-care SNAP test for NT-proBNP is

available for dogs and cats (Cardiopet® proBNP Test, IDEXX Laboratories).

Studies to date have suggested that NT-proBNP may be useful to help distinguish cardiac from noncardiac causes of respiratory abnormalities in dogs and cats [40–43]. Low or normal values are helpful to rule out cardiac disease, but NT-proBNP concentrations should be evaluated in context with clinical findings and other diagnostic tests. Studies have also examined the usefulness of NT-proBNP to detect occult cardiomyopathy. In one study, the combination of NT-proBNP (using the Cardiopet point-of-care assay) and Holter monitoring detected occult dilated cardiomyopathy in Doberman pinschers with 91% accuracy [44]. Measuring NT-proBNP alone, however, has shown low specificity for dilated cardiomyopathy resulting in numerous false-positive results [45]. In cats with risk factors for cardiomyopathy (such as murmur, gallop or dysrhythmia), NT-proBNP reliably identified those with occult cardiomyopathy with relatively high sensitivity and specificity (70–100% and 67–100% respectively, depending on the cutoff values used) [46, 47]. In cats suspected to have heart disease, the point-of-care Cardiopet NT-proBNP test, which reports results as either normal or abnormal, differentiated cats with occult heart disease with an accuracy of 83% [48]. In that study, cats with a normal test result were highly unlikely to have occult heart disease. Echocardiography is recommended for cats with an abnormal result.

Breed differences in NT-proBNP concentrations have been identified in healthy dogs. Breeds with the highest values, Labrador retrievers and Newfoundlands, had median concentrations three times higher than those of some other breeds [49]. The same study found intrabreed differences were pronounced. Similar to cTNI, data have shown high intraindividual variability in NT-proBNP values. If following an individual dog with serial measurements, an increase of 53% has been suggested to be confident that there is a changed clinical status [37].

Myoglobinemia and myoglobinuria

Myoglobin, a red heme protein containing ferrous iron (Fe^{+2}), is released from dead or dying muscle cells into the blood as a result of severe, usually acute muscle injury [50]. Because myoglobin has a low molecular weight (MW = 17,000) and is not significantly bound to proteins in the blood, it quickly passes through the glomerulus and is excreted in the urine [51]. When large amounts of myoglobin enter the renal tubule lumen, it interacts with Tamm-Horsfall protein in acidic urine and precipitates [52].

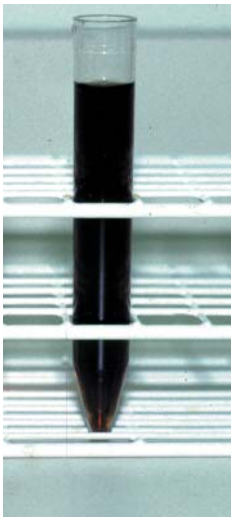

Figure 31.2 Urine from a horse with exertional rhabdomyolysis and myoglobinuria. High concentrations of myoglobin result in brown to red-brown urine.

In addition, reactive oxygen species promote the oxidation of iron to its ferric state (Fe^{+3}), thus generating a hydroxyl radical that can cause renal epithelial cell damage. This is the primary cause for acute kidney injury during myoglobinuria [52]. A higher volume of urine flow helps prevent this damage.

The urine will be brown to red-brown if the urinary myoglobin concentration is high enough (Figure 31.2). Myoglobin is detected as a positive reaction on the urine dipstick test for blood or hemoglobin because of its peroxidase activity. Therefore, myoglobinuria must be differentiated from hemoglobinuria (see Chapter 24 for further discussion of red urine). This differentiation can be aided by observing the packed cell volume and color of the serum. Hemoglobin released into the plasma because of hemolysis is quickly bound to a carrier protein, haptoglobin. Hemoglobin–haptoglobin complexes are large and do not readily pass through the glomerulus. If haptoglobin becomes saturated with hemoglobin, free hemoglobin dimers (MW = 32,000) in plasma are cleared by the kidney, resulting in red urine [51]. Since hemoglobin tends to be retained in the plasma after hemolysis, it imparts a red color to the plasma and serum. Myoglobin, however, is readily excreted by the kidneys, and does not typically cause a color change in the serum. Colorless to yellow serum in animals with evidence of muscle injury (increased CK or AST activity) and a positive reaction for hemoglobin on a urine dipstick test suggests myoglobinuria; red serum in an anemic animal is suggestive of hemolysis and hemoglobinuria.

32 Laboratory Evaluation of Lipids

M. Judith Radin

Department of Veterinary Biosciences, The Ohio State University College of Veterinary Medicine, Columbus, OH, USA

Lipids play diverse roles in normal physiology. The most obvious use is as an energy source that can be stored as triglycerides within adipocytes during times of nutritional plenty and mobilized when needed. Lipid stores within brown fat cells can be rapidly oxidized via uncoupling protein pathways to provide heat (thermogenesis). Fat pads provide thermal insulation and act as shock absorbers. Lipids function as structural components of cell membranes and organelles, as mediators of intracellular signal transduction pathways, as a constituent of surfactant in the lung, and as electrical insulators (myelin in the nervous system). Cholesterol is an important component in cellular membranes of animals and is the precursor for the synthesis of steroid hormones, vitamin D, and bile acids. Cholesterol metabolism also functions as a regulator of both innate and adaptive immunity [1]. Volatile fatty acids (propionate, acetate, and butyrate) are major products of rumen microbial fermentation of carbohydrates and play a significant role in ruminant energy metabolism. While often thought of as indicators of metabolic disturbances, ketones are normally present at low levels in the circulation and are an important energy source during times of negative energy balance.

A variety of lipids are present in the circulation. Alterations in their concentrations reflect energy balance and metabolic disturbances. Lipid abnormalities can contribute to development of serious clinical syndromes such as insulin resistance, hepatic lipidosis, and atherosclerosis. Measurement of different types of lipids is predicated on available test methodologies as well as clinical relevance. Circulating lipids of clinical interest that can be readily assessed include triglycerides, cholesterol, nonesterified fatty acids (NEFA), lipoproteins, and ketone bodies. Prior to discussion of laboratory evaluation and diagnosis of lipid abnormalities, a brief overview of lipid metabolism is presented. More detailed discussions of lipid chemistry and metabolism are available elsewhere [2, 3].

Dietary absorption of lipids

Lipids may be obtained from the diet or by synthesis. Dietary fat entering the small intestine stimulates release of cholecystokinin. Cholecystokinin causes the gall bladder to contract, releasing bile into the intestinal lumen. Bile salts and lecithin in the bile emulsify dietary fat to form micelles that consist of fatty acids, triglycerides, cholesterol, and the fat-soluble vitamins A, D, E, and K. Cholecystokinin also stimulates the exocrine pancreas to secrete lipases that interact with the micelle and break down the lipid into forms that may be absorbed by the intestinal enterocytes. Pancreatic lipase and colipase are responsible for hydrolysis of triglyceride to two fatty acids and a monoglyceride. Dietary cholesterol esters are hydrolyzed by cholesterol esterase to release cholesterol and a fatty acid. Long chain fatty acids (LCFA, fatty acids having more than 12 carbons), monoglycerides, cholesterol, and fat-soluble vitamins diffuse from the micelle across the brush border into the enterocyte, leaving the bile salts within the intestinal lumen (Figure 32.1). Short and medium chain fatty acids having fewer than 12 carbons may be absorbed without the need of micellar emulsification and may be transferred from the enterocyte directly to the portal blood. LCFA must be re-esterified to triglycerides and packaged into lipoproteins called chylomicrons for transport in the lacteals and blood.

Maldigestion and malabsorption of dietary fats can result in steatorrhea and deficiency of essential fatty acids and fat soluble vitamins. If pancreatic exocrine deficiency results in inadequate release of lipases into the intestine, maldigestion will result in high concentrations of triglycerides (also called neutral fats) in the feces. If the stool contains increased fatty acids and glycerol (referred to as split fats), this implies that sufficient lipase is present to hydrolyze triglyceride and that malabsorption of fats is occurring.

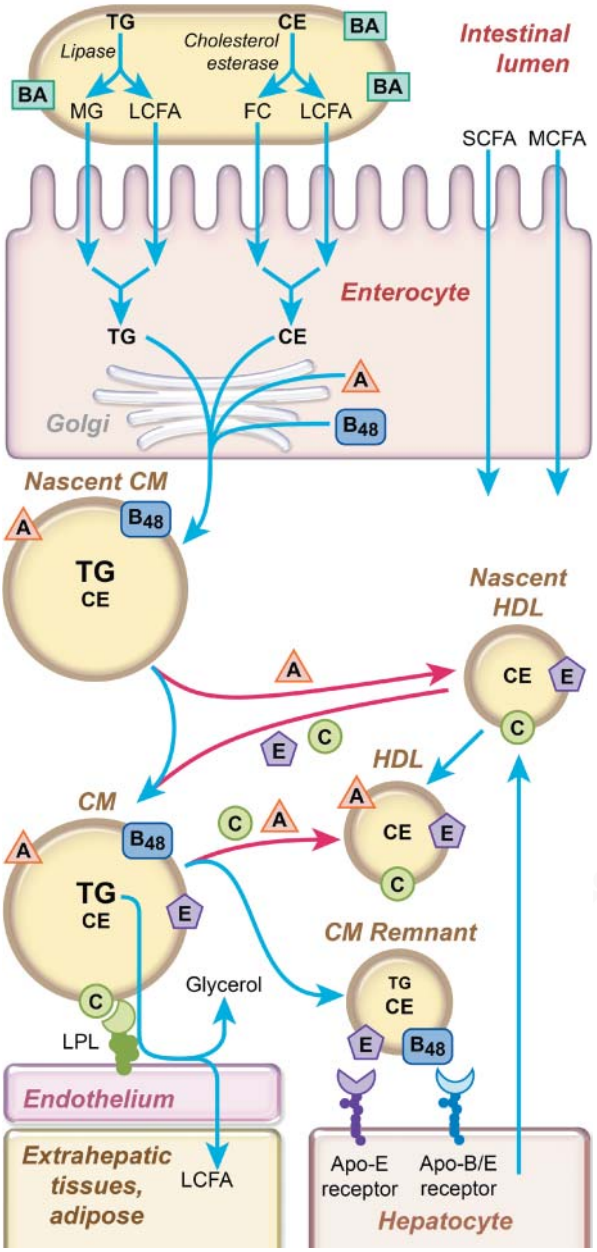

Figure 32.1 Dietary lipids in the intestinal lumen are solubilized by emulsification with bile acids (BA) to form micelles. Pancreatic lipases associate with the micelles and hydrolyze triglycerides (TG) to monoglycerides (MG) and long chain fatty acids (LCFA). Cholesterol esters (CE) are hydrolyzed by cholesterol esterase to free cholesterol (FC) and an LCFA. Short chain fatty acids (SCFA) and medium chain fatty acids (MCFA) do not require micellar emulsification for intestinal absorption. Following absorption by the enterocyte, MG, FC, and LCFA are re-esterified and assembled along with apoprotein-A and apoprotein-B48 into nascent chylomicrons (CM). In the blood, CM exchange apoproteins-A, -C, and -E with high-density lipoproteins (HDL). TG in the CM are hydrolyzed to LCFA and glycerol by lipoprotein lipase (LPL) on the surface of the endothelial cells. This process requires apoprotein-C. LCFA may be used by adipocytes to form TG while glycerol is released into the blood for use by the liver or other extrahepatic tissues. Apoprotein-A and apoprotein-C from CM remnants are transferred back to HDL. Removal of the cholesterol-enriched CM remnant from the blood is mediated by Apo-B/E and Apo-E receptors on hepatocytes.

Lipids present in the blood

Fatty acids

Unesterified fatty acids are referred to as free fatty acids or NEFA. Most mammalian fatty acids contain more than 12 carbon atoms and are referred to as LCFA. Fatty acids may be obtained from the diet or may be synthesized. Because they are hydrophobic, LCFA must be attached to plasma proteins, primarily albumin, for transport in the blood.

In nonruminants, biosynthesis of fatty acids occurs at the highest rates in liver, with lesser amounts produced in adipose tissue and mammary glands. In ruminants, adipocytes are the primary site for fatty acid formation, and the liver plays a less important role in fatty acid synthesis. During lactation, the mammary gland is a major synthetic site. Other tissues are capable of producing fatty acids but at much lower rates. Fatty acids are synthesized from acetyl-coenzyme A (acetyl-CoA) (Figure 32.2). Glucose is the main precursor for acetyl-CoA in nonruminants, while acetate serves this function in ruminants. Amino acids also can be used as precursors for formation of acetyl-CoA. Synthesis of fatty acids is stimulated by insulin and inhibited by glucagon and epinephrine via modulation of activity of acetyl-CoA carboxylase, the rate limiting enzyme of fatty acid synthesis. As a result, the rate of fatty acid synthesis is responsive to diet and metabolic state. For example, fatty acid synthesis is stimulated by high carbohydrate/low fat diets (high insulin and availability of glucose as a precursor). Fatty acid synthesis is decreased by fasting (low insulin, high glucagon), high fat/low carbohydrate diets (increased availability of preformed LCFA), and diabetes mellitus.

Fatty acids are an important energy source for peripheral tissues such as skeletal muscle and are oxidized back to acetyl-CoA as part of this process. Acetyl-CoA produced by mitochondrial β-oxidation of LCFA may be used to generate adenosine triphosphate (ATP) and CO_2 via the tricarboxylic acid (TCA) cycle (Figure 32.2). This process initially requires conversion of acetyl-CoA and oxaloacetate to citrate. If there is inadequate oxaloacetate, such as may occur with a low carbohydrate diet or diabetes mellitus, acetyl-CoA may be directed into ketogenesis. Acetyl-CoA also may be used for production of cholesterol.

Triglycerides

Triglycerides are formed by esterification of three LCFA to glycerol-3-phosphate (Figure 32.3). Triglyceride synthesis occurs in the intestinal mucosal cells, adipocytes, hepatocytes, mammary epithelial cells, and kidneys. Within the intestinal mucosal cell, dietary fatty acids and monoglycerides are re-esterified to form triglycerides. Triglycerides also can be produced by adding dietary LCFA to glycerol-3-phosphate that is newly synthesized from glucose by the enterocyte. Control of triglyceride synthesis by

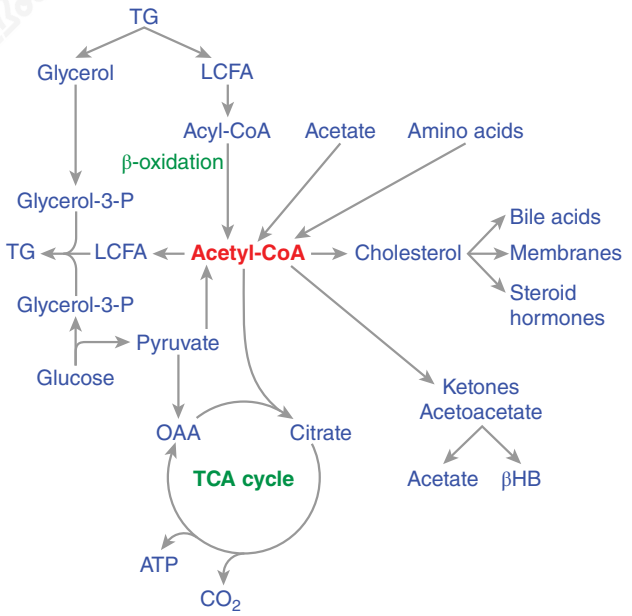

Figure 32.2 Acetyl-coenzyme A (acetyl-CoA) is central to both catabolism and synthesis of long chain fatty acids (LCFA) in the hepatocyte. LCFA derived from lipolysis are converted to acyl-CoA, which undergoes β-oxidation to acetyl-CoA. Other sources of acetyl-CoA include acetate, amino acids, and glucose. Acetyl-CoA may be used in the synthesis of LCFA or cholesterol. Triglycerides (TG) are synthesized by esterification of LCFA to glycerol-3-phosphate (glycerol-3-P) derived from either lipolysis or glucose metabolism. A major route for utilization of acetyl-CoA is for energy production through the tricarboxylic acid (TCA) cycle. This process requires combination of acetyl-CoA with oxaloacetate (OAA) to form citrate. OAA is obtained from glucose metabolism. If there is excess acetyl-CoA and/or insufficient OAA, acetyl-CoA may be shunted into ketogenesis to form acetoacetate. Acetoacetate is then converted to acetone and β-hydroxybutyrate (βHB). This last pathway is stimulated in conditions of negative energy balance characterized by excess lipolysis and undersupply of glucose.

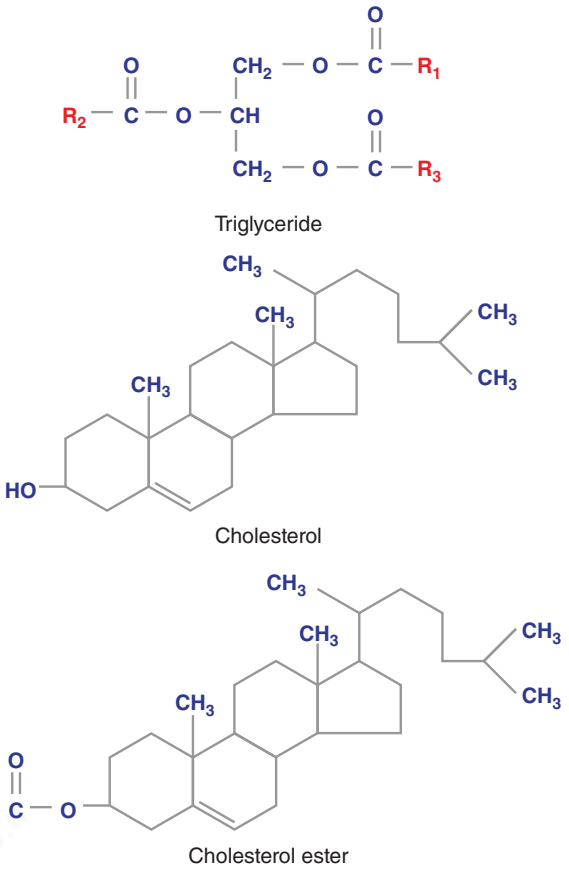

Figure 32.3 The structure of triglycerides, cholesterol, and cholesterol esters. R represents the carbon chain of a long chain fatty acid. The hydroxyl group on cholesterol confers some water solubility, allowing free cholesterol to be part of the outer shell of lipoproteins. Cholesterol esters are hydrophobic and contained within the center of lipoprotein particles.

the enterocytes is largely dependent on dietary availability of fatty acids. Once formed, triglycerides are not stored to any great extent in enterocytes but are packaged into chylomicrons and released into the lacteals.

Hepatocytes use LCFA obtained from the plasma or from de novo synthesis for production of triglycerides. Glycerol may be taken up from the plasma or may be synthesized from glucose. Synthesis of triglycerides by hepatocytes is decreased in conditions with high glucagon and low insulin (fasting, diabetes mellitus) and is stimulated by increased availability of LCFA. Under normal circumstances, triglycerides are released from the hepatocytes into the circulation as a component of lipoproteins called very-low-density lipoproteins (VLDL).

Adipocytes may synthesize LCFA or may obtain them via lipolysis of blood triglycerides present in chylomicrons or VLDL. The enzyme responsible for hydrolysis of chylomicron or VLDL triglycerides is lipoprotein lipase, which is located on the surface of capillary endothelial cells. Unlike hepatocytes, adipocytes lack the enzymes to use glycerol derived from lipolysis. Triglyceride synthesis by adipocytes depends on de novo production of glycerol-3-phosphate from glucose or gluconeogenesis. Insulin is an important regulator of adipocyte triglyceride synthesis through stimulation of activity of lipoprotein lipase (Table 32.1). Insulin also enhances glucose uptake by increasing membrane expression of the GLUT4 glucose transporter, thus increasing intracellular availability of glucose for glycerol-3-phosphate synthesis. Once triglycerides are formed, they are stored for future use as fat droplets in adipocytes.

Mobilization of triglycerides stored in adipocytes is mediated by the enzyme, hormone sensitive lipase (HSL). Hydrolysis of triglycerides results in the release of LCFA and glycerol to the blood for transport to tissues. A variety of hormones directly and indirectly affect lipolysis through modulation of the activity of HSL (Table 32.1). Catecholamines rapidly activate HSL by promoting phosphorylation of the enzyme. This permits a rapid increase

Table 32.1 Effect of hormones on key regulatory steps in lipid metabolism.

	LPL	HSL	Acetyl-CoA carboxylase	HMG CoA reductase	LDL receptors
	Hydrolysis of triglycerides from chylomicrons and VLDL	Lipolysis of triglycerides to LCFA and glycerol	Rate limiting enzyme in the synthesis of fatty acids	Rate limiting enzyme in the synthesis of cholesterol	Clearance of LDL from the blood
Insulin	↑ enzyme activity; ↑ synthesis of the enzyme; ↑ translocation of the enzyme to the endothelium	↓ enzyme activity; ↓ cortisol-induced gene transcription	↑ enzyme activity	↑ activity	↑ synthesis of the receptor
Glucagon		↑ activity	↓ enzyme activity	↓ activity	
Glucocorticoids		↑ gene transcription and synthesis of enzyme		↓ gene transcription and synthesis of the enzyme	↓ synthesis of receptor due to secondary decrease in thyroid hormones
Thyroid hormones		↑ synthesis of adrenergic receptors, which increases the effect of catecholamines		↑ synthesis of the enzyme	↑ synthesis of the receptor
Catecholamines		↑ enzyme activity	↓ enzyme activity		
Growth hormone		↑ enzyme activity			↓ synthesis of receptor due to secondary decrease in thyroid hormones

CoA, coenzyme A; HMG CoA, 3-hydroxy-3-methylglutaryl coenzyme A; HSL, hormone sensitive lipase; LCFA, long chain fatty acids; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

in lipolysis to supply fatty acids for energy production. Thyroid hormone acts synergistically with catecholamines by increasing the number of receptors for catecholamines on adipocytes. Glucocorticoids facilitate lipolysis by increasing gene transcription and synthesis of HSL. Insulin and insulin-like growth factor inactivates HSL by promoting dephosphorylation of the enzyme. Insulin also opposes the effect of glucocorticoids on HSL gene transcription.

Cholesterol

Cholesterol may be in the form of free cholesterol or may be esterified with a fatty acid to form a cholesterol ester (Figure 32.3). Because it is not synthesized by plants or microbes, only carnivores or omnivores may obtain cholesterol from the diet. Herbivores must synthesize their own cholesterol. The primary site for cholesterol synthesis is the liver, and the rate limiting enzyme is 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase. Several hormones modulate HMG-CoA reductase activity and consequently cholesterol synthesis (Table 32.1). HMG-CoA reductase activity is increased by insulin and decreased by glucagon. Thus, cholesterol synthesis increases following a meal (high insulin) and decreases with fasting (high glucagon, low insulin) or with diabetes mellitus. Thyroid hormone increases HMG-CoA reductase activity by increasing synthesis of the enzyme. Glucocorticoids have the opposite effect, decreasing synthesis of HMG-CoA reductase and consequently cholesterol synthesis. Statins, a class of cholesterol lowering drugs, have their effect on serum cholesterol by inhibiting HMG-CoA reductase.

Once formed, cholesterol may be utilized through several routes. The liver can export cholesterol and cholesterol esters to the blood as a constituent of lipoproteins. Cholesterol is a structural component of cell and organelle membranes and is a precursor for vitamin D synthesis. Cholesterol also is used for production of steroid and sex hormones by tissues such as the adrenal gland and gonads. Alternatively, cholesterol may be used by hepatocytes to synthesize bile acids. Bile is a major route for elimination of cholesterol from the body.

Lipid transport in the blood

Because lipids are largely immiscible in water, transport in the blood must be accomplished by binding to carrier proteins. LCFA bind to albumin, while triglycerides,

cholesterol, cholesterol esters, and phospholipids are transported by lipoproteins. Lipoproteins consist of a shell of apoproteins, cholesterol, and phospholipids oriented so that amphoteric portions of the molecules are on the outside, facing the aqueous environment of the blood. The hydrophobic ends are oriented toward the center of the particle. Triglycerides and cholesterol esters constitute the hydrophobic core of lipoprotein particles. Lipoproteins are traditionally named based on their density as determined by ultracentrifugation and are further characterized by lipid and apoprotein constituents. Apoproteins may be integrated into the shell of the lipoprotein or be more loosely associated with the surface of the lipoprotein. Integrated apoproteins include apoprotein-B48 (Apo-B48) of intestinal origin and apoprotein-B100 (Apo-B100) of hepatic origin. Peripheral apoproteins such as apoprotein-A (Apo-A), apoprotein-C (Apo-C), and apoprotein-E (Apo-E) are exchanged between lipoproteins in circulation (Figures 32.1 and 32.4).

Enterocytes package fat from the diet into lipoproteins called chylomicrons, which are released into the lacteals with eventual delivery into the blood. Chylomicrons contain mostly triglycerides with lesser amounts of cholesterol, cholesterol ester, fat soluble vitamins, Apo-B48, and Apo-A. In the circulation, Apo-C and Apo-E are transferred from high-density lipoproteins (HDL) to the chylomicron. Chylomicrons are the largest and least dense of the lipoproteins. When present in large quantity, they confer a visible haziness to the serum, contributing to the appearance of lipemia. Apo-C is a cofactor for lipoprotein lipase, which is found on the surface of endothelial cells within tissue beds such as adipose and muscle. Lipoprotein lipase is synthesized by extravascular tissues and transferred to the surface of endothelial cells where it is anchored by heparan sulfate. Injection of heparin can cause release of lipoprotein lipase into the circulation and this technique has been used to clear serum of lipemia. Lipoprotein lipase hydrolyzes triglycerides to LCFA and glycerol for use by extrahepatic tissues. In adipose and muscle, insulin increases lipoprotein lipase activity, facilitating hydrolysis of chylomicron triglycerides and absorption of LCFA. The remaining lipoprotein, now depleted of triglycerides, is called a "chylomicron remnant" and is subsequently removed from the circulation by hepatocytes. Uptake of chylomicron remnants is mediated by binding of Apo-B48 and Apo-E on the chylomicron remnant to either Apo-E or Apo-B/E receptors on the hepatocyte.

Triglycerides synthesized by hepatocytes are packaged into VLDL for transport in the blood (Figure 32.4). VLDL contain a large quantity of triglyceride along with lesser amounts of cholesterol, cholesterol esters, and Apo-B100. Apo-C and Apo-E are obtained from HDL in the circulation. If present in high quantities, VLDL also can contribute to a lipemic appearance of the blood. Like chylomicrons, binding of VLDL to lipoprotein lipase in the tissues is facilitated

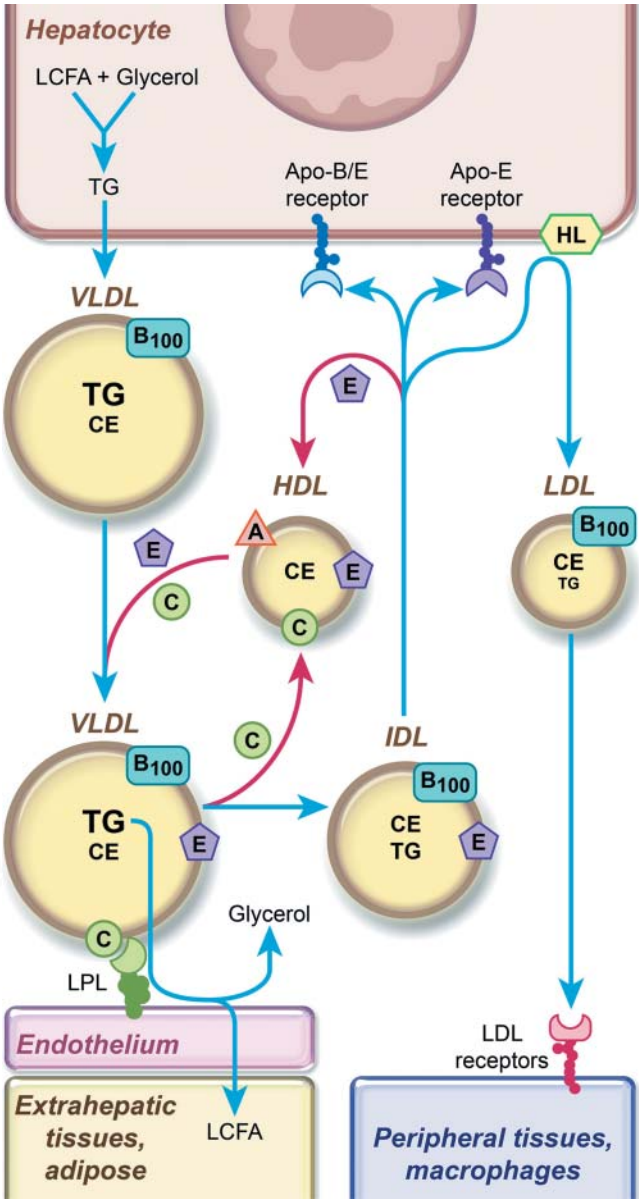

Figure 32.4 Triglycerides (TG) synthesized in hepatocytes are packaged along with cholesterol, cholesterol esters (CE), and apoprotein-B100 into very-low-density lipoproteins (VLDL) for transport in the blood. VLDL pick up apoprotein-C and apoprotein-E from high-density lipoproteins (HDL). TG are hydrolyzed to long chain fatty acids (LCFA) and glycerol by lipoprotein lipase (LPL) on the surface of endothelial cells. LCFA may be used by adipocytes to form TG, while glycerol is released into the blood for use by the liver or other extrahepatic tissues. Depletion of TG results in formation of an intermediate density lipoprotein (IDL) or VLDL remnants. Apoprotein-C and apoprotein-E recirculate back to HDL. IDL may be removed from the circulation by hepatocytes, a process mediated by Apo-B/E and Apo-E receptors. Alternatively, IDL may be further depleted of TG by hepatic lipase (HL) and converted to low-density lipoproteins (LDL). Uptake of LDL by peripheral tissues is mediated by binding of LDL to LDL receptors. Macrophages are also capable of removing LDL from circulation through scavenger receptors.

by Apo-C, and triglycerides are hydrolyzed to LCFA and glycerol for utilization by extrahepatic tissues.

After the VLDL is depleted of triglycerides, the remaining lipoprotein is an intermediate density lipoprotein (IDL) or VLDL remnant, depending on the species [4]. IDL and VLDL remnants may be taken up by hepatocytes, a process mediated by binding of Apo-B and Apo-E to hepatocyte receptors. Alternatively, additional hydrolysis of triglyceride by hepatic lipase converts IDL and VLDL remnants to low-density lipoproteins (LDL). As the lipoprotein loses triglyceride, Apo-C and Apo-E are transferred back to HDL while Apo-B100 is retained. The primary function of LDL is transport of cholesterol to the liver and other tissues. Removal of LDL from circulation is receptor mediated and depends on the presence of Apo-B. LDL receptor expression is stimulated by insulin and thyroxine. Most cells have receptors for LDL and can acquire cholesterol by binding LDL; however the liver plays the major role in LDL clearance.

Cholesterol transport is mediated by HDL. Nascent HDL are synthesized by hepatocytes and contain phospholipids, a small amount of cholesterol, Apo-C, and Apo-E. As previously described, HDL provide a source of Apo-C and Apo-E for exchange with chylomicrons and VLDL. As HDL mature, Apo-A is acquired by exchange with chylomicrons. The small intestine also produces HDL that initially contain Apo-A but lack Apo-C and Apo-E. Intestinal HDL must pick up Apo-C and Apo-E from hepatic-origin HDL in the blood. Importantly, HDL incorporate excess cholesterol from extrahepatic tissues in a process called "reverse cholesterol transport." Cholesterol is then esterified to cholesterol esters by lecithin cholesterol acyl transferase (LCAT) in the HDL, an enzyme that requires Apo-A for activation.

There is species variation in the relative amounts of HDL and LDL (Table 32.2) [5, 6]. In species that typically have high HDL and low LDL in the blood, such as dogs and cats, HDL are the primary transporters of cholesterol and cholesterol esters to the liver. In low HDL/high LDL species such as humans, cholesterol esters may be transferred by cholesteryl ester transfer protein (CETP) to VLDL remnants and LDL for subsequent delivery to the liver. High LDL species are at risk for the development of atherosclerosis because macrophages are capable of scavenger receptor-mediated removal of LDL from the circulation. Accumulation of LDL cholesterol in macrophages results in subendothelial lipid deposits or atherosclerotic plaques. High cholesterol diets can favor increased concentrations of LDL and exacerbate development of atherosclerosis.

Table 32.2 Examples of HDL mammals and LDL mammals [5, 6].

HDL mammals	LDL mammals
Dogs	Guinea pigs
Cats	Hamsters
Ferrets	Pigs
Horses	Camels
Cattle	Rabbits (some strains)
Sheep	Spider monkey
Mice	Humans
Rats	
Chimpanzee	
Most Old World monkeys	

HDL, high-density lipoprotein; LDL, low-density lipoprotein.
HDL mammals are defined as those having HDL as >50% of total lipoproteins, whereas LDL mammals have >50% LDL. Age, strain, breed, and diet may affect the relative distribution of lipoproteins.

Ketones

Ketogenesis is another option available for metabolism of fatty acids by the liver. As described above, LCFA may be repackaged into triglycerides and released as VLDL. Alternatively, LCFA may undergo β-oxidation to acetyl-CoA and subsequently be used for energy production via the TCA cycle, for cholesterol synthesis, or for ketogenesis (Figure 32.2). Under conditions of adequate nutrition, low levels of ketone bodies normally are produced by the liver. The rumen epithelium also appears to be capable of synthesizing β-hydroxybutyrate, which may account for the higher concentrations of ketone bodies in fed ruminants compared to fed monogastric species. The main ketone bodies are acetone, acetoacetate, and β-hydroxybutyrate. Acetyl-CoA is metabolized to acetoacetate, which subsequently is converted to acetone and β-hydroxybutyrate. These small lipids are water soluble and are transported by the blood to other tissues for use as an energy source. Because they are not bound to albumin, ketone bodies easily enter cells and cross the blood–brain barrier and placenta. Tissues such as the heart and brain readily utilize ketone bodies as an energy source.

Ketogenesis increases in conditions of negative energy balance and is a normal response to fasting. As plasma glucose falls, the concentrations of insulin decreases and glucagon increases. This stimulates lipolysis by HSL, mobilizing fatty acids from triglycerides stored in adipocytes. Fatty acids delivered to the liver are converted to acetyl-CoA. At the same time, enhanced gluconeogenesis consumes the available oxaloacetate without which acetyl-CoA cannot enter into the TCA cycle. As a result, acetyl-CoA is directed to ketogenesis.

Transient ketosis may develop following intense exercise and has been seen dogs and horses. During exercise, lipolysis by HSL is stimulated by catecholamines, cortisol and thyroxine, and the released fatty acids are consumed by muscle for energy production. Ketones formed during exercise are rapidly used, and circulating levels remain low to undetectable. In the postexercise period, muscle metabolism

switches from oxidation of fatty acids to gluconeogenesis and glycogen synthesis to clear lactate and replenish glycogen stores. Metabolism of acetyl-CoA through the TCA cycle declines as a result of decreased availability of oxaloacetate. Excess circulating fatty acids are cleared by the liver, and the resultant acetyl-CoA may be shunted into ketone production. The degree of post exercise ketosis appears related to intensity and duration of exercise, conditioning of the athlete, and diet.

Measurement of lipids

Because of the technical challenges associated with measurement of lipids, relatively few types of lipids are measured in routine biochemistry panels. Triglycerides and cholesterol can be measured in serum, heparinized plasma, or ethylenediaminetetraacetic acid (EDTA) plasma using spectrophotometric assays that are readily adapted to automated analyzers and are commonly part of biochemical profiles. Measurement of free fatty acids or NEFA in serum or EDTA plasma has been used to assess metabolism in ruminants, horses and camelidae. However, these assays are not as commonly available on routine biochemical profiles. Heparinized plasma or serum obtained using a serum separator tube are not recommended for measurement of NEFA as baseline NEFA concentrations will be higher and concentrations will rise with storage of the plasma [7].

Ketones may be measured on automated analyzers or at the cage side by dry reagent methods such as dipsticks, tablets, or nitroprusside powder. Measurement of ketones in the urine using dipsticks based on the nitroprusside test is frequently used as a less invasive, semiquantitative means to evaluate for accelerated ketogenesis in diabetes mellitus in small animals or in ketosis in cattle. The disadvantage of this method is that these dipsticks are more sensitive to acetoacetate than acetone or β-hydroxybutyrate and may underestimate ketones in some stages of diabetic ketoacidosis. The presence of some drugs or compounds in the urine also may produce a false-positive result. "Point of care" instruments have been evaluated for measurement of blood β-hydroxybutyrate in dogs, cats and cattle [8, 9]. In cattle, test strips are available for measurement of β-hydroxybutyrate in milk, which may prove more practical to obtain than urine.

Measurement of lipoproteins in veterinary species requires more sophisticated methods such as density gradient centrifugation or electrophoresis. Autoanalyzer and "point of care" methods designed to quantitate lipoproteins using precipitation and calculation techniques in humans have not been validated and may not give reliable results in veterinary species [10]. As a result, lipoprotein analyses are not routinely measured in veterinary medicine and require shipment of samples to specialized reference laboratories.

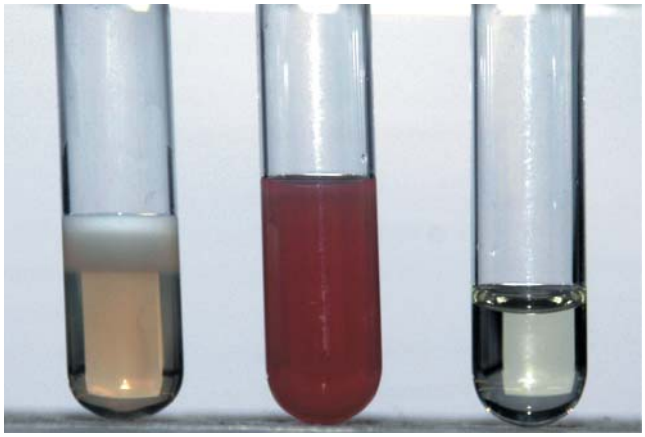

Figure 32.5 Lipemia is characterized by haziness to overt lactescence of a serum sample due to increased triglycerides in the form of chylomicrons and/or very-low-density lipoproteins (VLDL). Formation of a cream-like layer on the top of a sample indicates the presence of chylomicrons (left). Failure of a sample to separate indicates the presence of VLDL (middle). Normal samples are clear (right).

The term "hyperlipidemia" refers to increased circulating lipids. This may be due to hypertriglyceridemia and/or hypercholesterolemia. Lipemia or hyperlipemia refers to a visible haziness (usually when triglycerides exceed 300 mg/dL) to overt latescence of the serum or plasma (triglycerides exceed 600–1000 mg/dL). Lipemia is caused by increased triglycerides in chylomicrons and/or VLDL. Hypercholesterolemia without concurrent hypertriglyceridemia will not cause a sample to appear lipemic. The refrigeration test is a simple means to distinguish between chylomicrons and VLDL as the cause of lipemia (Figure 32.5). To perform this test, a sample is left upright in a refrigerator overnight. Chylomicrons will float to the top of the sample and form a milky or cream-like layer at the top of the sample. If the underlying serum clears, then chylomicrons are the cause of the lipemia. On the other hand, if VLDL are the cause of the lipemia, VLDL will not separate out into a cream layer, and the sample will remain hazy to turbid. If the lipemia is due to increases in both chylomicrons and VLDL, a cream layer will form over a sample that remains turbid.

Clinically relevant changes in serum lipids include hypertriglyceridemia, hypercholesterolemia, hyperketonemia, and hypocholesterolemia. Hypotriglyceridemia is of uncertain clinical relevance and may be most indicative of nutritional state.

Hyperlipidemias

Postprandial hyperlipidemia

Postprandial hyperlipidemia is due to a transient increase in triglycerides in the form of chylomicrons. Hyperlipidemia becomes apparent within 1–2 hours of consuming a meal

that contains fat and usually peaks by 6–8 hours. Because postprandial hyperlipidemia is primarily due to increases in triglycerides, blood samples may appear hazy to grossly lipemic. For dogs and cats, fasting for 12 hours should allow sufficient time for clearance of the hyperlipidemia. To evaluate for equine metabolic syndrome, horses should be fasted by confining them to a stall, leaving one flake of hay in the stall after 10:00 p.m. and drawing samples in the morning [11]. Because of continuous rumenal digestion and diet composition, ruminants do not show significant postprandial effects and so need not be fasted prior to sampling.

Persistence of hyperlipidemia after a 12-hour fast in dogs and cats suggests an alternative pathogenesis for the hyperlipidemia. In monogastric animals, consumption of a high fat diet may contribute to higher fasting and postprandial serum lipids compared to normal or low fat diets. The time it takes for serum lipids to decrease to fasting levels may be prolonged following a high fat meal and a 15 hour fast may be needed to establish true fasting lipid levels. As seen in Table 32.1, many key regulatory steps in lipid metabolism are influenced by hormones. It is not surprising that pathologic hyperlipidemia is commonly due to secondary causes such as hormonal or metabolic disturbances. Primary or idiopathic hyperlipidemias are rare and likely have a genetic basis.

Secondary pathologic hyperlipidemias

Secondary pathologic hyperlipidemias are caused by a variety of diseases (Figure 32.6). While described separately below, it is important to realize that there may be overlapping effects promoting abnormalities in lipid metabolism in any given patient. For example, pancreatitis may be complicated by diabetes mellitus due to damage to pancreatic parenchyma. Diabetes mellitus commonly occurs in conjunction with hyperadrenocorticism in cats as a result of corticosteroid-related insulin resistance. Many of these conditions also have an inflammatory component resulting in increased local and systemic release of pro-inflammatory cytokines capable of modulating lipid metabolism.

Hypothyroidism

Hypothyroidism in dogs is a common endocrinopathy and is frequently accompanied by hypercholesterolemia due to

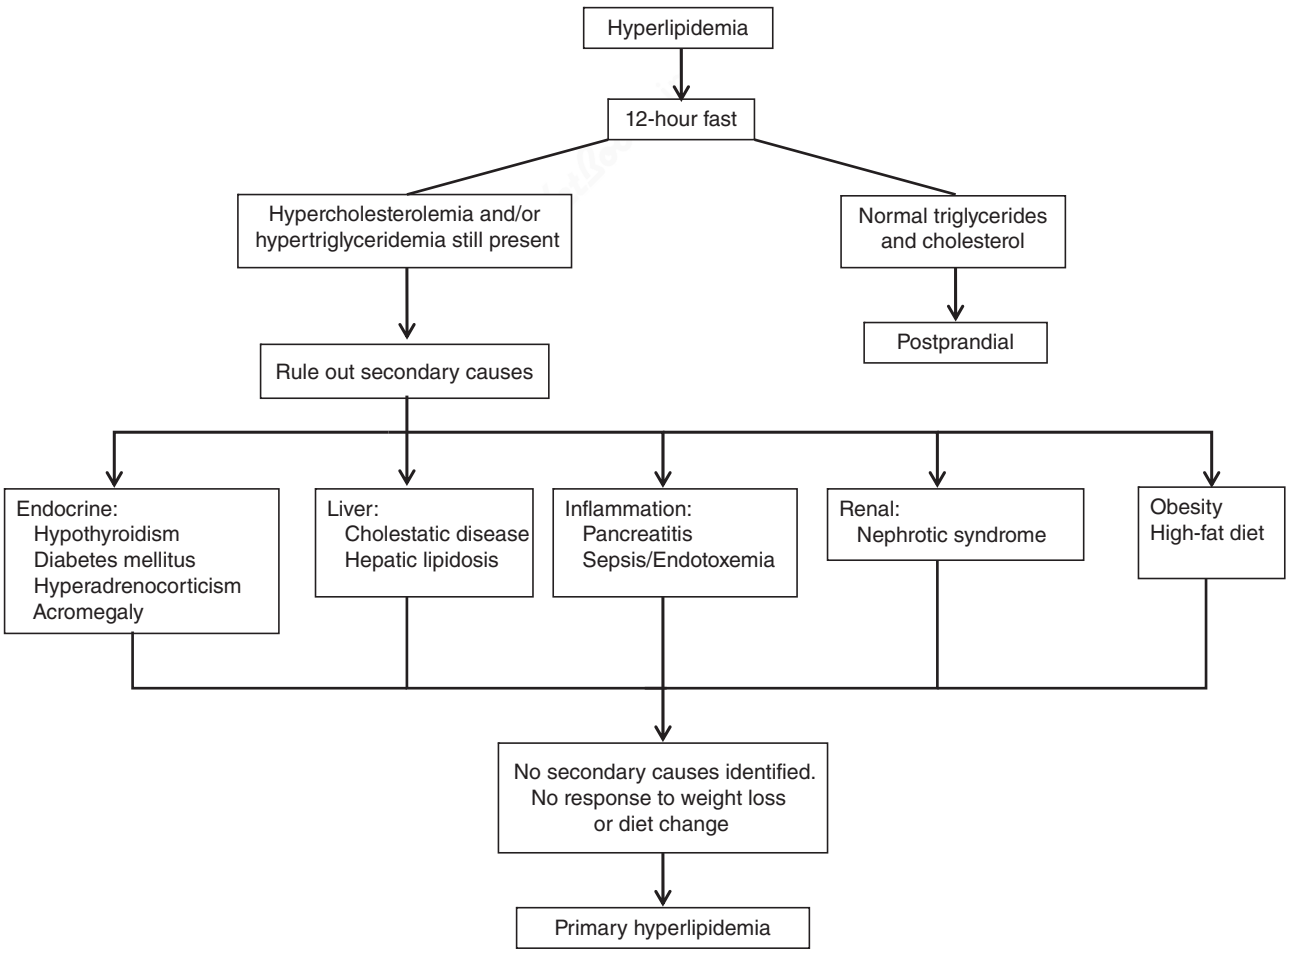

Figure 32.6 Approach to the hyperlipidemic patient.

increases in LDL and HDL [12–15]. Hypertriglyceridemia also is common and is due to increased VLDL and sometimes chylomicrons. In contrast to dogs, spontaneously occurring hypothyroidism is rare in cats but may develop as a sequela to treatment for hyperthyroidism. Congenital hypothyroidism has been described in kittens [16]. Hypercholesterolemia may be a feature of both spontaneous and iatrogenic feline hypothyroidism [16, 17]. In adult horses, the actual incidence of naturally occurring hypothyroidism is very low. Cases initially diagnosed as hypothyroidism may actually be attributable to equine metabolic syndrome or hyperadrenocorticism secondary to a tumor or dysfunction of the pituitary pars intermedia [18]. Experimental ablation of the thyroid glands of adult horses will result in hypercholesterolemia and hypertriglyceridemia characterized by increased LDL and VLDL, respectively [19].

In humans with hypothyroidism, decreased hepatic LDL receptor synthesis and increased receptor catabolism contributes to the hypercholesterolemia by impairing LDL clearance [20]. Biliary excretion of cholesterol also is decreased while intestinal cholesterol absorption is increased. Decreased lipoprotein lipase activity delays clearance of triglycerides from both VLDL and chylomicrons, while decreased hepatic lipase activity slows clearance of cholesterol-enriched chylomicron remnants. Similar mechanisms have not been thoroughly examined in domestic species.

Hyperadrenocorticism

Increased serum concentrations of triglycerides and cholesterol may be observed in dogs with Cushing's disease [15, 21–24]. Hypercholesterolemia also is reported in cats with hyperadrenocorticism [25–27]. As a consequence of corticosteroid-induced insulin resistance, hyperadrenocorticism, especially in cats, is often complicated by concurrent diabetes mellitus that exerts additional effects on lipid metabolism [27]. Horses with pituitary pars intermedia dysfunction (PPID) may develop pituitary-dependent hyperadrenocorticism. Stimulation of lipolysis in these horses results in elevated circulating NEFA as well as increased ketogenesis [28]. Reports vary on the incidence of hypertriglyceridemia in horses with PPID and hyperadrenocorticism [28–31]. Hyperlipidemia can become marked if there is concurrent type 2 diabetes mellitus and metabolic syndrome.

A combination of direct effects of corticosteroids and indirect effects due to steroid-induced insulin resistance contribute to the alterations in lipid metabolism in patients with hyperadrenocorticism [20]. Hypercholesterolemia results from impaired clearance of LDL along with decreased catabolism of cholesterol secondary to steroid-induced hepatopathy and cholestasis. Increased synthesis of VLDL by hepatocytes promotes hypertriglyceridemia.

Diabetes mellitus

Poorly controlled diabetes mellitus due to insulin deficiency (type 1 or insulin dependent diabetes mellitus) is associated with hypertriglyceridemia, increased serum LCFA, and hypercholesterolemia in dogs [12, 32, 33]. Type 1 diabetes mellitus is rare in the horse but may be accompanied by hypertriglyceridemia [34]. Insulin is required for synthesis and activity of lipoprotein lipase, so insulin deficiency results in failure to clear triglycerides from chylomicrons and VLDL. In addition, circulating LCFA are increased due to a combination of increased lipolysis and decreased triglyceride synthesis by adipocytes. A lack of insulin results in increased activity of HSL in adipocytes and subsequent hydrolysis of stored triglycerides and release of LCFA into the circulation. Because adipocytes require glucose for synthesis of glycerol-1-phosphate, impaired insulin-mediated glucose uptake by adipocytes results in decreased availability of glycerol-1-phosphate for esterification of LCFA to form triglycerides. LCFA are released into the blood and are subsequently taken up by hepatocytes, converted to triglycerides, and released as VLDL. If the concentration of LCFA exceeds the ability of hepatocytes to produce and release VLDL or to consume acetyl-CoA through the TCA cycle, acetyl-CoA generated from LCFA may be shunted into synthesis of ketone bodies, contributing to the development of ketoacidosis.

Insulin stimulates production of the LDL receptors so hypercholesterolemia appears to be primarily the result of a decrease in receptor-mediated uptake of LDL. Increased intestinal synthesis of cholesterol also appears to play a role in the genesis of the hypercholesterolemia in the dog.

Obesity, insulin resistance, and metabolic syndrome

Insulin resistance may vary from mild to overt type 2 diabetes mellitus. The pathogenesis of insulin resistance is complex and instigating causes are varied. Conditions associated with insulin resistance include obesity, hyperadrenocorticism, and hypersomatotropism. As a result, the effects of impaired response to insulin are superimposed on the disturbances in lipid profile caused by the original disorder. Type 2 diabetes mellitus is the most common form of diabetes mellitus in cats and horses.

Obesity is a frequently encountered problem in dogs, cats, and horses. Lipid profiles of obese individuals can exhibit a spectrum from normal to marked increases in triglycerides along with variable increases in cholesterol. Plasma NEFA often are increased. The variation observed in lipid profiles in obesity likely relates to the site of excess fat deposition, duration of obesity, and dysfunction of metabolic regulatory hormones such as insulin, cortisol, leptin, and adiponectin. Obesity is now recognized as a pro-inflammatory state, and fat pads are a source of inflammatory cytokines such as interleukin-6 and tumor necrosis

factor-α. These inflammatory mediators can have a significant impact on adipocyte and hepatic lipid metabolism (see section below on inflammation) and can promote insulin resistance. Intra-abdominal obesity appears to have more severe metabolic consequences compared to peripheral adiposity and predisposes to the development of insulin resistance and metabolic syndrome.

In addition to increases in absolute concentrations of triglycerides and cholesterol, the composition of lipoproteins may change. Obese dogs show a pattern of increased triglycerides and cholesterol in both VLDL and HDL [35, 36]. In cats, triglyceride and cholesterol content of VLDL are increased while HDL cholesterol is increased [37, 38]. Horses exhibit increases in VLDL-triglyceride and HDL-cholesterol content [11, 39]. Decreases in lipoprotein lipase activity has been documented in obese cats, suggesting that uptake of triglycerides by adipocytes and peripheral tissue beds is impaired [37, 40]. LDL fractions appear unaffected and may account for the relative resistance of these species to development of atherosclerosis even with obesity-related hyperlipidemia.

Hypercholesterolemia has been observed in cats with acromegaly [41]. Acromegaly is the result of increased production of growth hormone. While not specifically explored in cats, there are several mechanisms that may explain the hypercholesterolemia secondary to hypersomatotropism. These cats have metabolic complications from significant insulin resistance to type 2 diabetes mellitus. In addition, growth hormone decreases release of thyroid stimulating hormone resulting in secondary hypothyroidism.

Hepatic lipidosis

Hepatic lipidosis or fatty liver occurs when triglycerides accumulate in hepatocytes. This syndrome may be precipitated by negative energy balance, hormonal or metabolic disturbances, hypoxia, or toxins. It results from an imbalance between hepatic uptake of fatty acids, synthesis of triglycerides, formation of VLDL, and release of VLDL. Hepatic lipidosis may develop in association with conditions such as bovine ketosis, ovine pregnancy toxemia, fasting in obese cats and horses, and a variety of syndromes in camelids. In these syndromes, HSL activity and subsequent adipocyte lipolysis is accelerated, increasing the supply of LCFA. The supply of LCFA outpaces the ability of the liver to oxidize LCFA through the TCA cycle so LCFA are re-esterified to triglycerides. Triglycerides accumulate as the ability to either produce VLDL or transport VLDL out of the hepatocyte is exceeded. Excess fatty acids also may be shunted to ketone body production, and lipidosis is often accompanied by some degree of ketosis. Grossly, the liver appears pale to yellow in color. Microscopically, variably-sized clear fat vacuoles are seen within the cytoplasm of the hepatocytes (Figure 32.7).

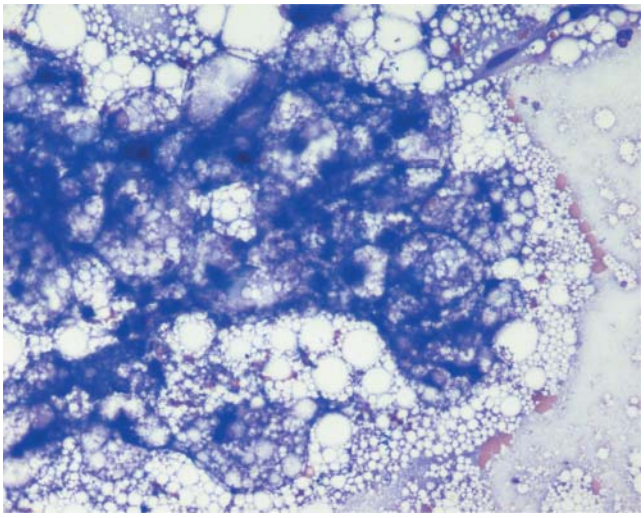

Figure 32.7 Fine needle aspirate of the liver of a cat with hepatic lipidosis. The cytoplasm of the hepatocytes contains variably sized, clear lipid vacuoles. Lipid-laden hepatocytes are often fragile and will break, leaving lipid droplets evident in the background. Wright-Giemsa stain, 400×.

Anorexia in horses, especially if they are obese to begin with, can prompt the development of hyperlipidemia and hepatic lipidosis [11, 39]. Ponies, miniature horses, donkeys, and mares are at increased risk, and the risk may be compounded by pregnancy or lactation. The syndrome in equids is characterized by increased circulating NEFA, triglycerides, and, to a lesser degree, cholesterol [42, 43]. However, ketonemia and ketonuria are not present. Increases in triglyceride concentrations may be marked and are primarily due to increased hepatic production of VLDL. Triglyceride concentrations in anorexic horses have been shown to be inversely related to survival [44, 45].

Obese cats that become anorexic due to illness or are subjected to a rapid weight reduction are at risk for development of hepatic lipidosis as a consequence of increased lipolysis [46]. Hypertriglyceridemia occurs as a result of increased VLDL production as well as impaired peripheral utilization. Although export of VLDL from the liver is increased, this appears insufficient to prevent accumulation of triglycerides in hepatocytes. Hypercholesterolemia is a less consistent finding.

Hepatic lipidosis occurs in camelids secondary to conditions that increase fat mobilization [47, 48]. The syndrome is accompanied by increased NEFA and, in some cases, ketonemia and ketonuria. Like other species, hepatic lipidosis may occur as a sequela to negative energy balance associated with pregnancy or lactation, in which case the dams will be hypoglycemic and ketonemic. In cases not associated with pregnancy and lactation, hyperglycemia may be observed due to the blunted insulin response and excessive gluconeogenesis typical of camelids. Hypertriglyceridemia may develop with severe, terminal lipidosis.

Pancreatitis

Dogs with naturally occurring pancreatitis may have hypertriglyceridemia and hypercholesterolemia, and the serum may exhibit overt lipemia [4, 12, 49, 50]. Hypercholesterolemia also is reported in cats with pancreatitis [51]. Changes in canine lipoprotein patterns include increases in VLDL, chylomicrons, and LDL with decreases in some subtypes of HDL. The hypertriglyceridemia arises from both a decrease in clearance of chylomicrons and VLDL due to decreased lipoprotein lipase activity as well as an increase in VLDL production. Hypercholesterolemia results from decreased biliary excretion due to pancreatitis-associated cholestasis as well as increased hepatic synthesis. Release of inflammatory cytokines likely contributes to the alterations in hepatic lipid metabolism. Pathogenesis of the hyperlipidemia may be further complicated by the comorbidity of diabetes mellitus as pancreatic parenchyma is damaged.

It is speculated that hypertriglyceridemia may contribute to the development of pancreatitis and may help explain the clinical impression that consumption of high fat meals can precede the onset of acute pancreatitis. The theory is that hydrolysis of chylomicron triglycerides by pancreatic lipase within the pancreatic microcirculation results in local release LCFA. LCFA have the potential to damage both the endothelial cells of the pancreatic microvasculature as well as the pancreatic acinar cells. This provides a mechanism for perpetuating a cycle of ongoing release of pancreatic lipase and generation of damaging LCFA as well as release of other potentially harmful pancreatic enzymes into the parenchyma.

Endotoxemia and inflammation

Alterations in serum lipids and lipoproteins may be seen as a response to endotoxin and endotoxin-induced release of inflammatory cytokines [52]. Inflammatory cytokines have been implicated in mediating the changes in lipid metabolism in a number of pro-inflammatory conditions such as obesity and pancreatitis. Response to endotoxin is characterized by increased circulating LCFA, triglycerides, and VLDL. Stimulation of lipolysis by adipocytes and hepatic fatty acid synthesis in concert with decreased fatty acid oxidation results in increased triglyceride and VLDL synthesis. Clearance of triglycerides is impaired due to decreased lipoprotein lipase activity. Decreased lipoprotein Apo-E content blunts receptor mediated removal of lipoproteins from the blood.

Cholesterol levels are more variable and likely depend on species, clinical severity, and time course in the disease. Mild hypercholesterolemia may develop secondary to endotoxin-induced decreases in biliary excretion of cholesterol as well as decreased uptake of LDL secondary to down regulation of LDL receptors. As part of a negative acute phase reaction mediated by inflammatory cytokines, patients may develop mild to moderate hypocholesterolemia due to a decrease in hepatic cholesterol synthesis. HDL may both decrease in concentration and alter in composition. Dogs with parvovirus enteritis exhibit hypocholesterolemia and hypertriglyceridemia that correlated with tumor necrosis factor-α concentrations [53].

Cholestasis

Cholestasis arising from a variety of mechanisms may result in mild to moderate increases in cholesterol with occasional mild increases in triglycerides. This is likely due to a combination of decreased hepatic cholesterol uptake and impaired cholesterol excretion in the bile. Alterations in lipoprotein composition and distribution have been documented in dogs, cats, and horses with natural and experimentally induced cholestasis [54–57].

Protein losing nephropathies and nephrotic syndrome

Nephrotic syndrome may develop as a result of glomerular damage and proteinuria arising from a variety of etiologies. The hallmarks of nephrotic syndrome include proteinuria, ascites, edema, hypoalbuminemia, hypercholesterolemia, and hypertriglyceridemia. Nephrotic syndrome accompanied by hypercholesterolemia and hypertriglyceridemia has been observed in dogs, cats, and horses [58]. While nephrotic syndrome with proteinuria and hypoalbuminemia has been described in cattle, effects on serum cholesterol and triglycerides were not reported [59].

A number of mechanisms have been suggested to explain the altered lipid metabolism secondary to proteinuria and hypoalbuminemia [60]. Experimental studies in human and animal models suggest that proteinuria and hypoalbuminemia are associated with increased activity of hepatic cholesterol synthetic enzymes, resulting in increased production of cholesterol and cholesterol containing lipoproteins. Urinary loss of key enzymes such as LCAT may affect maturation of HDL and impair the mechanism of reverse cholesterol transport. Decreased LDL receptor expression as well as altered binding of LDL to LDL receptors contributes to decreased clearance of LDL. Catabolism of cholesterol and subsequent excretion of cholesterol through the bile also may be impaired due to decreased activity of enzymes involved in bile acid synthesis.

Hypertriglyceridemia results from both increased hepatic synthesis of VLDL and decreased peripheral clearance of VLDL and chylomicrons. Impaired clearance of triglycerides appears to be the result of decreased activity of lipoprotein lipase and hepatic lipase. Loss of activity of lipoprotein lipase is mediated by inhibitors such as angiopoietin-like 4, the production of which by the kidney is stimulated by proteinuria.

Neonates and nursing young

Circulating triglycerides and cholesterol concentrations are higher in healthy young animals compared to adults, so age

appropriate reference intervals should be used when possible [61–65]. Higher triglycerides and cholesterol may be due in part to the difficulty in obtaining fasted samples from very young animals that are suckling and the relatively high fat content of a milk diet. Differences in lipid metabolism and enzyme activities between young and adults could also play a role.

Moderate to severe hyperlipidemia, characterized by moderate to marked hypertriglyceridemia and overt lipemia, can be seen in poor doing young kittens and foals. In both species, the syndrome is likely a consequence of negative energy balance due to failure to adequately nurse and, if severe, may result in hepatic lipidosis. Sick foals that become anorexic and fail to nurse often develop hypertriglyceridemia with increased NEFA due to lipolysis [66–68]. This can be accompanied by hypoglycemia that is usually more severe if the foal is septic. Some foals respond to parenteral nutritional therapy with hyperglycemia due to insulin resistance or impaired insulin responses.

A pattern of severe hypertriglyceridemia, hypercholesterolemia and anemia has been reported in 3- to 8-week-old kittens that can resolve in response to supportive therapy [69, 70]. The precipitating circumstances often include causes of negative energy balance such as failure to nurse and flea infestation.

Primary hyperlipidemia

Once other causes of hyperlipidemia have been excluded, a diagnosis of primary hyperlipidemia should be considered. These conditions are rare and usually believed to have a genetic basis, although pathogenesis often remains elusive. In dogs, idiopathic hyperlipidemia is most commonly observed in miniature schnauzers and is characterized by moderate to marked hypertriglyceridemia and moderate hypercholesterolemia [71, 72]. Decreases in lipoprotein lipase activity has been suggested as a mechanism underlying the increases in VLDL with or without increases in chylomicrons observed in this breed [72–74] This syndrome may be an incidental finding or may be associated with clinical signs such as seizures, abdominal pain, pancreatitis or ocular lesions. Proteinuria and renal lesions including glomerular lipid thromboemboli have been associated with hypertriglyceridemia in miniature schnauzers [74, 75]. Idiopathic hyperlipidemia has been reported in other dog breeds as well as sporadically in mixed breeds.

A syndrome of primary hypercholesterolemia and hypertriglyceridemia has been described in Shetland sheepdogs [76, 77] and beagles [78]. Idiopathic hypercholesterolemia with normal triglycerides has been observed in briards [79], while idiopathic hypertriglyceridemia without elevations in cholesterol have been documented in Brittany spaniels [80].

Primary hyperchylomicronemia resulting from a mutation in the lipoprotein lipase gene has been documented in cats [81]. It is suggested that the lipoprotein lipase enzyme cannot bind to the capillary endothelium. These cats have increases in serum chylomicrons, triglycerides, and cholesterol. This condition is associated with overall decrease in body fat mass, development of xanthomata and ocular lipid accumulation [82, 83].

Ketosis and ketoacidosis

Clinically significant ketosis occurs in conditions where energy supply and demand are out of balance. This may be seen in dairy cows in early lactation when high milk production results in a negative energy balance. Clinical bovine ketosis is characterized by increased plasma NEFA, hypoglycemia, hypoinsulinemia, high glucagon, low insulin, and metabolic acidosis [84]. Increased lipolysis supplies LCFA to hepatocytes at a rate that exceeds the ability to produce and export triglycerides or to oxidize them through the TCA cycle. As a result, fatty acids are shunted to ketone production. Hepatic lipidosis usually precedes clinical ketosis due to sluggish export of VLDL. While clinical bovine ketosis is not a fatal disease, it does result in significant loss of milk production and may predispose to other conditions such as displaced abomasum, metritis, and mastitis. Ovine pregnancy toxemia also is a consequence of negative energy balance. In this case, the energy drain is usually the result of late term pregnancy with twins. Ovine pregnancy toxemia is a severe, often fatal disease that may be precipitated by stress. Ewes typically are lethargic with hypoglycemia, severe metabolic acidosis, and ketosis. In sheep with pregnancy toxemia, an inability to either produce VLDL or transport triglycerides out of the hepatocytes occurs and hepatic lipidosis ensues.

Poorly controlled diabetics may develop ketosis and ketoacidosis. Diabetic ketoacidosis is characterized by hyperglycemia, hypercholesterolemia, hypertriglyceridemia, increased NEFA, and metabolic acidosis [32]. Enhanced lipolysis and gluconeogenesis result from a lack of insulin or poor insulin responsiveness. Increased glucagon, cortisol, and norepinephrine also have been implicated in the pathogenesis of diabetic ketoacidosis in dogs [32]. Triglycerides accumulate, resulting in hepatic lipidosis, while excess acetyl-CoA is converted to ketone bodies. Ketone production exceeds the ability to utilize them as an energy substrate and ketone bodies accumulate. Because ketones are strong acids, metabolic acidosis develops as the concentrations of ketone bodies increase.

Hypolipidemias

Table 32.3 lists diseases in which hypolipidemia may occur. Mild decreases in cholesterol and triglycerides alone may be of limited clinical significance and may just reflect a fasting

Table 32.3 Causes of hypolipidemia.

Protein losing enteropathy
Exocrine pancreatic insufficiency
Inflammatory bowel disease
Hepatic insufficiency
Hypoadrenocorticism
Hematopoietic neoplasia
Hyperthyroidism

state. Hypocholesterolemia can be a characteristic of illnesses that result in decreased production, decreased intake such as can be seen with malabsorption and maldigestion, or increased catabolism of cholesterol. Hypotriglyceridemia often is a reflection of inadequate nutrition such as starvation or malnutrition secondary to malabsorption and/or maldigestion.

Protein losing enteropathy, malabsorption, and maldigestion

Conditions resulting in malabsorption and/or maldigestion may be associated with hypocholesterolemia and hypotriglyceridemia, although these findings are inconsistent. Decreased serum cholesterol and triglycerides may occur with exocrine pancreatic insufficiency. In these patients, serum albumin is usually maintained within the reference interval. In contrast, patients that develop protein losing enteropathy may have concurrent hypocholesterolemia and hypoalbuminemia due to loss of both albumin and lipoproteins. Protein losing enteropathy can result from a variety of gastrointestinal pathologies including infectious, inflammatory, or infiltrative intestinal diseases as well as primary or secondary intestinal lymphangiectasia [85]. Five to 30% of cats with idiopathic inflammatory bowel disease (IBD) are reported to have hypocholesterolemia [86]. However, this finding is not consistent, and those same studies indicate that 3–5% of cats with IBD may have hypercholesterolemia. Some breeds of dogs are predisposed to protein losing enteropathy, including the soft-coated Wheaten terrier, Yorkshire terrier, basenji, and Norwegian Lundehund [85]. In soft-coated Wheaten terriers, concurrent protein losing nephropathy and nephrotic syndrome can have counterbalancing effects on serum cholesterol and triglycerides [87].

Hepatic insufficiency

Noncholestatic liver failure may be associated with hypocholesterolemia due to decreased cholesterol production. Hypocholesterolemia has been associated with cirrhosis, toxin-induced parenchymal damage, and portosystemic vascular anomalies. Hypotriglyceridemia also may be present. Hepatic insufficiency can be difficult to distinguish from intestinal diseases resulting in protein losing enteropathy as both may have concurrent hypocholesterolemia, hypoalbuminemia, low blood urea nitrogen (BUN), and gastrointestinal signs. Measurement of bile acids can distinguish between the two disorders.

Hypoadrenocorticism

Hypocholesterolemia is sometimes seen in dogs with hypoadrenocorticism [88, 89]. The incidence of hypocholesterolemia may be more common in atypical Addisonians in which there is a deficiency of glucocorticoid but not mineralocorticoid production [90]. Hypoalbuminemia and hypoglycemia also may be present and can make distinguishing Addison disease from other conditions such as liver or intestinal disease difficult.

Hematopoietic neoplasia

Decreased serum cholesterol is observed in some forms of hematopoietic neoplasia in humans and animals. Hypocholesterolemia was noted in 69% of dogs with hemophagocytic histiocytic sarcoma [91] and cats with multiple myeloma [92]. A recent report indicated that 24% of cats with nasal and nasopharyngeal lymphoma had hypocholesterolemia [93]. The mechanism underlying the hypocholesterolemia is uncertain but may relate to production of inflammatory cytokines such as interleukin-6 and tumor necrosis factor-α. These cytokines suppress hepatic cholesterol synthesis and contribute to the negative acute phase reaction observed with both albumin and cholesterol. Hypoalbuminemia was a relatively common finding in the cats with multiple myeloma and dogs with hemophagocytic histiocytic sarcoma, but not in the cats with nasal and pharyngeal lymphoma. Enhanced catabolism of cholesterol has been suggested as another mechanism to explain hypocholesterolemia in some human cancer patients.

Hyperthyroidism

Hypocholesterolemia and hypotriglyceridemia have been observed in hyperthyroid humans and in some experimental models of hyperthyroidism. While hyperthyroidism is common in older cats, decreases in serum cholesterol and triglycerides are uncommon findings. Concentrations of cholesterol and triglycerides may be near but often do not dip below the lower limit of the reference interval [94]. In one report, hypercholesterolemia was observed in 8% of cases, while hypocholesterolemia was not seen in any of the 131 cats included in the study [95].

Clinical endocrinology

Introduction

The endocrine system is unique in that its diseases cause hypofunction or hyperfunction of an endocrine organ. This is in contrast to other organ systems wherein disease causes only hypofunction (e.g., renal, liver, cardiac diseases). Lesions causing disease can be located in any organ within the endocrine axis; however, clinically we evaluate the endocrine gland (primary) and the pituitary gland's respective relationship (secondary). Likewise, an understanding of the normal endocrine physiology and hormone function is essential in identifying the underlying disease, recognizing clinical manifestations, as well as in the selection and interpretation of appropriate diagnostic tests. Before reading any further, let's clarify for the record that there are no perfect diagnostic tests. For diagnostic use, we need tests that distinguish animals with a specific disease from the other differentials that are clinically similar. As veterinarians, we utilize multiple facets of information, including our medical knowledge, the patient's history, clinical signs, and physical exam findings to guide use of diagnostic testing. Endocrinopathies are notorious for being diagnostically challenging, especially if the disease is in the early stages and has not developed fulminate clinical signs or classical laboratory abnormalities. As a result, multiple diagnostic modalities may be required to reach a definitive diagnosis. These include key features in the patient's history, clinical presentation, and physical exam findings along with complete blood count (CBC), serum chemistry, urinalysis results, serologic testing, and diagnostic imaging. Frequently, multiple tests are required to confirm or refute a diagnosis, and they should be performed in logical order. An important principle for almost all diseases and the lab tests used to recognize the disease is that the earlier diagnostic tests are used during the progression of a disease, the more likely that the results can be equivocal. The stages of the patient's disease will influence the clinical signs and laboratory results that are being expressed at that time.

Thus, the general approach to diagnosing an endocrine disorder begins with the same basics used to diagnose all diseases: history, clinical presentation, and physical exam findings. This is followed by routine laboratory evaluation (CBC, chemistry, urinalysis). If endocrine disease is still suspected, appropriate special screening, confirmatory, and differentiating tests are then employed. It is essential to combine all of the data in a case and not rely on single abnormalities. When this is done in logical steps, a definitive diagnosis is obtained.

Endocrine tests are categorized into screening, confirmatory, and differentiating tests. A test's sensitivity (true positive) and specificity (true negative) greatly influence the value of each test. The sensitivity and specificity of lab results can be extreme. For example, an increased serum alkaline phosphatase (ALP) activity, when evaluated in isolation, is extremely sensitive for hyperadrenocorticism (HAC) because >90% of patients with hyperadrenocorticism have an increase in ALP. However, it is not specific for HAC (i.e., many other diseases have an increase in ALP). How we use test results influences their utility. In this example, if a patient has a serum ALP within reference interval (RI/WRI), it is highly unlikely the patient has HAC. Therefore, rule out this differential or at least move it lower on the list of differentials. Nonetheless, when an increased ALP is noted in the presence of other clinical and laboratory signs of HAC, this prompts additional diagnostic testing with screening tests. In HAC, a commonly used screening test is the low-dose dexamethasone suppression test (LDDST). If a dog does not suppress with LDDST, then it supports the diagnosis of HAC. The LDDST is highly sensitive (95% of dogs with HAC will not suppress) but not specific (50% of dogs that do not suppress do not have HAC). Therefore, this test is reliable when negative, and you can rule out HAC with confidence.

However, LDDST is prone to false-positive results, therefore only rule in HAC if other tests agree with LDDST. Similar to routine laboratory testing, when a dog fails to suppress with LDDST, it prompts the use of confirmatory tests. Confirmatory tests have higher sensitivity and specificity values and therefore clinical utility. Ultimately one would like to integrate sensitivity and specificity values with disease prevalence to know the positive and negative predictive values of each test. As a generalization, tests progress from routine lab data to screening tests, and then confirmatory tests. Finally, when an endocrine disorder has multiple pathogeneses, tests that identify the underlying lesion or "differentiating tests" are employed. In the example of HAC, these tests help identify if the lesion is the adrenal gland (primary) or in the pituitary (secondary). This differentiation is critical for HAC in dogs because the treatments are different (e.g., surgical for adrenal dependent and medical management for pituitary).

In this chapter, we will be exploring the clinicopathologic diagnosis of several common endocrinopathies involving the thyroid gland, adrenal glands, and pituitary gland.

Thyroid disorders

Thyrotropin-releasing hormone (TRH) from the hypothalamus stimulates the release of thyroid-stimulating hormone (TSH, thyrotropin) from thyrotropes in the pituitary, which in turn stimulates thyroid gland follicular cell hypertrophy and a cascade of intracellular events that result in the production of thyroxine (TT4, tetraiodothyronine) and smaller amounts of triiodothyronine (TT3), and trace amounts of reverse triiodothyronine (rT3). Approximately 99% of secreted TT4 is bound to plasma proteins and less than 1% is free tetraiodothyronine (fT4). However, fT4 is biologically active, enters cells, leads to intracellular TT3 production, and causes negative feedback to TSH release. Free T4 that passes into cells is metabolized into TT3 or rT3 based on physiologic needs. In normal metabolic states TT3 is produced, and this is the biologically active hormone that stimulates cellular events, but when patients are sick there is preferential conversion to biologically inactive rT3. Reverse TT3 increases in nonthyroidal illness and is responsible for the decrease in TT4 seen in the euthyroid sick syndrome. Increased concentrations of serum rT3, combined with measurement of TT4 and TT3 were used to identify patients with the euthyroid sick syndrome, but measurement of rT3 and TT3 are seldom done anymore. Measurement of rT3 can help identify the euthyroid sick syndrome, or nonthyroidal illness. Although TT3 is the biologically active form of thyroid hormone it is of limited diagnostic value. TT4, the storage form of thyroid hormone, and fT4 are of greater diagnostic value. All of the serum TT4 and fT4 come from the thyroid gland and only a portion of TT3 arises in the thyroid. This may explain the greater utility of TT4 and fT4 as opposed to TT3 to indicate thyroid gland function. The majority of T3 is produced outside of the thyroid glands via deiodination of T4 in nonthyroid cells.

The major diseases of the thyroid gland are neoplasia, hyperthyroidism, and hypothyroidism. Generally, thyroid tumors in cats are benign and thyroid gland tumors that are large enough to be detected clinically in dogs are malignant. Hyperthyroidism is a very common disease of cats but is uncommon in dogs and other species. The majority of thyroid tumors in dogs do not cause hyper or hypothyroidism. Hypothyroidism is very common in dogs and does not occur spontaneously in adult cats. Hypothyroidism in cats is almost always iatrogenically induced following treatment of hyperthyroidism. Hypothyroidism is associated with goiter, or hyperplastic thyroid glands, in ruminants, birds, and horses.

Thyroid tests

TT4

This is an excellent test to rule in hyperthyroidism in cats and rule out hypothyroidism in dogs. Increased serum TT4 in a cat is due to hyperthyroidism until proven otherwise. Serum TT4 concentration within RI rules out hypothyroidism in dogs. TT4 is stable at room temperature for one week, an unusual benefit compared to most hormones that degrade postcollection if not frozen. TT4 can be measured via radioimmunoassay (RIA), chemiluminescent enzyme immunoassay, and ELISA, all of which have similar diagnostic value. Point-of-care ELISA can be used in clinics and provide results within minutes. Numerous drugs and nonthyroid diseases and can suppress serum TT4, the latter being known as euthyroid sick syndrome. It can also be lower in large body size and certain breeds (see Table 33.1). Retesting for the possibility of drug-induced suppression requires cessation of most drugs for 4 weeks. The greater the severity of the nonthyroid disease the greater the suppression of TT4 in both dogs and cats. Low concentrations of TT4 in a dog should prompt consideration of fT4, TSH, and possibly other tests to distinguish primary hypothyroidism, secondary hypothyroidism, and euthyroid sick syndrome.

TT4 <11 nmol/L, with classic clinical signs and routine lab data, may be diagnostic for some cases. When clinical signs and other routine lab data seem inconsistent, measurement of fT4 and TSH may be helpful. Markedly decreased TT4 and fT4 is considered diagnostic for primary or secondary hypothyroidism. Decreased fT4 with increased TSH is diagnostic for primary hypothyroidism. Decreased fT4 with decreased TSH is diagnostic for secondary hypothyroidism.

fT4

Although fT4 is less than 1% of total serum thyroxine, it is of excellent diagnostic value and is suppressed less by nonthyroid diseases and drugs than is TT4. Similar to TT4, the greater the severity of the nonthyroid disease the greater is the suppression of fT4 in dogs and cats. Nonthyroid disease is also associated with increased fT4 in some cats, which

Table 33.1 Summary of thyroid tests.

TT4	Most common test, excellent screening for dogs and cats, used to rule out hypothyroidism in dogs and rule in hyperthyroidism in cats, stable *in vitro*
fT4	Excellent diagnostic utility, use equilibrium dialysis to measure, biologically active hormone; approximately 10% cats false positive
TSH	Endogenous, from thyrotrophs in pars distalis, use with TT4 and/or fT4 to evaluate hypothyroidism, do not use as standalone test
TT4 & TSH	Panel used to diagnose and distinguish type of hypothyroidism
fT4 & TSH	Panel used to diagnose and distinguish type of hypothyroidism
TT3	Most abundant thyroid hormone, biologically active but poor diagnostic value, in some canine thyroid panels but do not use, rely on TT4 and fT4
r' T3	Used infrequently, helpful to diagnose euthyroid sick syndrome
TRH stim	Substitute for TSH stimulation, GI side effects
TSH stim	Tests thyroid reserve, bovine medical-grade TSH is not available; human TSH is available but expensive; endogenous TSH and TRH stim used if injectable TSH not available
T3 suppression	Used in cats with suspected hyperthyroidism
anti-T3, anti-T4, and anti-thyroglobulin autoantibodies	Antibodies produced in lymphocytic thyroiditis, increased in <5% of cases, used to explain unusual increases or decreases in TT4 or TT3, suggests lymphocytic thyroiditis is present
Thyroid testing by species	
Dog	**Cat**
TT4	TT4
fT4	fT4
fT4 & TSH; TT4 & TSH	
If needed	
Thyroglobulin, T4, and T3 autoantibodies	T3 suppression
TSH, TRH stimulation	TSH, TRH stimulation

could interfere with interpretation when used to evaluate hyperthyroidism. fT4 is useful in dogs and cats in which the concentration of TT4 and the rest of the data are not definitive for a diagnosis. fT4 is not influenced by autoantibodies. Anticonvulsant therapy and glucocorticoids will lower fT4. fT4 within RI rules out hypothyroidism. Decreased values suggest but do not prove hypothyroidism unless other data are supportive. Concentrations of fT4 correlate with the thyroid status at the cellular level and correlate very well with TSH.

Equilibrium dialysis (ED) is the technique of choice for fT4. This means that serum is dialyzed in some manner to separate protein bound from free hormone and remove nonspecific substances in the serum that may interfere with the assay. RIA is performed on the dialysate. It is preferable to measure fT4 by ED if a dog is on levothyroid and results will be used to assess adequate dosage.

TT3 triiodothyronine

TT3 is not recommended for testing in animals. It offers no diagnostic value over TT4 or fT4 in recognizing hyper- or hypothyroidism.

TT3 is often in reference interval in hypothyroid dogs; it is interfered with more by antibodies than is TT4. It is the most abundant and biologically active thyroid hormone, but it has poor diagnostic value perhaps because most is produced outside of the thyroid gland. It is offered in some canine thyroid panels.

r'T3 reverse triiodothyronine

This is used infrequently. It is used to diagnose euthyroid sick syndrome in humans and experimentally in dogs; see euthyroid sick syndrome at end of this chapter. It is available in some labs and clinical investigations for its utility should be done. Anticipated results in euthyroid sick dogs are: decreased TT4, reference interval fT4, reference interval TSH, and increased r'T3 due to preferential conversion of T3 to r'T3.

Thyrotropin, thyroid-stimulating hormone (TSH)

Endogenous TSH is measured in diagnostic labs with various techniques. It is a highly stable analyte, and can be safely stored for up to 8 days at 4, 20, and 37°C [1]. TSH is used primarily to differentiate primary hypothyroidism, secondary hypothyroidism, and euthyroid sick syndrome (see "screening tests hypothyroidism"). In human medicine TSH is used as a standalone diagnostic test for hypothyroidism [2]. In veterinary medicine standalone TSH has a poor sensitivity. One study suggests that TSH may be within the RI in up to 33% of hypothyroid dogs [3]; however, this study did not account for secondary (pituitary-dependent) hypothyroidism. When interpreted alongside with TT4 and

fT4, endogenous TSH has a high specificity. For example, in cases of primary hypothyroidism an increased TSH concentration combined with a decreased TT4 and fT4 results in a specificity of nearly 100% (i.e., very few false positives) and localizes the cause of hypothyroidism to the thyroid gland [4]. There are multiple theories as to why TSH has a low sensitivity in animals including biologic variation, pituitary exhaustion, and assay interference secondary to TSH heterogeneity [2].

Endogenous TSH is produced by the pituitary gland and is regulated primarily by negative feedback effect of thyroid hormones (T3, fT4). Therefore, TSH concentration will vary depending on the site of the lesion (primary vs. secondary hypothyroidism). In principle, TSH is increased in primary, decreased in secondary, and within RI with euthyroid sick cases. However, diseases are in stages of progression with different degrees of severity; therefore, results may not be clear-cut. If TSH is WRI and hypothyroidism is still the best clinical diagnosis, then retesting in several weeks or performing a stimulatory test or imaging studies of the thyroid are options. Additionally, continuing the search for a nonthyroid cause of the decreased TT4, fT4 is prudent.

Hypothyroidism is traditionally treated with a replacement hormone (levothyroid). TSH can be used to monitor treatment of true hypothyroid dogs if TSH was measured in a thyroid panel prior to treatment with levothyroid. Endogenous TSH should decrease by 33% or more post-treatment if the dose of levothyroid being administered is sufficient to break the pituitary thyroid gland axis. Levothyroid treatment of a dog that does not have hypothyroidism will suppress TSH production and cause secondary thyroid atrophy if the dose is large enough. Retesting for this possibility requires cessation of levothyroid for 8 weeks [2].

Most diagnostic labs save serum samples for several days to 1 week. If TT4 is reported as decreased consider contacting the lab to determine if there is sufficient serum for additional tests. If the clinician and owner wish to pursue further diagnostics for hypothyroidism then measure fT4 and TSH in the saved serum sample.

Autoantibodies

These are produced by lymphocytes and plasma cells in the thyroid with lymphocytic thyroiditis. They may be detected in the serum and are used to indicate lymphocytic thyroiditis may be present but are not predictors of thyroid gland function status. These antibodies contribute to the destruction of the gland and are directed against thyroglobulin (aaTg present in 35–50% of hypothyroid dogs), TT3 (35% of hypothyroid dogs), and TT4 (15% of hypothyroid dogs). Thyroglobulin antibodies predominate and thyroglobulin is the protein that TT4 and TT3 are attached to, hence dogs with antibodies against TT4 and TT3 will also have aaTg, but the opposite is not true. Autoantibodies directed against thyroglobulin, TT4, or TT3 may increase or decrease TT4 and TT3 concentrations as measured by RIA depending on methodologies of the separation used. Falsely increased values of TT4 or TT3 are seen if antibody coated tubes are used in a single-step separation technique. However, falsely decreased values of TT4 and TT3 are seen if less specific separation techniques are used such as activated charcoal or ammonium sulfate. Consult the reference lab for clarification of interference.

These antibodies are used primarily to explain unusual increases in TT4 in the serum of dogs being evaluated for hypothyroidism. This happens in some cases of lymphocytic thyroiditis, probably early in the disease while inflammation is present. Results are reported as positive, negative, or inconclusive. A positive result can explain an increased concentration of TT4 in a dog with clinical signs of hypothyroidism. A very infrequent finding is that the antibodies increase the TT4 into reference interval in a dog with true hypothyroidism. A positive antibody test does not prove hypothyroidism, it indicates autoantibodies are in the serum and that lymphocytic thyroiditis is the likely lesion. There may be adequate reserve such that hypothyroidism is not present and may not develop. It is recommended that TT4 and fT4 be repeated some months later if the patient is suspected of developing hypothyroidism. Many of the breeds predisposed to develop hypothyroidism are the breeds with a high prevalence of aaTg. The false-positive rate for aaTg is approximately 6% and transient increases are reported postvaccination. They are not part of initial screens for hypothyroidism and generally are only requested when unusual results for TT4 (or TT3) are obtained.

Stimulation tests: TSH and TRH response tests

TSH stimulation (response) test historically was a gold standard for diagnosis of hypothyroidism. However, exogenous bovine medical-grade TSH is no longer commercially available and endogenous TSH is an alternative as described above. Chemical-grade bovine TSH is not recommended due to life-threatening complications. Recombinant human TSH is available but is expensive. TSH stimulation is used to predict thyroid reserve and differentiate primary hypothyroidism, secondary hypothyroidism, and euthyroid sick syndrome by evaluating the magnitude of increase of TT4 post-TSH administration. In principle TT4 will not increase in primary hypothyroidism because the thyroid gland is destroyed and there are "no" target cells for TSH to stimulate. TT4 values that are less than reference interval (<1.5 μg/dL) pre- and post-TSH are diagnostic. A euthyroid sick dog should increase TT4 normally (twofold or greater increase in TT4, or an increase of TT4 >3 μg/dL). A dog with secondary, pituitary-dependent hypothyroidism will have variable results depending on the degree of atrophy in the thyroid gland, but partial stimulation is expected unless atrophy is severe. Unfortunately, intermediary results occur

and it is not known if these represent early stages of the three differentials or mild to moderate lesions.

TRH response test is used in place of TSH to evaluate dogs with potential hypothyroidism and cats with hyperthyroidism when results of other tests are not conclusive or waiting several weeks to months and retesting is not an option. Some euthyroid dogs do not respond to TRH and therefore this dynamic test is less reliable. Both TT4 and TSH can be measured in dogs. Dogs with primary hypothyroidism should have values for TT4 below reference interval, <1.5 µg/dL pre- and post-TRH. Euthyroid dogs should demonstrate an increase of TT4 >2 µg/dL or a doubling of the pre-TT4 value. If TSH is measured there should also be a doubling of the pre TSH value. The principle is similar to the TSH response test in dogs, but distinction of primary and secondary hypothyroidism is not clear. Side effects of TRH are notable and include vomiting, defecation, urination, salivation, tachycardia, and/or tachypnea. They can be reduced by using the lower dose of TRH; see protocols under hyperthyroidism.

In cats suspected of occult hyperthyroidism (TT4 in reference interval) the TRH response test checks for a failure of TT4 to increase post-TRH. Normal cats should double TT4 post-TRH because TRH stimulates release of TSH, which in turn stimulates normal thyroid follicular cells to increase production of TT4. However, hyperthyroid cats do not increase TT4. This is because neoplastic follicular cells do not respond to the increase in TSH caused by the injected TRH and the adjacent non-neoplastic follicular cells are atrophic and cannot respond to the TSH signal. Why the neoplastic thyroid cells do not respond to TRH-TSH has not been determined, but this could be due to lack of TSH receptors.

Thyroid gland biopsy

This is not recommended to diagnose hypothyroidism or hyperthyroidism, but it may prove useful to evaluate thyroid neoplasia in dogs. Fine needle aspiration cytology is recommended for suspected thyroid tumors and biopsy is only needed on those cases in which cytology is not definitive. Approximately 80% of thyroid gland masses in dogs are malignant if an enlarged mass is found clinically, and 40% or less are malignant if necropsy data are used. Size correlates with aggressive behavior and *bilateral* tumors are 16 times more likely to metastasize than unilateral tumors.

Hyperthyroidism

General

Hyperthyroidism or thyrotoxicosis is one of the most common diseases of cats and is the most common endocrine disease of cats. It is caused by adenomas in the thyroid gland. Multinodular adenomatous hyperplasia is another term used to describe the lesion in cats, but the lesions are best explained by neoplasia for the following reasons. A small percentage of cases progress to carcinoma and metastasize. Non-neoplastic tissue is atrophic and is adjacent to neoplastic nodules, whereas functional hyperplasia of endocrine organs produces uniform enlargement of the entire gland. Hyperplastic endocrine lesions respond to stimulatory and suppressive signals, whereas neoplastic lesions generally do not. Cats with these adenomas do not respond to these stimuli. Furthermore, there is overexpression of the c-ras oncogene in the adenomas, and a decrease in inhibitory G protein permitting uncontrolled mitosis and thyroid hormone production. A small percentage of cats will have neoplastic tissue in the anterior mediastinum from rests of thyroid tissue. Some cases have nodules in both thyroid lobes and anterior mediastinum that could suggest multicentric hyperplastic or neoplastic stimuli. Numerous attempts have tried to identify a goitrogenic etiology and none has been found. Attempts to demonstrate antibodies to thyrotropin receptors in hyperthyroid cats, as seen in hyperplastic thyroid disease in humans with Grave's disease, have been negative in multiple studies. Regardless of the term used, 99% of the lesions are benign and they need to be removed surgically, medically, or with radiation if the disease is to be reversed. Approximately 75% of cases have *bilateral* involvement, 20% are unilateral, and 5% have ectopic thyroid proliferation in the anterior mediastinum or thyroid carcinoma.

Hyperthyroidism is uncommon in dogs and when present is due to thyroid adenoma or more likely, carcinoma. Although hyperthyroidism is uncommon, thyroid tumors are relatively common in dogs. Occasionally thyroid tumors may induce hypothyroidism in dogs, but most dogs with thyroid tumors are euthyroid. The size of the thyroid tumor correlates with aggressiveness. Approximately 50% of dogs have rests of thyroid tissue in the anterior mediastinum and occasionally these rests become neoplastic. Even if excessive quantities of TT4 and TT3 are produced, the efficient catabolism and metabolism of thyroid hormones in the dog (up to 20 times the capability of people and cats) leads to rapid degradation of the hormones and a euthyroid status.

Hyperthyroidism is very rare in horses and ruminants. Hyperthyroidism in horses is reported with thyroid tumors and the clinical syndrome and clinical pathology is similar to that seen in hyperthyroid dogs and cats. Horses are hyperactive, have polyphagia, weight loss, and increased serum concentrations of TT4, TT3, and fT4.

Hyperthyroidism summary

Occurs in older cats; adenoma(s); weight loss; polyphagia, hyperactive; one or more liver enzymes (ALP, ALT, AST) increased in 90% of cases; increased TT4 is diagnostic, if fT4 is needed measure by equilibrium dialysis and correlate value with TT4 concentration as fT4 can be falsely increased by nonthyroid diseases (false positive).

Clinical problems

Hyperactivity, weight loss, and polyphagia in a middle aged to old cat is the most common clinical presentation. Weight loss is the most commonly observed clinical problem and may produce cachexia in severe cases. Mean age is 13 years; fewer than 5% of cases are in cats less than 10 years old. Chronic renal failure and cancer look similar, but cats with these diseases will not be polyphagic and hyperactive. Cardiac abnormalities can be detected in more than 50% of hyperthyroid cats, but only 10% are in congestive heart failure. The most common cardiac lesion is left ventricular hypertrophy. Other signs include polydipsia/polyuria, vomiting, tachycardia, patchy alopecia, unkempt hair coat, bulky stools, diarrhea, and apathetic signs such as decreased activity, lethargy, anorexia, and weakness. Apathetic signs may be due to concurrent illnesses in these older cats such as heart failure or renal failure. Due to the incorporation of TT4 in geriatric panels of cats and clinical awareness of this disease, a diagnosis of hyperthyroidism is often established before owners are aware of clinical signs. Clinical signs of hyperthyroidism in dogs are similar to those in cats but are less severe.

Routine lab data

The most consistent lab abnormality is a mild to moderate increase in serum ALP that occurs in approximately 70% of the cats. There may be mild increases in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), and one or more liver enzymes will be increased in 90% of hyperthyroid cats. This nonspecific increase in these liver enzymes is mild to moderate and the pathogenesis is not known. Approximately one-third of the increase in ALP is due to the bone isoenzyme and the rest is liver isoenzyme. Although the increase in ALP is only mild, any increase in ALP should be investigated in cats due to the short half-life of feline ALP. If the ALT is more than 1000 IU/L and TT4 is not markedly increased, pursue other differentials.

Azotemia occurs in 20–50% of hyperthyroid cats and is due to prerenal or concurrent renal disease. If urine specific gravity (SG) is less than 1.025, suspect concurrent renal disease. If it is greater than 1.040 it is probably prerenal. Since cats with hyperthyroidism are geriatric, it is likely that some will have concurrent chronic interstitial nephritis. Hyperthyroid cats that are not azotemic may have decreased serum creatinine concentrations. The mechanism is not known but may be due to muscle cachexia and decreased production of creatinine. Prevalence of concurrent urinary tract infections in hyperthyroid cats is 10–20%. Most of these cats are asymptomatic for this problem, but urinalysis will reveal pyuria and culture will yield *Escherichia coli* in the majority of infections.

Hyperphosphatemia without azotemia is seen in 25–40% of hyperthyroid cats and the mechanism is not known. Total serum calcium is usually in the reference interval, but a mild decrease in ionized serum calcium without associated clinical signs is observed in up to 50% of hyperthyroid cats. Increased concentrations of parathyroid hormone are also reported in hyperthyroid cats. Hypocalcemia, hyperphosphatemia, hyperparathyroidism, and renal problems are a common series of events. The parathyroid hyperplasia may help explain why some cats do not develop postsurgical hypocalcemia and may help explain why postsurgical hypocalcemia is usually not permanent. Although hypercalcemia has been reported for dogs with hyperthyroidism, it is mild and the mechanism is not known.

Nonspecific hematologic abnormalities may occur in about half of cats with hyperthyroidism. Reported abnormalities include mild polycythemia and a stress leukogram. Less frequently, lymphocytosis and eosinophilia are observed, perhaps secondary to a decrease in cortisol due to increased thyroid hormones. Heinz bodies are often present, as they are in many diseases in cats.

Serum fructosamine is decreased in hyperthyroid cats secondary to the increased protein turnover (high metabolic rate, cachexia) and presumably a decrease in available proteins to bind with glucose. Therefore, fructosamine should not be relied upon to assess long-term glucose status in hyperthyroid cats being evaluated for diabetes mellitus.

Screening tests: TT4, if TT4 in reference interval fT4

When this disease was first recognized essentially 100% of the hyperthyroid cats tested had increased serum TT4. Now, basal concentrations of TT4 are increased in 90–95% of the cases. Some (5–10%) of cases have TT4 within the RI. False-positive increases in TT4 are not reported in cats; specificity is 100%. Decreased concentrations of TT4 or concentrations at the low end of reference interval rules out hyperthyroidism with 99% confidence. fT4 is increased in 98% of hyperthyroid cats and it is increased in 6–12% of cats that do not have hyperthyroidism. False positives are 6–12%; therefore the specificity is 88–94%. If a cat has some of the physical and clinical laboratory abnormalities characteristic of hyperthyroidism, and an increased TT4 concentration, it is diagnostic of hyperthyroidism and fT4 or any additional tests are not needed. This will account for the majority of cats with characteristic clinical signs. However, because the disease is common and up to 10% of hyperthyroid cats have TT4 in the reference interval, a considerable effort is placed in correctly identifying this population.

Concentrations of TT4 in the middle to high end of reference may be hyperthyroid, especially if some of the clinical signs and lab data characteristic of hyperthyroidism are present. This is the diagnostically challenging group. Below are some examples of correlation of TT4 with other data.

Examples

- TT4 >4.0 µg/dL rule in hyperthyroidism, if clinical signs and lab data are supportive.
- TT4 3.0–4.0 µg/dL favor hyperthyroidism, if clinical signs and lab data are supportive.
- TT4 2.5–3.0 µg/dL gray zone; perform another test if clinical signs and lab data are supportive.
- TT4 2.0–2.5 µg/dL probably not hyperthyroidism, especially if no other data are supportive; request additional tests if still suspicious.
- TT4 <2.0 µg/dL rule out hyperthyroidism unless other evidence is compelling.

The top two and the bottom two examples above are easy to interpret and will explain TT4 results for the majority of situations. It is the middle gray zone that is difficult and where fT4 can be then be measured as an aid. This scenario is being recognized more frequently. This may be due to more widespread testing that detects cats early in the disease progression. Wellness exams often include TT4 on chemistry panels of geriatric cats, hence we may see clinical chemistry evidence of the disease before signs are easily recognized. When faced with conflicting lab data while trying to confirm a diagnosis of hyperthyroidism, consider approaches in this order, depending on the urgency of a diagnosis:

1. Measure free fT4 (via equilibrium dialysis).
2. Repeat the TT4 concentration at some other time, i.e., 1–2 weeks or later.
3. Palpate and/or image the thyroid gland and find nodule(s)
4. Find the nonthyroid disease that is concurrently suppressing the concentrations of thyroid hormones (euthyroid-sick syndrome just like in dogs).
5. Perform a TT3 suppression test.
6. Perform TRH stimulation; see protocols at end of this section.

Concurrent illness will suppress TT4 in dogs and cats and the greater the severity of the illness, the greater the suppressive influence. Concurrent illness in a hyperthyroid cat can suppress mild or moderate increases of TT4 into the reference interval and therefore explain some of the cases of hyperthyroidism that have concentrations of TT4 within the RI. This suppression also occurs with fT4, but the effect is not as great and therefore measuring fT4 is a logical step to determine if a cat with a normal TT4 is hyperthyroid. However, fT4 may actually be increased in some cats with concurrent illness. Sampling during a pulsating period when not much hormone is being released can also explain TT4 concentrations within the RI. Repeat sampling for this possibility should be delayed for 1–2 weeks or longer because degrees in fluctuations of thyroid hormone secretion are seen over days rather than hours.

Dogs

Routine laboratory data are similar to that in cats, but this is less characterized because of the much lower incidence of hyperthyroidism in dogs. TT4, fT4 are increased. TSH is decreased due to negative feedback on thyrotrophs. Increased TT4 in a dog with a cervical mass and clinical signs of hyperthyroidism is sufficient for diagnosis. The cause will be a thyroid tumor. Therefore palpation, imaging of the neck and thorax, and aspiration cytology of the cervical mass are important diagnostic steps in dogs with suspected hyperthyroidism. Cytology is a preferred step as these tumors are highly vascularized and biopsy procedures will have considerable hemorrhage. Although hypercalcemia has been reported, it may not be due to hyperthyroidism.

Increased TT4 in a dog without a cervical mass and with or without clinical signs of hypothyroidism should be tested for thyroid antibodies that may falsely increase TT4. An increase in TT4 or especially TT3 may be due to cross-reactivity of autoantibodies. Antibodies to various thyroid antigens are attributed to lymphocytic thyroiditis, some of these dogs progress into hypothyroidism and some do not. TT4, fT4, and TSH on the same serum sample should be requested to confirm hypothyroidism.

Confirmatory tests: fT4, T3 suppression, TRH or TSH stimulation, fT4

Usually TT4 is all that is needed to diagnose hyperthyroidism in cats. If the serum TT4 is increased in a cat with clinical signs of hyperthyroidism, then there is no need to measure fT4, as it will also be increased in 100% of these cats. If results of TT4 are not clear-cut, then measure fT4 via equilibrium dialysis and *correlate* with TT4 concentration and *clinical signs*. However, some cats with nonthyroidal disease may have high serum concentrations of fT4, therefore do not diagnose hyperthyroidism based only on the serum fT4.

Endocrine tests should be integrated with all of the laboratory and clinical data.

Serum fT4 is not suppressed by nonthyroidal illnesses to the same degree as is TT4, and therefore fT4 is valuable when concurrent illnesses are suspected to be lowering TT4 into the reference interval. However, nonthyroidal illnesses may increase the serum fT4 concentrations. In a study of more than 900 hyperthyroid cats, 205 were categorized as mildly hyperthyroid, and of these, 125 (61%) had increased TT4 and 191 (93%) had increased fT4. However, increased fT4 concentrations are also present in some cats with nonthyroidal diseases that do not have hyperthyroidism (false positives), and this can confuse interpretation of fT4. The false-positive rate for fT4 is about 10%, but false positives are not seen with serum TT4 (Table 33.2; Figure 33.1). Therefore, it is important to correlate fT4 with TT4 and all of the other lab and clinical data for correct interpretation. The increase in fT4 seen with concurrent diseases is the reason that fT4 should not be relied on solely to diagnose

Table 33.2 Summary of test results in cats with hyperthyroidism.

TT4:
- 90–95% of hyperthyroid cats increased concentrations; sensitivity 90–95%.
- 5–10% of hyperthyroid cats have results within RI = false negative; explanations:
  1. Early in the disease.
  2. Fluctuations in secretion of TT4.
  3. Concurrent nonthyroid diseases that decrease TT4.

"Solutions"
1. Repeat TT4 (1–2 wk, 2 mo, whatever owner will tolerate).
2. Measure fT4 via equilibrium dialysis.
3. Examine thyroid for nodules: palpate, US, radioactive imaging.
4. Find concurrent nonthyroid disease.
5. T3 suppression test.
6. TRH, TSH stimulation test.

freeT4:
- 98.5% of hyperthyroid cats have increased fT4.
- 6–12% false positive = increased fT4 with nonthyroid disease.
- Correlate fT4 with TT4, do not diagnose just on fT4.
- If fT4 is increased, highly probable hyperthyroidism.

TT3:
- Approximately 25% of hyperthyroid cats have TT3 within RI.
- Do not use; better tests are available.

hyperthyroidism and why the fT4 concentration should be correlated with TT4. The greater the increase of both fT4 and TT4, the more likely the diagnosis is hyperthyroidism. However, if TT4 is not increased or is decreased, then the increase in fT4 may be due to nonthyroidal illness.

T3 suppression test

Suppression and/or stimulation tests are recommended when repeat testing for TT4 and fT4 have not provided a diagnosis. Usually, finding the concurrent illness and treating it or repeating the TT4 and fT4 at different time intervals are easier ways to confirm hyperthyroidism than is performing functional thyroid tests. If a functional test is desired, try T3 suppression first as it has fewer side effects and is easier to interpret than the others.

The T3 suppression principle is to administer TT3 orally and see if this decreases serum TT4 by suppressing the secretion of TSH. Normal cats will suppress and hyperthyroid cats do not suppress. Oral TT3 will suppress the secretion of TSH from thyrotrophs, which in turn decreases production and release of TT4 (and TT3) from the thyroid gland in normal cats because the thyroid pituitary axis is intact and the thyroid follicular cells are normal. Hyperthyroid cats already have increased thyroid hormones in their serum from the secreting thyroid tumors, and therefore they already have decreased TSH. Adding more TT3 cannot suppress this axis any further. The neoplastic thyroid follicular cells will continue secreting TT4 independent of TSH and therefore there is no decrease in TT4.

This suppression test is accomplished by administering TT3 orally for six doses; some protocols use three doses. At the start of the study, take a blood sample for a basal TT4, fT4, TT3 and 6–8 hours after the last dose of TT3 take another sample for the same measurements. TT3 determines if the cat successfully received TT3. The concentration of TT4, fT4 after the administration of TT3 should decrease in a euthyroid cat and they do not suppress in hyperthyroidism. If there is no suppression, even if the concentrations of TT4, fT4 are still within the RI, it supports hyperthyroidism.

Thyrotropin releasing hormone response test – TRH response

Principle

Exogenous TRH administered to euthyroid cats will stimulate release of TSH, which stimulates increased TT4 production and secretion. This response will be blunted in hyperthyroid cats because the neoplastic follicular cells are not responding to normal physiologic stimuli and the adjacent atrophic cells are incapable of responding.

Interpretation guidelines

Increase TT4 60% or more from basal = euthyroid.
Increase TT4 50–60% of basal = nondiagnostic.
Increase TT4 <50% to 0 = hyperthyroid.

Side effects can be significant, occur within minutes of administration, and are transient for a few hours. Side effects include vomiting, defecation, salivation, and tachypnea.

Thyroid-stimulating hormone response test – TSH response

Principle

Same as the TRH response test.

Interpretation

Increase TT4 60% or > from basal = euthyroid.
Increase TT4 50–60% of basal = nondiagnostic.
Increase TT4 <50% to 0 = hyperthyroid.

Human recombinant TSH is expensive but can be used in place of bovine medical-grade TSH. Hyperthyroid cats with values in mid to low range of TT4 have a response to TSH that is the same as normal cats.

It is recommended to consult with your reference laboratory to obtain specific suppression and stimulation protocol information and interpretation guidelines.

Endogenous TSH

Assays for feline specific TSH are not yet available, but assays used for dogs and humans are. Consult the reference lab for which antibodies are used and more importantly the

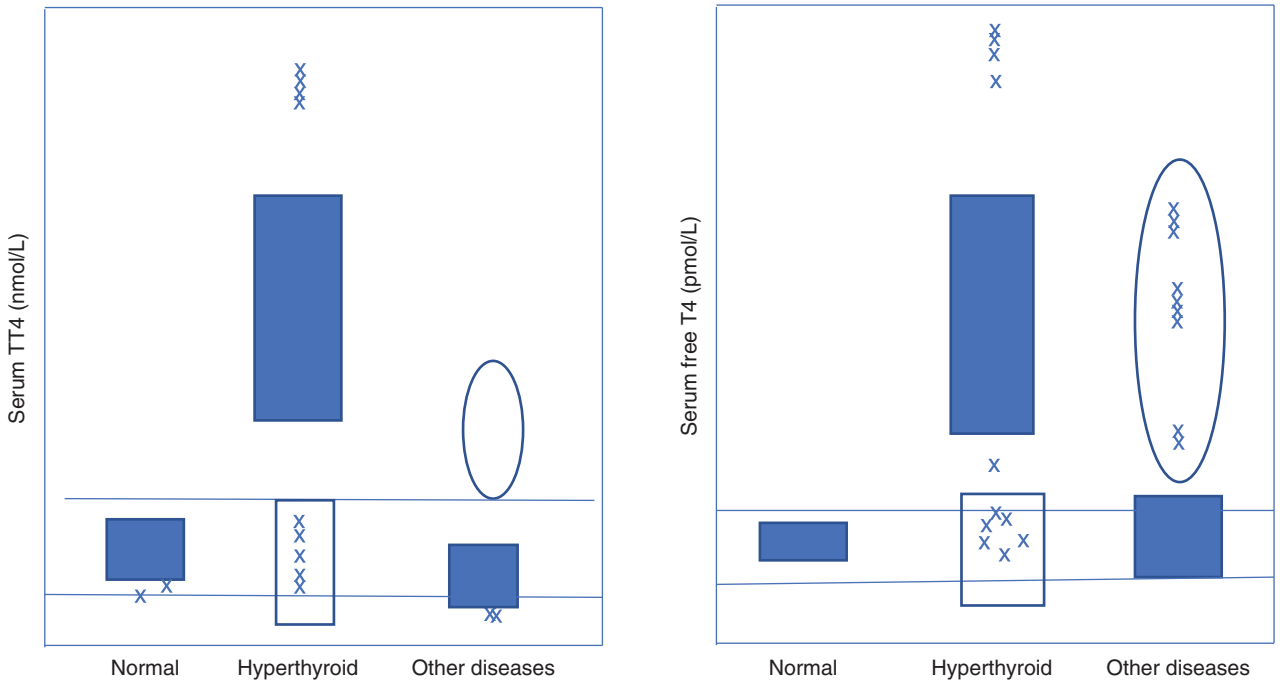

Figure 33.1 Blue boxes represent serum thyroid hormone concentrations expected in cats that are "normal," hyperthyroid, or have a variety of other diseases. Horizontal lines approximate reference intervals. "X" represents outliers; cats with concentrations of TT4 and fT4 not expected for the three classifications. A small percentage of hyperthyroid cats will have serum concentrations of TT4 and fT4 that are not increased – false negatives, open rectangles. Ovals represent false-positive results; there are none for TT4 but there are false-positives value for fT4 (approximately 10%). These cats are not hyperthyroid but fT4 is increased. All tests have false negatives and positives; tests should be integrated with all of the data on a case; no test should be used as a standalone.

reference interval values and cutoff values used to interpret results. Measurement of TSH is not needed when TT4 is increased and is only used in dogs when TT4 and fT4 results are not definitive. When TT4 is normal to high normal, TSH that is decreased and/or below the detectable limit is diagnostic for hyperthyroidism.

Hypothyroidism

General considerations

Hypothyroidism is a common disease in dogs. About 95% of the cases are due to a primary lesion in the thyroid gland defined as lymphocytic thyroiditis and/or idiopathic follicular collapse. These lesions are part of the same disease. It starts as lymphocytic thyroiditis and ends as follicular collapse, with a continuum in between. A dog with primary hypothyroidism late in the disease will have decreased TT4 and fT4 and increased concentrations of TSH. Increased TSH is in response to decreased thyroid hormones and loss of negative feedback on the pars distalis. Other lesions in the thyroid gland that cause hypothyroidism are uncommon. These include thyroid neoplasia, aplasia, hypoplasia, and dyshormonogenesis. Secondary hypothyroidism, due to a structural or biochemical lesion in the pituitary gland that decreases TSH production, is uncommon, 5% or less of cases. A dog with secondary hypothyroidism will have decreased TT4, fT4, and TSH. Decreased TSH is due to the pituitary lesion (tumor) that is destroying or crowding out thyrotrophs. Lesions associated with this are pituitary tumors, pituitary cysts, hypoplasia, dysfunctional thyrotrophs, and an apparent deficiency of TSH production in giant schnauzers. The lack of TSH results in atrophy of the thyroid gland, which theoretically could be reversed if the primary lesion in the pituitary could be corrected. Tertiary hypothyroidism due to a lesion that decreases TRH has not been reported in veterinary medicine. An increased concentration of TSH with concurrent decreases in TT4 and fT4 confirms primary hypothyroidism.

Lymphocytic thyroiditis is an immune-mediated destruction of the thyroid gland directed at thyroid follicular cells, sparing C-cells. It is nonreversible and affected dogs require life-long thyroid replacement therapy. Clinical signs develop gradually over several years and are detected when approximately 75% or more of the gland is destroyed. Lymphocytes and plasma cells produce antibodies directed at thyroid follicular cells, with antigens including thyroglobulin (most common), colloid, TT3, and TT4. There is a genetic component to this disease, and the list of dog breeds that have an increased prevalence of thyroid antibodies in their serum

is long. These antibodies and the inflammation gradually destroy the follicular cells. Over time, the inflammation evidenced by inflammatory cells subsides. Histologically, the gland at this point appears as idiopathic follicular collapse.

Autoantibodies directed against thyroglobulin, TT4, or TT3 may increase or decrease TT4 and TT3 concentrations as measured by RIA depending on methodologies. Falsely increased values of TT4 or TT3 are seen if antibody-coated tubes are used in a single-step separation technique. Increased concentrations of TT4 in a dog with clinical signs of hypothyroidism can confuse interpretation of the results. This is uncommon, occurring in less than 5% of the cases and can be confirmed by measuring the different antibodies. Furthermore, the clinical signs of hyperthyroidism versus hypothyroidism are very different. Even more confusing is the situation where the antibodies "raise" the TT4 and/or TT3 into the reference interval. In either situation, if hypothyroidism is the likely differential, then the next step is to consult with the reference lab and to measure antibodies for thyroglobulin, TT3, and/or TT4. If any of these are increased then antibody interference is the most likely explanation for the confounding data. Free T4 is interfered with less than TT4 or TT3, so it is hoped that in these uncommon situations the fT4 will be decreased while TT4 is increased, which further supports antibody interference. This pattern is rarely observed (<5% of cases) and when seen is probably in an early or active phase of the disease when inflammation and antibody production are occurring. The key is to correlate clinical suspicion with the laboratory data. Recent vaccination can also produce antibodies to thyroglobulin, but there is no association with hypothyroidism.

Other causes of hypothyroidism in dogs are rare: neoplastic destruction of the gland, iodine deficiency, iatrogenic destruction (surgery, radioiodine), dyshormonogenesis, pituitary cysts (dwarfism), and congenital – giant schnauzer and an autosomal recessive form in toy fox terriers, in which there is a deficiency of thyroid peroxidase. A genetic test can recognize the carrier trait in fox terriers.

Spontaneous hypothyroidism is very rare in adult cats. An autosomal recessive form of congenital hypothyroidism is reported in Abyssinian cats. Decreased concentrations of TT4 in a cat are much more likely to be due to nonthyroidal illness than true hypothyroidism. Iatrogenic causes from surgical, chemical, or radiation-induced thyroidectomy for the treatment of hyperthyroidism is the most common cause in cats. Disproportionate dwarfism occurs in kittens and causes polyendocrinopathies including growth hormone (GH) defects and hypothyroidism. Other rare causes in kittens are defects in thyroid hormone synthesis, dysgenesis, and an autosomal recessive form of congenital hypothyroidism in Abyssinians. Iodine deficiency may cause hypothyroidism and goiter in kittens fed all meat or home designed diets.

Hypothyroidism in large animals (horses and small ruminants) is almost always due to the intake of some exogenous substance that interferes with the production of TT3 and TT4. Many substances can do this, and they interfere with the production of thyroid hormones at various stages. A few of the more common and/or high-profile substances are sulfa compounds, decreased iodine intake, increased iodine intake, plants (kale, seaweed), and various chemical substances (thiouracil). The decreased production of TT3 and TT4 due to these substances, results in reduced or no negative feedback to the hypothalamus and pituitary gland and, therefore increased TSH production. The increased TSH stimulates follicular cell hypertrophy and hyperplasia, resulting in an enlarged, goitrogenic thyroid gland. These animals have goiter, mild to massive thyroid gland enlargement, and hypothyroidism indicated by decreased TT3 and TT4. Goiter in neonates is the most common thyroid disorder in the horse and small ruminant. In small ruminants it is usually due to iodine deficiency during pregnancy and is associated with dead fetus, poor suckling, weak, hypothermia, and abnormal wool or hair coat. In foals it is associated with prolonged gestation, poor ossification, ruptured tendons, contracted tendons, prognathism, and unthrifty weak foals. It is seen in northwestern USA and western Canada. The etiology is not known, but it is associated with lush pastures. The thyroid gland is not grossly enlarged, but it is hyperplastic microscopically. In weanlings to 2-year-olds hypothyroidism is due to ingestion of excess iodine (supplements, kelp, etc.).

Hypothyroidism is uncommon to rare in adult horses but is often diagnosed in overweight horses and fat ponies with "cresty" necks; it is not usually confirmed with lab data. The horses may have decreased TT4 and TT3, but rarely is endogenous TSH measured or stimulatory tests performed before the horses are empirically placed on thyroid supplements. Most of these horses probably have equine metabolic syndrome (EMS) and are resistant to insulin from being overweight, a form of type 2 diabetes mellitus. Horses with EMS test negative for hypothyroidism and equine Cushing's disease. Furthermore, drugs such as phenylbutazone and food deprivation are known to lower serum thyroid hormones in the horse.

Signalment

Canine breeds

Golden retrievers, Doberman pinschers, dachshunds, Irish setters, miniature schnauzers, Great Danes, miniature poodles, boxers, Shetland sheepdogs, Newfoundland dogs, chows, English bulldogs, Airedales, cocker spaniels, Irish wolfhounds, toy fox terriers, giant schnauzers, Scottish deerhounds, and Afghan hounds may be regarded as high-risk breeds for hypothyroidism. The disease may also occur in all other breeds regarded to be at lower risk. High-risk breeds may present as early as 2 years of age and low-risk breeds after 5 years of age. Both sexes may be equally affected.

History and physical examination abnormalities

These are numerous and some combination of problems may be detected in hypothyroid dogs. These include weight gain to obesity without increased feed consumption, lethargy, dull haircoat, cold intolerance detected as heat-seeking behavior, decreased libido, reproductive failure, alopecia usually at wear points with no pruritus, and hyperpigmentation in areas of alopecia. Secondary skin diseases such as seborrhea, dry coat, and pyoderma may be observed. Uncommon clinical signs include keratoconjunctivitis sicca, polyneuropathy, vestibular disease, and facial nerve paralysis. Myxedema is uncommon but is considered pathognomonic. Thyroid hormones stimulate the immune system and there is decreased T-cell immunity in hypothyroidism that may predispose to the secondary skin infections such as pyoderma, Malassezia, generalized demodicosis, and otitis externa.

The majority of dogs with lymphocytic thyroiditis present as just hypothyroidism, but other immune-mediated diseases and/or endocrinopathies may appear concurrently. These may include lymphocytic adrenalitis, lymphocytic diabetes mellitus, hypoparathyroidism, and lymphocytic orchitis. Most of these will be detected as one endocrinopathy. However, in some cases a second or third endocrine disease is recognized months or years later.

Clinical signs in cats are similar to those in dogs. Clinical signs in dwarf kittens include disproportionate growth, large head, short broad neck, lethargy, retained deciduous teeth, and retained kitten hair coat.

Routine laboratory data

Routine laboratory test abnormalities are nonspecific and may include the following. Mild nonregenerative anemia (30% of cases) due to decreased responsiveness to erythropoietin is recognized in about 30% of cases. More cases may have a decreased hematocrit, but it is still in the reference interval. Increased liver enzymes are attributed to hepatic lipidosis that is often present in these dogs. Increases in muscle enzymes (CPK, LDH) are reported but are not consistent. Hypertriglyceridemia and hyperlipidemia occur in a majority of cases. Hypercholesterolemia is seen in approximately 80% of hypothyroid dogs and a serum cholesterol concentration greater than 500 mg/dL is very suggestive of hypothyroidism. A concentration >600 mg/dL in a dog with appropriate clinical signs is essentially diagnostic. Perhaps as many as 20% of the cases can be diagnosed based on sufficient clinical signs in a middle-aged dog combined with a cholesterol >500 mg/dL and a TT4 <2 µg/dL. This will be enough for many veterinarians to diagnose and start treatment. "Confirmation" with a panel of TT4, fT4, and TSH may not be needed in cases this fully developed. The need to confirm the diagnosis of hypothyroidism with additional tests depends on how advanced the disease is.

Screening tests TT4, fT4; panel TT4 and TSH or fT4 and TSH on same sample

Basal concentration of TT4 should be the initial endocrine diagnostic test utilized when hypothyroidism is suspected. For convenience, TT4 is included in some routine chemistry panels. About 95% of hypothyroid dogs have decreased concentrations of TT4, resulting in a sensitivity 95%. Approximately 20% of dogs without hypothyroidism may also have decreased TT4, resulting in a false-positive rate of 20% or specificity of 80%. Euthyroid sick dogs will account for most or all of these false positives. Therefore, TT4 is an excellent screening test to rule out hypothyroidism because only 5% of hypothyroid dogs will have TT4 in the reference interval. If a panel is selected, choose TT4, fT4, and TSH performed on the same sample, fT4 by equilibrium dialysis (see Table 33.3). Interpretive guidelines are:

fT4 > 1.5 ng/dL or 20 pmol/L

= typical of euthyrid in dogs

fT4 < 0.5 ng/dL or 7 pmol/L

= typical of hypothyroidism in dogs

A dog with primary hypothyroidism late in the disease should have the following abnormalities (see Table 33.4): decreased TT4 and fT4, increased concentration of TSH, and failure to increase TT4 in response to a TSH or TRH stimulation test, if performed. Ninety percent of these dogs will have lymphocytic thyroiditis or idiopathic follicular collapse. The glands will never regenerate and the dog will need lifelong medication. A dog with secondary hypothyroidism will have decreased TT4, fT4, and TSH. Decreased TSH results from the pituitary lesion that is destroying or crowding out thyrotrophs, resulting in thyroid gland atrophy due to the

Table 33.3 Expected results for canine thyroid profiles.

Reference intervals	TT4 nmol/L 20–55	fT4 pmol/L 10–45	TSH ng/mL <0.5	TT4 µg/dL 1.5–4.3
Hypothyroid likely	<11	<10		<1
Hypothyroid unlikely	>20	>15		>2
Gray zone	12–20			
Primary hypothyroid	<15	<10	>1.0	<1
Primary hypothyroid	<15	<15	>1.0	<1
Secondary hypothyroid	15	<10	UD	<1

UD, undetectable, below limit of detection, <0.03 ng/mL; if a lower limit of reference is set, then values below this number are also confirmatory.
Reference intervals and cutoff values used should be from the laboratory performing assays.

Table 33.4 General considerations for interpreting canine thyroid profiles.

Diagnosis/test	T4	fT4	TSH	TSH stimulation
Rule out hypothyroidism	WRI	WRI	WRI	Not performed
Primary late	Decreased	Decreased	Increased	None to suppressed
Primary early	WRI	Decreased	Increased	None to suppressed
Euthyroid sick	Decreased	WRI	WRI	Increased; mild illness
Euthyroid sick	Decreased	Decreased	Variable	Increased; severe illness
The above scenarios cover most cases; the number of tests selected will depend on the veterinarian's experience and how characteristic the clinical signs and routine lab data are. Not all cases require all tests. The following are less commonly observed results that we spend considerable effort trying to understand and diagnose.				
Primary early	WRI	Decreased	WRI	None to suppressed
Primary early	WRI	WRI	Increased	None to suppressed
Primary <2%	Increased	Decreased	Increased	None to suppressed
Autoantibodies[a]	Increased	WRI	WRI	
Secondary	Decreased	Increased	Decreased	Pituitary lesion
Euthyroid sick	Decreased	WRI	WRI	Mild illness
Euthyroid sick	Decreased	Decreased	Variable	Severe illness
False positive inc of TSH	WRI	WRI	Increased	Increased, doubles or >
Drugs	Decreased	Depends on drug and mode of action		If excessive ingestion
Iodine intake	Decreased	Decreased	Increased	
Sight hounds	Normally decreased to half of RI; they need their own RI			
Obese	Increased			
Young	2–5×	Increased		

WRI, within reference interval.
[a]Autoantibodies are not a thyroid function test; they may falsely increase TT4; they indicate lymphocytic thyroiditis is likely; some of these dogs progress into the hypothyroid state and many do not.

absence of trophic hormone. Findings supportive of secondary hypothyroidism include decreased TSH, indications of other endocrine diseases, and visual or central nervous system (CNS) signs.

It is important to not diagnose hypothyroidism on one endocrine test result in isolation. The test(s) must be combined with signalment, history, physical exam, and routine lab data to determine the likelihood of hypothyroidism (Tables 33.4 and 33.5). The more pieces of the puzzle that fit with hypothyroidism, the fewer tests are needed to diagnose and start treatment. If multiple abnormalities are present, especially if the results are marked, then a diagnosis can be made with confidence. The lower the concentration of TT4 and fT4, the greater the likelihood of hypothyroidism. For example, if the TT4 and fT4 are <10 nmol/L (<0.5 µg/dL) and <7 pmol/L (<0.5 ng/dL) respectively, the best diagnosis is hypothyroidism. If cholesterol is markedly increased and TT4 and fT4 are both decreased, and the dog has multiple signs, then this is sufficient for a diagnosis without further testing.

More challenging diagnostic scenarios

The guidelines above are for classic cases that are fully developed. However, use of thyroid hormone tests to confirm hypothyroidism can be frustrating because the disease can be in various stages of development and there are situations in which the test results present conflicting or ambiguous findings. Breed, superimposed disease, drug, and age variables influence results. However, in more than 80% of situations the results are definitive and it is possible to rule out or rule in hypothyroidism. A minority of cases requires more extensive testing evaluation, perhaps over a period of weeks to months. These challenging cases may require more intensive diagnostic procedures such as measurement of antibodies to thyroid antigens, repeat testing in 4 weeks, removal of concurrent drug therapy followed by repeat testing in 4 weeks, stimulation tests (TSH or TRH), imaging of the neck (ultrasound, magnetic resonance imaging [MRI], technetium pertechnetate), and response to T4 trial replacement therapy. Sometimes, there is merit in trial therapy in place of extensive, complex testing. Unlike Cushing's disease, hypothyroidism is a disease that can be misdiagnosed, missed and/or treated for when it does not exist and the consequences are not great. Missing a diagnosis of hypothyroidism is not life-threatening and sometimes repeat testing in a month or more will yield clearer results as the disease progresses. Treating a dog with levothyroid that does not have hypothyroidism also does not have serious

Table 33.5 Examples – use all of the case data; here are some key components.

Cases	Cholesterol mg/dL RI 130–350	TT4 nmol/L RI 20–55	fT4 pmol/L RI 10–45	TSH ng/mL RI <0.5	Other tests	Diagnosis
1 alopecia	>500	<10	NN	NN	NN	Hypothyroid
2 alopecia	>500	<15	<10	NN	NN	Hypothyroid
3 alopecia	>400	<20	<5	NN	NN	Hypothyroid
4 alopecia	400	<25	<15	Increased	NN	Primary hypothyroid
5 alopecia	400	<20	<15	?	?	Hypothyroid

13 vague	WRI	WRI	WRI	WRI	Positive for antibodies	

WRI, within reference interval; consult laboratory doing measurements for RI and recommended cutoff values used for diagnostic, gray zone, etc.
NN. not needed, this is the veterinarian's decision; the more characteristic the clinical signs and routine lab data are for hypothyroidism, the fewer tests are needed.
Examples 1–4 = hypothyroidism confident of diagnosis but have not distinguished primary vs. secondary; primary much more likely, both treated the same.
Example 5 = hypothyroidism likely; additional testing discretion of the veterinarian.
Example 6 = hypothyroidism likely, TSH did not help recommend TSH stim.
Examples 7–9 = rule out hypothyroidism; if clinical signs or other data were strongly suggestive of hypothyroidism, consider a TSH stim. Examples 8 and 9 are consistent with euthyroid sick syndrome; the decrease in TT4 is disproportionately lower than the expected change in fT4.
Example 10 = hypothyroidism, secondary ruled in; consider imaging.
Example 11 = primary hypothyroidism with increased TT4 due to antibodies; <2% of cases have this profile.
Example 12 = TT4 and fT4 diagnostic for hypothyroidism unless a sight hound breed, then a profile like this is normal; diagnostic ranges for sight hounds are approximately half that of other breeds.
Example 13 = dog likely has lymphocytic thyroiditis; dog is euthyroid at this time; some develop hypothyroidism and most do not; repeat testing recommended especially if from a breed with increased prevalence of hypothyroidism.

biologic consequences. In fact, the term "thyroid responsive disease" has evolved to categorize dogs that respond well to levothyroid but actually do not have hypothyroidism. Thyroid hormones may benefit sick patients similar to the nonspecific stimulatory effects of steroids. Perhaps accepting some of the above before testing panels are begun will make the 10–20% of gray zone cases less frustrating. Furthermore, primary and secondary hypothyroidism are treated the same, with synthetic thyroxine (T4), levothyroid supplementation. This supplement is inexpensive and a fat dog may benefit from a little T4 regardless of their thyroid status. The important clinical distinction is to differentiate hypothyroidism from the euthyroid sick syndrome and recognize the correct concurrent disease that is suppressing thyroid hormones. Differentiating primary and secondary hypothyroidism can be done as well. Summary findings of a study of endocrine tests in 108 dogs are shown in Table 33.6. The effects of some variables on thyroid hormone testing are presented in Table 33.7.

A relatively common diagnostic challenge is to determine if a dog with a decreased TT4 is really hypothyroid when only some of the physical and laboratory abnormalities of hypothyroidism are present. This is the syndrome known as "euthyroid sick." The laboratory tests are abnormal, but function of the thyroid gland and the biologic activity of the thyroid hormones is considered normal or "euthyroid." This is a syndrome that occurs in dogs and cats in which a non-thyroid disease causes the suppression of measured thyroid hormones (Figure 33.2). The decrease in thyroid hormones is a physiologic adaptive response stimulated by a variety of cytokines that lower the basal metabolic rate and reduce cellular metabolism in times of illness. There are a variety of mechanisms postulated to decrease the thyroid hormones and some of these may even decrease TSH secretion. These animals will have decreased concentrations of TT4 but are euthyroid. A variety of illnesses can cause this syndrome and the more severe the illness the more pronounced is the decrease in TT4. Approximately 20% of sick dogs that do not

Table 33.6 Thyroid hormones in hypothyroid and euthyroid dogs.

	Hypothyroid		Euthyroid	Sensitivity/specificity
TT4 (n = 108 dogs)	n = 54 dogs Decreased: 48 (90%) WRI: 3 (5%) Increased: 3 (5%)	**Good**	n = 54 dogs Decreased: 10 (18%)	90%/82%
TT3 (68 dogs)	n = 31 dogs Decreased: 3 (10%) WRI: 23 (74%) Increased: 5 (16%)	**Not good**	n = 37 dogs Decreased: 3 (8%)	
freeT4 (n = 108 dogs)	n = 54 dogs Decreased: 53 (98%) WRI: 1 (2%) Increased: 0	**Great**	n = 54 dogs Decreased: 4 (7%)	98%/93%
TSH (n = 108 dogs)	n = 54 dogs Increased: 41 (76%) WRI = 13 (24%) Low normal = 5 (9%)[a]		n = 54 dogs Increased: 4 (7%)	76%/93%

	Sensitivity %	Specificity %	Accuracy %
free T4	98	93	95
TT4	89	82	85
TSH	76	93	84

WRI, within reference interval.
In this study, only one euthyroid sick dog had low T4, low fT4, and increased TSH = false positive.
Author comment: The more fully developed a disease, the easier it is for diagnostic tests to "recognize" the disease.
[a]Some of these five dogs may have had secondary hypothyroidism.

Table 33.7 Interpretation of thyroid hormones in dogs with unique situations.

Consideration	Effect
Body size	
<10 kg	Higher TT4; median 31.5 nmol/L
>30 kg	Lower TT4; median 25 nmol/L
Breed	
Sight hounds	Decrease TT4 and fT4 50% less than other dogs
Nordic breeds	No effect on TSH
Age	
<3 mo	Increase TT4 2–5 times adult
>6 yr	Decrease TT4
Nonthyroidal illness	Decrease TT4 dogs and cats; the greater the severity of illness the greater the decrease
Nonthyroidal illness	fT4 influenced less but can decrease in dogs and cats; can also increase fT4 in cats
Drugs	Decrease TT4 and fT4: glucocorticoids, sulfonamides, propylthiouracil, aspirin, phenobarbital, carprofen, methimazole Decrease TT4, little or no effect on fT4: furosemide, phenylbutazone, progestagens Sulfonamides may decrease TT4 and fT4 and increase TSH and cause hypothyroidism

Obese dogs have mild increases in serum TT4 concentrations; 50–75% higher.
Sight hounds have TT4 and fT4 much lower than other breeds; normal concentrations for sight hounds would be hypothyroid values for other breeds.
Pregnancy and diestrus will increase TT4.
An age-related decline occurs in serum total TT4 concentrations and response to TSH stimulation in dogs.

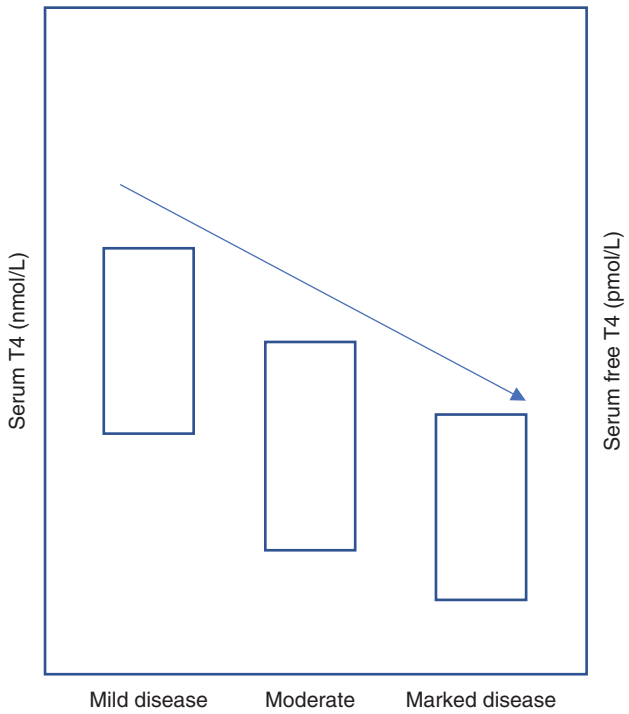

Figure 33.2 Relative serum concentrations for total T4 and free T4 are indicated by open boxes for dogs and cats that have nonthyroid diseases. Nonthyroid diseases cause the serum concentrations of TT4 and fT4 to decrease, and the more marked the disease the greater the decrease in both thyroid hormones. In dogs this phenomenon is relatively common and can lead to misdiagnosis of hypothyroidism if stimulation tests are not performed. Interestingly, nonthyroid disease can increase the serum fT4 in some cats (Figure 33.1).

have hypothyroidism will have decreased concentrations of TT4, a false-positive test result for hypothyroidism. Free T4 is only decreased in 5–10% of these dogs, but similar to TT4, the more severe the illness the more the suppression in fT4. If the decrease in TT4 is disproportionately greater than the decrease in fT4 then it favors the interpretation of euthyroid sick syndrome. The key feature for considering euthyroid sick is decreased TT4 without supporting changes in fT4 and TSH. Another helpful assessment is that dogs with euthyroid sick syndrome are not expected to have the more specific clinicopathologic features of hypothyroidism such as hypercholesterolemia, alopecia, and weight gain. It is important to recognize this group in order to correct the primary disease that is suppressing thyroid hormones.

The euthyroid sick syndrome is also recognized in cats, but the challenge presented is in the diagnosis of hyperthyroidism. The dilemma is recognizing hyperthyroidism when the secondary disease has suppressed TT4 into the reference interval. The severity of the nonthyroid disease is proportional to the decrease in TT4. This happens in older cats with concurrent diseases such as chronic interstitial nephritis, cancer, and debility. Serum fT4 is not suppressed as much as TT4, so that measurement may be helpful. However, fT4 is actually increased in some severely sick cats, which adds a new diagnostic challenge. If TT4 is in reference interval, fT4 is increased it is either true hyperthyroidism or the euthyroid sick syndrome. Distinguishing these two differentials requires correlation of all of the data and perhaps additional testing. See hyperthyroidism discussion for these approaches. Hopefully the clinical expression of these nonthyroid diseases is such that they are recognized or suspected.

Another diagnostic challenge occurs is when the clinical presentation and clinical lab abnormalities support hypothyroidism, but TT4 is increased or perhaps within the mid to upper RI. This creates endocrine testing data that is inconsistent with the clinical picture. It's more likely such a dog is in an early or mid-phase of primary hypothyroidism with lymphocytic thyroiditis and increased concentrations of antibodies directed against thyroid antigens. The way to solve this problem is to measure antibodies for aaTg and possibly TT4 or TT3. The antibodies cross-react with reagents in the *in vitro* measurement of T_4 and T_3, and therefore, cause a "false increase" in T_4 and T_3. These dogs are hypothyroid yet will "appear" to have increased measurable concentrations of T_4 and T_3 but, most importantly, increased concentrations of T_4 and T_3 antibodies.

Diagnostic challenge may occur as a result of ongoing drug therapy. Most of the problems caused by drugs are interference with assays, and usually this is observed as a decrease in TT4 and/or fT4; see Table 33.7. Sulfonamides, however, can cause hypothyroidism characterized by decreased TT4, fT4 and increased TSH. Sulfonamides block iodination of thyroglobulin and prevent production of thyroid hormones if the dose is high enough and given 4 weeks or longer. Cessation of the sulfonamides reverses the effects. Glucocorticoids affect metabolism of thyroid hormones and inhibit TSH secretion resulting in variable combinations of decreased or normal concentrations of TT4, fT4, and TSH. Phenobarbital does not cause hypothyroidism but does decrease TT4 and fT4 and may cause a slight increase in TSH. It is beyond the scope of this chapter to review all of the influences of therapy on thyroid hormones. A general recommendation is to discontinue medications that affect the thyroid gland for 4 weeks before measuring thyroid hormones or doing dynamic testing. Levothyroid should be discontinued for 8 weeks before retesting the thyroid pituitary axis.

It is occasionally useful to determine if the hypothyroidism is secondary to a pituitary lesion. The determination is somewhat academic because thyroid replacement therapy is the same, but documentation of a pituitary lesion may uncover additional endocrinopathies and have longer term case management and prognostic implications.

Sight hounds such as Salukis, greyhounds, whippets, Scottish deerhounds, Irish wolfhounds, Sloughs, and Basenjis have low serum TT4 that is physiologic and considered normal. Salukis and greyhounds also have low fT4 that are

in the range of hypothyroidism for other breeds. TT4 may be below the lower limit of reference intervals for normal dogs in 90% of greyhounds and below the limit of detection in up to 33%. Therefore, the diagnosis of hypothyroidism in one of the sight hound breeds should include tests other than TT4. For sight hound breeds it may be more important to measure TSH and fT4 concurrently no matter how low the TT4 concentration is. However, hypothyroidism can be ruled out in a sight hound breed with confidence if TT4 is within the RI used for all dogs. Cutoff values for TT4, fT4, and TSH for hypothyroidism in the sight hound breeds are not established. The cause for low thyroid hormones in sight hound breeds is not known.

Diagnosis in cats

Spontaneous or naturally occurring hypothyroidism is almost nonexistent in cats. Congenital hypothyroidism, lymphocytic thyroiditis, and secondary hypothyroidism are reported but are rare. The most common cause of true hypothyroidism is iatrogenic from treatment of hyperthyroidism. The most common cause of decreased TT4 and/or fT4 in a cat is euthyroid sick syndrome. For true hypothyroidism, essentially all adult cats should have a history of thyroidectomy, radiation, or methimazole treatment. In most of these, thyroid hormones are being assessed periodically to gauge success of treatment. Nonregenerative anemia and hypercholesterolemia are expected if the cat is hypothyroid. TT4 is the initial step and if in the reference interval the cat is euthyroid sick. If it is decreased and the history has an iatrogenic cause, then it is hypothyroid. These cats probably just need their medications adjusted. If TT4 is decreased and there is no history of thyroidectomy, it is either true hypothyroidism or more likely the euthyroid sick syndrome. The most common cause of a decreased TT4 in a cat that has not undergone thyroidectomy is a concurrent illness. Now consider finding the nonthyroid disease and/or evaluate fT4 and TSH via a canine assay. The canine assay for TSH has been validated for cats. If fT4 is decreased and TSH is increased and the clinical signs and laboratory fit then it is hypothyroid. If in doubt consider a TSH or TRH stimulation test or a trial response to levothyroxine, followed with removal of levothyroxine to see if clinical and laboratory abnormalities return.

Horses and small ruminants

Hypothyroidism in large animals is almost always due to the intake of some exogenous substance that interferes with the production of TT3 and TT4. These animals have goiter, characterized as a mild to massive thyroid gland enlargement with decreased TT3 and TT4 and associated hypothyroidism. Many substances can do this, and they interfere with the production of thyroid hormones at various stages. A few of the more common and/or high-profile substances are sulfa compounds, decreased iodine intake, increased iodine intake, plants (kale, seaweed), and various chemical substances (thiouracil). The decreased production of TT3 and TT4 due to these substances results in reduced or no negative feedback to the hypothalamus and pituitary gland and, therefore, increased TSH production. The increased TSH stimulates follicular cell hypertrophy and hyperplasia, resulting in an enlarged, goitrogenic thyroid gland. Goiter in neonates is the most common thyroid disorder in the horse and small ruminant. In small ruminants it is usually due to iodine deficiency during pregnancy and is associated with dead fetus, poor suckling, weakness, hypothermia, and abnormal wool or hair coat. In foals it is associated with prolonged gestation, poor ossification, ruptured tendons, contracted tendons, prognathism, and unthrifty, weak foals. It is seen in northwestern USA and western Canada. The etiology is not known, but it is associated with lush pastures. The thyroid gland is not grossly enlarged, but it is hyperplastic microscopically. In weanlings to 2-year-olds, hypothyroidism is due to ingestion of excess iodine (supplements, kelp, etc.). It is uncommon to rare in adult horses. It is often clinically diagnosed in overweight horses with "cresty" necks but is not usually confirmed with lab data. The horses may have decreased TT4 and TT3, but TSH measurement or stimulatory tests are rarely performed before the horses are placed on thyroid supplements, reduced feed intake, and increased exercise. It is difficult to know which of these treatments is responsible for clinical improvement.

Adrenal gland disorders

Hypoadrenocorticism: Addison's disease

Primary

Lymphocytic adrenalitis – destroys all three zones of adrenal cortex; accounts for 90% or more of cases. The result is mineralocorticoid- and glucocorticoid-deficient hypoadrenocorticism (MGDH).

Secondary

This is caused by pituitary neoplasm or prolonged exogenous steroid administration. Either decreases adrenocorticotrophic hormone (ACTH) causing *bilateral* adrenocortical atrophy of zona fasciculata (ZF) and reticularis. The result is glucocorticoid-deficient hypoadrenocorticism (GDH).

Hyperadrenocorticism (HAC): Cushing's syndrome

Primary AT

Adrenal-dependent HAC is due to a functional adrenal cortical neoplasm resulting in one large adrenal and atrophy of contralateral adrenal. There is also atrophy of zona fasciculata in the ipsilateral adrenal. The cortisol from the adrenal neoplasm provides negative feedback to the pars distalis

resulting in decreased production of ACTH and therefore decreased ACTH in the serum.

Secondary PDH

Pituitary-dependent HAC is due to a functional pituitary neoplasm that secretes ACTH stimulating cells in zona fasciculata to undergo hyperplasia and hypertrophy, resulting in *bilateral* adrenal gland enlargement. ACTH is increased in the serum. This accounts for 80% or more of HAC cases in dogs. Pathogenesis is different in horses.

Adrenal gland background

The adrenal gland has a cortex and a medulla. The outer most region of the cortex is the zona glomerulosa (ZG). It produces the mineralocorticoid aldosterone that helps regulate the serum concentration of sodium and potassium, extracellular fluid volume, and blood pressure. The major regulation mechanism is via serum potassium concentrations and by the renin-angiotensin system, with a minor contribution from ACTH. Hyperkalemia will stimulate the release of aldosterone from the ZG to increase potassium excretion via many epithelial cells including renal, salivary, intestinal, and sweat glands. Concurrently aldosterone stimulates renal sodium reabsorption that may increase blood pressure. Renin is released from the juxtaglomerular apparatus near glomeruli in response to decreased blood pressure, decreased sodium, and several other factors. Renin then stimulates a cascade of events that leads to increased angiotensin II that stimulates vasoconstriction and release of aldosterone. The majority of the stimulus to release aldosterone comes from the steps outlined above. Approximately 10% of the overall stimulus to release aldosterone comes from ACTH, and in the absence of ACTH, there is mild atrophy of the ZG but severe atrophy of ZF. The major disease of the ZG is hypoadrenocorticism, or Addison's disease, due to lymphocytic adrenalitis. An uncommon disease is hyperplasia of the ZG, primary hyperaldosteronism that increases aldosterone production.

Subjacent to the ZG is the largest region of the cortex, the ZF, producing many hormones of which glucocorticoids are the most clinically important. Corticotrophs in the pituitary adenohypophysis produce ACTH that stimulates ZF to release glucocorticoids immediately. Glucocorticoids complete the regulatory loop by providing negative feedback to (i) corticotrophs, which decreases ACTH secretion, and (ii) receptors in the paraventricular nuclei in the hypothalamus to decrease corticotrophic release hormone. The major disease of the ZF is HAC or Cushing's disease. This is usually secondary to a pituitary adenoma that secretes excessive amounts of ACTH. HAC may also be caused by an adrenal cortical tumor that autonomously produces glucocorticoids or iatrogenically by the exogenous administration of glucocorticoids. Regardless of the cause, all of the clinical signs and laboratory abnormalities of HAC are due to increased serum cortisol. The inner most region of the adrenal cortex is the zona reticularis (ZR) that produces glucocorticoids and sex hormones. In dogs, cats, and horses this zone has a minor role in HAC. In ferrets, this zone has a significant contribution because most of the clinical abnormalities are due to increased sex steroids.

The medulla is in the middle of each adrenal gland, it produces epinephrine and norepinephrine. The major disease is neoplasia of the adrenal medulla or pheochromocytoma that causes increased serum epinephrine production and resultant hyperactivity, hypertension, and tachycardia.

Hypoadrenocorticism: Addison's disease

The following is an outline of the two types of hypoadrenocorticism with expected major abnormalities and associated diagnostic test findings (Table 33.8).

Table 33.8 Major laboratory findings in various forms of hypoadrenocorticism.

	Primary	Atypical	Secondary
Lesion	Lymphocytic adrenalitis: ZG ZF ZR	Early?	Atrophy ZF
Basal cortisol	Decreased	Decreased	Decreased
ACTH stimulation	No response, post-stimulation cortisol <2 μg/dL for all types		
Plasma ACTH	Increased	Increased	Decreased
Na	Decreased	Within RI	Within RI
K	Increased	Within RI	Within RI
Cl	Decreased	Within RI	Within RI
Na:K ratio	<23 : 1	>25 : 1	>25 : 1
Glucocorticoids	Decreased	Decreased	Decreased
Mineralocorticoids	Decreased	Not affected	Not affected
Outcome	Irreversible	Progressive?	Reversible

Primary

Typical: lymphocytic adrenalitis that destroys the ZG, fasciculata and reticularis; there is decreased mineralocorticoids and glucocorticoids (MGDH). The decrease in aldosterone results in the major electrolyte abnormalities hyponatremia and hyperkalemia. The sodium: potassium ratio (Na:K) is decreased, which is one of the most helpful diagnostic clues. A rare variant is *atypical primary hypoadrenocorticism; glucocorticoid-deficient hypoadrenocorticism*. This may be an early form of primary, but one in which most of the manifestations are related to glucocorticoid deficiency. Some of these cases will develop mineralocorticoid deficiency, but some do not.

Secondary

The cause is either a pituitary lesion ablating ACTH release or prolonged exogenous steroid administration that results in atrophy of zona fasciculata and reticularis resulting in inability of adrenal response to ACTH when steroid administration is abruptly stopped. Glucocorticoids are decreased, but mineralocorticoids and sodium potassium ratio are not affected. GDH is a difficult disease to diagnosis. Fortunately, it is uncommon, accounting for <10% of Addison's cases.

Primary

Primary hypoadrenocorticism accounts for approximately 90–95% of Addison's disease in the dog. The two most common lesions, lymphocytic adrenalitis and idiopathic collapse, represent different stages of the same disease. Early, the lesion is an immune-mediated lymphocytic adrenalitis and in the late stage, it is severe atrophy, similar to primary hypothyroidism. The adrenal cortex cannot regenerate from these destructive lesions and therefore these patients require lifelong replacement therapy. Lymphocytic thyroiditis, parathyroiditis, adrenalitis, and lymphocytic destruction of islets are processes that occur in dogs usually as separate diseases. It is rare that they occur in the same animal and produce polyglandular failure. Failure of multiple endocrine glands is more likely due to pituitary destruction. Infrequent other causes of primary hypoadrenocorticism include neoplasia, granulomatous inflammation, infarction, and iatrogenic chemotherapy (mitotane, trilostane). Mitotane (lysodren) is used in the treatment of HAC and it selectively causes necrosis of zona fasciculata and reticularis. In about 5% of treated dogs, or in overdosed dogs, destruction of the ZG may occur. In the majority of these dogs the necrosis is permanent. The cortical zones do not regenerate and the dogs subsequently require lifelong therapy with mineralocorticoids and glucocorticoids. This is a separate situation from transient glucocorticoid deficiency associated with induction or maintenance therapy with Mitotane. Farm animals may have herpesvirus induced cortical necrosis or bacterial emboli from neonatal septicemia that destroy sufficient adrenal cortex to produce hypoadrenocorticism. Additionally, there is a condition referred to as relative adrenal insufficiency (RAI) syndrome that is diagnosed in weak and/or septic foals.

Approximately 75–90% of both adrenal cortices must be destroyed before clinical signs are observed. Partial deficiency is probably the early stage of lymphocytic adrenalitis and is one explanation for primary atypical cases when there is cortical reserve, but the reserve is inadequate to cope with stresses such as shipping, boarding, and fights. Like all diseases it can be difficult to establish a definitive diagnosis while the disease, the clinical signs, and clinical pathology data are evolving. Eventually the lesions progress and the clinical signs and laboratory data become fully developed and more clearly diagnostic.

Atypical – glucocorticoid-deficient hypoadrenocorticism

These cases could represent either secondary hypoadrenocorticism in which the cause of the decrease in ACTH is not known or is an unusual form of primary hypoadrenocorticism. In the latter possibility they most likely represent early phases of lymphocytic adrenalitis when there is adequate cortical reserve such that some, but not all manifestations of primary hypoadrenocorticism are present. It is also associated with drugs that selectively attack zona fasciculata (mitotane and trilostane) and concurrent diseases that mask the characteristic electrolyte abnormalities. These dogs initially do not have serum sodium and potassium abnormalities. Some of these dogs will progress and have a decreased sodium potassium ratio while others do not develop electrolyte abnormalities even after a year or more of follow up. Because of increased awareness of this subtype of hypoadrenocorticism, ACTH stimulation is performed on dogs with vague clinical signs coupled with suspicion of the disease. Failure of ACTH stimulation to increase cortisol >2 µg/dL is diagnostic of hypoadrenocorticism even if sodium and potassium concentrations are normal.

Secondary

The lesion of secondary hypoadrenocorticism is atrophy of zona fasciculata. Naturally occurring cases are caused by a primary pituitary lesion such as a tumor or cyst that destroys corticotrophs in the pars distalis resulting in decreased ACTH production (Figure 33.3). Probably the most common cause of secondary hypoadrenocorticism is iatrogenic from the sudden withdrawal of exogenous steroid therapy. Prolonged exogenous cortisol therapy causes negative feedback to corticotrophs, decreased serum ACTH, and subsequent atrophy of zona fasciculata. In contrast to irreversible lymphocytic adrenalitis, the adrenal cortex will regenerate if steroids are either gradually stopped or if the pituitary tumor is successfully surgically removed. Atrophy is in ZF and ZR, therefore

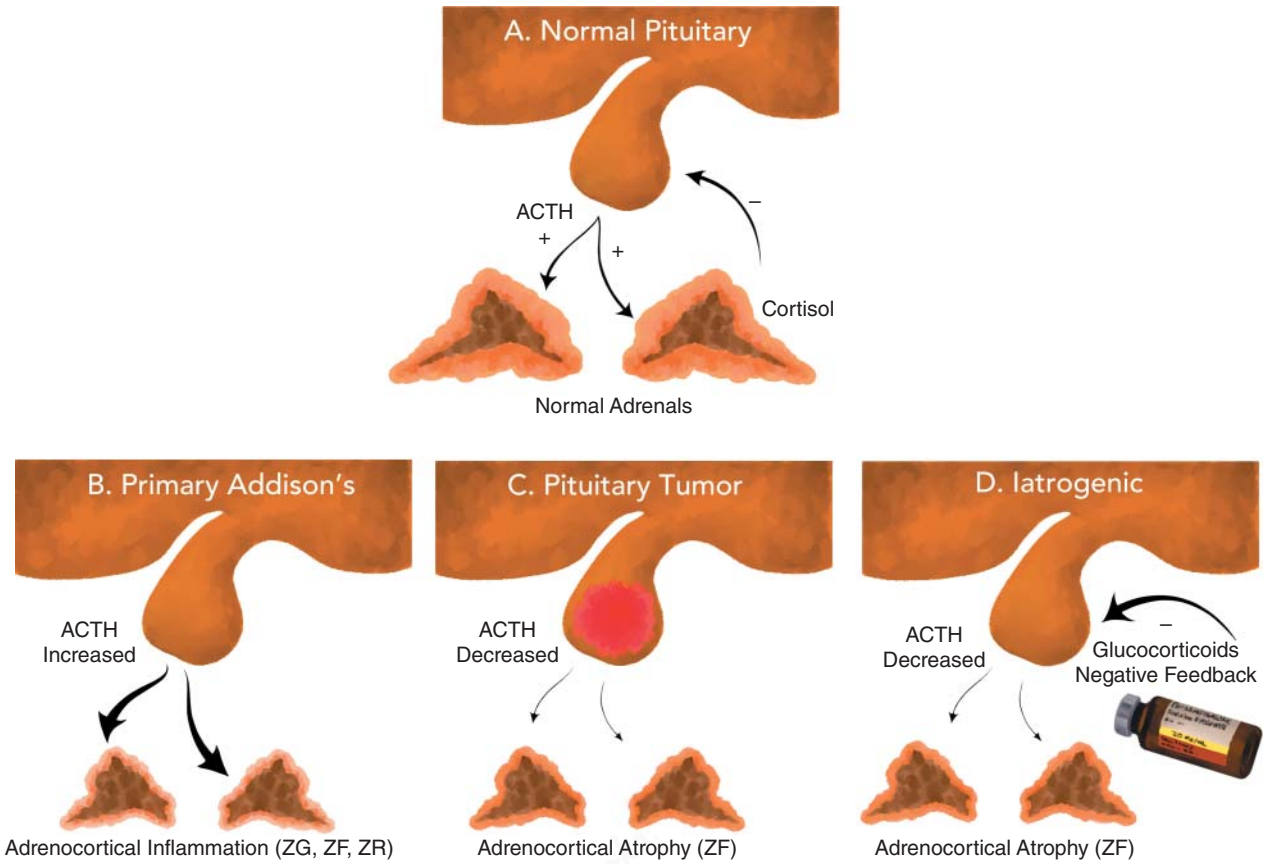

Figure 33.3 Mechanisms of hypoadrenocorticism (Addison's). Arrows represent relative amounts of hormones being secreted with a normal pituitary-adrenal axis and in three disease states. Adrenal gland sizes are relative for normal (A), primary Addison's caused by lymphocytic adrenalitis (B), and two types of secondary Addison's disease (C, D). The medulla is dark brown and is the same size in all of the diseases depicted here. In lymphocytic adrenalitis (B), an immune-mediated process destroys all three zones of the adrenal cortex (ZG, ZF, ZR), resulting in decreased production of mineralocorticoids and glucocorticoids. The decreased glucocorticoid production stimulates corticotrophs in the pars distalis to produce and secrete ACTH, a fruitless effort because the adrenal glands lack the target cells to be stimulated. The end stage of adrenalitis is "idiopathic collapse." A pituitary tumor (C) is an example of a corticotroph-destroying lesion in the pars distalis. As corticotrophs are destroyed, ACTH production and secretion declines and cells in the adrenal ZF are not stimulated. This drives *bilateral* atrophy of the ZF and results in decreased glucocorticoid production. The ZG is spared; mineralocorticoid production is not affected. Iatrogenic Addison's (D) is due to exogenous glucocorticoids that cause negative feedback to the pituitary, resulting in decreased ACTH and *bilateral* adrenocortical atrophy (ZF). These patients may appear Cushingoid on physical examination and laboratory analytes (stress leukogram, increased ALP) due to excess steroids. If the glucocorticoids are stopped too abruptly, the atrophic adrenal glands cannot respond rapidly enough to stress, and the patient may have an Addisonian crisis.

there is glucocorticoid deficiency, but ZG and mineralocorticoids are spared. Atrophy may be secondary to injectable, oral, or topical administration of glucocorticoids. Cortical function usually returns approximately 2–4 weeks after these medications are stopped. Longer-acting steroids are potent suppressants and may suppress the adrenal pituitary axis for 6 weeks or longer.

Clinical signs

Usually dogs are young to middle aged, 3–6 years. It can occur in dogs and cats as early as 2–3 months of age. Seventy percent are females, and intact females have a greater prevalence other than for standard poodles, Portuguese water dogs, and bearded collies. There are multiple breeds associated with this disease; several with a higher risk are standard poodles, Great Danes, Rottweilers, West Highland white terriers, Saint Bernards, Nova Scotia duck trolling retrievers, bearded collies, and Portuguese water dogs. Inheritance of the disease is established for standard poodles, Portuguese water dogs, Nova Scotia duck trolling retrievers, and bearded collies. Chromosomes and loci locations have even been identified in Portuguese water dogs. The disease is rare in cats and therefore no age or sex predisposition has been recognized. Some of the clinical signs are due to deficiency in glucocorticoids and some are due to mineralocorticoids and electrolyte abnormalities. Some may have clinical signs

referable to both. Lethargy, weakness, vomiting, diarrhea, abdominal pain, and anorexia are due to glucocorticoids. Bradycardia is due to hyperkalemia and therefore decreased mineralocorticoids. Polyuria and polydipsia is due to chronic hyponatremia leading to renal medullary washout. Microcardia is due to hypovolemia and hypotension from the hyponatremia, as are decreased blood pressure, lethargy, nausea, and depression.

The history often indicates the dog has periodic bouts of vaguely not feeling good, vomiting, anorexia, lethargy. Over time they may either recover spontaneously or benefit by symptomatic treatment with fluids and steroids. A history reporting some of the problems listed above, especially if they recur and respond to symptomatic therapy of cage rest, fluids, and steroids is "classic" for chronic hypoadrenocorticism. Symptomatic treatment of a sick vomiting dog often includes fluid therapy and steroids, which in the case of an Addisonian is an ideal symptomatic treatment. A differential diagnosis for dogs that appear to have renal disease, gastrointestinal upset, and/or a "garbage hound syndrome" should include hypoadrenocorticism, especially if clinical symptoms are vague and recurring. Addison's and renal disease mimic each other clinically and in much of the routine lab data: 90–95% of dogs with Addison's are azotemic. The majority have hyperphosphatemia, and many cannot adequately concentrate urine due to medullary washout. Therefore, these Addisonian patients may be clinically indistinguishable from patients with chronic renal failure. Other signs seen in hypoadrenocorticism include weakness, muscle tremors, intestinal and gastric bleeding, shaking, and hypoglycemic seizures.

Some cases present as a medical emergency in an "Addisonian crisis." Features include total collapse, weak pulse, dehydrated, shocky, hypothermic, and marked bradycardia. The paradoxical combination of bradycardia and shock should trigger the differential of hypoadrenocorticism.

Dogs and cats with a pituitary lesion will have nonspecific signs and lab data referable to decreased glucocorticoids because mineralocorticoids are spared. However, patients on steroid therapy may have clinical signs and laboratory data that look like HAC due to the excess cortisol they were receiving. These dogs may have alopecia, pot belly appearance, and prominent cutaneous blood vessels due to the cortisol as well as increased serum ALP and dilute urine. If steroids are stopped abruptly the patient may collapse, have hypoglycemia, and signs of decreased cortisol. The atrophic ZF cannot respond quickly enough to produce sufficient cortisol to prevent the crisis. Although steroid usage has stopped, and cortisol has decreased, it will take some time before the corticotropes in the pars distalis produce ACTH. Even under the influence of ACTH there is a further delay in glucocorticoid production as the ZF must regenerate. During this phase the dog or cat is susceptible to a crisis should a stressful event happen.

Table 33.9 Laboratory abnormalities of hypoadrenocorticism.

Lab abnormality	% of dogs	Related to or caused by
Hyponatremia	60–80	Aldosterone decreased
Hyperkalemia	95	Aldosterone decreased
Na:K <23:1[a]	95	Aldosterone decreased
Hypochloremia	50–75	Aldosterone decreased
Hyperphosphatemia	90	Dehydration
Hypercalcemia	33	Obscure
Hypocalcemia	10	Hypoalbuminemia
Azotemia	90–95	Prerenal
Hypoglycemia	20–30	Glucocorticoids
Increased albumin	50	Dehydration
Increased serum protein		Dehydration
Decreased albumin	10+	Unknown
Urine SG variable; <1.030	60	Medullary washout
No stress leukogram	90	Glucocorticoids decreased
Anemia	10–30	Glucocorticoids; GI bleeding
Polycythemia		Dehydration

[a]Na:K <15 : 1; when ratio is this low Addison's is the most likely diagnosis, but it is still not pathognomonic and may be seen with other diseases.

Routine clinical laboratory data

A summary of expected routine laboratory findings is presented in Table 33.9.

Some of the laboratory data are caused by glucocorticoid deficiency, while others are caused by mineralocorticoid deficiency. Therefore, dogs with a pure glucocorticoid deficiency (secondary) or those with atypical Addison's do not exhibit the classical problems of mineralocorticoid deficiency such as reduced Na:K ratio and associated hypovolemia and bradycardia.

CBC

Absence of a stress leukogram or a totally normal leukogram in a sick/stressed dog may be the first indicator but is often overlooked. Eosinophilia and mild lymphocytosis can be attributed to decreased glucocorticoids and therefore may be present in both primary and secondary cases. Red blood cell parameters can vary from a mild nonregenerative anemia to a low-normal packed cell volume (PCV) that then enters the anemic range after fluid therapy. The anemia is attributed to lack of steroid stimulus to the bone marrow and possible gastrointestinal bleeding. If the anemia is more severe, look for gastrointestinal bleeding or a second disease. Less frequently there may be polycythemia (PCV 60–70) associated with marked dehydration. There is no direct effect from mineralocorticoids on the CBC.

Urinalysis

The urine SG is expected to be increased due to dehydration, but in about 60% of cases it is <1.030. Infrequently it is

even hyposthenuric in primary Addison's due to "medullary washout" from chronic hyponatremia. The renal medulla is not saturated adequately with sodium ions and therefore tubules cannot passively reabsorb water from the glomerular filtrate. Dogs with medullary washout may not be able to concentrate their urine adequately even with concurrent dehydration. Dilute urine or at least urine with a SG of 1.020 or less while the patient is dehydrated, coupled with azotemia and hyperphosphatemia leads to a logical, but erroneous, diagnosis of chronic renal failure. If fluid therapy rapidly reverses the azotemia the patient did not have true renal failure, it had prerenal azotemia. Prerenal azotemia was not recognized because the urine was dilute due to concurrent medullary washout. The remainder of the urinalysis in cases of primary hypoadrenocorticism usually has no abnormalities and if abnormalities are detected, they are unrelated to hypoadrenocorticism. Long-term steroid administration leading to secondary hypoadrenocorticism in dogs may predispose them to development of cystitis and associated inflammatory elements in the urinalysis.

Clinical chemistry

Results for clinical chemistry vary depending on if it is primary (MGDH) or secondary (GDH) hypoadrenocorticism (Table 33.9). Hyperkalemia and hyponatremia are the classical abnormalities and the hallmark of primary hypoadrenocorticism. A Na:K ratio <23 : 1 is the key abnormality to indicate primary hypoadrenocorticism and is present in up to 95% of the cases. If the ratio is <15 : 1 it is very suggestive for hypoadrenocorticism, but by itself is not pathognomonic. Other ratios reported include <27 : 1 or <25 : 1; normal ratios are 27 : 1–40 : 1. Most of the ratio shift is due to hyperkalemia, present in 95% of cases rather than hyponatremia, present in 80% of the cases. Any condition that causes hyperkalemia may result in a Na:K ratio consistent with hypoadrenocorticism. Cases of secondary hypoadrenocorticism and early primary ("atypical" hypoadrenocorticism) should not have decreased Na:K ratios. Therefore, some estimate that up to 25% of all types of canine Addisonians will not have abnormal Na:K ratios. Hypochloremia is also present and may be below 100 mEq/L.

Azotemia is reported in up to 95% of cases and is almost always due to dehydration and prerenal azotemia. Dehydration is due to hypovolemia, fluid loss, and decreased aldosterone. Renal failure is an obvious differential diagnosis and must be ruled out via urinalysis, UN:Ct ratio, and response to fluid therapy. Hyperphosphatemia is also due to dehydration, decreased GFR, and prerenal azotemia. The differentiation of prerenal versus renal azotemia is critical in these patients and is best done by examination of urine SG and response of the azotemia to fluid therapy. If the urine SG is >1.030 in a dog and 1.035 in a cat that is azotemic it indicates adequate concentrating ability and prerenal azotemia. Renal azotemia is associated with urine SG in the 1.007–1.016 range. However, many cases of hypoadrenocorticism have urine SG in the 1.010–1.030 range and if the patient is also azotemic it may be difficult to distinguish renal failure vs hypoadrenocorticism. The decreased ability to concentrate urine is due to chronic hyponatremia and medullary washout. If the serum UN is disproportionately increased compared to serum creatinine, a UN:Ct ratio >25, it suggests prerenal azotemia rather than renal azotemia. Last, if azotemia is corrected rapidly by fluid therapy this indicates prerenal azotemia.

Hypercalcemia is seen in approximately one-third of dogs with hypoadrenocorticism. When present with azotemia and a decreased Na:K ratio the hypercalcemia helps favor the diagnosis of hypoadrenocorticism over renal failure. The pathogenesis of hypercalcemia is not clear. It is considered multifactorial due to increased calcium absorption from the GI tract and urine filtrate in the absence of glucocorticoids (cortisol promotes calciuria). Increased serum citrate permits more calcium to be complexed in the serum and the cortisol effect of inhibition of osteoclastic bone resorption is not present. Ionized calcium was increased in five of seven dogs that had increased total serum calcium and there were no consistent increases in PTH, PTH rp, or 1,25 di-hydroxyvitamin D concentrations to explain the hypercalcemia. The hypercalcemia seen with hypoadrenocorticism is moderate, 12–15 mg/dL as compared with the more marked hypercalcemia characteristic of hyperparathyroidism or hypercalcemia of malignancy. Hypoglycemia is present in about 10–30% of the cases and is due to decreased glucocorticoids. Hypoalbuminemia or hyperalbuminemia can be seen. Hyperalbuminemia is due to dehydration; hypoalbuminemia is difficult to explain in light of hypovolemia and hemoconcentration but is reported to be present in 10–40% of the cases. Possible causes of hypoalbuminemia may include intestinal hemorrhage, concurrent protein losing enteropathy, or chronic hepatopathy. Mild to moderate increases in liver enzymes in 30–50% of dogs with primary hypoadrenocorticism is also difficult to explain and is probably nonspecific. They resolve post-treatment of the hypoadrenocorticism. Total carbon dioxide and bicarbonate concentrations are decreased due to decreased tissue perfusion and decreased tubular excretion of hydrogen ions secondary to decreased aldosterone. The metabolic acidosis contributes to hyperkalemia because potassium shifts out of cells in exchange for movement of hydrogen ions into cells in an attempt to buffer acidosis.

An increase in the activity of serum corticosteroid isoenzyme of alkaline phosphatase (CiALP) is present in >90% of dogs with hypoadrenocorticism. However, an activity for this isoenzyme is within the RI and is not useful to diagnose hypoadrenocorticism (Borin-Crivellenti).

Addison's disease is nicknamed the *great pretender* because it mimics so many other diseases. These include GI disturbances, liver disease, and in particular renal failure. As mentioned, more than 90% of dogs with Addison's have

azotemia, and some have a concurrent urine SG suggestive of renal failure. A "clue" to support hypoadrenocorticism rather than renal failure is hypercalcemia, which is present in about one-third of the dogs with Addison's. Hyperkalemia can occur with acute renal failure, but concurrent hyponatremia is seen much more frequently with hypoadrenocorticism than acute renal failure. Urethral obstruction in male cats will produce azotemia and a low Na:K ratio that is due to marked hyperkalemia, but these cats are not hyponatremic and the diagnosis of a urethral obstruction is obvious from physical examination. Uroabdomen will produce hyponatremia and hyperkalemia, Na:K ratios <23, and azotemia. Identification of uroabdomen is done by concurrent measurement of creatinine in peritoneal fluid and blood. The concentration of creatinine will be greater in the peritoneal fluid than blood. Differential diagnoses for these electrolyte abnormalities and tests to help differentiate diagnoses are presented in Table 33.10.

Table 33.10 Differential diagnosis (DDx) for Na:K less than 25 : 1.

- Hypoadrenocorticism.
- Uroabdomen.
- Urethral obstruction with intact bladder.
- Renal failure – acute or chronic.
- GI disease – whipworms, salmonella; calves and foals with diarrhea.
- Spurious – due to failure to separate serum and cells.

Practical DDx are listed above; a more complete list is below. Most of these cause the ratio shift by inducing hyperkalemia:

- Severe acidosis.
- Chlyothorax – especially with repeated drainage.
- "Third space" expansion by any cause: pregnancy, pleuritis, ascites (with or without drainage).
- Spurious – from RBCs and/or platelets and leukocytes.
  - Unique breeds and species have potassium-rich RBCs:
    - Dogs – Akita, Shiba, and others; potassium-rich RBCs
    - Horses – young RBCs; certain breeds
    - Sheep – certain breeds; potassium-rich RBCs

  If there is hemolysis or if the RBCs are not separated from the plasma, then K will leach out of the RBCs, increasing the concentration of K in the plasma/serum. Separate serum from RBCs to prevent this event.
- Leukocytosis >100,000/μL.
- Thrombocytosis >1,000,000/μL.
- Phosphofructokinase deficiency – springer spaniels with respiratory alkalosis.
- Variety of GI diseases – diarrhea; gastric dilation volvulus.
- Release of potassium: crush injury, aortic thrombosis, rhabdomyolysis, heat stroke.
- Diabetes mellitus.

Tests to perform to rule in or rule out the common differentials:

Differential Dx	Test to rule in/rule out
Hypoadrenocorticism	Basal cortisol; ACTH stimulation
Uroabdomen	Compare serum and abdominal creatinine
Urethral obstruction	Male, cat, history, anuria, palpation
Renal failure	All data, urinalysis and response to fluids
GI disease	Fecal for parasites and culture
Spurious	Separate serum from blood

Screening tests – ACTH stimulation and basal cortisol

Summary: ACTH stimulation is flat line and <2 μg/dL rule in hypoadrenocorticism. Basal cortisol decreased: if <1 μg/dL 100% there is sensitivity 98% specificity, rule in hypoadrenocorticism. If <2 μg/dL there is 100% sensitivity and 78% specificity (if Na:K ratio is also decreased Addison's is likely). Basal cortisol is an excellent screening test to rule out hypoadrenocorticism. A basal cortisol >2 μg/dL rules out Addison's.

Basal cortisol and ACTH stimulation screening tests are performed after a diagnosis of hypoadrenocorticism is suspected. Recently a model was developed to aid in the screening and final diagnosis of Addison's disease by using results from routine lab requests. These include the Na:K ratio, eosinophil count, UN, albumin, creatine kinase, and CiALP. Authors developed multiple models but indicated that their calculations may not replicate when reference intervals from different labs are used. The combination of these parameters had high sensitivity and specificity and the authors concluded that the models were practical and could obviate the need for an ACTH stimulation test (Borin-Crivellenti).

Basal cortisol is decreased and is a good screening test for primary and secondary hypoadrenocorticism due to a pituitary lesion. However, if the cause of secondary hypoadrenocorticism is exogenous steroids then basal cortisol may be increased if the steroid cross-reacts with the assay (hydrocortisone, prednisone, and prednisolone) or decreased if the steroid used does not cross-react with the assay (dexamethasone). Depending on the dose and duration of the exogenous steroid the patient may appear clinically like a Cushingoid dog and the lab data will be more consistent with HAC. If glucocorticoids are being given to treat a suspected Addisonian patient they should be stopped for at least 24–48 hours before cortisol is measured and it is preferable to use dexamethasone as it does not cross-react with assays for cortisol. One dose of dexamethasone at 5 mg/kg causes only mild decreases in cortisol post-ACTH stimulation.

Basal cortisol will be less than 1 μg/dL in 85% of canine cases and less than 2 μg/dL in 90+% of cases. A basal cortisol <1 μg/dL has 100% sensitivity and a specificity of 98% in dogs, therefore it is a very good screening test for hypoadrenocorticism. If the Na:K ratio is also decreased, a diagnosis of hypoadrenocorticism can be ruled in. A basal cortisol <2 μg/dL still has a 100% sensitivity, but the specificity is

reduced to 78%, indicating there will be some dogs that have serum cortisol <2 µg/dL that do not have hypoadrenocorticism and therefore are false positives, about 22%. If the basal cortisol is >2 µg/dL (>60 nmol/L), it is highly unlikely the dog has hypoadrenocorticism and the differential can be ruled out. The gray zone for basal cortisol is 1–2 µg/dL and when values fall in this range ACTH stimulation is needed. In cats the cortisol concentrations pre- and post-ACTH administration should be <2.0 µg/dL to confirm hypoadrenocorticism. Only primary hypoadrenocorticism and iatrogenic hypoadrenocorticism have been observed in cats. An important consideration is that the dog or cat was not given steroids, mitotane, ketoconazole, or other drugs that interfere with steroid production. Samples should be collected for basal cortisol and routine lab data before treatment is started. Based on the results of these tests decide if ACTH stimulation is needed. If there are inconsistent clinical findings or laboratory data, then ACTH stimulation should be performed.

The gold standard to confirm an equivocal diagnosis of hypoadrenocorticism is the ACTH stimulation test. Both primary and secondary Addisonians fail to respond to exogenous ACTH by either doubling their cortisol or increasing post-stimulation cortisol beyond 2 µg/dL (Tables 33.11 and 33.12).

Secondary hypoadrenocorticism, glucocorticoid deficiency (GDH) with normal Na:K ratio, should be confirmed with ACTH stimulation. Although basal cortisol will be decreased in cases of secondary hypoadrenocorticism caused by a pituitary lesion, the clinical signs and laboratory data are too nonspecific to rely on just a basal cortisol. The model described above was successful in recognizing GDH. Secondary hypoadrenocorticism due to iatrogenic use of steroids requires ACTH stimulation and knowledge of the type of steroid used. Depending on the steroid used, the basal cortisol measured could be decreased or increased.

ACTH stimulation is expensive, but it is the gold standard and the case management decision at stake is lifelong therapy with mineralocorticoid and glucocorticoid medications. Consider using the low-dose ACTH stimulation test to reduce costs (protocol below). ACTH stimulation requires a basal sample and samples at 30, 60, 90, or 120 minutes post-ACTH administration depending on the protocol used. Failure of ACTH stimulation to either double the basal cortisol or to increase it above 2.0 µg/dL is diagnostic of hypoadrenocorticism in dogs and cats. It is recommended to consult the reference lab used for the diagnostic guidelines they use for pre and post-ACTH cortisol values for diagnostic purposes. Common protocol recommendations include the following. Collect a serum/plasma sample for prestimulation basal cortisol. For a high-dose ACTH procedure, administer 0.25 mg (250 µg) of synthetic ACTH IV to dogs and cats >5 kg and 0.125 mg IV if <5 kg. Collect a second sample for cortisol in 30–60 minutes post-ACTH for dogs. For cats collect two samples post-ACTH, one at 60 minutes and again at 90–120 minutes.

A low-dose ACTH stimulation protocol uses synthetic ACTH (cosyntropin) at 5 µg/kg IV in dogs. Collect a basal sample and the second sample 60–90 minutes later. The low dose of 5 µg/kg of cosyntropin will maximally stimulate the adrenal cortices of normal dogs and dogs with hyperadrenocorticism and can be used as a screening test for hyperadrenocorticism. False positive or increased cortisol post-stimulation in dogs without hyperadrenocorticism is seen in about 15% of dogs.

Protocols for intramuscular ACTH that are used to diagnose hyperadrenocorticism may not be as reliable in Addisonian suspects as ACTH absorption may be impaired due to hypovolemia and poor hydration. For intramuscular protocols collect a serum sample for prestimulation basal cortisol, administer 2.2 U/lb of ACTH IM, and 2 hours later collect a sample for post-stimulation cortisol. Newer reagents use a one hour stimulation protocol; consult the reference lab and/or package insert with the ACTH. In cats inject 125 µg of cosyntropin IM and collect samples at 0, 30 and 60 minutes.

Multiple ACTH stimulation protocols are available and all work well. An advantage of low-dose ACTH stimulation protocol is reduced costs. Clinical trials have demonstrated that any dose of synthetic ACTH greater than 5 µg/kg will maximally stimulate the adrenal cortices 60 minutes postadministration and therefore higher doses are not needed. It distinguishes dogs with hypoadrenocorticism from dogs with nonadrenal illnesses that appear clinically similar to hypoadrenocorticism. If repetition of the ACTH stimulation test was needed because of sample mishandling or other causes, then

Table 33.11 ACTH response test: A baseline measurement of cortisol is obtained, then inject ACTH, measure cortisol 60–90 minutes later.

Pre ACTH stimulation:
- Basal cortisol, healthy dog (reference interval [RI]): 0.5–6 µg/dL or 10–160 nmol/L.
- Basal cortisol: >2.0 µg/dL; rule out hypoadrenocorticism.

Post ACTH stimulation:
- Post-stimulation cortisol (RI): 6–18 µg/dL; 2–3× increase from basal cortisol is a normal response (dogs).
- Post-stimulation cortisol: <2.0 µg/dL; consistent with hypoadrenocorticism (flat line).

ACTH stim does not differentiate primary from secondary hypoadrenocorticism. Endogenous ACTH will aid this differentiation:
- Adrenal dependent (common) = increased ACTH.
- Pituitary dependent (rare) = decreased ACTH.
- Iatrogenic = decreased ACTH.

Hypoadrenocorticism patients fail to increase cortisol in response to exogenous ACTH.

Table 33.12 Expected results for primary and secondary hypoadrenocorticism.

	Na:K Ratio	ACTH stimulation Cortisol µg/dL			Adrenal lesion
		Basal	Post	e-ACTH	
Primary	<25 : 1	<1.0	<1.5	>300 pg/mL (>40 pmol/L)	Adrenalitis ZG, ZF, ZR
Secondary Pituitary lesion	>27 : 1	<1.0	<1.5	<20 pg/mL (<2 pmol/L)	Atrophy ZF
Secondary Iatrogenic	>27 : 1	<1.0[a]	<1.5	<20 pg/mL (<2 pmol/L)	Atrophy ZF
Reference interval	27 : 1 to 40 : 1	0.5–6	6–18	20–100 pg/mL (2.2–20 pmol/L)	Normal

Either basal cortisol less than 1.5–2.0 µg/dL and/or post-stimulation cortisol of <1.5–2.0 µg/dL are findings indicative of hypoadrenocorticism. Consult with the reference lab for specific recommended cutoff values. Consult with the reference lab for reference intervals and cutoffs for eACTH, as these vary with the methodology.

[a]This value could be increased if the steroid used cross-reacted with the assay for cortisol, e.g., prednisone, prednisolone, hydrocortisone.

the low-dose ACTH or the high dose of 0.25 mg/dog can be repeated in 24 hours with reliable results.

Confirmatory tests

Endogenous ACTH (eACTH) is increased in primary and decreased in secondary hypoadrenocorticism.

Basal cortisol and ACTH stimulation are used to diagnose hypoadrenocorticism, but they do not distinguish primary from secondary hypoadrenocorticism. Measuring the endogenous concentration of ACTH is an easy way to distinguish these two diseases. Dogs with primary hypoadrenocorticism have eACTH > than the reference interval (typically 40–1250 pmol/L) and dogs with secondary hypoadrenocorticism have eACTH < reference interval (typically 1–2 pmol/L) (Table 33.12). Dogs with primary hypoadrenocorticism have markedly increased concentrations of eACTH, dogs with atypical primary hypoadrenocorticism have increased concentrations, and dogs with secondary hypoadrenocorticism have decreased or undetectable concentrations of eACTH. Absolute statements such as this are dependent on the disease being fully developed. As the lesions develop, the concentrations of basal cortisol and eACTH are in transition. The earlier diagnostic tests are used during the progression of a disease, the more likely that the results may be equivocal. The stages of the patient's disease development will greatly influence the clinical signs and laboratory results that are being expressed at that moment. Primary hypoadrenocorticism has increased eACTH because the entire adrenal cortex is being destroyed and serum cortisol is decreasing. Eventually there is no negative feedback to the pars distalis and corticotrophs will secrete ACTH in attempt to stimulate cortisol production. This cycle continues unabated until treatment is started. Serum concentration of eACTH can be marked in these cases, >300 pg/mL to >500 pmol/L depending on the laboratory. Although helpful in the distinction of primary and secondary hypoadrenocorticism the collection, shipment, and measurement of eACTH is delicate. It is recommended that the laboratory be consulted regarding sample handling protocol and interpretation.

If there are the characteristic electrolyte abnormalities, primary hypoadrenocorticism is most likely. Greater than 90% of the cases are primary. When the Na:K ratio is <23 : 1 and basal cortisol and/or ACTH stimulation results indicate hypoadrenocorticism, measurement of eACTH may be optional or not needed. Secondary hypoadrenocorticism will have decreased to undetectable eACTH. The pituitary lesion destroys corticotrophs and therefore ACTH production is decreased. Alternatively, the steroids being administered cause negative feedback to corticotrophs that then decrease the production and secretion of eACTH.

Other species

Hypoadrenocorticism occurs rarely in cats and the information provided above is essentially the same for cats. An exception is that only primary hypoadrenocorticism and iatrogenic hypoadrenocorticism have been observed in cats.

It is rare in all other domestic animals and when present in calves and foals it is usually due to diarrhea or septicemia with an embolic shower to the adrenal gland, as well as other organs. Calves and foals develop hyponatremia and hyperkalemia with hypoadrenocorticism similar to dogs, but these electrolyte abnormalities are much more likely to occur with infectious diarrhea or sepsis than primary hypoadrenocorticism. Calves with *E. coli* septicemia are an animal model for the Waterhouse Friderichsen syndrome, characterized as an endotoxin-induced hypoadrenocorticism. Herpesvirus will produce adrenal cortical necrosis in fetuses and neonates such as piglets, calves, and foals.

There are reports that weak and/or septic foals may have a RAI syndrome, as reported in people. The concept is there is inadequate production of cortisol during critical illnesses, especially with sepsis. One report indicated that the mean ACTH to cortisol ratio was significantly higher in septic foals that did not survive than in septic foals that did survive. In a more recent report, the authors did not confirm this

correlation. They also found that the majority of ill foals had adequate responses to cosyntropin administration. Only a small group had low cortisol, low ACTH concentrations, and low responses to cosyntropin indicating a dysfunctional hypothalamic-pituitary-adrenal axis. However, the authors did not conclude this subgroup actually had RAI or that the endocrine status contributed to the illness in these foals. In fact, some foals with septicemia had markedly increased concentrations of ACTH. Endotoxin and the cytokines interleukin-1 and tumor necrosis factor alpha have been shown to cause an increase in ACTH in various species. They also reported that foals that survived had a higher concentration of cortisol in response to low-dose cosyntropin stimulation than did foals that did not survive. This finding suggested that an ACTH stimulation test may be useful to establish a prognosis in these cases. Approximately 50% of critically ill foals will have decreased basal cortisol and an inadequate response to ACTH. It would be beneficial to resolve these conflicting data in foals with sepsis and formulate a consensus to know if steroids should be administered to ill foals and which endocrine tests may be of use in case management.

Paired low-dose (10 µg) and high-dose (100 µg) protocols have been developed to evaluate normal and critically ill foals. Basal samples for cortisol are collected, 10 µg of cosyntropin is given IV as a bolus, and a sample is collected 30 minutes later to assess peak response. Ninety minutes after the 10 µg dose a basal sample is collected and 100 µg of cosyntropin is given IV as a bolus and samples are collected 30 and 90 minutes later for peak cortisol response. Other protocols inject cosyntropin intravenously at 0.1 µg/kg, and measure plasma cortisol concentrations before (baseline), and at 30 and 60 minutes after cosyntropin. Plasma ACTH concentration can be determined via an automated analyzer by enzyme based immunometric assay with chemiluminescent detection. This has been validated for use with equine samples.

Other tests

Plasma to aldosterone, aldosterone to renin, and cortisol to ACTH ratios have been used to help diagnose hypoadrenocorticism in a limited number of dogs. As clinical studies progress these tests may help differentiate primary, atypical, and secondary Addisonians and replace or supplement ACTH stimulation testing.

Primary hyperaldosteronism

Primary hyperaldosteronism (Conn's syndrome) is a rare disease in veterinary medicine but has been reported in dogs, cats, and ferrets. The lesion is hyperplasia or neoplasia of the adrenal cortex that involves the ZG. Cells in the ZG produce excess aldosterone, which causes hypokalemia and hypernatremia along with increased blood pressure and other effects. Aldosterone binds to mineralocorticoid receptors on cells in the distal convoluted tubules and collecting ducts stimulating increased production of Na-K ATPase and an increased number of sodium pumps in the nephron resulting in potassium excretion and sodium reabsorption. Confirmation requires measurement of serum aldosterone and renin combined with physical examination to rule out congestive heart failure and other possible causes of increased blood pressure. Secondary hyperaldosteronism is a normal reaction to decreased blood pressure and activation of the renin-angiotensin-aldosterone system to retain sodium and increase blood pressure. The laboratory differentiation of primary and secondary hyperaldosteronism requires concurrent measurement of aldosterone and renin.

Primary hyperaldosteronism has increased serum concentrations of aldosterone and decreased renin.

Secondary hyperaldosteronism has increased concentrations of aldosterone and renin.

Reference intervals for aldosterone are best obtained from the laboratory analyzing the samples. A guideline is 14–957 pmol/L for dogs and 194–388 pmol/L for cats.

Hyperadrenocorticism – HAC – Cushing's disease, syndrome

There are several causes of hyperadrenocorticism that are described below (Figure 33.4). All will have similar clinical signs and basic laboratory data. Special endocrine tests are useful in distinguishing the cause and this is useful for targeted therapy in case management.

Pituitary-dependent hyperadrenocorticism (PDH)

The primary lesion is a pituitary tumor that secretes ACTH autonomously and stimulates *bilateral* adrenal gland hypertrophy and cortisol secretion. Serum ACTH is increased. Pituitary-dependent hyperadrenocorticism (PDH) is the cause of HAC in more than 80% of dogs and 100% of cats. It is also the cause in 100% of horses with a tumor being in the pars intermedia that secretes various intermediary substances.

Adrenal-dependent hyperadrenocorticism (AT or ADH)

The primary lesion is an adrenal cortical tumor that autonomously secretes cortisol. Serum ACTH is decreased. This cause is responsible for 10–15% of HAC cases in dogs. It is rare in most other species. About half of functional adrenal cortical tumors are benign. In ferrets, adrenal cortical tumors are the most common cause of hyperadrenocorticism and these tumors secrete both sex hormones and cortisol.

Iatrogenic

Exogenous steroids produce the same clinical signs and routine laboratory abnormalities seen in spontaneous cases. Basal concentrations of cortisol will vary with the type of steroid used. It can be increased or decreased depending

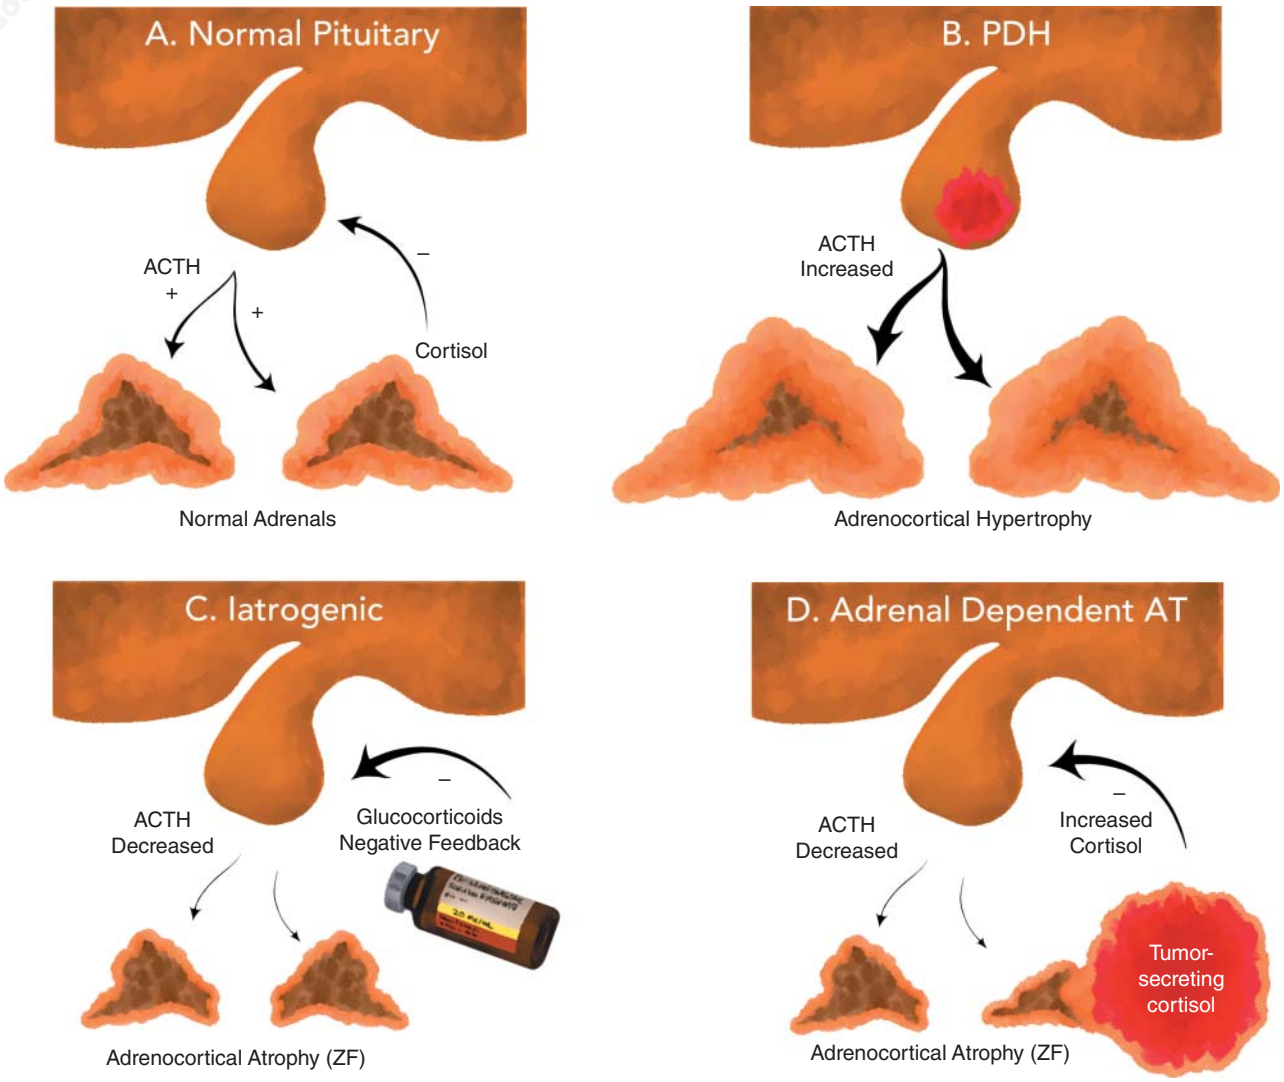

Figure 33.4 Mechanisms of hyperadrenocorticism (HAC) (Cushing's). Arrows represent relative amounts of hormones being secreted with a normal pituitary-adrenal axis and in three disease states. Adrenal gland sizes are relative for normal (A), two types of secondary hyperadrenocorticism (B, C), and primary hyperadrenocorticism (D). The medulla is dark brown and the same size in all of the diseases depicted here. Pituitary-dependent hyperadrenocorticism (PDH) (B) is caused by a functional ACTH-secreting pituitary tumor. PDH produces excessive ACTH, which stimulates bilateral adrenocortical hypertrophy and hyperplasia of the ZF. Iatrogenic HAC (C) is due to an exogenous steroid. The excess glucocorticoid causes negative feedback to the corticotrophs in the pars distalis. This results in decreased ACTH production and secretion. Decreased ACTH secretion leads to *bilateral* adrenocortical atrophy confined to the ZF and decreased endogenous glucocorticoid production. Adrenal-dependent AT (D) is due to a functional cortisol-secreting adrenal tumor. The increased cortisol secretion from the tumor increases negative feedback to the pituitary corticotrophs. The result is a decrease in ACTH production and secretion. Decreased ACTH leads to atrophy of ZF in the contralateral and non-neoplastic ipsilateral adrenal gland. The common feature of all three disease states is increased glucocorticoids, which produce "all" of the physical and clinical pathologic features of HAC.

on cross-reactivity with the cortisol assay. Serum ACTH is decreased. ACTH stimulation is the confirmatory test of choice.

Others

There are a few reports of ACTH ectopically produced by nonadrenal tumors and one report due to food-dependent hypercortisolemia in the dog. These mechanisms are very rare. Ectopically produced ACTH is much more common in human beings because they have a neuroendocrine lung tumor, oat cell tumor, that produces this syndrome. Perhaps because this tumor is rare in veterinary medicine, we do not see this paraneoplastic syndrome.

General considerations

This is primarily a disease of dogs and ferrets, but it also occurs less frequently in horses and rarely in cats. In dogs, the distinction of primary (adrenal dependent

10–15%) from secondary (pituitary dependent 80–85%) is important because primary hyperadrenocorticism is usually treated by surgical removal of the adrenal tumor, and pituitary-dependent hyperadrenocorticism is treated chemotherapeutically or by surgical removal of the pituitary. Mitotane (Lysodren, op'DDD) is capable of selective cytotoxicity of the adrenal cortex. If chemotherapeutic adrenalectomy is the preferred treatment option, it is still important to differentiate the cause of HAC because the dose of mitotane is increased when used on an adrenal tumor. The cause also has bearing on discussion of the prognosis related to treatment. First, the fact that about half of the adrenal tumors are malignant affects prognosis. Second, efficacy of chemotherapy is more variable in AT than in PDH. Furthermore, drugs that inhibit cortisol synthesis do not work as well if the cause is an AT.

Approximately 80% of the dogs with pituitary-dependent HAC disease have a microadenoma in the pituitary that autonomously produces excess ACTH. The increased ACTH stimulates *bilateral* adrenal gland hypertrophy and hyperplasia and increased secretion of cortisol. Only about 10–20% of PDH cases are due to a macroadenoma or a pituitary carcinoma. The tumor in these dogs is larger, invasive, and, therefore, may cause visual defects (pressure or invasion into optic chiasm) or other endocrinopathies due to compression of trophic cells in the pituitary (secondary hypothyroidism) and possibly central nervous system signs if the tumor invades the brain. If some of these problems are detected in a Cushingoid dog then a malignant pituitary tumor is more likely. These cases can be challenging to diagnose as the suppressive tests can respond similar to the results obtained in dogs with adrenal tumors.

Another 10–15% of HAC cases in dogs are due to adrenal cortical tumors that secrete cortisol autonomously. Approximately half of the tumors are benign the other half may metastasize into the vena cava, liver, regional lymph nodes, and lung. *Bilateral* tumors are present in 10% or less of the dogs with HAC; they may be cortical or medullary in origin. Not all adrenal cortical tumors secrete cortisol; some tumors are nonfunctional as is possible for any endocrine tumor. Adrenal cortical tumors do not respond as well to the suppressive and stimulatory tests used to diagnose HAC and these differences can be used to help distinguish PDH from AT.

The distinction of pituitary- versus adrenal-dependent HAC in cats is not as critical because both forms of the disease are treated by surgical adrenalectomy. Feline adrenal glands are less affected by chemotherapy. In cats the pituitary tumor is proportionally much larger than in dogs, however, they are benign. Most cats, 90–100%, with hyperadrenocorticism will have concurrent diabetes mellitus. Concurrent diabetes mellitus in dogs with Cushing's disease is variably reported as 10–33%. However, if resistance to insulin is discovered in either species then investigations for concurrent HAC is a recommended case management consideration.

In horses, Cushing's disease or *pituitary pars intermedia dysfunction* (PPID) is caused by a pituitary tumor or hyperplasia present in the pars intermedia. The pathogenesis and the clinical problems in horses are different from dogs and are discussed later in this chapter under pituitary disease.

About 80–85% of Cushingoid dogs, 90% of cats, and nearly 100% of horses should have a pituitary tumor. These expected results should be considered when trying to interpret the results of endocrine tests. Before the least common cause of HAC is ruled in, an adrenal tumor in a dog and especially an AT in a cat, the test results should be unequivocal. Any equivocal test results should be reconciled by performing multiple tests. Imaging studies to visualize the adrenal tumor and possibly the pituitary tumor have become viable options and should be considered in cases that have confounding endocrine data.

Clinical problems

Almost all of the clinical signs and lesions in dogs and cats are due to the increased concentration of glucocorticoids. Therefore, iatrogenic Cushingoid dogs look identical to spontaneous Cushingoid dogs. There are numerous abnormalities in dogs and cats with HAC. These include alopecia, polyphagia, polyuria/polydipsia, potbelly, muscle wasting, prominent cutaneous blood vessels, comedomes, calcinosis cutis, anestrus, decreased libido, bronchopneumonia, cystitis, and possible pulmonary thromboembolism (Table 33.13). If the cortisol concentration can be reduced, the clinical problems recede, even if a pituitary tumor remains. If blindness or other signs referable to the central nervous system are present, then a large pituitary tumor compressing the optic chiasm and the brain should be suspected. Cats and ferrets have many of the clinical problems seen in dogs with HAC.

Routine laboratory data

Complete blood count (CBC)

A stress leukogram is expected in dogs and is characterized by leukocytosis, mature neutrophilia, lymphopenia, eosinopenia, and monocytosis. Lymphopenia and eosinopenia are the most constant of these. This is present frequently in Cushingoid dogs but is obviously not specific. An increased PCV is seen in a small percentage of cases and some dogs exhibit nucleated red blood cells without regeneration, which is inappropriate and is suggestive of HAC or microangiopathies. Thrombocytosis is often present.

Cats receiving steroids may have a stress leukogram, but cats with naturally occurring HAC do not consistently exhibit a stress leukogram. Erythroid and platelet determinations are normal.

Ferrets may have anemia and/or leukopenia and thrombocytopenia late in the disease due to secretion of estradiol.

Table 33.13 Clinical signs of HAC and approximate percentage of dogs and cats with these abnormalities.

	Dogs	Cats
Polyuria and polydipsia	80–90	90
Alopecia	60–75	60
Fragile skin		50
Polyphagia	50–60	70
Potbelly	70	85
Hepatomegaly	50–70	35
Lethargy	80	50
Anestrus	55	
Calcinosis cutis	10, but considered pathognomonic	
Pyoderma		40
Hyperpigmentation	33	
Comedomes	33	
Concurrent diabetes mellitus depending on report	10–33	90

Others: Muscle wasting, prominent cutaneous blood vessels, testicular atrophy, decreased libido, bronchopneumonia, pulmonary mineralization, cystitis, facial nerve paralysis, and pulmonary thromboembolism.

Table 33.14 Laboratory abnormalities seen with HAC and approximate percentage of dogs and cats with these abnormalities.

	Dogs	Cats
Alkaline phosphatase increased	85–95	15
Alanine aminotransferase increased	50–80	40
Hyperglycemia, fasting	30–40	95
Urea nitrogen decreased	30–50	
Hypophosphatemia	20–40	
Hyperlipidemia	50–80	
Cholesterol increased	50	40
Urine SG <1.020	80	Infrequent, usually concentrated
Urinary infection[a]	50	Infrequent
Proteinuria	75	Common
Glucosuria	10	90
Stress leukogram	Common	Infrequent
Nucleated RBCs	Common	Infrequent
Thrombocytosis	85	
Decreased thyroxine	50	
Decreased free T4	25	
Alkaline phosphatase steroid isoenzyme	85–90	Does not exist

[a]Some canine cases will have bacteriuria, dilute urine, and no or few white blood cells.

The estrogen-induced bone marrow toxicity may cause pancytopenia similar to that induced by persistent estrus in intact female ferrets.

Clinical chemistry (Table 33.14)

ALP is increased in more than 90% of dogs with HAC (sensitive), but it is also increased with many other diseases (not specific). If serum ALP is not increased it is a good indicator that HAC is not present. The increase in ALP is mild, moderate, or marked. Mild and moderate increases are not very helpful to the diagnosis, but marked increases (e.g. 2000–10,000 IU/L) are very suggestive of HAC. However, there is no correlation between the magnitude of the increase and severity of the disease or predicting response to treatments. The increase in ALP in dogs is due to hepatic and a species-unique steroid-induced isoenzyme. Although the corticosteroid-induced isoenzyme (CiALP) activity increases in almost all dogs with HAC (sensitivity 95%) it is also increased in the serum of dogs with nonadrenal illnesses. Therefore, the low specificity (about 18%) limits the diagnostic value of CiALP. An activity for this isoenzyme within RI is not useful to diagnose hypoadrenocorticism (Borin-Crivellenti). Even small increases in serum cortisol, such as those occurring with exogenous steroid administration in ocular preparations, can induce CiALP. Gamma glutamyltransferase (GGT) parallels the increase in ALP in dogs. ALP has a short half-life in cats and therefore does not increase frequently or to the same magnitude as it does in dogs with HAC. Any increase in ALP is significant in cats and should be investigated. Cats and horses do not have a steroid isoenzyme.

Other liver enzymes may also be increased due to hepatomegaly caused by glycogen accumulation that produces hepatocellular vacuolation (not lipid). Glycogen accumulation in hepatocytes is characteristic of HAC, and lipid accumulation is characteristic of diabetes mellitus. Cats therefore will have a fatty liver or a mixture of fat and glycogen. The increases in ALT and AST are mild to moderate and are seen in the majority of dogs. Serum bile acids are increased in about one-third of the dogs and are a nonspecific change that is likely due to hepatomegaly caused by the glycogen hepatopathy. Total bilirubin should not be increased in dogs or cats with HAC. If it is increased look for concurrent diseases, e.g., diabetes mellitus or primary hepatopathies. Mild hyperglycemia is due to the effects of cortisol. If serum glucose is greater than 300 mg/dL in a dog or a cat with HAC consider concurrent diabetes mellitus. Consider HAC in any dog or cat in which it is difficult to regulate serum glucose with insulin as steroids are an insulin antagonist. The majority of feline cases are diagnosed after discovery of insulin resistance. Serum fructosamine may be increased due to chronic hyperglycemia in dogs and an increase is expected in cats. Cholesterol is increased in about

half of the dogs and cats. Triglycerides are increased in nearly 90% of dogs but are not increased in cats.

Serum phosphorus is decreased in dogs. The mechanism is not clear but is attributed to the phosphaturic stimulus of glucocorticoids. Urea nitrogen and creatinine may be low due to diuresis in approximately 33–50% of the dogs.

Thyroid status

Approximately 50% of dogs with HAC have decreased total thyroxine (TT4) and 15–50% will have decreased free thyroxine (fT4). Endogenous TSH is normal or decreased in most of these dogs, which means they do not have primary hypothyroidism. If TT4, fT4, and endogenous TSH are decreased they should have secondary hypothyroidism due to the ACTH-secreting pituitary tumor that is compressing thyrotrophs; this is a rare situation. Increased fT4 is seen in about one-third of the dogs and may be similar to the increase seen in cats with nonthyroidal illness. Glucocorticoids may also suppress the release of TSH from the pituitary. If endogenous TSH is in the reference interval, then the decrease in TT4 is attributed to drug interference. Similar abnormalities in thyroid hormones are seen with exogenous steroids and iatrogenic Cushing's. Steroids should be stopped for at least 4 weeks before thyroid profiles are performed to critically evaluate thyroid status.

Dogs with hyperadrenocorticism or hypothyroidism share many clinical problems such as alopecia, obesity, lethargy, and enlarged liver. They also share similar clinical chemistry abnormalities such as increased hepatic leakage enzymes, cholesterol, and triglycerides. Furthermore, TT4 is often included in geriatric panels and is therefore observed early in the evaluation of these cases. Testing to rule in or rule out HAC should be done prior to thyroid profiles when these two diseases are differential diagnoses. Thyroid hormone therapy is not needed in dogs that are successfully treated for HAC as thyroid values return to reference intervals.

Urinalysis

Dilute urine, 1.004–1.020; cystitis, bacteriuria with or without inflammation, proteinuria with or without inflammation.

Dilute urine is due to interference with antidiuretic hormone (ADH) and/or its receptors by the increased cortisol, resulting in a "biochemical nephrogenic diabetes insipidus." Urine SG <1.020 is seen in 85% of dogs with HAC. Polyuria and polydipsia are compensatory responses and are seen in more than 85% of the dogs. If water is withheld, these dogs can usually concentrate into the 1.025 range. Glucosuria is uncommon in dogs, present in 10% of the canine HAC cases, but is present in 90% + of feline cases. Ketonuria does not occur in HAC. If ketonuria is present it should alert one to the possibility of concurrent diabetes mellitus. Persistent glucosuria and/or moderate to marked hyperglycemia are more consistent with diabetes mellitus. Proteinuria is seen in up to 75% of the dogs and in many dogs this is due to cystitis. Proteinuria is also seen in the absence of cystitis, and in these cases it may be due to concurrent glomerulonephritis, which is common in dogs more than 9 years old. It could also be due to steroid-induced glomerular lesions. Urine protein:creatinine ratios range from 1 to 6 (normal <1.0), and successful treatment of HAC does not always reverse proteinuria; therefore, concurrent glomerulonephritis seems likely in some dogs with HAC. Typically, there is not concurrent hypoalbuminemia or other features of nephrotic syndrome if the dogs only have HAC.

Bacterial urinary tract infections are present in half of the dogs with HAC. Bacterial infections are attributed to the compromised immune state due to the corticosteroids. Some dogs will have bacteria in their urine without inflammatory cells. Dilute urine and bacteria without inflammation is an unusual combination and when observed is suggestive for Cushing's disease. Consider urine culture in dogs even if no inflammation or bacteria are observed.

Screening tests – low-dose dexamethasone suppression (LDDS), urine cortisol:creatinine ratio (UCCR), and ACTH stimulation

If the history, clinical signs, and routine laboratory data are suggestive for HAC then the diagnosis at this stage is a two-step process: first rule in or rule out HAC with screening tests and then try to differentiate PDH and AT with confirmatory tests. Differentiation is critical because they are treated differently: chemotherapeutic destruction of the hypertrophic adrenal cortex for PDH and adrenalectomy for adrenal tumors. If surgical correction is not an option and the AT will also be treated with mitotane, differentiation is still appropriate as the dose of mitotane selected is generally higher for an AT than for PDH. Since approximately half of the adrenal tumors are carcinoma, the correct identification of the cause of HAC has prognostic implications. Regardless, this first step is critical. Obtain a correct diagnosis of HAC because either treatment is rigorous.

Each of the screening tests has value. LDDS is the most popular test and is the test of choice if the dog has characteristic signs and lab data of HAC. It also has the highest false-positive rate and should therefore not be used, or used cautiously, if clinical signs and lab data are not classical of HAC. If surgical adrenalectomy of an adrenal tumor is not an option, then LDDS is the test of choice. ACTH stimulation has the lowest false-positive rate and should be used when clinical signs and lab data are not classical of HAC. UCCR is an inexpensive and easy screening test to rule out HAC but should not be used to rule in HAC. When these tests are used in combination very few cases are misdiagnosed. These tests must be used in conjunction with routine clinicopathologic data. They are not stand-alone diagnostic tests used in isolation.

UCCR (urine cortisol:creatinine ratio)

Depending on the study, 90–100% of dogs with HAC will have excess quantities of cortisol in the urine (high sensitivity). However, urine cortisol has low specificity (20%) because it is increased in 80% of dogs with nonadrenal diseases that look like HAC. Therefore, it cannot be used to rule in HAC. More than 90% of dogs that have urine cortisol in the reference interval or below do not have HAC. Therefore, this is a very good, easy, and inexpensive screening test to rule out HAC. If a dog has an increased UCCR then LDDS or ACTH stimulation is required before HAC is diagnosed. The greatest ratios for UCCR are seen in dogs with PDH as opposed to dogs with AT. If UCCR is >100 the dog is very likely to have PDH. A UCCR is the least expensive screening test.

It is imperative to perform this test on urine collected at home in the morning when physiologic stress is at a minimum. Urine for this test should not be collected during a visit to the veterinary hospital as the stress of visitation will produce increased concentrations of serum and urine cortisol that produce false-positive results. Dogs that visit a veterinary hospital, especially if an orthopedic examination is performed, will have moderate increases of UCCR that are in the range seen with Cushing's. Have the owners collect a midstream urine sample, deliver it to the office, and submit at least 1 ml of centrifuged urine to the laboratory. The lab measures cortisol and creatinine and reports a number without units. A UCCR $>20 \times 10^{-6}$ is consistent with a diagnosis of HAC, depending on the lab and the techniques used to measure cortisol. Reference interval values vary with the laboratory. Cortisol may be present in the urine in free form or as metabolites and the assays used will vary in what they recognize, and therefore so will the reference intervals. Creatinine is used in the denominator as it is excreted at a relatively constant rate in the urine and therefore adjusts for differences in urine volume and degree of urine concentration. UCCR permits the use of spot urine or single point determinations as opposed to 24 hour collections of urine.

A good way to utilize this test is the following. If HAC is a differential on initial examination or after the CBC and chemistry panel are reviewed, then avoid returning the dog to the hospital. Instead, have the owner(s) collect a morning urine sample for UCCR. If it is within RI, then rule out HAC, and if it is increased, continue to pursue HAC.

Summary – UCCR

Good estimate of cortisol production for last 24 hours.

- >90% of dogs with normal UCCR do not have Cushing's, ruling out HAC.
- >95% of dogs with Cushing's have increased UCCR (sensitivity 95%)
- 80% of sick dogs with nonadrenal disease have increased UCCR, specificity 20%; false positives (80%). This is too high to rule in HAC.
- UCCR is sensitive to detect increased cortisol in dogs with Cushing's and in dogs with other nonadrenal diseases (stressed).
- If a dog with undiagnosed polyuria/polydipsia (PU/PD) has a UCCR in reference interval and serum ALP is not increased, then HAC is highly unlikely and can be ruled out.

Reference interval

$0.5–17.7 \times 10^{-6}$ check with lab that performed assay.
<15 rule out HAC.
≥20 consistent with HAC.
15–19 gray zone.

Low-dose dexamethasone suppression (LDDS) test

Patients with HAC will not suppress and "non-Cushingoid" patients will suppress.

The principle of the LDDS test is that dogs or cats that have HAC (PDH or AT) will not decrease their serum cortisol in response to the administration of a low dose of dexamethasone. Dexamethasone will cause a decrease in serum cortisol in "non-Cushingoid" dogs that are normal and in about 50% of dogs with other diseases. In normal dogs dexamethasone is recognized by receptors in the pituitary/hypothalamus resulting in a decreased release of ACTH. The decrease in ACTH results in decreased release of cortisol from the adrenal cortex that is interpreted as suppression. This suppression is used to rule out HAC. In normal dogs, LDDS will decrease serum cortisol in 2–3 hours and cortisol will remain decreased for 24–48 hours. LDDS is an excellent test to distinguish normal dogs from Cushingoid dogs, but it is not entirely reliable to distinguish Cushingoid dogs from sick, stressed dogs that have a variety of other diseases.

The concentration of cortisol at 8 hours post-dexamethasone administration is used to determine HAC. Dexamethasone sodium phosphate or dexamethasone in polyethylene glycol can be used. The recommended dosage is 0.01 mg/kg intravenously for the low-dose protocol. Samples are collected before (basal) the administration of dexamethasone and at 4 and 8 hours postadministration. Use the eight-hour sample to rule in or rule out HAC, use the four-hour sample to differentiate PDH from AT. Reagents used to measure cortisol do not cross-react with or recognize dexamethasone. Therefore, there is no "false," cross-reactive increase from the administration of dexamethasone. Because of cross-reactivity, prednisolone or prednisone cannot be used as the suppressing steroid. Dexamethasone is approximately 40 times as potent as cortisol, hence it can suppress ACTH when the concentration of endogenous serum cortisol cannot.

The reference interval for plasma (serum) cortisol is 0.4–6.0 µg/dL (10–160 nmol/L). However, dogs suspected of having HAC or other nonadrenal causes of increased cortisol will have a cortisol concentration at the high end or above

this range. Reference intervals and suggested cutoffs for interpretation should be provided by the reference laboratory used. LDDS will decrease serum cortisol to <1.5 µg/dL (<30 nmol/L) at 4 and 8 hours postdexamethasone in normal dogs. If a dog has PDH or AT the eight-hour postdexamethasone sample will be >1.5 µg/dL (>40 nmol/L). Some labs use greater than or equal to 30 nmol/L or 1.4 µg/dL. If a dog has PDH, the low dose of dexamethasone will not decrease ACTH secretion from the pituitary tumor sufficiently to suppress cortisol secretion from the hyperplastic adrenal glands. If a dog has an AT the concentration of ACTH is already suppressed, the AT continues to secrete cortisol independent of ACTH. If the eight-hour cortisol is equal to or greater than 1.5 µg/dL (>40 nmol/L) then there was no suppression. The patient has HAC, either PDH or AT, or the test result is a false positive. All dogs with AT fail to suppress and 90–95% of dogs with PDH fail to suppress.

Many veterinarians prefer this test because 95% of the dogs with Cushing's disease do not suppress, which is similar to the high sensitivity of UCCR. LDDS is a test that recognizes 95% of the dogs with the disease that is being looked for, a very positive feature. However, it "recognizes" another 50% of dogs that do not have the disease, but the results of the test suggest that they do. The specificity of LDDS is between 75% and 44% depending on the study, which means the false-positive rate is 25–56%. Sick, stressed dogs with a variety of illnesses may have hyperplastic adrenals that do not suppress cortisol secretion in response to LDDS and the more severe the nonadrenal illness, the more likely there will be a false-positive test result.

An additional use of LDDS is to differentiate PDH from AT in a dog that has classical signs and lab data of Cushing's, see confirmatory or differentiating tests, below.

Summary – LDDS

- An 8-hour cortisol <1.5 µg/dL is suppression, rule out HAC.
- An 8-hour cortisol >1.5 µg/dL is no suppression, rule in HAC.
- 95% of dogs with HAC do not suppress, 95% sensitivity.
- 25–56% of dogs without HAC do not suppress, false positives; 44–75% specificity; therefore could rule in HAC when the dog does not have HAC.
- 5% of dogs with HAC suppress; false negative; may miss the diagnosis.
- Excellent test to rule out Cushing's when suppression occurs. If UCCR is not increased and a dog suppresses with LDDS, rule out HAC.
- LDDS can also be used to differentiate PDH and AT in about 25% of dogs.
- Popular test, but the false-positive rate is 25–50%. Therefore, signs and lab data must be characteristic of Cushing's before this test is used to rule in HAC.

ACTH stimulation test

The principle of the ACTH stimulation test (ACTH stim) is that dogs or cats with HAC will have an exaggerated increase in the concentration of serum cortisol in response to an injection of ACTH. Normal dogs will increase their serum cortisol approximately twofold; but remain at less than 15 µg/dL. Dogs with hypoadrenocorticism will not increase their serum cortisol (<2 µg/dL). Dogs with PDH or AT will have increases of serum cortisol greater than 2–5 times the basal concentration and greater than 22 µg/dL (>500 nmol/L); see Table 33.15. The protocols for this test require 1 or 2 hours depending on the product used. This test will recognize approximately 80–85% of dogs with PDH but only 60% of dogs with AT. Dogs with PDH have hyperplastic adrenal cortices that are primed to respond to exogenous ACTH. The AT dogs have neoplastic cells that are functioning independent of endogenous ACTH and therefore may not respond to exogenous ACTH. However, only 10% of dogs with HAC have AT and AT is rare in cats. So, although this test only recognizes 60% of dogs with AT, this is an uncommon cause of HAC and therefore few HAC cases are missed. This negative fact is offset by one its best features: it has the lowest false-positive rate of any of the screening tests, only 15%. A false-positive test result for HAC has serious case management consequences. Therefore, this test may be the test of choice in a dog that only has a few of the problems associated with HAC and the clinician is searching for a diagnosis. A reasonable first step in cases that have limited features of HAC is to perform UCCR as it is inexpensive, easy, and does not require a new office visit. If UCCR is in the reference interval, and especially if serum ALP is not increased, then rule out HAC. If UCCR and ALP are increased, then follow up with an ACTH stimulation test. ACTH stim is a relatively expensive diagnostic test due to the cost of ACTH.

There are other uses for the ACTH stimulation test. It recognizes iatrogenic HAC. It is the test of choice to monitor response to therapy and provides a baseline response for monitoring therapy. Last, it may identify rare and unusual cases of HAC that have increases in precursors to cortisol (17-hydroxyprogesterone) but normal concentrations of the end product, cortisol.

Patients that look Cushingoid but have low UCCR, low basal cortisol, and a flat line response to ACTH stimulation may have iatrogenic HAC when the steroid being used does not cross-react with the cortisol assay, e.g., dexamethasone. Patients that look Cushingoid and have a high UCCR, high basal cortisol that remains high, and in a flat line response to ACTH stimulation have iatrogenic HAC and the steroid being used cross-reacts with the cortisol assay, e.g., prednisone. If a LDDS was performed on this latter group, they would react like an AT with high basal cortisol that does not suppress at 4 or 8 hours postdexamethasone.

Table 33.15 Expected responses to ACTH stimulation test in dogs.

	Cortisol µg/dL
Normal basal	0.5–6 µg/dL; 10–160 nmol/L
Normal post-stim	6–18 µg/dL; >220–560 nmol/L; 2–5 times basal
HAC diagnostic	>22 µg/dL
Gray zone	18–22 µg/dL
Iatrogenic HAC	<5 if product does not cross-react
Basal Addison's	<1.5
Post-stim Addison's	<1.5 flat line response

ACTH stimulation protocols:
- Easy, done in 1–2 hours; several types of products
- 2.2 U/kg IM ACTH aqueous porcine gel
- Basal sample and 2 hours post-ACTH dog or cat and 8 hours horse
- or
- Cosyntropin IM or IV 250 µg (one vial)
- 5 µg/kg will maximally stimulate adrenal cortex
- Basal sample and 60 minutes post-ACTH for dog; two post-ACTH samples for cats, at 60 and 90 min
- Store reconstituted ACTH in plastic syringes at −20 °C for 6 mo
- Results: cortisol µg/dL reference interval (RI)

Cortisol	Dog	Cat	Horse
Basal normal (RI)	0.5–6 µg/dL	0.5–4	3–6

False positive or increased cortisol post-stimulation in dogs without HAC is seen in about 15% of dogs.

When both ACTH stim and LDDS were used on a group of approximately 65 dogs with HAC, no dog had normal results for both tests. Results of any test are not always clear-cut and therefore tests may need to be repeated at different times or used in combination, especially when investigating endocrine diseases. Multiple ACTH stimulation protocols are available for dogs, cats, and horses and all work well (Table 33.15). The protocols are presented in this chapter under discussion of hypoadrenocorticism. An advantage of the low-dose ACTH stimulation protocol is reduced costs, at least for smaller dogs. The low dose of 5 µg/kg of cosyntropin will maximally stimulate the adrenal cortices of normal dogs and dogs with hyperadrenocorticism and can be used as a screening test for both hyperadrenocorticism and hypoadrenocorticism.

Summary – ACTH stim

- Approximately 80–85% of dogs with PDH will stimulate abnormally high.
- It has the highest specificity (85%) and therefore lowest false-positive results of the screening tests.
- It is affected less by nonadrenal illnesses than the other screening tests.
- It recognizes iatrogenic HAC and atypical HAC and is used to monitor treatment.

Various attributes and comparisons of screening tests are presented in Tables 33.16–33.18.

Confirmatory-differentiating tests: endogenous ACTH, HDDS, LDDS, oral dexamethasone, UCCR, and ultrasonography

These tests are designed to distinguish AT from PDH. This will aid in the selection of treatment and providing a prognosis (Table 33.19).

Endogenous ACTH (eACTH)

Pituitary dependent = increased eACTH.
Adrenal dependent = decreased eACTH.
Iatrogenic = decreased eACTH.

Pituitary tumors that cause HAC synthesize and secrete ACTH and therefore plasma from these dogs will have high concentration of eACTH. AT secretes cortisol, which suppresses ACTH synthesis and release, and therefore these dogs will have decreased or undetectable plasma eACTH. Like all tests this works well on advanced cases or cases that are classical, but there will be cases that fall into the gray zone of equivocal results. Reference intervals should be generated by the lab performing the eACTH assay and the assay must be validated for dogs. Reference interval for eACTH via RIA is approximately 20–100 pg/mL. Values <20 indicate AT, values in the 20–45 range are nondiagnostic or equivocal, and values >45 are consistent with PDH. Some cases of PDH may have values greater than 200 µg/dL. Approximately 90% of dogs with PDH will have eACTH >45 pg/mL, 70% of dogs with AT will be <20 pg/mL. There is some overlap of each category with each other and with reference intervals. These latter cases require another differentiating test or resubmission for eACTH at a later time. Approximately 80% of samples tested from 245 dogs had concentrations of eACTH that were diagnostic for PDH or AT. When new samples were analyzed from dogs in which the initial result was equivocal, 235 out of the 245 dogs, or 96%, had diagnostic results. Although there may be overlap with reference intervals, eACTH is being used to distinguish PDH from AT after HAC has been ruled in. It is not used to distinguish normal dogs from dogs with HAC. Endogenous ACTH is a differentiation test and is not to be used as a screening test to rule in HAC.

Endogenous ACTH concentration measured via a two-site solid-phase chemiluminescent immunometric assay (immunoluminometric assay) was very discriminating in 109 dogs with HAC separated into two groups, 91 with PDH and 18 with AT. The reference interval was determined to be 6–58 pg/mL and a threshold for diagnosis was set at 5 pg/dL. For example, adrenal-dependent hyperadrenocorticism was <5 pg/mL and pituitary-dependent hyperadrenocorticism was >5 pg/mL. The limit of detectable ACTH is 5 pg/dL, and the working range of the assay is 5–1250 pg/mL. All 18 dogs

Table 33.16 Screening tests for hyperadrenocorticism in dogs.

Test	Use	Interpretation		Cortisol µg/dL	Comment
UCCR	RO HAC	RO HAC if $<15 \times 10^{-6}$			
			Basal	*Post-stim*	1- and 2-hour protocols
ACTH stim	Dx HAC	RO HAC	2–10	8–19	
		RI HAC	2–10	>24	15% false positive
		Favor HAC	2–10	18–24	
		Iatrogenic	<8	<8	
			4 h	*8 h*	
LDDS	Dx HAC	RO HAC	—	<1.5 µg/dL	
		RI HAC	—	>1.5 µg/dL	25–50% false positive

Consult reference laboratory for reference intervals and interpretation.
RO, rule out; RI, = rule in; HAC, hyperadrenocorticism.

Table 33.17 Comparison of screening tests for HAC.

Screening test	Positive (sensitivity)	False positive	False negative
UCCR	95%	75–85%	0–5%
LDDS	95% at 8 h	55% at 8 h	0–5%
ACTH (when PDH)	80–85%	15%	10–25%
ACTH (when AT)	60%	—	40%
Basal cortisol	Do not use	35%	25–35%

Some dogs with nonadrenal disease will have false-positive test results; therefore it is essential to correlate results with clinical signs, lab data, and more than one screening test when needed. The percentages summarized above change depending on the cutoff values used for abnormal test results.

Table 33.18 Comparison of LDDS and ACTH stimulation.

ACTH stimulation	LDDS
Good features	
Fewest false positive	Popular
Easy, 1–2 h	95% sensitivity
Recognize iatrogenic	May differentiate AT vs. PDH
Used for atypical HAC	Rules out HAC
Provides baseline for treatment	
Not so good features	
60% sensitive for AT	High false positive 25–55%
Expensive	8+ hours

with adrenal-dependent HAC had concentrations of ACTH below the limit of detectability and all dogs with PDH had detectable ACTH that ranged from 6 to 1250 pg/mL with a median concentration of 30 pg/mL. Using a cutoff of 5 pg/mL there was no overlap between dogs with AT and dogs with PDH. However, there is considerable overlap of eACTH between dogs with PDH and normal dogs. The reference interval is 6–58 pg/mL and therefore many dogs with PDH had concentrations of ACTH within RI.

This is perhaps the easiest and most straightforward way to differentiate PDH and AT; however, sample collection requires attention to details. It is recommended that samples be collected in the morning, between 8 and 9 a.m., but different studies reporting on eACTH have not adhered to this time frame but still achieved diagnostic results. ACTH is best measured in plasma, heparin or EDTA as anticoagulant, and the sample should never be in contact with regular glass tubes as this will bind the ACTH and artifactually decrease ACTH. Use only plastic syringes and tubes for the collection and the storage of samples that are used to measure eACTH. Silicon-coated EDTA tubes can also be used to collect blood. Then use plastic tubes for all other steps to harvest plasma. Most EDTA tubes are silicone coated. Try to collect in chilled tubes. Centrifuge chilled right after collection and transfer plasma to plastic tubes for freezing at −20 to −70 °C. Pack samples on dry ice for over-night shipping to the lab. ACTH is very unstable at room temperature. The most critical event to avoid is freeze thawing, as this will degrade almost all proteins, especially hormones. Aprotinin (Trasylol) is a proteinase inhibitor that blocks trypsin, plasmin, and kallikrein and greatly prolongs activity of ACTH. It is used as a preservative that can be added to the blood as soon as it is collected and it will help prevent *in vitro* decay from time and temperature. It is available from diagnostic labs or the manufacturer. Follow directions supplied; add 500 units per mL of blood collected. With this preservative the activity of ACTH is preserved at 4 or −20 °C for 4 days. Samples are acceptable if shipped in a container with frozen packs for

Table 33.19 Differentiating tests for hyperadrenocorticism in dogs.

Test	Interpretation	Cortisol µg/dL	ACTH pmol/mL
e-ACTH	AT		<20
via RIA	PDH		>100
	Gray zone		20–100
e-ACTH via immunometric	AT <5 µg/dL > PDH		
LDDS		*4 h*	*8 h*
	RO HAC	—	<1.5
	PDH	<1.5	>1.5
	PDH	<50% basal	>1.5
	PDH	—	>1.5 and <50% basal
	PDH or AT	>1.5	>1.5
HDDS		*8 h*	
	PDH	<1.5	Suppression
	PDH	<50% basal	Suppression
	PDH 25% of cases	>1.5 or >50% basal	No suppression
	AT	>1.5 or >50% basal no suppression UCCR postdexamethasone	
Oral DS	PDH	<50% basal	
	PDH or AT	≥50% basal	

Consult reference laboratory for reference intervals and interpretation.

4 days. Loss is approximately 10% activity at 22 °C in 4 days. Avoid freeze–thaw cycles. However, do not use aprotinin if the assay for ACTH is immunoluminometric as aprotinin causes a negative bias that may result in inability to quantitate ACTH. It is best to follow all instructions provided by the laboratory where the samples are sent.

ACTH can be measured via RIA, immunoradiometric and immunoluminometric assays. Reference intervals and units will vary with the assay used therefore use a reference lab that has validated the assay for animals and that provides reference intervals and expected values for AT versus PDH for their methodology.

Examples of interpretation guidelines for eACTH measured via RIA:

	eACTH[a]
Reference interval	20–100 pg/mL
Adrenal tumor	<20 pg/mL; seen in approximately 75% of cases
Gray zone	20–45 pg/mL; repeat in a few weeks or perform another test
Pituitary tumor	>45 pg/mL; seen in approximately 90% of PDH, and often markedly increased, e.g., >200

[a]Consult reference lab that performs the assay for their recommended values to interpret results.

Example of interpretation guidelines for eACTH measured via immunoluminometric assay:

	eACTH[a]
Reference interval	6–58 pg/mL
Adrenal tumor	<5 pg/mL
Pituitary tumor	>5 pg/mL

[a]Consult reference lab that performs the assay for their recommended values to interpret results and where they set the threshold for diagnosis: e.g., adrenal-dependent hyperadrenocorticism <5 pg/mL and pituitary-dependent hyperadrenocorticism >5 pg/mL. Do not use aprotinin for ACTH measured via immunoluminometric assay.

High-dose dexamethasone suppression test

75% of dogs with PDH suppress. 100% of dogs with AT and 25% of dogs with PDH do not suppress. Dogs that suppress have PDH and dogs that do not suppress have either AT or PDH; this latter group is small overall and will require another test to differentiate, such as eACTH and/or abdominal ultrasound.

A high-dose dexamethasone suppression test (HDDS) can identify approximately 75% of the dogs that have PDH, but it cannot definitively identify an AT. The principle of HDDS

is that when the concentration of dexamethasone gets high enough, it will decrease the release of ACTH from pituitary microadenomas and the decrease in ACTH will cause a decrease in serum cortisol that is interpreted as suppression. This decrease in cortisol post-HDDS also occurs if the dog is normal, or if the dog is sick and stressed by a nonadrenal disease. This has important diagnostic implications because if a HDDS is performed on a dog with a false-positive LDDS result, this dog would now suppress with HDDS and lead to an erroneous diagnosis of PDH. HDDS should not be performed on dogs in which the clinical diagnosis is uncertain and it should never be used as a screening test. Dogs with an adrenal tumor secrete cortisol independent of ACTH. These dogs already have low concentrations of ACTH (decreased by the negative feedback of cortisol secreted from the adrenal tumor), therefore the administration of dexamethasone has no observable effect on ACTH and cortisol secretion continues from the adrenal tumor, hence there is no suppression in the serum concentration of cortisol. However, approximately 25% of dogs with PDH also do not suppress. This latter group may have pituitary macroadenomas or carcinomas or the tumor may be arising from the pars intermedia, which does not respond to negative feedback from corticosteroids. Differentiation of the dogs that are resistant to dexamethasone suppression requires eACTH and/or ultrasonography. Dexamethasone resistance means the dog has either PDH or AT and the odds are about 50 : 50. There is also some data to suggest that a HDDS only provides a clearer interpretation of the 4- and 8-hour LDDS in about 10% of the cases.

This test is performed similar to the LDDS except the dose of IV or IM dexamethasone is now 0.1–1.0 mg/kg or 10 times greater than LDDS. Basal, 4-, and 8-hour samples are collected. An alternate protocol omits the four-hour sample. Suppression indicates PDH and is defined as:

- Cortisol less than 1.4 µg/dL (40 nmol/L) at 4 or 8 hours.
- Cortisol <50% of basal cortisol at 4 or 8 hours.

If a portion of the IV injection becomes extravascular cancel and repeat the procedure after 72 hours or longer.

LDDS as a differentiating test

An additional use of LDDS is to differentiate PDH from AT in a dog that has classical signs and lab data of Cushing's. If suppression is detected, the diagnosis is PDH. If there is no suppression, the diagnosis may be either AT or PDH. Suppression is defined as any of the following in a dog that has an 8-hour cortisol >1.4 µg/dL:

- 4-hour cortisol <1.4 µg/dL (consult reference lab for cutoff value they use).
- 4-hour cortisol <50% of basal cortisol (4-hour could still be >1.4 µg/dL).
- 8-hour cortisol <50% of basal, but >1.4 µg/dL.

Critical to correct interpretation is that there is no suppression at 8 hours, they "all" have a value of cortisol >1.4 µg/dL, consistent with HAC. Overall, approximately 60–80% of dogs with PDH meets one or more of the above criteria and therefore demonstrates a type of suppression with LDDS. These results make the LDDS a useful adjunct to distinguish PDH and AT. However, approximately 20–40% of dogs with PDH do not demonstrate suppression via these criteria. Similarly, 25% of dogs with PDH also do not suppress with HDDS. There are data to suggest that the dogs with PDH that do not suppress, those that are resistant to dexamethasone, have larger pituitary tumors, macroadenomas or carcinomas. It is logical that the pituitary tumor could be so large that a low dose of dexamethasone would not totally suppress the secretion of ACTH or that the tumor lacks receptors for cortisol or is located in the pars intermedia. One hundred percent of dogs with AT do not suppress with LDDS, therefore when no suppression is observed with a LDDS the dog has either an AT or PDH, perhaps a large pituitary tumor. Abdominal ultrasonography or eACTH may help differentiate these. The pattern of suppression at 4 hours followed by an increase at 8 hours is called a "rebound" response and is considered diagnostic of PDH. Critical to the correct interpretation of all of the confirmatory tests is that the patient meets clinical and laboratory criteria for a diagnosis of HAC.

Oral dexamethasone at high dose and UCCR

Urine is collected at home in the morning for 2 consecutive days and stored individually in the refrigerator in closed containers. After urine is collected on day two, dexamethasone is given orally by the owner at 0.1 mg/kg every 8 hours (three doses). Urine is collected on the third morning and all urine samples are analyzed for cortisol and creatinine and UCCR determined. The UCCR on the first two samples is averaged for a baseline value. A baseline value in reference interval will rule out HAC. If the baseline value is increased, then compare this value with the postdexamethasone ratio. If the UCCR postdexamethasone is <50% of baseline it indicates suppression occurred and the diagnosis is consistent with PDH. If the postdexamethasone sample is >50% of basal it indicates suppression did not occur and this is consistent with an AT or PDH, similar to the HDDS test when suppression does not occur. Since there is a high false-positive rate with spot UCCR, it is recommended that a positive test result be correlated with a poster card ideal case of Cushing's and that one other screening test confirm HAC is present.

Diagnostic imaging: US, CT, MRI

These are obviously not clinical pathology tests, but they are procedures used in conjunction with laboratory data. Abdominal ultrasonography can differentiate AT from PDH. However, it is not sensitive enough to differentiate hyperplastic adrenal glands secondary to PDH from other causes of adrenal hyperplasia or even some normal adrenal

glands. Therefore, it is not a screening test to diagnose HAC. Furthermore, not all adrenal tumors can be found. Some are missed because the tumor is too small to be visualized or the affected adrenal gland could not be located. If present, adrenal mineralization is a strong indicator of HAC and is seen in hyperplastic and neoplastic adrenal glands in plain radiographs as well as other imaging techniques. Approximately half of the adrenal tumors have mineralization. Ultrasonography may identify invasion of blood vessels or masses in the liver, but it cannot differentiate adenomas from carcinomas unless there is evidence of metastasis such as vascular invasion, masses in the liver, or enlarged regional lymph nodes. The larger the adrenal mass the more likely it is malignant. Diagnostic accuracy of abdominal ultrasonography is dependent on the experience of the ultrasonographer and confounders in the patient such as abdominal fat, large body size, hepatomegaly, gastrointestinal distension, renal mineralization, nodular adrenocortical hyperplasia of old dogs, small size of normal adrenals, and their position in the abdominal cavity. Similar to endocrine testing abdominal ultrasonography is used to distinguish PDH from AT after there is a diagnosis of Cushing's disease. Also similar is that there are false-positive and false-negative results.

Computed tomography (CT) can be used to look for characteristic abdominal lesions or visualize the pituitary. It is more discriminating than abdominal radiographs or ultrasonography, but it also has limitations and conflicting reports as to its discriminating capabilities. CT and MRI are used to visualize a pituitary tumor, especially if a large tumor is suspected. They are more useful in the cat due to the larger size of pituitary neoplasms in cats with HAC or acromegaly. They do not replace endocrine testing as they can only visualize about half of the pituitary tumors in dogs because the tumors are so small. Imaging cannot differentiate a functional versus nonfunctional pituitary mass. However, if the endocrine data suggests a large pituitary tumor versus an AT, then CT or MRI are useful techniques to separate these differentials. If neurologic signs exist then CT or MRI may identify a large pituitary tumor.

Newer technology will continue to improve diagnostic imaging and eventually they may be sensitive enough to accurately distinguish PDH from other forms of adrenal hyperplasia and to visualize pituitary microadenomas. Just like the suppression and stimulatory tests, there will be false-positive and false-negative test results with imaging studies. Clinical pathology and especially clinical endocrinology have done a good job reporting false negatives, positives, sensitivities, and specificities.

Summary of endocrine testing

Dogs and cats that have classical signs for HAC are relatively easy to identify based on clinical signs and laboratory results. However, it can be a diagnostic challenge to recognize HAC in animals that only have some of the signs of HAC or are early in the development of the disease. These are the cases that laboratory testing is needed the most. Each test has its advantages and disadvantages. UCCR is a good first screening test to rule out the differential of HAC as it is easy. The sample can be collected at home, it does not require another office visit, and it is relatively inexpensive. The test's high sensitivity and low specificity mean that most of the time the result is increased (positive). So if it is normal or decreased, it is very unlikely the patient has HAC. A negative UCCR combined with a reference interval ALP is sufficient evidence to rule out HAC. LDDS is the test of choice when the patient looks Cushingoid because of its high sensitivity of 95%. Like the UCCR there are numerous false positives (up to 55%), so avoid LDDS if the pet does not have multiple clinical signs or lab data characteristic of HAC. Because an animal may be stressed by its primary disease, its LDDS can be falsely "positive"; that is, it does not suppress, but it does not have HAC. If HDDS is used in this situation, the results will show suppression that indicates PDH. This is a false-positive diagnosis with serious consequences. Never use HDDS as a screening test. In patients that do not look typical for HAC and may only have a few of the lab data characteristic of HAC, then ACTH stimulation is preferred as it has the fewest false positives, 15%. In patients that look typical for HAC and that have multiple laboratory results characteristic of HAC, then LDDS is preferred. Phenobarbital therapy infrequently produces abnormal results for LDDS, but it does not induce abnormalities for ACTH stimulation tests or e ACTH.

Clinical pathology does a good job of telling its users what the sensitivity and specificity are of lab tests. For endocrine testing, this has led to clarification and some confusion because the ranges provided and cutoff values for diagnoses may vary due to different methodologies. If the reference intervals are wider, the lab tests are less discriminating. Where the cutoff is set for diagnostic values changes sensitivity and specificity. Therefore, use reference intervals and cutoff values from the lab providing results. No test can be 100% positive or negative, or 100% sensitive and specific because there are too many biologic and methodologic variables.

Summary ideas

- If serum ALP is not increased, HAC is very unlikely.
- If UCCR is not increased, rule out HAC. If both ALP and UCCR are not increased, rule out HAC. Consider retesting in future if HAC remains a differential.
- UCCR is a good test to rule out HAC; never use to rule in HAC.
- UCCR avoids a visit; easy first step.
- If characteristic signs and lab data are present, use LDDS.
- If limited signs and lab data are present, use UCCR to rule out, follow with ACTH stim if UCCR is increased. Avoid LDDS as false-positive rate is too high.

- If a nonadrenal illness is more likely than HAC, use UCCR and then ACTH stim if needed.
- PU/PD with characteristic other signs, use LDDS.
- PU/PD with few signs of HAC, use UCCR to rule out and follow with ACTH stim if needed.
- Suspect an adrenal tumor, use of LDDS is preferred. ACTH stim has lower sensitivity for AT. Consider imaging to search for AT.
- Suspect iatrogenic HAC, use ACTH stim and evaluate history.
- Suspect hypoadrenocorticism, measure basal cortisol and then ACTH stim if needed.
- How long to withdraw steroids before retesting: It is difficult to be certain when the pituitary adrenal axis will return to normal. It ranges from 2–8 weeks depending on dosages and duration of steroid administration.
- Unit conversion: To convert cortisol to μg/dL (mcg/dL) from nmol/L, divide cortisol reported in nmol/L by 27.6.

Differentiating tests

- eACTH: It is easy, just submit one sample. It differentiates PDH and AT.
- LDDS: This can rule in HAC and identify 60–80% of dogs with PDH.
- HDDS: This is a traditional test to differentiate AT and PDH. Dogs that suppress have PDH and dogs that do not suppress have either AT or PDH.
- HDDS: An HDDS may successfully identify the only 10% of the cases that LDDS did not distinguish.
- 100% of AT do not suppress with HDDS or LDDS.
- If resistant to dexamethasone consider imaging to look for AT and/or measure eACTH.
- If suspecting a large pituitary tumor, consider imaging by CT or MRI.

Unusual cases

Most dogs that look Cushingoid but that do not test positive with ACTH stim and LDDS do not have HAC. However, some of these dogs could have "atypical or occult HAC." This form of HAC may have increased concentrations of one or more precursors of cortisol. The most diagnostically important precursor is 17-hydroxyprogesterone (17-OHP). If dogs with this atypical form have a deficiency in one of the enzymes needed to convert precursor molecules into cortisol, then the molecule before this enzyme deficiency will increase. For example, 17-OHP will increase if the enzyme 21 beta hydroxylase is deficient or 11-deoxycortisol will increase if the enzyme 11 beta hydroxylase is deficient. If atypical HAC is suspected, then the test of choice is ACTH stimulation. The protocol is modified to measure both cortisol and 17-OHP pre and post-stimulation and comparing both concentrations to reference intervals provided by the laboratory. Post-stimulation cortisol that is not out of the reference interval combined with an increased concentration of 17-OHP is consistent with what is called atypical or occult HAC.

Although increases in 17-OHP can be measured in dogs, it is not clear if this hormone causes lesions or if the "syndrome" actually causes clinical disease. Dogs without adrenal disease can have increased serum 17-OHP just as they have increased serum cortisol due to stress of a concurrent disease. There also are reports of cases treated with trilostane that improved despite continued increase in serum 17-OHP. Furthermore, others have observed that as adrenal function is stimulated by a true adrenal disease or nonspecifically by stress that the production of all hormones increase, cortisol and sex hormones. Other sex hormones that can be measured are progesterone, estradiol, testosterone, and androstenedione, basal and post-ACTH stimulation. This has led to "steroid hormone profiles" or measurement of the parent products, cortisol and estradiol, as well as their various precursors. In ferrets these profiles are diagnostically helpful. If measured, estradiol is often increased in dogs being investigated for HAC. However, studies that correlate these hormone profiles with clinical disease, as well as determination of sensitivity and specificity, are needed for dogs and cats. If 17-OHP can increase post-ACTH in dogs that do not have adrenal disease it seems reasonable that other sex hormones would increase as well, further weakening the concept that occult HAC causes clinical disease. Additional studies are needed before the syndrome of occult HAC is recognized widely.

21-Hydroxylase deficiency does cause prolonged gestation in Holstein cattle because the adrenal gland cannot produce sufficient cortisol to stimulate delivery. The result is a fetal giant.

Ferrets

Hyperadrenocorticism is a common disease in ferrets and produces many of the clinical signs and lab abnormalities described for dogs and cats. The most striking physical abnormality is baldness. The adrenal lesion and the hormones that cause the disease, however, are very different. The lesion is in the adrenal gland. Approximately half of the lesions are hyperplasia and half are neoplastic. About 80% of the lesions involve the left adrenal gland and about 15% are *bilateral*. Unilateral adrenalectomy provides successful treatment for those cases with proliferations in the left adrenal. The principle hormone that causes the clinical signs is estrogen. Serum cortisol is rarely increased. If the disease exists for a long enough period the increased estrogens will cause bone marrow suppression leading to anemia and thrombocytopenia. Diagnosis is confirmed by measurement of estradiol or estradiol precursors (17-hydroxyprogesterone and/or androstenedione). The precursors to estradiol contribute to the disease and if estradiol is not increased, then

the precursors should be measured. Commercial assays for these hormone profiles are available.

Most of the neoplastic adrenal lesions are considered carcinomas based on histologic features. However, very few metastasize and therefore their biologic behavior is similar to an adenoma. Some cases have life-threatening hemorrhage from necrosis within the tumor.

Pheochromocytoma – tumor of adrenal medulla, increased epinephrine and norepinephrine

Pheochromocytoma is the most common tumor of the adrenal medulla, but it is rare. It occurs in all species, probably most frequently in cattle, dogs, rats, and a few horses. In bulls and people, it is associated with concurrent tumors of C-cells and is part of multiple endocrine neoplasia (MEN). A concurrent tumor in ectopic adrenal locations is seen in about half of the dogs with a pheochromocytoma. Clinical signs are attributed to the increased catecholamines in the blood, but they may also be due to direct effects of the tumor or concurrent neoplasia. Signs reported in dogs and horses include tachycardia, arrhythmias, tachypnea, panting, weakness, collapse, and seizures. Polyuria and polydipsia are reported frequently in cats with pheochromocytomas. Routine clinical pathology is usually of little help. Nonspecific observations include increased liver enzymes in 10–50% of dogs, mild proteinuria in 50% perhaps secondary to increased blood pressure–induced glomerular leakage, and dilute urine due to inhibition of vasopressin by the increased catecholamines. Approximately half of the dogs will have a stress leukogram and 75% will have increased ALP. A few of these dogs have concurrent HAC. Sometimes the initial consideration of pheochromocytoma is when abdominal ultrasonography reveals a mass in the adrenal region and/or masses in the vena cava. Metastases in dogs are reported in 20–50% of the cases.

Norepinephrine is the principal catecholamine secreted from pheochromocytomas in dogs. Urinary vanillylmandelic acid and free unconjugated catecholamines are increased in bulls with pheochromocytoma. Stimulatory and inhibitory tests are used but have side effects, and the measurement of catecholamines in these tests should be coordinated with a lab that will perform assays and provide reference intervals. Cytology of the suspected tumor reveals "naked nuclei" or nuclei with very little cytoplasm, but this cytologic description is nonspecific.

Pituitary disorders

The pituitary gland is composed of the adenohypophysis (pars distalis or anterior lobe), neurohypophysis (pars nervosa or posterior lobe), pars intermedia (intermediate lobe), and pars tuberalis (infundibular stalk). The adenohypophysis is formed by the differentiation of embryonic oral ectoderm, Rathke's pouch, into trophic secretory cells producing GH or somatotropin, prolactin, TSH, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and ACTH. The most common disease and lesion from the pars distalis is hyperadrenocorticism due to an adenoma secreting ACTH (Table 33.20). Neoplasms that produce other trophic hormones and that cause disease are rare. An example is a GH producing adenoma that causes acromegaly. Nonsecretory neoplasms, inflammation, and embryonic cysts that destroy the pituitary gland are uncommon and result in panhypopituitarism, dwarfism, or selective decrease in specific trophic hormones. Hypoadrenocorticism and hypothyroidism are the most common diseases due to pituitary destruction. These diseases are described in the adrenal and thyroid sections of this chapter.

The neurohypophysis is composed of axons that originate within the supraoptic and paraventricular nuclei of the hypothalamus. Separate neurons within both nuclei synthesize vasopressin (ADH) and oxytocin. These hormones migrate through the infundibular stalk in axons as precursor proteins to be stored in secretory granules in the neurohypophysis, pars nervosa, and are released under appropriate stimuli. Oxytocin stimulates uterine contraction and milk secretion. ADH stimulates water reabsorption in the distal and collecting tubules.

Various pituitary disorders are described below.

Equine Cushing's-like syndromes

Pituitary pars intermedia dysfunction (PPID)

Equine Cushing's disease is more appropriately called PPID. This term is deemed more appropriate because the pituitary lesion does not have to be neoplastic. It is located in the pars intermedia. There are dysfunctional biochemical events and it stimulates a unique pathogenesis with a different profile of pituitary hormones that do not result in marked adrenal cortical hypertrophy. The pituitary lesions range from hyperplasia to large tumors. Clinical disease, hormone profiles, and biochemical changes may occur without overt pituitary adenoma formation. Rare causes of Cushing's in the horse is a neoplasm in the pars distalis or in the adrenal cortex. Nodular

Table 33.20 Regions in the pituitary gland and associated lesions and the most common diseases.

Pars distalis	Neoplasia	Hyperadrenocorticism; acromegaly – cat
Pars distalis	Cyst	Dwarfism
Neurohypophysis	Varied	Diabetes insipidus
Pars intermedia	Neoplasia	Pituitary pars intermedia dysfunction – horse
Pars tuberalis	Obstruction	Diabetes insipidus

adrenocortical hyperplasia does not cause clinical disease and is similar to the lesion in older dogs.

Classical signs such as an aged horse (mean age 24 years, range 15–32) with swayback, hirsutism, laminitis, muscle atrophy, lethargy, abnormal fat distribution, hyperhidrosis, polyphagia, intermittent fever, and secondary infections are adequate to diagnose many cases and start treatment with pergolide. Owners often complain that each year the horse sheds hair later or not at all and the excessive sweating leads to the characteristic long curly coat that mats and persists in warm months. Hirsutism is a unique abnormality present in 80–100% of horses with PPID and it is considered pathognomonic. It probably is a manifestation that occurs late in the course of the syndrome. PU/PD is reported, but owners do not consistently observe it. Secondary skin infections and poor wound healing are observed in 25–50% of horses. Up to 80% of horses with PPID develop laminitis, apparently from carbohydrate intolerance. The hypothalamus is the primary control center for cyclic shedding of hair, appetite control, and temperature regulation. One proposal is that pressure on the hypothalamus from the expanding tumor in the pituitary is responsible for the clinical signs of polyphagia, hypertrichosis, and fever. Tumors may compress the hypothalamus due to their relatively large size and an incomplete sella turcica in the horse. Pressure on the hypothalamus and increased concentrations of intermediary substances and cortisol produce the characteristic physical abnormalities that are diagnostic of this syndrome. Despite large pituitary tumors in some horses, neurologic or visual signs are infrequent and variably reported at 5–50%. PPID is also seen in horses with small pituitary lesions that are hyperplastic. Therefore, size is not the major reason for the disease, but larger lesions correlate with older age of affected horses and more fully developed clinical signs that have characteristic endocrine profiles. PPID is a progressive disease and identification of the starting point is vague. Early disease recognition is difficult because the lab tests and physical characteristics are not definitive in the early stages.

The pars distalis processes the precursor peptide pro-opiomelanocortin into ACTH. Melanotrophs in the pars intermedia synthesize pro-opiomelanocortin and cleave it into ACTH and further processes it into α-and β-melanocyte stimulating hormone (MSH), β-endorphins, and corticotrophin-like intermediate lobe peptide (CLIP). Plasma and tumor concentrations of ACTH are only mildly increased in horses with this syndrome, but the tumor and plasma concentrations of the intermediary peptides listed above are markedly increased. These data help explain the mild to moderate increases in ACTH and cortisol combined with modest adrenocortical hyperplasia versus the marked increases in plasma concentrations of MSH, CLIP, and beta endorphin seen in horses with PPID. Measurement of these peptides is more useful in the diagnosis of PPID in horses than is the measurement of basal cortisol or ACTH. Cortisol strongly inhibits ACTH secretion from the pars distalis but has little effect on peptides secreted by the pars intermedia because melanotrophs do not express glucocorticoid receptors. Hence the dexamethasone suppression tests (DSTs) used in dogs are less useful in horses and require modifications.

Physical and historical data are more helpful to the diagnosis than are routine clinical pathology abnormalities that are common in small animals. Urine SG ranges from 1.022 to 1.047, which helps explain why PU/PD is infrequently reported in horses. This seems paradoxical given that cortisol can be increased and large pituitary tumors could interfere with function of the pars nervosa and ADH release.

When PPID is fully developed, the horse has marked hypertrichosis and the diagnosis is easy to confirm with endocrine tests. It is the early cases that are problematic to diagnose. The standard method of testing is the 19-hour (overnight) DST when confirmation is desired in a horse with hypertrichosis. Normal horses should suppress and failure to suppress is diagnostic for PPID. Inject dexamethasone IM at a dose of 40 μg/kg. Serum cortisol should be <1 μg/dL (27.6 nmol/L) 19 hours later in 97% of normal horses. Horses with PPID do not suppress. Cortisol is >1.0 μg/dL, at least when the disease is fully developed. Confounding factors of the DST include concurrent laminitis, time of the year, and stage of the disease. Therefore, test results should be correlated with all of the other clinical and laboratory information. DST may fail to suppress normal horses and ponies in the fall (false positives). Steroids may induce laminitis and early on in the disease horses with PPID may suppress with DST, which is a false negative. A concern of DST is that it may exacerbate laminitis in horses with a history of current or past laminitis. However, in a study of 43 PPID horses in which DST was used, this was not observed. There are no other diseases that look similar to PPID in its late stages and therefore the main distinction is to separate horses with PPID from horses with normal aging changes. DST is successful in distinguishing these two groups. However, recognizing PPID early in its development, when the pituitary lesion is small and the clinical signs mild, requires tests other than DST.

Other tests that have value are endogenous ACTH, α-MSH, TRH (thyrotropin-releasing hormone response test), combined hormone response tests, and measurement of ACTH after oral administration of domperidone. These tests may prove helpful in recognizing PPID in its early stages. DST is useful for more advanced cases and it is easy to perform. Basal cortisol is not diagnostic and loss of diurnal secretion of cortisol is controversial. ACTH stimulation is not a useful test as it recognizes <20% of the cases. This lack of stimulation is likely because adrenocortical hyperplasia is not a prominent feature of PPID. Endogenous ACTH is also used to diagnose PPID. Using a 10–50 pg/mL reference interval and

a cutoff of >55 pg/mL indicates PPID with a disease range of 104–1000 pg/mL. Variables include where the cutoff value is set (critical), time of day, and different reference intervals for ponies versus horses. It is critical to use values set by the reference lab that analyzes the samples. Although this is a simple one-collection procedure, it does not recognize horses in the early stages of PPID and misses some horses in the late stages of the disease. Therefore, basal ACTH is not ideal, and provocative testing is recommended. Assays for ACTH should be validated for equine and collection procedures for ACTH outlined for dogs should be followed.

Measurement of α-MSH may be better than ACTH in horses because MSH is produced primarily in pars intermedia and ACTH is primarily secreted from pars distalis. Plasma α–MSH hormone concentration >91 pmol/L is considered diagnostic of PPID. However, there is seasonal variation in mean concentrations and ranges: fall = 50–60 pmol/L + 65 pmol/L, spring, summer, winter = 11 pmol/L + 4 pmol/L. Therefore, additional guidelines considered diagnostic for PPID are if either plasma α-MSH is >19 pmol/L of mean concentration in spring, summer, winter or if plasma α – MSH is >148 pmol/L of mean concentration in the fall. Plasma α-MSH and ACTH concentrations increase as daylight decreases, from maximum daylight hours to 12 hours of daylight (September), but serum insulin does not fluctuate. This occurs in normal horses and ponies and in horses and ponies with PPID, hence the season of the year should be considered when interpreting results. Ambiguous results can be repeated at a later time, even in a different season. Horses and ponies receiving pergolide, dopamine antagonists have a significantly less increase in α-MSH and lower plasma ACTH. Another diagnostic approach is to measure α-MSH after a DST. A α-MSH >90 pmol/L post-DST is the cutoff value between normal horses and horses with PPID.

The pars intermedia is partially regulated by dopaminergic input from neurons in the hypothalamus and loss of dopaminergic inhibition is hypothesized to stimulate the pars intermedia causing the hyperplastic lesions that lead to neoplasia and PPID syndrome. Domperidone is a synthetic benzimidazole used to treat fescue endophyte agalactia in mares and it blocks dopamine receptors. Therefore, the correct dose of domperidone should block dopamine receptors, thereby permitting melanotrophs to release the pars intermedia peptides α-MSH, β-endorphin, CLIP, and ACTH, and the concentrations of these substances should be greater in horses with PPID than in normal horses. A recent study tested this theory on 33 horses and discovered that horses with histologic lesions in the pars intermedia characteristic of PPID had increased concentrations of ACTH in response to domperidone that distinguished them from aged horses without pituitary lesions. Samples were collected before oral administration of domperidone, 3.3 mg/kg and at 4 and 8 hours postadministration (see below):

Pituitary grade	ACTH (pg/mL)	Lesion, n; mean age (yr); 33 total horses
Grade 1	20.0	Normal 3, 7.5 yr
Grade 2	27.1	Focal lesion of hyperplasia 9, 14.5 yr
Grade 3	64.4	Diffuse hyperplasia 5, 21.0 yr
Grade 4	128.0	Microadenoma 12, 23.3 yr
Grade 5	720.5	Adenoma 4, 25 yr
Reference interval	10–59	

This study used horses without hirsutism or obvious signs of advanced PPID. It found that although basal ACTH was not consistently increased in horses with pituitary lesions, ACTH postdomperidone was increased consistently in horses with pituitary lesions characteristic of PPID. Horses categorized as grade 3 and above had pituitary lesions and mean ACTH concentrations greater than twofold above horses without significant pituitary lesions and were consistent with a diagnosis of PPID. However, approximately 25% of the horses in grade 3 and 4 did not increase ACTH postdomperidone beyond the upper limit of the reference interval. Although horses were tested in all seasons of the year, the authors suggested the need to perform these evocative tests on a greater number of normal and affected horses to determine if there is any seasonal effect or any effect from repeated testing. It is known that season of the year influences concentrations of α-MSH, although it seems unlikely that repeat testing could interfere with the utility of evocative tests. Blood for ACTH is collected into silicon coated, EDTA tubes or plastic tubes with EDTA, plasma harvested, and kept frozen until assayed. The chemiluminescent immunoassay, Immulite ACTH has been validated for the horse.

Horses with PPID have increased basal concentrations of insulin: 35–260 μU/mL, reference interval 27–53 μU/mL. This is not a diagnostic test for PPID as insulin will be increased for other reasons, but it may help explain carbohydrate intolerance, obesity, and propensity for laminitis. The increase in insulin may be due to a combination of the antagonistic effects of cortisol and increased concentrations of CLIP that can stimulate release of insulin. The UCCR reference interval is reported as $4.7–16 \times 10^{-6}$ and a cutoff of $>20 \times 10^{-6}$ is consistent with PPID. However, additional studies are needed.

Horses that have classical signs for PPID are easy to identify from the results of physical examination and laboratory test results. However, it can be a diagnostic challenge to recognize PPID in older horses that only have some of the signs of PPID. These are the cases for which laboratory testing is most needed. Increased awareness of this disease and medications to treat the disease has resulted in increased testing for PPID when the disease is still developing. Horses can be treated medically with low doses of pergolide (0.0017 mg/kg/d)

divided in two oral doses or 0.75 mg/d for a 450 kg horse, cyproheptadine (anti-serotoninergic) and bromocriptine (dopaminergic agonist).

Peripheral Cushing's syndrome or equine metabolic syndrome (EMS)

This is a metabolic disorder of older horses (8–18 years) that have hyperinsulinism, activation of cortisol in peripheral tissues, obesity, and laminitis. The disease develops in genetically susceptible horses (Morgan and Spanish breeds) that are overfed and under-exercised. These horses will be overweight, have excess fat in the rump region, "cresty necks," and laminitis that is often attributed to hypothyroidism or PPID. However, DST is negative for PPID and thyroid stimulation tests are negative for hypothyroidism even though there may be a low TT4 concentration on single point determinations. Owners report the horses are "easy keepers" and they maintain their weight despite dietary attempts to reduce it. Fat cells in the abdominal region are important in the pathogenesis of obesity as apparently adipocytes in the abdomen are hormonally different from fat cells in other locations and compound the effects of obesity.

Horses with EMS have hyperinsulinemia and a resistance to the action of insulin that results in increased serum glucose and glucose intolerance or delayed reduction of glucose similar to type 2 diabetes. The mechanism of the insulin resistance is unknown. Substances released or produced in fat cells that lead to insulin resistance are free fatty acids, tumor necrosis factor, leptin, cortisol, and resistin. Resistin is an adipocyte hormone that may be pivotal in this syndrome. Apparently, there is conversion of inactive cortisone to cortisol in peripheral tissues with excess cortisol activity in skin, fat, and laminar tissue of horses with EMS. The enzyme 11 beta-hydroxysteroid dehydrogenase-1 converts inactive cortisone to active cortisol in adipocytes and other tissues. Equine diets rich in grains are referred to as having a high glycemic index because they stimulate increased serum glucose and insulin for sustained periods. Feeding adult horses excess grain for the amount of exercise performed leads to obesity and may start the cascade of events in susceptible individuals. Typically, fasting blood glucose in the horse is 60–90 mg/dL and insulin is <5–20 uIU/mL. Glucose >250 mg/dL and insulin >200 uIU/mL are clearly abnormal.

Diabetes insipidus

Central diabetes insipidus (CDI) may manifest as partial or complete forms. They are characterized by decreased concentration of ADH, PU/PD, and low urine SG ranging from 1.002 to 1.012. They may be dehydrated in the face of dilute urine. They have few to no abnormalities in the CBC or chemistry panel. Typically, there is no renal disease and the patient responds to exogenous ADH by gradually increasing urine SG. The main differentials are nephrogenic diabetes insipidus (NDI) and psychogenic polydipsia. Polydipsia is usually water consumption of >100 ml/kg/d and polyuria is urine production >50 ml/kg/d in dogs and cats.

General

ADH is released or retained under appropriate stimuli from osmoreceptor neurons located in the hypothalamus that sense changes in plasma osmolality. As plasma osmolality increases beyond 310 mOsmo/kg these osmoreceptors stimulate the release of ADH that binds to specific V2 receptor sites and stimulate cellular events leading to the creation of channels in the renal distal tubular and collecting duct epithelial cells to transport water from the glomerular filtrate into the medulla and then into blood vessels. Failure to produce or release ADH results in excretion of dilute urine with a SG less than 1.012, but typically much lower.

CDI is due to inadequate release and/or production of ADH (vasopressin). Idiopathic is the most common "cause," either because a structural lesion cannot be found or one is not looked for. Known causes include tumors, inflammation, head trauma, parasitic, cysts, and pituitary surgery. CDI secondary to surgery on the pituitary may be transient or permanent. Tumors are usually of pituitary origin but can be neural in origin. In dogs and cats there are two forms of CDI, partial and complete. Complete is essentially no ADH and is associated with little to no increase in urine osmolality with increasing plasma osmolality. Animals with complete CDI will have persistent hyposthenuria, severe urine diuresis, and urine specific gravities of 1.005 or less, even if dehydrated. Partial diabetes insipidus is associated with a small,but insufficient increase in urine osmolality with increasing plasma osmolality. These animals can concentrate urine into the isosthenuric range of 1.008–1.015 but cannot increase the SG beyond 1.020 even if dehydrated.

Inhibition of adequate quantities of ADH at the level of renal tubules is referred to as NDI and can be due to decreased tubular cells or compounds in the blood that interfere with the action of ADH. These include corticosteroids, hypercalcemia, *E. coli* toxin in pyometra, and hypokalemia. A rare congenital form occurs in Siberian huskies and cats and may be due to a receptor defect.

Measurement of ADH in serum has not been applied to these diseases because assays are not readily available or used. As assays become available and affordable they may be used to define the syndromes and aid diagnoses. Until then the diagnoses will be established via formulation of differential diagnoses, rule in/rule out tests for each, and use of water deprivation studies to distinguish CDI, NDI, and psychogenic polydipsia. The other causes of PU/PD are identified without water deprivation studies (Table 33.21).

Table 33.21 Causes of polyuria (polydipsia) and dilute urine via associated mechanisms.

Decreased ADH – central diabetes insipidus (DI/CDI)
Pituitary (hypothalamic rare) tumor, abscess, idiopathic, congenital
Inadequate response of tubular cells to adequate ADH – nephrogenic DI
Hypercalcemia, steroids, hypokalemia, pyometra *Escherichia coli* endotoxin, congenital lack of response of tubular cells to ADH
Decreased renal mass = lesions in kidneys, loss of tubular cells
With azotemia = >75% involvement; especially if lesions in medulla and pelvis
Without azotemia = 66% to 75% involvement of total renal mass
Excess fluid intake
Psychogenic polydipsia
Fluid overload diuresis
Medullary washout – medullary interstitium not saturated with sodium and urea
Addison's – prolonged hyponatremia
Liver failure – decreased urea nitrogen (other lab data also); congenital and acquired shunts; end stage liver disease
Psychogenic polydipsia
Fluid overload diuresis
Solute overload
Diabetes mellitus, acromegaly, Fanconi's syndrome, salt toxicity
Diuretics – many; they act on different regions of the tubules
Others, poorly understood mechanism
Hypoparathyroidism, hyperthyroidism, polycythemia, myeloma without hypercalcemia

History, signalment, and routine laboratory data

There is no age, breed, or sex predilection for CDI, but young adults are most commonly affected. The disease has been recognized in dogs ranging range 8 weeks to 14 years, with a mean of 5 years. In cats the observed age range is 8 weeks to 6 years, with a mean of 1.5 years. The major clinical signs of DI are moderate to marked polyuria (up to 100 ml/kg/d) and a nearly constant demand for drinking water, polydipsia. Neurologic signs are infrequent and if present are associated with neoplasms of the CNS or pituitary. The severity of clinical signs varies if CDI is partial or complete. In severe cases nocturia may be hourly and incontinence may be of sudden onset or of several months duration. Weight loss occurs because drinking is so excessive it interferes with eating. The Brattleboro rat has a hereditary form of complete DI such that it will exceed 70% of its body in water consumption and urine output daily.

Routine CBC and serum biochemical panel are normal in animals with CDI. Persistent low urine SG of <1.012 is often the only abnormality detected in routine clinical pathology data. If plasma osmolality is measured it is often high (>310 mOsm/L) due to mild dehydration. They cannot drink sufficient water to keep up with urinary water loss. Mild hypernatremia may be observed in a chemistry panel and is secondary to the dehydration. If water is withheld from dogs with the complete form of CDI they can develop marked hypernatremia, >170 mEq/L, marked hyperosmolality, >380 mOsmol/kg, and lethal hypertonic encephalopathy within hours of water restriction. The combination of hyposthenuria and hypernatremia favors DI. When abnormalities such as slightly increased hematocrit or hypernatremia are present at initial evaluation, they usually are secondary to dehydration from water restriction by the owner. Animals with primary polydipsia have low plasma osmolality (<290 mOsm/L) as a result of overhydration. The reference interval for plasma osmolality in normal dogs and cats is 280–310 mOsm/L.

At the time of initial presentation, the majority of dogs with DI will have urine SG <1.006 and many will be 1.001–1.003 if unlimited water is available. If the urine SG can go below 1.005 then occult renal disease is unlikely because a SG this low implies the kidneys function sufficiently to remove solutes, diluted the glomerular filtrate to the 1.005 range, but then had inadequate ADH to remove water in the collecting tubules. Urine SG of 1.007–1.013, proteinuria, and white blood cells in the urinalysis favor renal failure. This is often due to chronic pyelonephritis in which there is fibrosis in the renal medulla.

Examples of urinalysis findings useful for disease differentiation are:

Patient	A	B	C	D	E
Urine SG	1.003	1.016	1.011	1.002	1.010
Proteinuria	Neg	++	Neg	Neg	+
Glucosuria	Neg	+	Neg	Neg	Neg
Cells	Neg	++	Neg	Neg	Neg
Interpretation	CDI	Renal	Renal	CDI	Renal

A and D: Severe hyposthenuria with no abnormalities in urinalysis favor complete CDI. The urine SG is lower than expected for renal disease. Other differentials are partial CDI, psychogenic polydipsia, and NDI caused by interfering substances such as hypercalcemia or steroids.
B: Urine SG is higher than expected for CDI. The combination of proteinuria, glucosuria, and cells favor nephritis, structural lesion, or possible pyelonephritis. Recommend culture of urine and do not perform a water deprivation study. Partial CDI can concentrate into this range if water is restricted. This type of renal failure patient may not be azotemia (<75% nephron loss) but may be polyuric (>66% nephron loss).
C: If urine SG is persistent in this range it is isosthenuric. With no other abnormalities in urinalysis (UA), then chronic renal disease is most likely, with or without azotemia. Partial CDI can concentrate into this range if water is restricted.
E: If the urine SG is persistent in this range, then the patient has isosthenuria. Proteinuria at one plus in dilute urine is abnormal. Recommend protein:creatinine ratio, microalbuminuria determination, and periodic UA to confirm urine SG range and persistence of proteinuria. If cellular abnormalities develop consider urine culture. This pattern favors chronic renal insufficiency, therefore consider fractional excretion of sodium, creatinine clearance and/or palpation, visualization studies of kidneys before a water deprivation study is recommended.

Diagnostic tests

Table 33.21 lists the causes of PU/PD, and most of these are diagnosed from history, physical examination, routine lab data, and appropriate diagnostic tests. The first step is to determine urine SG at several times during the day. One of these must be a morning collection when concentration is usually at its maximum. The main differentials that have few to no abnormal diagnostic results other than dilute urine are central DI, nephrogenic DI, and psychogenic polydipsia. The test used to differentiate these is one of the water-deprivation tests or response to ADH supplementation. The modified water-deprivation test is indirect evidence of ADH responsiveness designed to determine whether endogenous ADH is released in response to dehydration and whether the kidneys respond by concentrating the urine. However, the more common causes of PU/PD should be ruled out before this procedure is performed. Failure to recognize azotemia before water is restricted is a major clinical error. NDI is due to a structural lesion that decreases renal tubular cells or a biochemical lesion such as substances in the blood that interfere with the action of ADH. These include corticosteroids, hypercalcemia, *E. coli* toxin in pyometra, and severe hypokalemia. These inhibitory factors are ruled out by diagnostic procedures for each substance or the disease that causes them. That leaves the possibility of an occult renal lesion that has resulted in loss of greater than 66% of the renal mass, hence polyuria and dilute urine before enough mass is lost to result in appreciable azotemia. This situation is easier to diagnose or at least suspect if the history indicates the patient survived a previous bout of renal azotemia, but PU/PD have persisted or are now present. If the patient had a prior diagnosis of pyelonephritis, then this scenario is even more likely. An inherent risk of a water deprivation study is the possibility of exacerbating renal problems in these patients. They have renal failure (polyuria, dilute urine) and a structural renal lesion, but they are not yet azotemic. The diagnosis of occult renal lesions should be suspected if there is proteinuria (increased protein:creatinine ratio), isosthenuria, and/or white blood cells in the urine. If these are present avoid a water deprivation study and perform fractional excretion of sodium or creatinine clearance study to rule in/rule out structural renal lesions. If the urine SG can go below 1.005 then occult renal disease is unlikely. If the urine SG can increase beyond 1.020 then occult renal disease and CDI are unlikely and psychogenic polydipsia is more likely. Another risk of a water deprivation study is induction of marked hypernatremia, hyperosmolality, and hypertonic encephalopathy within hours of water restriction in patients with complete CDI. For these reasons patients must be evaluated frequently during water deprivation studies.

The water deprivation principle is to stimulate endogenous ADH production and release by withholding water and inducing mild dehydration of less than 5%. If an animal can start to concentrate urine with water withdrawal then psychogenic polydipsia is the diagnosis. If the patient does not concentrate until exogenous ADH is administered, then central DI is diagnosed. If water withdrawal and exogenous ADH administration do not stimulate urine concentration, then renal disease is diagnosed. Never perform this test on an azotemic patient. Before the study is started the bladder is emptied and baseline urinalysis data are gathered. Urine is then evaluated and recorded every 1–3 hours, depending on the severity of the PU/PD until the study is stopped. The bladder is emptied at each collection period and body weight, skin turgor, PCV, plasma protein, UN, urine SG, and osmolality of plasma and urine are optimal parameters to monitor. Osmolality does not have to be measured, but it is ideal if immediately available. Urine SG and body weight are usually more practical substitutes. Three to 5 % weight loss is maximum stimulus to release endogenous ADH. If the urine is not concentrating at this point in the study, then it is time to administer exogenous ADH. Another means to

determine it is time to give ADH is if urine SG has increased less than 10% for three consecutive collections. If plasma osmolality is known during the study, then administer ADH when plasma osmolality is >310 mOsm/kg because this is adequate stimulus to release endogenous ADH. When urine SG is in the 1.025–1.035 range it indicates the kidneys can concentrate urine and the study can be stopped. The urine SG may not increase rapidly in a water deprivation study. The urine SG may sometimes increase in a stepwise fashion due to medullary washout (Figure 33.5). The prolonged polyuria and rapid transit of the tubular filtrate has resulted in dilution of the medullary interstitium sodium and urea concentrations. Until the interstitium is resaturated with solutes, the kidneys can only concentrate the glomerular filtrate a limited amount. Depending on the severity of the medullary washout it may take up to 24 hours or longer of complete or partial water restriction for dogs with primary polydipsia to concentrate into the 1.030 range. Monitor the UN and if azotemia develops stop the study. Serum UN and/or creatinine should not increase in a water deprivation study. The renal failure patient has between 2/3 and 3/4 decreased renal mass and the closer the reduced mass is to the 3/4 mark the easier it will be to induce azotemia via dehydration.

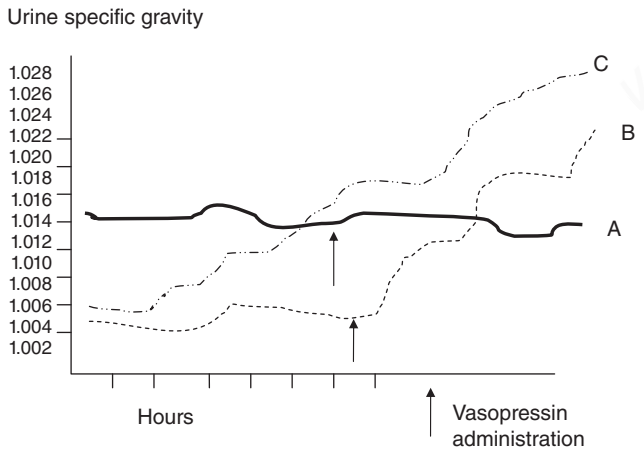

Figure 33.5 Water deprivation study results for dogs with renal insufficiency (A), central diabetes insipidus (B), and psychogenic polydipsia (C). All three dogs are not azotemic. The dog with renal insufficiency has urine SG that starts and remains in the isosthenuric range, even after administration of vasopressin (ADH). The dog with CDI has more dilute urine than the dog with renal insufficiency because the tubules can function and therefore have diluted the glomerular filtrate. This dog has urine SG that starts in the hyposthenuric range and starts to concentrate only after the administration of ADH. A dog with psychogenic polydipsia (C) should have a urine SG in the hyposthenuric range that starts to concentrate after water is withheld and before it is necessary to give ADH. The dogs with CDI and psychogenic polydipsia increased urine SG in a gradual or stepwise fashion because the concentration gradient in the medulla had been "washed out" and needed to reestablish.

If the urine SG increases beyond 1.025 with just water restriction, then primary polydipsia is the diagnosis. If urine remains nonconcentrated after several hours with concurrent mild dehydration, then the disease present is either CDI or NDI (Figure 33.5). The NDI patient will not concentrate urine in response to ADH. The CDI patient that has a complete form of the disease will increase urine SG by approximately 50% and the partial form will increase SG by 15–20% in response to exogenous ADH. The time it takes to lose 3–5% of the body weight (dehydration) is also a clue to the diagnosis. CDI patients often attain this weight loss in less than 6 hours while partial CDI and psychogenic polydipsia dogs will take 8–10 hours or longer.

Pituitary dwarfism and acromegaly

General

GH, or somatotropin, is a single-chain protein that is species-specific in its activity. It is produced by acidophilic somatotrophs. Hypothalamic GH-releasing hormone stimulates production and release of GH, while somatostatin inhibits release. Further inhibition is caused by insulin-like growth factors (IGFs) that stimulate somatostatin release from the hypothalamus and directly inhibit GH in the adenohypophysis. Canine mammary gland epithelial cells produce GH that is identical to pituitary GH. Administered progestins stimulate production of mammary GH, increase plasma GH concentrations, are not inhibited by somatostatin, and can cause acromegaly. The luteal phase of the estrous cycle of healthy bitches has high serum progesterone concentrations that also increase serum concentrations of GH. This progesterone-induced production of mammary GH is important in stimulating lactational mammary tissue and in the development and progression of mammary tumors in the bitch. GH concentration in colostrum is hundreds of times greater than in plasma and may stimulate neonatal gastrointestinal development.

GH stimulates the production of IGFs (IGF-1 or somatomedin) from the liver that in turn stimulates protein synthesis, chondrogenesis, and longitudinal and appositional bone growth. GH may also stimulate these events directly. Absence of GH during the period of growth results in pituitary dwarfism and excessive amounts of GH in adults causes acromegaly. GH also inhibits the action of insulin and therefore increases the serum glucose concentration via reduced glucose transportation into cells, increased gluconeogenesis, and lipolysis leading to insulin resistant diabetes. This form of diabetes mellitus is transitory if associated with the estral cycle or pregnancy. However, diabetes can be permanent if a pituitary tumor secretes GH and these antagonistic effects on insulin are prolonged. Beta cells will increase insulin production in an attempt to balance the hyperglycemia. If transitory, there is glucose stabilization, but if prolonged, this

can result in beta cell exhaustion, vacuolation, degeneration, and permanent diabetes mellitus.

Diseases caused by increased concentrations of GH are acromegaly, diabetes mellitus, and mammary neoplasms. Dwarfism is caused by decreased concentrations of GH.

Acromegaly (hypersomatotropism)

Increased serum GH may be due to a GH-secreting pituitary tumor in cats or endogenous or exogenous progesterone that stimulates GH production from the mammary gland in dogs. Measurement of increased IGF-1 is a screening test. Clinical features include soft tissue proliferation, thick coarse facial features, hyperglycemia, and insulin-resistant diabetes mellitus.

Chronic excessive GH causes insulin resistance and acromegaly in adult dogs and cats. Canine acromegaly is due to increased progesterone from the luteal phase of the estrous cycle or the administration of progestational compounds for suppression of estrus in intact female dogs. Both of these cause excessive secretion of GH from mammary epithelial cells. The GH producing pituitary tumor in cats is rare or at least infrequently recognized. They are of acidophilic origin, large, grow slowly, and may be present for a long period of time before the onset of clinical signs. Feline acromegaly occurs in older male cats (8–14 years of age).

Initial signs in dogs are usually changes in their physical appearance. This may include soft tissue proliferation of the neck, head, tongue, mouth, gingiva, and pharynx, with abnormal respiratory noises. Characteristic enlargement of extremities, body size, jaw, tongue, gingival hyperplasia, widened interdental spaces, thick folds of facial skin-subcutis, and inspiratory stridor from proliferation of laryngeal soft tissue (50% of cats) are characteristics of the disease. Visceromegaly, including enlarged kidneys, liver, and endocrine organs, may result in abdominal enlargement. Cardiomegaly, hypertrophic cardiomyopathy, murmurs, and congestive heart failure develop late in the course of disease in cats. Neurologic signs in cats, if present, are due to the large pituitary macroadenoma. Physical changes are not as dramatic in cats and therefore most of the easily recognized signs are related to diabetes mellitus. PU/PD and polyphagia are common problems in cats with acromegaly and these will also occur in some dogs. Acromegaly is most often tested for in cats when insulin resistance cannot be explained via other mechanisms.

Routine clinical pathology

Laboratory tests may reveal hyperglycemia and increased liver enzymes, but there are no specific abnormalities. The more common causes of hyperglycemia and increased liver enzymes must be ruled out before acromegaly is considered. Dogs tend to have hyperglycemia without glucosuria. Cats have hyperglycemia with glucosuria but are not usually ketotic. Hypercholesterolemia and mild increases in serum liver enzymes activities are attributed to hepatic lipidosis from the diabetic state. ALP may be increased due to bone or liver production. Hyperphosphatemia without azotemia is reported but was absent in another study. Increased serum phosphorus may be due to GH-stimulated bone growth. Urinalysis is unremarkable, except for glucosuria and persistent proteinuria. There is usually increased serum protein in the range of 8–9.5 g/dL. Azotemia develops late in the course of disease in approximately 50% of acromegalic cats. Azotemia may be caused by chronic interstitial nephritis, concurrent dehydration, or unregulated diabetes. Measurement of endogenous insulin reveals increased serum insulin concentrations. Resistance to insulin (insulin requirement >2–3 U/kg/BID; or >20 U/d) is common in diabetic cats and consideration of a concurrent pituitary tumor inducing hyperadrenocorticism or acromegaly is done after more common causes of insulin resistance are ruled out.

Establishing a definitive diagnosis of acromegaly in an animal with characteristic signs is accomplished by one or more of the following: cessation of exogenous progestogen in dogs, staging the estral cycle, response to ovariohysterectomy in dogs, measurement of increased plasma GH, and measurement of increased IGF-1. All of the endocrine assays are infrequently performed and some may not be commercially available. The reference laboratory used should be consulted for protocol. Basal GH concentration greater than 6 µg/L is consistent with acromegaly if appropriate signs are present. Concentrations of GH greater than the upper limit of reference interval are considered diagnostic, >5 µg/L dogs, >7 µg/L cats, especially if other data are corroborative. Like any endocrine disease concentrations of GH may not be increased early in the progression of the disease. The diagnosis of acromegaly in dogs is centered on response to treatment rather than hormone assays. Physical examination abnormalities may be a clue to consider acromegaly. Diabetes mellitus in dogs is usually transitory and therefore hyperglycemia and glucosuria are reversed and can be used to monitor response.

The diagnosis in cats uses a combination of insulin resistance increased IGF-1, physical characteristics of acromegaly, and if available imaging of the pituitary region and GH values. It is very difficult to regulate insulin and hyperglycemia in acromegalic cats. Insulin rates >2–3 U/kg/BID or >20 U/d should prompt consideration of concurrent acromegaly. Often the main reason these cats are seen is resistance to insulin and the only clinical pathology abnormalities are referable to diabetes mellitus. Imaging studies of the pituitary are not 100% accurate but are very useful. Cats with hyperadrenocorticism or acromegaly have insulin resistance, and both have macroadenomas of the acidophils. Therefore, imaging studies of the pituitary do not distinguish these differentials. Serum IGF-1 combined with stimulatory and inhibitory tests of the pituitary adrenal axis (LDDS, ACTH stimulation) should be used to screen for these differentials.

Serum IGF-1 or somatomedin C is increased by GH and can be used as a screening test for acromegaly in cats. It has a sensitivity of 84% and a specificity of 92%. IGF-1 is not a species-specific assay. Therefore, assays designed for humans can be used. The reference interval for cats is 208–443 ng/mL. Concentrations >1000 ng/mL are suggestive of acromegaly and can be used to screen for this disease. However, increased IGF-1 has been reported in diabetic cats unrelated to acromegaly and the concentrations of IGF-1 can vary widely. Administration of large doses of insulin, particularly in poorly perfused sites such as the back of the neck, can cause a cross-reaction with the IGF-1 assay. Additionally, cats with hyperadrenocorticism have weight loss in acromegalics as opposed to weight gain. Cats with hyperadrenocorticism may have fragile skin that tears easily as opposed to thick, coarse soft tissue proliferation and skeletal abnormalities of acromegaly. Some individuals consider acromegaly more common than previously thought and is an underdiagnosed endocrinopathy in cats.

Pituitary dwarfism

Major features include decreased GH, cystic Rathke's pouch, proportionate dwarfism, and panhypopituitarism.

Pituitary dwarfism results from failure of the embryonic ectoderm to differentiate into trophic secretory cells of the adenohypophysis. There is a cyst of Rathke's pouch that is primary or secondary to the failed differentiation. It is seen most frequently in German shepherd littermates or related litters and has a simple autosomal recessive mode of inheritance. Affected German shepherds have a deficiency of GH, TSH, and prolactin but adequate ACTH secretion. There is a panhypopituitarism in Carnelian bear dogs associated with decreased production of TSH, ACTH, LH, FSH, and GH. Other affected breeds include spitz, miniature pinschers, Labrador retrievers, and Weimaraner dogs. It may also occur in cats. Pups with pituitary dwarfism are indistinguishable from littermates until 2–4 months of age when reduced growth rate is noticed and mental retardation is manifested as difficulty in house-training. Two diagnostic physical examination findings are proportionate dwarfism and retained puppy hair coat. The hair coat is wooly due to retention of puppy or lanugo hairs, which epilate easily. Therefore, a gradual alopecia is seen that may involve the total body but sometimes spares the limbs. Other clinical problems are delayed dental eruption, alopecia, cutaneous hyperpigmentation, skin infections, infantile genitalia, cryptorchidism, and anestrus. Craniopharyngioma is a very rare tumor of remnants of craniopharyngeal duct that also can produce dwarfism in dogs.

Results of CBC, serum biochemistry panel, and urinalysis are usually normal. Eosinophilia, lymphocytosis, mild normocyctic normochromic anemia, and occasionally hypoglycemia are seen if ACTH is deficient. GH deficiency is associated with abnormal development of glomeruli, decreased glomerular filtration rate, and azotemia. Secondary hypothyroidism occurs in most forms of pituitary dwarfism, therefore TT4, fT4, and TSH are decreased. Response tests for TSH, ACTH, and GH are decreased and can be used to establish a diagnosis. Basal GH and IGF-1 (somatomedin) are decreased. In pituitary dwarfs, GH fails to increase two to fourfold after administration of intravenous stimulants such as GH-releasing hormone (1 μg/kg), clonidine (10 μg/kg), or xylazine (100 μg/kg). Samples are collected basal and at 20 or 30 minutes after the stimulant is given. A GH value <10 μg/L is an inadequate response.

Other diseases of the pituitary

Other diseases of the pituitary gland are prolonged gestation in Jersey and Guernsey cattle due to inherited aplasia of the adenohypophysis in the fetus. Gestation may be prolonged by >200 days. The fetus is underdeveloped, often hairless, and looks like development stopped at 6–7 months. It may have alopecia and short legs, and it will have hypoplasia of all endocrine organs that are dependent on the pituitary for trophic stimulation. Holstein and Ayrshire cattle have prolonged gestation due to an inherited autosomal recessive enzyme deficiency in the adrenal cortex of the fetus such that cortisol is not produced. In the absence of cortisol, there is stimulation to secrete ACTH, which in turn causes marked *bilateral* adrenal cortical hypertrophy with fetal giants of up to 225 lb with long shaggy hair. The cycle of decreased cortisol, increased ACTH and adrenal cortical hypertrophy continues because of the inherited enzyme deficiency. Sheep grazing the teratogenic plant *Veratrum californicum* at 9–14 days of gestation will have fetuses that have an abnormal pituitary gland or a pituitary that functions autonomously from the hypothalamus. The result is prolonged gestation, cyclopia, facial abnormalities, and other musculoskeletal malformations.

Parathyroid Glands and Calcium and Phosphorus Metabolic Pathology

Donald Meuten
North Carolina State University, Raleigh, NC, USA

General introduction

A change in the serum calcium concentration of as little as 5–10% can stimulate or inhibit the secretion of parathyroid hormone (PTH). Hypoparathyroidism caused by lymphocytic parathyroiditis and hyperparathyroidism due to a parathyroid adenoma are the two primary diseases of the parathyroid gland.

The parathyroid gland is a simple endocrine organ with intricate cellular events that closely regulate the serum concentration of calcium. The parathyroid or chief cells primarily respond to calcium. Low calcium stimulates the parathyroid cells to undergo hypertrophy and hyperplasia as well as increasing the production and release of PTH. High calcium inhibits these events, resulting in decreased secretion of PTH and, eventually, atrophy of the glands. A change in the serum calcium concentration of as little as 5–10% (total calcium 0.25–0.5 mg/dL, or ionized calcium 0.1 mmol/L) can stimulate or inhibit the secretion of PTH within minutes. Therefore, calcium does not need to be out of reference interval before it changes the production and secretion of PTH. This concept is important when interpreting serum concentrations of PTH and calcium. Calcium-sensing receptors (CaSRs) in parathyroid chief cells and other CaSR-expressing cells detect changes in the concentration of ionized calcium and make adjustments to PTH secretion that rapidly normalize serum calcium. CaSR in the kidney stimulates cellular events that influence calcium and water homeostasis, and these pathways may play a pivotal role in the development of hypercalcemia seen in some animals with renal failure.

PTH rarely needs to be measured. The only time it is "required" is to confirm primary hypoparathyroidism and in some cases of primary hyperparathyroidism. In these diseases, it seems logical the concentration of serum PTH would be decreased or increased, respectively. However, PTH is often within reference intervals in each of these diseases, which seems paradoxical, but the PTH value is *inappropriate* for the serum concentration of calcium. These situations happen regularly because of the close regulation of PTH, calcium, and CaSR. A serum calcium concentration of 15 mg/dL (increased) should trigger the parathyroid gland to decrease and/or stop the secretion of PTH. Therefore, if the concentration of PTH is within reference interval it is "inappropriately high" and diagnostic of hyperparathyroidism. In fact, 75% of dogs with hypercalcemia due to primary hyperparathyroidism have serum concentrations of PTH within the reference interval.

What is equally or more important to parathyroid chief cells than the absolute concentration of serum calcium is the delta in calcium as the CaSR and parathyroid chief cells can reset their signals based on the change of calcium in the blood or at the receptor. For example, in nutritional hyperparathyroidism, the serum concentration of calcium is often in the reference interval, which also seems paradoxical given the pathogenesis of the disease and the marked bone resorption (fibrous osteodystrophy or "rubber jaw"). Even though a dietary imbalance of calcium and phosphorus are constantly lowering the serum and cellular concentration of calcium, the compensatory parathyroid hyperplasia and secretion of PTH are normalizing the serum concentration of calcium, at the expense of decreasing bone mass.

This chapter will discuss the laboratory tests related to basic blood calcium and phosphorus concentrations as well as the less frequently measured parathyroid regulatory peptides. This is followed by discussion of primary parathyroid disorders that affect calcium metabolism. Lastly, numerous causes of calcium and phosphorus metabolic pathology are outlined. Because of the frequency of calcium metabolic pathology, serum calcium and phosphorus are measured in all routine chemistry panels. This practice is established convention because hypocalcemia and hypercalcemia usually provide clues to diagnosis of underlying disorders that affect calcium metabolism.

Background on relevant laboratory tests

Summary

Total serum calcium

This is an excellent screening test and therefore integral on chemistry panels. It is the most common way serum calcium is measured and reported to veterinarians. Total serum calcium consists of ionized (biologically active fraction), complexed (minor fraction) and protein bound (approximately 50% of total calcium).

Ionized calcium

Ionized calcium is the biologically active fraction in blood. Ideally, it is measured in critical care patients no matter what their primary disease or total calcium concentration is. It is excellent for STAT needs and can now be measured by point of patient care instrumentation. It is more useful in hypocalcemic than hypercalcemic patients. Special sample handling is required (see Chapter 1). If ionized calcium is needed it must be measured. Total calcium adjusted for albumin concentration was never intended to estimate ionized calcium and newer adjustment formulae have not been validated.

Adjusted calcium

This calculation should be used because hypoalbuminemia explains the most common cause of hypocalcemia. This is not needed for hypercalcemia or if patient is hyperalbuminemic. It cannot be used to estimate ionized calcium.

The adjustment formula for calcium is used to determine if a decrease in total serum calcium is due to hypoalbuminemia. The adjusted calcium is not a real number; the real and important concentrations of calcium in the blood are the measured total or ionized.

Use and interpretive guidelines

- Calcium disorders are usually discovered by the routine chemistry panel. There are very few clinical signs referable to hypercalcemia. Tetany may be seen with hypocalcemia in dogs, and paresis is seen in cows.
- Differential diagnoses for hyper- and hypocalcemia are the same if either total or ionized calcium is used.
- Examine Ca and P together, then albumin, azotemia, and lipase. Determine the Ca × P product to predict risk of soft-tissue mineralization (use total serum Ca; not ionized Ca).
- Hypercalcemia and hypophosphatemia – two differential diagnoses are (i) hyperparathyroidism, which is rare, and (ii) hypercalcemia of malignancy (HCM), which is common. This finding occurs with renal failure in some horses.
- PTH is rarely needed; it may be measured in a panel with parathyroid hormone related protein (PTH rp) and total or ionized calcium.
- Veterinarians can now select total serum calcium and ionized calcium, and they can use an adjustment formula for hypoalbuminemia if total serum calcium is low. The determination of total serum calcium will remain the screening test on routine chemistry panels to detect abnormalities in serum calcium, predict soft-tissue mineralization, and formulate differential diagnoses. Measurement of ionized calcium is now available in practice. It can be used to formulate differential diagnoses just as well as using total calcium. It is the test of choice for monitoring hypocalcemia in critically ill patients.
- Adjustment formula for calcium is used to help determine if a decrease in total serum calcium is due to hypoalbuminemia, which is the most common cause of hypocalcemia. Only use a formula if the serum concentration of albumin is low; it is not needed if the serum albumin is normal or increased or if hypercalcemia is present.

Calcium and phosphorus metabolism measurements

Total serum calcium

Of the body's calcium 99% is in bones, 1% is intracellular, and only 0.1% is in extracellular fluid. It is this small latter fraction that is measured in the blood. Positively charged calcium ions in the blood are bound to anionic sites on proteins (primarily albumin) or nonprotein anions (citrate, phosphate, lactate) and as an unbound free ionic form. These are listed as protein-bound calcium, approximately 40–50% ionized calcium 35–50% and complexed calcium (citrate, phosphate, etc.) approximately 5–10%. The latter two fractions are freely diffusible, stimulate cellular events, and the ionized fraction is the most prevalent of the two and biologically active. Each fraction can be measured individually. However, total calcium concentration is the only serum measurement routinely needed for screening in animals. Total serum calcium is stable *in vitro*. It can be determined in chemistry panels by various methodologies and reference intervals from different labs are fairly similar. Interfering substances depend on the methodology. For example, hemolysis may artifactually increase total serum calcium by some methods, but not others. Always consult with the lab or procedure documentation about possible interference or sample handling concerns. If an abnormality in total calcium is detected, the concentrations of calcium and phosphorus should be compared to help formulate differential diagnoses. The total serum calcium value multiplied by the phosphorus value should be calculated to predict the risk of soft-tissue mineralization, especially when there is hyperphosphatemia. Then examine albumin, urea nitrogen, and lipase and make a decision if ionized calcium is needed. Ionized calcium is of value if hypocalcemia is detected and is also more useful in critically ill patients. The list of differential diagnoses for hyper- and hypocalcemia are the same if either the total or

ionized calcium is used. The magnitude of hypercalcemia for ionized or total serum calcium does not predict a disease, but in general HCM and hyperparathyroidism have the highest concentrations of either total or ionized serum calcium. Hypoparathyroidism and lactational tetany are associated with the lowest calcium concentrations.

Interpretive discrepancies between abnormal total and abnormal ionized calcium concentrations may occasionally occur. Notable discrepancies are that some dogs and cats with renal failure may have increased total serum calcium, but the ionized calcium is in reference interval or mildly decreased. However, this is not absolute as some dogs and cats in renal failure will have both increased ionized calcium and total calcium. In fact, if ionized calcium is used to rank diseases that cause hypercalcemia, then renal failure is the second most common cause in dogs. The total serum calcium is increased in 100% of dogs with primary hyperparathyroidism, and ionized calcium is increased in 90–95%. If primary hyperparathyroidism is a differential diagnosis, then measure total serum calcium. Some hyperthyroid cats have a mild decrease in ionized calcium and normal total calcium. Urinary obstructed cats may have a more pronounced decrease in ionized calcium as compared to the decrease in total calcium. If hypocalcemia is marked or there are clinical signs of tetany, then measure ionized calcium. If it is not available, then treatment decisions are made from total serum calcium and/or tetany. Ionized calcium is preferable to total calcium in critically ill patients, hypocalcemic patients, and animals with sepsis. These differences point out some of the situations when having both the total and ionized calcium values are beneficial. Perhaps if total and ionized were measured in the same sample, or on the same day, there would be better interpretive concordance.

Ionized and total serum calcium measurements result in the same list of differential diagnoses for hypocalcemia or hypercalcemia (Tables 34.2 and 34.3).

Ionized calcium

Ionized calcium and other electrolytes are now easily measured in practice (Chapter 1). Ionized calcium is not measured in serum chemistry profiles, it requires a second sample. For routine screening the total serum calcium will remain the sample of choice. It is important to follow specific sample handling instructions when measuring ionized calcium. Ionized calcium is reported in two different units (Table 34.1). Interpret the values compared to appropriate reference intervals exactly as total serum calcium is interpreted.

Ionized calcium is more valuable if hypocalcemia is detected, especially if total serum calcium is less than

Table 34.1 Example reference intervals and conversion factors for calcium measurements.

To convert mmol/L to mg/dL multiply by 4; mEq/L to mg/dL multiply by 2. Do not convert ionized to total calcium or vice versa; ionized Ca is approximate half of the total calcium when the same units are used.

To convert from mg/dL to mmol/L multiply by 0.25; convert from mg/dL to mEq/L multiply by 0.5; convert from mEq/L to mmol/L multiply by 0.5.

Reference intervals (RIs) of serum calcium in dogs and cats and expected problem ranges; consult with reference lab performing determination.

		Total serum calcium mg/dL	Ionized calcium mmol/L	Ionized calcium mEq/L
Dogs	RI	9–11	1.2–1.5	2–3
Dogs	RI	8.7–11.2	1.12–1.40	2.5–3.0
Dogs	RI		1.25–1.45	2.3–2.8
Dogs	RI	9.2–11.3	1.12–1.32	
Clinical problems may be detected:				
Hypocalcemia		<6.5	<1.0	<2
Hypercalcemia		>12	>2	>4
Cats	RI	8.3–10.5	1.15–1.35	2.2–2.6
Cats	RI	9.2–10.3	1.15–1.40	2.1–2.7
Clinical problems may be detected:				
Hypercalcemia		>11	>1.5	
Horses	RI	11.5–13.5	1.45–1.75	
Horses	RI		1.53–1.61	
Horses	RI		1.61–1.85	

Young dogs: 0.2–1.0 mg/dL higher in total calcium, with concurrent mild hyperphosphatemia; horses and rabbits have the highest RIs for total and ionized calcium of any species, up to 13 mg/dL total serum calcium.

Table 34.2 Differential diagnoses for hypercalcemia.

↑ Ca and N or ↑ P	↑ Ca ↓ P
Hypercalcemia of malignancy	Hypercalcemia of malignancy
Primary hyperparathyroidism	Primary hyperparathyroidism
Idiopathic – cats	Renal failure – only horses
Hypoadrenocorticism	
Renal failure – chronic more common than acute	
acute – grapes and currant toxicities	
Vitamin D toxicosis – rodenticides, plants, iatrogenic	
Granulomatous diseases – blastomycosis, other fungi, FIP, schistosomiasis, mycobacterium, toxoplasmosis	
Iatrogenic – calcium supplements	
Young, rapid growing, esp. large breed dogs and horses	
Xylitol toxicity – concurrent hypoglycemia can be severe	
Hyperthyroidism – uncommon in dogs vs. decreased calcium in cats	
Hypothermia – rare, may not be cause and effect	
Spurious – lipemia, hemolysis, type of heparin, methodology dependent	
Acidosis – ionized calcium increased	
Osteolytic bone lesions – doubtful; cases of hypertrophic osteodystrophy are probably due to young age of affected dogs	
Bone metastases – probably humoral and not just the osteolysis from local tumor	

With the exception of primary hyperparathyroidism, entities listed above the first solid line are common and entities listed below are physiologic, spurious, or the hypercalcemia may not be caused by the entity listed.

7.0 mg/dL. Decreased ionized calcium is important in the care of critically ill patients. Ionized hypocalcemia has been shown to be a predictor of longer duration of care in the intensive care unit (ICU) and hospital stay of critically ill dogs but is not associated with decreased survival. This study did not examine the same variables for total serum calcium to determine if it was predictive. Septic foals and cattle appear to have calcium aberrations as well. Determining the serum concentration of ionized calcium could be very beneficial during and postsurgery of thyroid glands for hyperthyroidism or parathyroid adenomas. However, even knowing the ionized calcium does not predict clinical signs. For example, within hours post-treatment of hypocalcemia in lactational paresis of cattle the concentrations of ionized calcium have returned to pretreatment concentrations, yet no clinical signs are observed. Similarly, some of the indicators used to determine if calcium and vitamin D supplementation is needed post-thyroidectomy or postparathyroidectomy in cats and dogs are not only the concentration of total or ionized calcium but if clinical signs are present. Like any laboratory test, correlation of calcium and phosphorus with clinical signs is vital.

Shifts in ionized calcium happen with shifts in acid/base balance. Acidosis shifts calcium to the ionized compartment and alkalosis decreases ionized calcium. Alkalosis will increase the available negatively charged binding sites on albumin and lead to increased calcium bound to albumin. These compartmental shifts in calcium may have clinical importance. Acidotic animals with hypocalcemia may not show clinical signs because more calcium is in the ionized compartment, whereas alkalotic animals with the same serum calcium theoretically could have clinical signs of hypocalcemia. Correcting acidosis rapidly in a patient with hypocalcemia could produce tetany. This would warrant calcium supplementation in IV fluids. This could happen when correcting the acidosis seen in ethylene glycol toxicity or neonatal diarrhea in calves, both of which may have severe acidosis with total and ionized hypocalcemia. Because large acid-base changes may occur during critical care, it is prudent to monitor both ionized calcium and blood gases if any clinical signs of tetany are present.

Recently formulae have been created to calculate the ionized calcium in dogs and cats through a cumbersome mathematical calculation that uses creatinine, UN, albumin, total Ca, K, Cl, gamma glutamyltransferase (GGT), and cholesterol. In this author's experience and guidance, use of such a formula may be possible but is too difficult to be reduced to practice and is difficult to validate in a universally applicable way. For example, each of the primary measurements are subject to individual routine systematic measurement variability and can have variation in reference intervals across the employed methodologies. There may also be other unmeasured pathologic biochemical factors that could alter the reliability of the calculation. In addition, and more importantly, adjusting total calcium for albumin was never intended to estimate the ionized calcium. It is recommended that only direct measurement of ionized Ca be used when the ionized fraction is indicated. The ubiquitous availability of this measurement in point of care analyzer technology makes direct measurement more practically implemented and reliable.

Protein adjusted calcium

The majority of the calcium bound to serum proteins is bound to albumin. As the concentration of albumin decreases, the protein-bound fraction of calcium as well as the total calcium decreases. Therefore "adjust" a low total serum calcium concentration if hypoalbuminemia is present. If the adjusted calcium concentration is within the reference interval, then the cause of hypocalcemia is hypoalbuminemia. There is a limit to this relationship; if serum calcium is <7.0 mg/dL in a hypoalbuminemic animal there probably is a second cause of hypocalcemia. Depending on the species, approximately 20–30% of the decrease in total calcium is due to changes in serum albumin. If ionized calcium is desired it must be directly measured. The correction formula does not predict ionized calcium. The real calcium in the

Example 34.1.

Measured calcium 7.8 mg/dL. Measured albumin 1.5 g/dL.
Adjusted calcium = 7.8 + (3.5–1.5) = 9.8

patient is the value that is measured, ionized or total. The adjusted calcium is not a real number. It simply helps the clinician determine that a decrease in total serum calcium is due to hypoalbuminemia. If serum albumin is normal or increased do not use any correction and investigate the cause of hypocalcemia; it is not due to a protein abnormality.

The most common cause of hypocalcemia in animals is hypoalbuminemia. This cause of hypocalcemia is asymptomatic, likely because ionized calcium is within the RI. Hyperalbuminemia does not cause hypercalcemia. The relationship between albumin, total protein and calcium has resulted in "correction formulas" that adjust the measured total serum calcium concentration for the degree of hypoalbuminemia, or hypoproteinemia. These formulas are most reliable in dogs are somewhat helpful in cats and are less reliable in horses and cows. While other formulae exist, the recommended, commonly used correction formula is:

$$\text{Adj. calcium} = \text{measured calcium} + (3.5 - \text{measured albumin})$$

In the example above, the hypocalcemia was corrected for the hypoalbuminemia and the adjusted calcium is now in reference interval (8.8–11.2 mg/dL). Therefore, the cause of the hypocalcemia in this case has been determined. It is important to now determine the cause of the hypoalbuminemia.

Calcium – phosphorus product (Ca × P)

Calcium and phosphorus should be interpreted together in a chemistry panel as the list of differential diagnoses will vary depending on their concurrent values. Additionally, the product of these two electrolytes is predictive of soft-tissue mineralization. A product of Ca × P >70 indicates soft-tissue mineralization is possible and a product >90 indicates mineralization is occurring. Phosphorus and vitamin D are more important in the process of mineralization than is calcium. If phosphorus is increased, the likelihood of mineralization is greater than if calcium is increased. If they are both increased and/or if the product is greater than 90, mineral is being deposited in characteristic locations such as blood vessels, kidney, stomach, lung, heart, intercostals, and intestinal submucosa. If mineralization is severe it can be seen in radiographs and induce or amplify renal failure via nephrocalcinosis. Use total serum calcium in the product formula. See example 34.2.

Example 34.2. Total serum Ca × P

1. Ca 10.2 mg/dL × P 14 mg/dL = 143
2. Ca 8.1 mg/dL × P 21 mg/dL = 170
3. Ca 15.5 mg/dL × P 1.8 mg/dL = 28

1. Normocalcemia and hyperphosphatemia with an increased product is common in renal failure. Soft-tissue mineralization is occurring and making the renal failure worse because kidneys are one of the most common tissues to become mineralized. The mineralization starts in basement membranes and mitochondria of tubular cells and progresses to glomeruli and interstitium.

2. Hypocalcemia and marked hyperphosphatemia with a product of 170. Despite hypocalcemia, the Ca × P product is markedly increased, leading to predictable soft-tissue mineralization. These values can occur with renal failure, and the uremia will hasten soft-tissue mineralization.

3. Hypercalcemia and hypophosphatemia and a normal Ca × P product may be seen in dogs with primary hyperparathyroidism and HCM. Despite hypercalcemia, soft-tissue mineralization is not occurring at this time. However, there can still be side effects from hypercalcemia (dilute urine, paresis, blood pressure changes).

Clinical signs

The most critical signs of imbalances in calcium relate to synaptic neural signal transmission, skeletal muscle contraction, and cardiovascular muscle function. Ionized and complexed calcium are critical to the development of clinical signs. Tetany and seizures are classical signs of hypocalcemia in small animals and horses, but paresis is the predominant sign in cattle. The signs referable to hypocalcemia are distinctive but are generally only seen with severe hypocalcemia. Therefore, signs are usually only seen with lactational hypocalcemia or primary hypoparathyroidism. Clinical signs and history are so obvious with lactational tetany or paresis (milk fever) that measurement of serum calcium is seldom performed. The rapidity in a shift in calcium and the acid base status at that moment will influence development of impending clinical signs. Rapid onset hypocalcemia, especially with alkalosis, may produce tetany or paresis, while a comparable concentration of total or ionized would not if the onset was slower and/or the blood gas status was acidotic.

The clinical signs referable to hypercalcemia are paresis and polyuria/polydipsia (PU/PD). Both are mild and often unapparent to owners. In many cases there are no detectable clinical problems. Therefore, with both hypo- and hypercalcemia there are relatively few clinical signs that cause suspicion of calcium abnormalities. In the majority of cases, the abnormality in calcium homeostasis is found from routine chemistry panels. Primary hypoparathyroidism and primary hyperparathyroidism are two diseases in which the results

from a chemistry panel are the clue to the diagnosis in the absence of physical examination findings.

Parathyroid hormone

Ionized calcium is the key signal to calcium receptors on chief cells of the parathyroid gland. Minor contributions come from other factors such as the following. Calcitriol decreases production and secretion of PTH. Hypomagnesemia decreases production and secretion of PTH. Epinephrine has a minor influence on PTH secretion. Phosphorus directly or indirectly stimulates the opposite effects of calcium. PTH is a peptide hormone; it has a half-life that is so short it is measured in minutes and PTH reacts within minutes to changes in the serum concentration of calcium. The chief cells use a CaSR to recognize the serum concentration of ionized calcium and adjust the secretion and production of PTH. This relationship is sigmoid such that at high and low concentrations of calcium the secretion of PTH flattens. A continued increase or decrease in calcium does little to change the amount of PTH secreted. However, in the linear part of the curve a small change in the serum concentration of calcium will change the secretion of PTH in minutes so that physiologic adjustments can be made to keep the serum calcium in a tight physiologic reference interval. This is referred to as the calcium set point and the set point of ionized calcium is approximately 1.2 mmol/L for dogs, 1.37 mmol/L for horses, and 1.0 mmol/L for humans. Acquired and familial diseases may change this set point and/or CaSR. PTH stimulates an immediate rise in serum calcium via multiple steps, one of which is the osteocytic osteolysis pump. PTH also stimulates a sustained increase in serum calcium by stimulating osteoblasts and osteocytes to secrete cytokines that in turn stimulate osteoclastic osteolysis for long-term calcium homeostasis. It is these latter steps that lead to lesions in bones associated with renal and nutritional hyperparathyroidism and HCM. PTH exerts its effect primarily through the binding and activation of PTH receptors, PTH1R.

Receptors for PTH reside on osteoblasts and osteocytes and activation triggers an interaction between these cells and development/activation of osteoclasts. PTH causes the release of calcium and phosphorus from bone, increasing both into the serum. In the kidney, PTH increases the reabsorption of calcium and decreases the maximum renal reabsorption of phosphorus, thereby promoting urinary phosphorus excretion. Ionized and complexed calcium, but not albumin-bound calcium, passes freely into the glomerular filtrate. 99% of the calcium that enters the urinary filtrate is reabsorbed from various locations within the tubules. Hence hyperparathyroidism is associated with hypercalcemia because of bone and renal factors (indirectly through the gastrointestinal [GI] tract and calcitrol). Hypophosphatemia occurs because of the strong phosphaturic stimulus of PTH that exceeds phosphorus resorption from bone. PTH rp, operative in HCM, uses the same PTH1R receptors. Therefore, it acts identically to native PTH and produces hypercalcemia and hypophosphatemia as seen in HCM. Primary hyperparathyroidism and HCM are the only two diseases that cause hypercalcemia and hypophosphatemia in dogs and cats. Due to the phosphaturic effect of PTH the fractional excretion of phosphorus in the urine can be used to estimate an increased serum PTH. If the fractional excretion of phosphorus is greater than reference interval in a nonazotemic animal, then PTH (or PTH rp) is increased. This can be determined on the day serum and urine are sampled, while waiting for the return of PTH measurements. This is clinically useful when distinguishing between primary or nutritional secondary hyperparathyroidism. Serum PTH measurement should complement fractional excretion studies.

PTH also stimulates 1-alpha hydroxylase located in renal proximal tubular epithelium. This enzyme is the rate limiting step in the synthesis of the most potent form of vitamin D, calcitriol or 1,25-dihydroxycholecalciferol. Calcitriol stimulates the production of calcium and phosphorus binding proteins in the intestinal tract to increase the absorption of calcium and phosphorus. Calcitriol also inhibits the production of PTH and has a minor effect on the kidney to increase calcium and phosphorus reabsorption. It stimulates osteoclastic osteolysis releasing calcium and phosphorus into the serum. Only PTH and PTH rp have phosphorus lowering effects hence only primary hyperparathyroidism and HCM are associated with hypercalcemia and hypophosphatemia. Vitamin D toxicity is associated with hypercalcemia and hyperphosphatemia. Calcitonin is secreted from C cells in the thyroid gland and acts to decrease the serum concentration of calcium. Calcitonin may prevent postprandial hypercalcemia, but its effect otherwise is relatively weak compared with PTH. C cells can form medullary carcinomas but reports of tumor-induced hypocalcemia in animals are rare.

The only other cells in the parathyroid gland that can produce lesions are remnants of the duct that connected the thymus and the thyroid. These cells and the ductular remnants can become cystic, referred to as a "Kursteiner cyst." They are of no clinical significance. The only time they may cause problems is during exploratory neck surgery, or imaging of this area, if they were confused with a parathyroid adenoma. These cysts will be fluctuant and light gray in color. A tumor of parathyroid cells will be solid and tan-red in color. It is much more likely that the cysts would be identified microscopically; in fact, they are present in approximately 75% of histological sections of the thyroid and parathyroid glands of dogs. They can be located in the parathyroid gland, thyroid gland, or in the adjacent tissues. Occasionally they even have remnants of thymus with them.

PTH and PTH rp assays

Reference labs have assays for PTH and PTH rp that can be used on plasma or serum from dogs, cats, and horses.

Because of peptide stability factors, it is critical to consult the reference lab for specific sampling procedures, handling and interpretive guidelines.

The most diagnostic information is gained when PTH, PTH rp, and calcium are measured in the same sample or in samples collected at the same time. Usually the final diagnosis is not established when these substances are being measured so request all three as a mini-panel. This will avoid resubmission and delays if the primary differential is not confirmed. Furthermore, clinical interpretation depends on the relative concentration of each compared to the others. Heparinized plasma is preferred for PTH and PTH rp, but serum can be used.

Assays for PTH can measure the amino-terminus (biologically active fragment), mid-region, carboxy-terminus (biologically inactive but immunologically detectable), the entire 1–84 amino acid sequence of PTH, or large fragments of PTH. Studies have not been done in animals to compare which assay is the most diagnostically useful. It would seem the biologically active terminus, amino fragment, would be best, but studies in humans have shown the carboxy-terminal assays have equal or better diagnostic relevance. A two-site assay is available and has been validated to measure serum PTH in dogs, cats, and horses. This is useful when the cause of hypercalcemia or hypocalcemia cannot be determined by other diagnostic aids. The principle of this assay is to use two antibodies. One is specific for the carboxy-terminal region and the other for the amino-terminal region. The assay requires that both bind the respective epitope. It is designed such that the final assay recognizes only intact PTH or at least only large fragments of PTH. The sample can be measured via immunoradiometric (IRIA) technique, which is what most commercial labs use, or via a chemiluminescent technique (Immulite) that is a 20-minute rapid assay. This latter technique can be used to measure PTH during surgery at a veterinary center to determine when all of the hyperactive parathyroid tumor(s) has been removed. The antibody reagents developed to date are not species specific, but they cross-react sufficiently to make meaningful assays. This may explain some of the ambiguous or gray zone results obtained when these assays are used in animals.

If the patient is azotemic, PTH should not be measured, as it will be increased. PTH increases in renal failure due to hypocalcemic-induced parathyroid hyperplasia, hyperphosphatemia, decreased degradation of PTH, and decreased renal clearance of PTH fragments.

Assays designed for humans to measure the complete molecule of PTH rp use an IRIA technique and have been used in dogs, cats, and horses. PTH rp shares a nearly identical amino acid sequence at its amino terminal end as native PTH. Since the amino terminal end is the biologically active fragment, both molecules are recognized by and stimulate the same receptors (PTH1R) and therefore produce the same biological responses. The mid-valent and carboxy regions of native PTH and PTH rp molecules are sufficiently different that antibodies directed at each molecule will recognize one, but not the other, and therefore can be used in diagnostic assays. The ranges for interpretation should be obtained from the laboratory. Example guideline interpretations for PTH and hypercalcemia are shown in the following. It is important to correlate the PTH value with the total or ionized calcium and PTH rp value.

	PTH independent	Equivocal	PTH dependent
Cat hypercalcemic	<2.3	2.3–4.6	>4.6 pmol/L
Dog hypercalcemic	<2.0	2.1–8.0	>8 pmol/L

The coefficient of variation for a measured substance is a number that indicates the expected variability with repeat measurements. For hormone assays the coefficient of variation can be as high as 20%. A much lower percent is preferred, <2% is the approximate coefficient of variation for a hematocrit. This indicates there is considerable variability for hormone assays independent of any real change in the concentration of the hormone measured in the patient. Assays for PTH and PTH rp report coefficient of variations <10%, which is good for hormone assays. The practical application is that the value reported actually has a range; do not take it as an absolute number as there can be considerable variability within assay runs and especially between assay runs. When performing mini-panels of hormones from one patient, whether it is cortisol, thyroid hormones, or PTH and PTH rp request they be placed in the same assay run. If comparisons are to be done, try to send all of the samples together and request all of the samples from one animal be analyzed in the same assay run to decrease interassay variability. Stand-alone absolute values of hormones are rarely diagnostic. They need to be correlated with other laboratory and clinical findings.

Primary parathyroid disorders

Hypoparathyroidism

Lesions and pathogenesis

Spontaneous hypoparathyroidism is due to lymphocytic plasmacytic destruction of parathyroid tissue, which eventually leads to fibrosis, absence of inflammatory cells, and few if any parathyroid cells (sometimes called idiopathic atrophy). The damage is permanent and requires life-long treatment with calcium and/or vitamin D. Do not try to biopsy as very little of the glands remain and they are extremely difficult

to visualize during surgery. The histologic lesion is similar to immune mediated destruction of the thyroid or adrenal glands. The disease is uncommon to rare in dogs, extremely rare in cats, and not reported in other animals.

Iatrogenic hypoparathyroidism is due to thyroidectomy in cats with hyperthyroidism. The inadvertent removal or damage of parathyroid tissue results in surgical hypoparathyroidism. If this is recognized during surgery the excised parathyroid tissue can be reinserted in adjacent muscles and it may establish blood supply and function. Despite the removal of the parathyroid glands, these cats rarely require calcium and/or vitamin D supplementation beyond the first month after surgery. Transitory hypocalcemia is expected postoperatively, but most cats stabilize long term and do not require life-long calcium supplementation. Regeneration of damaged parathyroid tissue may explain this. The mechanism for compensation in others is not known. Studies to investigate the possible role of ectopic parathyroid tissue producing PTH or the production of PTH rp by other tissues are inconclusive. Since most animals eventually normalize their serum calcium it is important not to "overtreat" with calcium and vitamin D. Supplements administered in excess may induce hypercalcemia that will prevent damaged parathyroid glands from regenerating. Many animals with total serum calcium and ionized calcium that are decreased do not exhibit clinical signs. It is nice but not necessary to have calcium in the reference interval similar to regulating serum glucose in a diabetic. However, if there are no signs of hypocalcemia try not to overtreat because the hypocalcemia is a stimulus for parathyroid hypertrophy.

Animals with lactational tetany or milk fever do not have hypoparathyroidism. If PTH is measured in cattle with milk fever it is secreted and responding to the stimulus of hypocalcemia. This is discussed under differentials for hypocalcemia.

Signalment

Lymphocytic parathyroiditis is seen most frequently in young to middle aged spayed female dogs. A few sporadic cases are reported in cats.

Signs

Tetany, seizures, fever (due to seizure activity), cataracts, stilted gait, vomiting, diarrhea, panting, and facial pruritus that results in chewing, rubbing, and licking are reported. However, in most cases hypocalcemia is not suspected on initial examination and hypocalcemia discovered in a routine chemistry panel is often the first clue to the diagnosis. The only hypocalcemic disease that is consistently associated with clinical signs is lactation hypocalcemia, tetany in bitches and mares, and paresis in cattle. If the hypocalcemia goes on long enough even dogs will become paretic.

Routine clinical pathology abnormalities

Moderate to severe hypocalcemia and mild hyperphosphatemia with normal albumin, urea nitrogen, creatinine and lipase is essentially diagnostic. If the serum calcium is less then 6 mg/dL and the patient is not azotemic and not lactating, then primary hypoparathyroidism is the most likely diagnosis. Ionized calcium can be measured to confirm hypocalcemia (<1.0 mmol/L; <2.5 mEq/L) and monitor treatment. Total serum calcium can be <6.5 mg/dL in animals with ethylene glycol toxicity but these patients are very sick and are azotemic or will develop azotemia and markedly increased phosphorus shortly. Of all of the causes of hypocalcemia, lymphocytic parathyroiditis, parathyroidectomy, and lactational tetany result in the lowest observed concentrations of calcium. Serum phosphorus is decreased in cattle with milk fever.

Serum phosphorus is greater than the serum total calcium in some animals with hypoparathyroidism. Hyperphosphatemia is expected due to decreased PTH. However, the magnitude of the increased phosphorus is usually mild and if phosphorus is not increased do not rule out hypoparathyroidism. Renal failure causes hypocalcemia and hyperphosphatemia, but these patients will be azotemic, have dilute urine, and the hyperphosphatemia is much greater than the mild hyperphosphatemia of hypoparathyroidism. The distinction of these two diseases is clear. Pancreatitis is associated with hypocalcemia and hyperphosphatemia, but lipase will be increased three- to fivefold. The pancreatitis patient may be icteric, have increased liver enzymes, and the clinical signs are very different.

Any cause of hypocalcemia if severe enough can be associated with hyperglycemia. In addition to the stress induced by the primary disease, calcium is required for microfilament and microtubular contraction, which is needed for the intracellular transportation and secretion of neurosecretory granules containing insulin. Inability to secrete insulin results in hypoinsulinemia and hyperglycemia.

Confirmatory test

Concurrent PTH and ionized or total calcium is measured on the same sample or collected at the same time.

Serum PTH will be decreased or undetectable depending on the stage of the disease. When all of the parathyroid tissue is destroyed, PTH will be undetectable. However, depending on when the disease process is recognized, there may be viable foci of chief cells, in which case, if the concentration of PTH was measured in the serum, it may be detectable. However, if PTH is in the reference interval and especially at the low end of reference interval while there is concurrent and severe hypocalcemia this is an inappropriate response and is still diagnostic of primary hypoparathyroidism.

Examples that are all consistent with primary hypoparathyroidism:

Case	Total Ca	P	PTH
1	5.5	6.6	2.6
2	6.1	7.4	0
3	4.4	6.8	1.3
4	5.8	8.1	0.8
5	5.2	4.7	3.9
Reference interval	9–11 mg/dL	3–5 mg/dL	2–13 pmol/L

Eventually all of the parathyroid gland tissue will be destroyed, in which case, the concentration of PTH in the serum will be undetectable (case 2). In each case above, hypocalcemia is severe and the concentration of PTH is "inappropriately" low for the serum concentration of calcium and therefore each case is diagnostic for hypoparathyroidism even though some PTH was detected in cases 1, 3, 4, and 5. Hypocalcemia of these magnitudes should be associated with increased concentrations of PTH in an attempt to increase serum calcium. Concentrations of PTH below the lower limit of reference interval should be regarded as undetectable (zero). When the serum concentration of PTH is very low the assay may not be measuring true PTH. Every test has a limit of detectability. When a sample contains so little of the substance being measured that the value is below the level of detectability or linearity, then the lab should report "undetectable."

Primary hyperparathyroidism (primary HPTH) – parathyroid adenoma (hyperplasia, carcinoma)

HPTH is due to functional, autonomous secretion of PTH resulting in persistent hypercalcemia and hypophosphatemia. Parathyroid adenomas account for >90% of canine cases of HPTH, carcinoma for less than 5%, and the remainder are considered hyperplasia because a nodule is in more than one gland. These latter cases may represent multiple adenomas, especially if only two glands contain nodules. Rarely are three or more parathyroid glands enlarged in dogs. Histologic and molecular distinction of adenoma versus hyperplasia is not always easy. The tumors can be found via ultrasonography, but they are small, 4–10 mm in diameter, and are unilateral in most cases. If a large neoplastic mass is found it is more likely of thyroid origin. Kursteiner cysts are present in or near the parathyroid thyroid glands microscopically in more than 75% of dogs and occasionally are macroscopic and could be confused with an adenoma. These cysts will be fluctuant and light tan to gray in color and contain fluid. A tumor of parathyroid cells will be solid, tan-red in color and do not contain fluid. The prognosis for full recovery following surgical removal is excellent with a recurrence rate of less than 10%. Postsurgical hypocalcemia is expected because the adjacent non-neoplastic parathyroid glands are atrophic.

The disease is much less common in cats. Most lesions in cats are benign adenomas, but hyperplasia of all four glands may occur. Most tumors are small, 3–5 mm, but they can be >4 cm and may be localized with ultrasonography and less frequently via palpation.

Clinical signs are generally vague, mild, and nonspecific. They may include weakness, PU/PD (50–80%), hematuria, stranguria, crystalluria, urolithiasis, urinary tract infections, lethargy, inappetence, and signs referable to the nervous system. Weakness and PU/PD are due to hypercalcemia and are seen with regularity in dogs. PU/PD is seen less frequently in cats with hypercalcemia. However, many dogs and cats are asymptomatic. The diagnosis is first considered when hypercalcemia and hypophosphatemia are observed in a routine chemistry panel submitted during an annual wellness exam. Clinical signs such as lethargy may be so gradual and mild that owners either do not recognize them or attribute them to aging.

Most dogs, 75%, will have no abnormalities on physical examination. Dogs are older, mean 11 years, with no sex or breed predilection. It also occurs in the cat. The disease is inherited as an autosomal dominant trait in keeshonds, and genetic testing is available. There is one report of a hereditary form in German shepherd pups. Most cases do not have detectable bone lesions clinically or radiographically. If the mandible or maxillas are enlarged, have osteolysis and new bone formation, then the diagnosis is more likely to be secondary hyperparathyroidism. Urinary calculi, crystalluria, and hematuria are reported in approximately 30% of cases. If urinary calculi or crystals are identified as calcium oxalate or calcium phosphate, then consider a diagnosis of primary HPTH or idiopathic hypercalcemia.

Laboratory abnormalities are fairly characteristic. Total serum calcium will be increased in all dogs with primary HPTH. Serum phosphorus is decreased in 90% of dogs and is expected based on the inhibition of phosphorus reabsorption by PTH in the kidneys. There are only two differentials for a dog or cat with hypercalcemia and hypophosphatemia: primary hyperparathyroidism and HCM (Table 34.2). There are many causes of hypercalcemia and the concentration of serum phosphorus is usually increased or within the reference interval in other causes. The serum concentration of calcium and phosphorus should always be compared and not interpreted individually. Horses can have hypercalcemia and hypophosphatemia with renal failure, but dogs and cats with renal failure-induced hypercalcemia have concurrent hyperphosphatemia. Hypophosphatemia is expected in more than 90% of the cases of primary hyperparathyroidism; however, if the animal develops azotemia, the serum phosphorus may be within the reference interval because of reduced

glomerular filtration and retention of phosphorus. Hypercalcemic renal injury and hyperphosphatemia is much more likely with HCM than primary HPTH.

Hypercalcemia is constant and is of variable magnitude. Most cases in dogs will be in the 12–16 mg/dL range, but some will exceed 18 mg/dL and infrequently greater than 20 mg/dL. Of all of the differentials for hypercalcemia, the highest concentrations of serum calcium are seen with primary HPTH and HCM. Total and ionized calcium concentrations are increased and are due to PTH stimulated bone resorption, renal reabsorption of calcium, and indirectly from calcitrol stimulated intestinal absorption of calcium. The total serum calcium is increased in 100% of dogs with primary hyperparathyroidism, yet ionized calcium is increased in 90–95% of these dogs. If primary hyperparathyroidism is a differential diagnosis, but ionized calcium is in reference interval then measure total serum calcium.

Despite marked hypercalcemia, less than 5% of primary HPTH cases have azotemia. They rarely develop soft-tissue mineralization. Because of concurrent hypophosphatemia, the Ca × P product is typically less than 70. The concept that hypercalcemia is a medical emergency should probably be modified based on the Ca × P product as chronic hypercalcemia with mild or no symptoms is typical of primary HPTH in dogs, cats and people. Renal injury and azotemia is seen with more regularity in dogs with HCM.

Animals with primary HPTH often have dilute urine and PU/PD due to the inhibitory effect of calcium on ADH. The urine specific gravity will be less than 1.020 in 95% of the cases and the average urine specific gravity is 1.012. Calcium oxalate crystaluria is a diagnostic tip to consider hypercalcemia. Approximately one-third will have urolithiasis and a similar percentage will have urinary tract infections. The calculi are usually calcium oxalate or calcium phosphate. Approximately 20% of the cases will require surgical removal of calculi.

The approach to the diagnosis involves use of screening and confirmatory tests. By way of screening tests, it is recommended to repeat the serum calcium and phosphorus to be certain there is hypercalcemia and hypophosphatemia. If they persist, then there are only two diagnoses, primary hyperparathyroidism (relatively rare) and HCM (relatively common). The easiest way to distinguish these two differentials is to find the tumor in dogs with HCM. Lymphoma is the most common tumor and adenocarcinoma of the anal sacs is next most likely, although any tumor can produce this syndrome. In cats the cancer is usually a carcinoma followed by lymphoma, myeloma, and others. However, the HCM syndrome is uncommon in cats. If a nonparathyroid tumor cannot be localized, then consider confirmatory tests such as measuring PTH, PTH rP, and calcium and/or performing ultrasonography of the neck to search for the parathyroid tumor. PTH, PTH rP, and calcium should be measured in the same sample or samples collected concurrently. It is important to measure both PTH and PTHrp and compare results because there can be overlap of the values for both hormones in dogs with primary HPTH and HCM.

Expected findings

Ca	P	PTH	PTH rp	Diagnosis
Inc	Dec	RI to inc	Dec	Primary HPTH
Inc	RI	RI	Dec	Primary HPTH
Inc	Dec to RI	Dec to RI	Inc	HCM
RI	Inc	Inc	–	Secondary HPTH
Inc	Inc	Dec	Dec	Vitamin D toxicity

See discussion of hypercalcemia for results seen with granulomatous disease, Addison's, etc.

If PTH and serum calcium are increased, and the patient is not azotemic then the diagnosis of primary hyperparathyroidism is easy. However, increased PTH is only present in about 30% of dogs and the majority of dogs (75%) with primary HPTH will have a concentration of PTH within the reference interval: mean = 11.3 pmol/L; reference interval 2.0–13.0, 210 dogs. In fact, 45% of the cases had serum PTH concentrations in the low to middle range, 2.3–7.9 pmol/L. Increased PTH is more typical in humans with primary HPTH probably because of better crossreactivity of the antibody used to measure PTH. Increased concentrations of PTH are the exception in dogs, but if PTH is detectable in an animal that is hypercalcemic and not azotemic, then this combination is inappropriately abnormal because PTH should be decreased or undetectable in response to nonparathyroid-induced hypercalcemia. If PTH is within the reference interval (RI), it is inappropriately high in the face of hypercalcemia, and therefore diagnostic for primary HPTH. It indicates the parathyroid gland is secreting PTH at a time when secretion should be suppressed. It is critical to measure PTHrp concurrently as many dogs with HCM will have detectable PTH. Measure PTH, PTHrp, and calcium as a mini-panel and compare results of each for the best interpretation. It is not recommended to measure PTH or PTH rP if the patient is azotemic because PTH is degraded and excreted via the urinary system and may be increased due to delayed clearance. Increases in PTH can be enormous in dogs with chronic renal failure, >10 000 pg/dL, especially in assays that measure the carboxy-terminus of PTH. However, even mid-valent and amino terminal assays will measure an increased PTH and confuse interpretation. These marked increases are due to concurrent secondary HPTH and decreased clearance of PTH.

Cats with primary HPTH usually have concentrations of PTH within the RI, which is inappropriate for their hypercalcemia. Consult the reference laboratory about validity of the

assay for cats and RIs, which are usually considerably lower than dogs, 0–4.6 pmol/L; PTH rp <1.5 pmol/L. Assays for PTH and PTH rp have been validated for cats.

Primary HPTH is rare in horses, as is HCM. However, PTH and PTH rp can be used to establish a diagnosis in horses, but only if hypercalcemia and hypophosphatemia are not due to renal failure.

Ultrasonography of the neck region may clarify ambiguous hormone data and localize the site of the tumor. If HCM is ruled out in a dog with hypercalcemia and hypophosphatemia, then ultrasonographic identification of a mass in the neck region is equally as diagnostic as or better than serum assays for PTH. Based on positive imaging findings, treatment can be started before results of hormone assays are returned. Furthermore, this technique localizes the site for surgery or ethanol or heat ablation. Of dogs with primary HPTH in which ultrasonography was performed, 129 of 130 had one or more masses detected in the parathyroid region.

Hyperparathyroidism: summary

- Hypercalcemia – 100%, hypophosphatemia – 90%.
- 100% if total serum calcium is measured; 90% if ionized calcium is used.
- Azotemia occurs in less than 5% of the canine cases.

The total serum calcium is increased in 100% of dogs with primary hyperparathyroidism, but ionized calcium is increased in 90–95% of these dogs. If primary hyperparathyroidism is a differential diagnosis, then measure total serum calcium.

Laboratory tests are helpful during and following treatment. Measurement of PTH during surgery can now be performed via a rapid assay that helps determine when all neoplastic, hyperfunctioning parathyroid tissue is removed. The half-life of PTH in a nonazotemic animal is only 5–10 minutes. Therefore, serum or plasma PTH will decline within minutes of removal of a secreting parathyroid lesion. The remaining atrophic parathyroid glands will not start secreting PTH for hours to days depending on the severity of their atrophy. If plasma PTH does not decrease within minutes of parathyroidectomy, then continued surgical exploration for additional hyperfunctioning parathyroid tissue is indicated. Ideally a new baseline plasma PTH is measured just prior to the start of surgery, during anesthesia and without palpating the thyroid-parathyroid area (avoids spiking secretion of PTH). After the tumor is removed, 5–10 minutes are lapsed, and postremoval PTH is measured to determine if there is a >50% decrease in PTH, indicating successful removal of the offending lesion. While waiting the 10–20 minutes for the assay results exploration should be performed to search for other enlarged parathyroid tissues. This is essential in keeshonds, and cats in which more than one enlarged parathyroid gland is expected. Excision is considered successful when the plasma concentration of PTH decreases by >50%. However, if a second enlarged gland was found while waiting for the results of PTH it should be removed even if PTH decreases. This latter situation was found in three of five dogs with multiglandular parathyroid disease indicating the necessity to continue surgical exploration and not rely entirely on the change in PTH to determine successful removal of all hyperactive tissue. Whether these tissues would have caused subsequent hyperparathyroidism is not known. If a third sample is required, wait 5–10 minutes from the last sample. This technique is used in our university teaching hospital approximately six times a year. Measurement of PTH is via the chemiluminescent rapid assay, Immulite.

Calcium is monitored postoperatively. If serum calcium does not return to the RI following parathyroidectomy, then there was a second parathyroid tumor, or excessive vitamin D was used preoperatively, or there is a different diagnosis than primary HPTH. Measurement of PTH, PTH rp, calcium, and phosphorus should clarify these possibilities. Recurrence of primary HPTH happens in 5–10% of dogs and takes months to a year.

Postoperative hypocalcemia occurs in about one-third of the dogs following parathyroidectomy. It is usually asymptomatic and may happen immediately or take up to 1 week to develop. Ionized calcium is the ideal fraction to monitor because it can be determined rapidly and is biologically active, but total calcium can be used as well. The atrophic parathyroid glands cannot produce and secrete sufficient PTH rapidly enough in some patients to prevent hypocalcemia after the parathyroid tumor is removed. Hypocalcemia may be dependent on the severity and chronicity of the hypercalcemia and therefore the severity of parathyroid gland atrophy. If the remaining parathyroid glands are not too atrophic, they will start to secrete PTH in response to the declining calcium and prevent postoperative hypocalcemia. The higher the serum calcium prior to parathyroid surgery the more likely there will be postoperative hypocalcemia. The duration of hypercalcemia, if known, may be predictive as well.

Therapy for hypocalcemia postsurgery can induce hypercalcemia and delay the return of the normal Ca–PTH axis. Vitamin D requires several days before it exerts its effects on calcium. If the dose of oral calcium is increased during this time or additional vitamin D is given, then these will work in concert and may increase the serum calcium into the hypercalcemic range. Overzealous treatment with calcium and vitamin D is the correct interpretation for hypercalcemia that occurs in the first week postsurgery rather than recurrence of tumor if normocalcemia was confirmed after surgery. Treating the symptoms of endocrine diseases may be more important than treating the absolute values of hormones or their end products. If clinical signs referable to hypocalcemia are not present, supplementation should be avoided.

There is a report of concurrent hyperparathyroidism in dogs with hyperadrenocorticism. Individual data are not provided, but observations from averaging values from these dogs are the following. There is increased PTH in 92%, threefold increase in PTH in 34%, and no differences or consistent pattern in ionized and total calcium. Serum phosphorus is higher than controls, but the actual incidence of hyperphosphatemia was not reported. Dogs with renal failure were not included in data sets. The authors concluded there is unexplained hyperparathyroidism in dogs with adrenal and pituitary dependent hyperadrenocorticism. Measuring PTH in dogs with hyperadrenocorticism did not change clinical decisions. The status of adrenal function should be considered when interpreting increased concentrations of PTH in dogs.

Disorders of calcium and phosphorus metabolism

There are a number of diseases that disturb calcium metabolism to a degree that cannot be managed by functional parathyroid gland regulation (Tables 34.2 and 34.3). These diseases result in either hypocalcemia or hypercalcemia that occasionally is recognized by clinical signs but is more often detected by routine biochemical test results.

Hypocalcemia

Hypocalcemia – differential diagnoses, summary

Causes of hypocalcemia that are more much common than primary hypoparathyroidism include hypoalbuminemia, hypoproteinemia, renal disease, ethylene glycol toxicity, pancreatitis, and eclampsia/"milk fever." Most of these differential diagnoses are easy to establish without knowledge of serum calcium. Serum calcium is rarely measured for a diagnosis of lactational tetany, and if measured is usually done as confirmation after symptomatic treatment. A complete list of differentials is provided in Table 34.3. The list of differential diagnoses for hypocalcemia is much shorter if hyperphosphatemia is present. Most cases of hypocalcemia are easy to diagnose. Some situations are diagnosed from signalment and presentation without measurement of serum calcium or any other analytes. These include lactation in any species, endurance horses, and grass tetany. If a pet had neck surgery and was not hypocalcemic prior to surgery but is so postsurgery, then trauma to the parathyroid glands is the cause.

If the signalment and history are not diagnostic and a chemistry panel reveals hypocalcemia, then examine albumin and urea nitrogen (or creatinine). If albumin is decreased apply the correction formula. If the patient is azotemic that is the most likely explanation for hypocalcemia. If serum calcium is <7 mg/dL in a patient with acute renal failure, test for ethylene glycol toxicity. If these do not identify the cause of hypocalcemia, then examine lipase to rule in or rule out pancreatitis. The only hypocalcemic disease that serum PTH may be required to confirm is primary hypoparathyroidism. Ruling out other causes of hypocalcemia usually rules in this diagnosis, but it can be confirmed by measuring PTH, which should be undetectable or markedly low and therefore is inappropriate for the degree of hypocalcemia. The determination of ionized

Table 34.3 Differential diagnoses for hypocalcemia.

Ca decreased, P variable	Ca decreased, P increased
Hypoalbuminemia intestinal, liver, renal	Azotemia – prerenal, renal, or postrenal
	Hypoparathyroidism – P mild increase
Renal failure – any cause	Secondary hyperparathyroidism renal or nutritional
Ethylene glycol – severe decrease in Ca	
Pancreatitis; diabetic ketoacidosis	Phosphate enemas – P marked increase
Lactation – eclampsia, milk fever	Tumor lysis syndrome
Critically ill / sepsis	
Hypomagnesemia – dogs; cattle – grass tetany; horses – blister beetle	
Cantharadin toxicity – horse; blister beetle	
Thyroidectomy – damage and/or removal of parathyroid glands	
Hyperthyroidism – ionized decrease, unknown mechanism	
Parathyroid atrophy secondary to hypercalcemia	
Nutritional hyperparathyroidism – dietary imbalances Ca:P	
Oxalate-rich plants	
Endurance racing – horses	
Myopathies – exertional, hyperthermia	
Sick patients – all species; critically ill, sepsis, unspecified illness	
Urinary tract obstruction – azotemia	
Preparturient hypocalcemia – cats, severe hypocalcemia	
Hypovitaminosis D – rickets; GI disease, exocrine pancreatic deficiency	
Hyperadrenocorticism – uncommon, unknown mechanism	
Metaboloic alkalosis	
Tumor lysis syndrome	
Soft-tissue trauma	
Healing long bone fractures – mild, first 20 days of callus formation	
Medullary carcinoma C cell of thyroid – rare	
Pseudohypoparathyroidism – not reported in animals	
Chelation	
EDTA, oxalate – if *in vitro* = calcium is zero	
Citrate – anticoagulant used in blood transfusions	
Iatrogenic: anticonvulsants, furosemide diuretics, IV phosphate solutions; calcium-free IV solutions; transfusions with citrate as anticoagulant; excess bicarbonate infusions, bolus infusion tetracycline	

Diseases above the line are common and account for the majority of cases of hypocalcemia. Whenever phosphorus is increased, there is potential for calcium to be decreased.

calcium is of value in critically ill patients no matter what their primary disease or total calcium concentration is.

Artifactual hypocalcemia due to use of calcium binding anticoagulants such as EDTA or oxalate is often listed. Although this is possible, the serum concentration of calcium is usually "zero." Nothing else will do this and therefore there is no confusion as to the diagnosis. If in doubt repeat the measurement and be sure to use a serum sample. The purpose of anticoagulants such as EDTA (purple top tubes) or oxalate (black top) is to chelate calcium as the means of anticoagulation.

Hypocalcemia disorders

The following is a more in-depth discussion of various causes of hypocalcemia.

Hypoalbuminemia

This is the most common cause of hypocalcemia by a large margin in all species. Because hypoalbuminemia is associated with a decrease in the protein-bound fraction of calcium, there are no clinical signs associated with this hypocalcemia. "Adjust" the total serum concentration of calcium for the hypoalbuminemia and if the adjusted-calcium concentration is within the RI, then other causes of hypocalcemia do not need to be pursued. There is a limit to this relationship and if serum calcium is <6.5 mg/dL in a hypoalbuminemic animal there may be a second cause of hypocalcemia and measurement of ionized calcium is recommended. If ionized calcium is desired it must be measured, the correction formulas do not predict ionized calcium. They simply provide an index of how much the decrease in total calcium is due to hypoalbuminemia. The real calcium in the patient is the value that is measured, ionized, or total. The adjusted calcium is not a real number it simply helps the veterinarian determine that the decrease in total serum calcium is due to hypoalbuminemia. Diagnostic efforts are now directed at the cause of hypoalbuminemia. The adjustment formula for total protein can also be used but is not necessary. Just use albumin correction. If serum albumin is normal or increased do not use any correction and investigate the cause of hypocalcemia; it is not due to a protein abnormality. If gastrointestinal disease is the cause of the hypocalcemia there may be multiple mechanisms involved such as hypoalbuminemia, malabsorption, hypomagnesemia, and/or abnormalities of vitamin D absorption and metabolism. Similarly, if there is pancreatic atrophy or pancreatitis there may be multiple mechanisms working in concert to produce hypocalcemia. These include maldigestion, malabsorption, hypomagnesemia, decreased vitamin D, and hypoalbuminemia.

Renal disease

This is the second most common cause of hypocalcemia. Renal failure may be associated with hyper, normo, or hypocalcemia. Most animals with renal failure are normocalcemic. Most cases follow the same pattern for total and ionized calcium, but there are examples where total and ionized concentrations disagree. The stage of renal failure is important in predicting the serum calcium. In compensated renal failure (early or mild) the serum concentrations of total or ionized calcium are usually in the RI. However, as renal failure advances into the uncompensated stages and finally end stage renal failure, hypocalcemia is expected. An exception occurs in some horses where hypercalcemia may be seen.

The diagnosis of renal failure is obvious when there is concurrent hyperphosphatemia (often marked), azotemia, and urine that is not concentrated, especially if isosthenuric. With chronic renal failure there will be marked parathyroid gland hyperplasia and hypertrophy, accompanied by marked increases in the serum concentration PTH. This is a result of the parathyroid response to a decreasing serum calcium that may still be in the RI as well as decreased renal excretion of PTH due to the renal failure. The decrease in calcium happens first and this induces parathyroid hypertrophy, hyperplasia, and secretion of PTH in attempt to compensate for the urinary loss of calcium and raise the serum calcium. In end stage renal failure there are radiographic and microscopic bone lesions (osteoclastic osteolysis), but only a small percent of chronic renal failure animals will have bone lesions severe enough to produce clinically detectable disease (fibrous osteodystrophy = "big head," rubber jaw). Bone lesions are more common in dogs than cats, horses, or ruminants. The most sensitive areas to detect these bony changes in radiographs are teeth, calvarium and "flat" bones that are more metabolically active in the adult than the long bones. Cases of "rubber jaw" or fibrous osteodystrophy still occur in all species, but only with chronic renal failure, not acute.

The hypocalcemia of renal failure is due to (i) decreased reabsorption of calcium from tubules due to loss of tubular cells, (ii) decreased concentration of vitamin D due to destruction of renal cells that produce vitamin D, (iii) increased concentration of phosphorus that reciprocally decreases calcium, (iv) soft-tissue deposition of Ca × P (mineralization), (iv) hypoalbuminemia, if present, and (vi) if the cause of renal failure is ethylene glycol toxicity the calcium will be "complexed" with oxalate. Renal failure-induced hypocalcemia is accompanied by moderate (9 mg/dL) to marked (>15 mg/dL) hyperphosphatemia. When the Ca × P product is greater than 70 the possibility of soft-tissue mineralization is likely and when it is greater than 100 it is occurring, even if hypocalcemia is present. Phosphorus and vitamin D are major precipitators of mineralization and are more important for mineralization than calcium. Mineralization is enhanced with renal failure due to uremic-induced vasculitis and tissue damage (dystrophic mineralization).

The following are examples of TCa × P in dogs with renal failure and azotemia:

Case	Total Ca	P	Ca × P
1	8	10	80
2	7	15	105
3	9	18	162
4	7.4	16.6	123
RI	9–11 mg/dL	3–5 mg/dl	

Soft-tissue mineralization is occurring in all of these examples even though serum calcium is decreased or within the RI. There are no studies that predict soft-tissue mineralization using an ionized calcium × phosphorus product.

Although it is easy to explain the hypocalcemia associated with renal failure, most cases of renal failure are normocalcemic and some are hypercalcemic. This is true if the calcium status is determined via either total or ionized calcium. Emphasis is placed on examples of increased total serum calcium while the ionized calcium is normal or decreased in dogs and cats with renal failure. Ionized calcium can also increase with renal failure and if ionized calcium is used to classify hypercalcemia in dogs then renal failure is the number two cause. The diagnosis of renal failure is usually straightforward. What is clinically more important than the serum calcium is determination of why the patient is in renal failure and what the Ca × P product is. However, dogs in renal failure that have a total serum calcium <8.6 mg/dL have a poorer prognosis for survival and discharge from a hospital than do dogs with higher serum calcium concentrations. This probably reflects the severity of the renal failure and associated magnitude of hyperphosphatemia.

Hypocalcemia is also seen with prerenal and postrenal azotemia, probably secondary to the increase in serum phosphorus. Anytime serum phosphorus is increased there is potential for hypocalcemia due to the physiologic balance of calcium phosphorus homeostasis, soft-tissue mineralization, increased renal excretion of phosphorus anion and therefore calcium cation, and phosphorus inhibition of vitamin D production.

Obstructed tom cats have hyperphosphatemia, hyperkalemia, and azotemia that is associated with hypocalcemia. The decrease in ionized calcium may be disproportionately greater than the decrease in total calcium. For example, more obstructed cats have a decrease in ionized calcium as compared to total calcium. Tetany is not typically observed even when ionized calcium is as low as 1.10 mEq/L or total calcium less than 5 mg/dL. Fluid therapy that rapidly corrects acidosis, thereby decreasing the ionized fraction, may precipitate tetany.

Secondary hyperparathyroidism

This is a chronic parathyroid response secondary to one of two disorders of calcium–phosphorus metabolism. In secondary hyperparathyroidism, either renal disease or a nutritional calcium-phosphorus imbalance problem initiates absolute or relative hypocalcemia and hyperphosphatemia. Parathyroid hypertrophy and hyperplasia occurs in all of the glands as a secondary response to the hypocalcemia caused by the underlying disease. Serum calcium does not need to decrease below the RI to produce this syndrome. The decreasing serum calcium is recognized by CaSRs that trigger parathyroid secretory and cellular responses in an attempt to raise the serum calcium via usual actions in bone, intestines, and kidneys. Until the primary renal or nutritional problem is corrected, these cyclic events continue and eventually produce clinical disease. Both nutritional and renal secondary HPTH will produce bone lesions that range from mild osteolysis only detected radiographically to fractured bones to enlarged bones from excess fibrous tissue deposition.

Examples of expected calcium and phosphorus values are as follows:

Serum	Ca	P	PTH
1° Hyperparathyroidism	↑	↓	↑ or N
2° Hyperparathyroidism	↓ N	↑	↑
Renal	↓ N	↑↑↑	↑↑↑
Nutritional	N ↓	↑	↑↑↑

N, normal value, within RI.

Renal secondary hyperparathyroidism is usually easy to diagnose. It is associated with hypocalcemia, hyperphosphatemia, and in severe chronic renal disease there is marked azotemia, inability to concentrate urine, and nonregenerative anemia. Measurement of ionized calcium and/or repeat measurements of total and ionized calcium may detect a nadir of hypocalcemia, but there will be wide fluctuations if calcium is measured frequently. Younger animals are more likely to develop bony abnormalities that are associated with soft flexible "rubber" bones that result in lameness, bowing of the limbs, and mild to marked facial swellings and distortions. The increase in size of bones is due to excessive fibrous tissue deposits in response to the bone resorption and probable cytokine driven fibroplasia. If radiographs are taken, especially of the head, severe loss of bone can be seen around the teeth and in the calvarium. Radiographically detectable bony lesions are observed

rarely with primary hyperparathyroidism or HCM although, osteolysis is present microscopically in both diseases. The most significant clinical problem is the renal failure, which is always chronic and usually severe.

Nutritional secondary hyperparathyroidism is a disease of carnivores, exotics (iguanas, etc.), and horses. Ruminants are more likely to have osteoporosis or rickets (vitamin D or phosphorus deficiency). In the majority of cases, the serum concentration of calcium is within the RI and there is mild to moderate hyperphosphatemia. It is associated with diets that either have insufficient calcium or too much phosphorus, or that have a calcium: phosphorus imbalance, such that the ratio of calcium: phosphorus in the diet is no longer 2 : 1. Diets associated with this disease include all meat diets for carnivores and excessive grain diets (high phosphorus, low calcium) in horses and high grains/nuts diets for reptiles (high phosphorus, low calcium). Horses and reptiles need less grain/nuts and more hay, legumes, or green leafy vegetables to balance dietary Ca:P. It can also be seen in herbivores that graze pastures with oxalate containing plants that chelate and lower serum calcium. The low dietary intake of calcium and/or the reciprocal lowering of calcium by the high dietary phosphorus intake lower the serum calcium concentration resulting in PTH production and release and parathyroid hypertrophy and hyperplasia. To stimulate these events, the ionized serum calcium need only change by 0.1 mmol/L or the total calcium by 0.25–0.5 mg/dL. It is not necessary for the serum calcium concentration to be reduced below the RI to trigger PTH production and release; e.g., serum calcium decreases from 9.7 to 9.2 mg/dL, and the 0.5 mg/dL decrease in serum calcium will stimulate PTH production and secretion. Ionized calcium is the biologically active trigger and it is decreasing as the total serum calcium decreases. The release of PTH stimulates the mechanisms to normalize serum calcium by increasing calcium absorption and resorption. In nutritional HPTH this will continue until the dietary imbalance is corrected. Therefore, when total serum calcium is measured diagnostically it is usually "normal," but at the lower end of the RI. Phosphorus, on the other hand, is not regulated as well as calcium. It may be high in the diet and it is also being released from bone, therefore serum phosphorus is usually increased, and this is a key to the diagnosis. As always examine serum Ca and P concurrently. The increased PTH will stimulate compensatory increased P excretion in the urine. This compensatory mechanism is usually not enough to prevent hyperphosphatemia but can be used to help establish the diagnosis by measuring the fractional excretion of phosphorus, an indirect indicator of PTH activity.

Fractional excretion of electrolytes, measurements of PTH, and dietary evaluation with measurements of calcium and phosphorus in feed are usually the best ways to screen and confirm the diagnosis of nutritional secondary hyperparathyroidism.

Fractional excretion (Fx Exc) of electrolytes:

$$\frac{\text{Serum creatinine}}{\text{Urine creatinine}} \times \frac{\text{Urine electrolyte}}{\text{Serum electrolyte}} \times 100$$

A key to the diagnosis of nutritional secondary hyperparathyroidism is an increased serum PTH that results in an increased Fx Exc of phosphorus.

Dietary analysis should demonstrate a calcium to phosphorus imbalance, with increased phosphorus or decreased calcium. Often the history of the diet is helpful to establish the final diagnosis. As described above, the diagnosis of renal secondary hyperparathyroidism is easy because of chronic azotemia. A Fx Exc Na of >1% indicates renal impairment. Fractional excretion studies of calcium or phosphorus are not indicated when there is azotemia.

Ethylene glycol toxicity

This can result in marked hypocalcemia, <7.0 mg/dL, because of the mechanisms associated with renal failure. Severe hypocalcemia is due to the chelation of calcium with oxalate. However, these dogs and cats rarely have tetany, probably because they are severely acidotic and sick (uremic). The acidosis will preferentially shift calcium to the ionized compartment and therefore make more "biologically active" calcium available, thus preventing tetany. The possibility exists that if the acidosis was corrected rapidly the calcium would shift away from the ionized compartment and tetany could be induced, especially if calcium was not added to the IV fluids. Diagnosis of ethylene glycol toxicity is described in Chapter 24.

Pancreatitis

This is associated with mild hypocalcemia, often in the 8 mg/dL range. All of the clinical problems are referable to pancreatitis and not hypocalcemia. The mechanism of the low serum calcium is unknown. Investigations that evaluated ionized calcium, PTH concentrations, and precipitation of calcium in the areas of fat necrosis, have not established a definitive pathogenesis. Correction of the pancreatitis results in normalization of the serum calcium concentration. The diagnosis is usually obvious because the hypocalcemia is associated with history, clinical signs, and other laboratory abnormalities that are consistent with pancreatitis. If hyperphosphatemia is present it is due to concurrent prerenal azotemia. Ionized calcium is also decreased. Ionized hypocalcemia is also present in about half of the dogs with diabetic ketoacidosis and is associated with a higher likelihood of death.

Lactation tetany

This is the most common cause of hypocalcemia that has associated clinical signs.

Eclampsia, or puerperal tetany, is most commonly recognized in the dog. The hypocalcemia associated with eclampsia is not a diagnostic mystery. The patient is usually a bitch that is approaching peak lactation, approximately 3 weeks postparturient. It is more common in smaller breeds of dogs and seen less frequently in large dogs, cats, ewes, and horses. The hypocalcemia is often severe, <6.0 mg/dL, and is one of the few hypocalcemic disorders associated with tetany. If the condition remains untreated the tetany will progress to paresis. If examined the pupils are often dilated and respond slowly to light. Other signs include tachycardia, fever, salivation, restlessness, and muscle spasms that may progress to seizures. Treatment is usually started before results of serum calcium are known. An ionized calcium measurement is ideal to rapidly confirm the diagnosis and monitor treatment. Symptomatic treatment of the hypocalcemia coupled with reduced lactation and/or supplementation (calcium + vitamin D) to the bitch usually corrects the problem.

Preparturient hypocalcemia has been reported in queens. The condition appears to be rare. The hypocalcemia can be severe, with total calcium <5.0 mg/dL. Similar to cows with milk fever, cats tend to be hypothermic. Ewes may also develop signs prior to parturition, usually in the last month of gestation. This may be part of the pregnancy toxemia syndrome of sheep and is associated with stress and decreased food intake.

Milk fever is the common name for lactation hypocalcemia in cattle. The clinical diagnosis is easy. It is a cow, 1–4 days postparturient. A Channel Island breed is most common (Jersey or Guernsey, but it can occur in any breed). It is much less frequent in beef cows. The affected cow is recumbent, head and neck often folded toward flank, and has bradycardia with possible arrhythmias. Fever is a misnomer as affected cows have a normal or subnormal temperature. Serum calcium is rarely measured. Treatment is started based on classical presentation. If serum is sampled total and ionized calcium are markedly decreased, phosphorus is mildly decreased, and magnesium and glucose will be increased. Total serum calcium can be <4.0 mg/dL and ionized calcium <2.0 mEq/L, <1 mmol/L. The relatively high calcium in the diet during the dry period (not lactating) has resulted in suppression of the parathyroid gland, which in turn has decreased the osteoclastic pool. At and shortly after parturition there is a combination of events that result in the syndrome. These include anorexia, estrogen surge, and increased milk production and secretion. As a result, serum calcium rapidly decreases. The parathyroid gland recognizes the decreasing serum calcium and secretes an adequate amount of PTH. However, the bone pool of osteoclasts is so suppressed that they cannot respond to the PTH rapidly enough to mobilize sufficient calcium to prevent paresis. Calcium continues to exit into milk and there is inadequate influx of Ca from bone, renal, and intestinal sources so hypocalcemia progresses to the point the cow collapses with paresis. If serum total or ionized calcium is measured at this time they will be markedly decreased. However, if measured several hours after successful treatment the serum total and ionized calcium has often returned to pretreatment levels, but there are no signs of paresis. There is more to this disease than simply the serum concentration of total or ionized calcium and acid-base status. Hyperglycemia is common and is due to stress and decreased insulin due to the hypocalcemia.

Ionized and complexed calcium, but not albumin-bound calcium, passes freely into the glomerular filtrate, CSF, and aqueous humor. Therefore, the concentration of total calcium in these fluids is normally approximately half of the serum concentration, 4–5 mg/dL. If CSF or aqueous are used postmortem to confirm hypocalcemia, the concentration of total calcium must be less than 4 mg/dL to be compatible with milk fever.

Iatrogenic – thyroidectomy or removal of a parathyroid adenoma

Removal of the thyroid glands to treat hyperthyroidism in cats often results in complete or partial parathyroidectomy. Therefore, hypocalcemia and hyperphosphatemia may occur within 24–48 hours of the surgery but can be delayed for up to 1 week. This also happens in dogs when a parathyroid tumor is excised. In dogs there is usually not damage to the other parathyroid glands, but they are atrophic due to chronic hypercalcemia induced by the parathyroid adenoma. After removal of the parathyroid secreting adenoma the remaining atrophic glands cannot resume synthesis of PTH rapidly enough to prevent postsurgical hypocalcemia. The degree of atrophy is a combination of the severity and duration of the hypercalcemia. Interestingly, this does not occur following surgical or chemical removal of anal sac tumors or with chemotherapy of lymphomas and other tumors associated with HCM.

Cats and dogs with iatrogenic hypocalcemia usually only require treatment with intravenous or oral calcium and/or vitamin D if clinical signs occur or if the total calcium is <7 mg/dL, ionized <3 mEq/L, <1 mmol/L. In dogs the treatment period is short, days to a week, and even in cats oral treatment is usually only necessary for 1–2 months postsurgery. If cats are weaned off the calcium and vitamin D therapy, their serum calcium concentrations usually remain within the RI. The exact mechanism for normalization of the serum calcium is not known. Investigations that tried to determine if there was ectopic parathyroid tissue that hypertrophied and produced PTH in response to postoperative hypocalcemia indicated this is not the case. Even dogs with experimental complete surgical parathyroidectomy will eventually stabilize their serum calcium and not require calcium or vitamin D supplementation. PTH rp could have a role in the normalization of serum calcium in these patients as the hormone is produced by many tissues in adults and fetuses.

Dogs or cats with hypercalcemia due to a parathyroid tumor often develop hypocalcemia postexcision of the tumor. One dilemma of treatment is to provide just enough oral calcium and vitamin D to prevent symptoms but not enough to induce hypercalcemia and continued suppression of the atrophic glands. It is preferable to keep the serum calcium slightly below the RI to stimulate the atrophic parathyroid glands to undergo hypertrophy. If possible, only treat with calcium as it is easier to monitor and change the dose of calcium than it is to regulate serum calcium with vitamin D. Vitamin D requires 3–7 days to reach peak effect. Therefore, it is more difficult to adjust the dose of vitamin D since there is a delayed response before an effect is observed. It is relatively easy to increase the dose of calcium and vitamin D such that therapy induces postoperative hypercalcemia. Treatment related hypercalcemia persists until the vitamin D is metabolized (up to 1 week).

Endurance racing – horses

Hypocalcemia is due to loss of calcium, along with other electrolytes in sweat and insufficient replacement during 50–100 mile races. Contributing to the hypocalcemia may be an alkalosis induced by hypochloremia and rapid respirations. Equine sweat is hypertonic and rich in calcium, potassium, sodium, and chloride. There is greater loss of electrolytes than water in the sweat of horses and therefore electrolytes must be supplemented during races especially in hot and humid weather conditions. Human sweat is isotonic and electrolyte replacement is not as critical as is water replacement. The hypocalcemia seen in endurance horses can be symptomatic and cause tetany, "thumps" or diaphragmatic flutter (tetany in muscles of diaphragm), weakness, cramping, and a variety of neuromuscular dysfunctions including ileus and colic. This can usually be prevented by adequate supplementation with forced electrolytes during the event. High calcium in the prerace diet such as alfalfa hay (regular feed program) could precipitate this condition similar to milk fever in cattle. The most common electrolyte disturbance in endurance horses is hypochloremia.

Cantharidin toxicity

The hypocalcemia of cantharidin toxicity can be severe and is an important clue to the diagnosis of blister beetle toxicosis in the horse. The mechanism of the hypocalcemia is not clear but is possibly related to concurrent hypomagnesemia. Hematuria, hypocalcemia and hypomagnesemia in a colicky horse eating alfalfa is sufficient to diagnose this toxicity. Toxicosis is confirmed via high pressure liquid chromatography that quantifies cantharidin in the urine (20 ml of urine), in gastric contents (one pint of stomach contents), liver, or kidneys of dead horses. Some horses will have increased muscle enzymes and myoglobinuria. Tetany, diaphragmatic flutter, paresis, and facial muscle spasms can be seen. The toxin causes acantholysis of esophageal and gastrointestinal mucosa, myocardial necrosis and renal tubular necrosis.

The blister beetles are found in alfalfa hay near the time of bloom. If hay is cut before the bloom phase it reduces the likelihood of the beetles being present and if crimping is not done it gives the beetles a chance to leave the cut plants. The crimping process crushes the alfalfa stems and any beetle present, leaving them in the hay to be ingested. Crimping is done to crush the stems, squeeze out water and speed drying of hay in eastern U.S. states. Alfalfa hay produced in the arid West is not crimped and the beetles simply walk out of the cut hay. The toxin is secreted by males, given to the female during mating and the female covers her eggs with it as a defense against predators. Horses are highly sensitive to cantharidin; the lethal dose-50 for horses is approximately 1 mg/kg body weight.

Hypomagnesium

Hypomagnesemia results in impaired PTH release and calcitriol resistance leading to secondary hypocalcemia. This is an uncommon or uncommonly recognized problem. Hypomagnesemia and hypocalcemia are associated with protein-losing enteropathy (PLE) in small animals, grass tetany in cattle, and cantharidin toxicity in horses. If PLE is present, then the most likely cause of hypocalcemia is hypoalbuminemia. Contributing factors may be intestinal loss, malabsorption, and/or abnormalities of vitamin D and PTH metabolism. If the concentration of ionized calcium is decreased there are other factors involved than just hypoalbuminemia, such as hypomagnesemia and decreased PTH. Electrolyte replacement may be required to avoid neurologic and metabolic problems. It is reported to be more common in Yorkshire terriers.

Hypomagnesemia causes grass tetany in beef and dairy cattle when they graze lush grass pastures. Animals are usually recumbent and generalized tetany is present or is especially obvious in cervical muscles. Tetany is preceded by an uncoordinated gait, "grass staggers," and an agitated behavior. Lush grass predominant pastures tend to be deficient in magnesium. Adequate serum concentrations of magnesium are dependent on adequate dietary intake. Cattle tend to be hypocalcemic and treatment includes calcium and magnesium preparations. Tetany versus paresis in cattle with hypocalcemia is most easily explained by examination of serum magnesium. If magnesium is decreased as in grass tetany, they will be tetanic and if increased as in milk fever they will be paretic. If hypocalcemia goes untreated long enough even dogs with lactational tetany may become paretic. The serum glucose may be increased due to stress and hypocalcemia-induced hypoinsulinemia.

Oxalate

Plants rich in oxalates may lower serum calcium in herbivores. In chronic cases this has been associated with

nutritional secondary hyperparathyroidism and fibrous osteodystrophy. Example plants with excess oxalates are halogeton, dock, rhubarb, greasewood, and soursob.

Critically ill animals – measure ionized calcium, total, and ionized hypocalcemia

Measurement of ionized calcium in critically ill patients, regardless of the primary disease may influence therapy and prognosis. A mild decrease may not be important, but moderate to marked decreases could influence treatments, especially those aimed at stabilizing cardiovascular deterioration. Serum ionized hypocalcemia in critically ill dogs is associated with a longer duration in ICU and total days in the hospital but is not associated with decreased survival. Critically ill dogs with renal failure, diabetic ketoacidosis, or pancreatitis were more likely to have ionized hypocalcemia, but diseases associated with hypocalcemia were not ranked. The study in dogs did not look at total serum calcium to determine if it was associated with predictive outcomes. Previously it has been shown that dogs in acute renal failure with total serum calcium <8.6 mg/dL have a poorer prognosis for survival and discharge from a hospital than do dogs with higher serum total calcium concentrations.

Critically ill adult horses with endotoxemia and gastrointestinal disease may have hypocalcemia, hypomagnesemia and parathyroid gland dysfunction. Decreased total and ionized calcium can cause or be associated with ileus and colic. Nearly 90% of horses with colic had decreased ionized calcium at the time of admission. Horses with very low ionized calcium were 12 times more likely to develop ileus. A fatal outcome was nine times more likely for horses in the very hypocalcemic group. Ionized calcium and response to calcium replacement was used to predict prognosis. Endurance horses with marked hypocalcemia and hypochloremia can have an ileus that is so severe that it is erroneously diagnosed as a surgical colic. Septic foals were reported to have ionized hypocalcemia, hyperphosphatemia, and increased serum PTH but no differences in magnesium, PTH rp, or calcitonin. However, in this study it is impossible to determine if these changes were related to renal function because creatinine (or urea nitrogen) and PTH concentrations were not reported for individual animals. Therefore, comparisons of Ca to PTH, or PTH to azotemia cannot be made. Calves with severe neonatal diarrhea will have hypocalcemia, but due to concurrent acidosis, the ionized hypocalcemia may not be as severe. With fluid therapy and correction of the acidosis both total and ionized calcium will decrease further. Tetany may develop during therapy as alkalinization shifts calcium from ionized to protein bound.

Sick patients

Hypocalcemia is seen in a variety of illnesses in small and large animals in which the pathogenesis is not known. It becomes difficult to know if there is cause and effect or simply an association. Pancreatitis, ketoacidosis, critical illness, sepsis, colic, endotoxemia, inflammatory diseases, protein abnormalities, cantharidin toxicity, and others could fit in this category of associated problems. There may be a mechanism that is reasonable, such as hypomagnesemia, cytokines or it may represent overlap of common problems. Hypocalcemia is seen in sick cattle with a wide variety of conditions including retained placenta, rumen overload, lymphoma, neonatal calf diarrhea, foot diseases, and abomasal ulcers, to list a few. There may be specific diseases to be aware of or it may be that the severity of the disease/illness in animal and human patients correlates better with the degree of hypocalcemia than the specific disease.

Feline hyperthyroidism

There is a calcium, phosphorus, and parathyroid imbalance in some cats with hyperthyroidism that is not understood. Hyperphosphatemia without azotemia is seen in 25–40% of hyperthyroid cats and total serum calcium is usually in the RI. However, a mild decrease in ionized serum calcium, without clinical signs is observed in approximately 30% (4 of 15) but the mechanisms are not known. The number of cats studied was small. Increased concentration of PTH is reported in up to 77% of hyperthyroid cats studied (small numbers) and hyperparathyroidism and hyperthyroidism are listed as coexistent problems in cats. These abnormalities could be due to concurrent renal disease, which is common in geriatric cats. However, urea nitrogen and creatinine are usually in the RI. Another possibility is the growing association of hypocalcemia with or without an increase in PTH in a variety of concurrent illnesses. The parathyroid hyperplasia may help explain why some cats do not develop postsurgical hypocalcemia and may help explain why postsurgical hypocalcemia is usually not permanent. Humans with hyperthyroidism tend to have the opposite pattern: increased bone turnover, hypercalcemia, and decreased PTH. Hypercalcemia has been reported for dogs with hyperthyroidism. It is mild, the mechanism is not known, and it may not be related to hyperthyroidism. Although the phosphorus, ionized calcium, alkaline phosphatase (ALP), and bone relationship is an interesting paradox in hyperthyroid cats, it is clinically insignificant.

Iatrogenic

Various treatments such as anticonvulsants, intravenous phosphate solutions, calcium-free IV solutions, transfusions with citrate as anticoagulant, excess bicarbonate therapy, tetracycline, and furosemide diuretics can be associated with hypocalcemia. Furosemide inhibits sodium and chloride reabsorption in the loop of Henle and secondarily inhibits calcium reabsorption that can lead to hypocalcemia. Furosemide can be used to lower serum calcium in hypercalcemic patients with adequate hydration. Tetracycline will chelate calcium and rapid intravenous boluses may

decrease calcium. Hypocalcemia induced by transfusions is only associated with massive transfusions; e.g., open heart surgery, transfusion equal to 50% of blood volume in a 3-hour period, or transfusion equal to total blood volume over 24 hours can decrease ionized calcium by 1.2 mg/dL (0.3 mmol/L).

Hypercalcemia

Causes of hypercalcemia are outlined in Table 34.2. If ionized calcium is used to classify and rank the frequency of causes of hypercalcemia in dogs they are: HCM (58%), renal failure (17%), hyperparathyroidism (13%), hypoadrenocorticism (5%), miscellaneous diagnoses (4%), and vitamin D toxicity (3%). Cats and horses have the same differentials. Following is discussion of various causes of hypercalcemia that are not related to autonomous PTH hypersecretion. A general diagnostic approach for evaluation of the hypercalcemic patient is outlined in Table 34.4.

HCM is the term used to describe a common syndrome in which a nonparathyroid tumor produces a substance that acts like PTH and causes hypercalcemia and hypophophatemia. There are a variety of substances produced by tumors and the one that is most important from a clinical diagnostic perspective is PTH rp. Total and ionized calcium are increased, but concurrent hypophosphatemia, when present, is the major diagnostic clue because the only two diseases of dogs and cats that do this are HCM and primary HPTH. Historically, HCM was called pseudohyperparathyroidism because the disease resembled primary HPTH. The reason for this is that many tumors produce the protein PTH rp, which shares a nearly identical amino acid sequence at the amino terminal end of the molecule to native PTH. Since the amino terminal end is the biologically active fragment, both molecules are recognized by and stimulate the same receptors (PTH1R) and therefore produce the same biological responses. Many cells throughout the body produce PTH rp, but the only disease associated with this molecule in veterinary medicine is HCM. PTH rp is important for fetal calcium regulation, transplacental calcium transportation, calcium homeostasis of the fetus, important in milk, and no doubt will be linked to other physiological functions and diseases. It can be identified via immunohistochemistry in tumors that cause hypercalcemia and in tumors from normocalcemic animals. In addition to PTH rp, a group of less commonly recognized substances can be produced by tumors and act individually or in concert to amplify this syndrome. These include interleukin-1, interleukin-6, tumor necrosis factor, prostaglandin E2 (PGE_2), fibroblast stimulating factor, epidermal growth factor, transforming growth factor, PTH, and vitamin D derivatives. Some of these factors are important in the hypercalcemia associated with lymphomas and may act synergistically. The only two substances on this list that are diagnostically practical in veterinary medicine are PTH and PTH rP. However, if a malignant tumor was present and both PTH and PTH rp were decreased, then one of these other humoral/local osteolytic substances may be causing the hypercalcemia.

HCM is the most common cause of hypercalcemia in dogs and it has been associated with numerous tumors. The two most common tumors are lymphoma (by a wide margin) and apocrine gland adenocarcinoma of the anal sac. Lymphoma associated with hypercalcemia in dogs is usually a T-cell lymphoma, as it is in people. Approximately 50% of the dogs will have a mass in the anterior mediastinum. Only 6% are leukemic and osteolytic bone lesions are seen rarely in conventional radiographs. If neither of these tumors are present search for multiple myeloma, mammary carcinoma, pulmonary tumor, and histiocytic sarcomas in that order. If a tumor cannot be found, then measuring PTH and PTH rp are helpful diagnostic tests as is ultrasonography of the thyroid region and possibly the abdominal cavity to search for less physically obvious neoplasia.

HCM is not as common in cats when compared with dogs, but HCM is the number one or two cause of hypercalcemia in cats. It is associated with carcinomas, especially squamous cell carcinoma (SCC), lymphoma, feline leukemia virus (FeLV) with or without lymphoma, myeloma, and rarely with a variety of other malignant tumors. Anal sac tumors are rare in cats and only a few are associated with hypercalcemia. Most cats with this tumor are normocalcemic. Ferrets also have this anal sac tumor, but hypercalcemia is not seen. HCM is rare in horses and has been associated with lymphoma, myeloma, ameloblastoma, and gastric SCC. Although lymphoma is common in cattle, there have been no reported cases associated with hypercalcemia. Interstitial cell tumors of the testes are associated with HCM in rats and an integumentary carcinoma will produce the disease in rabbits. There are multiple animal models in rabbits, rats and mice.

In most cases of HCM, the diagnosis is easy and is based on physical examination and/or laboratory findings of neoplasia in the categories described above. Essentially any tumor could produce this syndrome, most are malignant, but some are benign. Aspirational cytology of enlarged lymph nodes or the perineal mass or other tumors can easily confirm the diagnosis. Measurement of PTH and PTH rp is not needed if a tumor can be identified. Glucocorticoids are useful in lowering the serum concentration of calcium but avoid their use until a diagnosis is established. Steroids will cause lymphocytolysis, which will greatly interfere with interpretation of any lymph node aspirates examined via cytology. If an injection of steroids corrected hypercalcemia in a dog with enlarged lymph nodes, then the diagnosis was very likely lymphoma. Aspiration of lymph nodes at this time will probably be nondiagnostic, but when hypercalcemia returns, cytologic confirmation of lymphoma is indicated.

Most clinical signs are referable to the cancer, but some are due to hypercalcemia. These are weakness and PU/PD.

Table 34.4 Evaluation of a hypercalcemic patient.

1. Consider age of patient, compare calcium and P, examine for azotemia.
2. If increased calcium is not due to young age, then consider repeating serum calcium to confirm hypercalcemia; consider ionized calcium if available; if P is decreased, there is no need to repeat serum calcium.

If **hypercalcemic and hypophosphatemic: HCM vs. primary hyperparathyroidism:**

1. If a horse and it is azotemic, done, renal failure is the cause of hypercalcemia, pursue causes of renal failure; more likely to be chronic and have a poor prognosis.
2. If dog or cat, pursue HCM first followed by primary HPTH.
3. Hypercalcemia of malignancy (number one cause of persistent hypercalcemia in dogs and cats); perform a cancer search, do not measure PTH or PTH rp initially.

   Lymphoma most likely; #1 tumor associated with HCM

   Evaluation of lymph nodes, anterior mediastinum, bone marrow, FeLV; 50% of dogs have an anterior mediastinal mass; <10% leukemic; determination of hepatosplenomegaly; aspirational cytology of enlarged lymph nodes and/or organs

   Adenocarcinoma apocrine glands of anal sac, #2 tumor associated with HCM in dogs

   Thorough rectal-perirectal examination; metastases in pelvic canal and/or sublumbar present at time of initial diagnosis; 50% do not protrude caudally and therefore are not visible but can be palpated

   Myeloma

   Markedly increased total protein, monoclonal gammopathy; multiple lytic bone lesions; aspirational cytology; Bence Jones proteinuria

   Other tumors

   Mammary, pulmonary, malignant histiocytosis, squamous cell carcinoma any tumor possible, perform search

   Horse – squamous cell carcinoma of stomach; endoscopy; paracentesis; lymphoma search

If one of the tumors above is found, that is the cause of hypercalcemia; if further confirmation desired, then measure PTH and PTH rp concurrently

4. If a cancer cannot be found or only a benign skin cancer is found, then consider primary hyperparathyroidism: ultrasound the thyroid-parathyroid complex and/or measure PTH and PTH rp concurrently. Small mass in thyroid region with hypercalcemia and hypophosphatemia is usually sufficient evidence for diagnosis and localizes the tumor to left or right; if further confirmation desired, measure PTH and PTH rp concurrently.

Hypercalcemia and hyperphosphatemia:

1. Rule in or out malignancy first as outlined above; HCM much more likely to be hyperphosphatemic than patients with primary HPTH; <5% of dogs with primary hyperparathyroidism are hyperphosphatemic; it is "practical" to rule out hyperparathyroidism if hyperphosphatemic; exceptions always exist.
2. Examine for azotemia, which is likely, and assess degree of azotemia; the higher the azotemia the greater likelihood of primary renal; attempt to rule in/rule out acute vs. chronic renal failure; if a young dog, especially purebred, then progressive familial renal nephropathy is most likely; if acute renal failure consider grape toxicity.

If azotemia is mild to moderate, then the order of differential diagnoses are Addison's, renal disease, and vitamin D toxicity; all are likely to have dilute urine: <1.025 while azotemic.

90% of Addison's are azotemic, rule in with basal cortisol <2 μg/dL and Na:K <23, decide if ACTH stimulation needed; rule out with cortisol >2 μg/dL.

Rule in/out renal failure: response to fluids; acute vs. chronic; imaging of kidneys; Fx Exc Na; etc.

Differentiation of renal causing vs. caused by hypercalcemia: >P more likely primary renal and > calcium more likely hypercalcemia came first; if total calcium increased and ionized normal or decreased renal more likely; but ionized can be increased in renal failure in dogs and cats.

Consider vitamin D toxicity from history, possible exposure, soft-tissue mineralization, assay for vitamin D; plants unlikely in carnivores, more likely in herbivores.

Table 34.4 (*continued*)

3. If all above ruled out, pursue idiopathic in cats; granulomatous diseases: blastomycosis, other fungi, FIP, schistosomiasis, mycobacterium, toxoplasmosis; iatrogenic.

Hypercalcemia and normophosphatemia – consider all of above

- Patients with HCM – cancer search more practical than PTH PTH rp determinations. Lymphoma first, followed by anal sac, lung, mammary, malignant histiocytosis.
- Hypoadrenocorticism: Na:K <23 : 1; basal cortisol; ACTH stimulation test.
- Renal disease – azotemia, very rare to have normophosphatemia if they are also hypercalcemic; evaluate renal size; acute vs. chronic.
- Primary hyperparathyroidism: serum PTH PTH rp; ultrasound, exploratory surgery of cervical region.
- Idiopathic – cat; rule out others, calcium crystalluria; steroid responsive.
- Bone lesion – other mechanisms besides direct osteolyis are involved.
- Granulomatous – aspirational cytology is test of choice, find etiologic agent.
- Ionized calcium – if desired measure; same list of differential diagnoses and diagnostic approaches; ionized calcium more important to measure in hypocalcemic than hypercalcemic situations.
- Do not use adjustment formulae for protein or albumin if hypercalcemia is present.

Animals with HCM have more dramatic clinical signs than animals with primary HPTH due to the malignancy. These include cachexia, mass lesions, pulmonary metastases, generalized ill health, and azotemia. Hypercalcemia and hypophosphatemia are the key diagnostic laboratory abnormalities. Apocrine adenocarcinomas are one of the best examples to demonstrate how the tumor induces these electrolyte abnormalities. In the following example of an 8-year-old female spayed German shepherd dog, there is hypercalcemia and hypophosphatemia at the time of diagnosis that is rapidly corrected following the first surgical removal of the malignant tumor. When the tumor recurred, so did hypercalcemia and hypophosphatemia, and this cycle repeated itself until the dog's death.

Serum	Total calcium	Phosphorus
Initial diagnosis	21.2	2.4
24-hour postsurgical removal	10.4	3.9
Recurrence 13 months later	16.8	1.8
24-hour postsurgical removal	9.6	4.2
Recurrence 13 months later	18.1	3.4
RI	9–11 mg/dL	3–5 mg/dL

Hypercalcemia can be used as a marker of tumor recurrence and/or metastases. These sequential changes in serum calcium and phosphorus associated with surgical removal of tumors and their recurrence was part of the initial evidence that tumors were producing humoral factors that acted like PTH. In the preceding example, the serum concentration of PTH was appropriately undetectable prior to surgical removal of the tumor and increased rapidly after surgery, preventing postoperative hypocalcemia. Despite the malignant behavior of anal sac tumors, they spread slowly, and surgical resection or chemotherapy often gives affected patients months or even years of life postdiagnosis. Only about half of the tumors protrude caudally to be visible in the perineum, but all can be detected on rectal palpation. They tend to enter the pelvic vault and sublumbar lymph nodes before spreading to liver and/or lungs. This tumor is distinct from benign circumanal or perianal gland adenomas that are common in male dogs and are visible in the perineum.

The hypophosphatemia in dogs, cats, horses, lab animals, and people with HCM is due to the phosphaturic effect of PTH rp on the renal tubules. Causes of hypercalcemia other than HCM and primary HPTH do not stimulate renal phosphorus excretion; hence the serum phosphorus is normal or increased in other diseases. Given time, dogs with HCM often develop normophosphatemia or hyperphosphatemia. This is likely due to concurrent dehydration and prerenal azotemia. Other contributing factors include lymphoma involvement of the kidneys or renal mineralization after the phosphorus increases. Animals with HCM are much more likely to be hyperphosphatemic or normophosphatemic and azotemic than are animals with primary HPTH. This is probably due to the more frequent development of renal complications and

subsequent phosphorus retention. Once the Ca × P product is over 90, soft-tissue mineralization is likely, and one of the common tissues that is predisposed to this is the kidney. Hence, nephrocalcinosis is a frequent complication, which further contributes to renal problems.

Urine specific gravity is dilute due to hypercalcemia inhibiting the action of ADH. The triad of azotemia, dilute urine, and hypercalcemia produces the diagnostic challenge of what came first, either renal failure or hypercalcemia. This raises the challenge to determine the cause of hypercalcemia. There are multiple ways to solve this. First, it is much more likely that the hypercalcemia is due to a tumor than renal failure. Second, the physical examination finding of a malignant tumor (particularly lymphoma or anal sac adenocarcinoma) establishes a cause for the hypercalcemia. Next, the greater the serum calcium the more likely it is HCM and not primary renal failure. The lower the serum P, the more likely it is HCM, while the higher the phosphorus, the more it favors primary renal disease. Lastly, if a primary renal disease can be diagnosed then that it is the cause. Since both diseases tend to be in geriatric patients, they may have both HCM and chronic renal failure.

Following the use of screening tests such as physical findings, calcium, and phosphorus, confirmatory tests may be used. Measurement of PTH and PTH rp are the best laboratory methods for confirmation. Use these if an obvious cancer cannot be found. Request PTH, PTH rp, and calcium on the same sample or samples drawn concurrently in a nonazotemic patient. Ideally PTH will be decreased or undetectable and PTH rp will be increased in patients with HCM. The increase in PTH rp is usually diagnostic, but other substances may cause HCM. Therefore, a decreased value of PTH rp does not rule out HCM. The PTH concentration could be within the RI making interpretation difficult because PTH is often in the RI in primary hyperparathyroidism. However, PTH rp will be decreased or undetectable in patients with primary hyperparathyroidism while PTH is normal or increased. There is overlap of the absolute values for each disease and that is why both hormones should be measured concurrently, and the results compared to each other and the serum calcium concentration. If just one hormone is measured, interpretation is difficult and may necessitate repeat sampling.

The easiest and more practical way to differentiate primary HPTH from HCM, however, is simply to find the cancer associated with HCM and then perform aspirational cytology. If a cancer cannot be located, then consider performing ultrasonography of the thyroid region to search for a parathyroid adenoma. The measurement of serum/plasma PTH and PTH rp may be useful adjuncts when physical examination and ultrasonography are not conclusive. Identification of the other humoral factors associated with HCM is difficult and is a research and/or investigative situation.

Examples of interpretation of PTH and PTH rp results for hypercalcemia include:

PTH	PTH rp	Diagnosis
Inc	Dec	Primary HPTH
RI	Dec	Primary HPTH
RI	Inc	HCM
Dec	Inc	HCM
Inc	Inc	Primary HPTH and HCM
Inc	Inc	Renal
Dec	Dec	Other causes of hypercalcemia
Dec	Dec	An ectopic substance other than PTH rp
Dec	Dec	*In vitro* decay

If both PTH and PTH rp are increased, check the serum UN, creatinine, and phosphorus as a likely explanation is decreased clearance due to renal failure.

Interestingly, hypocalcemia does not happen after surgical resection of a tumor associated with HCM or after chemotherapy for tumors causing HCM, which has significant clinical application. PTH secretion is suppressed for several days following the removal of a parathyroid adenoma in dogs with primary HPTH and hypocalcemia develops in some of these dogs. However, PTH is secreted rapidly following surgical removal of anal sac gland adenocarcinomas, preventing postsurgical hypocalcemia. Following removal of anal sac tumors, the concentration of serum calcium returns to normocalcemic ranges in less than 24 hours as serum PTH, which was decreased or undetectable before surgery, now increases. Apparently, the suppression and atrophy of parathyroid glands is greater in primary hyperparathyroidism than in HCM. An explanation for this observation is not clear.

Renal disease with hypercalcemia

In cats this is the number one or number two cause of hypercalcemia. In horses it is the number one cause. It is a relatively common cause in dogs. If ionized calcium is used to classify causes of hypercalcemia in dogs, renal failure is the number two cause. Dogs with renal failure are usually normocalcemic, but hypocalcemia is common, and hypercalcemia may be present in about 10%. Chronic renal failure is more commonly associated with hypercalcemia than acute renal failure, although grape and currant toxicities are examples of acute renal failure that may be associated with hypercalcemia. The cause of hypercalcemia with renal failure is not known. It is referred to as tertiary hyperparathyroidism. Increases in total and ionized calcium are usually mild compared to the hypercalcemia seen in HCM or primary HPTH, e.g., total calcium 11.5–13 mg/dL for renal failure versus >16 mg/dL for HCM or primary

HPTH. Examine the phosphorus and determine the Ca × P product. The product is often increased with renal failure. The pathogenesis probably involves an abnormality with the calcium receptor for PTH located on the parathyroid chief cells and other cells. CaSR controls PTH secretion and arms parathyroid chief cells and other CaSR-expressing cells to detect changes in the concentration of calcium and to make adjustments that normalize serum calcium. Several disorders in humans are due to inherited or acquired abnormalities of these CaSR pathways such that the receptor is reset at a serum calcium concentration that disrupts normal regulation and there is resulting hypercalcemia or hypocalcemia. These pathways may play a pivotal role in the development of hypercalcemia seen in some animals with renal failure. Acquired abnormalities in this receptor may result in a failure of an increasing concentration of calcium to decrease the production and release of PTH. It is as if the thermostat was turned up and it no longer shuts off production of PTH at a high concentration of calcium. Therefore, PTH continues to be produced and secreted even though the present concentration of calcium (high) would normally inhibit the release of PTH. PTH concentrations are increased in patients with renal failure due to hypocalcemia (relative or absolute), hyperphosphatemia, parathyroid hyperplasia, and decreased clearance and degradation of PTH as kidneys excrete PTH. PTH is considered one of the "uremic toxins."

When hypercalcemia is present in dogs with renal disease, it is usually seen in younger dogs that have progressive familial renal dysplasia. This includes breeds such as Lhasa Apso, elkhound, Doberman, Wheaten terrier. Nearly all of these patients will also have hyperphosphatemia and be azotemic. Patients with hypercalcemia and hyperphosphatemia are very prone to the formation of soft-tissue mineralization. Attempts to lower the serum phosphorus and azotemia should be vigorous because renal mineralization will compound the renal failure and may make it irreversible. The differentiation of hypercalcemia due to renal failure from azotemia caused by another hypercalcemic disease is problematic. A generalization is the higher the serum phosphorus, the more likely the cause is renal disease, and the higher the serum calcium, the more likely the cause is not renal. If renal failure is causing the hypercalcemia, the serum phosphorus concentration is usually in double figures in dogs and cats, e.g., 10–25 mg/dL. The lower the concentration of serum phosphorus, the more likely the cause of the hypercalcemia is something other than renal failure. For example, there is a substance in circulation that is both increasing calcium and decreasing phosphorus, such as PTH or PTH rp. These substances have a phosphaturic effect and if phosphorus is decreased or even if in RIs while a patient is azotemic that is strong evidence that the patient has increased PTH or PTH rp. If the total serum calcium is increased but ionized calcium is in the RI or decreased, this pattern is more characteristic of primary renal failure.

Patients with hypercalcemia and renal failure are expected to be hyposthenuric. This is due to either the renal disease or the action of calcium blocking the function of ADH on the collecting ducts. Approximately one-third of horses in chronic renal failure develop the unusual combination of hypercalcemia and hypophosphatemia. This is unique to the horse. The mechanism for hypercalcemia and hypophosphatemia in horses is unknown. Other horses have the traditional hyperphosphatemia expected with azotemia and either hypocalcemia or normocalcemia.

Addison's disease

Approximately one-third of dogs with hypoadrenocorticism will have hypercalcemia. The mechanism is not entirely known, but postulated components are increased complexed calcium to citrate, an absence of glucocorticoids, and therefore absence of corticoid calciureic effects. Steroids promote calciuria and block osteoclastic osteolysis. In the absence of steroids, these two physiologic events may contribute to hypercalcemia. Ionized calcium was increased in five of seven Addisonian dogs that all had increased total serum calcium, but there were no consistent increases in PTH, PTH rp, or 1,25 dihydroxyvitamin D concentrations to explain the hypercalcemia. Almost all dogs with hypoadrenocorticism are azotemic, many do not concentrate their urine beyond 1.020, and most are hyperphosphatemic. Because renal failure and Addison's disease can have similar electrolyte abnormalities, these diseases can appear similar. If hypercalcemia is present with the above laboratory abnormalities it favors hypoadrenocorticism. If the Na:K ratio is <23 in an azotemic patient it favors hypoadrenocorticism, although this lowered ratio may be seen in renal failure and uroabdomen.

Vitamin D toxicity

This usually produces hypercalcemia and normo- or hyperphosphatemia since vitamin D stimulates both calcium and phosphorus absorption from the GI tract and resorption from bone, without a direct phosphorus lowering effect on the kidneys. The combination of hypercalcemia and hyperphosphatemia can produce lethal soft-tissue mineralization. Mineralization of muscles, tendons, heart, lungs, gastrointestinal tract, and blood vessels is expected and is the cause of death. Sources of vitamin D include dietary supplements, rat poisons, and plants (*Cestrum diurnum* or day blooming jasmine, *Solanum malacoxylon, Trisetum flavescens*). Plant toxicities are more common in herbivores. Rodenticides are more common in dogs and cats. Day blooming jasmine is a house plant and has been reported to cause hypercalcemia in pets that eat it. Overzealous treatment of hypocalcemia with vitamin D and calcium products can cause hypercalcemia. This happens with some regularity in the postoperative treatment of hypocalcemia following removal of a parathyroid tumor. Production of one or more metabolites of vitamin

D is involved in the pathogenesis of some cases of HCM and granulomatous diseases (fungi, parasitic). Ingestion of a topical cream used to treat psoriasis in people, calcipotriene, tacalcitol, or Dovonex is another source of vitamin D that has caused hypervitaminosis D in dogs. Calcipotriene is a synthetic derivative of calcitrol that was used to treat osteoporosis in people, and it is not detected by assays for 25-hydroxyvitamin D. Assays for vitamin D are available and include precursors or 1,25 di-hydroxycholecalciferol. Most assays detect 25-hydroxylated forms of vitamin D2 or D3. Consult the reference lab for sample handling, RIs, and interpretation guidelines.

Granulomatous diseases

Hypercalcemia has been associated with granulomatous diseases caused by a variety of organisms in dogs and cats. Blastomycosis is a fairly well-known cause of hypercalcemia, but very few dogs with blastomycosis are hypercalcemic. Blastomycosis may involve bones. However, increased production of vitamin D by macrophages in the granulomas is a more likely mechanism than direct osteolysis from granulomas in bone. Macrophages and some cancer cells can convert vitamin D precursors into calcitrol. Eleven of 22 dogs infected with the flatworm *Heterobilharzia americana* that causes canine schistosomiasis were hypercalcemic. Resolution of hypercalcemia required treatment with praziquantel. Increased serum PTH rp was demonstrated in two dogs with schistosomiasis. Feline infectious peritonitis (FIP), tuberculosis, toxoplasmosis, cryptococcosis, and actinomyces are other granulomatous diseases associated with hypercalcemia infrequently in cats. These "causes" should be viewed as "associated with" until studies confirm a mechanism.

Diagnosis is established by ruling out other causes of hypercalcemia, by confirming the etiologic agent by serology and/or cytology, and by response to treatment.

Young animals

Young, rapidly growing dogs may have mild asymptomatic hypercalcemia and hyperphosphatemia. The increase is seen more frequently in giant breeds but may occur in any breed. The total serum calcium is seldom over 12 mg/dL in young dogs, and by 6 months of age the total serum calcium should be in the RI for adult dogs. Serum concentrations of calcium and phosphorus that are slightly greater than the RI in young growing animals should be interpreted as normal for their age. This pattern is not seen in kittens or foals.

Idiopathic

Idiopathic hypercalcemia is one of the more common causes of hypercalcemia in cats and it may be on the rise. This disorder is unique to cats. It has been suggested that the increased use of acidifying diets introduced in the 1990's for the control of struvite urolithiasis is a contributing factor. Fractional excretion of calcium is increased and urolithiasis (calcium oxalate or struvite) is expected in 50–75% of these cats. Taken together, the data suggests that some susceptible cats develop hypercalcemia, hypercalciuria, and calcium oxalate urolithiasis while on acidifying diets. However, many cats on acidifying diets do not develop this syndrome, or at least it is not recognized. Presence of calcium crystals in the urine should prompt consideration to measure serum calcium. Diagnosis is established by ruling out other causes of hypercalcemia and a test trial of steroids.

Cats with this syndrome are normophosphatemic and hypercalcemic (total and ionized). Treatment with prednisone (5–12 mg/cat/day) seems to reverse the hypercalcemia. Hypercalcemia may be increased for years in some cats with or without clinical signs. FeLV and feline immunodeficiency virus are not causative. Individuals do not believe it is caused by hyperparathyroidism, because the concentrations of PTH are not increased and because subtotal parathyroidectomy only corrects the hypercalcemia temporarily. However, others could interpret the normal concentration of PTH as inappropriately high for the degree of hypercalcemia. Increased and decreased concentrations of PTH rp are reported, but neither PTH rp nor vitamin D is believed to be causative. Another possible undocumented cause could be a congenital or acquired defect in the calcium-regulating receptor.

Xylitol toxicity

This is reported naturally and experimentally in dogs, most of these describe severe hypoglycemia and/or liver failure. Hypercalcemia is reported as are increases in liver enzymes, hypokalemia, and hyper- and hypophosphatemia. Xylitol is a sugar substitute found naturally in trees, vegetables, and fruits and is used as a sweetener in sugar-free gum, candy, baked goods, desserts, oral care products, and in granulated forms for baking. It is lower in calories than sugar and has low impact on serum glucose, but it stimulates rapid insulin release and causes severe hypoglycemia in dogs. Xylitol's effects on glucose are clinically more important than hypercalcemia.

Bone lesions

Osteolytic bone lesions caused by bone metastases, hypertrophic osteodystrophy, or osteomyelitis have been associated with hypercalcemia, but it is unlikely these are a true cause of hypercalcemia. Or at least the mechanism is more complicated then direct osteolysis by a focal lesion and instead involves one or more humoral components. Any increased release of calcium into the blood from bone resorption around a localized lesion will be normalized by

renal excretion. Bone metastases associated with hypercalcemia are more likely due to production of tumor factors that act locally to resorb bone and also stimulate renal calcium reabsorption and phosphorus excretion. Dogs with hypertrophic osteodystrophy may have increased serum calcium. It is likely due to their young age and not the infection in the bones, unless cytokines work locally and in the kidneys. These "causes" of hypercalcemia should be viewed as "associated with" until additional studies confirm a mechanism.

35

Clinical Chemistry of Mammals: Laboratory Animals and Miscellaneous Species

Terry W. Campbell

Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Blood biochemistry profiles are commonly used to assess the health of nondomestic, mammalian patients. The reason is that diseases are usually associated with specific changes in the blood and urine that are detected using specific analytical techniques. In general, biochemical panels used by most laboratories include glucose, blood urea nitrogen (BUN), creatinine, total protein (TP), albumin (Alb), globulin (Glob), calcium (Ca), phosphorus (P), sodium (Na), potassium (K), chloride (Cl), and total cholesterol. In addition, these panels generally include two or more hepatocellular functions tests, such as alanine aminotransferase (ALT), aspartate aminotransferase (AST), sorbitol dehydrogenase (SDH), lactate dehydrogenase (LD), or total bile acids [1]. The panels will also include two or more hepatobiliary function tests, such as alkaline phosphatase (AP), gamma glutamyltransferase (GGT), total bilirubin, or bile acids [1]. Additions to the biochemical panels may include creatine kinase (CK), triglycerides, magnesium (Mg), and protein electrophoresis. The results of these tests are compared to the reference values that are either produced in the same laboratory conducting the testing or with published normal values for the same or similar species. Biomedical research involves use of laboratory animals such as mice, rats, and rabbits, resulting in a large amount of information concerning the interpretation of biochemical profiles in these species. Fewer clinical chemistry studies, however, have been performed on other nondomestic mammals, such as ferrets, sugar gliders, and hedgehogs. In general, interpretation of clinical chemistry results in nondomestic mammals is the same as that described for domestic species.

It should be noted that many parameters of the patient as an individual, such as age, gender, hydration, and nutritional status, affect biochemical test results. Environmental conditions such as photoperiod, temperature, and husbandry as well as the sampling and analytic methods and the instrumentation used are other sources of variation. Sampling variables include restraint methods, type of anesthetic used, time of day when sampled, anticoagulant used, site of sample collection, and sample processing and storage. For example, a 16–18-hour fast is required in rats to obtain nonlipemic plasma samples, whereas a 16-hour fast in rabbits results in decreased plasma glucose and insulin concentrations but increased glucagon and fatty acid concentrations [2, 3]. Release of epinephrine related to excitement of transportation and blood collection in rabbits results in increased plasma glucose and free fatty acid concentrations. Blood collected by cardiocentesis may be contaminated with muscle enzymes such as CK, AST, LD, and ALT, which are found at high concentrations in cardiac muscle. In rodents, plasma biochemistry results tend to vary in samples obtained from the orbital sinus compared with those obtained by cardiocentesis [4–6].

Results of clinical chemistry analyses performed on identical serum or plasma samples often vary significantly among laboratories; thus, published reference values exhibit considerable variation for many analytes. Therefore, reference ranges obtained by differing methods are not necessarily useful for the veterinary in-house laboratory [7]. Instead, in-house analyzers require their own specific reference ranges. Possible reasons for the differences in reference ranges of the compared studies may be due to undetected subclinical diseases and the use of differing chemical or statistical methods.

Sample collection and handling

Blood samples for biochemical studies can be collected using the same techniques as those described from hematologic studies (see Chapter 19). Many modern analyzers can

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

perform as many as 20 tests on as little as 50 µl of serum or plasma. Heparinized plasma is routinely used for clinical chemistry evaluations in small rodents such as mice, hamsters, and gerbils; because collection of serum commonly results in hemolysis and a larger sample volume can be obtained with plasma than with serum. The aqueous form of lithium heparin is the preferred anticoagulant for plasma biochemical analysis. As a general guideline, a blood sample volume comprising 10% or less of the total-body blood volume (or 1% of the body weight) can be safely taken from a healthy mammal.

Hemolysis or prolonged contact between serum and blood cells produces changes in the analyte concentrations. Increases in the potassium, phosphorus, LD, and bilirubin concentrations as well as decreases in the glucose concentration may be observed. Serum samples from guinea pigs and rabbits have greater LD and GGT activity compared with that in plasma samples produced by leakage of these enzymes from erythrocytes during the clotting process [3, 8]. In mice, serum CK activity decreases with freezing [9]. Because of the cryoprecipitation of some proteins in serum or plasma samples from rats, protein concentrations may decrease during freezing [9].

Plasma biochemical analyte reference intervals for common small mammals are provided in Tables 35.1–35.4. Tables 35.5 and 35.6 compare serum or plasma hormone concentrations of rodents and rabbits, respectively.

Rodents

Laboratory evaluation of the kidneys

Laboratory evaluation of rodent kidneys is the same as that for domestic mammals, and it involves evaluation of blood parameters, such as urea nitrogen, creatinine, and electrolytes, and urinalysis. The plasma urea nitrogen is influenced by diet, liver function, gastrointestinal absorption, and hydration. Increases in plasma urea nitrogen and creatinine concentrations only occur when more than 75% of renal function is compromised; therefore, these tests lack sensitivity for renal disease. Common causes of renal azotemia in rodents, especially mice, include amyloidosis, immune complex diseases, and polycystic disease. Serum or plasma urea nitrogen concentrations increase with high protein diets because of increased nitrogen metabolism rather than renal disease. Age should be considered when evaluating plasma urea nitrogen in rodents; aged hamsters demonstrate increased plasma urea nitrogen concentrations. Other laboratory abnormalities that may be associated with renal disease are hyperphosphatemia, resulting from decreased glomerular filtration, and hypoproteinemia, resulting from glomerular disease and urinary protein loss.

γ-Glutamyltransferase, N-acetyl-β-D-glucosaminidase, and AP have high tissue activity in the kidney, and measurement of these enzymes in urine may improve the sensitivity of clinical chemical testing for renal disease in rodents. Testing of endogenous creatinine clearance may provide a specific and sensitive test for decreased glomerular filtration before plasma urea nitrogen and creatinine concentrations are increased.

Urine may contain artifacts if proper attention is not paid to the collection technique. The urine should be collected on a clean, dry surface. Without use of commercially available metabolism cages, urine commonly is contaminated with feces, food, hair, bedding, or drinking water. Rodents often spontaneously urinate when handled, thereby providing a clean sample for those who are prepared to collect this urine. Cystocentesis eliminates much of the artifact associated with voided urine but may result in blood contamination. Urinalysis should be performed within 2 hours of collection; otherwise, urine may be refrigerated at 4 °C for as long as 48 hours. Refrigerated urine should be warmed to room temperature before testing.

The urine of normal rodents usually is yellow, but it may vary in both shade and transparency depending on the hydration status of the animal. Urinary pH is influenced by diet. Diets that are high in animal proteins contain high concentrations of sulfates and phosphate precursors, which produce more acid urine; cereal protein–based diets tend to produce a neutral to slightly alkaline urine. Rodents tend to have alkaline urine because of the bacterial conversion of urea to ammonia. The urine pH is helpful in determining the acid-base status of the animal. Rodents suffering from catabolic conditions such as starvation, ketosis, or fever commonly have acidic urine.

Urine specific gravity and osmolality are used to evaluate the ability of the kidneys to concentrate or dilute urine. A water-deprivation test for detecting renal disease in rodents can be conducted by withholding water for 24 hours, after which the urinary specific gravity is determined. Those animals that are unable to concentrate their urine to a specific gravity greater than 1.030 either have significant renal disease with the inability to concentrate their urine or suffer from diabetes insipidus. The urine specific gravity value obtained from a refractometer will be erroneous if the urine contains significant quantities of glucose, protein, or other metabolites that normally are not found in urine. Urine osmolality is the definitive method for measuring the concentrating ability of the kidneys; it depends on the number of particles in solution and is not affected by the degree of ionization or the mass of molecules and ions that are present. The normal urine osmolality of rats and hamsters ranges from 331 to 445 and 307 to 355 mOsm/kg, respectively [4, 13, 14].

The urine of normal rodents may contain a trace amount of glucose. Large amounts of ascorbic acid normally are found in mouse urine and may interfere with urine chemical strips

Table 35.1 Plasma biochemical values in rodents.

	Mouse	Rat	Hamster	Gerbil	Guinea pig	Chinchilla
Glucose (mg/dL)	196–278	114–143	65–144	—	89–95	—

Top row of data in each column is compiled from the ranges of mean values without consideration of stain, age, gender, and method of blood collection as published in Loeb and Quimby [10], pp. 417–509.
Second row of data in each column is obtained from Quesenberry and Carpenter [11], pp. 243 and 290.

that use glucose oxidase, thus resulting in a false-negative glucose determination.

Proteinuria is common in normal mice and rats. The semiquantitative urine chemical strips detect large-molecular-weight proteins such as albumin but not the low-molecular-weight glycoproteins of renal origin that are found in the urine of rodents. The normal proteinuria of rodents is associated with a variety of urinary proteins, which include a- and b-globulins, uromucoid protein, and prealbumin. The degree of proteinuria increases with age, and male mice tend to be more proteinuric than female mice.

Rodent urine sediment normally contains fewer than five erythrocytes and leukocytes per high-power field. Increases in the concentration of these cells are suggestive of urinary tract inflammation, calculi, or neoplasia. If urinary casts containing erythrocytes and leukocytes are concurrently present, cells are likely of renal origin, whereas increased numbers of cells without casts are suggestive of lower urinary tract inflammation, such as cystitis and urethritis. Interpretation of rodent urine sediment findings is the same as that described for domestic mammals.

Table 35.2 Plasma biochemical values in rabbits.

	a	b
Glucose (mg/dL)	89–144	75–155
Urea nitrogen (mg/dL)	14–23	13–29

Data from Quesenberry and Carpenter [11], pp. 335 and 345.

Electrolytes and acid-base

Interpretation of serum or plasma electrolyte and acid-base changes in rodents is the same as that described in domestic mammals. Normal serum and plasma sodium concentrations in mice (174 ± 23 mEq/L or mmol/L) tend to be slightly greater than those reported for other mammals. Hypernatremia resulting from neurogenic diabetes insipidus occurs as a hereditary disorder in some strains of rat. Nephrogenic diabetes insipidus, which usually is associated with renal amyloidosis, frequently occurs in certain strains of mice and aged Syrian hamsters. Chronic nephropathies causing abnormal retention of sodium in rats may cause hypernatremia, which in turn results in myocarditis. Renal amyloidosis alters the renal tubular permeability to water, thereby resulting in hyperchloremia. Increased serum and plasma phosphorus concentrations occur in younger rodents compared with concentrations in adults. Serum or plasma magnesium concentrations increase in hamsters during hibernation.

Laboratory evaluation of the liver

Serum or plasma enzymes commonly used to detect liver disease in rodents include AP, GGT, AST, ALT, LD, and SDH. Serum or plasma concentrations of these enzymes increase with increased production, increased release, or decreased clearance. Other biochemical tests to detect liver disease in rodents include serum or plasma total bilirubin, bile acid, and cholesterol concentrations.

Table 35.5 Plasma concentrations of the major hormones in rodents.

	Rats	Mice	Hamsters	Guinea pigs
Triiodothyronine (ng/dL)	30–100	30–100	30–80	20–60
Free triiodothyronine (ng/dL)	—	—	—	0.20–0.32

Table 35.6 Plasma concentrations of the major hormones in rabbits.

Triiodothyronine (ng/dL)	130–143
Thyroxine (µg/dL)	1.7–2.4
Thyroid-stimulating hormone (µU/mL)	40–100
Protein-bound iodine (nmol/L)	400 (adults)
Adrenocorticotropic hormone (pg/dL)	25[a]
Cortisol (µg/dL)	2.6–3.8 (early morning)
Aldosterone (ng/dL)	20[a] (early morning) 50[a] (late afternoon)
Calcitonin (pg/mL)	1125–1200
1,25-dihydroxy-vitamin D (pg/mL)	27–47

[a] Average concentration.

AP is a membrane-bound enzyme with highest activity in osteoblasts, biliary epithelium, and epithelial cells of the kidneys and intestines. Young rodents have higher plasma AP activity than adults because of osteoblastic activity, and male rats tend to have higher plasma AP activities than female rats. Hepatic AP of rodents is heat labile at 56 °C and sensitive to levamisole inhibition [5]. Significant increases in serum or plasma AP activity occur in rodents with hepatic cholestasis. Ligation of the bile duct in rats produces elevation of both hepatic and intestinal AP isoenzymes. Plasma or serum AP activity is a more sensitive test than bilirubin or ALT for detection of hepatic disease in hamsters [14, 15]. Drugs that increase AP synthesis and plasma activity in rats include cortisol, phenobarbital, and theophylline [7]. Increased plasma AP activity occurs in zinc- and manganese-deficient guinea pigs [16].

Plasma GGT activity is significantly increased in hamsters and rats with experimentally induced hepatic injury resulting in cholestasis. Guinea pigs have higher hepatic GGT activity than rats and demonstrate higher plasma GGT activities with cholestasis. Serum GGT activity is increased in guinea pigs after *in vitro* blood clot formation, which can be avoided with use of plasma for enzyme testing. The kidneys of rodents have the highest GGT activity, but the enzyme is nondetectable in the plasma or serum of most rodents. The kidneys of rats have 200–300-fold the GGT activity of the liver.

AST is a mitochondrial and cytosolic enzyme with high activity in the liver, heart, skeletal muscle, and kidney and low activity in the intestines, brain, lung, and testes. Increases in plasma or serum AST activity usually are associated with hepatic, cardiac muscle, or skeletal muscle injury.

In rats and mice, the activity of ALT, which is a cytosolic and mitochondrial isoenzyme, is highest in the liver. The ratio of the cytosolic to mitochondrial ALT isoenzymes in the liver and heart muscle of rats is 5 : 1 and 50 : 1, respectively. In rodents, the intestines, kidneys, heart, skeletal muscle, brain, skin, and pancreas also have ALT activity. In guinea pigs, ALT activity in the heart is almost equal to that in the liver. Plasma and serum ALT activity increases with hepatocellular damage in most rodents, and the enzyme appears to be liver specific in rats and mice. Plasma ALT, however, does not appear to have diagnostic value for hepatic disease in guinea pigs, which have only half the hepatic ALT activity of rats and mice. Increases in serum ALT activity correlate with the degree of hepatic necrosis in rats. A threefold increase in plasma ALT activity occurs in mice that are restrained by holding the body compared with those that are restrained by the tail.

LD is a cytosolic enzyme with the highest activity in skeletal muscle, followed by cardiac muscle, liver, kidney, and intestines, respectively. In the mouse, LD is characterized by five isoenzymes: LD-1 and LD-2 are found in cardiac muscle, LD-5 in the liver and skeletal muscle, and LD-3 in most other tissues. Serum or plasma LD activity elevates with hepatocellular disease in rodents; however, normal values are highly variable and depend on the analytic method used.

SDH is a cytosolic enzyme that is found in the liver, kidney, and seminal vesicles of mice but is liver specific in rats. Increases in serum or plasma SDH activity occur with hepatic disease in rodents and is a more sensitive test than ALT for detection of hepatocellular disease in rats. SDH assays usually are not performed by veterinary laboratories.

Serum and plasma total bilirubin concentration increases in rodents with primary hepatobiliary disease, extra hepatic biliary obstruction, or hemolysis. Increases in plasma or serum total bilirubin concentration should be evaluated by determining the erythrocyte mass and performing other tests that evaluate the liver or biliary system.

The total serum and plasma bile acid concentration is a sensitive and specific test for hepatobiliary disease and disorders of the enterohepatic circulation. Plasma bile acid concentration has an excellent potential for detecting hepatobiliary disease in rodents, especially rats with a high concentration of circulating bile acids.

The plasma cholesterol concentration may increase in rodents with extrahepatic biliary obstruction. Normal plasma cholesterol concentration varies between strains of mice. Hypercholesterolemia often is associated with fatty infiltration of many tissues. In guinea pigs, the intestine, rather than the liver, is the primary site of cholesterol production [8]. Normal plasma cholesterol concentration (112–210 mg/dL or 2.90–5.43 mmol/L) of hamsters is higher than that of other rodents and decreases during short photoperiods but increases with cold temperatures [4, 14].

Laboratory evaluation of proteins

The normal plasma protein concentration in mice varies among strains. In mice, hyperproteinemia often is associated with severe dehydration and often occurs with loss of urinary protein from renal disease. The major classes of serum or plasma proteins in rodents are evaluated using electrophoresis. The major globulins of rats are α_1- and β-globulins, with lower concentrations of α_2- and γ-globulins. In hamsters, albumin concentrations decrease during the first year of life, α_2-globulins increase during the first 6 months of age, and β-globulins decrease at 8 weeks of age [4, 14, 17]. Fibrinogen migrates into the γ-globulin peaks in hamster protein electrophoretic scans. Amyloidosis is a common disease of hamsters older than 18 months and results in hypoalbuminemia and hyperglobulinemia.

Laboratory evaluation of glucose metabolism

Cells must be quickly separated from the serum or plasma of rodents, or fluoride added to the collection tube, to prevent decreased glucose concentration because of *in vitro* glycolysis (a decrease by 7% is expected if the sample sits for 1 hour at room temperature). The plasma glucose concentration in rats and mice decreases with age, with an average decrease of 2 mg/dL per month in the latter. Blood glucose concentrations are also affected by nutrition/diet, hormonal changes, hibernation, restraint, fasting, and anesthesia.

Many strains of mice are used as animal models for diabetes mellitus; therefore, glucose tolerance tests have been developed for mice [18]. A 1-hour glucose tolerance test compares the preinjection plasma glucose concentration to the glucose concentration obtained 1 hour after an intra peritoneal injection of glucose at a dose of 2 mg/g body weight. A 4-hour oral glucose tolerance test compares the baseline plasma glucose concentration with a plasma glucose concentration obtained 4 hours after the oral administration of a 10% glucose solution at a dose of 10 ml/kg. Certain strains of rodents, such as ob/ob obese mice, Zucker fatty rat (fa/fa), and the LA/N corpulent rat, are used as animal models for noninsulin-dependent diabetes mellitus. The Chinese hamster and Wistar BB rat are animal models for insulin-dependent diabetes mellitus. Insulin-dependent diabetes may result in guinea pigs from an infectious agent that causes fatty degeneration of the pancreas and affects both exocrine and endocrine pancreatic functions; affected guinea pigs have hyperglycemia, glucosuria, ketonuria, and beta-cell hypoplasia. Immunoassays for the determination of insulin in rats can be calibrated to measure plasma insulin in mice, but guinea pig insulin is immunologically different

and cannot be determined using rat antibodies. Rat glucagon is measured using human immunoassay techniques; however, guinea pig glucagon, like insulin, is immunologically different and cannot be determined with human antibodies.

Laboratory detection of muscle injury

CK is a dimeric cytosolic enzyme that is composed of M and B subunits. Skeletal muscle contains MM subunits, and cardiac muscle contains MM, MB, and BB subunits. Brain contains BB subunits. As in domestic mammals, plasma CK activity is a useful marker for muscle injury in rodents. Nutritional myopathies, such as those resulting from hypovitaminosis E and selenium deficiency, cause increased plasma CK activity in rats and mice.

Laboratory evaluation of endocrine disorders

The major hormones of rodents are secreted into the peripheral blood in a circadian rhythm that may vary among species. Hormonal secretion also is influenced by environmental factors, such as light-dark cycle. An ultradian rhythm, in which hormones are secreted in an episodic or pulsatile manner with a periodicity of less than 24 hours, can be superimposed on the normal circadian secretion of a hormone. Suggested ranges for the major plasma hormones in rodents are provided in Table 35.5.

Normal male rats have higher plasma thyroid-stimulating hormone (TSH) concentrations with use of reference preparation-1 standard from the National Hormone and Pituitary Program compared with normal female rats. Plasma TSH concentrations of normal female rats peak at the onset of the light cycle. Mice and hamsters have lower normal plasma TSH concentrations compared with rats (according to the same assay method used for rats). A bioassay method using radio-labeled iodine also can be used to obtain plasma TSH concentrations in rodents.

Plasma or serum thyroxine (T_4) and triiodothyronine (T_3) concentrations in rodents can be measured by radio immunoassay. Transport proteins and binding affinity for T_4 and T_3 vary among species. In rats and mice, approximately 80% of the bound T_3 and T_4 are bound to albumin and 20% to T_4-binding prealbumin. Approximately 0.05% of plasma T_4 and 0.25% of T_3 in rats is the free, physiologically active form. Normal plasma total T_4 and T_3 concentrations in rats and mice vary between different strains but generally range between 3 and 7 µg/dL and 30 and 100 ng/dL, respectively. Plasma T_4 and T_3 concentrations exhibit a diurnal rhythm, in which peak concentrations occur during the light phase and minimum concentrations during the dark phase.

Normal plasma adrenocorticotropic hormone (ACTH) concentrations in rodents have been determined using either radioimmunoassay or bioassay techniques. The plasma ACTH concentration in normal mice exhibits a normal circadian rhythm, in which minimal concentrations occur during the morning and peak concentrations during the afternoon.

Corticosterone, which is the primary glucocorticoid in the plasma of mice and rats, exhibits a marked diurnal variation that is affected by the light cycle. In mice, maximum plasma corticosterone concentrations occur at the start of the dark period and minimum concentrations at the end of the dark period. Male mice have lower plasma corticosterone concentrations compared with female mice. Maximum plasma corticosterone concentrations occur late during the light period in rats, and minimum concentrations occur during the end of the dark period. In rats, approximately 80% of plasma corticosterone is bound to transcortin and 10% to albumin, thereby leaving 10% or less in the free, unbound state. Both corticosterone and cortisol are found in the plasma of normal hamsters. The total plasma glucocorticoid concentration 5.5 hours after onset of the light period in hamsters averages 1.8 µg/dL, with an average corticosterone : cortisol ratio of 3.5. The plasma corticosterone concentration is greater in male hamsters than in female hamsters. Cortisol is the primary glucocorticoid in the plasma of normal guinea pigs. Guinea pigs demonstrate maximum plasma cortisol concentrations late in the light period and, again, late in the dark period. Minimum concentrations occur early during the light period and, again, during the middle of the dark period. The stress of restraint or removal of a cagemate significantly increases plasma glucocorticoid concentrations. A twofold increase in plasma corticosterone concentration occurs in rats with 2 minutes of restraint, and a 12-fold increase results after 20 minutes of restraint.

In rodents, plasma concentrations of the calcium-regulating hormones parathormone, calcitonin, and 1, 25-dihydroxyvitamin D_3 are influenced by dietary calcium, age, gender, photoperiod, and strain. Using radio immunoassay techniques, the normal plasma parathormone concentration in male rats tends to be greater than that in female rats.

Normal plasma calcitonin concentrations of rats are extremely variable because of age, stage of light cycle, strain, and gender. Plasma calcitonin concentrations also are influenced by the stage of estrus in females, in which maximum concentrations occur during proestrus. Six- to 8-month-old male Wistar rats have lower plasma calcitonin concentrations compared with 12–14-month-old Wistar rats. Male Wistar rats also have lower plasma calcitonin concentrations than female rats. Plasma concentrations of 1, 25-dihydroxyvitamin D vary in rats with strain, gender, and dietary calcium intake. Normal male Wistar rats have lower plasma 1, 25-dihydroxyvitamin D concentrations than females.

Cholesterol and triglycerides are the most commonly measured lipids, and significant interspecies differences in normal values are expected. High levels of lipids cause lipemia, which interferes with other biochemical assays using photometric analytics. Because cholesterol typically peaks following a meal, fasting is required to improve accuracy of the test.

Lipoproteins are macromolecules that transfer lipids and cholesterol and are classified by a density value that varies inversely with molecular size. Low-density lipoproteins (LDL), also known as beta lipoproteins, carry cholesterol from the liver to the tissues. High-density lipoproteins (HDL), also known as alpha lipoproteins, carry cholesterol from the tissues to the liver. Very-low-density lipoproteins (VLDL) are primarily made up of triglycerides, glycerol bound to three fatty acids, which are broken down by pancreatic lipase.

Rabbits (*Oryctolagus cuniculus*)

Laboratory evaluation of the kidneys

Laboratory evaluation of the kidneys in rabbits is the same as that for rodents and domestic mammals. Plasma urea nitrogen (BUN) and creatinine commonly are used as markers for renal function in rabbits. In general, the normal BUN of rabbits lies between 10 and 30 mg/dL (3.57–10.71 mmol/L) and the normal creatinine between 0.5–2.5 mg/dL (44.2–221 µmol/L). However, the normal plasma urea nitrogen of rabbits is influenced by breed, strain, and gender. Protein catabolism associated with high dietary protein intake, vigorous exercise, dehydration, or urinary tract disease (such as urolithiasis, obstruction of urine flow, urethral ligation, and kidney disease) increases plasma urea nitrogen concentration. Decreases in BUN may be associated with hepatic insufficiency and wasting of body mass caused by dental disease. The time of day when the blood sample is taken also influences the plasma urea nitrogen concentration in rabbits, in which peak concentrations occur between 4.00 and 8.00 p.m. Plasma urea nitrogen and creatinine are insensitive tests for renal disease in rabbits, however, requiring a 50–75% loss of function before plasma concentrations increase. Renal failure in rabbits is often associated with increased plasma BUN, creatinine, calcium, phosphorus, and potassium concentrations. Renal failure rabbits may also exhibit isosthenuria and depending upon the cause (i.e., nephritis) may exhibit proteinuria, ketonuria, pyuria, and urinary cast formation.

Calcium and phosphorus

The normal plasma calcium concentration of 13–15 mg/dL (3.24–3.74 mmol/L) of rabbits is higher than that of most other mammals. The mean urinary fractional calcium excretion of rabbits is 45–65%, compared with less than 2% in other mammals. Excess dietary calcium is absorbed and excreted in the urine of rabbits compared to other animals where it is excreted in the bile. This predisposes rabbits to urinary calculi. Increases in calcium concentration may be associated with renal disease and decreases may be associated with poor diet, hypoalbuminemia, diarrhea, chronic renal disease, and hyperparathyroidism.

The normal plasma phosphorus concentration of rabbits is 2.3–6.7 mg/dL (0.74–2.16 mmol/L). An increase is often associated with renal disease but can be artificially elevated with hemolysis. A decrease can be associated with urinary calcium excretion [1].

Electrolytes and acid-base

Normal plasma electrolyte concentrations of rabbits vary with the breed and strain. The normal plasma sodium concentrations of rabbits generally range between 131 and 155 mEq/L (mmol/L). Because sodium values vary significantly between breeds, it is often not a useful diagnostic indicator in rabbits [1]. Increased sodium concentrations are expected with dehydration, fluid loss with diarrhea, excess dietary salt, peritonitis, and burns. Decreased sodium concentration is seen with acute and chronic renal failure, polyuria, and polydipsia.

Normal plasma chloride values of rabbits generally range between 92 and 120 mEq/L (mmol/L). Increased chloride values are expected with dehydration and excess dietary salt and decreased values are expected with diarrhea and low dietary salt.

Normal plasma potassium concentrations of rabbits generally range between 3.5–6.9 mEq/L (mmol/L). Hyperkalemia is seen with acute renal failure, obstructed urine flow, metabolic acidosis, and severe tissue trauma. Hypokalemia is associated with renal failure, starvation, low dietary potassium, and stress-induced increase in catecholamines.

Normal plasma magnesium concentrations of most rabbits are between 2.0 and 4.5 mg/dL. Magnesium is excreted mainly in the urine of rabbits compared to excretion in the bile by other mammals [1]. Increased magnesium values can be associated with dehydration, hyperthyroidism, tissue trauma, and adrenocortical insufficiency.

The normal bicarbonate concentration in the plasma of rabbits generally ranges between 16.2 and 38.0 mEq/L (mmol/L). Because the kidneys of rabbits have a weak ability to correct acid-base imbalances, these animals are susceptible to electrolyte abnormalities [1].

The serum iron- and total iron-binding capacity of normal rabbits vary with the time of day when the blood was collected, with the lowest concentrations occurring at 8:00 a.m. and the highest at 8:00 p.m. Serum iron concentrations of normal rabbits range between 165 and 250 µg/dL (29.6–44.8 µmol/L) [2].

Laboratory evaluation of the liver

Plasma enzymes used to detect liver disease in rabbits include ALT, AST, LD, glutamate dehydrogenase, AP, and GGT. In rabbits, ALT activity is equal in the liver and cardiac muscle; however, increased plasma ALT activity (normally 14–80 IU/L) is considered by some to be a specific indicator of liver disease in rabbits. The degree of hepatic necrosis correlates positively with the increase in plasma ALT activity.

Interestingly, the rabbit liver ALT activity (approximately 5 hours) is less than half that of the dog causing some to find this enzyme not to be a useful indicator of liver damage in rabbits. Significant AST activity occurs in the liver, heart, skeletal muscle, kidney, and pancreas of rabbits. Therefore, increases in plasma AST activity (normally 14–113 IU/L) are suggestive of injury to one or more of these tissues. Increased plasma AST activity can be associated with liver damage, hepatic coccidiosis, heat stress, or muscle cell damage or excursion (associated with restraint). Increases in plasma AST activity may be associated with cardiac or skeletal muscle injury during blood collection by cardiocentesis or use of restraint methods that cause exertion. LD activity is present in a wide variety of tissues, with each demonstrating a different isoenzyme composition that corresponds with isoenzymes 1 through 5 in humans. Isoenzyme LD-1 and LD-2 predominate in the liver and skeletal muscle. Because erythrocytes have high LD activity, hemolysis may result in high plasma LD activity. The plasma LD activity (normally 30–140 IU/L) can be used to detect liver disease in rabbits, but because of its wide tissue distribution and the effect of handling and hemolysis on plasma activity, it is not commonly used. Plasma glutamate dehydrogenase activity (range, 5.5–7.0 IU/L) and SDH (range, 170–177 IU/L), although not commonly measured in veterinary laboratories, may be useful in the evaluation of hepatocellular injury in rabbits.

The normal plasma AP activity (range, 10–140 IU/L) of rabbits varies with age, breed, and strain. Young rabbits are expected to have two to four times the plasma AP activity of adult rabbits. Rabbits are unique in having three AP isoenzymes. Rabbits have an intestinal and two liver/kidney forms, compared with the intestinal and liver/kidney/bone forms found in mammals other than primates. The predominant liver/kidney isoenzyme of rabbits is similar to the intestinal form and the minor liver/kidney isoenzyme to the liver/kidney/bone isoenzyme of other mammals. The predominant liver AP isoenzyme is not inhibited by levamisole or heating to 56 °F, as the hepatic AP isoenzyme of other mammals is. The plasma GGT activity of normal rabbits is less than 8 IU/L (mmol/L), is derived primarily from bile duct epithelial cells, and increases significantly in rabbits with hepatobiliary obstruction (lipidosis, hepatic coccidiosis, liver lobe torsion, hepatic abscesses, and neoplasia).

Rabbit bile contains approximately 70% biliverdin and 30% bilirubin, of which 90% is conjugated as a mono conjugate. Normal rabbit plasma lacks biliverdin, however, and the normal bilirubin concentration (range, 0–0.8 mg/dL or 0–13.68 µmol/L) is low. A marked increase in plasma bilirubin concentration is expected in rabbits with biliary obstruction (hepatic coccidiosis, hepatic neoplasia, lipidosis, liver lobe torsion, hepatic fibrosis).

The normal plasma cholesterol concentration of rabbits varies with age, breed, strain, and gender. In general, the normal plasma cholesterol concentration will range between 10 and 80 mg/dL (0.26–2.07 mmol/L). At birth, the plasma cholesterol concentration is approximately that of adults, increases by 25 days of age, and then returns to the adult concentrations by 60–80 days of age. Normal adult male rabbits have twice the plasma cholesterol concentration of adult female rabbits. A diurnal variation in plasma cholesterol occurs as well, with peak concentrations being seen between 4:00 and 8:00 p.m. This may be associated with cecotrophy. The plasma cholesterol concentration may increase in rabbits with extrahepatic biliary obstruction. Rabbits are used extensively as animal models for cholesterol metabolism studies because of their ability to rapidly develop cholesterolemia with high-cholesterol diets. Daily feeding of 1 g of cholesterol increases the serum cholesterol concentration to greater than 1000 mg/dL. The Watanabe heritable hyperlipemic rabbit, which primarily exhibits LDL cholesterol, is an animal model for familial hypercholesterolemia in humans.

Increased plasma cholesterol concentration may be associated with anorexia and representing end stage hepatic lipidosis; pancreatitis; diabetes mellitus; nephrotic syndrome; and chronic renal failure. Decreased cholesterol may be associated with liver failure, malnutrition, or pregnancy.

The normal serum lipoprotein distributions of adult female rabbits are 46–58% HDL, which transports approximately two-thirds of the total cholesterol; 9–15% pre- or intermediate-density lipoprotein or VLDL; and 30–42% LDL. High-cholesterol diets fed to rabbits lead to a 20–40-fold increase in VLDL and a four to fivefold increase in LDL. Pregnant rabbits show a decrease in HDL and an increase in LDL [1].

Liver function tests that evaluate plasma disappearance and biliary excretion of dyes, such as sulfobromophthalein (BSP) and indocyanine green (ICG), have been characterized for rabbits. The overall rate of BSP clearance for rabbits has been reported as 1.8 mg/min per kg, in which 75% of the BSP is excreted in the conjugated form. Intravenous BSP dosages of 30, 60, and 120 mg/kg result in 32-minute plasma concentrations of 1, 2, and 20 mg/dL, respectively [19]. ICG is excreted in the bile in the unconjugated form. Rabbits have a curvilinear plasma ICG clearance curve, with a greater capacity to remove ICG from the circulation than either dogs or rats. Rabbits that are given intravenous ICG dosages of 8, 16, and 32 mg/kg demonstrate disappearance rates of 46%, 20%, and 10% per minute, respectively [2].

The normal plasma bile acid concentration of rabbits generally ranges between 0 and 40 mmol/L, but comparison of pre- and postprandial values in healthy rabbits is difficult because of cecotrophy. Persistent high bile acid concentrations may be associated with liver disease.

Laboratory evaluation of proteins

The normal plasma total protein concentration in rabbits (range, 5.4–8.3 g/dL or 54–83 g/L) varies slightly with

breed, strain, and gender. Approximately 40–60% of the total plasma protein is albumin (range, 2.4–4.6 g/dL or 24–46 g/L). The normal plasma globulin concentration generally ranges between 1.5–2.8 g/dL or 15–28 g/L. The normal protein electrophoretic components of rabbit serum also include 5–10% α_1-globulin, 5–10% α_2-globulin, 5–15% β-globulin, and 5–15% γ-globulin. The normal albumin to globulin ratio ranges between 0.5 and 1.2. Female rabbits tend to have higher plasma albumin concentrations than male rabbits. Severe renal and hepatic diseases are responsible for most disorders that result in hypoproteinemia and hypoalbuminemia in rabbits. Hyperproteinemia commonly occurs with dehydration, shock, and hyperthermia. Increased globulin concentrations may be associated with coronavirus infections [1].

Laboratory evaluation of glucose metabolism

The normal plasma glucose concentration of rabbits is influenced by genetics, age, and diet. Pre- and postprandial plasma glucose variation occurs, in which the lowest plasma glucose concentrations are found 1 hour before feeding and the highest 3 hours after a meal. Healthy rabbits can maintain normal plasma glucose concentrations during short periods of fasting (e.g., <16 hours). Extreme hyperglycemia (values greater than 500 mg/dL or 27.76 mmol/L) occurs with diabetes mellitus. Hyperglycemia and increased plasma urea nitrogen concentration occur with the increased protein catabolism associated with hyperthermia. Hyperglycemia resulting from glycogenolysis because of stress occurs early in the course of mucoid enteropathy. This common digestive tract disorder of the rabbit causes anorexia, and when glycogen stores become depleted, the rabbit develops hypoglycemia. Hypoglycemia can also be associated with acute sepsis, liver failure, or other chronic disease. It should be mentioned that the use of the human portable blood glucose meters are acceptable for point-of-care testing of blood glucose concentration in rabbits when laboratory analyzers are not available; however, the use of the veterinary portable blood glucose meters often result in overestimation of glucose concentrations in some rabbits [20].

Laboratory detection of muscle injury

Laboratory detection of muscle injury in rabbits follows the same methods as that in rodents and domestic mammals, in which plasma CK, AST, and LD activities are sensitive to muscle injury. Blood collected by cardiocentesis contains CK-MB isoenzyme activity that is not found in serum collected from the ear vein. Blood collected by jugular venipuncture also contains CK-MB activity. Plasma CK activity (normal range, 150–5000 IU/L), primarily the CK-MM isoenzyme, is a rapid, sensitive, and specific indicator of muscle disease in rabbits, and it increases more rapidly than AST and LD activities after muscle injury (which could be associated with restraint). Nutritional-related myopathies, such as those caused by hypovitaminosis E and selenium deficiency, result in increased plasma CK activity.

Laboratory evaluation of endocrine disorders

Laboratory evaluation of endocrine disorders in rabbits follows the same methods as that in rodents and domestic mammals. The TSH concentration in rabbit serum can be obtained using a bioassay method that measures the percentage increase in blood levels of radiolabeled iodine. Serum T_4 and T_3 concentrations from normal rabbits are listed in Table 35.6. The serum protein-bound iodine concentration, as an indicator of thyroid function in rabbits, increases by 20 days of age before decreasing to adult concentrations by 60 days of age. The serum protein-bound iodine concentration varies with strain, gender, and time of day. The plasma ACTH concentration of rabbits as determined by bioassay is subject to circadian variation. The major plasma glucocorticoid of rabbits is cortisol. Evidence is suggestive that genetics and circadian rhythms influence the plasma aldosterone concentration of rabbits, but little information is available regarding the plasma concentration of parathyroid hormone in rabbits.

Laboratory evaluation of amylase

The normal plasma amylase activity of rabbits generally ranges between 200 and 500 IU/L. Increases are associated with pancreatitis, pancreatic duct obstruction, peritonitis, renal failure, and treatment with corticosteroids [1].

Ferrets (*Mustelus putorius furo*)

Laboratory evaluation of the kidneys

Laboratory evaluation of renal function in ferrets involves blood biochemical tests, such as plasma urea nitrogen, creatinine, protein, bicarbonate, and electrolyte concentrations, and urinalysis. Interpretive considerations for the biochemical tests used to evaluate the kidneys are the same as those in domestic carnivorous mammals such as cats and dogs. In normal and azotemic ferrets, the plasma creatinine concentration is lower than that in dogs and cats. The mean plasma creatine concentration of healthy ferrets is 0.4–0.6 mg/dL (35.4–53.0 μmol/L) with a range of 0.2–0.9 mg/dL (17.7–79.6 μmol/L) [21]. As a result, a moderate increase in the plasma creatinine concentration (i.e. 1–2 mg/dL or 88.4–176.8 μmol/L) in a ferret is significant and suggestive of renal disease [22]. Insulin and exogenous creatinine clearance are sensitive tests for measuring glomerular filtration in ferrets; however, delayed clearance may occur before significant increases in plasma urea nitrogen or creatinine concentrations.

Electrolytes and acid-base

Interpretations of plasma electrolyte and acid-base disturbances in ferrets are the same as those in dogs and cats.

Disorders that commonly result in electrolyte disturbances in dogs and cats, hypoadrenocorticism, hyperaldosteronism, primary hyperparathyroidism, pseudohyperparathyroidism, hypoparathyroidism, and hypercalcitonism, have been poorly documented in ferrets.

Laboratory evaluation of the liver

Evaluation of the livers in ferrets by laboratory testing is the same as that for those in dogs and cats. The ferret liver has 3–10-fold more ALT activity than any other tissue, and the plasma ALT activity is a sensitive and specific test for hepatocellular disease in ferrets. Ferrets with hepatocellular disease commonly have increased AST and LD activities as well. Those with cholestasis likely have increased plasma AP and GGT activities. Ferrets rarely become icteric or have plasma bilirubin concentrations greater than 2.0 mg/dL, even when hepatobiliary disease is severe [22, 23].

Laboratory evaluation of proteins

The causes of hypoproteinemia and hyperproteinemia in ferrets are the same as those in dogs and cats. Ferrets with Aleutian disease typically demonstrate hypoalbuminemia and hyperglobulinemia, in which more than 20% of the total protein is γ-globulins [22].

Laboratory evaluation of glucose metabolism

A high incidence of insulin-secreting pancreatic neoplasms (i.e., insulinomas) resulting in hypoglycemia occurs among domestic ferrets in North America. The normal plasma glucose concentration of ferrets varies with the genetic type. A 4–5-hour fasting plasma glucose level often is used to screen ferrets for insulinomas. It should be noted that significant underestimation of blood glucose concentrations has been detected with use of portable blood glucose meters, which will have a substantial impact on clinical decision making; therefore, verification of blood glucose concentrations in ferrets with a laboratory analyzer is highly recommended [24]. Fasting plasma glucose concentrations less than 60 mg/dL (3.33 mmol/L) are supportive of a presumptive diagnosis of insulinoma, whereas concentrations between 60 and 90 mg/dL (3.33–5.0 mmol/L) merely are suggestive of an insulinoma. Concentrations greater than 90 mg/dL (5.0 mmol/L) usually are considered to be normal. Normal serum reference intervals for serum immunoreactive insulin and the insulin:glucose ratio have been reported as being 4.6–43.3 μU/mL (SI units, 33–311 pmol/L) and 3.6–34.1 μUmg (SI units, 4.6–44.2 pmol/mmol), respectively [1]. To compare immunoreactive insulin and the insulin:glucose ratio results from other laboratories using different radioimmunoassay kits to these reference intervals, however, one must validate the results by demonstrating a high correlation between the two assay methods. Although rarely utilized because measurement of a fasting plasma glucose concentration provides the most reliable method for establishing a strong presumptive diagnosis for insulinoma in the ferret, calculation of an amended insulin:glucose ratio (AIGR) may aid in establishing the diagnosis of hyperinsulinism where

$$\text{AIGR} = \text{insulin}\ (\mu\text{U/mL}) \times 100/\text{fasting glucose}\ (\text{mg/dL}) - 30$$

in which AIGR values greater than 30 are suggestive of hyperinsulinism [25]. Other occasional causes for hypoglycemia in ferrets include delayed separation of plasma from erythrocytes, starvation, chronic hepatic disease, septicemia, and endotoxemia.

Other than a postprandial increase in plasma glucose concentration, hyperglycemia in ferrets may result from glucocorticoid excess (e.g., stress induced, exogenous corticoids, and hyperadrenocorticism), epinephrine release related to exertion, and diabetes mellitus. Diabetes mellitus in ferrets usually is iatrogenic and associated with surgical removal of pancreatic insulin-secreting neoplasms or with drugs, such as megestrol acetate, that affect insulin production and secretion.

Laboratory detection of muscle injury

Detection of muscle injury in ferrets follows the same methods as those described in dogs and cats. Increases in the nonspecific plasma enzymes AST and LD and in the specific muscle enzyme CK are to be expected with muscle injury.

Laboratory evaluation of endocrine disorders

The mean basal plasma T_4 concentration as reported for ferrets ranges between 0.99 and 2.63 μg/dL (12.7–33.8 nmol/L) [26]. A thyroid function test using 1 IU of TSH given intravenously to a ferret and measuring changes in the plasma T_4 concentration is preferable to use of thyrotropin-releasing hormone and measuring changes in the plasma T_3 concentration. The plasma T_4 concentration increases significantly as early as 2 hours after TSH stimulation in normal ferrets, whereas no increase in the plasma T_3 concentration is observed. Plasma T_4 concentration should at least double after TSH stimulation; failure to do so is suggestive of hypothyroidism.

Cortisol is the predominant circulating glucocorticoid in ferrets. The mean basal plasma cortisol concentration as reported for ferrets ranges between 0.45 and 2.13 μg/dL (12.4–58.8 nmol/L) [27]. Intravenous or intramuscular injection of ACTH at a dose of 0.5–1.0 mg/kg to a normal ferret results in a three to fourfold increase in plasma cortisol by 30 minutes that persists for as long as 1 hour. A threefold decrease in plasma cortisol concentration occurs in normal ferrets after intravenous injection of 0.2 mg of dexamethasone. This dexamethasone suppression continues even after 5 hours, when plasma cortisol concentrations demonstrate a four to fivefold decrease.

Domestic ferrets in North America experience a high incidence of adrenal gland neoplasms that produce a number of hormones. Excessive production of estradiol is a common occurrence with adrenal gland neoplasms of ferrets, but excessive cortisol production also can occur. The ACTH stimulation and dexamethasone suppression tests have not been useful in establishing the diagnosis of hyperadrenocorticism associated with adrenal neoplasia in domestic ferrets. Also, primary hyperaldosteronism should be considered as a possible cause in ferrets with hypokalemia, hypertension, and an adrenal gland mass [28].

Less common small mammal pets

African hedgehogs (*Atelerix albiventris*) and sugar gliders (*Petaurus breviceps*) are often presented for veterinary care and blood is often sampled for biochemical testing [15, 24]. Little is known about interpretation of plasma biochemical testing in these omnivorous animals; therefore, results are interpreted in the same manner as domestic nonherbivorous mammals.

Blood for plasma biochemical evaluation can be collected from hedgehogs and sugar gliders by puncture of the jugular vein or cranial vena cava. Both structures cannot be visualized; however, knowledge of their anatomical location should guide one's approach. Jugular venipuncture is performed by inserting a small gauge needle (i.e. 25 gauge) on the ventral aspect of the neck midway between the point of the shoulder and the ramus of the mandible avoiding the trachea and esophagus. Puncture of the cranial vena cava is performed by inserting the needle at the thoracic inlet (sternal notch) using a 30° angle and pointing the needle in the direction of the opposite hip.

36 Clinical Chemistry of Birds

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

Sample collection and handling

A blood sample representing 1% of the bird's body weight is generally accepted to be a safe volume of blood that can be obtained from nonanemic and dehydrated birds. Avian veterinarians often collect the blood sample into a syringe that contains sodium heparin; however, this is not necessary because a quality sample can be collected in a nonheparinized syringe as long as the blood is immediately transferred into a microcollection tube containing lithium heparin, which must be filled to the appropriate volume. Adding heparin to the syringe has the risk of causing sample dilution and interference with analytical testing of sodium and protein. Once the sample has been collected into a syringe, it should not be passed through the needle a second time, especially small bore needles (25 gauge or smaller); the needle should be removed before blood is dispensed into collection tube to minimize hemolysis of the sample.

Most chemical analyses are conducted on plasma, although testing could also be performed on a serum sample. The reason for this is that collection of serum from birds frequently yields a very small sample size compared to what can be obtained from plasma. This is especially important when collecting blood from very small birds. Also, avian serum often clots once it has been harvested, and the gelled sample is difficult to analyze. Therefore, based on higher sample yield and lack of clinically relevant differences from serum, plasma is a better sample choice for clinical chemistry analysis in birds.

The method by which blood samples are collected and handled during processing has a significant effect on the test results. Blood should be collected rapidly, immediately transferred into the lithium heparin collection tube, and mixed well with the anticoagulant. Hemolysis of the sample during collection and handling should be avoided. Hemolysis results if blood is placed into tubes too quickly, agitated too vigorously while mixing with an anticoagulant, or improperly stored. Blood that is stored at room temperature for a period of greater than 1 hour, kept at too high a temperature, or frozen will hemolyze. In general, the significant changes that occur with hemolysis in the avian sample involve the analysis of potassium, phosphorus, albumin, and lactate dehydrogenase (LD) [1].

Fasting samples are not often obtained from birds, because withholding food from birds that are sick is not advisable. Also, considering the nature of their digestive physiology and anatomy, a fasting state may be difficult to achieve safely. As a result, plasma samples obtained from birds are often lipemic, which can interfere with many biochemical tests. In some avian species, it is normal for the plasma to be yellow because of carotenoid pigments from the diet. It is important to note that such samples do not represent icterus and the pigment does not interfere with biochemical testing.

Reference intervals and decision levels

Published reference intervals for biochemical tests for a few of the common species of birds seen in veterinary practices traditionally have been established to produce a 95% confidence interval for each analyte. Establishment of normal reference intervals for a given species of bird depends on many factors, including age, state of health, and nutrition. Because of the avian patient's ability to mask illness, it is often difficult to guarantee that a given bird is free of disease for inclusion into a population of normal healthy birds. Likewise, because the nutritional requirements for most birds are unknown, it is difficult to determine if their nutritional needs are being met. Both environmental factors and the physiologic status of the birds should be considered when establishing reference values. Factors such as gender, age, temperature, humidity, photo period, season of the year, and time of day may influence the results of a particular analyte [2]. Also, methodology often varies among veterinary laboratories, which can create difficulty when comparing laboratory data obtained from one center with reference values provided by another. For these reasons, reference

values should be established for an individual bird during health, and the same laboratory should be used so that subtle changes in the blood biochemistries can be detected.

Use of a point-of-care analyzer has proven to be useful in avian medicine because of the ability to perform a basic avian biochemistry panel on 0.1 ml of whole blood or plasma. Other advantages of this technology include a short turnaround time of obtaining results, the small size of the analytical instrumentation, affordability, minimal requirement technical training to perform the analysis, and acceptable clinical performance with avian samples for some analytes. The results obtained from point-of-care analyzers when compared to those obtained from reference laboratory analyzers (considered to be the gold standard) has often shown that the two methods are not analytically equivalent [3]. These studies have generally involved small sample sizes, healthy birds, and just a few species. Therefore, use of heterogeneous data to assess the agreement between the two methods in a wide analytic range require larger studies on a widely varying sampling of birds is required to properly investigate the clinical adequacy of the point-of-care analyzer technology in avian blood biochemistry [3].

Because of the difficulty in obtaining meaningful reference intervals for each species of bird that may be presented to a veterinary hospital, many avian clinicians use decision levels when assessing avian biochemical profiles. Although variations associated with factors such as seasonal variability, circadian rhythm, and gender may be significant, they may be too small to influence the clinical decision making process. Decision levels are threshold values above or below which a decision is made to respond to the abnormality. The response may vary from repeating the test, ordering additional tests, or treatment of the patient. Decision levels may be obtained by using published reference intervals and by applying these values to those obtained by the laboratory. Decision levels may vary among avian clinicians depending on their experience and the laboratory results. Values suggested in this text for each analyte in the avian blood profile are simply guidelines that can be used as decision levels. Obtaining a set of normal values from the healthy individual bird housed in a stable environment with a consistent husbandry protocol can refine the process of evaluating that avian patient later when it becomes ill. Therefore, when the bird becomes ill, it has its own set of normal reference values for comparison.

Laboratory evaluation of the avian kidney

Normal anatomy and physiology of the avian kidney

The avian urinary system consists of paired kidneys that are located in the renal fossa of the synsacrum. Each kidney is composed of three divisions: cranial, middle, and caudal. In turn, each division is composed of lobules that contain poorly demarcated, large cortical areas and smaller medullary areas. A ureter transports urine from each kidney to the urodeum of the cloaca. Unlike mammals, birds lack a renal pelvis and a urinary bladder.

Birds have two types of nephrons [4]. The superficial cortical or reptilian-type nephron has a glomerulus with a tubular system that is devoid of loops of Henle and is located entirely in the cortex. Cortical nephrons radiate around the central efferent veins to form lobules, and they empty at right angles to the collecting ducts. The deeper medullary or mammalian-type nephron has a glomerulus with a tubular system that contains loops of Henle. Therefore, medullary nephrons are involved in the countercurrent multiplier and osmotic gradient process to form urine as in mammalian kidneys. The glomeruli of birds are smaller with lower filtration rates (glomerular filtration rate [GFR]) compared to those of mammals; however, they more numerous and as a result the overall GFR of birds is similar to that of mammals [4]. The loops of Henle and the collecting ducts that drain both types of nephrons are bound by connective tissue to form a medullary cone, and each cone ends as a branch of the ureter.

Birds have a juxtaglomerular apparatus but only a rudimentary macula densa. The juxtaglomerular apparatus consists of an afferent arteriole, secretory juxtaglomerular cells that produce renin, and extaglomerular mesangial cells. Renin leads to the formation of angiotensin I and II, which are vasoconstrictors that stimulate the release of aldosterone. In turn, aldosterone stimulates NaCl and water reabsorption by the distal convoluted tubules and collecting ducts.

Blood is supplied to the kidney by the renal arteries, which eventually supply the afferent glomerular arterioles. Avian kidneys also receive blood from a renal portal system, in which the renal veins behave as arteries and supply blood to the kidney tubules; however, the amount of blood supplied in this manner varies with species, stress, and temperature [4]. The cranial and caudal portal veins, which receive blood from the pelvic limbs, intestines, and oviduct, form a vascular ring around the kidney. Valves at the junction of the bifurcation of the external iliac veins control the renal portal blood supply; these valves are controlled by both adrenergic and cholinergic nerves. The renal portal system facilitates tubular secretion by the cortical nephrons by supplying blood to the peritubular capillary plexus, which supplies the cortical nephron and the proximal and distal tubules of the medullary nephron.

The avian kidney plays a major role in osmoregulation by maintaining water homeostasis and electrolyte balance. The avian kidney filters large volumes of water that is later resorbed by the tubules. The medullary nephron concentrates urine by the counter current multiplier mechanism; however, it is less efficient than mammalian kidneys, perhaps because urea does not play a role in medullary hypertonicity among birds. Filtration occurs in the glomeruli, in which crystalloids and substances of small and medium molecular

size pass into the glomerular filtrate. Electrolytes, glucose, uric acid, urea, and creatinine are a few of the substances that are removed from blood by glomerular filtration. Some filtrates (e.g., glucose) are reabsorbed by the tubules. The GFR of birds is more variable than that of mammals because of intermittent filtration by avian glomeruli. The GFR, as measured by inulin clearance, varies between 1.2 and 4.6 ml/kg per minute and is affected by the state of hydration. Arginine vasotocin, like mammalian vasopressin, decreases the GFR and increases water reabsorption in response to dehydration or increases in plasma osmolality [5]. The avian kidneys respond to a decrease in the GFR as occurs with dehydration by shunting blood from the reptilian-type nephrons to the mammalian-type nephrons because of the latter's ability to concentrate urine. This urine concentration ability varies between species and appears to be related to the size of the bird; smaller birds have a greater ability to concentrate urine than do large birds.

The intestinal tract and salt glands of birds also aid the kidneys in their osmoregulatory function. Urine that makes its way to the urodeum of the cloaca can retropulse into the rectum via the coprodeum where water can be resorbed. This retropulsion can have a profound effect on the urinalysis.

Other important functions of the avian kidneys include excretion of metabolic wastes and toxins, metabolism of vitamin D, and production of erythropoietin.

Blood chemistry evaluation

Uric acid, produced by the liver and kidneys, is the major end product of nitrogen metabolism in birds. Uric acid is excreted primarily by renal tubular secretion and is largely independent of tubular water resorption; however, decreased GFR from severe dehydration may result in stasis of uric acid movement through the tubules [5]. The principal site of uric acid secretion appears to be in the proximal tubules of the cortical nephrons. Approximately 90% of blood uric acid is removed by the kidneys [4]. Therefore, evaluation of the serum or plasma uric acid concentration has been widely used in the detection of kidney disease in birds. In general, a blood uric acid concentration greater than 13 mg/dL (750 Umol/L) is suggestive of impaired renal function from a variety of causes, including nephrotoxins such as lead or aminoglycoside antibiotics, urinary obstruction, nephritis, nephrocalcinosis, and nephropathy associated with hypovitaminosis A. The blood uric acid concentration is influenced by species, age, and diet. Juvenile birds tend to have lower blood uric acid values than adults, and carnivorous birds tend to have higher concentrations than granivorous birds. Increases in blood uric acid may be observed in birds shortly after consumption of a high-protein meal [6]. This is especially apparent among raptors, in which 24-hour fasting is required to avoid postprandial increases in plasma uric acid concentration. The uric acid concentration may also increase with severe tissue necrosis or starvation because of increased catabolism of nitrogenous compounds such as proteins and nucleic acids.

When the plasma uric acid concentration exceeds the solubility of sodium urate, uric acid (in the form of monosodium urate monohydrate crystals) precipitates in tissues, which is a condition known as gout. Birds with gout exhibit precipitation of urate crystals especially in the synovial joints and on the visceral surfaces. Blood uric acid concentrations are extremely increased (e.g., fivefold greater than normal) in birds with gout and result from severe renal dysfunction.

Uric acid is not a sensitive test for renal disease in birds, because a significant loss (approximately 75%) of renal function is required to increase the blood concentrations of this analyte. Uric acid is also not a specific test for renal disease, because increases can occur after ingestion of a high-protein meal, during starvation, or with severe tissue necrosis. Therefore, whereas the blood uric acid can be used as an indicator of renal function in birds, it does not provide a diagnosis, nor do normal values guarantee an absence of renal disease. Blood uric acid concentration when used as a sequential evaluation can be useful in monitoring treatment or progress of disease.

Because birds are uricotelic, they possess only very small quantities of urea in plasma. Urea is formed in the liver as a product of protein catabolism, and higher concentrations are present in carnivorous than in granivorous birds because of differences in dietary protein intake. The normal blood urea nitrogen (BUN) concentration of normal, noncarnivorous birds ranges between 0 and 5 mg/dL (0–1.8 mmol/L). Urea is generally considered to have limited diagnostic value in the detection of renal disease in birds compared with that of uric acid. Unlike uric acid, which is generally excreted independently of hydration, BUN may be a sensitive test for prerenal azotemia in some avian species because it is eliminated by glomerular filtration, which depends on the hydration status of the bird. Therefore, an increased BUN concentration may be useful in the detection of reduced renal arterial perfusion in some birds. Like the uric acid concentration, the plasma urea nitrogen concentration increases in birds, especially raptors, after ingestion of a high-protein meal. Plasma BUN and uric acid values are often evaluated together in an effort to differentiate prerenal azotemia, renal pathology, and postprandial effects.

Severe renal disease may result in an increased plasma creatinine concentration; however, creatinine is usually considered to have poor diagnostic value in birds. One reason for this is that in birds, creatine is excreted by the kidney before it is converted to creatinine. Therefore, physiologic creatinine concentrations of birds are below the limit of quantification of commonly used creatinine assays [7]. Thus, the measurement of plasma creatinine concentration in birds does not provide a useful assessment of the GFR as it does in mammals. Plasma creatine rather than the creatinine concentration may better detect a decreased GFR in birds.

Unfortunately, veterinary laboratories do not routinely provide creatine analysis.

Potassium is filtered and actively excreted by the kidneys. Birds with severe renal disease may retain potassium and develop hyperkalemia.

Sodium is filtered by the glomerulus and, depending on the osmotic needs, may be resorbed into the plasma or secreted by the kidney tubules for elimination. Birds with chronic renal disease may lose the ability to retain sodium, thereby resulting in hyponatremia.

Hyperphosphatemia can occur in birds with severe renal disease. However, it is not a consistent finding with decreased GFR.

The presence of upper gastrointestinal hemorrhage in mammals leads to a disproportionate increase in BUN concentration relative to reductions in the GFR resulting in a greater BUN:creatinine ratio. This does not appear to occur in birds where it has been demonstrated that plasma BUN, creatinine, and uric acid concentrations are unaffected by the presence of blood in the digestive tract.

Urinalysis

A urinalysis, which routinely is applied to mammalian urine, also can be performed on avian urine. Indications for performing a urinalysis on an avian patient include polyuria, azotemia, and abnormal appearance of the urinary component of the dropping. The urinalysis includes notation of the gross appearance, measurement of the specific gravity or osmolality, chemical evaluation, and microscopic examination.

Urine is collected by aspirating the liquid part of the dropping into a pipette or syringe once the dropping has been deposited onto a nonabsorbable surface (e.g., aluminum foil or wax paper). Aspiration of fecal material or urates along with the liquid urine should be avoided. Ureteral urine enters the cloaca and is forced into the colorectum by antiperistaltic activity, thereby allowing reabsorption of water and electrolytes to occur. For this reason, exposure of urine to cloacal membranes and the large intestine cannot be prevented; however, this exposure is presumed to be minimal when urine is produced at moderate to high rates. Catheterization of the ureter is possible but not routinely performed because it requires general anesthesia and is technically difficult.

Normal avian urine is the clear fluid component of a bird's droppings. The amount of urine produced varies with species, diet, and environmental factors, such as temperature and humidity. Generally, avian urine is hyperosmotic to plasma (362–2000 mOsmol/L), especially in birds that have adapted to arid environments; however, this is affected by the hydration status of the bird. The normal specific gravity of avian urine ranges from 1.005 to 1.020 depending on the species, hydration status, and osmolality [5]. Osmolality is a direct measure of the number of solute particles in the urine, whereas the specific gravity is a crude index of renal tubule function and is affected by the number, size, and weight of solute particles in the urine. The two determinations are related, however, and both can be used to determine the loss of concentrating ability in birds with renal disease. A urine osmolality of 450 mOsmol/kg represents the normal renal concentrating ability in the pigeon (*Columbia livia*) and can be used as a guide for water-deprivation studies in that species.

The color of avian urine can be helpful in detection of certain diseases. For example, a biliverdinuria represented by green urine is suggestive of severe liver disease or hemolysis in birds. Yellow urine is observed in some species such as macaws with liver disease, and this most likely represents bilirubinuria. Hematuria or hemoglobinuria is represented by red urine that changes to brown on standing. Polyuric birds produce liquid urine that may appear to be cloudy if contaminated with urates or containing large concentrations of cells, mucus, fat, or bacteria. Microscopic examination can determine the cause of the cloudy appearance. Green bile pigment from the feces and dietary pigments can stain the urine especially if the dropping is held in the cloaca for a prolonged period of time. A positive urobilinogen on the test strip is supportive of fecal contamination of the urine sample.

The principle difference in the nitrogenous components of avian urine compared with those of mammalian urine is the large amount of uric acid and creatine. Uric acid in avian urine typically occurs as a thick, mucoid, white to cream-colored colloidal suspension containing the small spherical conglomerates of insoluble sodium and potassium urates and protein. This semisolid material is not part of the specific gravity measurement of the urine supernatant.

Commercially available test strips for biochemical examination of mammalian urine can be used for avian urine as well [8]. These test strips usually indicate a negative to trace amount of protein in the urine of normal birds. Protein not reabsorbed from the proximal tubules becomes part of the urate conglomerate, which is not measured in the supernatant. For this reason, renal loss of protein may be difficult to detect by urinalysis; however, detection of significant proteinuria in the absence of hematuria, hemoglobinuria, and fecal contamination of the sample is suggestive of the renal proteinuria that occurs with abnormal glomerular permeability, such as that which occurs with glomerulonephritis. Alkaline urine (pH >8) can produce a false-positive reading in the protein portion of the test strip. Therefore, other methods for testing urine protein should be employed with alkaline urine. Postrenal proteinuria is associated with inflammation of the lower urinary tract and cloaca.

The pH of avian urine varies from 4.7 to 8.0 and depends primarily on the diet. Carnivorous birds that ingest large amounts of animal protein have acidic urine, whereas granivorous birds have more alkaline urine. Increased urine acidity (pH <5.0) may result from acidosis or increased

protein catabolism, such as that which occurs during starvation. Increased urine alkalinity (pH >8.0) may be associated with alkalosis. The urine pH also can vary with physiologic state. For example, in poultry, acidic urine is observed in laying hens that are depositing calcium into developing egg shells.

Urine from normal birds contains no glucose, because glucose is completely reabsorbed by the tubules after glomerular filtration. Glucosuria occurs when the renal threshold for glucose is exceeded. In most birds, this threshold is approximately 600 mg/dL. Birds with diabetes mellitus, however, often exhibit blood a glucose concentration of greater than 800 mg/dL and significant glucosuria.

Normal avian urine is devoid of ketones. Excessive ketone formation and ketonuria occurs with increased oxidation of fatty acids as an energy source. This may explain the ketonuria found in migratory birds following migration. Ketonuria may be expected with severe malnutrition or diabetes mellitus, but this has been poorly documented in birds. One explanation for negative ketones in avian urine may be a result of the urinalysis test strips that do not test for the major ketones produced by birds.

Biliverdin is the major bile pigment of birds; therefore, bilirubin is not normally present in the urine. Biliverdin does not react with the bilirubin portion of the urine test strip. Biliverdinuria is indicated by a green coloration of the urine and is suggestive of hepatobiliary disease or hemolysis in birds. The normal urinary urobilinogen concentration in birds ranges from 0 to 0.1 mg/dL. In general, this test has limited diagnostic value in birds and when positive suggests fecal contamination of the sample.

Occult blood in the urine of a normal bird measures negative to trace on the urinary test strips. A positive occult blood reaction is suggestive of erythrocytes, free hemoglobin, or myoglobin in the urine. Microscopic examination of the urine sediment can determine the presence of erythrocytes. A positive test of the supernatant after centrifugation is suggestive of hemoglobinuria, and increased plasma creatine kinase (CK) values may be supportive of myoglobinuria. Hematuria is indicative of hemorrhage originating from either the urinary, reproductive, or gastrointestinal tracts or the cloaca. Hemoglobinuria is suggestive of the intravascular destruction of erythrocytes or, perhaps, the lysis of erythrocytes in hypotonic urine. Hemoglobinuria has been reported in psittacine birds with heavy metal toxicity, especially lead poisoning.

Urinary nitrite tests are designed to detect bacteriuria. This test has limited diagnostic value, however, in the urine of birds.

Microscopic examination of urine is an important part of urinalysis. Whereas 5 ml of urine is suggested to provide a uniform semiquantitation in mammalian urine, this amount rarely is achieved in most avian samples. Microscopic examination, however, can still provide valuable information.

Normal avian urine contains few cells. As many as three erythrocytes and three leukocytes per high-power field (40×) are considered to be normal in direct smears of the urine. Epithelial cells are rare in normal avian urine samples and can originate from the urinary tract, gastrointestinal tract, reproductive tract, or cloaca. Increased cell numbers are a cause for concern.

Casts in the urine of birds are indicative of renal disease, because casts are formed within the renal tubules. Granular casts are the most common and are suggestive of renal tubular epithelial cell degeneration (i.e., tubular nephrosis). Cellular casts also may be present, and the types of cells that are observed reflect the renal pathology. Casts containing epithelial cells are suggestive of acute tubular damage that results in sloughing of the cells that line the tubules. Leukocytes in the casts are indicative of renal inflammation (nephritis). Erythrocytes within the casts are indicative of renal hemorrhage and, typically, occur after trauma to the kidneys.

Crystals in avian urine sediment are primarily sodium and potassium urates. These are round crystals with a spoke-like appearance that are refractile under polarized light. The needle-shaped uric acid crystals may also be present in avian urine. A few drops of sodium hydroxide can be added to the urine sample to dissolve the uric acid crystals to facilitate the examination of the cellular components in the urine.

Microorganisms in urine sediments usually originate in the intestinal tract or cloaca, and represent contamination of the sample. Large numbers of bacteria, however, may be indicative of a urinary tract infection, especially when they occur as a uniform population of a single morphologic type and when casts are present. Because bacteria frequently contaminate avian urine samples and multiply during storage, resulting in artificially high bacterial numbers, fresh samples should be examined.

Electrolytes and acid-base balance

Water consumption in birds is influenced by species, age, size, environmental temperatures, and both the type and amount of food that is consumed. Water intake often relates inversely to body size and ranges between 5% and 50% of body weight per day [4]. Young birds tend to consume more water than adults. Carnivorous birds as well as those that have evolved in arid environments normally drink little water.

Water deprivation, hemorrhage, or administration of hypertonic saline produces thirst in birds, which is caused by the release of angiotensin II [4]. Angiotensin II induces the release of arginine vasotocin (i.e., antidiuretic hormone [ADH]), aldosterone, and corticosterone. Arginine vasotocin increases the reabsorption of water in the renal tubules and collecting ducts; other neurohormonal factors

also play a role in the hypothalamic regulation of water intake. Disorders of the hypothalamus and deficiency of ADH from the posterior pituitary result in diabetes insipidus, thereby causing polydipsia and polyuria. These conditions have been reported in chickens and a few other species. A water-deprivation test or administration of exogenous ADH can be performed to differentiate polyuric disorders of birds. In chickens, water deprivation increases the plasma osmolality from 315 to 325 mOsm/L after 24 hours and to 340 mOsm/L after 72 hours. During dehydration and 24-hour water deprivation, the urine osmolality of normal birds is greater than 450 mOsm/L.

The ability of the avian kidney to conserve and excrete water has a wider range than that of mammals. The fractional excretion of water in birds can be as high as 33% during hydration and as low as 1% during dehydration. Cessation of renal water loss during dehydration results partially from shutdown of the cortical nephrons; it is not strictly a function of the tubular resorption of water.

Electrolyte metabolism in birds is similar to that of mammals. Therefore, predominate extracellular and intracellular anions and cations are similar in both types of animals.

Although point-of-care devices are commonly used to assess electrolyte, blood gas, biochemical, and hematologic values in humans and companion mammal critical care settings, few studies have assessed their use in birds. Studies suggest that these devices appear to be acceptable clinical tools in avian critical care, although reference ranges for each analyzer have been recommended [9].

Sodium

Sodium is the primary osmotically active electrolyte in the plasma and urine of birds. Dietary sodium is absorbed in the intestines and carried to the kidneys, where it is excreted by glomerular filtration. Depending on the need for sodium by the bird, sodium may be resorbed into the plasma or secreted by the renal tubules and then excreted.

Birds having salt (i.e., nasal) glands can excrete large amounts of sodium by an extrarenal route. The paired salt glands are located just above the orbits in most marine birds. Ducts from these glands deliver secretions into the nasal cavity, which flow through the nares and drip off the tip of the rhinotheca (i.e., beak). Nasal secretion of sodium occurs not only in marine species but also in at least two orders of terrestrial birds (falconiforms and cuculiformes) [4]. Salt glands also are found in ducks and geese. The typical concentration of sodium in the salt-gland secretions of most species that have been studied ranges between 500 and 1000 mEq/L (mmol/L) [4]. The rate of sodium secretion by the salt glands varies among species, however, as do the degrees of hydration and salt loading. The primary stimulus for salt-gland secretion is plasma osmolality, but hormonal influences also affect nasal secretion, which is increased by adrenal corticosteroids and aldosterone. Holopelagic species of birds whose physiologic regulation of salt depends upon the salt glands, gastrointestinal tract, and renal systems demonstrate significant decreases in serum sodium and chloride concentrations (as much as 72% of the normal reference values) when house in freshwater [10].

Hyponatremia in most species occurs when the plasma sodium concentration is less than 130 mEq/L (mmol/L). Diseases affecting the kidneys, gastrointestinal tract, or perhaps, the salt gland can be associated with excessive sodium loss. Excessive hydration because of polydipsia or iatrogenic delivery of low-sodium intravenous fluids (e.g., 5% dextrose in water) also can result in hyponatremia. Hyponatremia can be corrected by addressing the cause of the sodium loss, control of overhydration, or use of fluid therapy with an appropriate electrolyte balance.

Hypernatremia occurs when the plasma sodium concentration exceeds 160 mEq/L (mmol/L) and may be due to excessive dietary salt intake, decreased water intake, or increased water loss. After salt loading, hypernatremia occurs more rapidly in birds without functional salt glands. Marine birds that are given freshwater over a period of time exhibit atrophy of the salt glands, thereby resulting in hypernatremia after the ingestion of salt water. Hypernatremia associated with salt loading can be associated with excessive dietary sodium or administration of intravenous fluids containing excessive sodium. Hypernatremia associated with excessive free-water loss occurs with diarrhea, renal failure, or rarely, diabetes insipidus.

Chloride

Chloride is the anion of highest concentration in the extracellular fluid. Chloride and sodium represent the primary osmotically active components of plasma. For most species, hypochloridemia is indicated by a plasma chloride concentration of less than 100 mEq/L (mmol/L), whereas hyperchloridemia is indicated by a plasma chloride concentration greater than 120 mEq/L (mmol/L). These conditions rarely are reported in birds. Hyperchloridemia can be associated with dehydration and salt loading.

Potassium

Potassium is the major intracellular cation. Therefore, an artifactual increase in the serum or plasma potassium concentration occurs with hemolysis. Artifactual hyperkalemia or hypokalemia may occur with delayed separation of the cells in the sample, and these changes are species specific. For example, a 30% increase in plasma potassium occurs in macaws (*Anodorhynchus* sp.) following a four-hour delay in plasma separation, whereas a 30% decrease was found in chickens (*Gallus gallus*) following a two-hour delay in plasma separation [5]. True hyperkalemia in most species is indicated by a plasma potassium concentration of greater than 4.0 mEq/L (mmol/L). Hyperkalemia results from renal failure with decreased secretion of potassium, acidosis, and

severe tissue necrosis. Hypokalemia in most species of birds is indicated by a plasma potassium concentration of less than 2.0 mEq/L (mmol/L). Hypokalemia can be associated with chronic diarrhea, prolonged anorexia, and alkalosis. Hypokalemia has also been reported in birds with renal disease, which may be associated with chronic loss of potassium in the urine. Use of potassium-poor fluids during fluid therapy in chronically anorectic birds may dilute the plasma potassium to a hypokalemic level, which may enhance the renal loss of potassium. Diuretic therapy rarely is used in birds, but it may enhance renal potassium loss as well. Imbalances of plasma potassium may result in muscle weakness, serious cardiac disturbances (e.g., sinus bradycardia and arrest), or both. Hypokalemia can be corrected with the addition of potassium to supportive fluids.

Calcium

Control of calcium metabolism is mediated by parathormone (PTH), calcitonin, and vitamin D3 (i.e., 1,25-dihydrocholecalciferol, calciferol). Other hormones, such as estrogens, corticosteroids, thyroxine (T_4), and glucagon, also influence calcium metabolism. The primary function of PTH is to maintain normal plasma calcium concentrations by its action on bone, kidney, and intestinal mucosa. When plasma concentrations of ionized calcium decrease, the parathyroid glands are stimulated to release PTH. The primary effect of this is to mobilize calcium from bone; however, increased calcium absorption by intestinal mucosa and calcium reabsorption by renal tubules also aid in the restoration of normal plasma ionized calcium concentration. Parathormone also enhances the renal excretion of phosphorus to maintain a normal calcium:phosphorus ratio.

Calcitonin is produced by the ultimobranchial glands of birds. Avian C cells, which are the calcitonin-secreting cells, migrate from the sixth pharyngeal pouch during embryonic development to form the ultimobranchial gland. In some species of birds, C cells also can be found in parathyroid or thyroid tissue. Calcitonin has the opposite action from that of PTH. Therefore, as the plasma calcium concentration increases, calcitonin is released to inhibit calcium reabsorption from bones.

Calciferol, which stimulates calcium and phosphorus absorption by the intestinal mucosa, increases the sensitivity of bone to the effects of PTH and is important for bone mineralization. The kidney is involved with the conversion of vitamin D_3 to its hormonally active state, 1,25-dihydroxycholecalciferol (calciferol). Renal synthesis of 1,25-dihydroxycholecalciferol is regulated at least partially, by PTH.

Birds differ from mammals by the increased development of medullary bone in the long bones (of hens) before egg laying, hypercalcemia in response to estrogen (and reproductive activity) in females, and the ability of hens to use 10% of their total body calcium stores for egg production on a daily basis for extended periods without detrimental physiologic consequences. Calcium deposition occurs in the medullary spaces of the femur, tibiotarsus, and other nonpneumatic long bones in female birds during the first 10 days before oviposition (egg-laying). This is referred to as medullary bone formation, and it is under the influence of the ovarian hormones, estrogen and testosterone. Medullary bone formation occurs 1–2 weeks before the increase in total plasma calcium concentration and renal hydroxylase activity that increases formation of the hormonally active vitamin D_3. During the ovulation-oviposition cycle, periods of medullary bone formation alternate with periods of medullary bone depletion.

Prolactin and sex hormones influence the 1-hydroxylation of 25-hydroxyvitamin D_3 in the kidney, which in turn plays an important role in calcium metabolism. This activity increases just before egg laying and corresponds to the increase in total blood calcium concentration. Therefore, the renal vitamin D endocrine system is involved in the increased intestinal calcium absorption during the ovulation-oviposition cycle of laying hens.

The total blood calcium concentration of a laying hen ranges from 20 to 30 mg/dL (5.0–7.5 mmol/L). Total calcium consists of ionized calcium, which is the biologically active form, and calcium bound to anionic proteins and nonprotein anions. Estrogen stimulates the production of calcium-binding proteins such as vitellogenin and albumin; therefore, the total plasma calcium concentration increases because of an increase in protein-bound calcium. This occurs several weeks before oviposition in chickens. The ionized calcium level remains unchanged.

Calcium for egg formation is derived from intestinal absorption and bone mobilization. If the dietary calcium is adequate, then most of the eggshell calcium is derived from intestinal absorption. Bone is an important source of eggshell calcium during the night, when food is not being consumed, or if the dietary calcium intake is inadequate.

The normal plasma concentration of calcium in most nonlaying birds ranges from 8.0 to 11.0 mg/dL (2.0–2.8 mmol/L). Approximately one-third to one-half of the plasma calcium is bound to albumin. Therefore, the total plasma calcium concentration is affected by the plasma albumin or total protein concentration; however, this may vary with species. In general, the total plasma calcium concentration usually decreases with hypoalbuminemia and increases with hyperalbuminemia. A significant correlation between total calcium and albumin has been determined for African Gray parrots (*Psittacus erithacus*) with the following correlation formula:

$$\text{Adjusted Ca (mmol/L)} = \text{Ca (mmol/L)} - 0.015 \times \text{Albumin (g/L)} + 0.4$$

A significant correlation was found between total calcium and total protein in the ostrich (*Struthio camelus*) and

Peregrine falcon (*Hierofalco peregrinus*) with correlation formulae for the ostrich:

$$\text{Adjusted Ca (mmol/L)} = \text{Ca (mmol/L)} - 0.09 \times \text{Total protein (g/L)} + 4.4$$

And for the Peregrine falcon:

$$\text{Adjusted Ca (mmol/L)} = \text{Ca (mmol/L)} - 0.02 \times \text{Total protein (g/L)} + 0.67$$

These examples indicate that the total calcium, albumin, and total protein concentrations have a linear relationship that varies between species of birds [5]. These formulae may not be clinically useful when dealing with other avian species.

Evaluation of ionized calcium would be more clinically useful because it is the most physiological active fraction of the total calcium concentration; however, there have been few studies evaluating ionized calcium to disease states in birds and reference values have not been established. Ionized calcium concentration of birds that have been studied suggest that normal concentrations range between 1.0 and 1.6 mmol/L. The concentration of ionized calcium is affected by the acid-base balance. The ionized calcium level will increase during acidosis and decrease during alkalosis.

Most species of birds are considered to be hypocalcemic when the plasma total calcium concentration becomes less than 8.0 mg/dL (2.0 mmol/L), and hypocalcemia has been associated with dietary calcium and vitamin D_3 deficiency, excessive dietary phosphorus, alkalosis, and hypoalbuminemia. African Gray parrots often exhibit a hypocalcemic syndrome with a plasma calcium concentration of less than 6.0 mg/dL (1.5 mmol/L) that results in seizure disorders. The pathophysiology of this condition is unknown, but it has been considered to be a form of nutritional hypoparathyroidism or, possibly, a result of hypovitaminosis D_3. Secondary nutritional hyperparathyroidism commonly is observed in birds that are fed calcium-poor diets (e.g., all-seed or all-meat diets). Affected birds have a decreased plasma calcium concentration, normal plasma phosphorus concentration, and increased plasma alkaline phosphatase (AP) activity.

Hypercalcemia in most species of birds is indicated by a plasma calcium concentration of greater than 11 mg/dL (2.7 mmol/L). Hypercalcemia has been associated with hypervitaminosis D_3, osteolytic bone lesions secondary to neoplasms, and hyperalbuminemia. Causes of hypercalcemia in mammals, such as primary and pseudohyperparathyroidism, certain plant toxicities, and hypoadrenocorticism, have not been documented in birds but should also be considered as possible causes of this condition.

Phosphorus

Plasma phosphorus is primarily regulated via renal excretion stimulated by PTH. Young, growing birds tend to have higher plasma phosphorus concentrations compared with adult birds.

Hypophosphatemia in birds is indicated by plasma phosphorus concentrations of less than 5 mg/dL (1.6 mmol/L). This may occur with hypovitaminosis D_3 (hypocalcemia also occurs), malabsorption, or starvation. Long-term corticosteroid therapy also may result in hypophosphatemia in birds; other disorders in mammals that result in hypophosphatemia have not been reported in birds but should also be considered as possible causes.

Hyperphosphatemia in birds is indicated by plasma phosphorus concentrations of greater than 7.0 mg/dL (2.3 mmol/L), and may occur with severe renal disease because of reduced glomerular filtration, hypervitaminosis D_3 resulting in increased intestinal phosphorus absorption, and excessive dietary phosphorus. Hypoparathyroidism also may be considered in some cases of hyperphosphatemia in birds. Improper sample handling can cause artifactual hyperphosphatemia because erythrocytes contain a higher concentration of phosphorus than is present in plasma. Therefore, hemolysis or delayed separation of plasma from erythrocytes, which allows intracellular phosphorus to leak out, will increase the plasma phosphorus concentration.

Acid-base balance

The normal pH of birds is maintained between 7.33 and 7.45, and the buffering systems that regulate blood pH in mammals appear to be present in birds. The bicarbonate/carbonic acid buffer system is the most important because of the rapid rate of CO_2 elimination by the lungs after conversion from H_2CO_3. Therefore, alterations in plasma bicarbonate and CO_2 content are useful in the detection of acid-base disturbances in birds. Because most CO_2 in plasma is derived from bicarbonate, the clinical interpretation of the total CO_2 concentration is the same as that of the bicarbonate concentration. The total CO_2 concentration rarely is reported, but concentrations between 20 and 30 mmol/L are considered to be normal for most species. Increases in the total CO_2 concentration are suggestive of a metabolic alkalosis or a compensation for a respiratory acidosis, whereas decreases are suggestive of a metabolic acidosis or compensation for a respiratory alkalosis, as occurs with excessive ventilation. During active shell formation in laying hens, the plasma bicarbonate concentration decreases, thereby resulting in a metabolic acidosis.

Blood gases rarely are determined in birds. Avian erythrocytes continue to be metabolically active after blood collection, and alterations in blood gas values *in vitro* can occur quickly. These alterations are influenced by temperature; therefore, blood gas analysis should be performed as

quickly as possible after sample collection. Portable blood gas analyzers that are designed for bedside monitoring of human patients may provide a quick, reliable method for monitoring blood gases in birds.

Laboratory evaluation of the avian liver

Liver enzymes

Interpretation of liver enzyme activity, as commonly used in mammalian medicine, has been applied to birds. However, experimental studies evaluating the sensitivity and specificity of these enzymes for detecting liver disease have been limited to only a few avian species. Because the specificity and sensitivity of these enzymes may vary with the species and the type of hepatic disease, only general statements regarding alterations in enzyme activity can be made. Alterations in the plasma activity of enzymes used to detect hepatic disease in birds can reflect either hepatocellular injury or increased enzyme production.

Aspartate aminotransferase

High aspartate aminotransferase (AST) activity has been reported in the liver of birds. High AST activity has also been found in skeletal muscle, heart muscle, brain, and kidney. The distribution of AST among tissues varies with the species, thereby making interpretation of increased plasma AST activity challenging. In general, increases of plasma AST activity in birds are suggested when such activity is greater than 275 IU/L. Increases result from either hepatic or muscle injury, which allow the leakage of intracellular AST into the blood. Plasma AST activity is considered to be markedly increased when the activity is greater than 800 IU/L. Activity of this magnitude is suggestive of severe hepatic insult, especially in the presence of biliverdinuria or biliverdinemia. However, increased AST activity does not provide information about hepatic function. It is useful to evaluate CK activity (see Laboratory Detection of Muscle Injury) in conjunction with AST activity to differentiate between muscle and liver injury.

Alanine aminotransferase

Alanine aminotransferase (ALT) activity has been reported in the liver, skeletal muscle, and many other tissues of birds, and leaks into blood when such tissues are injured. Plasma ALT activity is considered to be neither a specific nor a sensitive test for hepatocellular injury in birds. Plasma ALT activity in most species of normal birds ranges from 19 to 50 IU/L and may be more useful for the detection of hepatic disease in carnivorous birds. Plasma ALT activity increases with significant liver or muscle injury in birds (especially carnivores) and has no advantage compared with AST as a test for hepatocellular disease.

Lactate dehydrogenase

Plasma LD activity is nonspecific for hepatocellular disease in birds. LD isoenzymes are found in nearly all avian tissues. Specific LD isoenzymes could be helpful in determining the source of increased plasma LD activity; however, verification studies evaluating LD isoenzymes in various avian tissues would be required for a large number of avian species.

Plasma LD activity is less than 1000 IU/L in normal birds, and increased activity has been associated with hepatocellular disease. Compared with plasma AST and ALT activity, plasma LD activity increases and declines more rapidly after injury to liver or muscle. The short mean elimination half-life of LD (0.48 hours) compared to that of CK (3.07 hours) makes LD a valuable test in differentiating between muscle and liver disease in the pigeon. Determination of the plasma LD activity has no diagnostic advantage compared with plasma AST activity, especially because the former typically has a wide normal reference interval in birds and its low specificity for liver disease in birds. In addition, avian erythrocytes have high LD activity; therefore, hemolysis results in increased plasma LD activity.

Glutamate dehydrogenase

Although not commonly offered by most veterinary laboratories, plasma glutamate dehydrogenase (GLDH) activity appears to be a specific test for hepatocellular disease in birds; however, sensitivity is low. Because GLDH is a mitochondria-bound enzyme, it is released when severe cell injury has occurred. Significant GLDH activity has been found in the liver, kidney, and brain of pigeons, chickens, ducks, turkeys, and budgerigars. In general, plasma GLDH activity of greater than 10 IU/L is considered to be increased and indicative of hepatic necrosis. The degree of increase in the plasma GLDH activity reflects the severity of the hepatocellular injury. Plasma GLDH activity does not appear to increase with muscle injury, as do the activities of AST, ALT, and LD, thereby making GLDH the most liver-specific plasma enzyme among those species of birds that have been evaluated. Plasma GLDH appears to have a shorter mean elimination half-life (0.68 hours) than does AST (7.66 hours) and ALT (5.69 hours), and it can be used to evaluate not only the severity of the hepatocellular injury but also the duration (if the insult is not ongoing).

Sorbitol dehydrogenase

Sorbitol dehydrogenase (SD) appears to be a liver-specific cytosolic enzyme, and it may be useful in establishing the diagnosis of hepatocellular injury in birds. Plasma SD has a short half-life, and its activity may remain increased for shorter periods of time than those of AST and other enzymes. Plasma SD assays are usually unavailable at most veterinary laboratories. Plasma SD appears to have no diagnostic advantage compared with plasma GLDH.

Alkaline phosphatase

AP activity occurs in multiple tissues including bone and intestine, and increased plasma AP activity results not from leakage of the enzyme but from increased cellular production. Plasma AP activity in birds results primarily from osteoblastic activity. Therefore, increases in the plasma AP activity are suggestive of skeletal growth, nutritional secondary hyperparathyroidism, healing fractures, and the preovulation condition of medullary calcification in hens. Plasma AP activity is not useful in the detection of hepatobiliary disease in birds. Aflatoxin B_1-induced liver necrosis and bile duct hyperplasia have not significantly increased the serum AP activity in the pigeon, cockatiel (*Nymphicus hollandicus*), great horned owl (*Bubo virginianus*), and red-tailed hawk (*Buteo jamaicensis*). Plasma AP activity appears to be a sensitive indicator of intestinal diseases, such as coccidial infections in the duodenum, jejunum, and cecum.

Gamma glutamyltransferase

Plasma γ-glutamyltransferase (GGT) activity does not predictably increase in birds with hepatobiliary disease. Similar to AP, increased plasma activity of GGT is due to increased cellular production rather than leakage. Measurable GGT activity occurs in the kidney, brain, and intestines of birds; however, disorders of these tissues do not increase the plasma GGT activity. The highest GGT activity is found in the kidney of birds. The plasma activity does not increase with renal disease, however, because the enzyme is excreted in the urine. Increased serum GGT activity has increased in some cases of birds with liver disease, but not others, suggesting that the plasma GGT activity may increase in some species of birds depending on the nature of the hepatic insult. Plasma GGT activity is not routinely measured in birds with hepatobiliary disease; therefore, the usefulness of this enzyme in detection of avian liver diseases has not been fully determined.

Biliverdin and bilirubin

Because the avian liver generally lacks the enzyme biliverdin reductase, which is required to convert biliverdin to bilirubin, the primary bile pigment in birds is biliverdin, which is a green pigment. In spite of the fact that birds produce little to no bilirubin, clinical icterus with an increased plasma bilirubin concentration has been reported in ducks and macaws (*Ara* sp.). Presumably, some biliverdin may be reduced to bilirubin by nonspecific extrahepatic enzymes or bacteria; however, bilirubin is considered to be a poor indicator for hepatobiliary disease in most birds. The healthy avian kidney is efficient in clearing bile pigments from the blood; therefore, green-colored urine and urates are suggestive of biliverdinuria and significant liver disease in birds. The presence of biliverdinemia is indicated by green sera or plasma, which reflects severe hepatobiliary disease in birds, and is associated with a poor prognosis for survival. Most veterinary laboratories do not offer biliverdin testing. Biliverdin is an unstable bile pigment that is sensitive to light degradation. The yellow color of the plasma in many avian species may be associated with carotenoid pigments from the diet and should not be misinterpreted as bilirubinemia.

Bile acids

Because plasma enzymes are neither sensitive nor specific for the detection of liver disease in birds and also do not reflect the degree of liver disease, other blood biochemical tests are necessary to evaluate avian liver metabolism and excretion. Moreover, biliverdin and bilirubin concentrations in the blood are either not available or applicable to the detection of liver disease. Bile acid determination, however, is a sensitive test for liver function in some species of birds [11]. Bile acids are produced in the liver, excreted in the bile, reabsorbed by the intestines into the portal circulation, and removed from the blood by the hepatocytes. This process is referred to as the enterohepatic circulation.

Bile acids normally occur in very small amounts in the peripheral blood of healthy birds. The primary bile acids in birds vary among species and may not be the same as those found in dogs, cats, and humans [5]. Fasting plasma bile acid concentrations are lower than postprandial concentrations. The length of required fasting varies between species. For example, plasma bile acid concentrations demonstrate a postprandial peak at 2 hours in Goffin cockatoos (*Cacatua goffini*), 4 hours in African Gray parrots (*P. erithacus*), and more than 8 hours in Amazon parrots (*Amazona* sp).

Increases in fasting plasma bile acid concentrations are suggestive of abnormal hepatic function, and may be due to failure of the liver to uptake bile acids from the portal blood, abnormal bile acid excretion caused by blockage or leakage, or portal circulation abnormalities. When measuring the bile acid concentration, a 12-hour fast is recommended because of the digestive physiology of birds. The emptying time of the ingluvies or crop varies both with diet and among species of birds; thus, the timing of postprandial sampling for bile acid testing is difficult. Moreover, ill birds often have a slow gastrointestinal transit time – or even stasis. Conversely, increased gastrointestinal motility may interfere with bile acid release from the liver and absorption from the intestines. Because fasting is better tolerated in carnivorous birds, such as raptors, and postprandial concentrations remain higher for longer periods of time, a 24-hour fast is recommended for bile acid testing for those species. Both the enzymatic and the radioimmunoassay (RIA) methods have been used for determination of bile acids in birds [12]. Results of the two methods correlate well in plasma samples obtained from six species of birds. The RIA method is linear to 50 μmol/L, whereas the enzymatic method is linear to 200 μmol/L. Lipemia and hemolysis interfere with bile acid testing using the enzymatic method but do not interfere with

the RIA method. Variable results have been reported using the RIA method, which is designed for use with human serum samples. Potential explanations include differences in the binding of antibodies to different binding sites in avian bile acids; the tendency of avian samples to have higher bile acid concentrations than are found in humans; and the different predominating bile acids in various species of birds. Others have reported that both methods have adequate precision and accuracy.

Reference intervals for fasting plasma bile acid concentrations have not been determined for many species of birds. Overall, the plasma bile acid concentration of normal birds is greater than that of mammals; therefore avian samples often require dilutions, especially with RIA methods, to stay within the linear parameters of the assay. In general, bile acid concentrations determined by the enzymatic method are considered to be normal if they are less than 75 μmol/L [5]. Assay-specific and species-specific reference intervals for normal fasting bile acid concentrations are recommended.

Cholesterol

The normal plasma cholesterol concentrations of most species of birds range between 100 and 250 mg/dL. Because cholesterol is eliminated in the form of bile acids, increases in the plasma cholesterol concentration may be associated with extrahepatic biliary obstruction, hepatic fibrosis, and bile duct hyperplasia. Hypercholesterolemia also can be associated with conditions other than liver disease, such as hypothyroidism, high-fat diets, lipemia, and during egg production. A hypercholesterolemia occurs during vitelogenesis in female birds preparing to lay eggs. Postprandial increases in cholesterol may occur as well. Hypocholesterolemia may occur with end-stage liver disease, maldigestion or malabsorption, and starvation.

Iron

Excessive iron storage (hemochromatosis) is a common hepatic disorder of ramphastids (toucans), hill mynahs (*Gracula religiosa*), and sturnids (birds of paradise) and occurs less commonly in psittacine birds and other species. It has been suggested that these species of birds develop this disorder because they are more efficient in absorbing iron form their intestines compared to other birds and like humans, some birds (i.e., mynahs) may have a genetic predisposition for the disorder. Birds with this condition may exhibit increased plasma AST activity because of iron-induced hepatocellular damage. Usefulness of serum iron concentration, total iron-binding capacity, and unsaturated iron-binding capacity testing for excessive hepatic iron storage have not been fully evaluated in birds. Studies in toucans with this condition suggest that these tests do not appear to correlate with hepatic iron concentrations. The disease is currently diagnosed based upon histopathology and tissue iron levels.

Other tests

Other abnormalities that may be suggestive of hepatic insufficiency in birds include hypoalbuminemia, hypoglycemia, hyperammonemia, and decreased levels of coagulation factors. Hypoglycemia and hypoalbuminemia could result from chronic liver disease in birds but rarely are reported. An increased plasma ammonia concentration with hepatic encephalopathy resulting from severe hepatic disease has not been documented in birds. Coagulation studies are performed only rarely in birds but could be used to help establish the diagnosis of hepatic insufficiency.

Laboratory evaluation of plasma and serum proteins

The normal plasma protein concentration in birds is less than that in mammals, generally ranging from 2.5 to 4.5 g/dL (25–45 g/L). Albumin, which represents 40–50% of the total plasma protein in birds, is produced in the liver. Other plasma proteins also produced in the liver include transport proteins, proteins of coagulation, fibrinogen, enzymes, and hormones. Immunoglobulins produced by B lymphocytes and plasma cells represent a significant component of the total plasma protein concentration. The normal plasma protein concentration is essential to the maintenance of the normal colloidal osmotic pressure, which preserves normal blood volume and pH. Hens demonstrate a marked increase in plasma total protein concentration just before egg production. This estrogen-induced hyperproteinemia is associated with an increase in vitellogenin and lipoproteins, which are necessary for yolk production. These proteins are produced in the liver, transported in the blood, and incorporated into the oocytes of the ovary.

The biuret method is the method of choice for determining plasma or serum total protein concentration in birds. This method provides accurate and repeatable results when the total protein concentrations fall between 1 and 10 g/dL (10–100 g/L). Because proteins in the serum are primarily responsible for changes in the refractive index, a refractometer commonly is used to obtain a total plasma or serum protein concentration in birds. Temperature-compensated refractometers, as well as those that are not temperature compensated, tend to overestimate the total protein concentration. The high glucose concentration and chromogens in the plasma of birds as well as lipemia and hemolysis affect the accuracy of the refractometric method, which frequently is used for a rapid estimate of the plasma protein concentration. The biuret method, however, is more accurate.

The plasma albumin concentrations generally range from 0.8 to 2.0 g/dL (8–20 g/L) in normal birds. These values may not be accurate, however, because most analyzers determine albumin spectrophotometrically using the bromcresol green

(BCG) dye-binding method using human albumin standards and controls that may have different binding affinity for the dye compared to that of avian albumin. Thus, the BCG method has not been validated in avian plasma samples and may be inaccurate at the low albumin concentrations found in avian plasma [5].

Protein electrophoresis provides a more accurate measure of the albumin concentration as well as those of other plasma proteins; however, there are species differences in albumin migration on gel electrophoresis [13]. Avian protein electrophoresis is typically performed on plasma samples, which is appropriate as it has been shown that there are negligible differences in electrophoretic patterns when using plasma versus serum. The total protein concentration as obtained by the biuret method combined with electrophoretic separation of plasma proteins provides an accurate absolute concentration of the plasma proteins. The primary plasma protein fractions include albumin, alpha globulins (alpha-1 and alpha-2), beta globulins (beta-1 and beta-2), and gamma globulin. A transthyretin (prealbumin) fraction may be present in some species (e.g., psittacines) and absent in others (e.g., waterfowl and raptors). Normal concentrations for transthyretin, albumin, alpha globulin, beta globulin, and gamma globulin as obtained by protein electrophoresis from birds vary. Prolonged refrigeration, repeated freeze-thawing, hemolysis, and lipemia will alter the results [14]. Established species-specific reference intervals are necessary to the interpretation of avian protein electrophoretic patterns and values as well as the knowledge of variations associated with sample handling and conditions.

Protein electrophoresis is a useful test for analyzing the relative distribution of protein fractions in the plasma and has become part of the normal diagnostic workup for many captive and free-ranging birds. Because these protein fractions often change before biochemical or hematological parameters, electrophoresis can be used as prognostic indicator in birds.

The normal albumin: globulin (A:G) ratio for most psittacine birds is between 1.2 and 3.6 when transthyretin is included with the albumin fraction, or 0.6–2.2 if it is not. Transthyretin can be considered to be an acute-phase reactant, which is reason not to include it with the albumin fraction. β-globulin predominates in the globulin electrophoretic fraction in psittacine birds; whereas α-1 globulin predominates in waterfowl and raptors. Acute-phase proteins (APPs) in cases of inflammation typically result in increases of the alpha (specifically α-2 globulins) and total globulin fractions of the electrophoretic tracing. Increases in α-2 globulins may also signal hepatic disease in psittacine birds. Chronic inflammatory disorders such as aspergillosis, sarcocystosis, and chlamydophilosis are often associated with increases in β-globulins. The γ-globulin fraction is composed of immunoglobulins such as IgA, IgM, IgG, and IgE, which increase with a humoral immune response. Some of the immunoglobulins (e.g., IgM and IgA) may migrate into the beta globulin fraction. A polygammopathy is indicative of active chronic inflammatory diseases, especially those associated with infectious agents such as *Chlamydophila*, *Aspergillus*, and *Mycobacterium* spp. The higher γ globulin concentrations demonstrated in wild birds versus captive birds of the same species are likely associated with increased antigenic exposure and immune stimulation [15]. Decreased γ-globulin fractions may be indicative of immunodeficiency.

Hyperproteinemia in most birds is indicated by plasma total protein (biuret) concentrations of greater than 4.5 g/dL (45 g/L). Hyperproteinemia is usually the result of dehydration, acute or chronic inflammation, or a preovulatory condition in hens. Increased albumin and globulin concentrations with a normal A:G ratio are commonly associated with dehydration. Hyperproteinemia caused by hyperglobulinemia with hypoalbuminemia results in a decreased A:G ratio and is frequently associated with chronic inflammatory diseases in birds, especially with diseases such as Chlamydophilosis, aspergillosis, tuberculosis, and egg-related coelomitis. A decreased A:G ratio with a normal total plasma protein concentration may also occur with these chronic disorders. Hyperproteinemia associated with normal albumin and elevated globulin concentrations is suggestive of acute inflammatory diseases or preovulatory conditions in egg-laying hens. With acute inflammation, electrophoretic patterns typically demonstrate increased concentration of alpha and/or beta globulins; however, gamma globulin increases may also be observed. Hens undergoing active folliculogenesis will exhibit a hyperproteinemia with a decreased A:G ratio as a result of estrogen-induced production of yolk proteins that migrate with globulins on electrophoresis. Hyperproteinemia associated with hyperalbuminemia and hypoglobulinemia results in an increased A:G ratio and suggests dehydration in birds with low plasma globulin concentrations. Dehydrated birds subjected to chronic stress or other immunosuppressive conditions may demonstrate this type of plasma protein profile.

Hypoproteinemia in birds can be associated with hypoalbuminemia and hypoglobulinemia. This can occur with overhydration during fluid therapy or a proportional loss of albumin and globulins. The latter can be associated with severe blood loss, effusions (especially birds with heart failure resulting in large volumes of intracoelomic effusion), and protein-losing enteropathies (e.g., intestinal parasitism and bacterial enteritis).

Hypoproteinemia in birds associated only with a hypoalbuminemia occurs with starvation, malnutrition, intestinal malabsorption, and gastrointestinal parasites leading to amino acid deficiencies. Hypoproteinemia also occurs with liver failure resulting in a decreased production of albumin or renal disease resulting in an increased loss of albumin in the urine.

Fibrinogen concentration is often evaluated in raptors to detect the presence of inflammatory diseases, especially those associated with bacterial infections. A plasma total protein/fibrinogen ratio in raptors that is less than 1.5 is indicative of inflammation and possible bacterial infection, whereas a ratio greater than 5 indicates dehydration [5].

Quantitation of APP via protein electrophoresis and specific assays has become a valid indicator of inflammation, both acute and chronic, and as a prognostic indicator in veterinary medicine. These proteins with their short half-life exhibit a rapid increase following inflammation. Some (positive APPs), such as serum amyloid A (SAA), haptoglobin, and α and β globulins increase in concentration in response to inflammation, while others (negative APPs), such as albumin, decrease in concentration in response to inflammation. Because these proteins respond differently among various species of animals, they must be validated for each species. Avian APPs have been studied in chickens, raptors, and psittacines. Measurement of individual APPs, such as haptoglobin that increases after tissue damage, has become common in veterinary medicine and been documented as a diagnostic tool to detect inflammation in birds, such as raptors. Birds do not actually express haptoglobin but instead express a homologous protein (PIT54) that is similar enough that it is referred to as haptoglobin in veterinary literature [16, 17].

Laboratory evaluation of glucose metabolism

In general, the blood glucose concentration in normal birds ranges from 200 to 500 mg/dL (11.10–27.76 mmol/L). The plasma glucose concentration varies according to a circadian rhythm; however, this variation is clinically insignificant in healthy birds. The normal blood glucose concentration is maintained by hepatic glycogenolysis during short-term fasting. Specifically, short-term fasting (e.g., 1–8 days) in birds does not decrease glucose utilization per unit body weight, as it does in fasted mammals. During fasting, the greatest energy loss is associated with fat depletion and protein mobilization, thereby resulting in the loss of body weight in birds, which is seen as a reduction in the pectoral muscle mass. The blood glucose concentration remains remarkably stable during short-term fasting in birds, and it is more stable in carnivorous birds during prolonged periods of fasting compared with granivorous birds.

Blood glucose regulation varies with avian species. Whereas insulin plays a key role in mammalian and carnivorous bird glucose homeostasis, glucagon plays a major role in the maintenance of normal blood glucose concentrations in granivorous birds. This idea is supported by the relative abundance of alpha cells in the pancreas of granivorous birds while the distribution of the pancreatic islet cells of carnivorous birds resembles that of mammals. Granivorous birds also have a lower insulin:glucagon ratio compared with that of mammals. Their pancreas insulin content is less than 20% of the insulin content of a mammalian pancreas while the glucagon content is two to five times greater. Also, pancreatectomy induces hypoglycemia in granivorous birds but hyperglycemia in carnivorous birds.

Glucagon is produced by pancreatic alpha cells that maintain normal plasma concentrations of 1–4 ng/mL, which is 10–50-fold greater than the normal mammalian concentrations. The blood glucagon concentration increases by 100–200% in birds during a 24–48-hour fast. As a result, the blood glucose concentration increases along with an increase in free fatty acids, insulin, and cholecystokinin. On the other hand, glucose decreases the release of pancreatic glucagon. A significant increase in glucose stimulates the release of insulin from pancreatic beta cells.

Hypoglycemia in most birds is indicated by blood glucose concentrations of less than 200 mg/dL (11.10 mmol/L) and results from prolonged starvation, severe liver disease (e.g., Pacheco disease), septicemia, enterotoxemia, or endocrine disorders (e.g., hypothyroidism). Delayed separation of serum or plasma from avian blood cells does not significantly decrease the glucose level in the sample, as it does in mammalian blood, because avian erythrocytes use fatty acids rather than glucose for energy. Hypoglycemia-induced seizures is a common disorder of falcons in which their blood glucose can fall as low as 80 mg/dL (4.44 mmol/L) with sudden exercise following prolonged food restriction during flight training [5].

In general, hyperglycemia in most birds is indicated by blood glucose concentrations of greater than 500 mg/dL (27.76 mmol/L). Hyperglycemia occurs with diabetes mellitus, catecholamine release, and glucocorticosteroid excess, such as occurs with stress or administration of corticosteroids. Excess glucocorticosteroids result in a mild to moderate increase in the blood glucose concentration (≤600 mg/dL [33.31 mmol/L]) in birds. Exertion, excitement, and extreme temperatures stimulate the release of catecholamines, which also results in a mild to moderate increase in the blood glucose concentration. Glucose concentrations of greater than 700 mg/dL (38.86 mmol/L) are suggestive of diabetes mellitus in most birds. The pathophysiology of diabetes mellitus in birds varies among different species and may result from increased glucagon secretion or hypoinsulinemia. Although glucagon appears to have a major role in glucose metabolism in granivorous birds, those with diabetes mellitus have been shown to respond to insulin therapy. Birds with diabetes mellitus have polyuria and urinary glucose concentrations exceeding 1 mg/dL (0.055 mmol/L). Pancreatic islet cell tumors and pancreatitis (bacterial and viral etiologies) have been suggested as being causes of diabetes mellitus in psittacine birds. Detection of pancreatitis by increased serum amylase activity has been

occasionally reported in birds. In some species (e.g., toucans, Ramphastidae), diabetes mellitus occurs commonly and appears to be related to a fruit diet. Excessive iron storage, another common disorder of toucans, can also be associated with diabetes mellitus in birds.

Plasma fructosamine and β-hydroxybutyric acid concentrations appear to be useful when monitoring the avian patient being treated for diabetes mellitus. It has been demonstrated that both analytes increase in diabetic birds with prolonged hyperglycemia and decrease following the correction of the hyperglycemic state with insulin therapy. Based on euglycemic psittacine birds, reference intervals for fructosamine are 113–238 μmol/L and intervals for β-hydroxybutyric acid are 450–1422 μmol/L. It has been demonstrated that blood glycated hemoglobin (HbG) can also be an indicator of the blood glucose status of the ostrich (*S. camelus*) and kestrel (*Falco sparverius*) [18]. The glycated hemoglobin of these birds is 1.2 ± 0.20% of the total hemoglobin compared to 3–6% in most mammals. The relatively low normal HbG of birds appears to be related to the lower permeability of the avian erythrocyte membrane to blood glucose. Blood glycated hemoglobin reflects the glucose status of the patient for a longer period of time than does fructosamine concentration because it reflects the blood glucose concentration during the lifespan of the erythrocyte. Although measurement of glycated hemoglobin may be useful in monitoring recovery from the hyperglycemic state, it takes longer to detect changes than does measurement of fructosamine because of its long life span in erythrocytes.

Laboratory evaluation of lipid metabolism

The lipoprotein panel, a standard diagnostic tool in human medicine, is rarely used and therefore, poorly understood, in avian medicine. Many types of captive birds (especially *Amazona* spp. and *P. erithacus*) fed high-fat diets and leading sedentary lifestyles are prone to obesity and atherosclerosis. In human medicine, these conditions are typically correlated with abnormalities in the lipoprotein panel. The components of the typical lipoprotein panel are the lipids cholesterol and triglyceride, as well as three lipoproteins: high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very low-density lipoprotein (VLDL). Measurement of total cholesterol levels includes both free cholesterol and cholesterol esters. The normal serum lipoprotein distributions for birds are likely to vary among species. Reference intervals established for the normal lipoprotein panel in Amazon parrots (*Amazona* spp) indicated a significant difference in HDL values between males and females but no differences associated with diet, body condition score, and age [19].

A high correlation with the prevalence of atherosclerosis in birds has been shown with increasing HDL but not LDL [20]. Dietary management of birds with atherosclerosis has been shown to decrease total and LDL cholesterol but not HDL cholesterol or even mortality; which is likely associated with the severity of the atherosclerotic lesions at time of the dietary changes [21]. However, feeding low-fat diets and monitoring the lipid profile may have long-term beneficial effects in the prevention of atherosclerosis, a condition where obesity and dyslipidemias are among the known risk factors. Daily exercise has also been shown to improve the lipid metabolism of pigeons, parrots, and chickens under varying experimental conditions. In birds, like humans and other mammalians, an increase in HDL cholesterol is the most consistent effect of exercise on circulating lipid and lipoprotein parameters [22].

Laboratory detection of exocrine pancreatic insufficiency

Exocrine pancreatic insufficiency is a disorder resulting from an insufficient secretion of pancreatic digestive enzymes. Clinical signs associated with this disorder result from digestive malabsorption and include voluminous feces with a chalklike appearance, polyphagia, and weight loss. This disorder is a result of a severe progressive loss of pancreatic acinar tissue, either from atrophy or destruction associated with an inflammatory disease (pancreatitis). A presumptive diagnosis can be obtained based upon clinical signs and response of affected birds to oral pancreatic enzyme supplementation. In birds there has been limited use of plasma assays for the activities of pancreatic digestive enzymes such as amylase and lipase that may leak from injured pancreatic cells into the blood. Reference values for pigeons indicate normal plasma amylase activity to be between 382 and 556 IU/L and lipase activity between 0 and 5 IU/L [23].

Laboratory detection of muscle injury

CK is a muscle-specific enzyme in birds that can be used to detect muscle cell damage [24]. The normal plasma CK activity in most species ranges from 100 to 500 IU/L. Increased plasma CK activity can result from muscle cell injury or marked exertion and is frequently observed in birds with seizure disorders or birds that are struggling against restraint during blood collection. Muscle tissue damage can occur with traumatic injury, intramuscular injections of irritating fluids, or systemic infections that affect the skeletal or cardiac muscle.

Skeletal muscle injury should also be considered when plasma AST activity is increased. Measurement of plasma CK activity can be useful for determining if muscle injury versus hepatocellular injury is the cause of increased plasma AST activity. Thus, an increased plasma AST activity without

an increased plasma CK activity is suggestive of hepatocellular disease in birds; however, other tests should also be employed to fully evaluate the presence of hepatic disease in birds. (See discussion under Laboratory Evaluation of the Avian Liver.) Severe skeletal muscle injury often results in marked increases of the plasma CK activity and moderate increases of the plasma AST activity. Plasma AST appears to have a longer half-life (mean of 7.10 hours from muscle) than CK (mean of 3.07 hours from muscle), and after a single insult to muscle, as may occur with an intramuscular injection of an irritating drug, the CK activity may return to normal before the AST activity. Regarding situations in which the plasma CK activity has returned to normal after muscle injury but the plasma AST activity remains increased, an erroneous diagnosis of hepatobiliary disease may be made if those two enzymes are the only analytes examined. Unlike plasma CK activity, plasma AST activity does not usually increase significantly with normal capture and restraint of struggling birds, but under these conditions, a bird with a preexisting hepatocellular injury may have increases in both the AST and the CK activity.

Increased plasma ALT activity may occur with muscle injury. Plasma ALT appears to have a longer half-life (mean of 11.99 hours from muscle) compared with plasma CK (mean of 3.07 hours from muscle); therefore, activity of ALT remains increased longer than does CK after muscle injury.

Plasma LD activity also increases with muscle injury. Because the plasma half-life of LD (mean of 0.48 hours from muscle) is shorter than that of CK (mean of 3.07 hours from muscle), the two enzymes can be evaluated concurrently to differentiate hepatocellular damage from muscle injury. In most birds, increased plasma LD activity with normal CK activity is suggestive of hepatocellular disease. Validation and evaluation of LD isoenzymes may be helpful in differentiating hepatic versus muscle disorders; however, most veterinary laboratories do not routinely offer LD isoenzyme determination.

Capture myopathy in Sandhill cranes (*Grus Canadensis tabida*) was associated with increased plasma activity of CK, AST, and LD within 1 hour of capture [24]. The peak activity of these enzymes occurred 3 days following capture and by 10–17 days, CK and LD activities had returned to normal; however, plasma AST activities were still two to five times higher than normal reference values.

Laboratory evaluation of endocrine disorders

Thyroid

Both thyroxine or tetraiodothyronine (T_4) and triiodothyronine (T_3) have been isolated from birds [25]. Most of the secreted hormone is T_4, whereas T_3 is formed peripherally by deiodination of T_4 and in comparison to mammals, birds contain less T_4 but similar T_3 concentrations. The plasma or serum T_4 concentration of adult birds of many species ranges between 5 and 15 ng/mL (6–19 pmol/mL) and the T_3 concentration ranges between 0.5 and 4 ng/mL (0.7–1.5 pmol/mL) [25]. Circulating T_4 and T_3 are bound to protein. A T_4-binding globulin is absent in birds; therefore, most of the thyroid hormones are bound to albumin. These hormones also are bound secondarily to other proteins (e.g., transthyretin [prealbumin] and alpha globulin). The binding of thyroid hormones to albumin and other blood proteins is weak, however, thereby resulting in greater free-T_4 percentages in the blood of birds compared with those in mammals [25]. Compared with T_4, T_3 is more metabolically active at the cellular level. The ratio of T_4 to T_3 in blood varies with the species, however. Thyroid hormones are excreted primarily in the bile and urine. In birds, T_3 and T_4 have relatively short half-lives compared with those in mammals, and a significant diurnal rhythm is more easily demonstrated in birds compared with mammals. In chickens, plasma T_4 concentrations decrease during the light phase and increase during the dark phase of the light cycle. Plasma T_3 concentrations behave in the opposite manner. The pattern of food intake may influence this rhythm.

Competitive protein binding and RIA are sensitive methods used to measure the plasma or serum T_4 and T_3 concentrations in birds. Protein-bound iodine determination is not a sensitive test for iodine-containing hormones in birds, primarily because avian blood contains a large amount of nonhormonal iodo-proteins compared with mammalian blood.

Secretion of thyroid hormones by the thyroid gland is governed by the concentration of circulating thyroid hormones. A decrease in the circulating concentration of thyroid hormones stimulates the pituitary gland to release thyrotropin-releasing hormone, which stimulates the release of thyrotropin (thyroid-stimulating hormone [TSH]) via neuroendocrine-controlled mechanisms. In turn, the release of TSH stimulates the secretion of thyroid hormones.

A TSH-stimulation test has been used to evaluate thyroid function in a variety of birds. In general, a prestimulation plasma T_4 concentration is obtained to compare with a poststimulation sample, which is obtained 4–6 hours after the intramuscular administration of TSH. A dosage of 1 IU of TSH per bird, regardless of the body weight, is typically used. A normal response is indicated by a 2.5-fold or greater increase in the T_4 level after TSH stimulation. Responses of lesser magnitude are suggestive of hypothyroidism. Measurements of T_3 concentrations appear to be inconsistent and unreliable. Low baseline total T_4 concentrations are poor indicators of hypothyroidism in birds, because many healthy birds normally have low T_4 concentrations. This may, however, reflect diurnal variation. Also, other conditions (e.g., stress and systemic disease) can decrease plasma T_4 concentrations. Therefore, TSH-stimulation testing provides a more reliable method for detecting hypothyroidism in birds.

Other blood biochemical abnormalities often associated with hypothyroidism in birds include increases in cholesterol, triglycerides, uric acid, AST, and LD. Hypothyroidism in birds may also result in a mild normocytic, normochromic nonregenerative anemia.

Hyperthyroidism is rare in birds. An increased plasma concentration of T_4 and T_3 is suggestive of hyperthyroidism.

Parathyroid

The primary function of parathyroid hormone (PTH), secreted by the parathyroid gland, is maintenance of the normal plasma calcium concentration by its action on bone, kidney, and intestinal mucosa. Unfortunately, plasma PTH analysis in birds is commercially unavailable. Therefore, detection of disorders associated with abnormal blood PTH concentrations (e.g., hyper- and hypoparathyroidism) depends on the evaluation of blood calcium and phosphorus concentrations in birds. Hypoparathyroidism has not been reported in birds.

Adrenal

Corticosterone is the primary glucocorticoid that is produced by the avian adrenal gland. Corticosterone secretion in birds is regulated by adrenocorticotropic hormone (ACTH), which is released from the pituitary gland in response to corticotropin-releasing factor. In birds given an intramuscular injection of ACTH, plasma corticosterone concentrations peak in 3 hours followed by a sharp decrease at 4 hours. The plasma corticosterone concentration increases during times of stress. Corticosterone also has mineralocorticoid activity. Plasma corticosterone concentrations exhibit a diurnal rhythm as well, with maximum concentrations occurring at the beginning of the day. Plasma corticosterone concentrations are also influenced by other physiologic factors, such as the ovulatory cycle of hens and changes in the seasons.

Plasma corticosterone concentrations in birds can be determined by RIA. Single baseline corticosterone determinations may have little value in establishing the diagnosis of hyperadrenocorticism in birds. An ACTH stimulation test may be more valuable, however, when pre- and 60- to 90-minute post–ACTH stimulation corticosterone concentrations are compared. Normal birds should demonstrate a greater than 10-fold increase in post–ACTH stimulation plasma corticosterone concentration compared with pre–ACTH stimulation concentration. Stimulation dosages of 50 and 125 mg of ACTH have been used in birds for this test.

Hyperadrenocorticism in birds is usually iatrogenic, caused by excessive administration of exogenous glucocorticosteroids; excess endogenous corticosterone is rare. The effects of glucocorticosteroid administration are variable and dependent on both dose and duration. Hematologic changes include lymphopenia, leukocytosis, and heterophilia. Blood biochemical changes include hypercholesterolemia and mild hyperglycemia, with blood glucose concentrations ranging between 500 and 600 mg/dL (27.76–33.31 mmol/L). Glucosuria should also be expected.

Adrenal insufficiency (i.e. Addison disease) is also rare in birds. The decreased production of corticosterone or aldosterone (or both) in this condition results in a decreased plasma sodium:potassium (Na:K) ratio. A Na:K ratio of less than 27, hypoglycemia, hypercalcemia, and low urine specific gravity are suggestive of adrenal insufficiency. Because hyperkalemia from other causes (e.g., delayed separation of plasma from cells, acidosis, hemolysis, and renal disease) may result in a decreased Na:K ratio, an ACTH stimulation test may be helpful in confirming the presence of adrenal insufficiency.

37 Clinical Chemistry of Reptiles

Terry W. Campbell
Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

The clinical chemistry of reptiles has not attracted the same level of attention as for mammals, and normal reference values for specific blood biochemical tests have been established for only a few of the 7500 or so reptilian species. Environmental conditions, such as temperature, season, geographic area, ecological habitat, and wild versus captive status as well as physiologic factors, such as species, nutritional status, reproductive status, sex, and age affect the blood analytes of reptiles [1–5]. It is well recognized that significant metabolic disorders occur in captive reptiles exposed to unhealthy conditions, such as inadequate nutrition, improper environment, and overcrowding. These factors often have not been considered when establishing reference intervals, thereby making those intervals less meaningful. Methods of sample collection, handling, and biochemical analysis are additional sources of variation in the published reference values. Sample collection and handling are specifically problematic for blood biochemical studies of wild reptile populations. Therefore, published reference intervals are best used as a broad guide to the interpretation of blood biochemical results in reptiles. Because of the difficulty in obtaining meaningful reference intervals for each reptilian species seen in clinical practice, most clinicians use decision limits or common ranges when assessing such patients. As discussed with the interpretation of avian blood biochemical results (see Chapter 36), decision limits may vary among clinicians dealing with reptiles depending on laboratory results and experience. The values suggested in this text are general guidelines that can be used as decision limits when evaluating each analyte in the reptilian blood biochemical profile. As suggested with valued avian patients, the process of evaluating the blood chemistries of reptilian patients can be refined by obtaining a set of normal values from that patient when housed under a given set of environmental and nutritional parameters. When that patient becomes ill, a more meaningful set of reference values, which are specific for that individual patient, can be used to evaluate the chemistry results.

Blood biochemistry profiles are frequently used to assess the health of reptilian patients; however, controlled studies designed to clarify the meaning of changes in the blood chemistries of reptiles compared with those of domestic mammals generally are lacking. Therefore, reptilian clinical chemistry has not received the same critical evaluation as that in domestic mammalian medicine.

Activities of diagnostically important enzymes have been examined in the serum and tissue lysates of reptiles in an effort to determine tissue specificity of these tests. Plasma or serum along with lysates of liver, kidney, skeletal muscle, heart, intestine, lung, and pancreatic tissues have been analyzed for alkaline phosphatase (ALP), lactate dehydrogenase (LD), aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyltransferase (GGT), and creatine kinase (CK) activities in a few reptile species including the green iguana (*Iguana iguana*), yellow rat snake (*Elaphe obsoleta quadrivitatta*), and loggerhead sea turtle (*Caretta caretta*) [6–8]. Low ALP and ALT and moderate LD and AST activities were found in the majority of the tissues in all of the reptile studies. Little to no plasma or serum and tissue activities of GGT were found in the reptiles. High CK activitiy was present in skeletal and cardiac muscle and moderate (in the turtle) to low activity in gastrointestinal samples. Plasma and tissue activities of glutamate dehydrogenase were low or undetectable in the lizard. Amylase and lipase showed the greatest tissue specificity, with activity found only in pancreatic samples in the lizard and turtle (this was not evaluated in the snake). The results of these studies indicate that the plasma enzymes commonly included in clinical chemistry panels have tissue distributions similar to those of mammals and birds.

In general, interpretations of reptilian blood biochemistries are considered to be the same as those for domestic mammals, with the consideration that external factors (e.g., environmental conditions) have greater influence on the normal physiology and health of ectothermic vertebrates compared with endotherms. As stated above, reptilian blood

Veterinary Hematology, Clinical Chemistry, and Cytology, Third Edition. Edited by Mary Anna Thrall, Glade Weiser, Robin W. Allison and Terry W. Campbell.

biochemistries are influenced by species, age, sex, nutritional status, season, and physiologic status, thereby making the interpretation of results challenging.

Sample collections and handling

Blood samples for biochemical studies can be collected from reptiles using a variety of methods; the choice depends on the species, needed volume, size of the reptile, physiologic condition of the patient, and preference of the collector (see Chapter 21). Depending on the collection site, blood samples from reptiles, especially chelonians, are often contaminated with lymphatic fluid. It has been suggested, based upon evaluation of plasma and lymph samples in red-eared sliders (*Trachemys scripta elegans*) that most of the analytes in lymph (i.e., glucose, calcium, phosphorus, sodium, urea, and enzymes) are comparable with those of plasma or serum in reptiles, while a few others (i.e., total protein and potassium) have a significantly lower concentrations in lymph compared with blood. The same comparisons, however, may not be true for all species of reptiles. Therefore, the amount of lymph contamination in the blood sample should be considered when interpreting the blood biochemical parameters of reptiles. The best results are obtained from blood samples that are uncontaminated with lymph.

Many clinicians prefer to collect blood using an anticoagulant (e.g., lithium heparin) for plasma biochemical testing of reptiles, primarily because a greater sample volume can be achieved for plasma compared with serum. Collection of blood into lithium heparin also allows for evaluation of both the hemogram and blood biochemistries using one sample. Plasma is preferred over serum because clot formation in reptilian blood is unpredictable and often prolonged, thereby producing significant changes in some of the chemistries (e.g., serum electrolytes). Reptilian blood clots slowly because of a low intrinsic thromboplastin activity and a strong natural circulating antithrombin factor, which compensates for the sluggish flow of blood. Therefore, based on higher sample yield and lack of clinically relevant differences from serum, plasma is a better sample choice for clinical chemistry analysis in reptiles.

The ideal sample for biochemical testing is obtained by separating the cells from the plasma by centrifugation immediately after blood collection. This may be difficult to achieve in field studies. The reason for immediate separation is that prolonged contact between the plasma and the cells may cause an artifactual decrease in plasma glucose due to cellular metabolism and an increase in plasma potassium due to leakage from the cells. Also, as erythrocytes age, the cell membranes become increasingly porous resulting in hemolysis, which affects biochemical testing of the blood. In mammals, hemolysis may, depending upon the specific assay used, result in increases in potassium, calcium, phosphorus, magnesium, glucose, AST, ALT, LD, CK, total bilirubin, total protein, lipase, and amylase with decreases in creatinine, ALP, and bile acids. In the green iguana (*I. iguana*), however, hemolytic plasma samples revealed no change in sodium, calcium, uric acid, or CK but did reveal an increase in potassium, phosphorus, total protein, albumin, and AST. Increased storage time or temperature resulted in a decrease in plasma sodium in two species of tortoises with variable effects on potassium. Blood from loggerhead turtles (*C. caretta*) stored up to 24 hours at 4 °C (39 °F) before the cells were separated from the plasma did not reveal significant changes in the majority of the biochemical analytes (only plasma γ-glutamyltransferase demonstrated significant decreased activity) [9]. In the same study, there were also no significant differences in plasma biochemistries between blood collected in lithium heparin or sodium heparin.

The plasma of most reptiles is colorless; however, it may be orange to yellow because of carotenoid pigments in the diets of herbivores such as the green iguana (*I. iguana*). The plasma of some snakes, such as pythons, may be a greenish yellow because of dietary carotenoids and riboflavin. Some lizards normally have green plasma because of high concentrations of biliverdin.

Depending upon the analytic method, the sample collected from small reptiles is often of sufficient volume for only a few tests and not for a complete panel. Therefore, the clinician must decide which tests are most beneficial in the evaluation of the reptilian patient. Blood biochemical tests that appear to be most useful include total protein, glucose, uric acid, AST, CK, calcium, and phosphorus. Other tests that may be helpful include creatine, LD, sodium, potassium, chloride, total CO_2, and protein electrophoresis. Modern blood chemistry analyzers can perform many of these tests using a small sample volume (10–30 μl). Commercial veterinary laboratories often offer chemistry profiles that require a minimal volume of serum or plasma (0.5 ml). Blood chemistry analyzers that use dry reagents and reflectance photometry for "in-house" testing may be used for reptilian samples and often require smaller sample volumes. The use of point-of-care analyzers has become popular in reptile medicine because of the ability to perform a basic biochemistry panel on 0.1 ml of whole blood or plasma. Other advantages of this technology include the short turnaround time of obtaining results, the small size of the analytical instrumentation, affordability, minimal technical training to perform the analysis, and acceptable clinical performance with avian samples for some analytes. However, comparisons of results obtained from reference laboratory analyzers (considered the gold standard) with those from point-of-care analyzers have shown considerable differences for many analytes [10, 11]. Therefore, it is important to identify the specific methodology used when reporting and interpreting biochemical data.

Laboratory evaluation of reptilian kidneys

The paired kidneys of many reptilian species are located within the pelvic canal. The elongated kidneys of snakes are located in the dorsal caudal part of the coelomic cavity, with the right kidney being cranial to the left. The ureters of snakes empty into the urodeum of the cloaca, as they do in birds. Most species of lizards and chelonians (i.e., turtles, tortoises, and terrapins) have a urinary bladder; however, it differs from that of mammals in that the ureters of these reptiles do not empty directly into the bladder but empty into the urodeum of the cloaca [12]. Terrestrial chelonians and, possibly, lizards use the urinary bladder primarily for water storage.

The reptilian renal cortex contains only simple nephrons (i.e., cortical nephrons) with a tubular system devoid of loops of Henle. Therefore, reptiles cannot concentrate their urine. Nitrogenous wastes excreted by the reptilian kidney include variable amounts of uric acid, urea, and ammonia, depending on the animal's natural environment. Freshwater turtles that spend much of their lives in water excrete equal amounts of ammonia and urea, whereas those with amphibious habits excrete more urea. Sea turtles excrete uric acid, ammonia, and urea. Alligators excrete ammonia and uric acid. Terrestrial reptiles such as tortoises must conserve water, and ammonia, urea, and other soluble urinary nitrogenous wastes require large amounts of water for excretion. Therefore, to conserve water, terrestrial reptiles produce more insoluble nitrogenous waste in the form of uric acid and urate salts, which are eliminated in a semisolid state.

Blood biochemical detection of renal disease in reptiles is more difficult than in mammals because of the physiologic differences in their kidneys. Blood urea nitrogen (BUN) and creatinine concentrations generally are poor indicators of renal disease in reptiles; however, plasma urea nitrogen concentrations may be more useful in the evaluation of renal disease among aquatic reptiles that primarily excrete urea. Because terrestrial reptiles are primarily uricotelic, the normal urea nitrogen concentration in these species is less than 15 mg/dL (<5.36 mmol/L), with the exception of terrestrial chelonians (especially desert species), which typically have plasma urea nitrogen concentrations that vary from 30 to 100 mg/dL (10.71–35.70 mmol/L). This is considered to be a mechanism to increase the plasma osmolarity and reduce water loss from the body. The plasma osmolarity of freshwater turtles and crocodilians is approximately the same as that of common domestic mammals, but it is higher in terrestrial reptiles. An increase in plasma urea nitrogen concentration in reptiles may be suggestive of severe renal disease, prerenal azotemia, or a high dietary urea intake; however, it does not reliably increase under these conditions.

Free-ranging desert tortoises (*Gopherus agassizii*) demonstrate a "water metabolism strategy" whereby BUN, uric acid, and osmolality values respond to the amount of available forage and water as determined by rainfall. Free-ranging tortoises that exhibit increased plasma uric acid, sodium, and potassium concentrations with decreased osmolality and urea nitrogen concentration are considered to be actively consuming water along with protein and electrolyte rich forage [3]. This is in contrast to the same population of tortoises that were not consuming significant amounts of food or water, as suggested by increased plasma osmolality and urea nitrogen along with decreased uric acid concentration. Increased urea nitrogen concentration was considered to be a reflection of increased protein catabolism and perhaps dehydration. Increased uric acid concentration was considered to be an indication of increased dietary protein intake. Tortoises that were feeding with restricted water intake revealed higher plasma osmolality with decreased BUN and increased uric acid concentrations. During wet seasons, plasma osmolality and uric acid, urea nitrogen, potassium, and sodium concentrations were lower than other seasons due to increased rates of water consumption and bladder emptying. Plasma concentrations of these analytes in captive tortoises having constant access to water are expected to resemble free-ranging tortoises in wet years.

Creatinine is a normal constituent of mammalian urine, but the amount formed in most reptiles is negligible (<1 mg/dL or 88.4 μmol/L) [1]. The blood creatinine concentration is generally considered to be of poor diagnostic value in the detection of renal disease in reptiles. By contrast, the blood creatine concentration may have diagnostic value in the detection of renal disease in some reptilian species, but the test is unavailable from most veterinary laboratories.

Uric acid is the primary catabolic end product of protein, nonprotein nitrogen, and purines in terrestrial reptiles, and it represents 80–90% of the total nitrogen excreted by the kidneys. The normal blood uric acid concentration in most reptiles is less than 10 mg/dL.

Hyperuricemia is indicated by uric acid values of greater than 15 mg/dL, and is usually associated with renal disease. Renal diseases that are associated with hyperuricemia include severe nephritis, nephrocalcinosis, and nephrotoxicity. Hyperuricemia is not sensitive or specific for renal disease in reptiles. Hyperuricemia associated with renal disease most likely reflects the loss of two-thirds (or more) of the functional renal mass. Hyperuricemia in reptiles can also be associated with gout or recent ingestion of a high-protein diet. Carnivorous reptiles tend to have higher blood uric acid concentrations than herbivorous reptiles, and their plasma uric acid concentrations generally peak the day after a meal, thereby resulting in a 1.5–2.0-fold increase in uric acid.

Xanthine oxidase and hydrolytic enzymes act upon proteins to form uric acid, which in the reptile is further converted into urate, the salt form of uric acid (sodium and potassium urates). Therefore, because urates are an end product of nitrogen metabolism, gout is commonly seen

in reptiles. Gout can result from an overproduction of uric acid (i.e., primary gout) or from an acquired disease that interferes with the normal production and excretion of uric acid (i.e., secondary gout). Conditions that result in secondary gout among reptiles include starvation, renal disease (especially tubular damage), severe and prolonged dehydration, and excessive dietary purines (i.e., herbivorous reptiles fed diets rich in animal proteins). Abnormalities seen in the plasma biochemical profile of reptiles with gout included a markedly increased uric acid concentration and moderate hyperglycemia (owing to the stress response) [13].

Although the kidney of some reptiles has high ALT and ALP activity, significant increases in the plasma activities of these enzymes do not occur with renal disease. The reason for this is that most of the enzymes released from damaged renal cells are pass directly into urine and are excreted and do not pass into plasma [7].

Reptiles rarely exhibit polyuria with renal disease. Therefore, urinalysis rarely is performed to assess renal disease because of a lack of available urine to perform the tests.

The normal glomerular filtration rate (GFR) based upon iohexol clearance has been established for the green iguana (*I. iguana*) and can be used to evaluate kidney function in that species [14, 15]. Reported values are 14.78–18.34 ml/kg/hr (mean and standard deviation of 16.56 ± 3.90 ml/kg/hr).

Electrolytes and acid-base balance

Water balance

Species, diet, and environmental conditions such as temperature and humidity influence the water consumption of reptiles. Desert species require less water than temperate and tropical species. Some reptiles have developed methods for conserving water. For example, tortoises and some lizards store water in the urinary bladder. Many reptiles can achieve water uptake through the cloaca by soaking. Water also is conserved in reptiles by the elimination of nitrogenous waste in the form of uric acid and urate salts, which are excreted in a semisolid state.

Sodium and chloride

Dietary sodium is absorbed in the intestines and transported to the kidneys where it then is excreted or resorbed, depending on the reptile's need for sodium. Some reptiles have nasal salt glands that participate in the regulation of sodium, potassium, and chloride concentrations in the blood. Therefore, disorders of the salt gland may affect the electrolyte balance.

The normal serum or plasma sodium concentration ranges between 120 and 170 mEq/L (mmol/L). The normal plasma sodium concentrations of tortoises and freshwater turtles range between 120 and 150 mEq/L (mmol/L). Sea turtles tend to have higher normal sodium plasma concentrations, which range between 150 and 170 mEq/L (mmol/L). The normal plasma sodium concentrations of lizards range between 140 and 170 mEq/L (mmol/L), and those of snakes, such as boas and pythons, range between 130 and 160 mEq/L (mmol/L). Hyponatremia can result from excessive loss of sodium associated with disorders of the gastrointestinal tract (i.e., diarrhea), kidneys, or possibly, the salt gland. Iatrogenic hyponatremia can occur with overhydration when administering intravenous or intracoelomic fluids that are low in sodium. Hypernatremia results from dehydration, either from excessive water loss or inadequate water intake, or from excessive dietary salt intake.

The normal serum or plasma chloride concentration of reptiles varies among species but generally ranges between 100 and 130 mEq/L (mmol/L). Plasma chloride concentrations of turtles tend to range between 100 and 110 mEq/L (mmol/L), whereas those of most lizards and snakes range between 100 and 130 mEq/L (mmol/L). The blood chloride concentration provides the least clinically useful information regarding the electrolytes. Hypochloremia in reptiles is rare and, when present, is suggestive of excessive loss of chloride ions or overhydration with fluids that are low in chloride ions. Hyperchloremia is associated with dehydration and, possibly, renal tubular disease or disorders of the salt glands.

Potassium

Normal serum or plasma potassium concentrations vary among reptilian species, but they generally range between 2 and 6 mEq/L (mmol/L). The normal plasma potassium concentration of most turtles, lizards, and snakes ranges between 2 and 6, 3 and 5, and 3 and 6 mEq/L (mmol/L), respectively. The amount of potassium in erythrocytes also differs among reptiles; therefore, the potential for artifactual hyperkalemia due to hemolysis varies with species. Common imbalances of serum or plasma potassium include inadequate dietary potassium intake or excessive gastrointestinal potassium loss (i.e., hypokalemia) or decreased renal secretion of potassium (i.e., hyperkalemia). Hypokalemia can also be associated with severe alkalosis. Hyperkalemia can also result from excessive dietary potassium intake or severe acidosis.

Acid-base

The normal blood pH of turtles and most other reptiles ranges between 7.5 and 7.7 at 23–25 °C. The normal blood pH of some snakes and lizards may fall below 7.4. The blood pH of reptiles is labile, however, and it changes with fluctuations in temperature. An increase in temperature or excitement may cause the blood pH to decrease. Cold-stunned sea turtles (turtles exposed to a wide range of temperatures and physiologic stressors) are initially affected by metabolic and respiratory acidosis [16]. The blood pH of most reptiles may increase to 7.7–7.8 during anesthesia. As in mammals, the oxygen dissociation curve for reptilian hemoglobin shifts to the left as the pH increases, thereby producing an increased

affinity of hemoglobin for oxygen but a decreased release to tissues. The buffering systems that regulate blood pH in mammals are most likely the same in reptiles, with the bicarbonate/carbonic acid buffer system being the most important because of the rapid rate of CO_2 elimination via the lungs after conversion from H_2CO_3. Total plasma CO_2 or bicarbonate concentrations are rarely reported in reptiles; however, normal total CO_2 values for most reptiles are expected to range between 20 and 30 mmol/L. A marked fasting physiologic metabolic alkalosis occurs in postprandial alligators because of an anion shift, with bicarbonate replacing chloride in the blood as chloride is lost (as HCl) via gastric secretions. Therefore, a postprandial decrease of chloride and increase of bicarbonate concentrations are seen in alligators and perhaps other reptiles.

Calcium

Both blood calcium metabolism and the amount of ionized calcium in reptilian plasma are mediated by parathormone (PTH), calcitonin, and activated vitamin D_3 (1,25-dihydroxycholecalciferol). Other hormones, such as estrogen, thyroxin, and glucagon, may also influence calcium metabolism in reptiles. The primary function of PTH is to maintain normal blood calcium concentration by its action on bone, kidneys, and intestinal mucosa. Low blood concentration of ionized calcium stimulates the release of PTH, which results in calcium mobilization from bone, increased calcium absorption from the intestines, and increased calcium reabsorption from the kidneys.

The exact role of calcitonin in reptiles is unknown, but it most likely has a physiologic role opposite that of PTH (i.e., inhibiting calcium resorption from bone). Increases in the blood calcium concentration stimulate the release of calcitonin from the ultimobranchial gland.

The active form of vitamin D_3 stimulates the absorption of calcium and phosphorus by the intestinal mucosa. Photochemical production of the active form of vitamin D_3 by exposure to ultraviolet radiation (wavelength, 290–320 nm) is believed to be essential for normal calcium metabolism in reptiles, especially basking species.

The calcium metabolism of female reptiles during egg production is similar to that of birds. During egg development, female reptiles exhibit hypercalcemia in response to estrogen and reproductive activity. The increase in total plasma calcium is associated with an increase in protein-bound calcium during follicular development before ovulation, and the total plasma calcium level may increase by two- to fourfold or more.

The normal plasma calcium concentration for most reptiles ranges between 8 and 11 mg/dL (2.0–2.7 mmol/L), and it varies both with the species and the physiologic status of the reptile. For example, some species of tortoises have low blood calcium concentrations (<8 mg/dL or 2.0 mmol/L) [1]. Sex-related differences have been reported for plasma calcium concentration in free-ranging populations of reptiles where females exhibit significantly greater calcium concentrations than males. This difference is likely to be associated with reproductive activity (vitellogenesis) at the time of sample collection. Regardless of age and sex, plasma ionized calcium concentrations remain consistent in healthy reptiles. The normal plasma ionized calcium concentration for healthy green iguanas (*I. iguana*) has been determined to be 1.47 ± 0.105 mmol/L (5.9 mg/dL ± 0.42) [17].

In most reptiles hypocalcemia occurs when the plasma calcium concentration is less than 8 mg/dL (2.0 mmol/L). Hypocalcemia can occur with dietary calcium and vitamin D_3 deficiencies, excessive dietary phosphorus, alkalosis, hypoalbuminemia, or hypoparathyroidism. Secondary nutritional hyperparathyroidism is a common disorder of herbivorous reptiles such as green iguanas (*I. iguana*) [18]. Diets fed to captive herbivores are often deficient in calcium and contain excessive amounts of phosphorus. In addition, dietary deficiency in vitamin D_3 or lack of proper exposure to ultraviolet light predisposes reptiles to hypocalcemia. Juvenile reptiles (especially green iguanas) with secondary nutritional hyperparathyroidism commonly develop metabolic bone disease with fibrous osteodystrophy and bone fractures. Adult reptiles often develop muscle tremors, paresis, and seizures with hypocalcemia. Carnivorous reptiles that are fed all-meat, calcium-deficient diets also develop hypocalcemia associated with nutritional imbalances in calcium and phosphorus. Secondary renal hyperparathyroidism may result in hypocalcemia as well.

Hypercalcemia in reptiles is indicated by a plasma calcium concentration of greater than 20 mg/dL (5.0 mmol/L). Typically, this is an iatrogenic condition that is associated with oversupplementation with oral or parenteral calcium and vitamin D_3. Other differentials for hypercalcemia include primary hyperparathyroidism, pseudohyperparathyroidism, and osteolytic bone disease; however, these disorders are rarely reported in reptiles.

Pseudogout is a joint disease that occurs due to accumulations of substances other than urate crystals, such as basic calcium phosphate (hydroxyapatite) in turtles and lizards. This condition must be considered a differential when crystal deposition is observed in joints as pseudogout is a disorder of calcium metabolism that clinically mimics gout [13].

Phosphorus

The normal plasma phosphorus concentration for most reptiles ranges between 1 and 5 mg/dL (0.3 and 1.6 mmol/L). Differences between sexes have been reported for plasma phosphorus concentration in free-ranging populations of

reptiles where females exhibit significantly higher concentrations than males. This difference is likely to be associated with reproductive (vitellogenesis) activity at the time of sample collection.

Hypophosphatemia may result from starvation or a nutritional deficiency of phosphorus. Hyperphosphatemia is indicated by a plasma phosphorus concentration of greater than 5 mg/dL (1.6 mmol/L). Disorders resulting in hyperphosphatemia include excessive dietary phosphorus, hypervitaminosis D_3, and renal disease. Rare causes of hyperphosphatemia include severe tissue trauma and osteolytic bone disease. In mammalian blood samples, an artifactual hyperphosphatemia can occur when serum or plasma is not promptly separated from the clot, thereby allowing phosphorus to be released from erythrocytes. A few studies have suggested this may be less likely with reptilian blood samples; however, hyperphosphatemia has been related to hemolysis in reptilian blood samples. The ideal sample for biochemical testing is obtained by the immediate separation of the cells from plasma with no hemolysis.

Laboratory evaluation of the reptilian liver

Liver enzymes in reptiles appear to be similar to those in birds and mammals. The LD and AST activities are high in reptilian liver tissue, and although few critical studies have examined the biochemical testing of reptilian blood to evaluate hepatic disease, increases in the plasma activities of these enzymes may suggest hepatocellular disease. The plasma AST activity is not considered to be organ specific because activity for this enzyme can be found in many tissues. In general, normal plasma AST activity for reptiles is less than 250 IU/L. Increased plasma AST activity suggests hepatic or muscle injury. Generalized diseases such as septicemia or toxemia, however, may damage these tissues, thereby producing increased plasma AST activity. Increased AST activity in the plasma of healthy free-ranging tortoises may be related to muscle activity and injury due to increased male aggression during the breeding season.

LD is considered to have a wide tissue distribution in reptiles. Therefore, increases in the plasma LD activity (>1000 IU/L) may be associated with damage to the liver, skeletal muscle, or cardiac muscle. Hemolysis also may result in increased plasma LD activity.

Like AST, plasma ALT is not considered to be organ specific in reptiles. The normal plasma ALT activity for reptiles is usually less than 20 IU/L. Although ALT activity occurs in the reptilian liver, increases in the plasma ALT activity may not be as reliable in the detection of hepatocellular disease compared with increases in the plasma AST or LD activity. However, it has been suggested that elevated plasma ALT activity can be associated with a prolonged diet of unnatural foods that causes liver disorders in captive tortoises.

ALP is also widely distributed in the reptilian body, and the plasma activity of this enzyme is not considered to be organ specific. Little information is available concerning the interpretation of increased plasma ALP activity in reptiles; however, increased activity may reflect increased osteoblastic activity rather than hepatobiliary disease. Increased plasma ALP has been associated with hyperparathyroidism and bone diseases, such as Paget's disease.

Biliverdin, a green bile pigment, is generally considered to be the primary end product of hemoglobin catabolism in reptiles. Green plasma results from the accumulation of biliverdin in reptilian blood, which is usually a pathologic finding that suggests hepatobiliary disease in these animals. A nonpathologic accumulation of biliverdin can occur in the blood of some reptilian species, such as arboreal scincid lizards (Scincidae) of the southwestern Pacific, which are rarely presented for clinical evaluation. The physiologic advantage of this is not known. Biliverdin appears to be less toxic to tissues compared with bilirubin, and the normal biliverdin concentration in the plasma of some species of lizards (i.e.,, *Prasinohaema*, green-blooded skinks) can be greater than 1000 μmol/L.

Laboratory evaluation of plasma and serum proteins

The plasma total protein concentration of normal reptiles generally ranges between 3 and 7 g/dL (30–70 g/L) depending on sex, species, collection technique, specimen storage, and method of analysis. Female reptiles demonstrate marked increases in their plasma total protein concentration (primarily globulin concentrations) during active folliculogenesis. This estrogen-induced hyperproteinemia is associated with increased levels of the proteins (primarily globulins) necessary for yolk production. The plasma total protein concentration returns to normal after ovulation. Captive reptiles may exhibit greater plasma total protein concentrations when compared to the same free-living species due to prolonged high-protein diets [2].

The biuret method is the most accurate for determining the plasma or serum total protein concentration. The refractometer method, however, is commonly used to rapidly estimate the plasma protein concentration in reptilian blood. Although the refractometric method tends to overestimate the total protein value, it is useful for clinical decisions.

Serum/plasma protein electrophoresis, a standard technique in veterinary medicine to investigate dysproteinemias, provides an accurate assessment of the albumin and globulin concentrations in reptilian blood [19]. Using this technique, absolute concentrations of the various plasma proteins are obtained by determining the total protein concentration

using the biuret method in conjunction with electrophoretic separation of the proteins. Difficulties arise, however when performing protein electrophoresis with samples obtained from reptiles. Whereas protein separation has been optimized for human and domestic mammals, no criterion for the identification of different protein fractions in reptiles has been defined. Therefore, the albumin peak is often identified arbitrarily as the first main peak of each study. Agarose gel electrophoresis (AGE) is recommended because of its higher resolution when compared to cellulose acetate electrophoresis (CAE). For example, in one study, a-globulins could usually be separated into α-1 and α-2 fractions when using AGE, but separation was more difficult with CAE [20]. Because difficulties in the identification of the main globulin subfractions (α1, α2, β1, β2) are frequently encountered in some samples, it is recommended to report only one α and one β globulin fraction when calculating minimum–maximum reference intervals [21]. Also, considerable variation in results occurs between species and among individuals within a species associated with environmental factors such as habitat, season, and diet, which create difficulty in the comparison of results with published reference intervals. In general, because globulins behave similarly in vertebrate metabolism regardless of the species, the interpretation of the changes in the different globulin fractions are considered to be comparable to the protein fraction changes in mammals.

Changes in serum and plasma proteins in chelonians have been reported with regard to sex, season, location, and diseases [22]. Albumin was reported to be higher in postprandial turtles in one study [23]. Higher albumin and globulin concentrations are expected to occur before hibernation in chelonians. The higher globulins are likely related to the abundance of α2 macroglobulin and lipoproteins (high- and very-low-density lipoproteins) as seen with hibernating mammals. The increased α2 macroglobulin is likely associated with an important circulating protease inhibitor involved in regulating a number of steps in the clotting cascade and in complement activation, which would prevent clot formation when the heart rate decreases and blood viscosity increases during hibernation as seen in hibernating mammals [24]. Other alpha globulins include lipoproteins. In mammals, α1-lipoprotein (HDL) is responsible for transporting cholesterol from peripheral tissues to the liver, and very-low-density lipoprotein (VLDL) is responsible for triglyceride delivery to peripheral organs [25]. The abundance of α2 macroglobulin in hibernating chelonians likely indicate a switch to a lipid-based metabolism, as reported for hibernating mammals [21]. In another study, significant differences were observed with total protein, α-1 globulins, α-2 globulins, β globulins, γ globulins, with regard to sex, season, and location [26]. Differences in β globulin fractions also occurred with regard to age.

Limited studies have been conducted on serum and plasma protein in lizards. A double peak with a migration rate similar to that of albumin was detected in healthy and diseased Green Iguanas (*I. iguana*) indicating that many of these animals have bisalbuminemia [20, 27]. Bisalbuminemia has been reported in certain salamanders (subspecies of *Salamandra*) as well as hereditary or acquired disorder of humans. In iguanas, bisalbuminemia probably has a genetic origin, based on the symmetric shape of the double peak and its lack of association with a specific disease or pharmacological treatment [20]. Studies also indicate the β-globulin fraction generally accounts for 28% of the total protein concentration in healthy green iguanas (*I. iguana*) [20]. Seasonal changes in albumin (between March and December) and γ globulins (between June and September) were also noted in this species [27].

There have been few attempts to establish reference intervals for protein electrophoretic fractions in snakes [28–30]. Variation in results occurs between species and among individuals within a species associated with age, sex, and environmental factors, such as habitat. For example adults have been shown to have higher gamma globulin fractions (0.47 g/dL) than juveniles (0.28 g/dL) and male snakes have higher α-2 globulins (0.98 g/dL) than females (0.85 g/dL) [28]. Total protein, albumin, and globulin concentrations may also vary with the location of snakes within the same species.

In most reptiles, hyperproteinemia is indicated by total protein values of greater than 7 g/dL (70 g/L); common causes include dehydration or hyperglobulinemia associated with chronic inflammatory diseases. The alpha, beta, and gamma globulins may increase with infectious diseases. A significant increase in total protein as measured by chemical analyzers can occur with hemolysis.

Hypoproteinemia, as indicated by a total protein value of less than 3 g/dL (30 g/L), is commonly associated with chronic malnutrition in reptiles. Other causes, however, such as malabsorption, maldigestion, chronic malnutrition, protein-losing enteropathy (usually associated with parasitism), severe blood loss, and chronic hepatic or renal disease, should also be considered.

Laboratory evaluation of glucose metabolism

In general, the normal blood glucose concentration of most reptiles ranges between 60 and 100 mg/dL (3.33–5.55 mmol/L), but this is subject to marked physiologic variation. The blood glucose concentration of normal reptiles varies with species, nutritional status, and environmental conditions. For example, an increase in temperature produces hypoglycemia in turtles but hyperglycemia in alligators. In aquatic reptiles, hypoxia associated with diving results in a

physiologic hyperglycemia because of anaerobic glycolysis. Normal oral glucose tolerance curves in reptiles differ both among species and with temperature. A significant sex-related difference in plasma glucose concentration has been observed in free-ranging tortoises where males have higher concentrations than females [31]. The reason for this is not known.

Common causes of hypoglycemia in reptiles include starvation and malnutrition, severe hepatobiliary disease, and septicemia. Clinical signs associated with hypoglycemia in reptiles include tremors, loss of righting reflex, torpor, and dilated, nonresponsive pupils.

In mammals, prolonged exposure of the serum to erythrocytes results in a glucose concentration that decreases at a rate of approximately 10% per hour. Limited studies have shown that this does not occur in reptiles. A significant decrease in plasma glucose concentration may not occur until erythrocytes have been in contact with the plasma for 96 hours [20]. This is likely a result of slower reptilian erythrocyte metabolism compared to that of mammals.

Hyperglycemia in reptiles often results from the iatrogenic delivery of excessive glucose. A persistent, marked hyperglycemia and glucosuria are suggestive of diabetes mellitus, which is a rarely reported disorder of reptiles. Hyperglycemia also may occur with glucocorticosteroid excess [32, 33].

Laboratory evaluation of lipid metabolism

The normal serum cholesterol concentration of reptiles varies depending upon the natural diet. In general, healthy herbivorous reptiles are expected to have lower normal cholesterol concentrations (77–270 mg/dL or 2–7 mmol/L) compared to that of omnivores and carnivores. Low-density lipoprotein (LDL) is the major carrier of cholesterol in the serum of tortoises (*Agrionemys horsfieldi*, *Testudo graeca*, and *Testudo hermanni*) with high-density lipoprotein (HDL) representing a minor carrier [34].

Seasonal and sex-related variation in the plasma lipid profile can occur in reptiles. For example, serum lipid concentrations tend to be higher in males than females. In one study, cholesterol represented 21% of the total lipid content in male Asian tortoises (*A. horsfieldi*) and only 14% in females [34]. Triglycerides and phospholipids are the major serum lipids in both sexes of these tortoises during reproduction (vitellogenesis). The lipid content of free-ranging tortoises changes immediately prior to hibernation as indicated by phospholipids and low-density lipoprotein cholesterol (LDL-C) being the major lipid fractions in serum, whereas triglycerides are very low [34].

Laboratory detection of muscle injury

CK is considered to be a muscle-specific enzyme and is used to test for muscle cell damage. Increases in the plasma CK activity can result from muscle cell injury or exertion. Increased plasma CK activity is frequently observed in reptiles that are struggling to resist restraint during blood collection, or that are exhibiting seizure activity. Increased plasma CK activity resulting from muscle cell damage occurs with traumatic injury, intramuscular injections of irritating drugs or fluids, and systemic infections that affect skeletal or cardiac muscle. Brain tissue generally has high CK activity; however, whether brain lesions contribute significantly to plasma CK in reptiles is not known.

Muscle injury also results in mild to moderate increases in plasma AST and LD activities. These enzymes are not organ specific for muscle, however, and their activities could increase with hepatobiliary disease. Increased plasma AST and LD activities associated with normal CK activity suggests hepatobiliary disease. Damage to both liver and skeletal muscle can occur simultaneously, such as occurs with trauma and septicemia, which would result in elevated plasma AST, LD, and CK activities.

Laboratory evaluation of endocrine disorders

Laboratory evaluation of reptilian thyroid and adrenal function is uncommon. Because of the ectothermic nature of reptiles, their physiologic status, which includes endocrine physiology, is highly dependent on the external environment. Therefore, correction of environmental and nutritional deficits usually results in restoration of normal physiologic health.

The hypothalamo-pituitary-adrenal axis of reptiles appears to be typical of most vertebrates; therefore, a reptile's response to stress has an influence on glucose utilization and other metabolic activities modulated by the adrenal gland. Use of plasma corticosterone concentration as the sole measurement of stress is not recommended due to physiological variations. For example, there is a circadian and seasonal variation in plasma corticosterone concentrations in free-ranging reptiles, which tend to have higher concentrations than do captive reptiles of the same species. Because a twofold increase in corticosterone is expected to occur in one hour following capture with peak increases in 3 hours, it is recommended that baseline concentrations be obtained within 10 minutes of capture.

38 Clinical Chemistry of Fish and Amphibians

Fish

Blood biochemical evaluation is not routinely part of the clinical assessment of piscine patients most likely owing to the expense involved and lack of meaningful reference intervals. As a result, much of the blood biochemical studies have focused on economically important (either as a food source or for exhibit) species, such as salmonids (salmon and trout), catfish, and cyprinids (carp, goldfish, and koi) [1–7]. Routine assay methods for the biochemical evaluation of mammalian blood appear to be useful for fish blood; however, interpretation of the results can be difficult. Many endogenous (i.e., species, age, nutritional status, gender, reproductive status) and exogenous factors (i.e., environmental conditions, population density, time of day [diel cycle], and method of capture) influence the plasma biochemistry results of fish.

Because the physiology of fishes is influence by the aquatic environment, the "normal" reference intervals for one group of fish from one environment may be considered "abnormal" from those of the same species living in a separate environment. Therefore, established reference intervals for each species of fish should include as many variables as possible. These should include sex, age, nutrition, water-quality parameters, stocking density, and sampling techniques [8].

Sample collection and handling

Blood samples for biochemical studies of fish are collected in the same manner as that described for hematologic studies (see Chapter 22). When collecting blood, emersion, and handling of fish for as little as 30 seconds can elicit changes in plasma biochemical analytes such as electrolytes and ammonia [9, 10]. Changes in plasma electrolyte concentrations resulting from transmembrane shifts of H^+, Na^+, Cl^-, and H_2O also may continue until the erythrocytes and plasma are separated. The magnitude of these changes varies directly with the handling time and with the time that elapses between blood collection and analysis. In sturgeon and presumably other fish, storage at 4°C limits serum glucose decline for at least 4 hours: however, at 25°C, serum-clot contact time should not exceed 2 hours [11]. *In vitro* changes after blood collection can be minimized by separating plasma from the erythrocytes as soon as possible after the specimen is obtained.

Capture stress is unavoidable when dealing with wild-caught fish or removal of fish from large exhibits. The stress response will have a significant effect on some plasma biochemistry analytes [9, 10, 12, 13]. For example, lactic acidosis may occur after 5 minutes of capture involving strenuous muscle activity as a result of lactate released from the white muscle of fish. The resulting intracellular fluid shift affects the majority of plasma constituents. Complete recovery of the blood parameters may require 2 weeks following 2-minute handling stress. Chemical restraint of captive fish may also affect plasma biochemical results. For example, tricaine methanesulfonate, a commonly used anesthetic for fish, can cause increases in plasma glucose and potassium and urinary electrolyte loss is teleost fish.

Biochemical evaluations on piscine blood can be performed using either serum or plasma [14]. Blood may be collected into an anticoagulant such as lithium heparin to harvest a plasma sample. Plasma is preferred over serum in some species of fish owing to the long time required for clot formation that may produce significant changes in some of the blood biochemical values. Furthermore, a larger sample volume can usually be obtained when performing biochemical tests on plasma versus serum; an important consideration when testing small fish. Collection of blood into lithium heparin also allows for evaluation of the hemogram and plasma chemistry parameters with use of only a single sample.

The sample size is often small, especially when blood is collected from small fish. Therefore, the clinician must decide which tests would be most beneficial in the evaluation of piscine patients. Blood biochemical tests that may be useful include those for total protein, glucose, aspartate

aminotransferase (AST), ammonia, creatinine, calcium, sodium, chloride, potassium, and bicarbonate.

Laboratory evaluation of the piscine kidney

Both grossly and histologically, the anatomy of the piscine kidney varies among species [15, 16]. Freshwater species have larger and more numerous glomeruli compared with those of marine species, some of which have aglomerular kidneys. When present, fish glomeruli resemble those of mammals. Fish kidneys lack a loop of Henle, and collecting ducts occur only in freshwater species. Fish also lack a true urinary bladder, although an enlargement of the distal ureter, which is of mesothelial rather than endothelial origin, resembles a bladder in some species. The primary urinary function occurs in the caudal kidney.

Normal renal physiology of freshwater fish

The kidney of freshwater teleosts (bony fish) have well-developed glomeruli, proximal and distal tubules, and collecting ducts. The proximal tubule has two subunits. The first (segment I) is homologous to the proximal tubule of tetrapod vertebrates, and the second (segment II) is found only in fish. Freshwater bony fish faced with a water volume load and salt loss maintain a high glomerular filtration rate (GFR) and urine production rate to counteract the marked osmotic uptake of water, whereas they conserve sodium chloride (NaCl) by reabsorption in the renal tubules and collecting ducts. The final processing of urine occurs in the water-impermeable "urinary bladder," where ion reabsorption is substantial.

Normal renal physiology of saltwater fish

The kidneys of marine teleosts have fewer and smaller glomeruli compared to those of freshwater species, and the distal tubule is usually missing. Glomeruli and proximal tubules also are missing in some marine species. Marine teleosts face water volume depletion and salt loading. In these fish, some reabsorption of urine occurs in the tubules and the "urinary bladder," which is permeable to water.

Normal renal physiology of sharks and rays

The kidneys of elasmobranchs (i.e., cartilaginous fish such as sharks, skates, and rays) are extremely complex and composed of glomeruli, proximal tubules, and distal tubules that are divided into segments, and collecting tubules and ducts. The GFR of marine elasmobranchs approaches that of freshwater teleosts to balance the osmotic influx of water across the gill [17]. The proximal tubules of these fish can secrete NaCl, and both fluid and salt are reabsorbed in the distal tubule to establish an osmotic gradient, thereby facilitating a tubular countercurrent system to promote the passive reabsorption of urea. The high urea concentration of marine elasmobranchs causes the plasma to be slightly hyperosmotic to the surrounding seawater. Thus, marine elasmobranchs face a net osmotic influx of water, because their gill epithelium is permeable to water but not to NaCl. The high plasma urea concentration of these fish would be fatal without the presence of trimethylamine oxide (TMAO), which, when present at 50% of the urea concentration, counteracts the toxic effects of urea. Both plasma urea and TMAO are derived from hepatic biosynthesis, and the concentrations are maintained by low branchial (gill) permeability and renal tubular reabsorption. Freshwater rays have lost the ability to reabsorb urea and actually excrete urea to lower the plasma osmolarity; therefore they produce dilute urine similar in composition to that of freshwater teleosts with the exception that urea is the primary osmolyte [18, 19].

Plasma urea, uric acid, creatine, and creatinine

Piscine kidneys primarily are involved in ion excretion and osmoregulation [20]. Because these kidneys contribute little to the excretion of nitrogenous wastes, interpretation of the plasma concentrations of urea nitrogen, uric acid, and creatinine may not be useful in the evaluation of renal disease in fish. Urea is derived primarily from degradation of purines via uric acid. Most fish produce small amounts of urea with the exception of marine elasmobranchs, a few ureogenic teleosts, and coelacanths that produce urea as the major end product of nitrogen metabolism. Little is known concerning factors that regulate urea metabolism in teleosts. The gills, however, appear to predominate over the kidneys as the major organ of urea excretion in most fish (except perhaps marine elasmobranchs). Therefore, increases in the plasma urea concentration may be more indicative of branchial epithelial disease than of renal disease in teleost fish [21]. Freshwater teleosts living in alkaline lakes with high pH have high plasma urea concentrations because of a possible interaction of acid-base with urea production. Plasma urea concentrations increase in species such as the lungfish (*Protopterus* sp.), which can survive out of water (i.e., estivation) for extended periods. These fish primarily are ammoniotelic when living in water, but during estivation, the plasma ammonia concentration decreases to negligible levels and the urea concentration increases to avoid ammonia toxicity. The plasma urea concentration also increases in cyprinids (carp, goldfish, and koi) exposed to high environmental levels of ammonia.

The normal plasma urea concentration of freshwater and marine teleosts is less than 10 mg/dL (3.57 mmol/L) and 5 mg/dL (1.79 mmol/L), respectively. Marine elasmobranchs (sharks and rays) have a normal mean plasma urea concentration that ranges between 350 (125 mmol/L) and 1000 mg/dL (357 mmol/L) or higher. Decreases in the plasma urea concentration, especially in marine elasmobranchs, suggest decreased production consistent with

hepatic disease or starvation. Captive individuals typically have higher blood urea nitrogen (BUN) concentrations compared to those of the same species living in the wild [22]. Renal disease in marine elasmobranchs also may produce a decreased plasma urea concentration owing to reduced reabsorption.

Fish produce small amounts of uric acid, creatine, and creatinine, but little is known regarding their physiologic role. Uric acid, a degradation product of purine nucleotides and protein catabolism (via purines), produced primarily in the liver and white muscle of fish is generally converted to urea for excretion. Creatine, an end product of glycine, arginine, and methionine metabolism primarily in white muscle, represents more than 50% of the nitrogenous waste that is excreted through the kidney. Therefore, the plasma creatine concentration may be valuable in the assessment of renal disease among fish. Unfortunately, studies have not been performed to evaluate the use of creatine as an indicator of such renal disease, and most veterinary laboratories do not offer creatine assays.

Creatinine is formed from creatine and it also is secreted by piscine kidneys. The normal plasma creatinine concentration is low in most fishes, 0.11 (9.7 μmol/L) to 0.88 mg/dL (77.8 μmol/L) [8]. In the English sole (*Parophrys vetulus*), increases in the plasma creatinine concentration have been associated with renal disease, although the urea concentrations remained normal [23].

Divalent ions

Excess divalent and monovalent ions are excreted in marine teleosts by different routes after the oral ingestion of seawater. The kidneys excrete divalent ions such as magnesium and sulfate, and increases in the plasma concentrations of these ions may indicate renal disease in these fish.

Laboratory evaluation of electrolytes and acid-base balance

Electrolytes are indicative of a fish's ability to osmoregulate and are the best understood biochemical analytes in fishes. Values are compromised by stress, disease, or gill lesions that increase permeability of the gills to ions.

Osmoregulation

Teleost (bony fish) plasma is hyperosmotic to freshwater but hypoosmotic to seawater. Freshwater teleosts are hyperregulators, and they face hyperhydration and ion losses by diffusion. They maintain osmotic and ionic homeostasis by active uptake of ions across the intestinal and branchial epithelium. Because plasma sodium and chloride concentrations are more commonly measured than plasma osmolarity, the formula $Osm_{NaCl} = [Na^+ + Cl^-] \times 0.91$ is frequently used as a measurement of osmolarity in the literature [20]. Marine teleosts (Osm_{NaCl} greater than 300) are hyporegulators and maintain plasma osmolality at approximately one-third that of seawater and slightly greater than that of freshwater teleosts (Osm_{NaCl} = 195–252) [17]. The resulting osmotic water loss compensated for by drinking seawater. A $Na^+/K^+/Cl^-$ co-transporter drives the water uptake in the intestinal epithelium, and the high uptake of monovalent ions is compensated for by excretion of these ions via the gills. Therefore, marine teleosts ingest saltwater to balance the osmotic loss of water across the gills, and freshwater teleosts excrete large volumes of dilute urine to balance the osmotic uptake of water.

Whereas plasma sodium chloride contributes to greater than 75% of the osmolarity of teleost fish, it contributes to only 50% or less in elasmobranchs (sharks, rays, and skates). Nonprotein nitrogen, primarily urea, makes up most of the balance in marine elasmobranchs to raise the osmotic pressure to slightly greater than that of the ambient seawater. Therefore, marine elasmobranchs, unlike marine teleosts, do not lose water across the gills; instead, they gain small amounts that allow for urine formation. Thus, marine elasmobranchs do not drink seawater. A decrease in plasma urea concentration and osmolarity occurs in marine elasmobranchs during fasting because of a decrease in urea biosynthesis. These decreases also occur when marine elasmobranchs move to environments with lower salinity because of increases in renal urea clearance.

Some freshwater elasmobranchs have higher plasma osmolarity (Osm_{NaCl} approximately 380) compared to that of other freshwater fish and yet maintain a high urea concentration, although it may be 50% that of marine elasmobranchs [18, 19]. These fish are considered to be more recent emigrants to the freshwater environment. Freshwater rays, known to be long-term inhabitants of freshwater habitats, have a lower osmolarity (Osm_{NaCl} approximately 281) with urea having negligible participation.

Osmoregulation of marine elasmobranchs involves the kidneys, rectal glands, gills, and diet. A high level of urea is maintained by renal tubular reabsorption. In freshwater, urea is excreted to lower the osmolarity. Rays adapted to living in freshwater have lost the ability to reabsorb urea. The rectal gland of marine elasmobranchs is a salt secreting organ. When exposed to freshwater, these fish exhibit regression of the gland. Freshwater rays have no functional rectal gland. Two-thirds of the total sodium and chloride excreted by elasmobranchs occurs in the gills. Their gills have low permeability to urea. Finally, metabolic urea is directly related to food availability.

Sodium chloride

Na^+ and Cl^- are the major ions in the blood of all fish [20]. Marine teleosts display a higher branchial permeability to salt; therefore, the unidirectional Na^+ and Cl^- fluxes are

10- to 50-fold greater than those of freshwater teleosts. Ionic gradients across the gill epithelium are of the same magnitude as those of freshwater fish, but they are reversed in direction. Because the kidney of marine teleosts cannot produce urine, which is hyper-osmolar relative to plasma, extrarenal salt secretion must occur. The mitochondria-rich chloride cells of the gills are most likely the sites of ionic and/or acid-base regulation involving Na/H [NH_4] and Cl/HCO_3 exchanges in fish.

The rectal gland is the site of extrarenal salt secretion in marine sharks and rays [24]. This gland produces a solution that is iso-osmotic to the plasma but that contains more NaCl than seawater (in a manner similar to the NaCl transport system in the thick, ascending limb of the loop of Henle in mammals). An increase in plasma volume, rather than in NaCl concentration, appears to stimulate rectal gland secretions in marine elasmobranchs [17].

Fish have adapted to marine or freshwater environments by using osmotic and ionic regulating mechanisms allowing them to maintain a relatively constant plasma and intracellular salt concentration as well as cellular volume. Whereas the kidney is the primary osmoregulatory organ of terrestrial vertebrates, fish use organs such as the gills, intestines, rectal glands, and to a lesser extent, the kidneys to regulate fluid volume and salt concentration.

The normal plasma sodium and chloride concentrations of freshwater teleosts and marine teleosts are approximately 150 mEq/L (mmol/L) and 130 mEq/L (mmol/L), respectively. Plasma sodium and chloride concentrations are affected by changes in ambient salinity, gill function, and stress. Within a few minutes of capture and handling trauma, catecholamines, and cortisol are released along with lactic acid release from muscles. Stress-induced release of catecholamines causes an increase in blood pressure resulting in an increased electrolyte permeability of the gills that causes a rapid decrease in sodium and chloride in freshwater teleost fish and increase in those ions in marine teleost fish. Hyponatremia and hypochloremia in freshwater fish can be associated with gill and renal disease or with acidic or soft-water environments.

Influx of Na and Cl in marine elasmobranchs from the environment is compensated for by efficient salt excretion mechanisms in both the kidney and the specialized rectal gland [24]. Variability seen in plasma and serum Na and Cl ion concentrations between wild-caught and captive elasmobranchs may relate to differences in environmental salinity and diet and subsequent alterations in ion regulation or may reflect normal variability [22].

Potassium

The normal plasma potassium concentration of freshwater fish is approximately 2–4 mEq/L (mmol/L). Less than 2% of the total body potassium is found in extracellular fluids; therefore, plasma levels are unaffected by changes in gill electrolyte permeability [20]. Greater than 95% of the potassium ingested by marine fish is absorbed in the intestines, and the excess is excreted extrarenally as part of the slime coat. Variability seen in plasma and serum K ion concentration between wild-caught and captive elasmobranchs may relate to differences in environmental salinity and diet and subsequent alterations in ion regulation or may reflect normal variability [22]. Hypokalemia may be associated with alkalosis, gastrointestinal or cutaneous potassium loss, or nitrite toxicity. Hyperkalemia may be associated with acidosis, such as occurs following strenuous muscle activity during capture and handling, and decreased renal secretion of potassium in freshwater teleosts. Hemolysis will also cause an artificial increase in plasma potassium.

Calcium

The normal plasma calcium concentration of teleosts is approximately 8–10 mg/dL (2–2.5 mmol/L). Because water is a readily available source of calcium, the plasma calcium concentration is influenced by the environmental calcium concentration. Fish have access to a continuous supply of calcium, so they must limit their calcium intake (unless the environmental calcium levels are low). In freshwater teleosts, calcium is transported by the chloride cells in the gills to the blood. Calcium ions enter these cells passively along the electrochemical gradient via calcium channels in the apical cell membrane. Stanniocalcin is a hormone that is unique to certain fish (e.g., teleosts) and that acts as a calcium-channel blocker to prevent the development of hypercalcemia [20]. Fish do not have parathyroid glands or a parathormone-like hormone. How fish that do not produce stanniocalcin regulate their blood calcium concentrations is not yet known.

In contrast to tetrapods, calcitonin whose role is to correct excessive calcium levels does not play a prominent role in calcium regulation in fish. Calcitonin is produced by the ultimobranchial bodies of fish and has a role in protecting the skeletal system during periods of increased demand for Ca^{2+} during active oogenesis.

In male and nongravid female freshwater teleost fish, 30–40% of the total plasma calcium is bound to protein. Approximately 22% of the total calcium is bound to protein in marine teleosts. Therefore, changes in plasma protein will affect the plasma total calcium concentration. For example, during vitellogenesis, a greater than threefold increase in total protein and calcium will be expected; however, free Ca^{++} concentration remains constant.

Both stress and circadian fluctuations have negligible effects on plasma calcium concentrations in freshwater fish [8].

Phosphorus

In general, the normal plasma phosphorus concentration of fish is approximately 3.5–8.9 mg/dL (1.1–2.9 mmol/L).

However, variations in diet, water quality, and age can lead to alterations in phosphorus concentrations [2, 4, 25].

Magnesium

The plasma magnesium concentration of freshwater fish and marine elasmobranchs is generally lower than the calcium concentration; however, marine teleosts have magnesium concentrations that are greater than calcium. In general, inorganic ions, such as Na, Cl, and Ca, are kept below levels found in the ambient marine water. Approximately 25% of the plasma magnesium concentration is bound to protein; however, the mechanism of magnesium regulation is unknown. Because magnesium concentration within erythrocytes is nearly 10 times that of plasma, hemolysis would be expected to produce an artificial increase in plasma magnesium concentration.

Acid-base balance

Acid-base regulation in fish is more challenging compared with that of terrestrial animals, because the composition of water varies to a greater degree than that of air. Large and rapid changes in oxygen and carbon dioxide (CO_2) levels, electrolyte concentrations, and temperature are significant challenges to acid-base regulation. The branchial epithelium is the site of gas exchange and principal ion regulation in fish; ions readily transfer across the gill surface. Therefore, changes in the water ionic composition affect the ionic transfer process across the branchial epithelium, which in turn affects osmotic and acid-base regulation.

Fish have a low blood CO_2 concentration compared with that of terrestrial animals [26]. This results from the high rate of gill ventilation and the much larger capacity of water for carbon monoxide (CO) dissolution. The small environmental CO_2 and arterial CO_2 differences limit the ability of fish to compensate for changes in arterial CO_2 by hyper- or hypoventilation. Therefore, changes in CO_2 are too small to contribute significantly to the acid-base balance in fish. However, even though respiratory regulation contributes little to acid-base balance, fish have a larger epithelial ionic transfer capacity than that of air-breathing mammals, and they also have the capacity for a net gain of bicarbonate from the environment to facilitate normalization of the acid-base status [27]. This epithelial ionic transfer is a function of the chloride cells located in juxtaposition to the secondary circulatory system of the central venous gill sinus. Ionic transfer for acid-base regulation also occurs, although to a lesser extent, across the skin and kidney of fish.

Laboratory evaluation of branchial epithelium

Because the gills of fish are important organs for osmotic, ionic, and acid-base regulation as well as for removal of nitrogenous waste, changes in the blood biochemistry may reflect damage to the branchial epithelium. Injury to gill tissue may result in thickening of the branchial epithelium and an increased distance for diffusion from blood to water. In turn, this may lead to an increased plasma concentration of analytes normally excreted by the branchial epithelium. Therefore, acid-base disturbances, electrolyte imbalances, and increases in the blood ammonia and urea concentrations may occur with damage to the branchial epithelium of fish.

Ammonia

Ammonia is the major end product of nitrogen metabolism in most fish except marine elasmobranchs. Ammonia is the most reduced and energy-efficient nitrogenous waste product of the biologic oxidation of dietary or structural proteins. The primary mechanism of ammonia excretion in freshwater teleosts is branchial excretion. The skin also contributes to ammonia excretion, especially in marine teleosts. The kidneys excrete less than 15% of ammonia.

The mechanism of branchial ammonia excretion primarily involves diffusion along a concentration gradient from blood to water and an electro-neutral Na^+/NH_4^+ exchange located on the apical membranes of the branchial epithelial cells [15, 21]. Electro-neutral H^+/NH_4^+ exchange also may occur in the gill membranes of fish. Marine teleosts excrete ammonia by NH_4^+ diffusion along an electrochemical gradient from blood to water.

The inflammation, swelling, and mucinification that occur with gill damage result in an increased diffusion distance between blood and water, thereby creating an increased blood ammonia concentration. Environmental toxins, changes in the environmental pH and ammonia concentrations, or infections can damage the gills of fish, thus resulting in increased blood ammonia concentrations. Increases in the environmental pH and ammonia concentration also can increase the blood ammonia concentration by the inhibition of ammonia diffusion, thereby reversing the blood-to-water gradient.

Plasma total ammonia is highly variable and rarely used in diagnostic testing of piscine patients. Both the site of blood collection and the duration of restraint affect the blood ammonia concentration in fish. Total plasma ammonia concentration is higher in samples obtained by caudal venipuncture (prehepatic blood) compared to samples obtained by cardiocentesis (posthepatic blood). Venous blood contains 50–60% more ammonia than arterial blood. During restraint, the release of ammonia from hypoxic muscles and the interference with branchial excretion also can increase the blood ammonia concentration in fish. Plasma ammonia levels increase with feeding, exhaustive exercise, exposure to air, and under certain water quality parameters, such as an increase in water temperature, increase in ammonia concentration, and alkaline pH.

Laboratory evaluation of the piscine liver

Little information is available regarding laboratory evaluation of the liver in fish. The liver tissue of teleosts appears to be rich in AST and possible alanine aminotransferase (ALT). Therefore, plasma activity of these enzymes may elevate with severe hepatocellular disease in some piscine species.

There is a general lack of information regarding the influence of nonpathogenic factors on the activities of these enzymes in the plasma of fish; however, a few studies have suggested that plasma enzyme evaluation in fish may not be as straightforward as it is in mammals. For example, the high ammonia levels of fish may lead to high transaminase activities; therefore, the increase in activities may be associated with liver disease or changes in plasma ammonia concentration. High activities of AST and creatine kinase (CK) also occur in muscle of fish; therefore, elevated plasma activities of these enzymes will increase following muscle injury or strenuous muscle activity associated with capture and restraint. Temperature changes have been reported to affect plasma enzyme activity of alkaline phosphatase (AP). The method of blood collection influences plasma lactate dehydrogenase (LDH) and CK activities in fish leading to the recommendation that blood collected by cardiocentesis be used for enzyme studies. Plasma LDH activity is also influenced by feeding and activity levels resulting in lower LDH values starvation and inactivity. It has also been shown that plasma LDH activity is positively correlated with water temperature and pH.

Bile pigments in most fish include both bilirubin and biliverdin; however, the percentages of these pigments vary between species. The serum usually is a light yellow color because of the presence of bilirubin. Hepatic disease in fish may not reliably cause an increased plasma bilirubin concentration. The serum from some fish (e.g., certain eels) is bluish green because of the presence of biliverdin.

There is little information about the normal bile acid metabolism in fish. Fish may continuously secrete bile acids into the intestines resulting in no change in plasma bile acid concentration associated with feeding.

Glucose

Plasma glucose concentration in fish is variable and can be as low as 30 mg/dL (1.67 mmol/L) in some species. The source of plasma glucose in fish is hepatic glycogen metabolism; therefore depletion of hepatic glycogen reserves may result in hypoglycemia. Plasma glucose concentration in fish is highly dependent upon the activity level of the fish. For example, sluggish benthic species have lower plasma glucose concentrations compared to the more active pelagic species. Plasma glucose concentration also varies with age, nutritional and reproductive status, and stress. The duration and magnitude of postprandial hyperglycemia in fish depends upon dietary carbohydrate intake. The effect of starvation on plasma glucose concentration is species and time dependent because many species of fish exhibit normal blood glucose concentrations (up to 150 days) following prolonged starvation. The mechanism allowing for maintenance of normal blood glucose concentrations with prolonged starvation is not known. Variation in blood glucose concentration also occurs with the reproductive status of fish were lowest blood glucose values in males and females are associated with spawning.

Stress-induced hyperglycemia is a common occurrence in fish and the extent and duration is influenced by the severity of stress. The increased plasma concentrations of catecholamines and adrenocorticosteroids associated with stress changes the muscle and hepatic glycogen reserves in fishes. Catecholamines mobilize glycogen stores and corticosteroids induce glycogen synthesis. Therefore, the plasma hyperglycemia associated with marked glycogenolysis in liver and muscle is likely due to stress-induced increases in catecholamines. Fluctuations in blood glucose concentrations appear to be linked to cortisol and thyroid hormone variations [28].

Cholesterol

It is not known whether changes in the plasma cholesterol concentration have significant meaning in regards to hepatic disease. Most fish, except for elasmobranchs, normally have higher blood cholesterol concentrations than do mammals. The majority of the blood cholesterol (60–90%) of fish is carried by high-density lipoproteins (HDL). The blood cholesterol concentration of elasmobranchs is lower than that of teleosts and varies with gender and reproductive status. Males undergoing active spermatogenesis have higher cholesterol values compared to inactive males. Females have lower blood cholesterol concentrations compared to males were females undergoing active egg production have the lowest values. Although the role of cholesterol is not well understood in elasmobranchs, the higher blood cholesterol concentration noted in captive elasmobranchs compared the same species caught in the wild may reflect a difference in nutritional plane between the two groups [22].

Protein

The total plasma protein concentration of fish ranges between 2 and 8 g/dL (20–80 g/L) when using the refractometric method. The normal plasma albumin concentration of fish ranges between 1.0 and 2.4 g/dL (10–24 g/l = L). The normal albumin: globulin ratio of fish is expected to be lower than that of mammals. Albumin and globulins are the major blood proteins in fish, with globulin levels being greater than those for albumin. These serum proteins play a large role in innate immunity, thus higher concentrations, in particular of globulins, in serum may be reflective of enhanced nonspecific immune responses in fish. Total plasma protein

is expected to have a higher value when determined by refractometry as compared to spectrophotometry. The use of the refractometer is often preferred because of its greater practicality compared to the more labor intensive and expensive spectrophotometer method. Protein is a major contributing factor of plasma refractive index, but nonprotein components such as glucose, cholesterol, and chloride can interfere with measurements in the refractometer. Due to these discrepancies, there should be awareness of the elevated values when using refractometry for estimating total plasma protein in fish. Plasma protein concentrations increase significantly with age in some species of freshwater fish [29]. The increase, mainly due to an increase in the globulin fraction, indicates that separate reference intervals for this analyte should be generated with respect to age in fish.

Changes in plasma protein can be an indicator of an underlying systemic infection or subclinical organ pathology. In veterinary medicine, plasma protein electrophoresis has been shown to be an important diagnostic tool when recognizing disease in various terrestrial species; however, there have been few studies involving its use in fish. The automated cellulose acetate electrophoresis and densitometry method, used widely in human and veterinary clinical biochemistry laboratories, is a practical method for estimation of serum protein fractions in freshwater teleost fish [30].

Gel electrophoresis was used to establish reference intervals for the following protein fractions: total protein, prealbumin, albumin, a-1 globulin, a-2 globulin, β globulin, c globulin, C-reactive protein, serum amyloid A, and haptoglobin in Whitespotted bamboo sharks (*Chiloscyllium plagiosum*) [31]. A significant difference was found in regard to sex, whereby females had higher β fractions and total protein concentrations when compared to males.

Laboratory evaluation of endocrine disorders

The neuroendocrine system of fish is similar to those of other vertebrates. Because fish have a very close interaction with the ambient aquatic environment, their endocrine system may differ functionally from those of terrestrial animals. For example, hormones such as prolactin, growth hormone, cortisol, glucagon, and somatostatin have important ionic regulating functions in fish that are not observed in terrestrial vertebrates. Fish also have unique hormones, including somatolactin, melanophore-concentrating hormone, urotensin, and stanniocalcin. Parathormone and aldosterone are not found in fish, however, and this implies the absence of a requirement for these hormones because of their close association with their aquatic environment.

Commercial kits for the measurement of hormones in mammalian plasma have been used successfully in the determination of hormones that are common to both types of animals [32]. Homologous radioimmunoassays (RIA) have been developed to assay the blood hormones of a few species of fish (salmonids and cyprinids).

Thyroid

Fish thyroid tissue appears to behave similarly to that of terrestrial mammals. It is stimulated by a thyroid-stimulating hormone to release thyroxine (T_4), which is de-iodinated to triiodothyronine (T_3) in target organs such as the gills and liver. There are species differences associated with blood thyroid hormone concentrations. The plasma concentration of thyroid hormones may be influenced by plasma protein concentration as they are bound to transport proteins. Increases in plasma T_3 and T_4 concentrations are associated with significant physiologic functions in fish, such as the adaptation of salmonids to seawater. Decreases in T_4 concentration indicate either decreased thyroid secretion or increased conversion of T_4 to T_3. In general, both hormones are elevated during growth and decreased during conditions such as stress, starvation, and vitelogenesis.

Adrenal (inter-renal tissue)

The inter-renal tissue of fish is homologous to the adrenal tissues of higher vertebrates. The major corticosteroid produced by this tissue in most jawed fish is cortisol. The major corticosteroid in elasmobranchs is 1α-hydroxycorticosterone. Plasma cortisol concentration is cyclic and affected by the photoperiod (diel cycle) and time of feeding with peak concentrations occurring prior to the onset of light and increased locomotory activity. Cortisol is involved in energy metabolism, ion regulation, and response to stress. Cortisol secretion is stimulated by the stress response (i.e., capture, handling, crowding, transport, rapid changes in water quality, and other physical disturbances) mediated by adrenocorticotropic hormone (ACTH) resulting in a rapid hyperglycemia. The corticosteroid stress response of elasmobranchs is small compared to that of teleost fish.

Amphibians

Blood samples for use in biochemical studies of amphibians are collected in the same manner as that described for hematologic studies (see Chapter 23). Blood to be evaluated for hematology and plasma biochemistry generally is collected into an anticoagulant (e.g., lithium heparin). Plasma is preferred to serum, because a larger sample volume usually can be obtained when collecting plasma.

Blood biochemical evaluation is not routinely part of the clinical assessment of amphibian patients. Routine assay methods for the biochemical evaluation of mammalian blood appear to be useful for amphibians. Interpretation of the results is difficult, however, because little information

Table 38.1 Normal serum biochemistry reference values for American bullfrogs (*Rana catesbeiana*) kept at 20–25 °C.

Urea (mg/dL)	3.00 ± 1.00[a]
Creatinine (mg/dL)	0.99 ± 0.20
Uric acid (mg/dL)	0.06 ± 0.05
Total protein (g/dL)	4.40 ± 0.30 (females)
	3.70 ± 0.80 (males)
Albumin (g/dL)	1.60 ± 0.30
Aspartate aminotransferase (IU/L)	45 ± 21
Lactate dehydrogenase (IU/L)	33 ± 20
Calcium (mg/dL)	8.7 ± 0.6 (females)
	7.4 ± 0.6 (males)
Phosphorus (mg/dL)	3.3 ± 0.7
Sodium (mEq/L)	111 ± 3.0 (females)
	105 ± 4.0 (males)
Potassium (mEq/L)	2.7 ± 0.4
Chloride (mEq/L)	77 ± 6.0
Total carbon dioxide (mmol/L)	25 ± 4.5
Anion gap (calculated)	9.9 ± 6.5

[a]All values represent mean +/– standard deviation.
Source: Modified from Cathers et al. [38].

is available regarding plasma or serum chemistry values. Table 38.1 demonstrates the expected normal serum biochemical values in bullfrogs (*Rana catesbeiana*). Extrinsic factors such as environmental temperature and humidity, photoperiod, season, water-quality parameters, diet, and population density likely affect the normal plasma biochemistries. Intrinsic factors such as gender and age also likely influence the variation in plasma biochemistry values. As an example, female bullfrogs have higher plasma total protein, calcium, and sodium concentrations than male bullfrogs.

Significant morphological and physiological changes take place during metamorphosis that is accompanied by biochemical changes that occur during organ differentiation and maturation. One important change during this period is an increase in total protein. Increased total protein serves to increase the osmotic pressure of the blood to improve its water carrying capacity as the aquatic larval form transforms into the postmetamorphic terrestrial adult. Albumin (which exerts 2–3 times the osmotic pressure per unit as does globulin) increases proportionately more than globulins during metamorphosis. During this period, serum proteins more than double and at least 20% of the increase is associated with an increase in albumin, which increases more than 10 times. In amphibian species where the adult remains aquatic, there is no change in serum protein. An increase in the serum albumin concentration has also been seen as an adaptation of amphibian species to a more arid environment. Therefore, because adult newts and salamanders and gilled aquatic amphibian larvae are more fishlike than adult toads and frogs, the interpretation of changes in their plasma biochemistry profiles may be more like those in fish. The plasma biochemical changes in adult toads and frogs may be more like those of reptiles.

Few biochemical reference intervals for wild and captive amphibians have been established. Higher serum concentrations of protein, cholesterol, glucose, urea, and uric acid have been found to be higher in female frogs compared to males; however, serum creatinine concentrations were higher in males [33]. Serum concentrations of calcium, total protein, albumin, HDL, amylase, potassium, carbon dioxide (CO_2), and uric acid were found to be significantly higher in aged frogs compared to young frogs [34]. Parameters found to be significantly lower in aged frogs included glucose, AST, ALT, cholesterol, BUN, phosphorus, triglycerides, low-density lipoprotein (LDL), lipase, sodium, chloride, and anion gap. These findings indicate that chemistry reference intervals for young amphibians may be inappropriate for use with aged frogs. Studies have also shown that wide interspecies and seasonal variations also occur, especially in wild populations [35]. These findings indicate the need to establish species-, season-, age-, and sex- specific reference intervals for amphibians.

Increases in serum gamma glutamyltransferase and alkaline phosphatase activities along with an increase in total cholesterol concentrations have been found useful in the detection of hepatic injury in amphibians exposed to cadmium toxicity [36]. Indicators of renal dysfunction, such as BUN, creatinine, and calcium were also useful in that same group of animals.

The pathogen *Batrachochytrium dendrobatidis* (Bd), which causes the skin disease chytridiomycosis, is one of the few highly virulent fungi in vertebrates and has been implicated in worldwide amphibian declines. Because the skin is critical in maintaining amphibian homeostasis, disruption to cutaneous function produces morbidity and mortality in these animals.

The electrolyte transport across the epidermis of amphibians with chitridiomycosis can be inhibited by greater than 50% resulting in a reduction of plasma sodium and potassium concentrations by 20% and 50%, respectively [37]. This results in death by asystolic cardiac arrest. Electrolyte depletion has been the most consistent finding in studies designed to determine the physiological effects of chytridiomycosis.

39 Cytology of Inflammation and Infectious Agents

Robin W. Allison
Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

Inflammation may be encountered in any cytologic sample and is, therefore, important to recognize. Inflammation is characterized by the types of inflammatory cells present, which may give clues to the underlying cause (Table 39.1). Inflammatory cells exfoliate readily, resulting in highly cellular cytologic samples. Inflammation can have noninfectious or infectious causes, and infectious agents may be visualized in cytologic specimens. Some infectious agents are morphologically distinct, allowing specific identification, while others may require additional diagnostics (culture, histopathology with special stains, polymerase chain reaction [PCR]) for identification.

Inflammatory cell types

Neutrophils

Inflammatory lesions characterized by a predominance of neutrophils are termed suppurative, purulent, or neutrophilic inflammation. Neutrophils are further characterized as nondegenerate or degenerate. Nondegenerate neutrophils appear similar to those in peripheral blood; nuclei have dense chromatin with distinct segmentation (Figure 39.1). Degenerate neutrophils have nuclear changes reflective of a toxic environment, most often associated with bacterial infections. Degenerate neutrophils have swollen nuclei that lose segmentation and stain pale pink (Figure 39.1). Such cells may eventually disintegrate and become unrecognizable (Figure 39.2). Neutrophils may appear degenerate in some microenvironments even in the absence of infection (i.e., airway or gastrointestinal tract samples, exposure to urine). Neutrophils may also lyse because of trauma from improper slide preparation or because of poor-preservation caused by improper sample handling. Neutrophils that are undergoing normal aging and cell death may be hypersegmented or pyknotic. Pyknotic neutrophils have nuclei that have become dense, dark purple spheres (Figure 39.1).

Underlying causes of suppurative inflammation include a wide variety of infectious and noninfectious disorders. Noninfectious causes include tissue inflammation secondary to neoplasia, necrosis, trauma, and immune-mediated disease. Many different types of infectious agents, especially bacteria, may cause predominantly suppurative inflammation. Neutrophils are phagocytic cells, thus microorganisms (most frequently bacteria) may be visualized within neutrophils, signifying septic, suppurative inflammation (Figure 39.2). If bacteria are only extracellular, potential contamination of the sample or presence of normal flora must be considered.

Macrophages

Inflammation characterized by a predominance of macrophages is termed histiocytic, granulomatous, or macrophagic inflammation. A mixed inflammatory cell population composed predominantly of neutrophils and macrophages may be termed either mixed or pyogranulomatous (Figure 39.3). Some pathologists prefer the term mixed, because a true pyogranulomatous process is an architectural arrangement that is best visualized by histopathology. Such mixed inflammatory processes may also contain small numbers of lymphocytes and plasma cells. Macrophage morphology can vary considerably in cytologic samples, causing confusion for even experienced cytologists. They may appear similar to peripheral blood monocytes but typically are large round cells with oval to indented nuclei and abundant lightly basophilic cytoplasm (Figure 39.4). Activated macrophages are vacuolated and often contain phagocytized cells or cell debris, erythrocytes or hemosiderin (evidence of previous hemorrhage), or microorganisms. Epithelioid macrophages are nonvacuolated and tend to cluster, mimicking epithelial cells. In chronic inflammatory conditions macrophages may fuse to become multinucleated inflammatory giant cells (Figure 39.5). Macrophages are capable of proliferating in tissues, in which case mitotic figures may be observed

Table 39.1 Inflammatory cells and associated conditions.

Type of inflammation	Predominant cell types	Commonly associated conditions
Suppurative (purulent, neutrophilic)	Neutrophils	Bacterial infections, immune-mediated disorders, necrosis, neoplasia, trauma
Histiocytic (macrophagic, granulomatous)	Macrophages	Foreign body reactions, mycobacterial infections
Lymphocytic/plasmacytic	Lymphocytes and plasma cells	Immune-mediated disorders, chronic inflammation, vaccine reactions
Eosinophilic	>10% eosinophil (± mast cells)	Eosinophilic granuloma, hypersensitivity reactions, parasite migration, some infections (*Pythium*, some fungal infections), neoplasia (mast cell tumor, lymphoma)
Mixed (pyogranulomatous)	Neutrophils and macrophages (± lymphocytes)	Foreign body reactions, fungal infections, some bacterial infections (*Mycobacteria*, filamentous bacteria), sterile panniculitis, chronic tissue injury, vaccine reactions

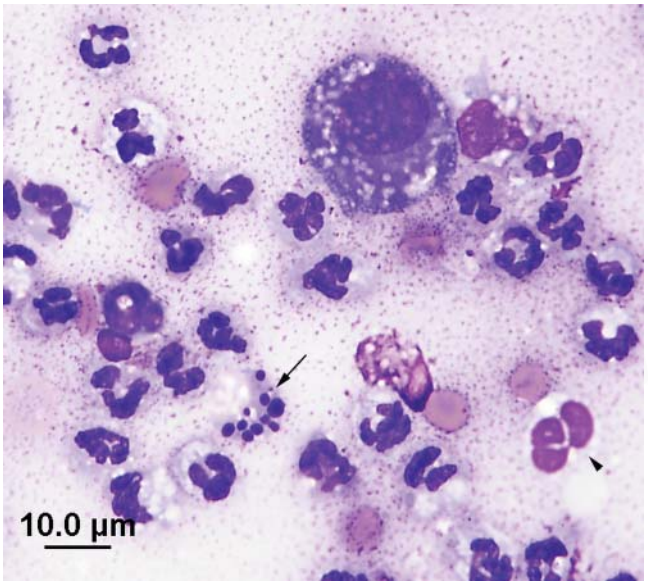

Figure 39.1 Suppurative inflammation. Most neutrophils are nondegenerate with distinct segmentations and dark chromatin. One cell has become pyknotic (arrow), with chromatin condensed into small dark spheres. One degenerate neutrophil (arrowhead) has swollen, pale-staining chromatin. One macrophage is present (large cell top center, round nucleus and cytoplasmic vacuoles). Aqueous Romanowsky stain.

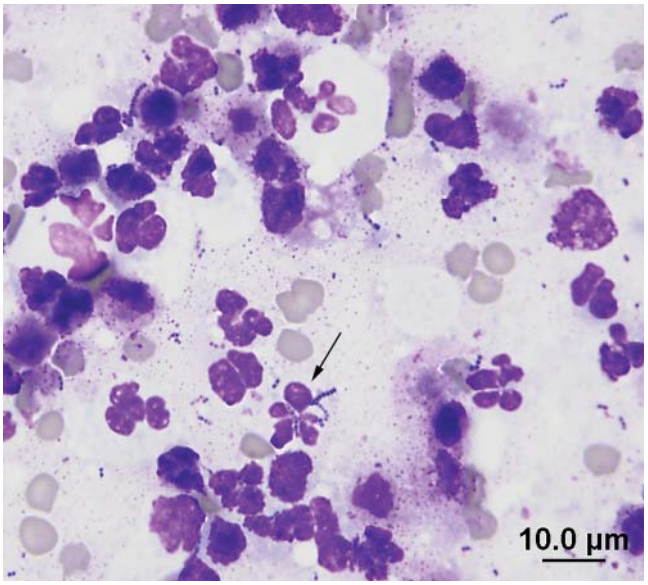

Figure 39.2 Septic, suppurative inflammation. Neutrophils are degenerate and barely recognizable; many have lysed. Dark blue bacterial cocci, most in chains, are present in the background and phagocytized by one neutrophil (arrow). There are also pink protein precipitates in the background. Aqueous Romanowsky stain.

(Figure 39.6). Because macrophages can normally have features that are considered criteria of malignancy (anisocytosis, bi- or multinucleation, prominent nucleoli, mitotic figures; see Figures 39.4–39.6), extreme caution is warranted when considering an interpretation of malignant neoplasia in the face of inflammation.

Lesions that typically contain moderate to large numbers of macrophages include chronic inflammation caused by foreign body reactions, sterile panniculitis, mycobacterial infections, fungal infections, infections caused by filamentous bacteria, and vaccine reactions. Vaccine reactions typically contain a mixture of macrophages, lymphocytes, plasma cells, and neutrophils. Vaccine adjuvant may be identified in cytologic samples from these lesions [1]. Adjuvant appears as magenta or blue (depending on the type of adjuvant) amorphous material that is often phagocytized by macrophages (Figures 39.7 and 39.8).

Lymphocytes and plasma cells

Lymphocytic inflammation is characterized by a mixed population of small and intermediate sized lymphocytes, often admixed with plasma cells and other inflammatory cells (neutrophils and macrophages). Lymphocyte

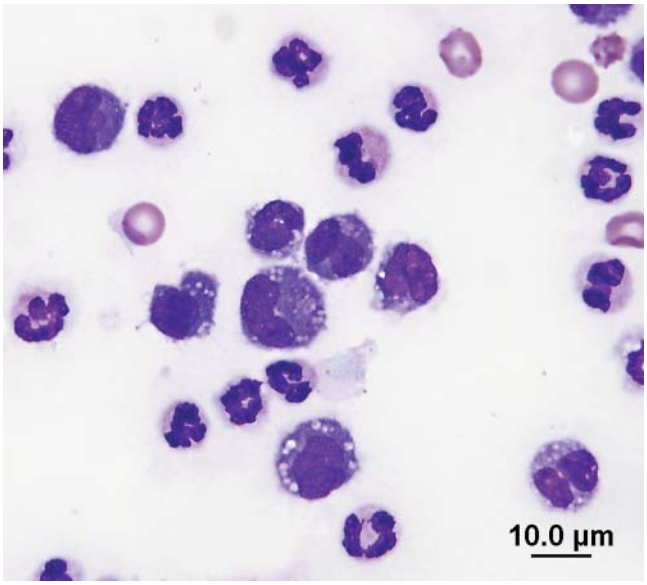

Figure 39.3 Pyogranulomatous inflammation. Neutrophils are nondegenerate. Macrophages vary from resembling blood monocytes to larger cells with indented nuclei and cytoplasmic vacuoles. Aqueous Romanowsky stain.

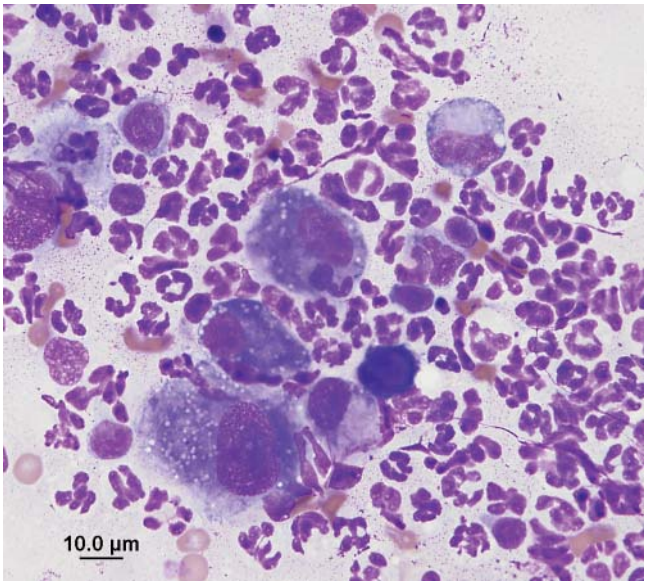

Figure 39.4 Pyogranulomatous inflammation. Neutrophils are a mixture of nondegenerate and degenerate cells. Macrophages are pleomorphic with variably sized nuclei, visible nucleoli, and cytoplasmic vacuolation. The pink granular proteinaceous background should not be confused with bacteria, which would stain blue. Aqueous Romanowsky stain.

and plasma cell morphology is similar to that found in hyperplastic lymph node aspirates (see Chapter 45). Lymphocytic/plasmacytic inflammation occurs with immune reactions (i.e., lymphocytic stomatitis and enteritis), vaccine reactions (Figure 39.7), and chronic inflammation.

Figure 39.5 Pyogranulomatous inflammation. One large multinucleated inflammatory giant cell (center) contains five nuclei with coarse chromatin and prominent nucleoli. Aqueous Romanowsky stain.

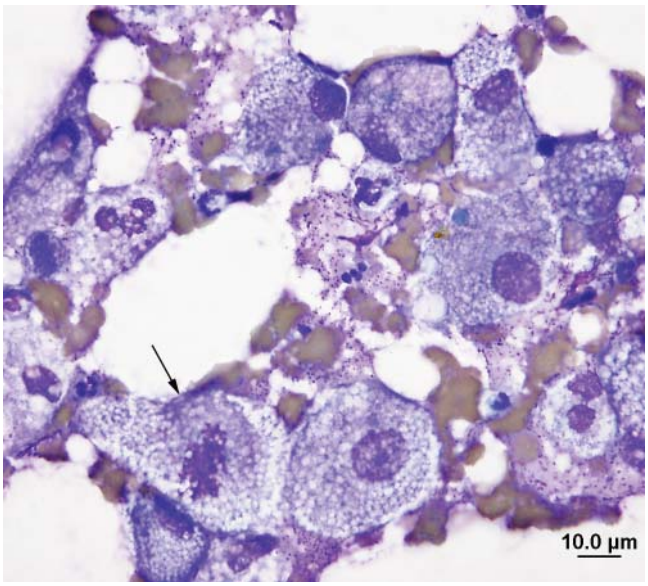

Figure 39.6 Histiocytic inflammation, steatitis. Large, vacuolated macrophages predominate. Macrophages are moderately pleomorphic and one mitotic figure is present (arrow). Aqueous Romanowsky stain.

Eosinophils and mast cells

An inflammatory process is considered to have an eosinophilic component if eosinophils comprise >10% of inflammatory cells. Eosinophils appear similar to those in peripheral blood, with abundant eosinophilic cytoplasmic granules (Figure 39.9). Mast cells are round cells containing round nuclei and moderately abundant cytoplasm that contains abundant dark purple (metachromatic) granules

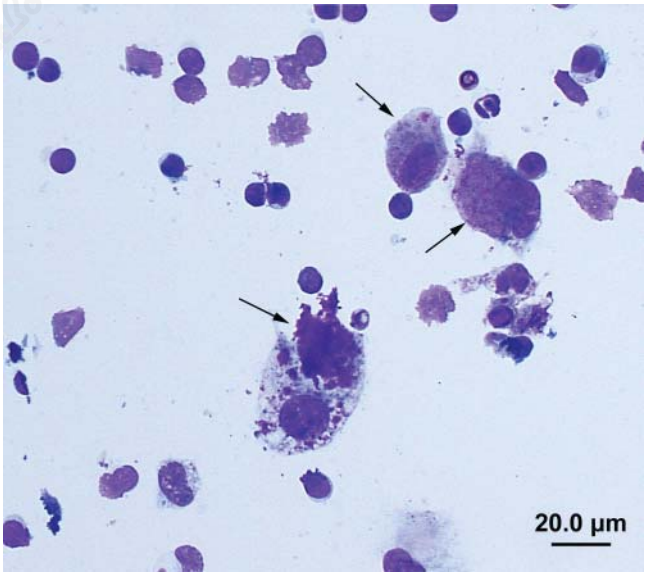

Figure 39.7 Vaccine reaction. Inflammatory cells are a mixture of small lymphocytes and macrophages, with fewer neutrophils. Amorphous magenta material is present within macrophages (arrows), consistent with vaccine adjuvant. Aqueous Romanowsky stain.

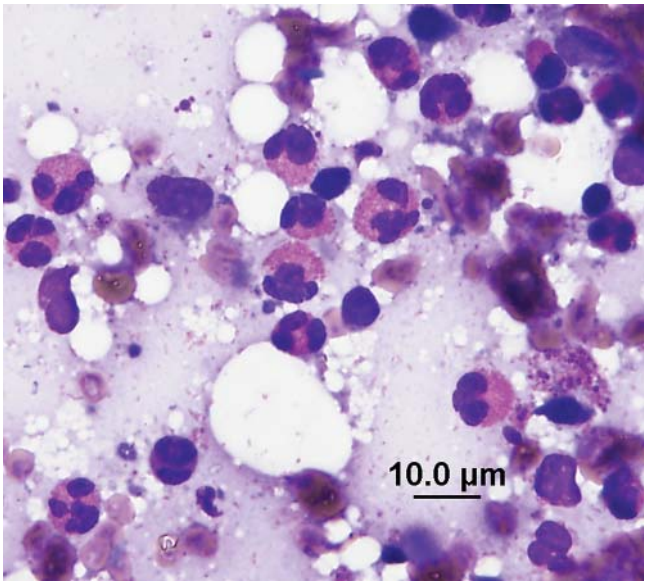

Figure 39.9 Eosinophilic inflammation, cat. Numerous eosinophils containing pink cytoplasmic granules are present in a background of erythrocytes and pale blue tissue fluid. Free eosinophil granules from lysed cells can also be seen. Aqueous Romanowsky stain.

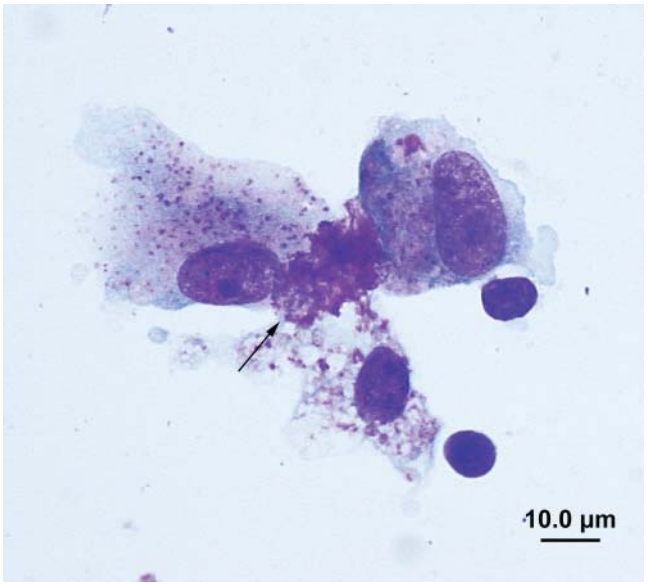

Figure 39.8 Vaccine reaction. Three macrophages and two small lymphocytes are present. Amorphous magenta material consistent with vaccine adjuvant is seen extracellularly (arrow) and is also present within the macrophages. Aqueous Romanowsky stain.

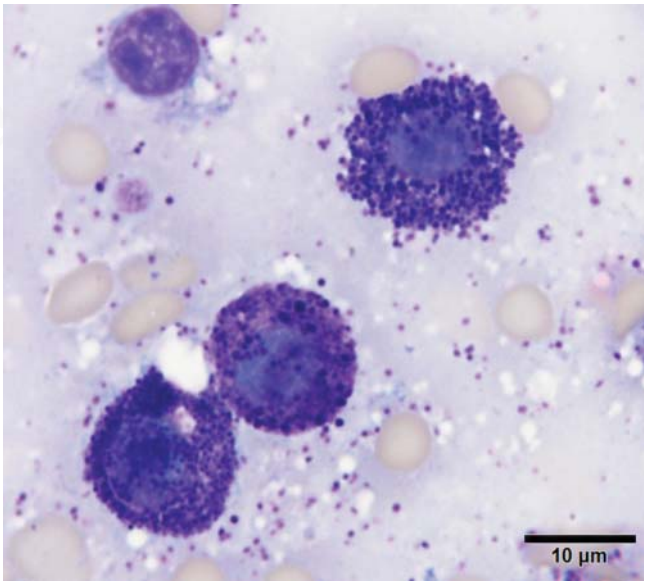

Figure 39.10 Mast cells. These mast cells have abundant dark purple (metachromatic) cytoplasmic granules that sometimes obscure the nucleus. Free granules from lysed cells are in the background and should not be confused with bacteria. Aqueous Romanowsky stain.

(Figure 39.10). Granules may stain poorly or not at all with aqueous Romanowsky stains (Figure 39.11) [2]. Low numbers of mast cells often accompany eosinophils in inflammatory conditions. If mast cells are numerous and/or have criteria of malignancy, mast cell tumor should be considered (see Chapters 40 and 41). Presence of significant numbers of eosinophils in addition to other inflammatory cells occurs with hypersensitivity reactions, parasitic migration, some fungal infections and pythiosis. Numerous eosinophils may also accompany neoplastic conditions, such as lymphoma and mast cell tumor (see Chapters 40 and 41).

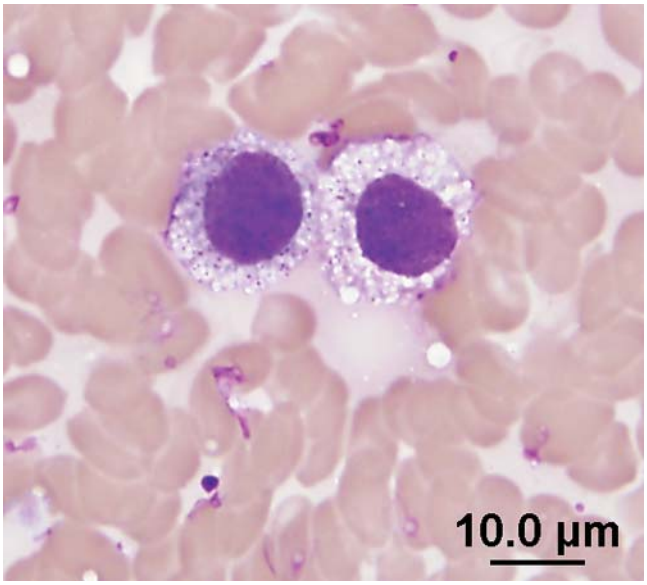

Figure 39.11 Mast cells. The cytoplasmic granules in these two mast cells failed to stain adequately, resulting in a vacuolated appearance. Aqueous Romanowsky stain.

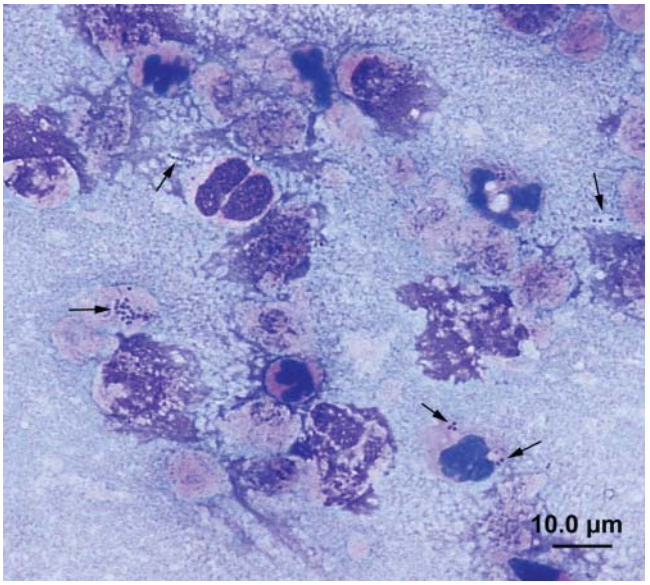

Figure 39.12 Septic, suppurative inflammation, horse abscess. Numerous small bacterial cocci are present in small clusters and short chains (arrows) and are both extracellular and intracellular. Neutrophils are degenerate and disintegrating, creating a thick background of debris that makes bacteria difficult to see. Culture identified the bacteria as *Streptococcus zooepidemicus*. Wright stain.

Selected infectious agents

Microorganisms may be present in cytologic samples for multiple reasons; the challenge is to recognize when they may be a significant finding and not part of normal flora or a result of contamination. Generally, some type of inflammatory reaction is expected if the microorganisms are part of a pathogenic disease process. Finding intracellular (phagocytized) organisms is considered evidence of pathogenicity. If only extracellular organisms are seen, contamination or presence of normal flora must be considered.

Bacteria

Bacteria stain blue with Romanowsky stains, with the exception of *Mycobacteria* spp. that do not stain at all. Phagocytized or dying bacteria may stain less intensely. Types of bacteria commonly identified include bacterial cocci, rods, filamentous bacteria, and spirochetes. Bacterial culture (aerobic and anaerobic) is required for definitive identification of bacteria observed in cytologic samples, and sensitivity testing is recommended to guide antibiotic selection.

Cocci appear round and may be individualized, in small clusters, or in chains (Figures 39.12 and 39.13). Cocci are usually Gram-positive organisms that may be aerobic (i.e., *Streptococcus* and *Staphylococcus* spp.) or anaerobic (i.e., *Peptostreptococcus* spp.). Bacterial rods may be seen individually or in chains and sizes are variable (Figures 39.14 and 39.15). Bacterial rods that are small are typically Gram negative (i.e., *Escherichia coli*, *Klebsiella* spp., *Pseudomonas* spp.), but some pleomorphic rods are Gram positive (i.e., *Rhodococcus* spp.). Large bacterial rods may be Gram positive (i.e., *Bacillus* spp.) or Gram negative (i.e., *Clostridium* spp.). Gram staining may be attempted on cytologic samples but results are not reliable; Gram staining is best performed on organisms grown in culture. Filamentous rods (i.e., *Actinomyces* and *Nocardia* spp.) grow in long, slender chains that may

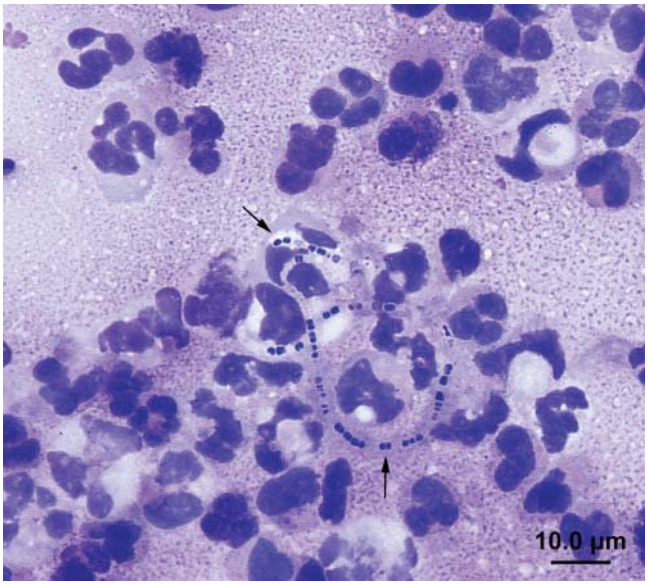

Figure 39.13 Septic, suppurative inflammation, horse abscess. Inflammatory cells consist of degenerate and nondegenerate neutrophils in a thick, stippled, pink proteinaceous background. One long winding chain of bacteria cocci is present (arrows). Wright stain.

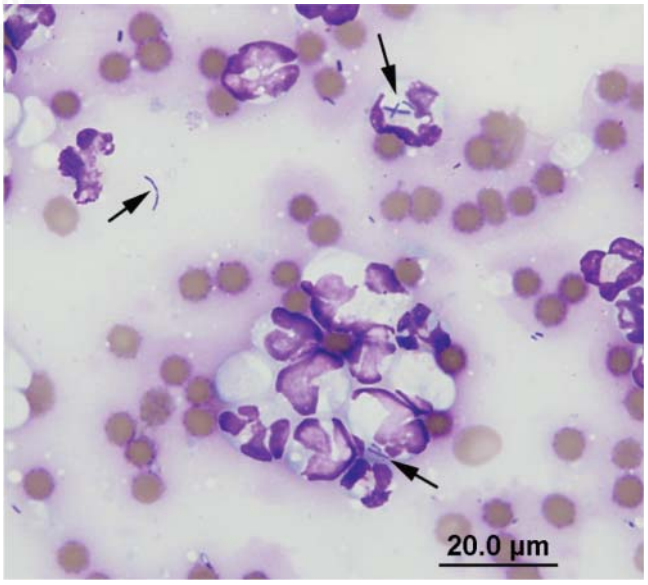

Figure 39.14 Septic, suppurative inflammation, dog toe lesion. Inflammatory cells are predominantly degenerative neutrophils. Bacterial rods are present individually and in short chains (arrows) and are both extracellular and intracellular. Aqueous Romanowsky stain.

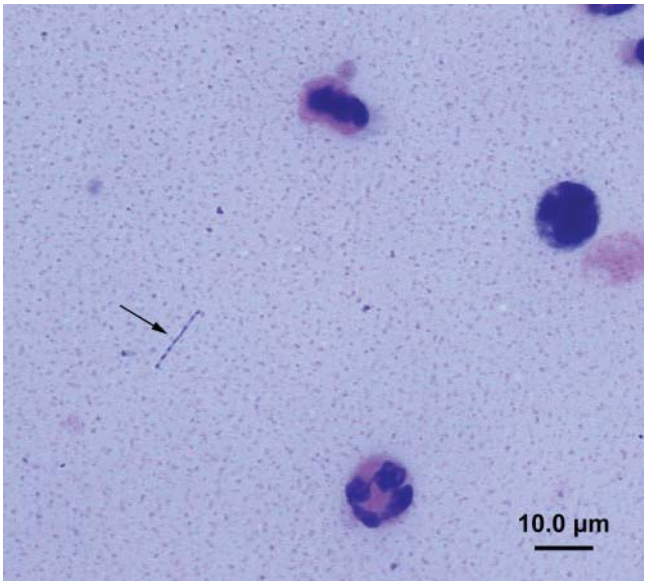

Figure 39.16 Filamentous rod bacteria (arrow), extracellular, bovine. The prominent proteinaceous background makes this thin, beaded filamentous organism difficult to see. Filamentous bacteria are usually considered pathogenic even when only visualized extracellularly. Wright stain.

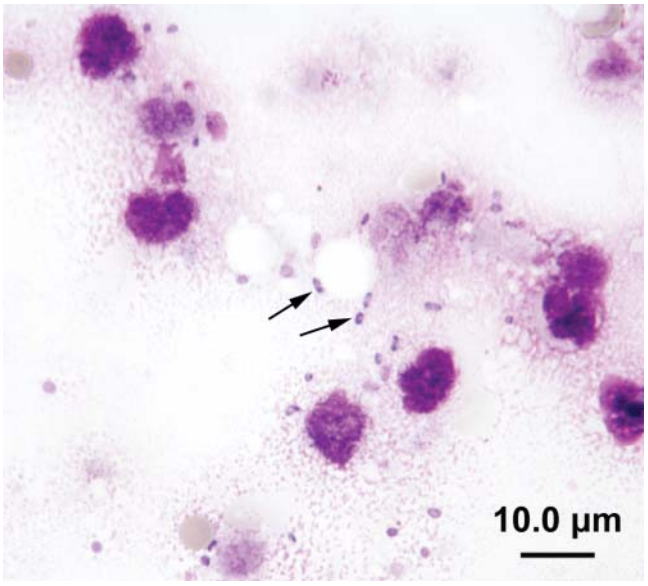

Figure 39.15 Septic, suppurative inflammation, cat abscess. Numerous plump bipolar bacterial rods (arrows) and coccobacilli are present extracellularly. The purple smudges are degenerating nuclei from lysed cells, presumably neutrophils. These organisms were identified as *Yersinia pestis*, the causative agent of plague. Wright stain.

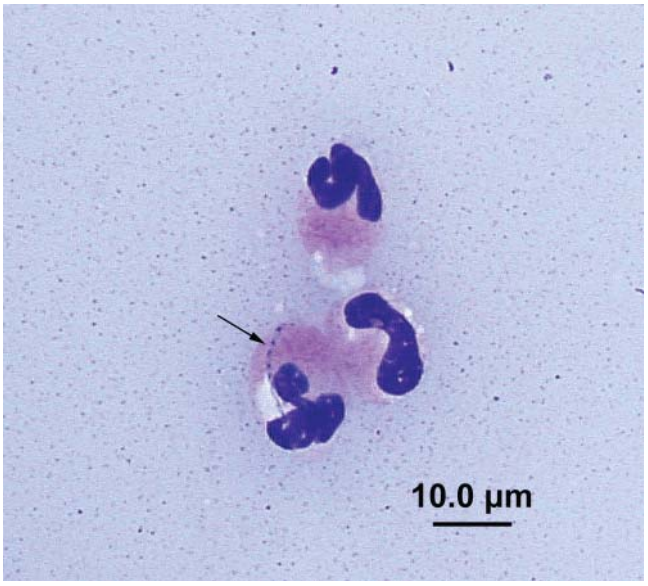

Figure 39.17 Filamentous rod bacteria (arrow), intracellular, bovine. Long, thin bacteria with this beaded appearance are suggestive of *Actinomyces* or *Nocardia* spp. Wright stain.

have a beaded appearance (Figures 39.16–39.19). These organisms can be exceedingly difficult to see, particularly if there is background debris present. Filamentous bacteria require special culture conditions, so it is useful to notify the microbiology laboratory when these organisms are seen in cytologic samples. Large, nonpathogenic rods that grow in parallel rows (*Simonsiella* or *Conchiformibius* spp.) are part of the normal oral flora and thus can be evidence of oropharyngeal contamination (Figure 39.20). Spirochetes can also be part of the normal oral and gastrointestinal flora, and thus may be found along with other bacteria in lesions caused by bite wounds or gastrointestinal leakage [3]. *Helicobacter* spp. may be found in gastric samples from

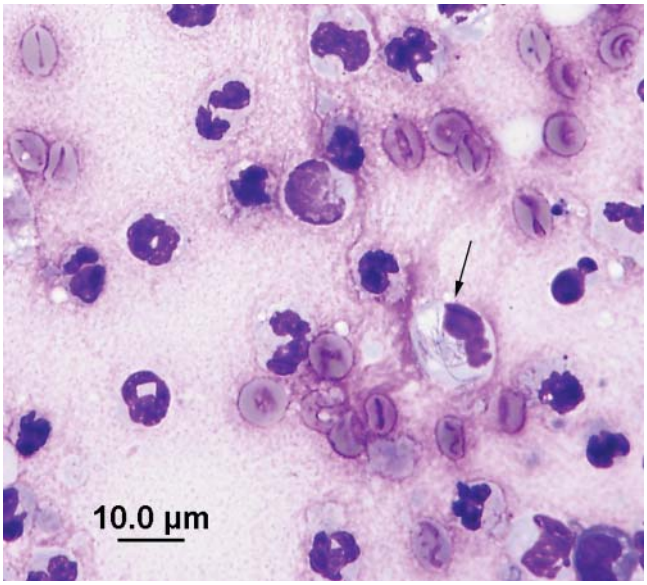

Figure 39.18 Septic, suppurative inflammation, toe lesion, dog. Inflammatory cells are predominantly neutrophils. One degenerate neutrophil contains multiple long, thin filamentous bacteria (arrow). Aqueous Romanowsky stain.

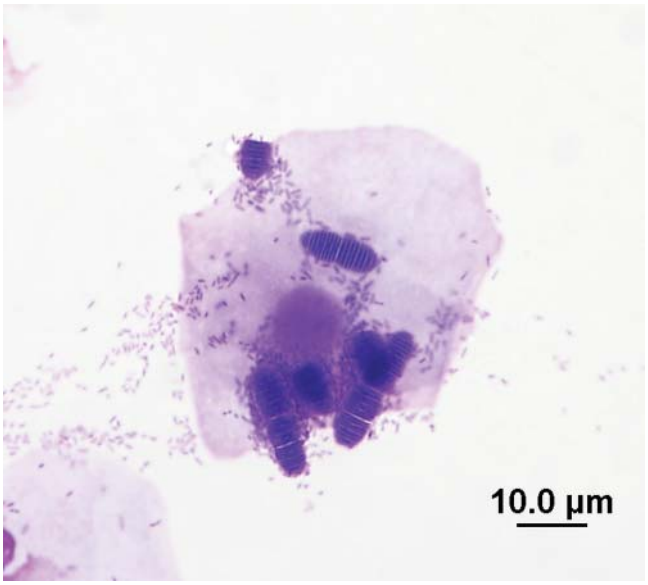

Figure 39.20 Nonpathogenic *Simonsiella* spp. bacteria attached to a squamous epithelial cell. These bacteria grow in distinctive parallel rows and are common oral flora. Numerous individualized rod bacteria are also present. Aqueous Romanowsky stain.

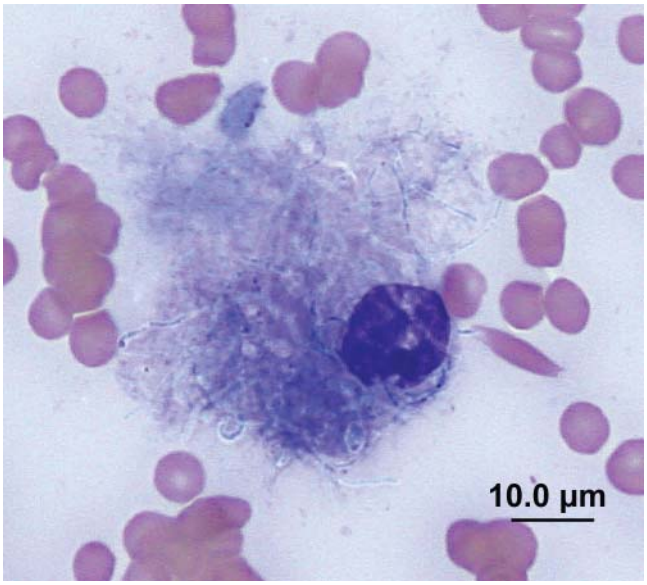

Figure 39.19 Filamentous rod bacteria within a macrophage, cat neck lesion. The inflammatory cells were predominantly macrophages, many of which were multinucleated giant cells. Numerous fine, filamentous bacteria, a few with bulbous ends, are present within this macrophage. Culture identified the organism as *Nocardia paucivorans*. Wright stain.

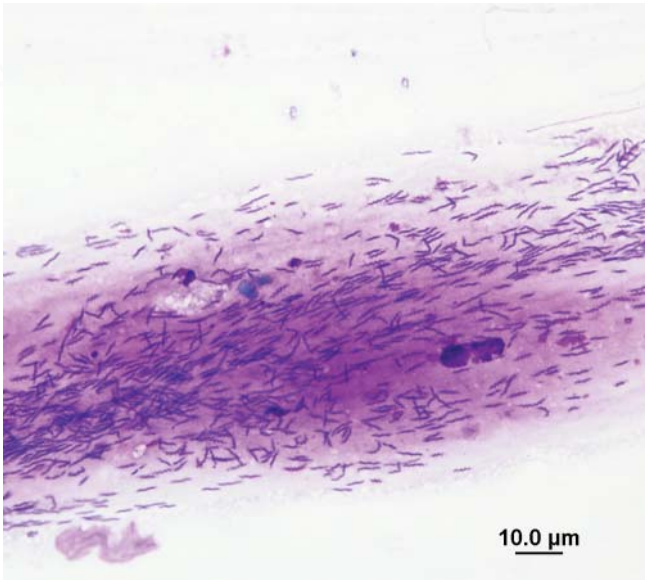

Figure 39.21 Numerous spiral bacteria (*Helicobacter* spp.) in a gastric biopsy imprint from a dog with chronic vomiting. Aqueous Romanowsky stain.

normal animals but have also been implicated as a cause of gastritis (Figure 39.21) [4, 5].

Typically, most bacterial infections are associated with predominantly suppurative (neutrophilic) inflammation. However, pyogranulomatous inflammation is expected with infections caused by filamentous organisms, and some bacteria (such as *Rhodococcus* spp.) are often phagocytized by macrophages instead of neutrophils (Figure 39.22) [6]. Mycobacterial organisms are also associated with predominantly granulomatous (macrophagic) inflammation, but these bacteria do not stain blue with Romanowsky stains. Instead, they appear as slender negative images in the cytoplasm of macrophages, and may be easily overlooked (Figures 39.23 and 39.24).

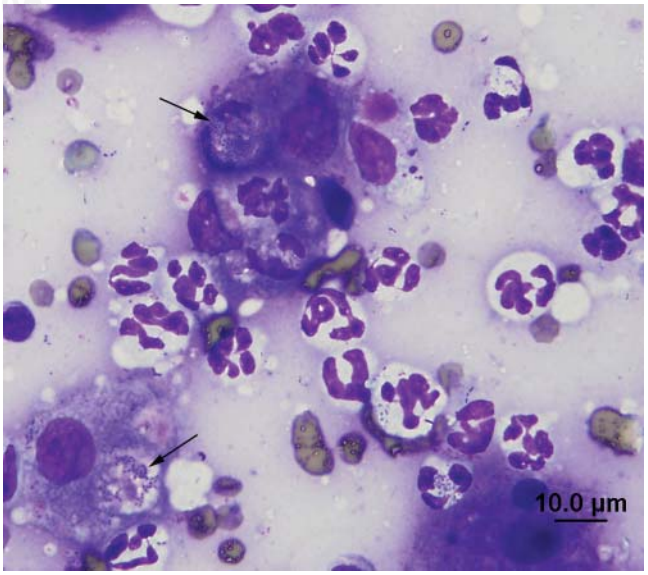

Figure 39.22 Septic, pyogranulomatous inflammation, submandibular lesion, cat. Small, pleomorphic coccobacilli are present in large numbers within macrophages (arrows) and in fewer numbers within neutrophils. Culture identified the organism as *Rhodococcus equi*. Wright stain.

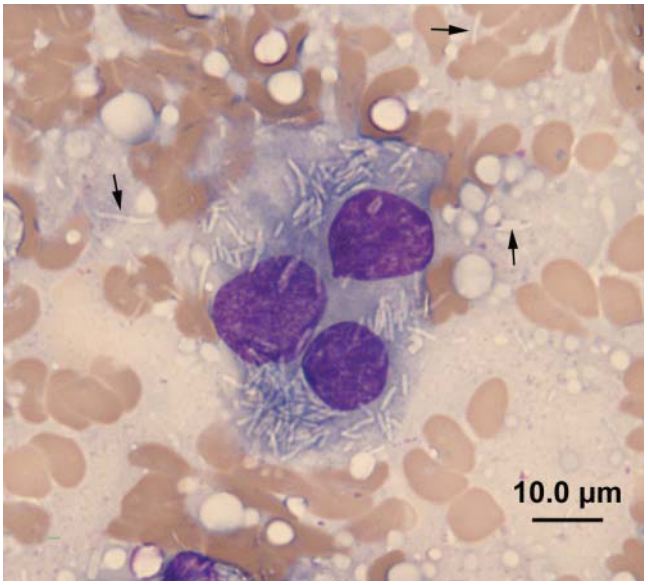

Figure 39.24 Multinucleated macrophage containing many mycobacterial organisms, ferret. Negative images of the bacteria are visible within the macrophage and also in the background (arrows), highlighted by the proteinaceous fluid. Wright stain.

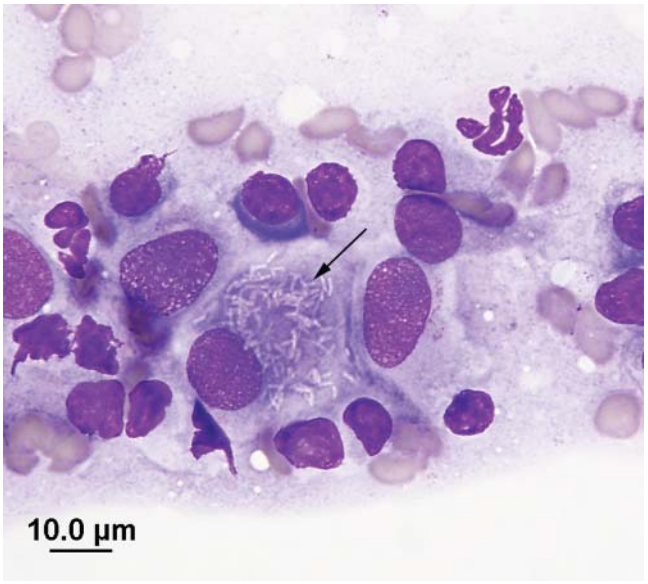

Figure 39.23 Septic, pyogranulomatous inflammation, ear lesion, dog. Negative images of nonstaining, elongated bacterial rods consistent with *Mycobacteria* spp. are visible within one macrophage (arrow). Aqueous Romanowsky stain.

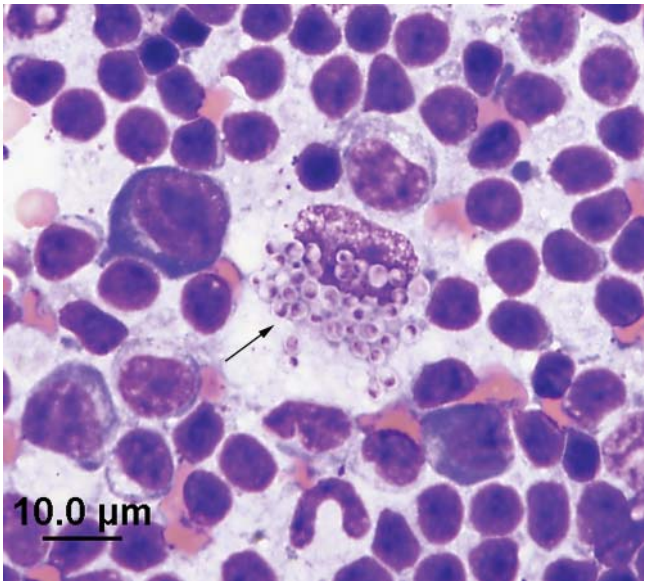

Figure 39.25 Histoplasmosis, lymph node, cat. One macrophage (arrow) contains numerous small fungal yeasts that have a crescent-shaped, eccentric nucleus, pale cytoplasm, and a narrow clear halo. Aqueous Romanowsky stain.

Fungi

Dimorphic fungi

The dimorphic fungi capable of causing systemic infections exist as yeasts at body temperature but can form hyphae in the environment. The morphologies of the yeast forms are distinctive, often allowing definitive cytologic identification.

- *Histoplasma capsulatum* is a small (2–4 µm diameter), round to oval yeast that replicates by narrow-based budding. They stain pale blue with an eccentric, magenta nucleus that is often crescent-shaped (Figure 39.25). There is usually a thin, clear halo surrounding the organism. The associated inflammation is usually pyogranulomatous, with organisms

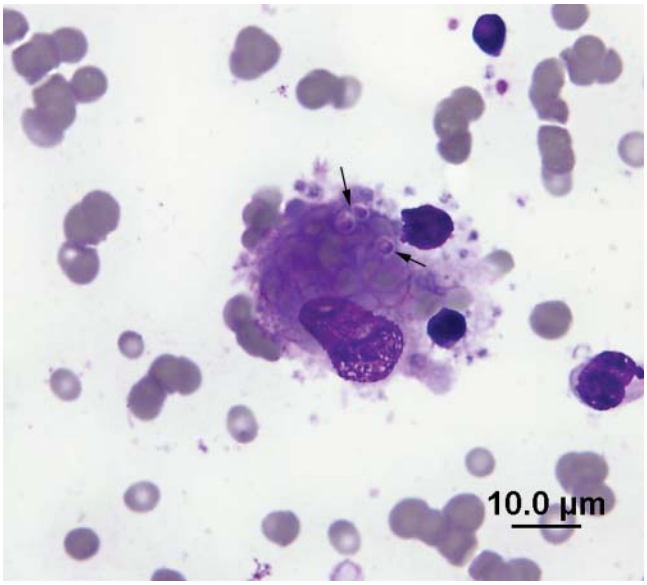

Figure 39.26 Histoplasmosis, kidney, cat. One macrophage contains three small fungal yeasts (arrows) as well as numerous erythrocytes (erythrophagocytosis). Aqueous Romanowsky stain.

phagocytized by both neutrophils and macrophages. In cats with histoplasmosis, erythrophagocytosis by macrophages is a common cytologic feature (Figure 39.26). Dead or dying yeast may be present in samples from animals undergoing treatment, and appear as faded or negative images (Figure 39.27). *Histoplasma* has a wide geographic distribution, thriving in nitrogen-rich organic matter in temperate regions. Disseminated disease often follows inhalation of organisms. Almost every body system may be infected, but dogs typically show clinical signs related to the gastrointestinal tract, while cats more often show respiratory signs [7].

- *Sporothrix schenkii* is a small, oval to elongated yeast with an appearance that is similar to *Histoplasma* [8]. The elongated, fusiform shape is distinctive, and the nucleus may be central to eccentric (Figure 39.28). The numbers of yeast organisms typically seen within skin lesions varies considerably. Cats and horses tend to have numerous organisms, but organisms are rare in lesions from dogs (Figure 39.29). There is generally marked suppurative to pyogranulomatous inflammation with yeast phagocytized by both neutrophils and macrophages. *Sporothrix* is widespread in nature, existing in decaying organic matter. Sporotrichosis is a zoonotic disease, and precautions should be taken especially when handling infected cats.
- *Blastomyces dermatiditis* is a medium-sized (8–20 µm diameter) round yeast that replicates by broad-based budding. Yeasts have a thick wall and are deeply basophilic (Figure 39.30). The associated inflammation is pyogranulomatous, and yeast are usually extracellular but may occasionally be seen phagocytized by macrophages. *Blastomyces* is endemic in river valleys of the midwestern and eastern United States and Canada, and may be expanding its distribution [9]. Canine infections are more common than feline infections, and dogs frequently develop disseminated

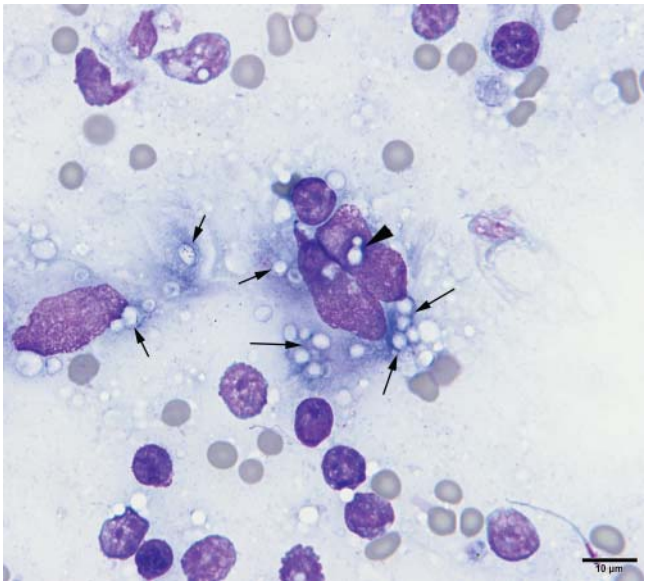

Figure 39.27 Histoplasmosis, lymph node, cat undergoing systemic antifungal therapy. Yeasts are still present within macrophages and in the background but appear faded or as negative images without clear internal structure (arrows), indicating they are dead or dying. One negative image of a budding yeast is seen (arrowhead). Aqueous Romanowsky stain.

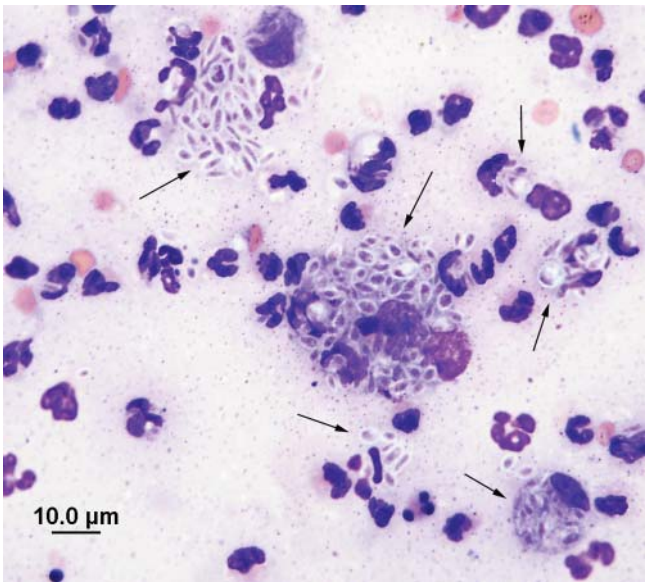

Figure 39.28 Sporotrichosis, skin lesion, cat. Numerous small fungal yeasts are present within macrophages, neutrophils, and free in the background (arrows). The elongated, fusiform shape of some organisms differentiates *Sporothrix* spp. from *Histoplasma* spp. Aqueous Romanowsky stain.

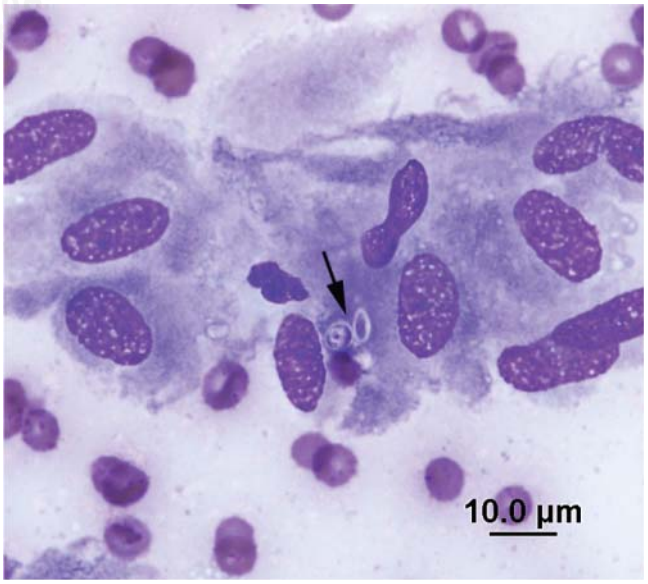

Figure 39.29 Sporotrichosis, skin lesion, dog. Epithelioid macrophages (nonvacuolated, clustered) are present. Fungal yeasts were rare; one round and one elongated yeast are visible here (arrow). Aqueous Romanowsky stain.

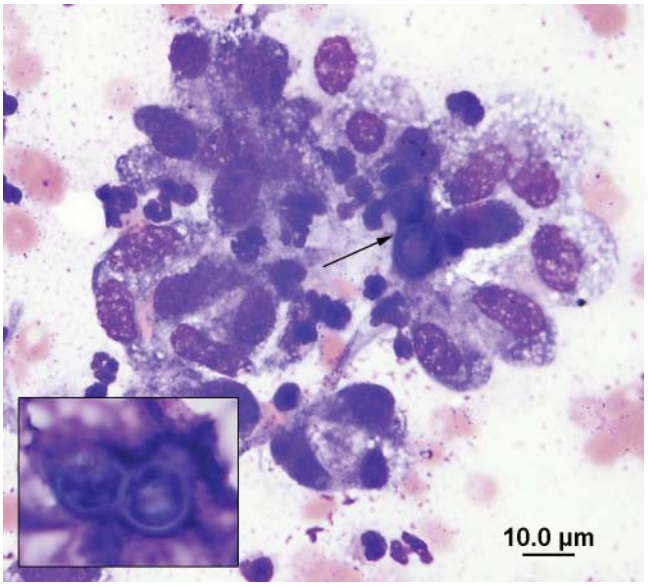

Figure 39.30 Blastomycosis, skin lesion, dog. There is pyogranulomatous inflammation with one deeply basophilic, budding fungal yeast present embedded within the inflammatory cells (arrow). Inset shows details of the broad-based budding typical of *Blastomyces* spp. Aqueous Romanowsky stain.

disease following inhalation of organisms [10]. *Blastomyces* may revert to the mycelial phase when skin lesions are bandaged, causing a health risk to veterinarians and technicians. Culture is not recommended except by specialized laboratories.

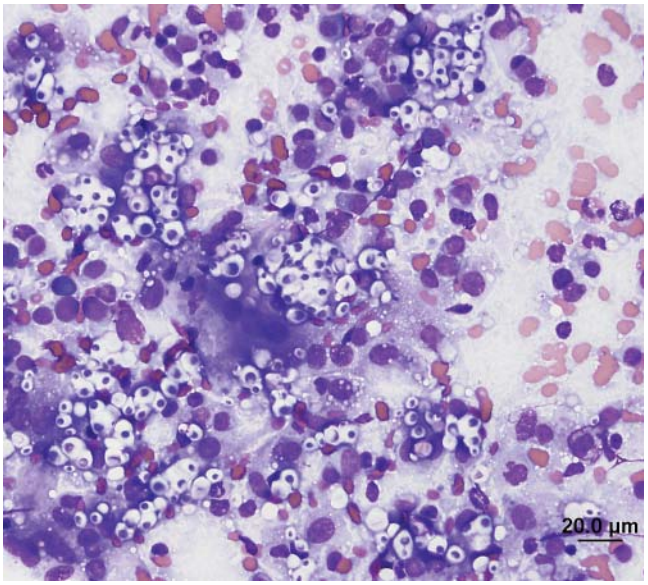

Figure 39.31 Cryptococcosis, lymph node, dog. Thick nonstaining capsules surrounding the yeast create a soap-bubble appearance from low power. Inflammatory cells are predominantly macrophages, some multinucleated, with fewer neutrophils. Lymphocytes and plasma cells are the normal resident population. Aqueous Romanowsky stain.

• *Cryptococcus spp*. are medium-sized, pleomorphic round to oval yeast that replicate by narrow-based budding (Figures 39.31 and 39.32). They frequently have a thick nonstaining capsule, but poorly capsulated forms also exist. Their size varies from 4 to 15 µm in diameter, excluding the capsule. The yeast stain variably from blue to magenta. The associated inflammation usually consists predominantly of macrophages and multinucleated giant cells (granulomatous) with low numbers of eosinophils, but inflammation may be minimal. *Cryptococcus neoformans* proliferates in bird droppings, while *Cryptococcus gattii* is an emerging pathogen in the northwestern United States and California that appears to be associated with tree bark [11, 12]. Cats tend to have respiratory signs and nasal lesions, and dogs more frequently have disseminated disease [11, 13].

• *Coccidioides* spp. are the largest organisms of this group, forming a round spherule measuring 10–200 µm in diameter. The larger, mature spherules contain endospores that are 2–5 µm in diameter (Figure 39.33). Spherules are blue to clear and may have a crumpled surface. The associated inflammation is granulomatous to pyogranulomatous; larger numbers of neutrophils are observed when free endospores are present. *Coccidioides* is endemic to desert regions of the American southwest, causing disease in people and animals following inhalation, and frequently resulting in disseminated disease in dogs [14]. The mycelial phase is highly infectious, so culture is not recommended.

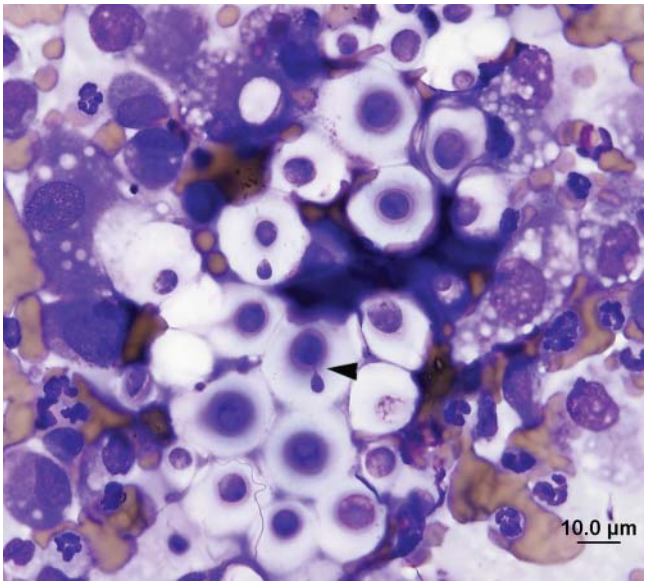

Figure 39.32 Cryptococcosis, cat. Numerous variably sized fungal yeasts possessing thick, nonstaining capsules are present. One yeast demonstrates narrow-based budding (arrowhead). The surrounding inflammation is pyogranulomatous. Aqueous Romanowsky stain.

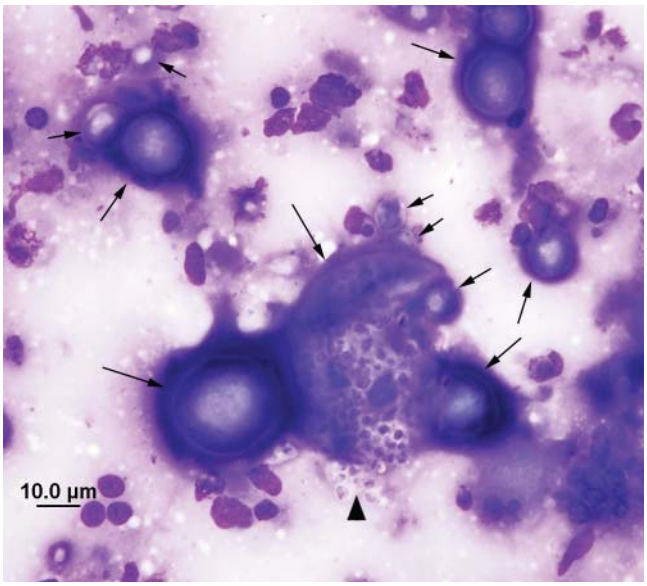

Figure 39.33 Coccidioidomycosis, dog. Spherules of *Coccidioides* vary markedly in size (arrows). The larger spherules have a visible internal structure. One mature spherule has broken to release small endospores (arrowhead). Most of the surrounding inflammatory cells are lysed and cannot be identified. Aqueous Romanowsky stain.

Hyphae-forming fungi

There are numerous hyphae-forming fungi capable of causing local or systemic infections in veterinary species, and fungal hyphae are occasionally encountered in cytologic specimens. Examples include the agents that cause candidiasis, aspergillosis, hyalohyphomycosis, and phaeohyphomycosis [15]. Hyphae are often present within thick aggregates of macrophages and can have variable shapes and sizes (Figures 39.34 and 39.35). Complicating recognition, fungal hyphae do not always stain well and may appear as negative images (Figures 39.36 and 39.37). The histochemical stain GMS can be helpful to highlight

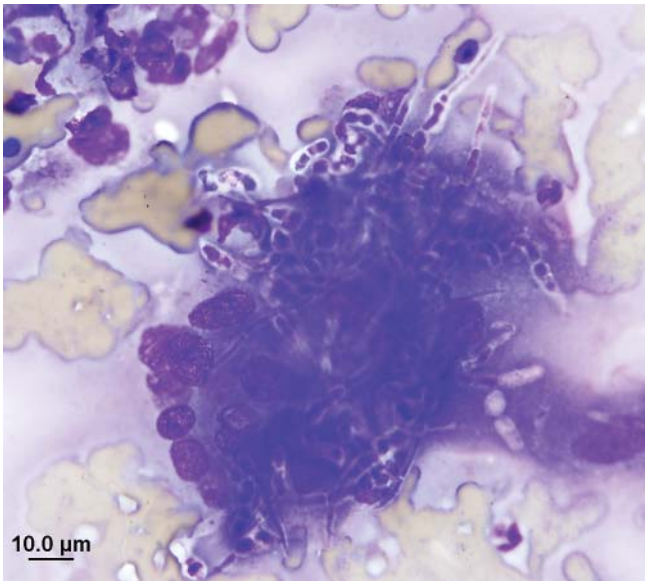

Figure 39.34 Fungal hyphae, lymph node, dog. A thick mat of fungal hyphae are present embedded within macrophages. Hyphae are pleomorphic; some are narrow and septate while others have rounded dilations. This fungus was identified using molecular methods as *Paecilomyces* spp. (hyalohyphomycosis). Aqueous Romanowsky stain.

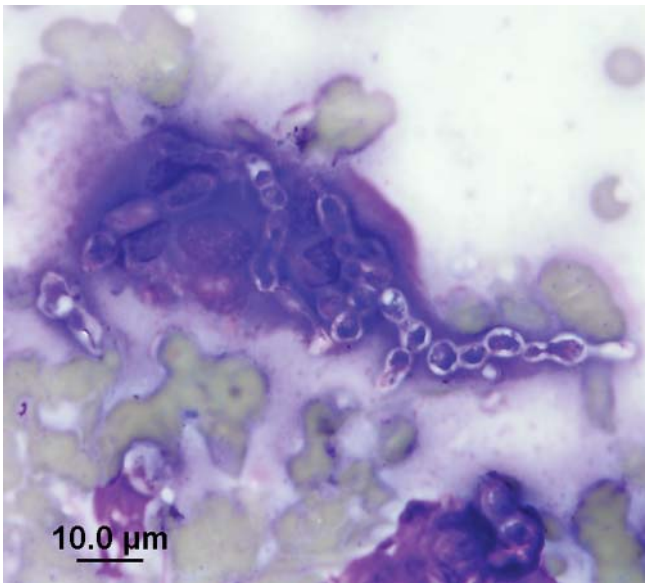

Figure 39.35 Fungal hyphae, same sample as Figure 39.34 (hyalohyphomycosis). The fungal hyphae seen here within a large macrophage have dilated, bulbous segments. Aqueous Romanowsky stain.

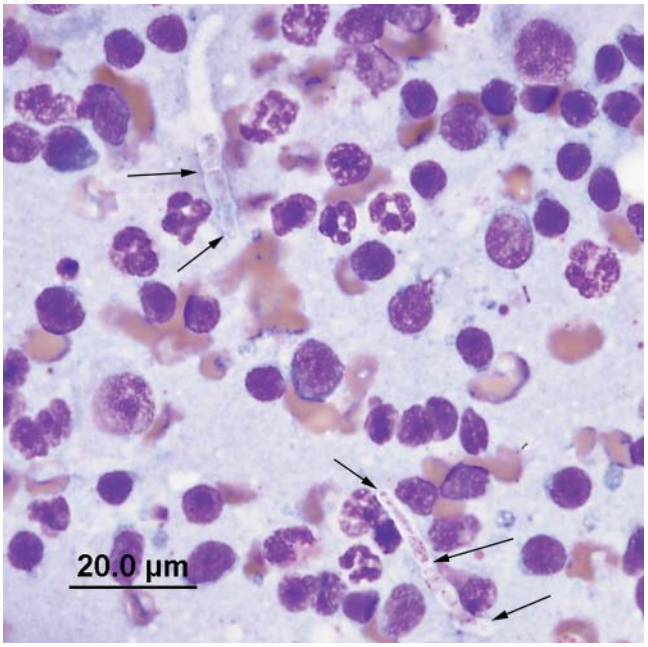

Figure 39.36 Fungal hyphae, lymph node, dog. Two long, septate pale-staining fungal hyphae are visible extracellularly (arrows). Aqueous Romanowsky stain.

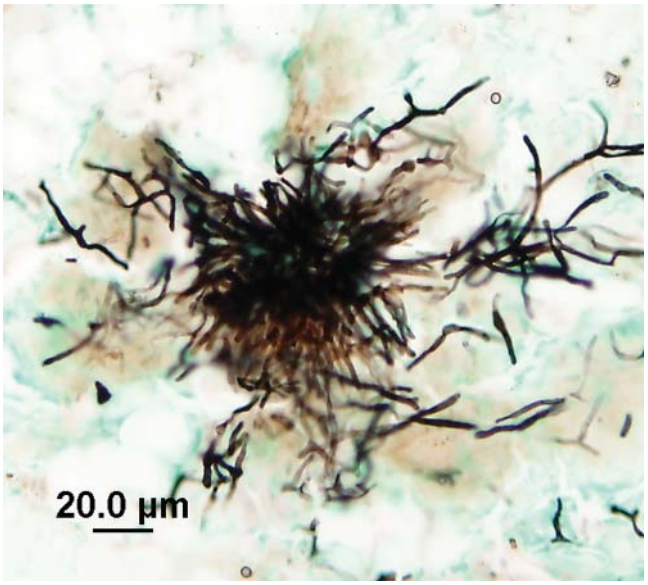

Figure 39.38 Fungal hyphae, same sample as Figure 39.36. The fungal hyphae stain black with GMS, which makes it easier to appreciate the numbers of organisms present. Gomori methenamine silver stain.

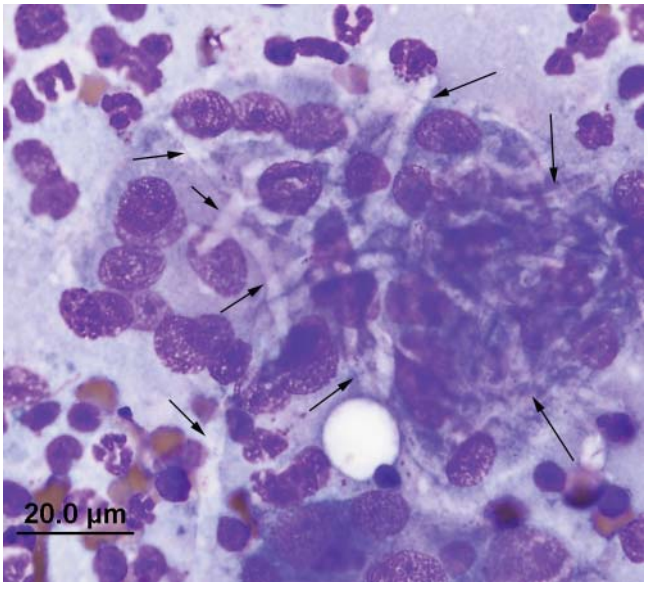

Figure 39.37 Fungal hyphae, same sample as Figure 39.36. A mat of nonstaining fungal hyphae can be seen as negative images (arrows) embedded within epithelioid macrophages. Aqueous Romanowsky stain.

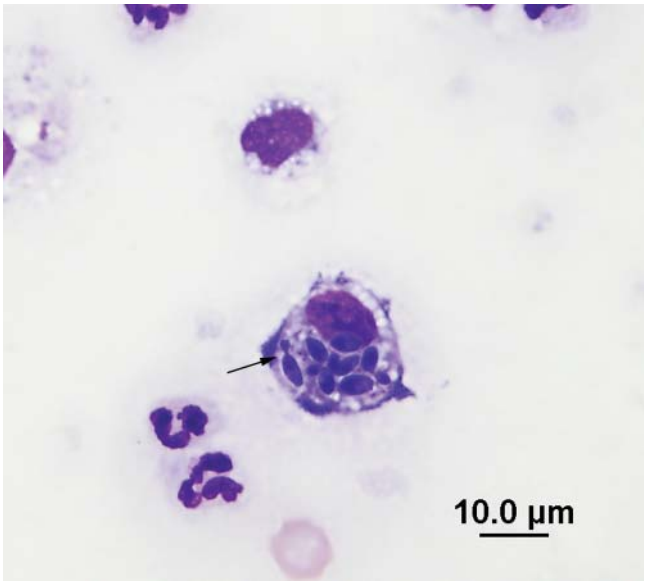

Figure 39.39 *Candida* peritonitis, dog. Multiple *Candida* yeasts are present within a vacuolated macrophage, and one demonstrates narrow-based budding (arrow). Aqueous Romanowsky stain.

fungal hyphae (Figure 39.38). Although there are differences in morphology that may suggest a particular group of fungi (presence or absence of septae and pigmentation, size and shape of hyphae), generally culture or molecular techniques are required for definitive identification [15]. *Candida* spp. can have multiple morphologies in cytologic samples including small yeast, yeast with germ tube formation, pseudohyphae, and true hyphae (Figures 39.39 and 39.40, also see Chapter 42) [16]. Some pseudofungal organisms that grow as elongated hyphal structures are actually aquatic pathogens of the class Oomycetes (i.e., *Pythium* and *Lagenidium*, discussed later).

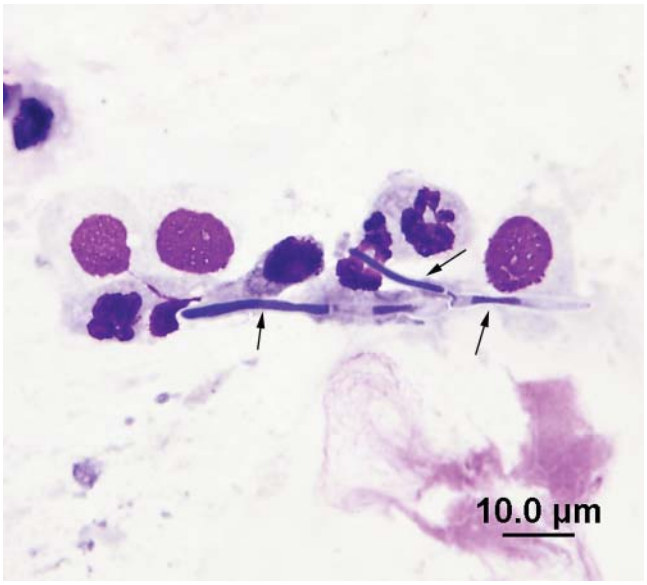

Figure 39.40 *Candida* peritonitis, dog, same sample as Figure 39.39. The fungus is present as true hyphae in this image (arrows). Aqueous Romanowsky stain.

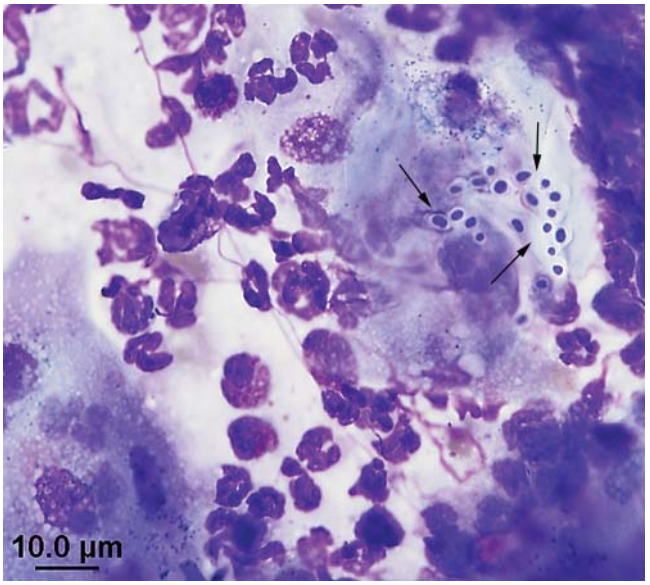

Figure 39.41 Dermatophytosis, skin scraping, dog. Multiple small, dark blue round to brick-shaped arthrospores are present (arrows). There are several squamous epithelial cells present and numerous inflammatory cells (neutrophils and eosinophils). Aqueous Romanowsky stain.

Dermatophytes

Dermatophytes (*Microsporum* and *Trichophyton* spp.) cause scaly hairless skin lesions (dermatophytosis or ringworm) and may be identified in deep scrapings taken from the edge of active lesions. Scrapings should be deep enough to result in oozing of tissue fluid or blood in order for the sample to adhere to a glass slide for staining. Heat-fixing of these samples is neither required nor recommended. Small, brick-shaped arthrospores appear dark blue with Romanowsky stains and may be seen free in the background or adhered to epithelial cells or hair shafts (Figures 39.41 and 39.42). There is usually a mixed inflammatory cell population present. Fungal culture is necessary for specific identification. Dermatophytosis is a zoonotic disease.

Malasezzia spp.

Malasezzia spp. are small budding yeasts that are normal inhabitants of skin. Overgrowth is associated with dermatitis and otitis externa. The yeast have a characteristic peanut or shoe-print shape and stain dark blue (Figure 39.43).

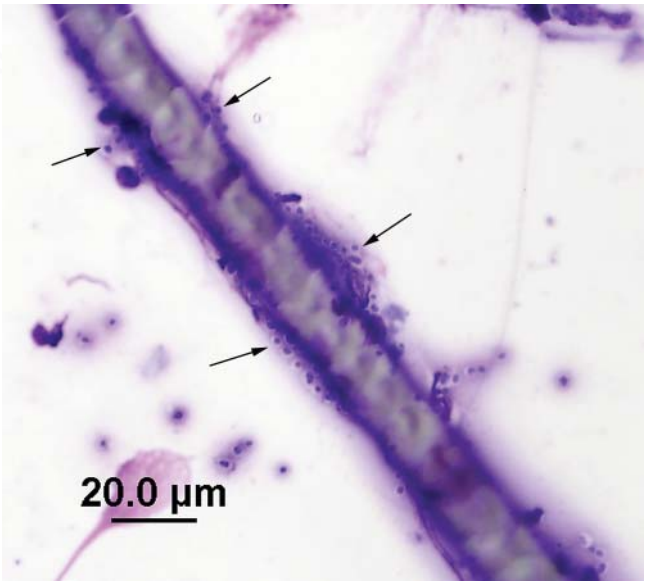

Figure 39.42 Dermatophytosis, skin scraping, cat. Arthrospores are visible attached to a hair shaft (arrows) and free in the background. Aqueous Romanowsky stain.

Protozoa

Cytauxzoon felis

C felis causes severe and often fatal disease in domestic cats [17]. The erythrocytic stage (piroplasm) is often the basis for diagnosis, which typically is made from a blood film (see Chapter 9). The tissue phase of the parasite (schizont) may be encountered in cytologic specimens from infected cats (i.e., aspirates of lymph node, spleen, lung, etc.). Schizonts develop within macrophages, which become enlarged with distended cytoplasm and large, prominent nucleoli (Figure 39.44). The appearance of the schizont varies depending on the stage of development, transforming from a poorly defined basophilic mass to circular blue merozoites with a purple nucleus (Figure 39.45). Schizonts develop in tissues prior to the appearance of piroplasms in peripheral blood.

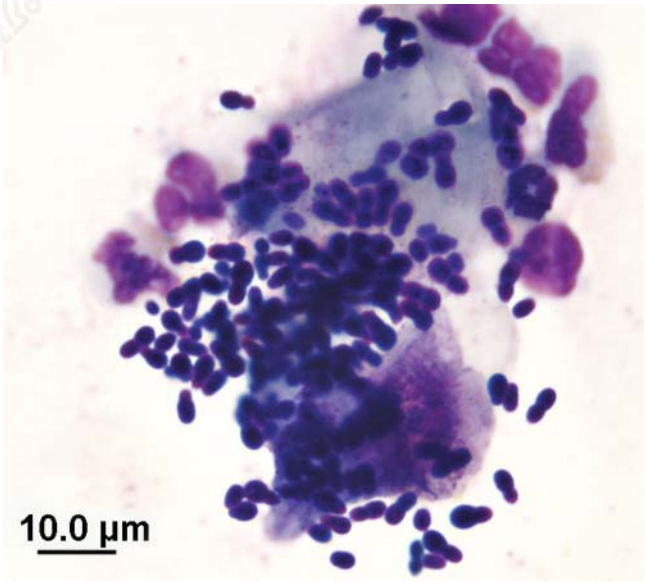

Figure 39.43 *Malassezia* spp., ear swab, dog. Numerous dark blue peanut-shaped *Malassezia* yeasts are present adhered to squamous epithelial cells. There are neutrophils out of focus in the background. Aqueous Romanowsky stain.

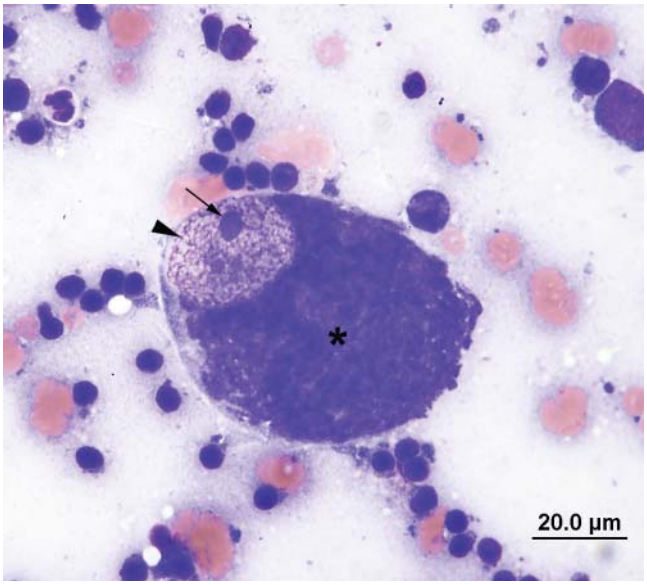

Figure 39.44 *Cytauxzoon felis* schizont, lymph node, cat. The enlarged macrophage contains a pale nucleus (arrowhead) with a large prominent nucleolus (arrow). The cytoplasm (*) is distended with ill-defined, dark blue developing merozoites. Surrounding cells are predominantly small lymphocytes and erythrocytes. Aqueous Romanowsky stain.

Toxoplasma and *Neospora* spp.

Tachyzoites of *Toxoplasma gondii* or *Neospora caninum* are occasionally encountered in cytologic specimens and have an identical microscopic appearance; molecular methods (PCR) can be used to differentiate them. The associated inflammation is often mixed. Tachyzoites typically are 2–4 µm long,

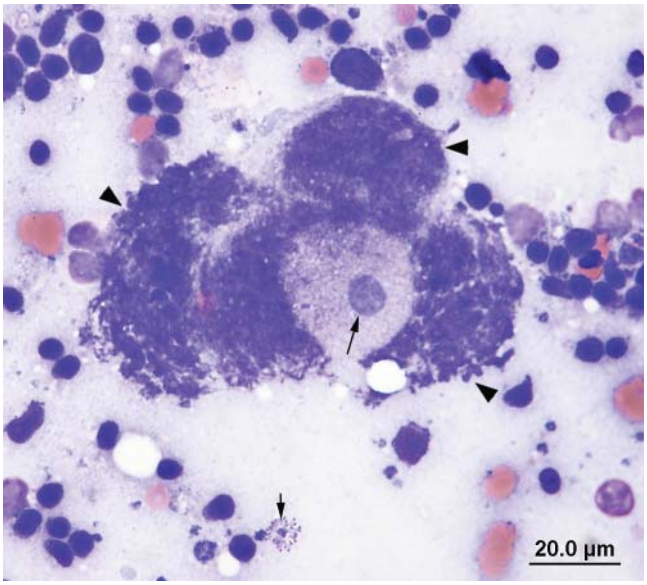

Figure 39.45 *Cytauxzoon felis* schizont, lymph node, cat. This macrophage is disrupted allowing better visualization of merozoites (arrowheads). The prominent nucleolus (long arrow) is as large as the surrounding small lymphocytes. One cluster of extracellular, nearly mature merozoites (short arrow) is present. Aqueous Romanowsky stain.

crescent- or banana-shaped, with pale blue cytoplasm and a central purple nucleus (Figure 39.46). Toxoplasmosis can affect both dogs and cats and tachyzoites may be found in a variety of samples including tissue aspirates (lung, lymph nodes) and body fluids (respiratory washes, ocular fluids, cerebrospinal fluid [CSF], and cavity effusions) [18, 19].

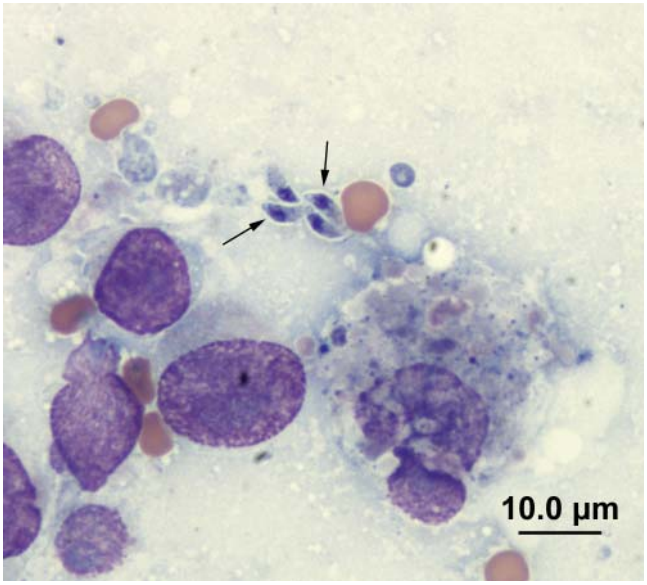

Figure 39.46 Toxoplasmosis, lymph node, cat. Four small, banana-shaped protozoal tachyzoites (arrows) are present extracellularly. The macrophage on the right contains phagocytized debris. Wright stain.

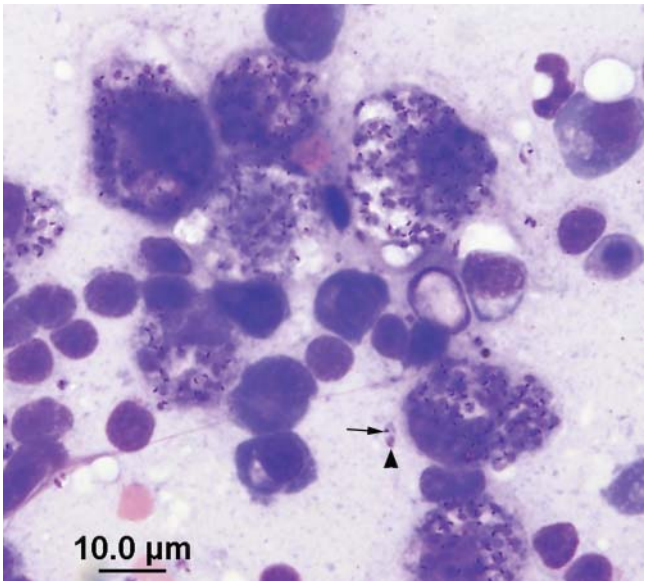

Figure 39.47 Leishmaniasis, lymph node, dog. Multiple macrophages contain numerous small protozoal amastigotes. The internal structure of the amastigotes can be visualized best in the extracellular organisms, which have a light purple nucleus (arrowhead) and dark purple, rod-shaped kinetoplast (arrow). Other cells present include lymphocytes and plasma cells. Wright stain.

Toxoplasmosis is a zoonotic disease; people are infected transplacentally or following ingestion of sporulated oocysts (cat feces) or tissue cysts (undercooked meat). Neosporosis is recognized most often as a cause of polymyositis and paralysis in dogs under a year of age. Similar to toxoplasmosis, a wide range of body tissues may harbor tachyzoites.

Leishmania spp.

Leishmaniasis causes visceral and cutaneous disease in animals and people worldwide, and has become a problem in the United States since 2000 [21]. Organisms (amastigotes) may be found in cytologic samples from infected dogs and are often present phagocytized by macrophages. They are 2–4 µm, oval, and pale with an oval purple nucleus and rod-shaped dark purple kinetoplast (Figure 39.47). The kinetoplast distinguishes this organism from the similarly sized *Histoplasma* yeast. Amastigotes of *Trypanasoma cruzi*, the cause of American trypansomiasis in dogs, have an identical appearance but are uncommon in cytologic samples [22]. The associated inflammation is pyogranulomatous to mixed. Leishmaniasis is a zoonotic disease that relies on the sandfly vector for transmission. However, human exposure to infected open wounds should be avoided.

Other

Pythium, Lagenidium

These organisms mimic fungi in cytologic samples, in which they appear as broad, poorly septate hyphae that often stain poorly (Figures 39.48 and 39.49). The histochemical stain GMS can be used to highlight the organisms (Figure 39.50). They are actually aquatic pathogens (class Oomycetes) that typically affect animals with frequent exposure to lakes or ponds in warm climates [15]. Horses may develop cutaneous mass lesions [23]. Canine pythiosis is often gastrointestinal or cutaneous; lagenidiosis may be cutaneous, locally

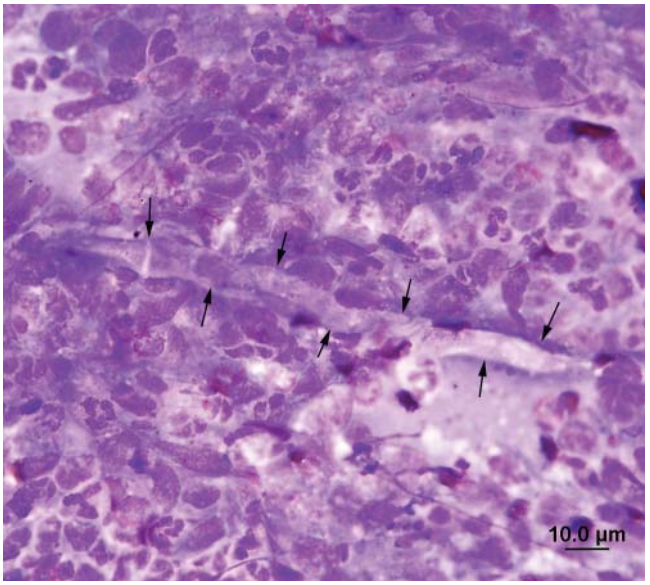

Figure 39.48 Pythiosis, mesenteric mass, dog. Buried within a thick aggregate of mixed inflammatory cells (neutrophils, macrophages, eosinophils) is the negative outline of a broad, poorly septate hyphal structure (arrows). Aqueous Romanowsky stain.

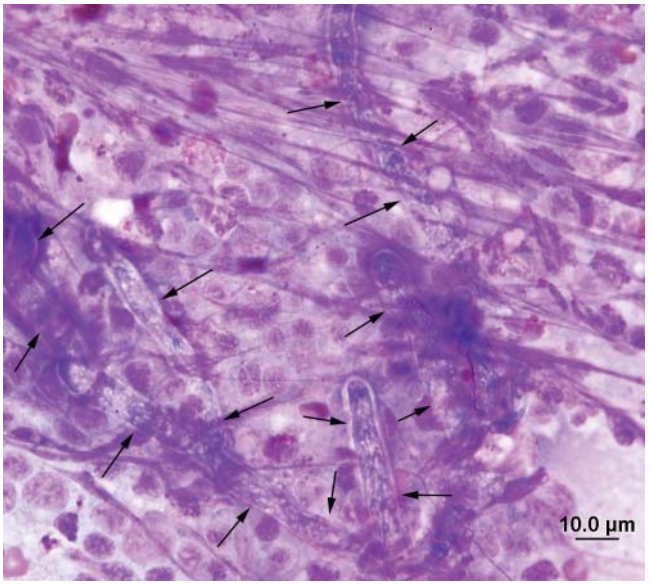

Figure 39.49 Pythiosis, same case as Figure 39.48. Multiple broad, branching, poorly septate, lightly staining hyphae are present (arrows). There is mixed inflammation with an eosinophilic component. Aqueous Romanowsky stain.

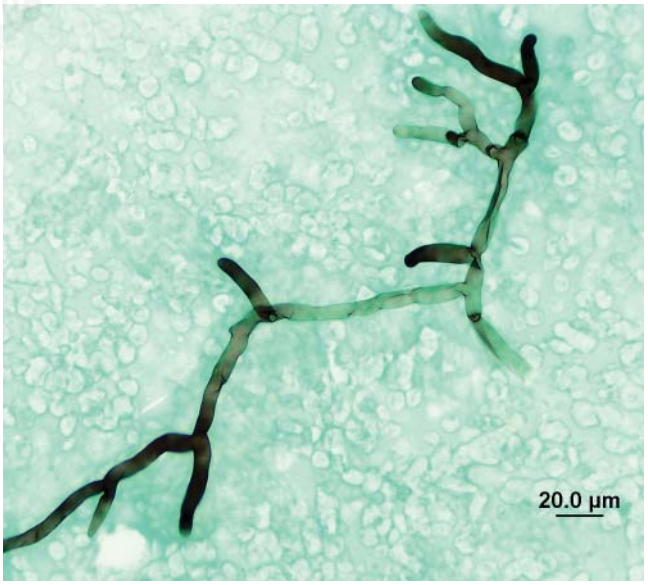

Figure 39.50 Pythiosis, same case as Figure 39.48. A large, branching hyphal structure is easily visualized when stained black with GMS. Gomori methenamine silver stain.

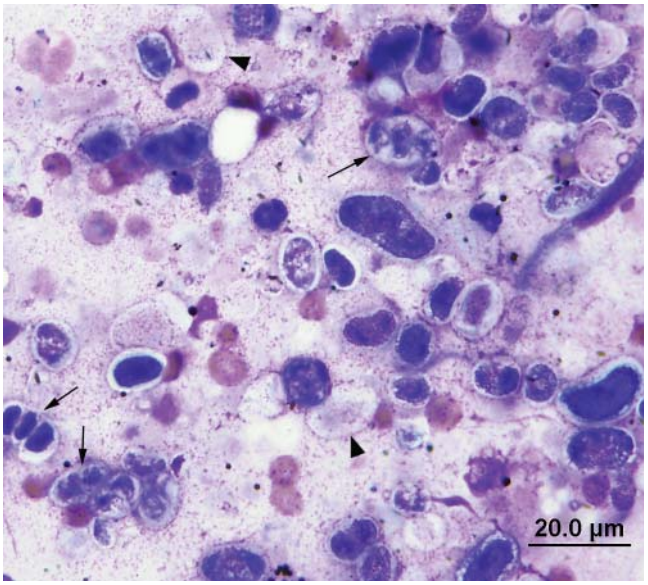

Figure 39.51 Protothecosis, vitreous, dog. Numerous oval *Prototheca* organisms are present and have variable staining qualities. Most are basophilic with a granular appearance. Internal endospores can be seen (arrows) and clear empty theca are also present (arrowheads). Aqueous Romanowsky stain.

invasive and occasionally disseminated. Associated inflammation is pyogranulomatous and may have an eosinophilic component.

Prototheca

These organisms are single-celled algae ubiquitous in nature, with canine infections occurring in warm, moist climates [25]. Cutaneous infections may be secondary to trauma, and disseminated disease is thought to be associated with immunosuppression. Dogs with disseminated disease often have involvement of the intestinal tract. The organisms are round to oval and 5–20 µm in diameter. Internal septation produces endospores. *Prototheca* stains variably basophilic with a granular appearance and a narrow clear halos; clear empty theca are often present (Figure 39.51). The associated inflammation is pyogranulomatous, occasionally mixed with lymphocytes and plasma cells.

Rhinosporidium

Rhinosporidium seeberi is an unusual aquatic protistan organism that exists near the animal-fungal divergence, classified as Mesomycetozoea [26]. *R seeberi* causes nasal mucosal polypoid masses in people and animals (dogs, horses, rarely cats) that live in warm, humid climates. The organism forms large sporangia in tissues, but the form most commonly identified in cytologic samples is the mature endospore (Figures 39.52 and 39.53). The endospores are round to oval, 8–15 µm in diameter, with a thick cell wall. Visible internally are numerous spherical, dark pink globular structures that are distinctive. Smaller, developing immature endospores, similar in size to *Histoplasma*, have also been described [27]. The associated inflammation is pyogranulomatous.

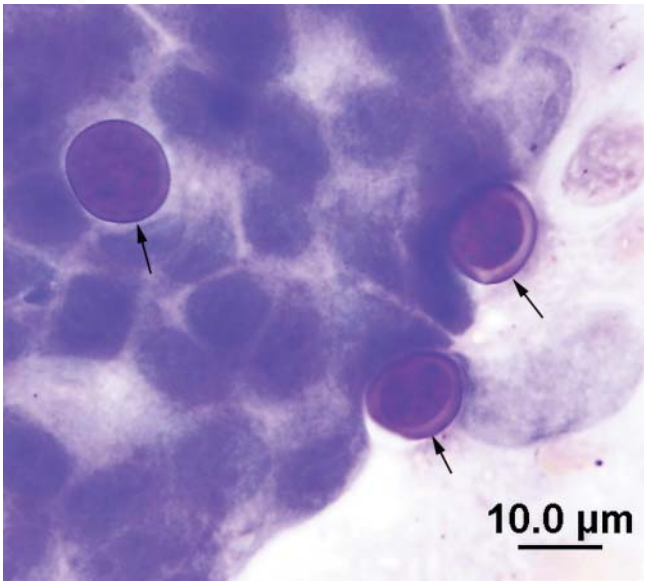

Figure 39.52 Rhinosporidiosis, nasal lesion, dog. Three round to oval, thick-walled endospores of *R seeberi* (arrows) are associated with a cluster of epithelial cells. The pink spherical internal globules are distinctive. Aqueous Romanowsky stain.

Neorickettsia helminthoeca

N helminthoeca is the cause of canine salmon poisoning disease in dogs that consume uncooked salmon infected with the trematode vector *Nanophyetus salmincola* [28]. The

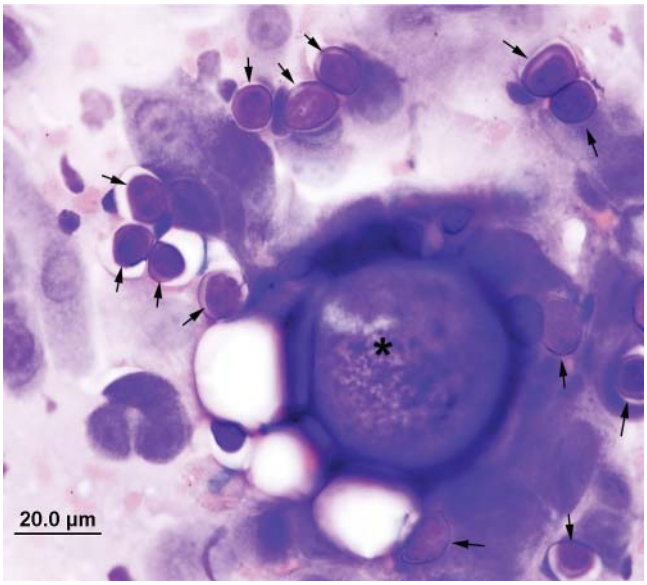

Figure 39.53 Rhinosporidiois, same case as Figure 39.52. One large, deeply basophilic, granular immature sporangium (*) and multiple endospores (arrows) are present with normal epithelial cells. Aqueous Romanowsky stain.

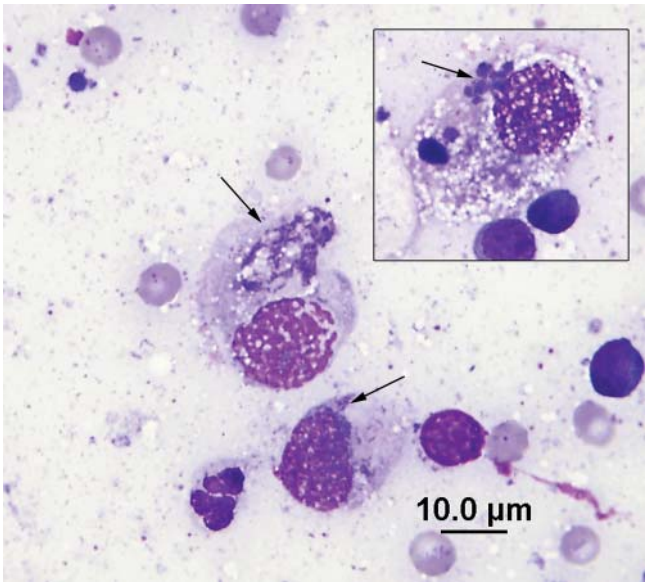

Figure 39.54 *Neorickettsia helminthoeca*, lymph node, dog. Rickettsial organisms that cause salmon poisoning disease are small, basophilic, and tend to occur in indistinct aggregates (arrows) within macrophages rather than distinct morulae. Aqueous Romanowsky stain.

rickettsial organism may be found in lymph node aspirates from infected dogs, where it replicates within macrophages. Cytologically, the organisms are pleomorphic, appearing individually and in diffuse clusters rather than distinct morulae (Figure 39.54) [29].

40 Cytology of Neoplasia

Donald Meuten[1] and Kristina Meichner[2]

Introduction

Cancer is an uncontrolled proliferation of cells due to nonlethal mutation(s) in the genome (genetic makeup of a species). Mutations are a constant event in DNA and RNA. There are genes that repair these mutations and genes that stimulate the mutations, and each can contribute to the formation of cancer. Etiologic agents such as viruses, chemicals, and radiation can cause tumors in animals, but for many tumors an etiology is not yet known, so we use the term *spontaneous*. The pathogenesis of cancer is complicated, and there are textbooks and review manuscripts that describe the many details required for a neoplasm to form, evade host defenses, transform into a malignant tumor, invade regionally, invade blood or lymphatic vessels, and spread (metastasize) [1, 2].

There is a considerable amount of jargon that accompanies cancer and the cytology of cancer. The jargon is less important than recognizing the cellular abnormalities associated with cancer. In this chapter the words *cancer, tumor,* and *neoplasm* will be used synonymously. Strict definitions reserve cancer for a malignant proliferation of cells, tumor for any swelling (one of the four components of inflammation), and neoplasm as an abnormal growth that usually results in a mass. The term *neoplasm* is derived from "neo" = new and "plasm" = formation. The neoplastic transformation of normal resident cells results in the proliferation of a new cell population. If host defenses cannot control those cells, then they proliferate and form a mass. The larger the mass the more likely it is neoplastic. Exceptions: there are some cancers that do not form masses, e.g., leukemia, and there are some cancers that proliferate within an organ and make the organ diffusely enlarged without forming a discrete mass, e.g., lymphoma in the liver or spleen.

Neoplasms can arise in any system in the body. In histopathology we identify a cancer by the organ in which it arose and then name the specific cell type, e.g., hepatocellular carcinoma, cholangiocarcinoma. In cytology we often separate cancer into three main groups: epithelial, mesenchymal, and round cell (Figure 40.1). Some cytologists add a fourth category, neuroendocrine; these tumors are uncommon but will be included in this discussion. Cytological diagnoses also attempt to name the specific tumor, but many times this is not possible. Histopathology uses histologic organization and cytology uses cellular features to identify cancer. There is no individual cytologic or histologic feature that identifies a cell as neoplastic. There are no histochemical, immunohistochemical, or molecular markers that identify a cell or a mass as neoplastic. These techniques are aids used to help diagnose cancer when the diagnosis is not clear. There are molecular markers that characterize specific human and animal tumors. The false-positive and false-negative rates are usually not known for these markers, nor are positive and negative predictive values known (based on prevalence). It is important to know the molecular marker(s) for a specific tumor and then what percent of those tumors express that marker (well differentiated? poorly differentiated?) as well as whether the marker can be present in other tumors, hyperplasia, or dysplasia. Research in the molecular fields of veterinary pathology and oncology is evolving rapidly, and results need to be integrated with clinical, cytologic, and histologic features and, most importantly, with accurate long-term outcome assessments [3–6]. A diagnosis of neoplasia is made by interpreting the overall cytologic and/or histologic findings and integrating these with clinical information such as species, age, and location. Do not separate the microscopic findings from the clinical information.

For the majority of cancers, histopathology provides a more definitive diagnosis than does cytology, but there are advantages and disadvantages of both techniques (Table 40.1).

There are some cancers or locations of cancer in which cytology is the preferred technique to establish a diagnosis and treatment plan: mast cell tumor (MCT), circumanal tumors, lipoma, lymphoma, leukemias, osteosarcoma, urothelial carcinoma (UC), transmissible venereal cell tumor (TVT), histiocytoma, plasma cell tumor, histiocytic

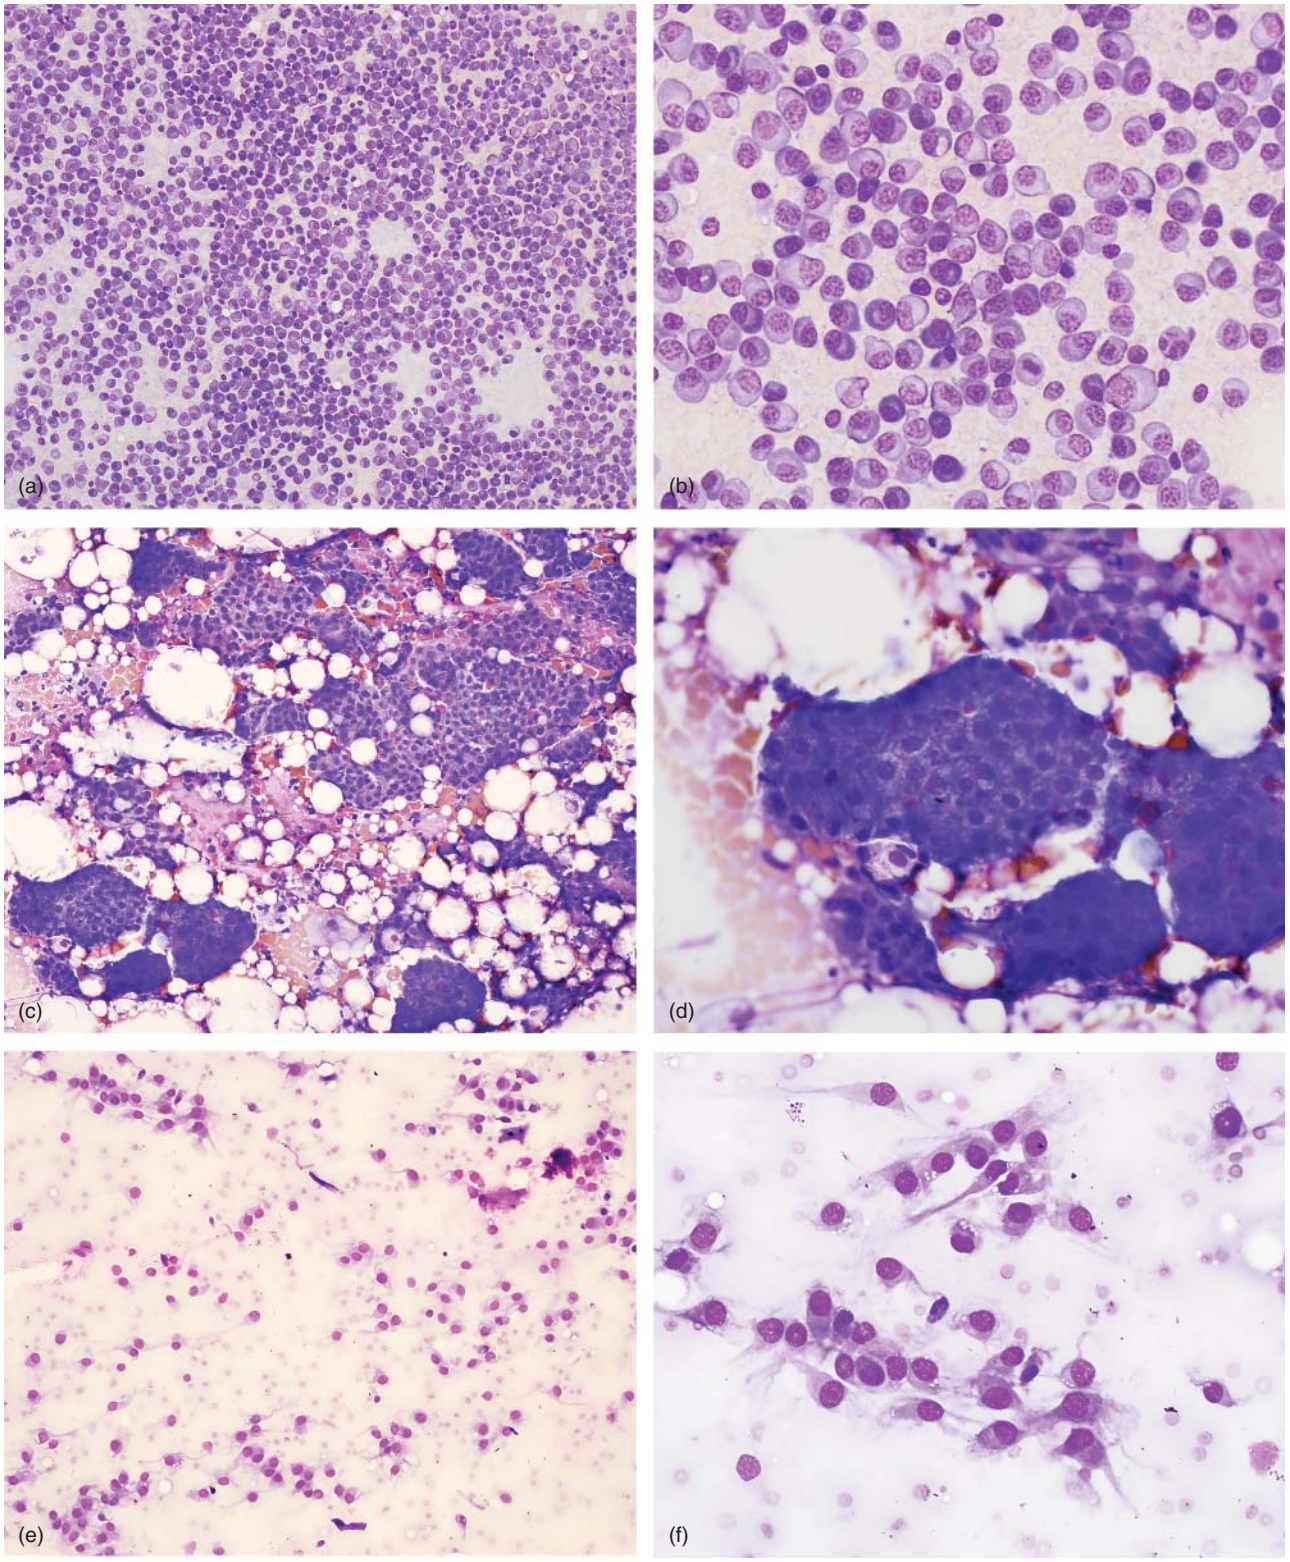

Figure 40.1 Cytologic patterns of neoplasia. Left column (a, c, e): 20× objective (low power). Right column (b, d, f): 50× objective (high power). (a, b) *Round cell*: high cellularity, individual cells, round shape. (c, d) *Epithelial*: high cellularity, cells adhered in aggregates. (e, f) *Mesenchymal*: low cell numbers, spindle-shaped cells with elongated cytoplasmic ends. Shape of nuclei is not reliable to estimate cell shape as they are round in all patterns; oval-shaped nuclei can be seen in some mesenchymal tumors. *Neuroendocrine* tumors are uncommon (see Figure 40.11). Wright-Giemsa stain.

Table 40.1 Comparison of cytology and histopathology for the diagnosis of neoplastic lesions.

Cytology	Histopathology
Noninvasive	Gold standard for tumor diagnosis
Grading being developed	Grades for many tumors aid prognosis
Margins cannot be evaluated	Margin evaluation and invasion by tumor
Preferred technique for lymph node, bone marrow, body cavity fluids, vaginal cytology	
Short turnaround time; if sample is inadequate can resample while patient is still in hospital	Allows application of histochemistry or immunohistochemistry to get additional diagnostic or prognostic information, e.g., immunophenotyping of lymphoma
Fast diagnosis to initiate treatment, determine if additional tests and/or staging is needed; e.g., mast cell tumor, majority of lymphomas	Definitive diagnosis when cytology is inconclusive, e.g., poorly exfoliative tumors, inflamed tumors
Evaluation of cellular details that is difficult to achieve with histopathology, e.g., bone marrow aspirates, diagnosis of large granular lymphocyte (LGL) lymphoma, infectious agents	Evaluation of tissue architecture, which is required for diagnosis of certain subtypes of lymphoma, to differentiate granulation tissue from fibroma, fibrosarcoma, or sarcoid, etc.
Targeted aspiration of lesions via ultrasound guidance	Evaluation of invasion, e.g., blood or lymphatic vessels, adjacent tissues, basement membrane
Less expensive	Higher costs
Light sedation, if at all, usually sufficient	General anesthesia may be required

Histology or other diagnostic tests may be requested by clinicians if they or the owner want additional information and are willing to pay for them; e.g., PARR, immunohisto- or immunocytochemistry, staging, etc. Tumors that can be reliably diagnosed from cytology, with histology or other tests being optional, include lipoma, perianal gland adenoma, adenocarcinoma of anal sac, lymphoma, leukemias, mast cell tumor, TVT, histiocytoma, plasma cell tumor, histiocytic tumors, transitional cell carcinoma (TCC)/urothelial carcinoma (UC), osteosarcoma.

tumors, and neoplasms in body cavity fluids. Using ultrasound guidance, almost any organ or location in the body can be sampled with fine needle aspirational cytology (FNA). Furthermore, cytology is much less expensive than histopathology, can be performed in-practice, which allows assessment while the patient is still in the hospital and available for reaspiration if needed, is less invasive, does not require general anesthesia (depending on location), and the turnaround time for results is short – immediate or less than 3 days. Cytology slides can be examined by the in-practice veterinarians and/or sent to a diagnostic lab or photographed via cell phone or other means and the images sent to referral centers for preliminary reports (Figure 40.2). Not everyone should try to diagnose lesions from cytology. Cytology is like all specialties: there are individuals certified in each specialty that have advanced training and expertise. However, many veterinarians perform procedures associated with a specialty because of their competence and sometimes because owners do not want to pay for a specialist. The information in this chapter is targeted for individuals not already certified in clinical pathology. An excellent time to use cytology is presurgery on masses in which excision for local cure is intended. Results of cytology can be used by the clinician to plan the surgical dose (i.e., extent and depth of resection) required for the type of tumor. Surgical dose will vary if the tumor is determined to be benign, malignant, round cell, epithelial cell, or mesenchymal. Note: each of these is a general category, yet knowing this information before surgery is one of the better uses of cytology.

Do not overlook the importance of the steps necessary to perform FNA, prepare good-quality slides, avoid artifacts, stain the slides, and adjust the microscope. An inadequate number of cells (QNS – quantify not sufficient), lysed cells, preparations so thick and smeared across the glass that they look like a hit-by-car, excessive amounts of blood, artifacts, understained slides, and using a poorly maintained and adjusted microscope will prevent a diagnosis and frustrate the diagnostician. If poor-quality slides are sent to a referral lab a diagnosis is unlikely, and the same charge is rendered as for good-quality slides that yield a diagnosis. Only attempt to interpret or send to a diagnostic lab slides that are of good quality. It is preferable to designate one microscope in the hospital for cytology and use another microscope of lesser quality for urinalysis and fecal examinations.

Throughout this chapter the authors will generalize. Please accept this approach and understand this is biology; therefore, there will always be exceptions. When the exceptions are important we will point these out; however, including every exception confuses the big picture. The chapter is an overview of how cytology is used to diagnose cancer and determine if it is benign or malignant. Benign means the tumor is indolent; it will not spread or directly result in the death of the patient. Malignant means the tumor is aggressive, and if the pet lives long enough, the tumor will likely lead to the death of the pet. There are other chapters

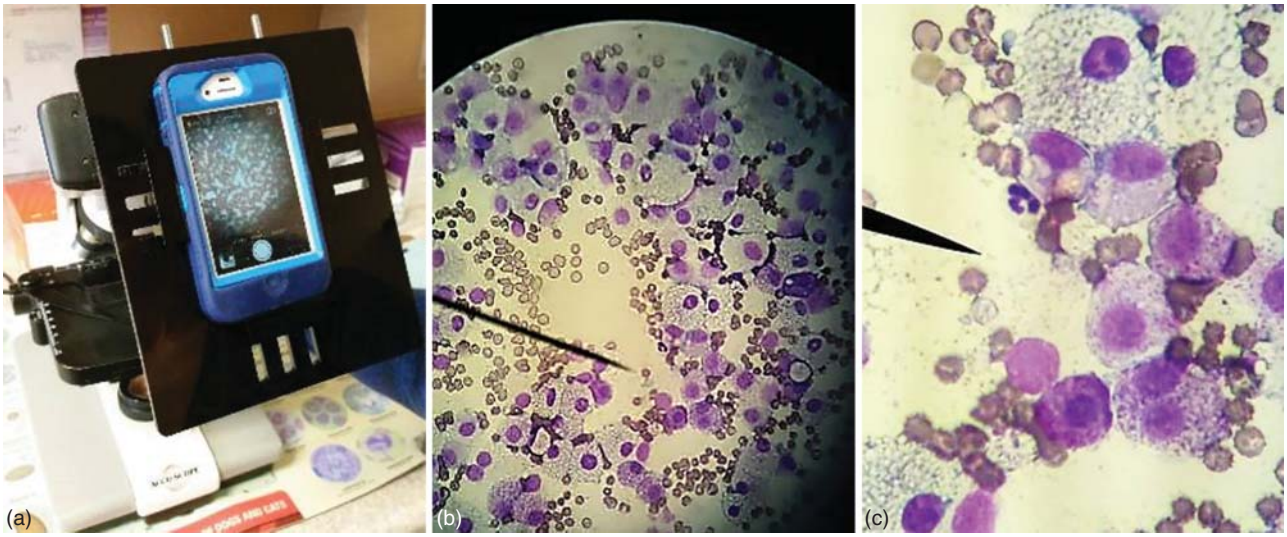

Figure 40.2 (a) Holsters are available that fit on microscopes, and a cell phone can then be attached and used to take a photograph of the fine needle aspirate. An internet search using "cell phone holsters for microscope" will give you options that can be used for different types of smartphones. (b) The central image was captured via this method and the image to the right (c) is enhanced sufficiently to diagnose a round cell tumor that contains cytoplasmic granules: mast cell tumor. Low granularity and binucleation (arrow) suggest aggressive behavior. Aqueous Romanowsky stain.

or sections in this book that describe how to diagnose cancer by where it is located: the organ system, body cavity fluid, lymph node, bone marrow, etc. Location of the suspected neoplasm is an absolutely critical piece of information, as the differential diagnoses for tumors and masses that look like a tumor will change based on organ location. For example: masses in the spleen or liver could be nodular hyperplasia, but this diagnosis is not even a consideration for masses in the skin or subcutis. Similarly, hyperplasia can cause lymphadenomegaly and splenomegaly, but hyperplasia does not produce skin masses. Therefore, the distinction of hyperplasia and hypertrophy from neoplasia is important when examining FNA from organs, but if a nodule or a mass is present in the skin it is most likely inflammatory, a cyst or a neoplasm, and hyperplasia and hypertrophy are not possibilities. Of course, there are exceptions: collagenous hamartoma, fibroadnexal dysplasia, nodular fasciitis, and nodular dermatofibrosis are non-neoplastic lesions of skin or subcutis and each may produce a mass.

Initial examination

Answers to the following clinical questions are part of interpreting the results of FNA. Is there a discrete mass, what is the size, and what is the consistency? Tumors form nodules and masses of various sizes, and they are solid on palpation, not flat, not cystic or fluid filled (exceptions: hemangioma, hemangiosarcoma, myxoma, leukemia, mammary tumors). Is the patient of "cancer age"? Generally, this means the pet is older (exceptions: histiocytoma occurs in young dogs and lymphoma can be seen in young animals of any species). Differential diagnoses for the mass will be formed based on species, history, breed, and location of the mass. Readers should consult specific sections of this book that describe cytological diagnoses by the organ in which the lesion is located. For purposes of this section, the authors will describe how to interpret cytology of a mass in the skin or subcutis, because lesions in this system are the most frequently aspirated, and there are fewer confounders compared to lesions in organs. The principles in this approach can be used in all other systems.

Prepare good-quality slides stained with a Diff-Quik type stain. If neoplasia is a differential diagnosis, do not use wet mounts stained with new methylene blue (NMB) because NMB preferentially stains nuclei and nucleoli. The enhanced staining of DNA and RNA by NMB will make the nuclei in non-neoplastic cells appear neoplastic. First, look at the slide to find regions that are stained and position the slide so these regions are under the 4× objective. Place a dry coverslip on top of the stained slide and examine at low to medium magnifications searching for an area free of artifacts and with an adequate number of cells. When that area is identified, scan with the 20× objective and then proceed to 40×. Avoid using the 100× objective and immersion oil during these first steps. Once oil is placed on the glass slide it is difficult to search for different areas to examine without coating the 40× objective with oil. Almost all diagnoses can be made with the 40× objective and a dry coverslip (exception: microorganisms). The 40× objective is manufactured such that a coverslip is required for uniform in focused view. If a coverslip is not applied to the glass slide, then the field of view will be hazy and appear as if immersion oil is on the objective of the 40× lens (Figure 40.3).

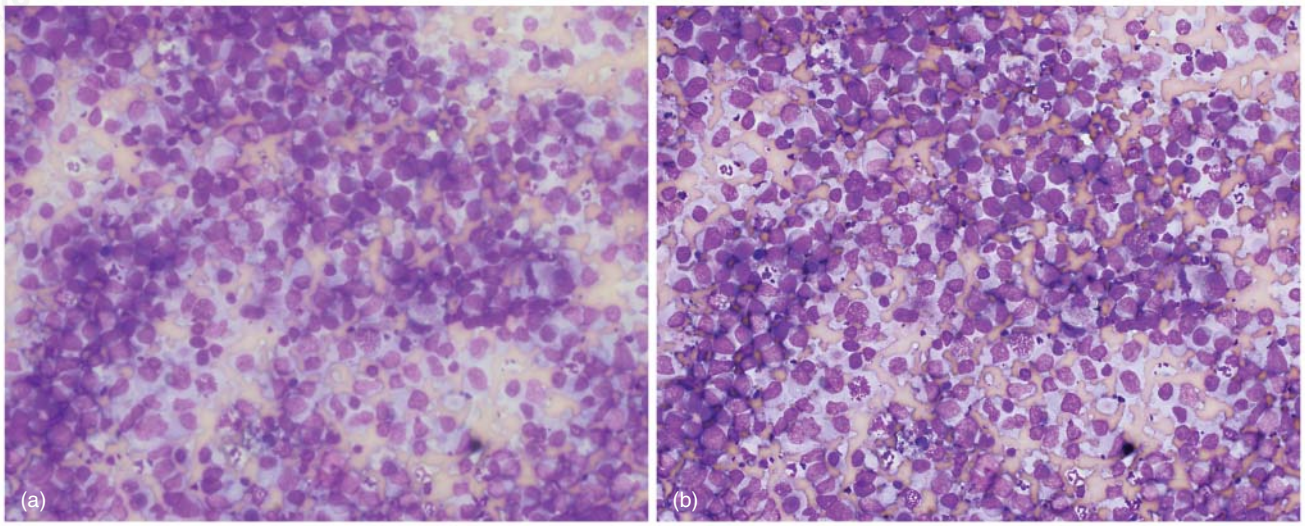

Figure 40.3 Both images (a, b) are as seen with the dry 40× objective. They are the exact same field but the image on the right (b) has a dry coverslip placed on the glass slide over the cells. The image on the left (a) is hazy because there is no coverslip. A fuzzy field of view that appears out of focus with 40× is usually due to the lack of a coverslip. A similar appearance happens if oil contaminates the 40× objective. If the cells are fuzzy and appear out of focus with lower power objectives, the glass slide may be upside down (just flip it over). Avoid oil immersion for the diagnosis of tumors. Wright-Giemsa stain.

For most cases, the critical distinction is inflammation vs. neoplasia. This is accomplished with the 10–40× objectives by determining if the most prevalent cell population is neutrophils. If neutrophils are the number one population, the diagnosis is an inflammatory lesion and not cancer (Figure 40.4 algorithm). Exception: body cavity fluids. Cancer within body cavities often stimulates an inflammatory response and neutrophils can be more prevalent than the neoplastic cells. Lymphoma in body cavities is one of the few neoplasms in which the neoplastic lymphocytes are usually the predominant cells in the fluid (see Figure 42.20). If neutrophils predominate, then determine if they appear healthy or degenerate, which is an indirect way to estimate the likelihood of sepsis. If other inflammatory cells (eosinophils, macrophages, small lymphocytes) are the predominant cells present, then consider inflammation, and refer to Chapter 39 for specific considerations associated with different types of inflammatory cells. If neutrophils are absent or only a few are seen and there are numerous mononuclear cells, then the likely diagnosis is neoplasia. This is relatively straightforward if the mass is in the skin, but in organs the diagnostician must also be able to recognize *normal resident cells* of that organ, which are also mononuclear.

Do not worry about identifying specific cells at this point. Focus on identifying the process: cancer vs. inflammation. Find an area with the most cells for that slide and in which the cells are in a thin monolayer (Figure 40.5). Decide if the cells are individualized or aggregated. The goal now is to decide if most of the cells are round, epithelial, or mesenchymal (spindle shape) (Figure 40.1). This is accomplished by assessing overall cellularity, organization of the cells, amount of cytoplasm per cell and shape of the cells. This can be done using the 20× and 40× objectives; oil immersion is not needed to classify the tumor. Relative size of cells can be estimated by finding red blood cells (7 µm, canine) and neutrophils (approximately 15 µm). Almost all neoplastic cells are larger than both cells. The smallest tumor cells are probably small T-cell lymphoma, and the largest are likely squamous cell carcinoma (SCC) and histiocytic sarcoma (HS). There is no specific size that predicts a cell is neoplastic and measuring cell sizes has little benefit. Exception: cell size as determined by flow cytometry is used to assess biologic behaviors of some lymphomas (see Chapter 45) [6].

Round cell tumors usually exfoliate a large number of cells. The cells are individualized (discrete); they may contact adjacent cells but do not pile together (unless preparation is thick and highly cellular). Volume of cytoplasm is low to moderate and the shape of the cell is round or oval. Do not consider the shape of the nuclei as most nuclei are round, even in mesenchymal cells. Round cell tumors are MCT, histiocytoma, plasma cell tumor, lymphoma, and TVT (Figure 40.6). The last two differentials rarely produce tumors on the skin; they are usually in lymph nodes (lymphoma) or on external genitalia (TVT). If lymphoma is in the skin the lesions are usually multiple hyperemic plaques (not a singular mass). The first three tumors are described in greater detail in the section on skin tumors. The most common skin tumor in dogs is MCT and it is usually easy to recognize because the tumor cells exfoliate readily and have numerous purple cytoplasmic granules. Granularity varies widely from barely visible to obscuring the nucleus (Figure 40.7). Although preparations from round cell tumors usually have high cellularity,

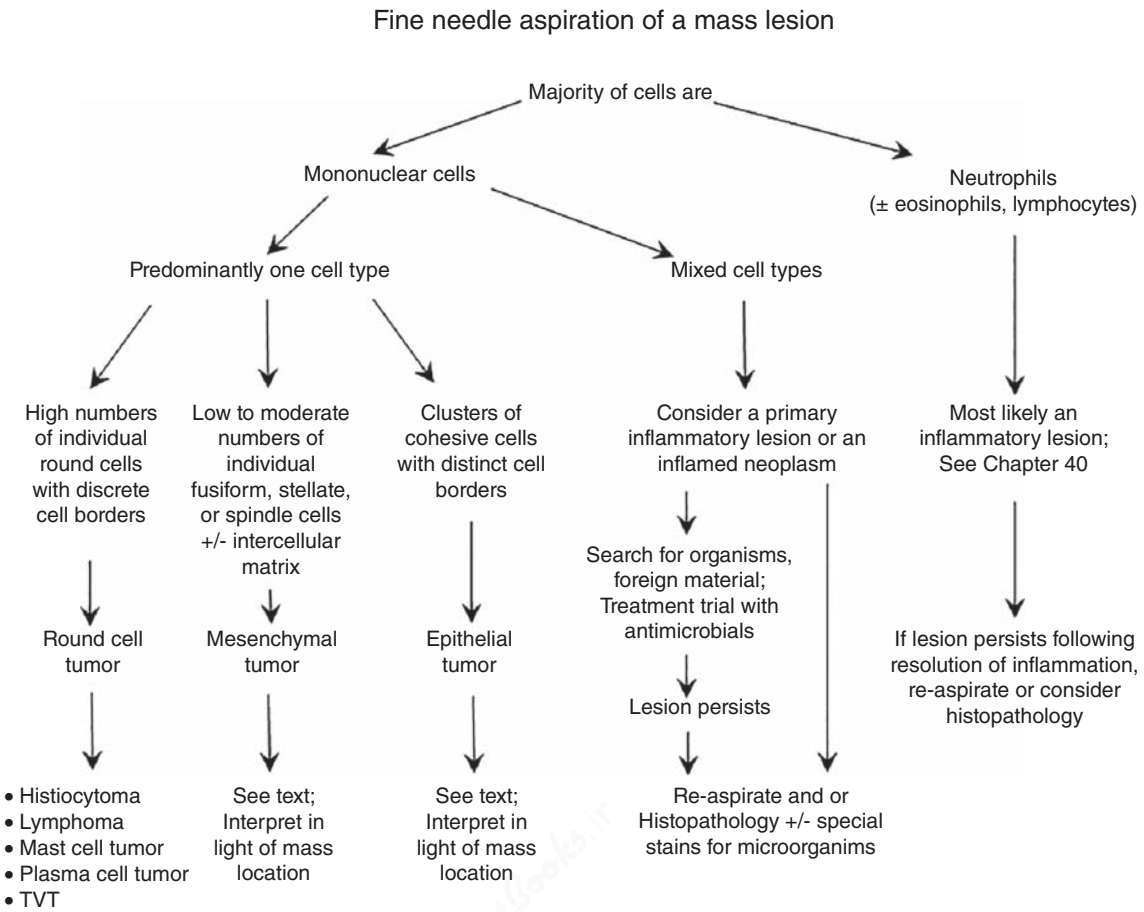

Figure 40.4 Cancer vs. inflammation algorithm.

the exception is histiocytoma, which may have a paucity of cells on the slide.

Epithelial cell tumors generally exfoliate numerous cells. The cells can be individualized, but the important feature is the presence of cohesive clusters of cells piled together (Figures 40.1 and 40.8). Search at low to medium magnifications for these cohesive units as they are the key to the correct diagnosis. Proceeding to high magnification before searching for these may result in a missed diagnosis. Generally, epithelial cells have abundant cytoplasm and cell shapes are cuboidal, columnar or polygonal. The shape of the cell is not critical to the diagnosis and shape may be difficult to discern in the aggregates. Epithelial cells are often organized into groups that form clusters, morula, or acini. These histologic structures form due to desmosomes that connect epithelial cells. It is rare, and not needed for the diagnosis, that an epithelial tumor yields distinct acini with a central lumen, as seen in histology. A few epithelial tumors are so distinct that their origin can be determined from cytological features: UC (transitional cell carcinoma [TCC]), sebaceous, circumanal, (perianal gland) tumor, anal sac apocrine gland adenocarcinoma, thyroid follicular carcinoma, etc. (Figure 40.8). Therefore, epithelial tumors are generally identified by knowing the organ from which they were aspirated: urinary bladder, mammary, prostate, etc.

Mesenchymal tumors usually exfoliate a low to moderate number of cells, the cells are individualized or may appear adhered but will not form circular acini, and cytoplasm is elongated such that the cells have a spindle shape, which is critical to the correct diagnosis (Figures 40.1 and 40.9). Most of the nuclei will be round, but if they are oval-shaped or elongated, it makes cell identification easier. Mesenchymal tumors have a wide range of appearances depending on their origin. They tend to yield few cells because the collagenous intercellular matrix holds the neoplastic cells within the tumor tightly. However, osteosarcoma and perivascular wall tumor (PWT) usually yield numerous cells (Figure 40.9). PWT is a term used for a group of spindle-shaped tumors that arise from cells in the wall of blood vessels, and histology and immunohistochemistry are required to accurately identity subtypes: *hemangiopericytomas, myopericytomas, angioleiomyomas, angiofibromas, adventitial tumors* [7, 8]. PWT is the most common mesenchymal tumor in the skin and subcutis of dogs, and they are rarely malignant. The intercellular matrix of mesenchymal tumors is seldom seen in FNA cytological

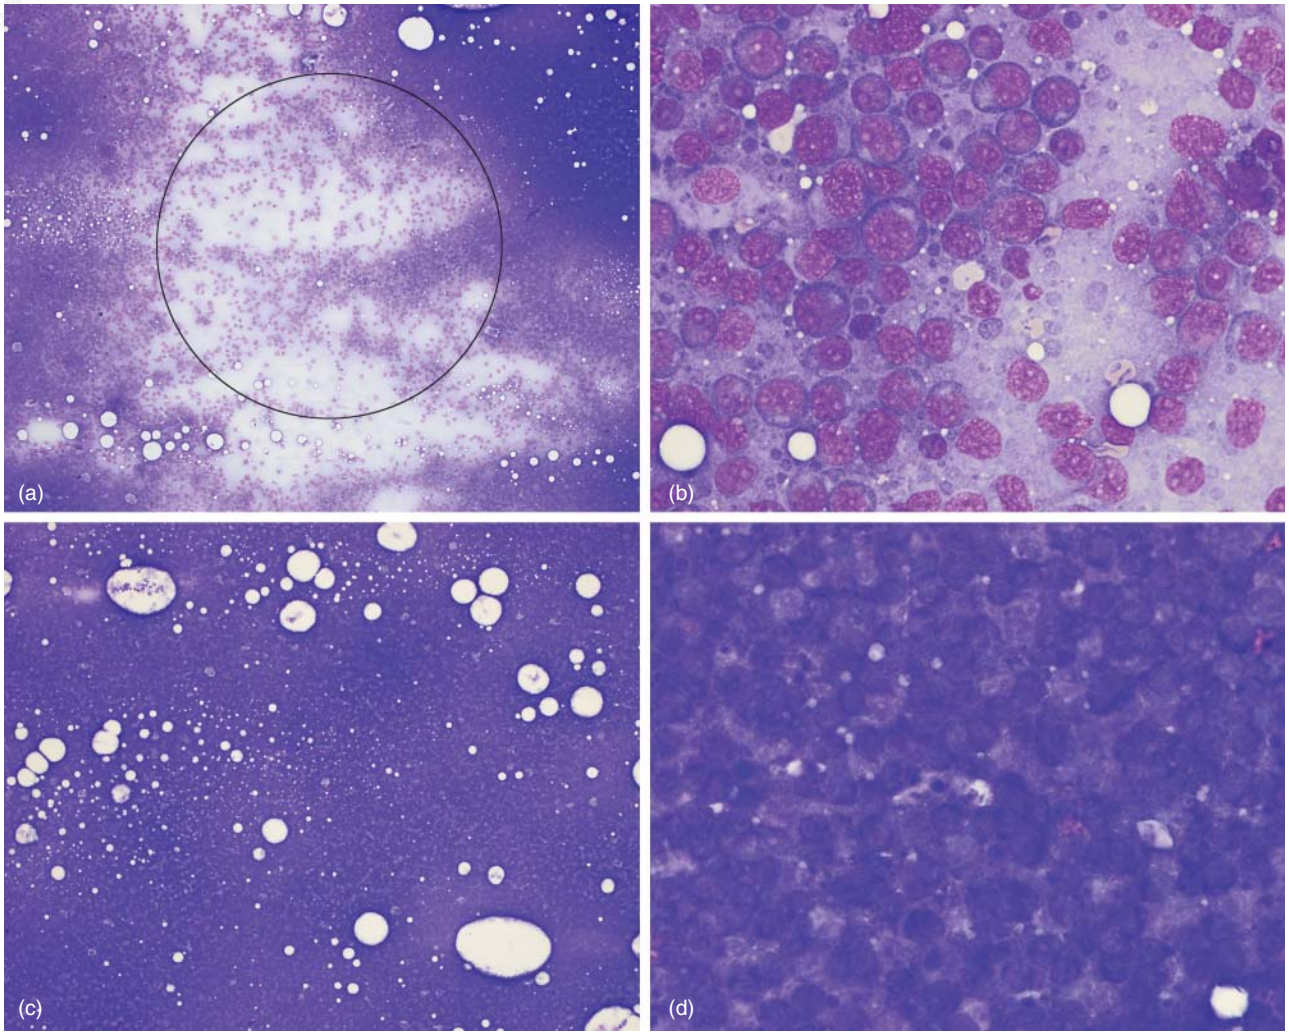

Figure 40.5 Thin monolayer (a, circle, 10× objective) will provide diagnostic regions (b, 100× objective) vs. thick areas outside of circle that are nondiagnostic. Search the slides with 10 or 20× objectives and no coverslip, then proceed to a higher magnification when the thinner regions are located. Two lower panels (c, d), are too thick, even at 100× (d); a diagnosis is not possible. Do not try to make diagnoses on poor-quality slides. Wright-Giemsa stain.

preparations but occasionally is found in osteosarcoma (Figure 40.9) and chondrosarcoma. HSs are so unique in their origin and cytological and histological appearances that they are described separately in this section; they do not have a visible intercellular matrix.

Melanocytic tumors are mesenchymal, but their cytological appearance can be a mixture of spindle, round and epithelial-like aggregates. Cytoplasmic pigment is the key to the diagnosis, and it ranges from green to black and from a light dusting to so heavily pigmented that nuclei cannot be seen (Figure 40.10). When no pigment is observed, they are sometimes referred to as amelanotic. Rarely is pigment truly absent. It may require extensive searching but almost always a few cells with pigment will be present. Histochemical stains (Fontana-Masson) and immunohistochemistry (Melan A, PNL-2) or immunocytochemistry can be requested if pigment is not identified to confirm the diagnosis of melanoma. Names for melanocytic tumors are quite varied: melanoma, melanosarcoma, melanocytic melanoma with benign histologic features; melanoma with low malignant potential; melanocytoma; well differentiated melanoma. The name is unimportant; predicting biologic behavior is important (see end of this chapter).

Endocrine/neuroendocrine tumors is a fourth category of cytologic tumor classification. Neuroendocrine tumors exfoliate moderate to high number of cells; however, the cells are often not intact and bare nuclei devoid of encompassing cytoplasm or embedded in a sea of cytoplasm are present. Apparently, these cells are fragile and cell membranes are easily broken during preparation, therefore cell borders are usually indistinct. If the slide is searched well, intact cells with a small to moderate amount of lightly stained cytoplasm can be found (Figure 40.11). Nuclei are round and uniform. Biological behavior of neuroendocrine tumors

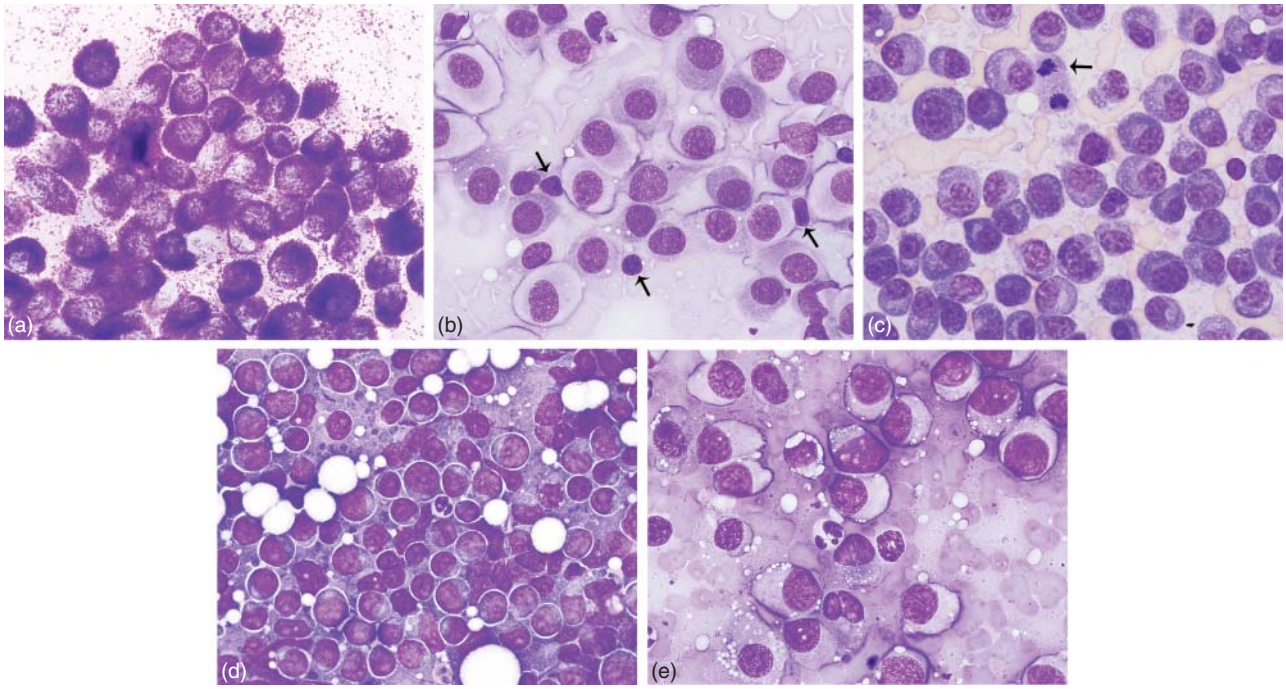

Figure 40.6 Round cell tumors. (a-e) 50× objective; common feature is individual round cells. (a) Mast cell tumor – numerous cells, obvious purple granules. (b) Histiocytoma – low number of cells, pale cytoplasm; the few dense nuclei with scant cytoplasm (arrows) are lymphocytes. (c) Plasma cell tumor – eccentric nuclei and pale paranuclear zone (Golgi) are diagnostic, arrow points to a mitotic figure (anaphase). (d) Lymphoma – high cellularity, uniform round cells with minimal cytoplasm and single large nucleus that fills the cytoplasm; note neutrophil in center for size comparison. (e) TVT – resembles histiocytoma but cytoplasmic vacuoles aid distinction and location on genitalia confirms diagnosis. Histopathology is not needed to establish diagnosis for any of these examples. Wright-Giemsa stain.

is better predicted from historical data and not from cellular and nuclear characteristics.

Neuroendocrine tumors are diagnosed infrequently in primary care centers due to their location in the abdominal (adrenal, pancreas) or thoracic cavities (aortic body tumors). They are also located at the carotid bifurcation in the jugular furrow (carotid body tumor), and therefore may be aspirated easily from this location. Another possible site is thyroid; however, most thyroid tumors in dogs and cats are of follicular origin, and these are epithelial (although these cells typically have a neuroendocrine appearance). C-cell tumors are neuroendocrine and are in or expanding from the thyroid gland. The distinction of follicular tumors from C-cell tumors usually requires histopathology and often immunohistochemistry or immunocytochemistry. Follicular tumors are more common than C-cell tumors in dogs and cats; they are aggressive in dogs and benign in cats. They usually do not cause functional thyroid problems in dogs but cause hyperthyroidism in cats. Nodular adenomatous hyperplasia in cats is a misnomer; the lesion is adenoma. Merkel cell tumors are neuroendocrine tumors found in the skin and are exceedingly rare.

Histiocytic sarcoma is a mesenchymal tumor, but the tumor cells are not spindle-shaped; in fact, they look cytologically like a pleomorphic round cell tumor (Figure 40.12). A malignant plasma cell tumor (poorly differentiated) and HS may look similar microscopically. Both tumors yield highly cellular preparations. Cells are individualized and large with abundant cytoplasm that contains one to numerous nuclei. Nuclei and nucleoli are highly variable in number, size, and shape. If giant cells, multinucleation, bizarre nuclei, and nucleoli are numerous, then favor HS over plasma cell. The most definitive way to distinguish these two tumors is to use the antibody MUM-1, which will stain plasma cells positively but not histiocytic cells [9]. Immunohistochemical stains that recognize histiocytic cells require special handling and expertise. Less technical ways to distinguish these tumors use clinical criteria: *breed of dog*: Bernese mountain dogs, flat-coated retrievers, Rottweilers, and golden retrievers are predisposed to develop HSs, but they can occur in any breed; *location*: articular joints, widely disseminated, or pulmonary favors histiocytic; oral, rectal favors plasma cell; *serum total protein*: very high concentration, especially with monoclonal gammopathy, favors plasma cell, but this and intratumor amyloid are uncommon to rare.

HSs are a disease complex with designated subtypes. The majority arise from interstitial dendritic cells that are present in perivascular tissues in many organs [10]. However, hemophagocytic histiocytic tumors arise from macrophages in the spleen. The distinctive microscopic

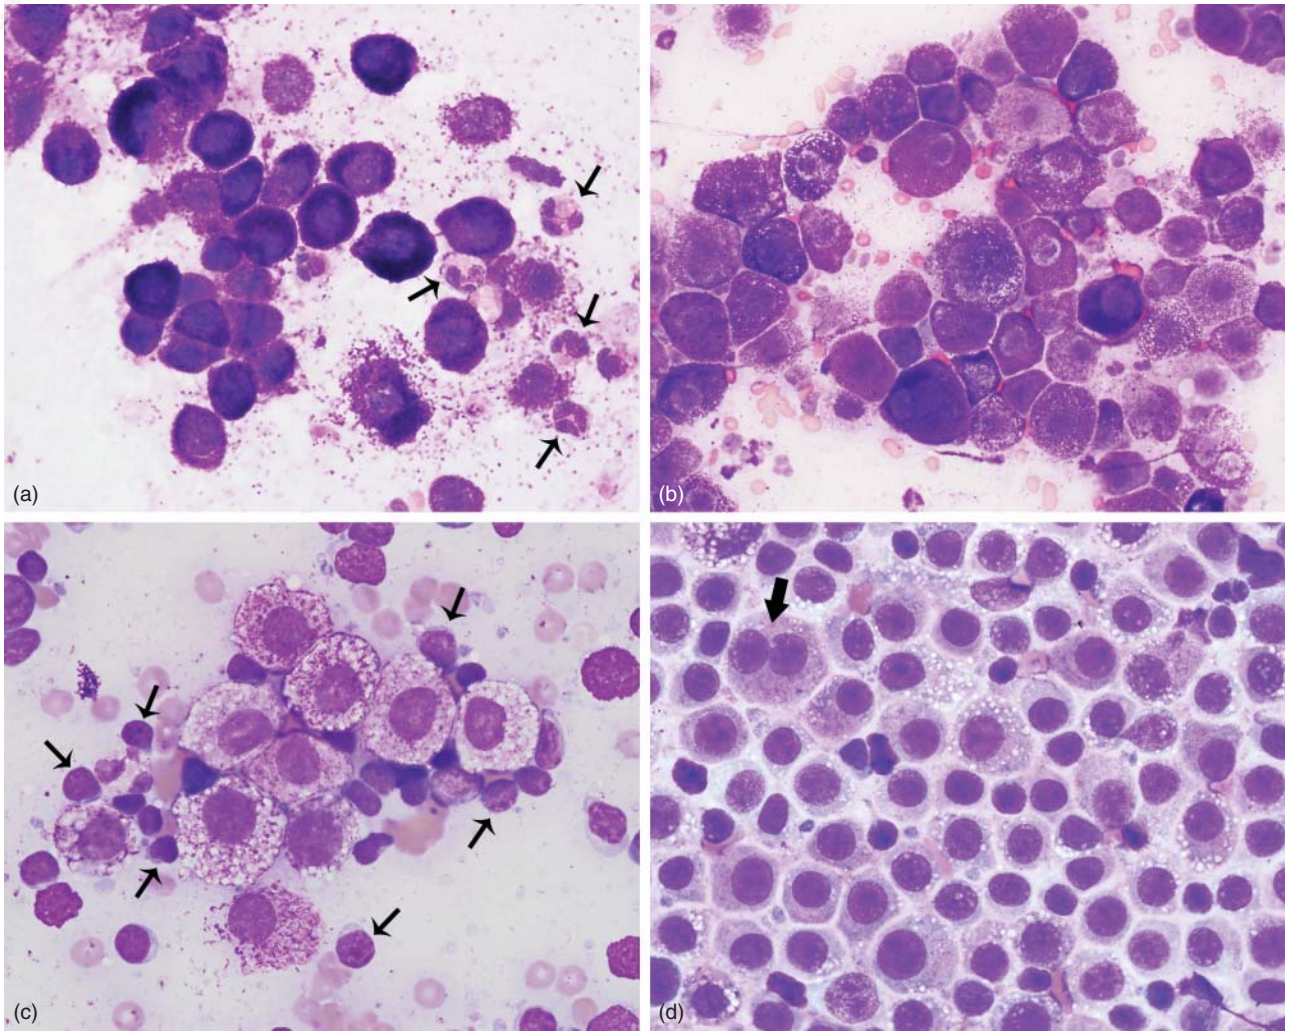

Figure 40.7 This collage is from four different canine cutaneous MCTs and demonstrates how tumors can have a range of cytological (and histological) appearances. Cytologic grading of canine MCT is based on the variability of cells and nuclei. Less aggressive MCTs are heavily pigmented (a, b) and cells are relatively uniform. Note the numerous eosinophils in (a) (arrows) and lymphocytes in (c) (arrows). More aggressive MCTs have less cytoplasmic pigment that may be faint (c) to absent (d). They also exhibit variability in cell and nuclear sizes and shapes including binucleation (arrow, d), as well as multinucleation and mitotic figures. Cytological grading schemes will estimate these features in a determined number of mast cells seen on the preparation. (a, c, d) 100× objective; (b) 50× objective. Wright-Giemsa stain.

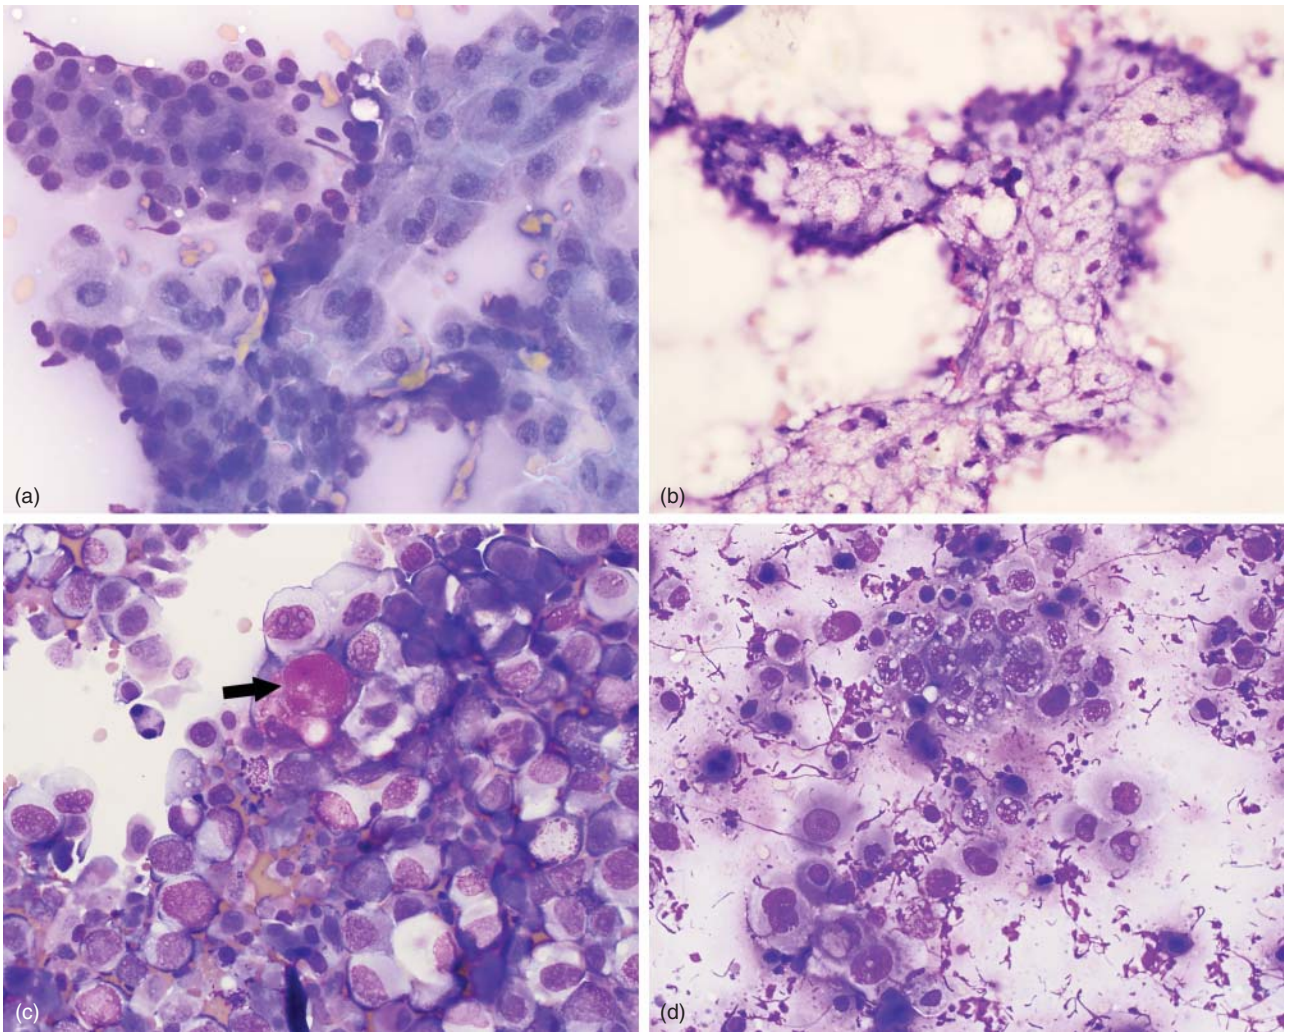
feature for this subtype is the presence of erythrophagocytosis (Figure 40.12). The tumor complex can be highly malignant but there are localized diseases as well. There are no definitive criteria to diagnose synovial cell sarcoma in dogs, and tumors previously classified as such are HSs. Deletion of tumor suppressor genes CDKN2A/B, RB1, and PTEN are part of the pathogenesis of HS in dogs [11].

Combine all known clinical facts with microscopic observations to identify the tumor categories, but the most important cytological features within each category are *round cell tumors* – individualized cells with a round shape; *epithelial tumors* – large cells adhered in clusters, morulae; *mesenchymal tumors* – spindle-shaped cells; *neuroendocrine* – uniform nuclei often without surrounding cytoplasm.

Benign vs. malignant

After the cytologist establishes a tumor is present, the next most important determination for an owner and clinician is to determine if the pet's tumor is benign or malignant. The cytological features associated with each are summarized in Table 40.2.

These criteria are standard in publications about cytology and neoplasia, but they should not be relied on too heavily



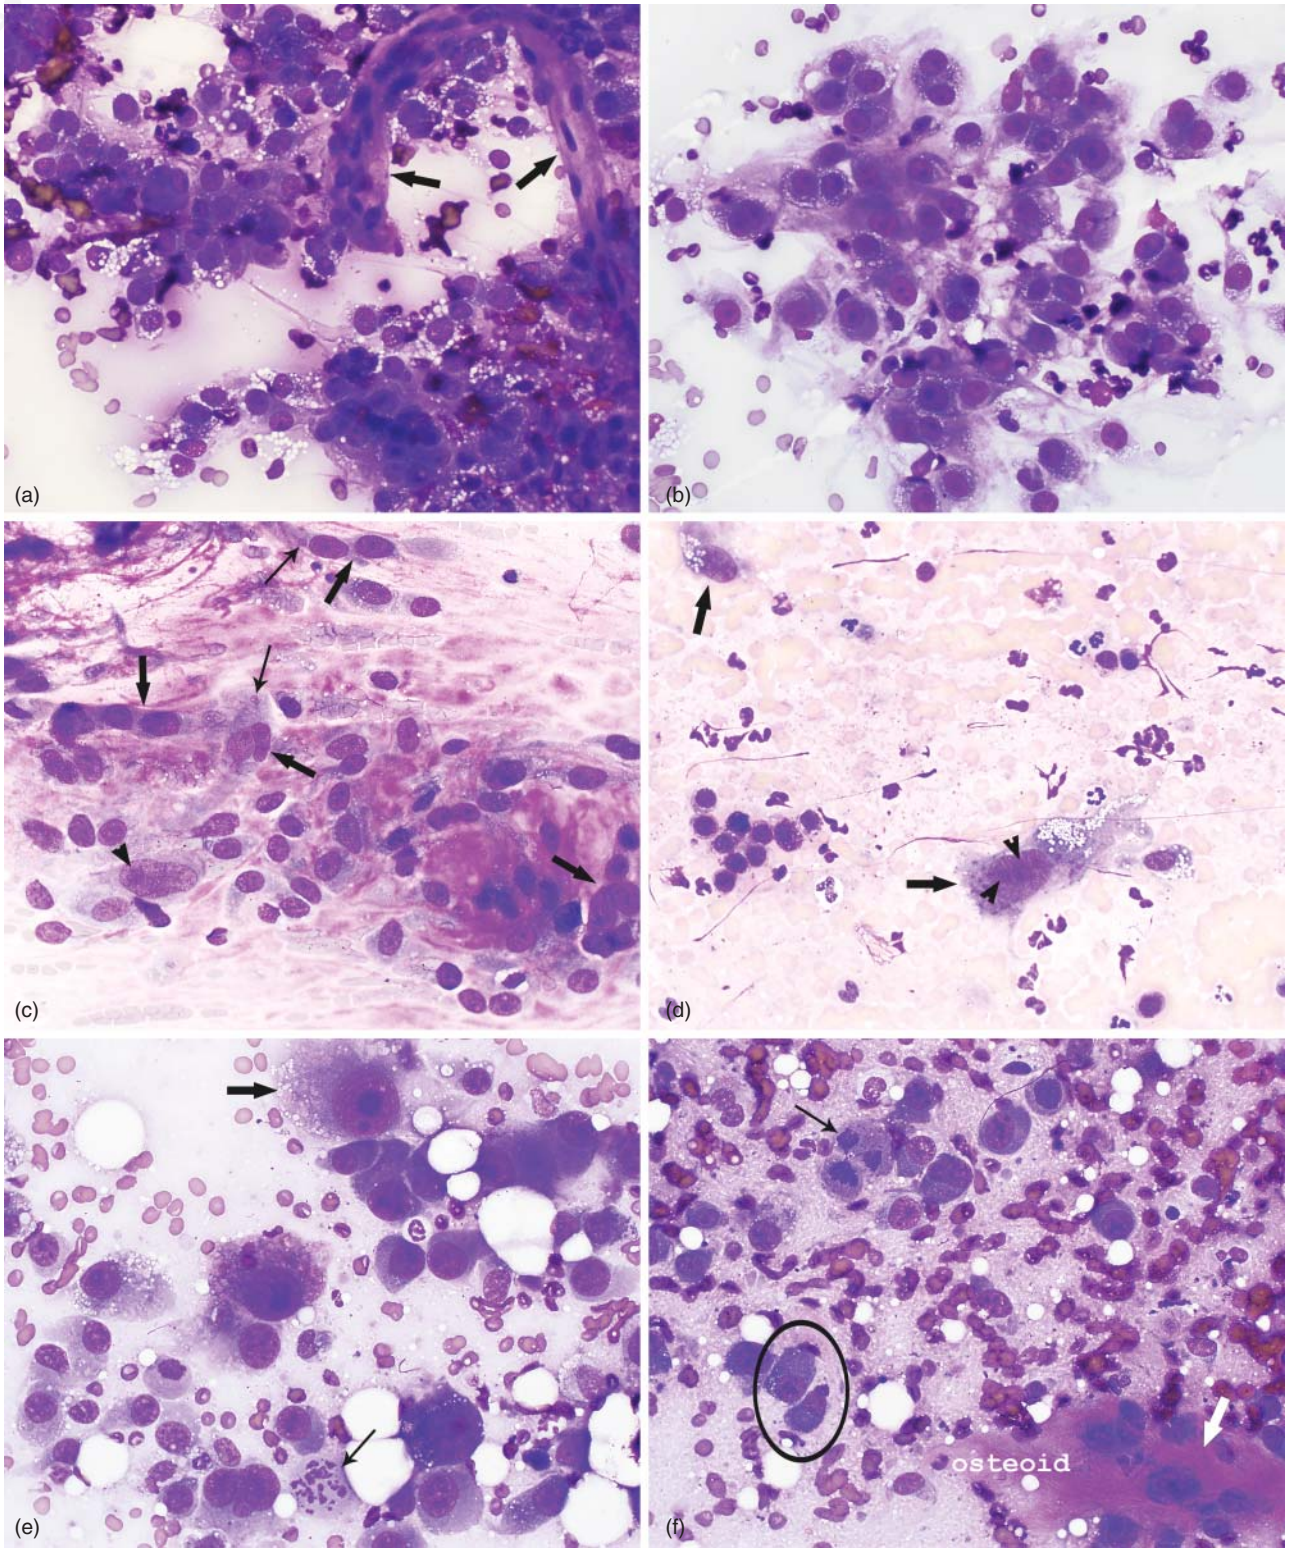


Figure 40.8 Epithelial tumors – the common feature in each image is large cells adhered together. (a, c, d) 50× objective; (b) 40× objective. (a) and (b) have numerous cells that overlap such that some regions are out of focus. Cytological features help name the tumor, but the key to each diagnosis and predicted behavior is location of the tumor. (a) Perineum, perianal gland tumor, benign. (b) Eyelid (or any location on skin) – sebaceous gland adenoma (typical abundant clear to vacuolated cytoplasm), benign. (c) Urinary bladder – urothelial carcinoma (TCC), malignant, arrow points to a Melamed-Wolinska inclusion body, which is diagnostic for urothelial cell origin. (d) Ear, eye, oral, or genitalia – squamous cell carcinoma, malignant. Epithelial cells are extremely pleomorphic; the numerous smaller cells in the background are neutrophils, many of which have degenerated. Neutrophils are a common finding in SCC. Biologic behavior of each tumor is based on diagnosis and location rather than cytological criterion. Wright-Giemsa stain.

Figure 40.9 Fine-needle aspirates of mesenchymal tumors. (a–f) 50× objective. (a, b) Perivascular wall tumor (PWT) or hemangiopericytoma; histopathology and ancillary tests are needed to subtype these tumors, but a clinical diagnosis and behavior can be provided from cytology and size of tumor. A blood vessel, characteristic of PWT, is indicated by arrows. Spindle shape is seen at higher magnifications but will not be seen in all cells. (c) Fibrosarcoma (injection-site sarcoma) from a cat; large subcutaneous mass located on the left thoracic wall. Note pleomorphic spindle cells exhibiting anisocytosis, anisokaryosis, binucleation (thick arrows), micronuclei (satellite nuclei, thin arrow), and macronucleoli (arrowhead); cells are surrounded by pink, fibrillar matrix. Such matrix is not always seen nor this abundant. (d) Hemangiosarcoma (spleen, dog); low numbers of highly pleomorphic spindle cells with punctate clear cytoplasmic vacuoles (arrows), large nuclei (compare size to surrounding neutrophils), and macronucleoli (arrowheads). It is uncommon to retrieve neoplastic cells in HSA with FNA because the majority of the mass is composed of blood vessels with large regions of hemorrhage and necrosis. (e, f) Osteosarcoma – distal radius, large-breed dog, lytic bone lesion. No neutrophils and numerous mononuclear cells with eccentric nuclei. There is variability in sizes of cells and nuclei. Spindle shape is only apparent in a few cells. Osteoid matrix (pink, white arrow) is present. Several mitotic figures are indicated by arrows, and the thick arrow is directed at a cell with a macronucleolus. The cells inside the circle are osteoblasts, which resemble plasma cells due to their eccentric nuclei, blue cytoplasm, and pale Golgi. Osteoblasts will stain positively for alkaline phosphatase. Histopathology is not needed when the cytological features and clinical data are this classic.

Figure 40.10 Canine melanocytic tumors, range of cytological patterns. (a, b, d, f) 100× objective. (c) 50× objective. (a) Cutaneous melanoma/melanocytoma, heavily pigmented individual cells, round nuclei; abundant pigment in background will make the slide black on gross inspection. Histology is needed to assess biological behavior. (b) Digit melanoma, aggregate of cells in middle are epithelial-like, arrow points to a spindle-shaped cell. (c) Metastasis in regional lymph node from an oral malignant melanoma; binucleated cell, moderate to marked variability in cell and nuclear morphology; amount of pigment is highly variable (large black globules, small black granules, and some cells are devoid of pigment). (d–f) Oral malignant melanoma, amelanotic; note the absence of visible melanin pigment in these pleomorphic cells (d); cells stained positive (brown) with a melanocytic marker (Melan A) on histopathology (f). (e) A pale gray mass is protruding from the soft palate in this dog. Touching the surface of tumors is futile; FNA into the mass is needed to yield cells that represent the tumor.

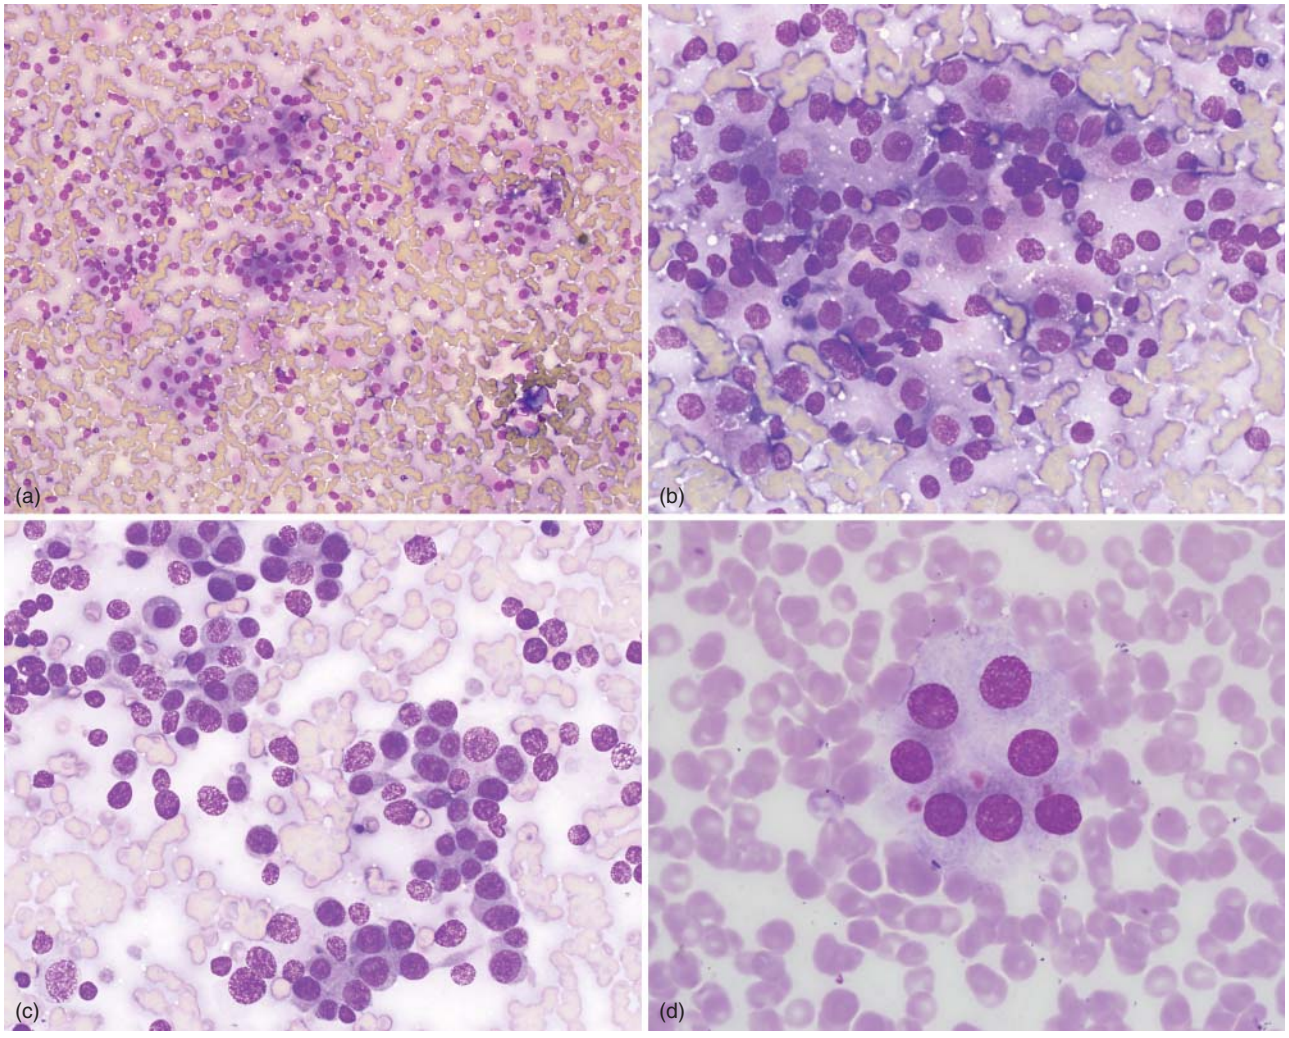

Figure 40.11 Neuroendocrine/endocrine – this is a fourth pattern of neoplasia that can be recognized by cytological examination. These tumors are seen infrequently in primary care facilities as most are located in the abdominal or thoracic cavities. Top panel is an insulinoma (a: 20× objective, b: 50× objective); the tumor cells were aspirated from the liver, which is a frequent metastatic site. Bottom panel is a thyroid tumor (c: 20× objective, d: 100× objective), likely follicular in origin, due to the circular or acinar pattern seen at higher magnification (d). Common features in both examples are uniform round cells that are in close proximity and appear to be adhered; pale cytoplasm and/or naked nuclei. The uniformity of cells and nuclei would suggest benign behavior, but both tumors metastasize readily: 90% of insulinomas will metastasize and thyroid follicular tumors that are palpable metastasize to lungs.

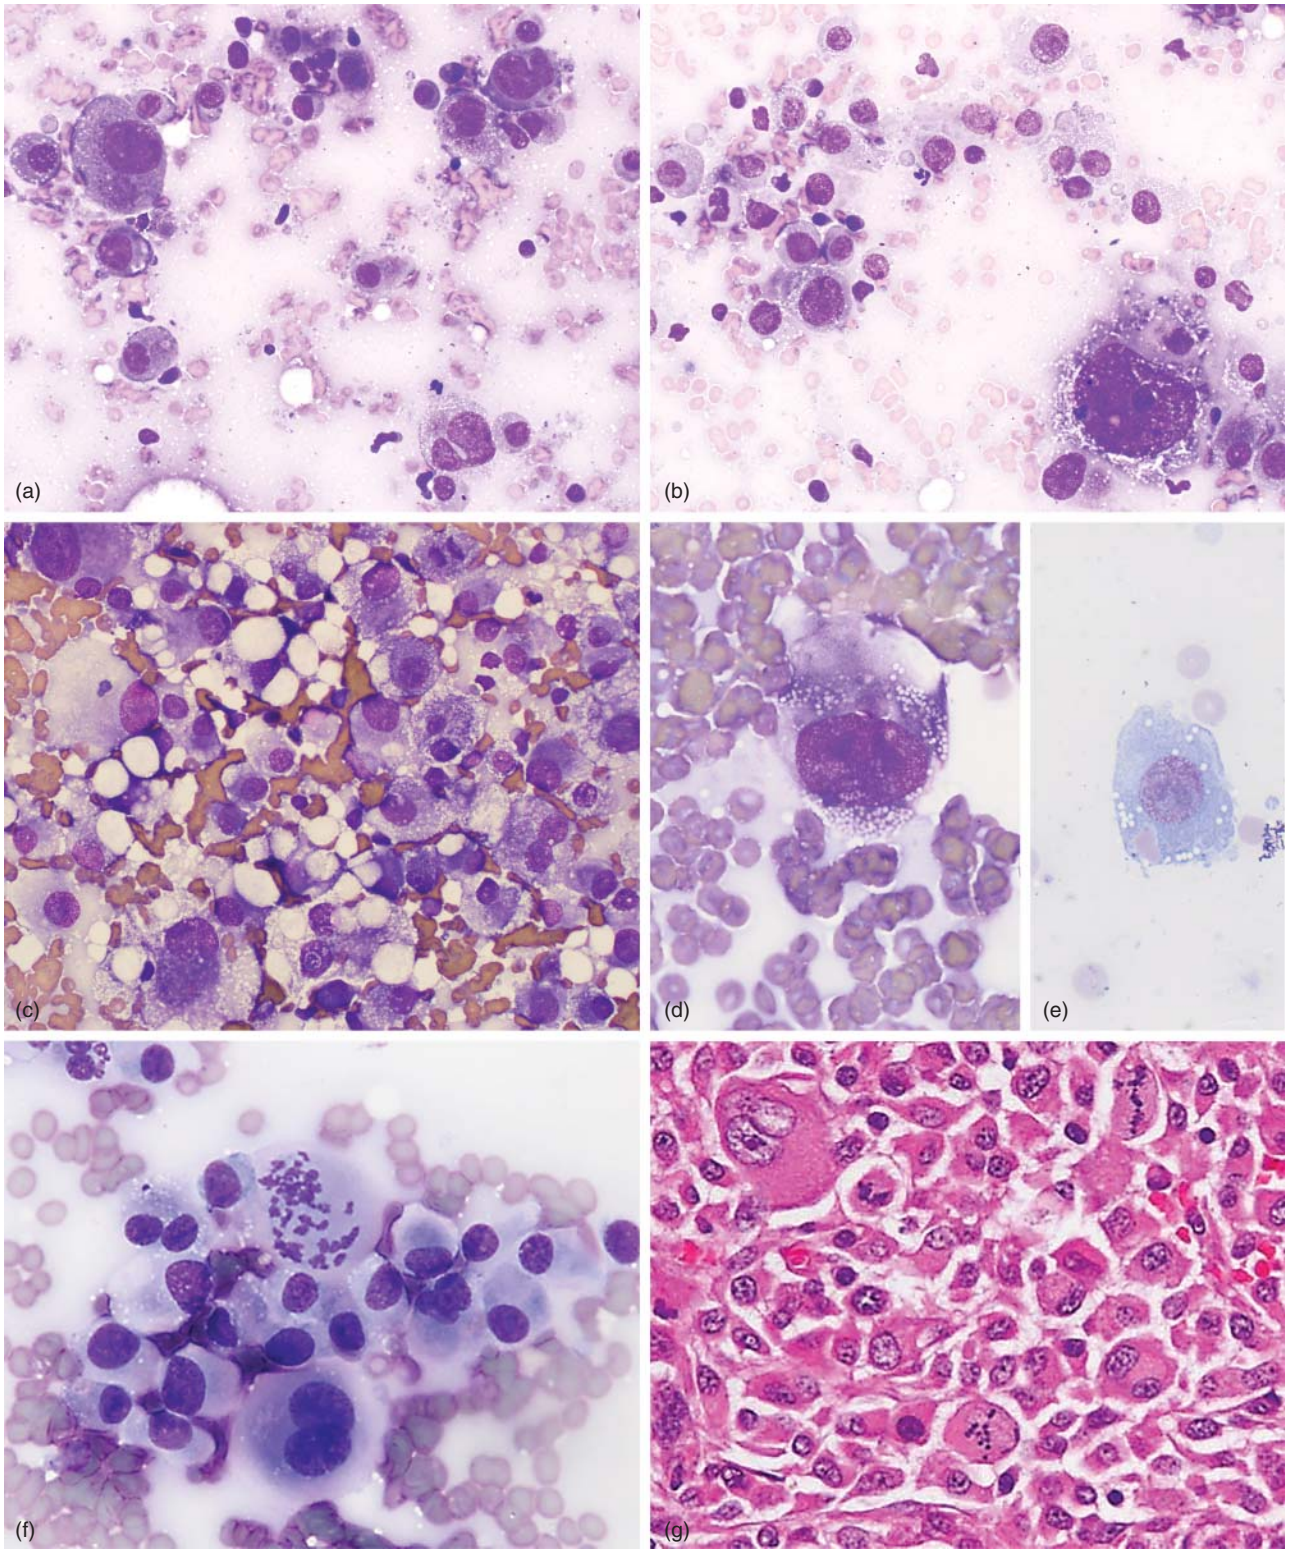

Figure 40.12 Histiocytic sarcoma. Tissue source in top two panels is lymph node (a, b: 50× objective); there are no neutrophils or lymphocytes but pleomorphic mononuclear cells predominate, indicating metastatic neoplasia. There is marked variability in the size of tumor cells and their nuclei. Image (c) (50× objective) is from the lung and images (d) and (e) (100× objective) are from the spleen. Each image contains at least one incredibly large cell with abundant cytoplasm. The nuclei in these cells are as large as three to six red blood cells. The tumor cells in (d) and (e) exhibit erythrophagia; although other tumor cells can be phagocytic, this feature is characteristic of histiocytic tumors. Images (f) (50× objective) and (g) (40× objective) are from the joint of a retriever dog, and they demonstrate the marked pleomorphism of this tumor on cytology (f) and histopathology (f, g; Source: Images courtesy of Keith Thompson). See text for other ways to diagnose this tumor and cells of origin. (a–f) Wright-Giemsa stain. (g) H&E stain.

Table 40.2 Criteria to help predict benign vs. aggressive (malignant) behavior.

General
Historical data about a specific tumor type and location are better than cytological criteria
Single-cell type, no inflammation, uniform cells and nuclei favor benign*
Small well-delineated mass (<2 cm) favors benign; large (>6 cm) poorly delineated or infiltrative/ulcerated favors aggressive
Cellular and nuclear pleomorphism – aggressive
Cells exfoliate in high numbers (especially for mesenchymal tumors) – aggressive, vs. low number of cells – benign
Variation in cell size (anisocytosis) and/or irregular cell shape – aggressive
Variation in nucleus-to-cytoplasmic (N : C) ratio – aggressive
Nuclear criteria of malignancy = *"variability" – pleomorphism*
Variation in nuclear size (anisokaryosis)
Irregular nuclear shape, sizes, giant nuclei
Multinucleated cells, binucleation – note: non-neoplastic monocytes/macrophages have these same features
Nuclei and cells that pile together with no respect to cell or nuclear borders
Micro-/satellite nuclei, fragmented nuclei
Large nucleoli, macronucleoli (exceeding the size of a red blood cell)
Multiple nucleoli of variable size and/or irregular shape
Increased mitoses with abnormal (bizarre) mitotic figures

[a] Notable exceptions are lymphoma, insulinoma, thyroid tumors, some carcinomas that appear uniform but are aggressive; other exceptions are described in the text of this chapter.

because there are no studies that correlate these features with outcome assessments, and exceptions to the predicted behavior patterns are numerous. The term "criteria of malignancy" in cytopathology implies a tumor is malignant when these features are present. Yet a tumor may have these features and not be malignant. Furthermore, inflammatory cells and reactive fibroblasts and young blood vessels can possess the nuclear features listed as criteria of malignancy (see "Confounders in Interpretation"). Alternatively, a tumor may not possess any of these cytologic criteria of malignancy, but it is aggressive: invades adjacent tissues, is present in blood or lymphatic vessels, and/or metastasizes. The term criteria of malignancy is better considered *criteria of neoplasia*.

If cytological criteria are imprecise, then what should be used at this juncture? Known historical data about the behavior of a type of tumor are more useful than trying to predict how an individual tumor will behave from the cytological criteria. For example: MCT in cats are benign, 90% of cutaneous MCT in dogs are benign, histiocytoma is benign, sebaceous tumors are benign, lymphoma is malignant, osteosarcomas are malignant, injection site sarcoma in cats is invasive, insulinoma in dogs appears cytologically benign but greater than 90% metastasize (see end of this chapter).

There are no cytological grading schemes for tumors in pets that have been shown to have statistical significance to predict prognosis, and there are few histologic grading schemes and no molecular markers that have been validated with robust cohorts in animals. Cytological grading schemes will be developed, and they will be plagued by problems inherent in our present studies: an absence of standardized parameters (microscopic, molecular, immunohistochemistry, outcome assessment), excessively subjective microscopic evaluations, limited number of cases, different stages of disease at enrollment, different therapies, weak or inaccurate follow-up data, and lack of concordance between pathologists. Outcome assessment determines if a test is predictive of treatment or prognostic of tumor behavior. Outcome assessment data must be collected as carefully and accurately as the cytological, histological, or molecular techniques used to assess tumors. Yet survival times and even disease-free intervals are heavily influenced by owners' decisions about euthanasia. Owner decisions are influenced by personal factors including the value of pets in a family, finances, and/or nursing care. These factors are part of but difficult to separate from the tumor's behavior or the host's defenses.

The best cytological feature to estimate behavior is uniformity vs. variability (pleomorphism) in cells, nuclei, and nucleoli (Table 40.2). The more uniform the cell size and shape, the more likely the tumor is benign (indolent). Uniformity is associated with benign behavior, whereas variable sizes, numbers, and shapes of nuclei and nucleoli are used to predict aggressive behavior (Figures 40.13 and 40.14). Nuclear and nucleolar pleomorphism are more important to assess than cellular features. Multiple nucleoli of various sizes is a widely used cytological feature associated with aggressive tumors. All living cells have nuclei and nucleoli; it is their variability that must be evaluated, not just their presence. Names can be applied to the cellular and nuclear features observed, but more important than the name is the recognition of the abnormality: anisocytosis, anisokaryosis, karyomegaly, abnormal mitotic figures, multinucleation, etc. The determination of uniformity vs. variability is done by evaluating many cells and recognizing a pattern, not just finding one large cell or nucleus with an abnormality.

Generally, the greater the nucleus to cytoplasmic ratio (N : C), the more aggressive the tumor. Cells with a paucity of cytoplasm and large nuclei that nearly fill the entire cell are often aggressive, e.g., lymphoma. These generalizations are guides; they should be used in concert and integrated with all of the other clinical data available, especially location and size of tumor. An obvious exception to the generalization that uniformity is associated with benign behavior is lymphoma, as most lymphomas are fairly uniform in appearance

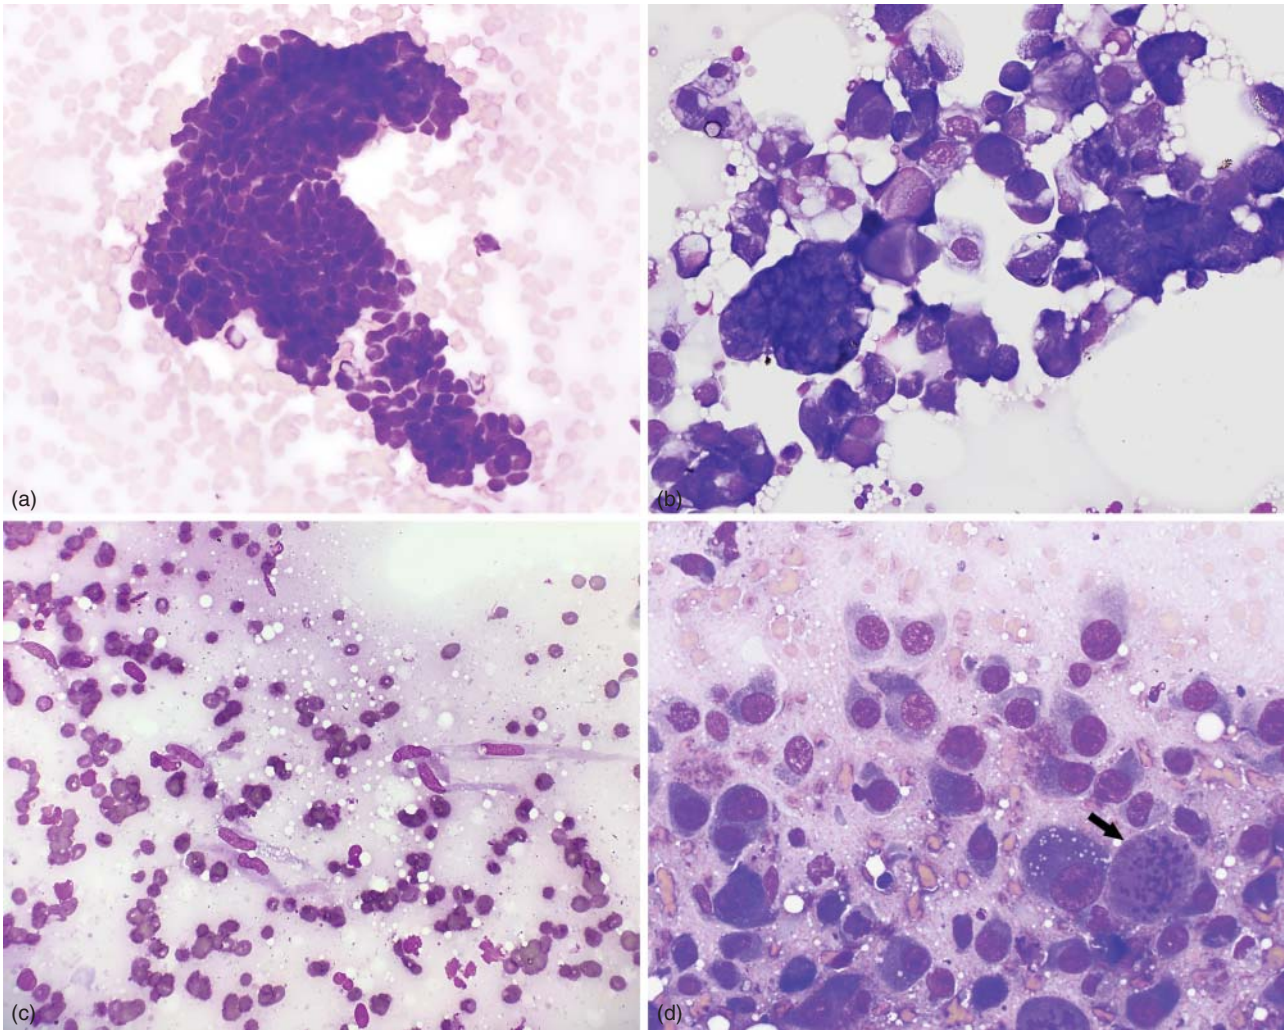

Figure 40.13 Cytological criteria to predict benign vs. malignant behavior are not precise but include uniform vs. pleomorphic patterns of cells, nuclei, and nucleoli. (a–d) 50× objectives. The left-hand images are benign tumors: (a) an epithelial tumor (basilar epithelial cell), and (c) a mesenchymal tumor (leiomyoma). The right-hand images are of malignant tumors: (b) carcinoma of the prostate and (d) an osteosarcoma. The malignant tumors have pleomorphic cells and nuclei. Aggressive tumors also tend to exfoliate numerous cells. The arrow in (d) points to a mitotic figure in which the chromosomes are so dispersed (abnormal) that they could be confused for an infectious organism. (a–d) Wright-Giemsa stain.

but are clinically aggressive. Lymphoma is not one tumor, it is an umbrella term; there are many types of lymphomas in animals. The chapter on lymph nodes provides details of how flow cytometry, B- vs. T-cell origin, and cell size can be used to predict survival times in dogs and cats with lymphoma. Other tumors that are cytologically uniform in appearance but behave aggressively are listed earlier and at the end of this chapter.

Mitotic figures are associated with neoplasia and linked to more aggressive tumors (Figure 40.15). However, mitoses are part of normal cell lines as they are required for cell replication. Certain tissues proliferate at faster rates, and therefore mitotic figures are expected in samples from non-neoplastic bone marrow, lymph nodes, and intestines. Young granulation tissue with proliferating fibroblasts and endothelial cells (neovascularization) will contain mitotic figures in histological and cytological preparations. Therefore, just finding a mitotic figure does not confirm a lesion is neoplastic. However, if multiple mitotic figures are found along with other microscopic and clinical information that suggest neoplasia, then they are a convincing piece of data. They are found regularly in lymphomas, HSs, TVT, and histiocytomas. The latter is the best example in veterinary medicine of a benign tumor that contains numerous mitotic figures. Abnormal mitotic figures (Figure 40.15) are a definite indicator of neoplasia, and even malignancy, but like many "abnormalities" they can be created artefactually. The process of cells drying and collapsing on a glass slide may distort chromosomes and the spindle apparatus producing what look like abnormal mitotic figures [12]. There are a

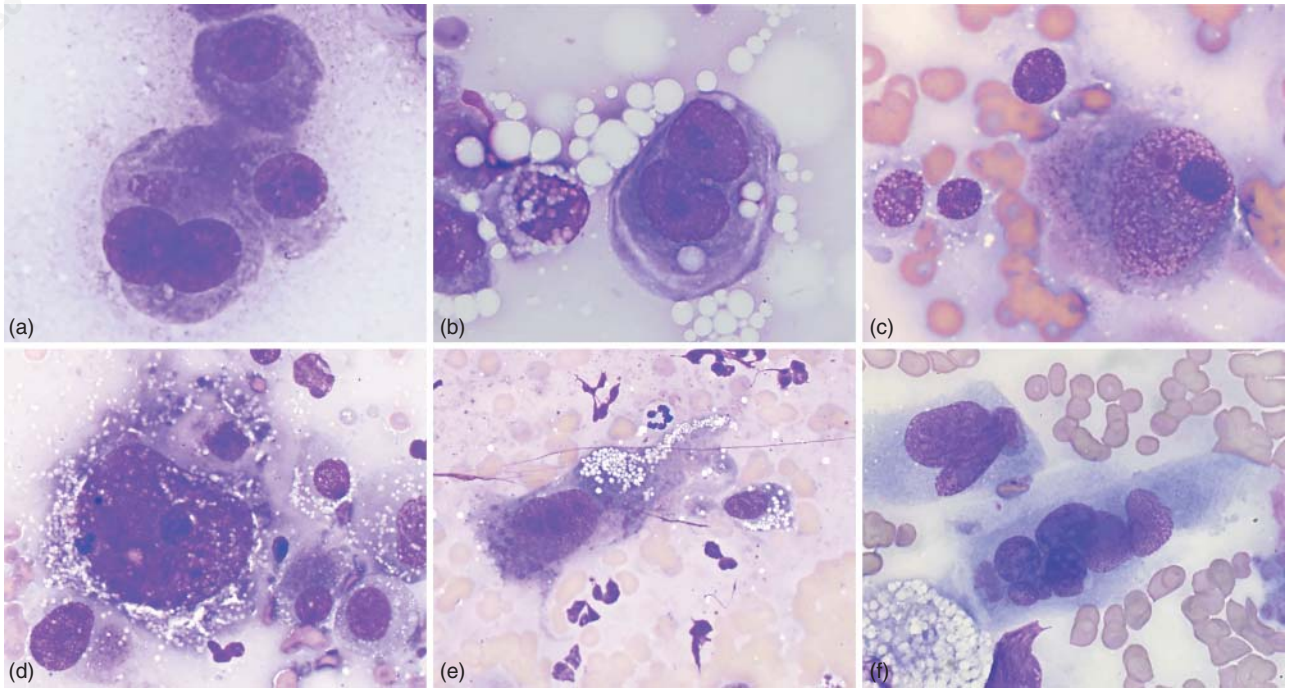

Figure 40.14 These images demonstrate nuclear and nucleolar pleomorphism (variability), which are features associated with malignancy (all oil immersion 100× objective). (a) Binucleation and presence of micro-/satellite nuclei in a pleomorphic variant of a plasma cell tumor (dog). (b) Binucleation and macronuleoli in a cell from a prostatic carcinoma (dog). (c–e) (dogs) Cell gigantism and macronucleoli (histiocytic sarcoma, spleen (c) and lymph node (d); hemangiosarcoma, spleen (e). (f) Bi- and multinucleated cells with marked anisokaryosis from an injection-site sarcoma (cat). Regenerating muscle cells can look identical, which is a good example of why cytological features associated with malignancy are not pathognomonic and require integration with all data available. In this case there were cells in adjacent fields consistent with sarcoma.

variety of names for abnormal mitoses: polar asymmetry, lagging chromosomes and anaphase bridging. Most of these names refer to "Y" shapes (tripolar) rather than a single dense line (metaphase), and chromosomes that are "lagging," which is a form of "dangling chads," reflect loose chromosomes in the cytoplasm that appear as dots adjacent to the dense spindle (Figure 40.15).

Identification of abnormal mitoses is probably best left for board-certified pathologists. Mitotic figures and abnormal mitoses are powerful observations to support the diagnosis of neoplasia. They will only be present when there is other compelling microscopic evidence of neoplasia. Counting mitotic figures in 10 high-power fields (2.37 mm^2) to predict behavior of a tumor is used commonly in histological preparations, but comparable methods for cytological preparations are not standard [13]. Methods have been described for using cytology to grade MCT in dogs [14, 15].

The color of tumor cell cytoplasm cannot be used to predict biological behavior. Basophilic cytoplasm means there is increased RNA and likely the cell is "young," but it does not mean the cell is neoplastic. As all cells mature, they tend to lose cytoplasmic RNA, develop other subcellular organelles, and become more eosinophilic. For example, as red blood cells mature their cytoplasm goes from deeply basophilic, to lighter blue, finally becoming blue gray in metabrubricytes, because even at this late stage of maturation they still have RNA on retained ribosomes. Similarly, hyperchromatic nuclei simply means there is increased color, i.e., darker nuclei, and it is not a criterion of malignancy. In fact, pyknotic and karyorrhectic nuclei are dark, have condensed hyperchromatic nuclei that indicate the cell is dead. Chromatin is nuclear DNA and is seen cytologically and histologically in two forms: *heterochromatin* has small, darkly staining, irregular particles or granules, often at periphery of the nucleus, and *euchromatin* (parachromatin) is loosely packed and appears uniformly lightly stained. Young nuclei tend to be large and have more euchromatin and these are referred to as vesicular or open nuclei. This can be seen in neoplastic and non-neoplastic cells. However, irregular clearing of chromatin forms by an abnormal distribution of heterochromatin granules with large uneven, clear areas of euchromatin between granules and this is a criterion of malignancy. Nuclear and nucleolar features are likely the best cytological evidence of neoplasia; however, rather than trying to identify the type of chromatin, look for variability of sizes, shapes, and number of nuclei and nucleoli per cell. These features are easier to recognize and indicate the lesion is likely neoplastic and aggressive; the more uniform nuclei appear the more likely the lesion is benign.

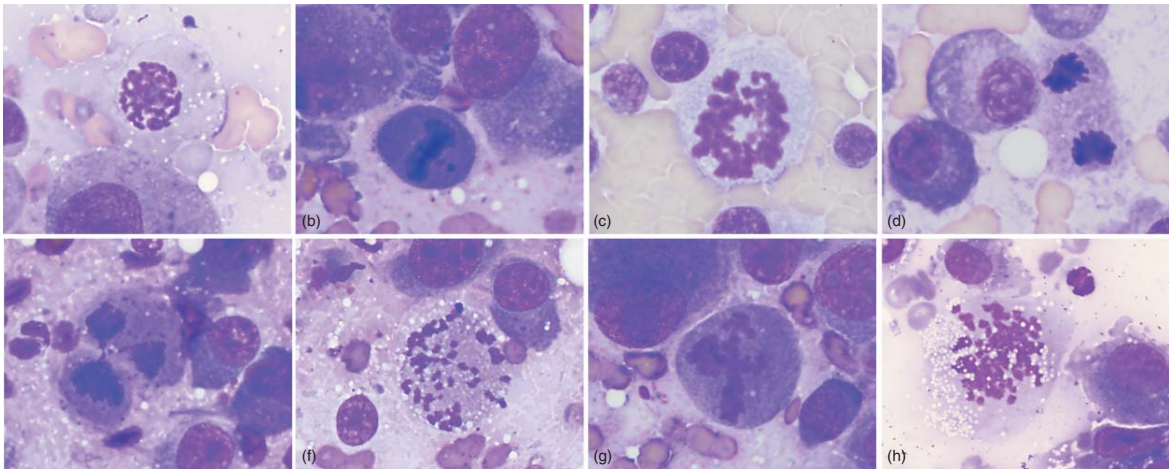

Figure 40.15 Mitotic figures. In all of these images the nuclear membrane is absent (all oil immersion 100× objective). Dissolution of the nuclear membrane is the first step in the process of nuclear division and is part of the definition of a mitotic figure. Naming the stage of mitosis is not as important as recognizing mitotic figures. (a) *Prophase/prometaphase* – chromosomes are a circular group of rope-like aggregates of similar sizes; this stage is often overlooked. (b) *Metaphase* – dark linear band of chromosomes are aligned perpendicular to the long axis of the spindle apparatus; this pattern is seen most frequently in histological preparations. (c) This is also *metaphase*, but the chromosomes are parallel to the spindle apparatus and form a circular pattern; this form can be confused with an abnormal mitosis. (d) *Anaphase* – recognized easily by chromosomes that form two distinct clumps, but the cell has not divided and a nuclear membrane is not present around either nucleus. (e) *Telophase* – two clumps with nuclear membrane forming and cytoplasm dividing into two cells. (f–h) Abnormal mitotic figures (sometimes referred to as "bizarre") with dispersed, unorganized chromosomes and lagging chromosomes.

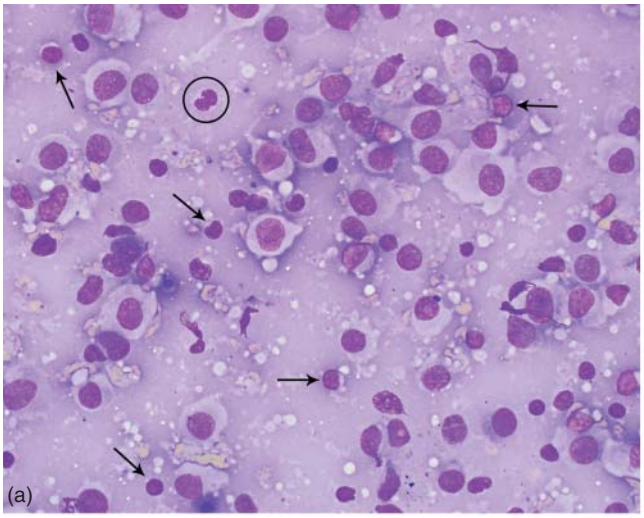
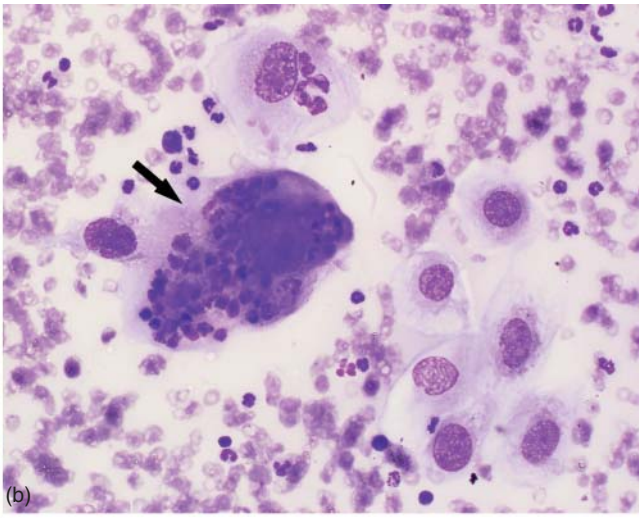
Very few grading schemes based on cytological criterion have been developed and none have been validated in a large cohort. A cytological grading scheme is described in the skin chapter for cutaneous MCT in dogs. A publication also describes how to assess regional lymph nodes in dogs with MCT [16]. Molecular profiles of MCT, urothelial tumors and lymphomas are used to assess biological behavior in dogs, help direct therapies, monitor progress, or substantiate a diagnosis [3–5, 11, 17, 18]. In human oncology molecular characteristics of tumors is used extensively to diagnose, predict behavior, monitor and select treatments. These methods are employed on tumors in pets but primarily in research centers that use the tumors in pets as models for similar tumors in humans. For some tumors, for example soft-tissue sarcoma (STS), a histological grading scheme can be offered to owners to help predict biological behavior of the tumor or select treatment options, as these tumors cannot be graded from cytology. There are tremendous opportunities to integrate cytological, histological, and molecular parameters to assess tumor behavior, or validate prior studies, if there are accurate long-term outcome assessments (RESIST, PERSIST, CASS) to determine which test(s) may be predictive of prognosis or predictive of treatment efficacy [19, 20].

Confounders in interpretation

If inflammatory cells are numerous, the lesion is more likely to be primary inflammation. When inflammatory cells are absent and FNA of a skin mass contains numerous mononuclear cells, the diagnosis of neoplasia is straightforward. However, if mononuclear cells predominate and there is a mixture of neutrophils, the distinction of neoplasia vs. primary inflammation is difficult. The mononuclear cells seen could be tumor cells, resident tissue cells, plasma cells, lymphocytes, monocytes, or macrophages (histiocytes). The presence of neutrophils in this cell mix suggests inflammation, likely pyogranulomatous. A generalization is to favor inflammation rather than neoplasia, because although many tumors contain areas of necrosis, inflammation within the neoplastic mass is uncommon. Table 40.3 lists tumors in which inflammation can be present and the type of inflammatory cells expected. This inflammation is seen more frequently in histologic sections than cytological specimens (Figure 40.16). In these ambiguous cases, consider additional approaches such as biopsy and histopathology, treatment for inflammation and/or infection, and reevaluation following clearance of the inflammation. If the mass persists, offer repeat FNA and/or biopsy.



The biggest confounder is granulomatous or pyogranulomatous inflammation vs. neoplasia. Either of these types of inflammatory lesions will have macrophages (histiocytes), multinucleated giant cells and granulation tissue. Some of the macrophages and giant cells will exhibit the cytological features that are characteristic of the "criteria of malignancy": large nuclei, prominent nucleoli, and multinucleation (Figure 40.17). Examining these suspect cells under oil immersion will not clarify the diagnosis; this simply enlarges the nuclei and nucleoli. A better approach is to drop to lower magnifications and search the entire slide for pattern recognition by answering these simple questions: are more neutrophils present than large cells? Search for etiologic agents associated with granulomatous and pyogranulomatous inflammation: fungi, protozoa, acid fast bacteria, microaerophilic bacteria (*Nocardia, Actinomyces,* etc.) and foreign material. (Note that oil immersion is usually needed to identify microorganisms.) Also consider location of the lesion and size of the lesion. Flat, ulcerated lesions, especially if located where trauma is possible (legs), are more likely to be inflammation. Masses >6 cm, especially if there is no skin ulceration, are more likely neoplastic.



The two neoplasms that could be confused with granulomatous inflammation are HSs and SCC. Therefore, consider facts about each tumor: breed of dog (HS has strong breed

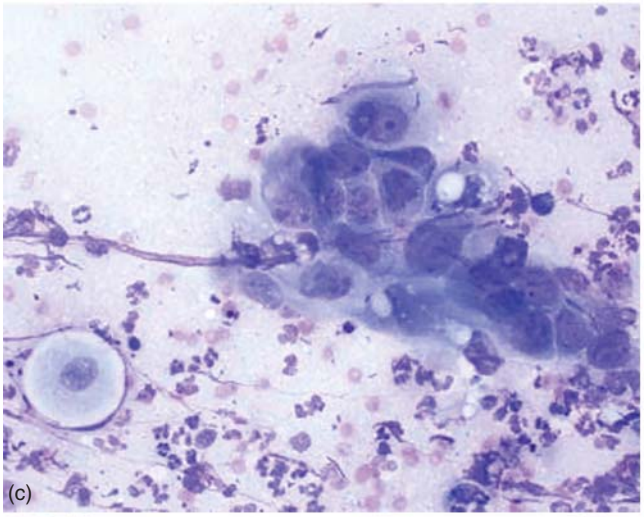


Table 40.3 Tumors that can have concurrent inflammation.

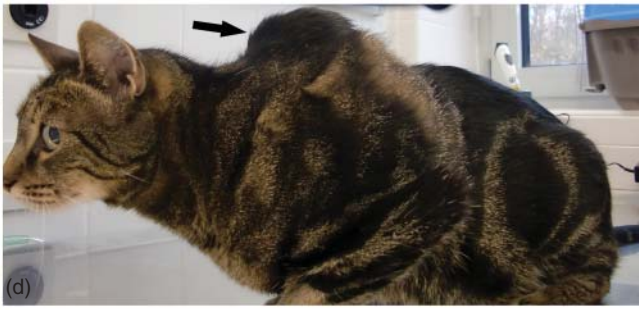
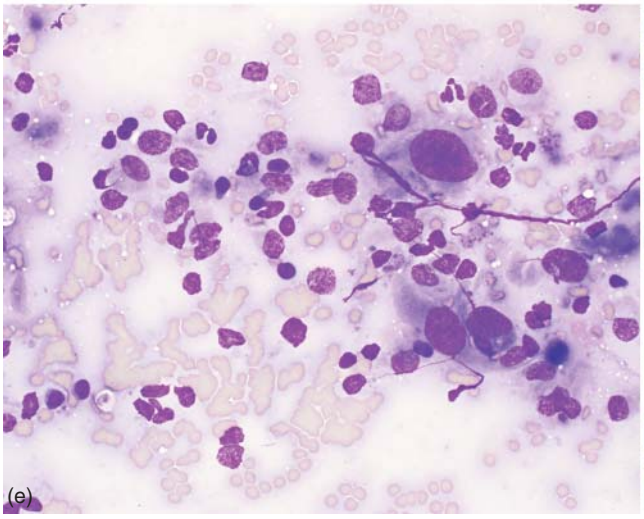


Tumor type	Inflammatory cells
Squamous cell carcinoma	Neutrophils, can be numerous
Feline injection site sarcoma	Lymphocytes ± plasma cells ± neutrophils ± eosinophils ± macrophages/multinucleated giant cells ± mast cells; lesion may be predominantly or start as inflammatory; multinucleated giant cells can be numerous and the number of nuclei/cells 20–100.
Mast cell tumor	Eosinophils common in dogs, rarely eosinophils may be predominant cells present on slide; few lymphocytes
Histiocytoma	Lymphocytes ± plasma cells, neutrophils – indicates regression
TVT	Lymphocytes, plasma cells, low numbers
Seminoma, dysgerminoma	Lymphocytes, few
Fibrosarcoma	Lymphocytes, eosinophils – eotaxin production by fibroblasts
Neoplastic body cavity fluids	Neutrophils, macrophages, reactive mesothelial cells; note – lymphoma can be 100% lymphoid cells (see Chapters 42 and 43).



Note: Any skin or gastrointestinal tumor that is ulcerated can have secondary inflammation near the ulcer. Therefore, do not touch the ulcerated surface with glass slides. Instead perform FNA some distance from the ulcer and penetrate deep below the surface. Figure 40.14 is a panel that demonstrates some of the tumors that may contain concurrent inflammation. Remember, before making a diagnosis of a tumor with inflammation, rule out granulomatous or pyogranulomatous inflammation.

Tumor
Large aggregates of surrounding inflammatory cells
(f)

Figure 40.16 Tumors with inflammation. Large tumors may have regions that are necrotic, but most do not have inflammation and, when present, it is a minor component. (a–c and e) 50× objective; (f) 10× objective. (a) Young dog, skin nodule – histiocytoma with lymphocytes (arrows) and neutrophils (circle); concurrent inflammation suggests this tumor is regressing. (b, c) Squamous cell carcinoma (SCC) – this neoplasm often has considerable inflammation, which is due to the tumor's location (skin, genitalia, oral, stomach) and the tendency for ulceration. The large cells are neoplastic, and the small dots are nuclei of neutrophils. One very large tumor cell (b, arrow) appears to have numerous neutrophils within the cell (emperipolesis) but these could also be on the cell surface. (d–f) Cat – injection site sarcoma. (d) Cat with a large interscapular injection-site sarcoma (arrow). (e) The three large nuclei are in tumor cells and the other nuclei are in inflammatory cells. Injection-site sarcomas often have inflammation, and the inflammatory reaction may precede the transformation into a neoplasm. (f) Histopathology of the mass shown in (d). Note the large tumor surrounded by aggregates of inflammatory cells (mainly lymphocytes, arrows).

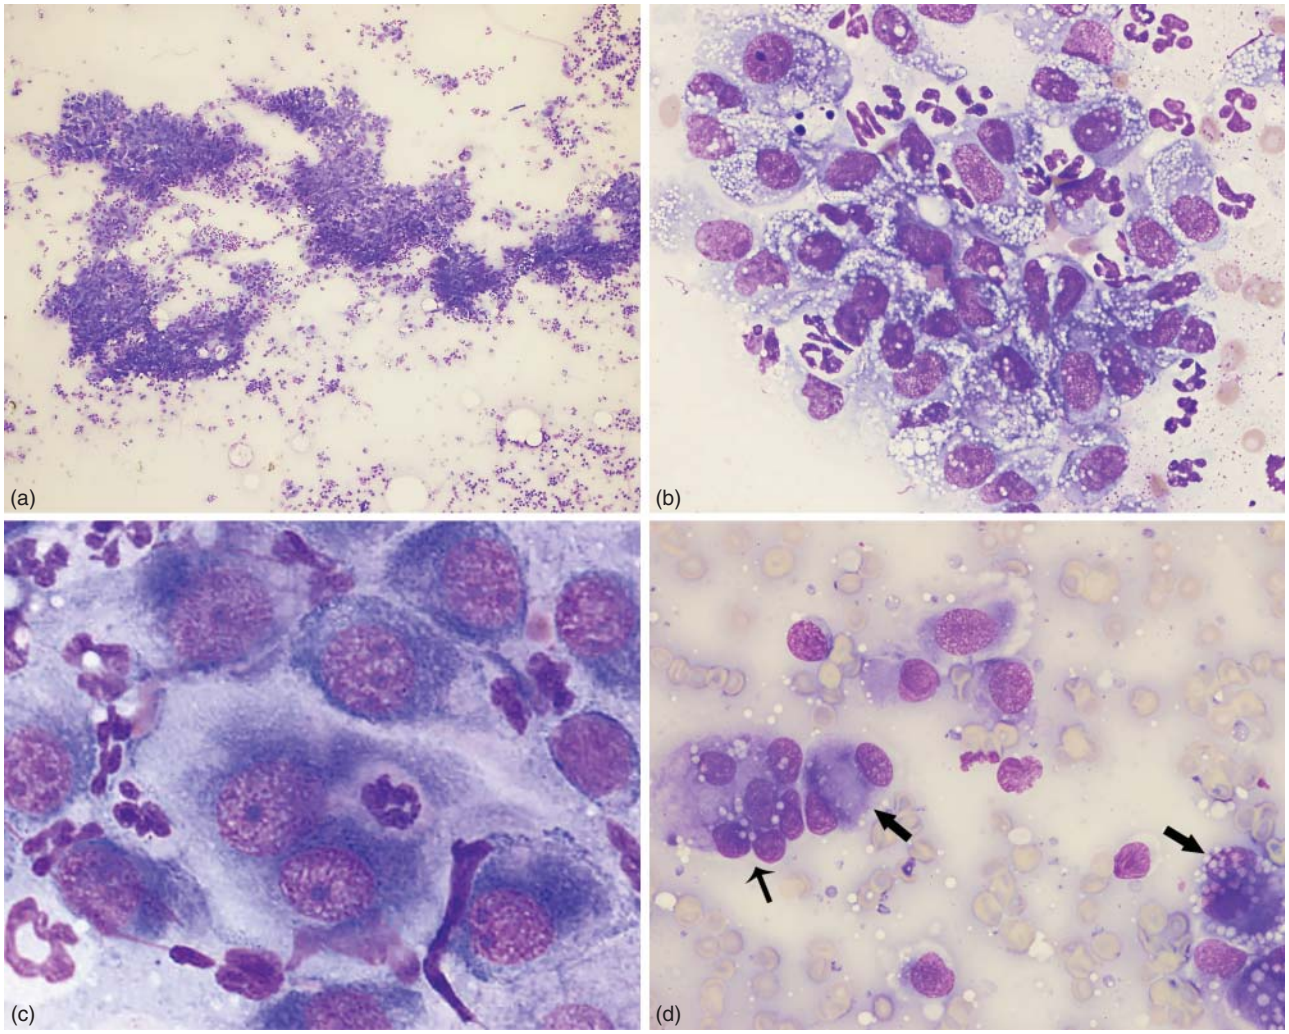

Figure 40.17 Pyogranulomatous/granulomatous inflammation, four different magnifications. (a) 20× objective; (b) 50× objective; (c) 100× objective; (d) 40× objective. This type of inflammation is sometimes misdiagnosed as a neoplasm with inflammation. At low magnification (a), there appear to be groups of cohesive epithelial cells. Higher magnifications (b–d) reveal large cells, some containing vacuoles in the cytoplasm (b). The large cells are macrophages, which are called histiocytes when in tissues. When macrophages are this large, they are also called "epithelioid macrophages" (c) to indicate how they resemble epithelial cells. They can get very pleomorphic (b–d), with binucleated (d, thick arrows) and multinucleated (d, thin arrow) forms; therefore be careful not to confuse them with a neoplastic population. The numerous neutrophils scattered in background are key to the correct diagnosis of pyogranulomatous inflammation. Search for fungi, yeast forms, foreign material, and protozoa when this pattern is seen.

associations), if location is a site where SCC is expected favor SCC (white cat with mass on ear or eye; vagina, etc.) or probe for foreign material (splinters, fox awn). Lesions and cases are puzzles, and the key is to put all of the pieces together (integrate) and do not rely too heavily on one piece of data (i.e., large cells with cellular and nuclear abnormalities). A clinician has an advantage in these cases vs. a diagnostic pathologist; the former can try a week or more of antibiotics to determine if the lesion regresses or expands. A diagnostic pathologist has the advantage of special stains such as acid fast, gram, and fungal stains (GMS, PAS), therefore the best approach is for the clinician and pathologist to work together! There is no stain or molecular test that can determine if the large cells are neoplastic. The diagnostic pathologist can employ markers for histiocytes, but both neoplastic and non-neoplastic histiocytes will be positive. Similarly, markers for epithelial cells will label both neoplastic and non-neoplastic epithelial cells. There are no *neoplastic markers* that can be applied to cytological or histological specimens to identify the process as neoplastic. Polymerase chain reaction (PCR) for antigen receptor rearrangement (PARR) identifies clonality of lymphoid populations, not neoplasia. The presence of a monoclonal pattern favors neoplasia, but this can also be present with a few infectious diseases (ehrlichiosis, leishmania, feline infectious peritonitis, and others) as well as regressing histiocytoma and hepatitis [21]. Like all tests, there are false-positive and false-negative results with PARR, and insufficient prevalence data are known to be able to report positive and negative predictive values. PARR is only one test and results must be integrated with all of the other case data.

Certainly, if mitotic figures are seen the lesion must be neoplastic. NO, absolutely not. Mitotic figures can be seen in reactive fibroblasts in proliferating granulation tissue, they can be seen in young endothelial cells entering an area of inflammation (angiogenesis) and any cell that proliferates locally could leave the fingerprints of mitotic figures (hematopoiesis). However, just like clonality detected by PARR or nuclear abnormalities, the observation of numerous mitotic figures favors neoplasia. One mitotic figure does not equal neoplasia. Nothing new has been said in these sentences; mitotic figures are just one more piece of the puzzle, and the more confusing the case the more pieces that must be integrated. A single test result does not replace the ability to think.

Prognosis

If an owner and clinician want additional information to help predict biologic behavior, cytology is useful to help direct the next level of testing. The two most common "tests" are staging (especially assessment of regional lymph nodes and imaging of lungs) and histopathologic grading. Below are examples, based on a cytological diagnosis of a specific tumor, of what other test could be offered as well as a general guide to the biologic behavior of that tumor. Knowledge of tumor type, host species, size, and location of tumor are critical to predicting behavior. These patterns of behavior are based on studies published in journals and textbooks as well as the authors' experiences. More detailed information is published in multiple resources; however, it should be noted that grading schemes and other tests used to help predict behavior of a tumor or select treatments are based on a specific study population, and it is not known how well that information will extrapolate when used on different groups of dogs, owners, and treatments. Furthermore, these studies predict how a tumor, purportedly to be of the same type, might behave in a *population* of dogs. There are no tests (yet) that will predict how an *individual tumor* will behave in an *individual pet*. For all tumors, there is no single parameter or combination that is 100% predictive; this is biology and exceptions and inconsistencies exist.

Round cell tumors

- MCT – cytological and histological grading schemes [14, 15, 18]; tumors in cats generally benign, in dogs 80–90% of cutaneous tumors are benign, 100% of subcutaneous tumors are benign; cytologic assessment of mast cells in regional lymph nodes of dogs has been correlated with survival times; increased numbers of mast cells is associated with shorter survival, but this may be a self-fulling prophecy (euthanasia) and dogs with MCT in regional nodes have been treated and determined to have long survival times [22]. Very few MCTs in dogs and cats cause cachexia or metastasize widely. MCTs have a wide range of clinical and cytologic appearances (Figure 40.18).
- Lymphoma – see Chapter 45, determine B vs. T vs. null cell, determine size of cells via cytometry. The most important step may be to determine if the lymphoma is small T cell because these tumors are indolent with survival times of years regardless if treated or not; an estimate of this lineage can be provided by observing cytoplasmic extensions (mirror handle cells; cone heads), but more sophisticated tests are available. Large-cell lymphomas are malignant.
- Plasma cell tumor – MUM-1 immunoreactivity helps identify. Cytology or histopathology to assess uniformity vs. variability; if single cutaneous tumor, no further staging required. If multiple cutaneous tumors, or located in other organs (e.g., spleen), screening for osteolytic bone lesions (radiographs), serum and urine protein electrophoresis to identify paraproteins, and bone marrow assessment for presence of plasma cells can be considered.
- TVT – no further testing as cytology is diagnostic; no tests to predict the relatively few cases that become malignant; consider staging.

Figure 40.18 Correlate cytological findings with all of the other data. Neoplasia is the most likely differential in both of these dogs based on size of lesion and gross appearance. If cytological examination suggests inflammation, then repeat FNA until you are absolutely certain there are no neoplastic cells. If neoplastic cell are not found, then consider biopsy for histopathology and special stains if needed (histochemistry, immunohistochemistry). (a) Tumor on rear leg was MCT. (b) Sedated dog had a fibrosarcoma.

- Histiocytoma – the majority are benign, may regress spontaneously; important to differentiate from HSs and intraepithelial lymphomas.

Epithelial tumors

- Additional tests and prognosis depend on location.
- Bladder – UC (TCC) – malignant 100%; one of the most aggressive tumors in veterinary medicine; additional tests include BTA [23], FISH [3].
- Mammary – histologic grade for dogs and cats; do not rely on cytological criteria to determine behavior.
- Circumanal – benign, generally male dogs, difficult to identify the rare malignant subtypes even with histopathology.
- Anal sac – malignant but cytologic appearance in primary and metastatic locations is benign; they are epithelial tumors but look "neuroendocrine"; cause hypercalcemia.
- Thyroid – cats benign; dogs – size is linked to behavior, if tumor is large enough to be palpated it is likely to be malignant; tend to spread to lung rather than regional node.
- Prostate – malignant; benign forms not seen in dogs.
- Nose – malignant; nasal adenomas not seen in dogs or cats; polyps are benign.
- Note: Benign tumors do not exist in the prostate or nose of dogs or have not yet been confirmed, and benign epithelial tumors in the urinary bladder are rare. Therefore, when reviewing samples from these tissues, the key is to differentiate hyperplasia and dysplasia from neoplasia. Inflammation in these organs will stimulate hyperplasia and dysplasia. Knowledge about tumors in specific locations is a tremendous help in predicting what to expect cytologically and what the behavior of a tumor will be.

Mesenchymal tumors

- In the skin these tumors are often referred to as STS; however, soft-tissue mesenchymal tumor (STMT) is a preferred name because the vast majority are not aggressive. Histological grading schemes exist but none have been validated. PWT is the most common subset of STMTs; previously most were classified as hemangiopericytoma. Histologic recognition of PWT provides prognosis: <5% metastasize, clean margins predict no recurrence, greater likelihood of recurrence if tumor is large (>5 cm) and infiltrates muscle [7].
- HS complex – as a group aggressive; localized and disseminated subtypes.
- Osteosarcoma – no validated grading schemes, >90% malignant, infrequent reports of less aggressive variants.
- Melanocytic tumors (Figure 40.10) – although these tumors are mesenchymal, the cytological appearance can be a mixture of spindle cells, round cells, and

epithelial-like aggregates. The amount of melanin pigment is variable. Oral tumors are usually malignant, but benign oral forms can be recognized with histopathology [24]; pedunculated oral or skin melanoma are benign; location in skin favors benign course. Mitotic counts in histological slides are predictive of behavior; other tests that can be requested are Ki67 immunoreactivity, nuclear atypia scores, etc. No test or combination of tests is 100% correct [18, 25].

Neuroendocrine tumors

- Prognosis varies with endocrine organ and tumor type; islet cells tumors appear cytologically benign (uniform) but invariably will metastasize. Aortic, carotid body, and C-cell tumors do not usually metastasize but can cause serious clinical problems; pheochromocytoma and adrenal cortical tumors are difficult to predict.

Introduction

Neoplasms (tumors) are classified into three main groups: epithelial, mesenchymal, and round cell (Figure 40.1). A fourth category, neuroendocrine, are common in endocrine organs but are rare in the skin (Merkel cell tumor). Chapter 40 details these types of tumors and how to diagnose neoplasia; Chapter 39 describes inflammatory lesions – those chapters complement the information in this chapter. The diagnosis of neoplasia (cancer) is made by integrating cytologic and/or histologic findings with clinical information (species, age) and appearance of the mass including location on the body. Cytological diagnoses attempt to name the specific tumor type, but many times this is not possible and often is not needed to plan treatment options.

Cytology uses cellular and nuclear features to identify cancer and histopathology uses histologic organization. Each discipline has its benefits, and they are discussed in Chapter 40. Various techniques are used to help diagnose the type of cancer, but the diagnosis of cancer is made by *integrating cytologic, histologic, and clinical features*.

This chapter emphasizes tumors in the skin and subcutaneous tissue. Other chapters or sections in this book describe how to diagnose cancer in different locations. Location of the suspected neoplasm is a critical piece of information, as the differential diagnoses for tumors and masses will change based on organ location.

Throughout this chapter the authors will generalize. Please accept this approach and understand this is biology; therefore, there will always be exceptions. When the exceptions are important, we will point these out; however, including every exception confuses the big picture.

Chapter 2 explains how to perform fine-needle aspiration (FNA), prepare good-quality slides, avoid artifacts, stain the slides, and adjust the microscope. Do not overlook the importance of each of these steps. An inadequate number of cells (QNS – quantity not sufficient), lysed cells, preparations that are too thick and smeared across the glass, excessive amounts of blood, artifacts, understained slides, and using a poorly maintained and adjusted microscope will prevent a diagnosis and frustrate the diagnostician. If poor-quality slides are sent to a referral lab a diagnosis is unlikely, and the same fee is charged as is for good-quality slides that yield a diagnosis. Diagnostic labs have pathologists with advanced training and expertise. However, many veterinarians perform procedures associated with a specialty because of their competence and sometimes because owners do not want to pay for a specialist. The information in this chapter is targeted for individuals not already certified in clinical pathology.

Numerous skin and subcutaneous diseases can result in mass formation, including inflammation, dysplasia, and neoplasia, as well as cyst, seroma, and hematoma formation. The distinction of hyperplasia and hypertrophy from neoplasia is important when examining FNA from organs and lymph nodes, but if a nodule or a mass is present in the skin, then hyperplasia and hypertrophy are unlikely. Of course, there are exceptions; collagenous hamartoma, fibroadnexal dysplasia, nodular fasciitis, and nodular dermatofibrosis are non-neoplastic lesions of skin or subcutis, and each may produce a mass, but they are not neoplasms. Fortunately, all of these are uncommon cytologic diagnoses.

Adnexal dysplasia occurs in dogs, is benign, and should be confirmed with histopathology. A common skin mass is a sebaceous adenoma, and sometimes these are determined to be hyperplastic by histopathology, but the distinction is unimportant because both lesions are benign. Cysts, seromas, and hematomas have fluid that is sometimes admixed with inflammation. If the mass is solid and cellular the critical distinction is *inflammation vs. neoplasia*. In most cases this will be straightforward, as inflammatory lesions are composed of numerous inflammatory cells, usually predominantly neutrophils, and neoplastic lesions are predominantly composed of either *round, epithelial, or spindle cells*, usually with no or minimal inflammatory cells (see Figure 40.1).

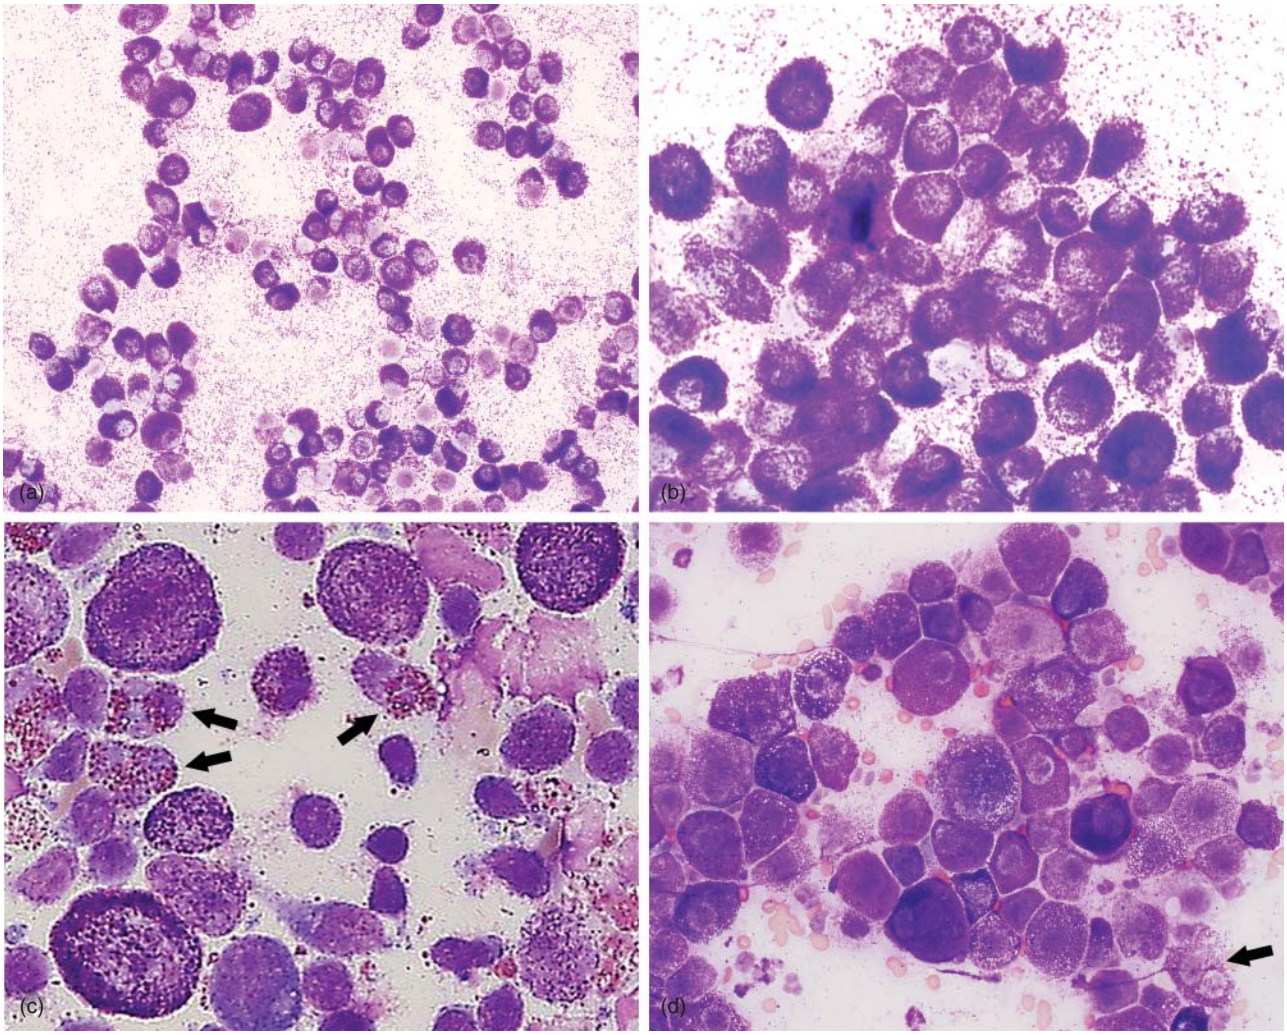

Figure 41.1 Canine cutaneous mast cell tumors. (a) 50× objective, (b–d) 100× objective. (a, b) Example of a low-grade (grade I) mast cell tumor. Mast cells are relatively uniform and packed with cytoplasmic granules that obscure cellular details. Numerous free mast cell granules are present in the background. (c) Note numerous eosinophils (arrows) in this mast cell tumor. (d) A high-grade (grade III) mast cell tumor. Neoplastic mast cells are variably granulated. Compare to (a) and (b), in which all of the mast cells are uniform and heavily granulated. Also note the presence of anisocytosis, anisokaryosis, binucleation (arrow), and nuclei with prominent nucleoli. Wright-Giemsa stain.

The classification of an inflammatory lesion and what etiology might produce that type of inflammatory cell response is located in Chapter 39. Hematomas, seromas, sialoceles, cysts, abscesses, mycotic granulomas, etc. can produce masses in the skin or subcutaneous tissues that have an inflammatory component, and examples are provided in different plates in this chapter and throughout this book (Figures 39.5, 39.6 and 40.16). A general rule is that skin lesions that are predominantly neutrophilic are inflammatory, and skin lesions that have no or only a few neutrophils are usually neoplastic. These patterns are recognized at low magnification (10–20× objectives) while you are assessing the cellular density and searching for regions to scrutinize. At higher magnifications you will examine the organization of cells and the shape of cells and their nuclei to decide if they are round (Figures 41.1–41.6), epithelial (Figures 40.1 and 40.8), or mesenchymal cells (Figures 40.1 and 40.9). Chapter 40 provides an overview of each general category of tumor. Identification of *intracellular pigment* commonly allows a specific diagnosis of tumor type. If intracellular pigment is seen, the diagnosis is usually easy to make. Purple granules are characteristic of *mast cells* (Figures 41.1 and 41.2) and black or green granules are features of *melanomas* (Figure 41.15).

The following descriptions for skin tumors are organized by clinical and cytologic characteristics. The cytologic observations are outlined by what you see at low through high magnifications. The descriptions are generalities, and of course there are a range of patterns for each tumor. All of these diagnoses can be made at 40–500× magnifications; higher magnification (1000×) using an oil immersion

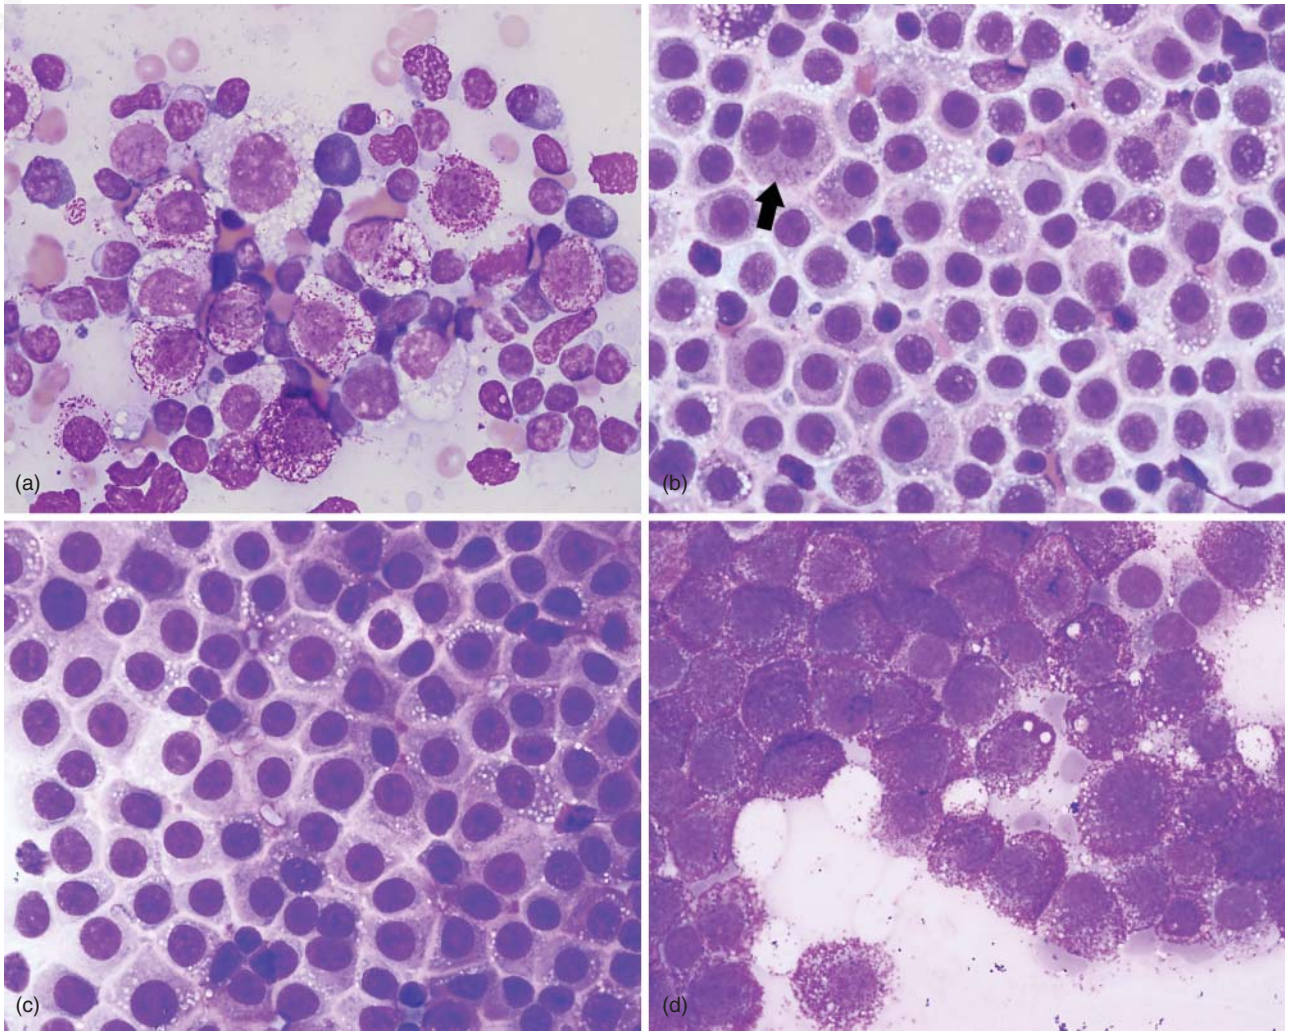

Figure 41.2 Canine mast cell tumors. (a) Poorly granulated, neoplastic mast cells and a few mature lymphocytes and plasma cells in a lymph node from a metastatic cutaneous mast cell tumor. Note the presence of cytoplasmic vacuoles, which are usually obscured by mast cell granules in heavily granulated mast cells. (b) Very poorly granulated mast cells in this tumor. Also note the variability in cell size and the presence of a binucleated cell (arrow). Cytological grading schemes will estimate these features in a determined number of mast cells seen on the preparation. (c) Fine-needle aspirate cytology from a cutaneous mast cell tumor stained with an aqueous Romanowsky stain (Diff-Quik). Cytoplasmic mast cell granules do not stain adequately compared to (d). (d) Same aspirate as in (c), stained with a methanolic Romanowsky stain (Wright-Giemsa). Cytoplasmic mast cell granules are evident. It would be easy to miss the diagnosis of a mast cell tumor in (c) with only Diff-Quik stain. (a–d) 100× objective. (a, b, d) Wright-Giemsa, (c) aqueous Romanowsky stain.

objective is usually unnecessary for diagnosis of neoplasia, although high magnification is needed to identify bacteria and other infectious agents.

Round cell neoplasms

Lymphoma, histiocytoma, transmissible venereal tumor (TVT), and plasma cell and mast cell tumors (MCTs) are considered round cell tumors. Basal cell tumor is an epithelial cell tumor but cytologically they may appear as round cells, especially if the groups of basal cells are small or one does not appreciate their organization. Systemic histiocytosis and malignant histiocytosis (MH) (histiocytic sarcoma, HS) may also mimic a round cell tumor. Some aggressive-appearing plasma cell tumors and poorly granulated MCTs can be confused with malignant histiocytosis.

Mast cell tumor (MCT)

Clinical features

MCT is one of the most common tumors in dogs; they may be cutaneous or subcutaneous. They are not common in cats and most of the following discussion refers to MCT in dogs. Well-granulated MCTs are easy to diagnose, and

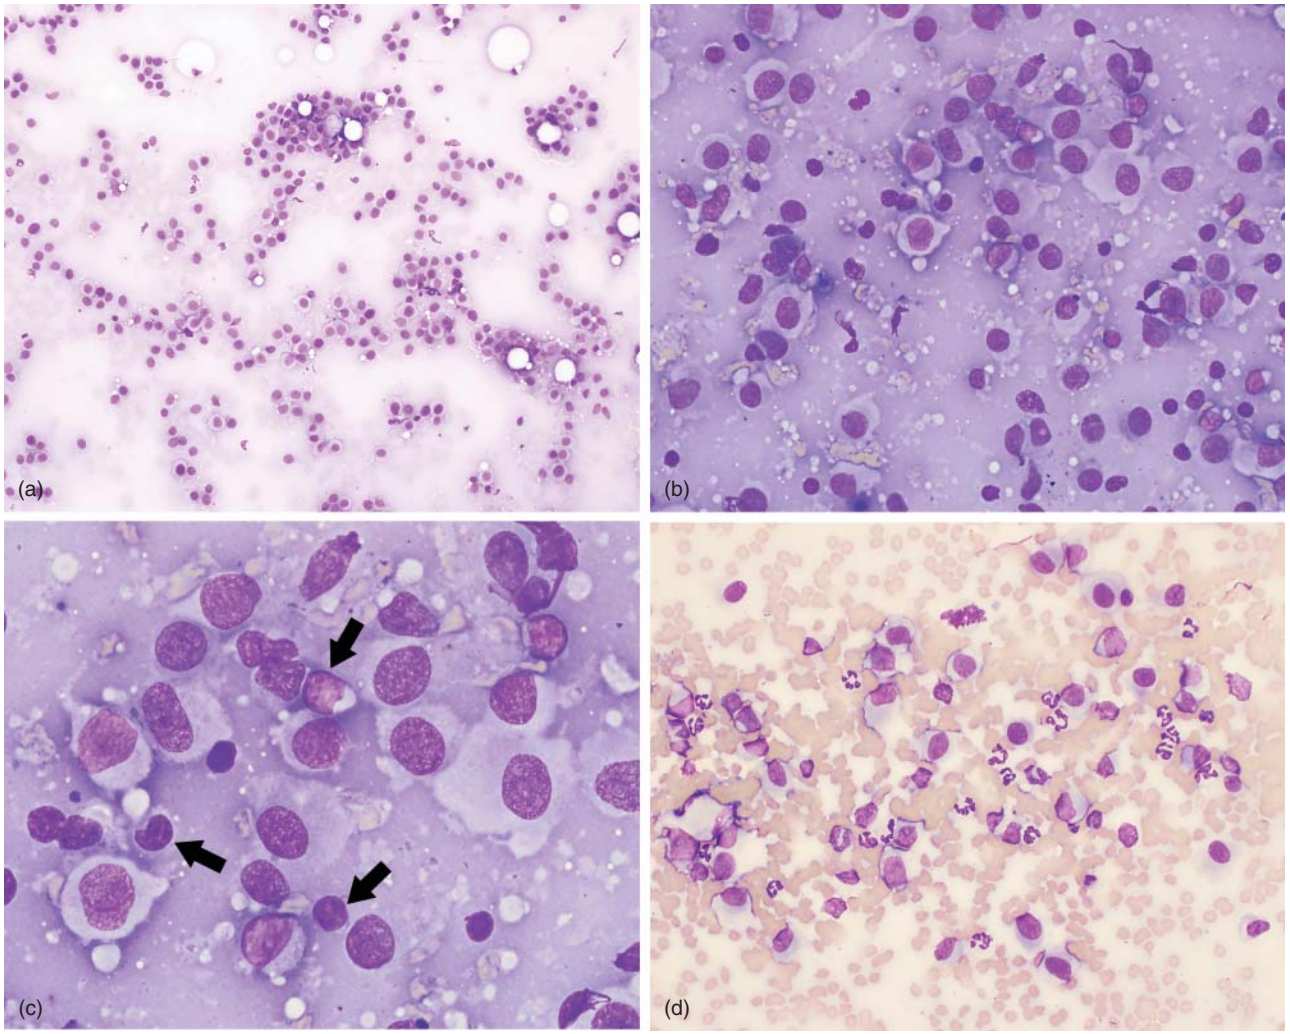

Figure 41.3 Cutaneous histiocytomas from dogs. (a) Note the moderate numbers of individual round cells on low power (20× objective). Histiocytomas exfoliate low numbers of cells. (b, c) Histiocytes have moderate amounts of gray-basophilic cytoplasm, which can have ruffled borders. Also note the blue proteinaceous background (b, 50× objective; c, 100× objective). (c) Small, mature lymphocytes (arrows) are a common finding in histiocytomas, especially during regression. (d) (50× objective) Another example of secondary inflammation of a canine histiocytoma, here indicated by the presence of neutrophils. Wright-Giemsa stain.

there is no need to consult with referral labs (diagnose these in clinic/hospital). MCTs produce one or more skin lesions that are often ulcerated and bulge outwards. They are overrepresented in boxers and Boston terriers. In dogs these tumors can be graded using histopathology; these grades are used to predict survival time (ST) and help make treatment selections. Grading using cytologic specimens is being evaluated.

Nodules identified as MCTs via cytology should be widely excised. Histopathology can be offered to owners for grading and to help ascertain a prognosis. Most MCTs are grade I or II, which carry a good prognosis. Using the two-tier system approximately 90% are low grade. Grades I and II predict the tumor will not recur, that it is not aggressive, and a good prognosis can be offered. However, approximately 5% of MCT do not behave as predicted by histopathology. If a grading scheme is not correlated with clinical outcomes it is useless. Completeness of surgical excision can be determined on histopathology. However, 90% of low-grade MCT do not recur even if the tumor extends to the surgical margin. Furthermore, a "histologic tumor free margin" that predicted nonrecurrence could not be determined for high-grade MCT in previous studies [1]. Grade of tumor is a more important predictor of recurrence than is evaluation of margins and is discussed in detail below.

MCTs usually exfoliate many cells and are one of the easiest tumors to diagnose via cytology, if the cytoplasmic granules stain. However, the staining intensity of the cells range from abundant deep purple granules that obscure nuclei (common), to lightly stained uniform granules

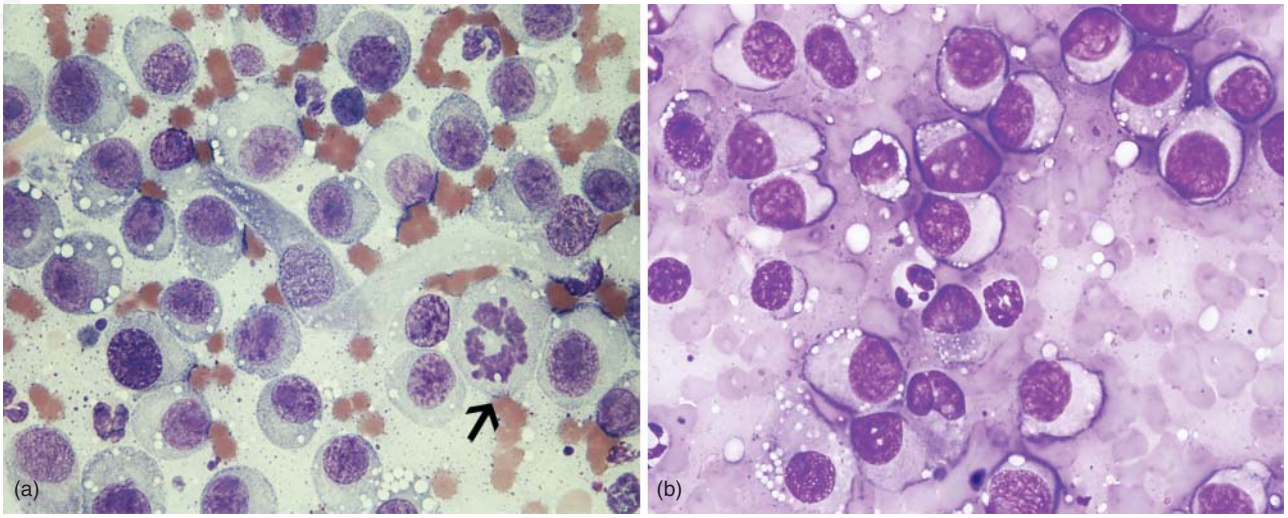

Figure 41.4 Transmissible venereal tumor (TVT). These tumors look very similar to histiocytoma (compare Figure 41.4b and Figure 41.3c). Location of the mass is critical to the correct diagnosis. However, TVT usually exfoliates numerous cells, cytoplasm tends to be more abundant with much deeper blue color, and clear, discrete cytoplasmic vacuoles are more prominent (a, b). A mitotic figure (arrow) is present in (a). (a) Source: Meuten DJ Tumors in Domestic Animals Ed 5, Wiley Blackwell 2017 p. 953–960; p. 957–959. (a and b, 100× objective). Wright-Giemsa stain.

(relatively common), to an absence of staining (uncommon to rare) (Figures 41.1 and 41.2). These latter cases can be problematic, but if you request a special stain for MCTs from a referral lab or if you recognize eosinophils scattered among the round cells that appear neoplastic, then you will be able to confirm your suspicion. Quick, dip-type stains are aqueous-based (e.g., Diff-Quik) and do not stain mast cell granules as well as alcohol-based stains such as Wright-Giemsa (Figure 41.2c, d). This is especially true for MCT in cats. Therefore, consider requesting or using an alcohol-based stain when you suspect a poorly granulated MCT. Lack of staining intensity is a cytologic and histologic criterion for higher-grade MCT.

Cytologic features

MCTs can often be correctly identified at 100–2000× (final magnification) by recognizing numerous, large, purple cells with barely discernible nuclei. A variant is numerous large cells with lightly violet to weakly stained cytoplasm and prominent round nuclei (Figures 41.1 and 41.2).

At medium (200×) to high (400–500×) magnification the tumor cells are numerous and large. Cytoplasmic granules range from poorly stained to deeply purple. Visualization of nuclei depends on the staining intensity of the granules. In densely stained cells nuclei may not be seen because they are obscured by the granules. Cells with lightly stained cytoplasmic granules have round nuclei with or without visible nucleoli. Tumors with well-stained purple granules usually have free purple granules in the background. Eosinophils are visible in the background of canine MCTs but are rare in feline MCTs. Eosinophils tend to be unilobed or bilobed rather than multilobed, cytoplasm is stained eosinophilic to red-brown to green-gray with variably sized granules in dogs and small uniform rod-shaped granules in cats. It is easy to overlook eosinophils in tissue preparations stained with aqueous Romanowsky stains such as Diff-Quik because the granules often do not stain brightly eosinophilic. Once eosinophils are recognized, the index of suspicion for MCT should markedly increase.

The following observations are for those MCTs that do not stain intensely. The cells are round or polygonal. A classic pattern is a round or oval-shaped cell with a centrally positioned round nucleus that gives a "fried egg" appearance (neuroendocrine tumors have a similar pattern). Few cells may be bi- or multinucleated. Nuclei are round to oval and contain prominent nucleoli and lightly vesiculated chromatin. Lymphocytic inflammation is infrequently seen in these neoplasms. More commonly, non-neoplastic spindle-shaped cells are seen admixed with the round mast cells. These are supporting stromal cells and are not neoplastic. Poorly differentiated MCTs may appear similar to histiocytic tumors or plasma cell tumors.

Tumor cells that stain intensely purple are not a diagnostic challenge. The staining intensity of the cytoplasmic granules varies with the type of stain used, the maturity of the cells and their granules and on the concentration of heparin in the cytoplasmic granules. It is heparin that accounts for the metachromasia (purple) characteristic of these cells. The quick-type stains *may not stain* the cytoplasmic granules of mast cells, especially in cats. Therefore, large round cells with abundant cytoplasm that completely encases the nucleus ("fried egg") with numerous eosinophils in the background is probably a MCT and should be confirmed by staining other slides with Wright-Giemsa, Giemsa, or toluidine blue stains.

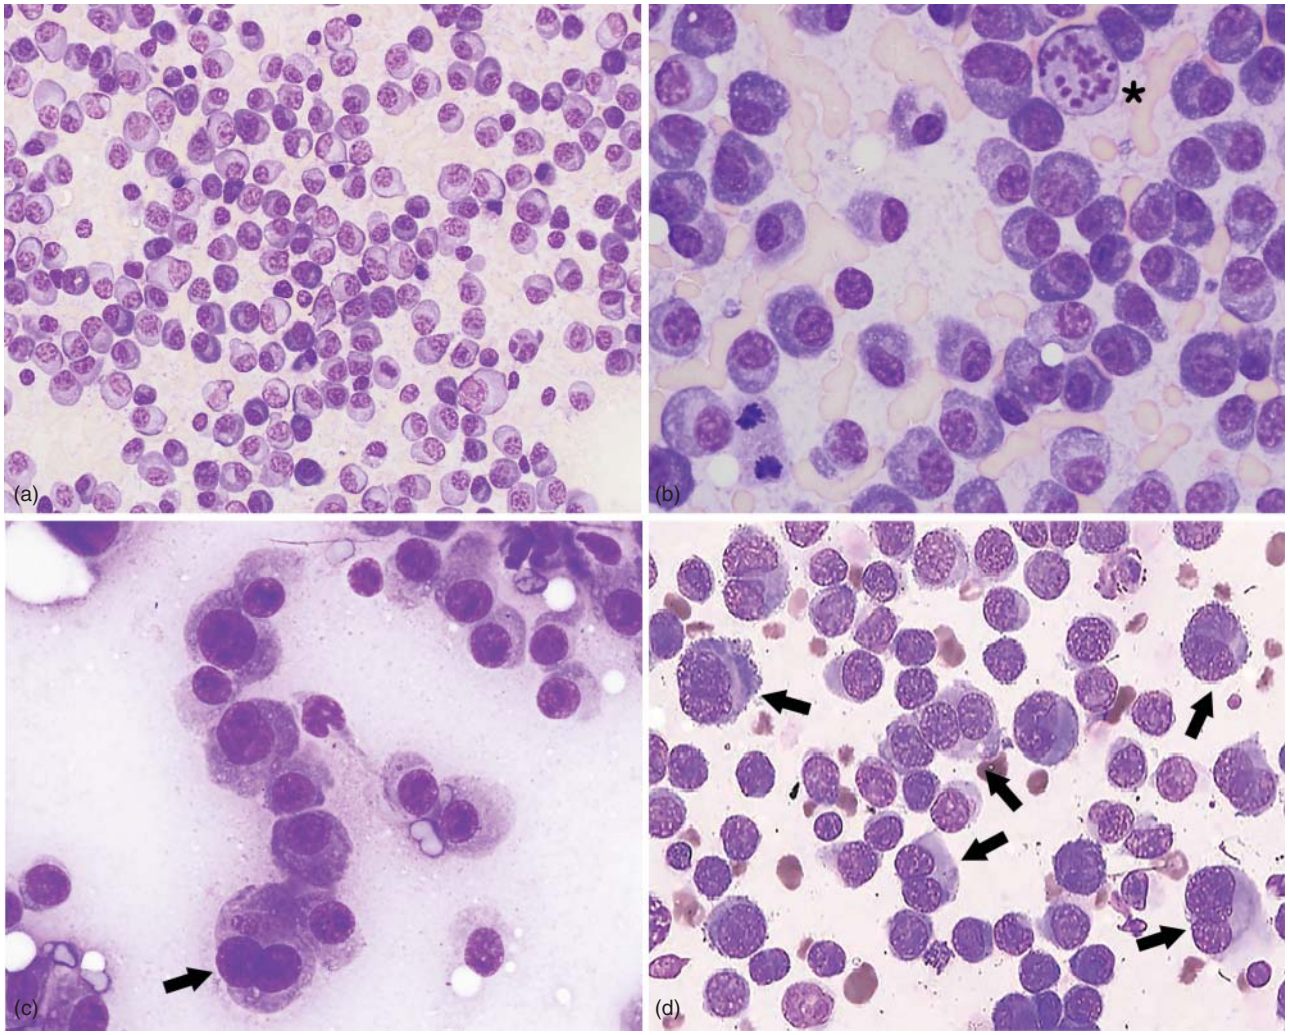

Figure 41.5 Plasma cell tumor. (a, b) A monomorphic population of round cells with very characteristic features of plasma cells: abundant deeply basophilic cytoplasm, a Golgi apparatus (pale paranuclear zone), eccentrically located nucleus with condensed and aggregated chromatin. An abnormal mitotic figure is also present (b, star). (c, d) Poorly differentiated, pleomorphic neoplastic plasma cells: these cells lack a Golgi zone, binucleation (thick arrows) is frequent, and nuclei in (c) contain prominent, bizarre nucleoli. Pleomorphic plasma cell tumors can be difficult to differentiate from histiocytic sarcoma or a high-grade poorly granulated mast cell tumor. Look at many fields and request immunocytochemical staining with MUM-1 (a, 50× objective; b–d, 100× objective). (d) Source: Meuten DJ Tumors in Domestic Animals Ed 5, Wiley Blackwell 2017 p. 953–960; p. 957–959. Wright-Giemsa stain.

Grading

Grading schemes are only established for canine cutaneous MCT. Subcutaneous and oral-perioral canine MCTs and feline MCTs do not have grading schemes, but there are gross and histological features used to predict outcomes for each [2]. Grading canine cutaneous MCT via histopathology is well established, and grading via cytology is being evaluated. Several studies used the two-tier histopathology system to develop a comparable grading scheme for cytology [3, 4]. Granularity of tumor cells, mitoses, and multinucleation were the three best cytologic features to determine grade. Nuclear pleomorphism, the fourth criterion in the histopathology scheme, was not reliable. Greater than 100 cells/tumor were evaluated, and slides must be stained with methanolic Romanowsky-type stains rather than an aqueous-based quick stain for grading. Cytoplasmic mast cell granules (and granules in large granular lymphocytes) do not stain adequately with water-based stains, even if fixed in methanol. A cytological diagnosis of low-grade MCT had a 98% likelihood of being low grade via histopathology; however, the correlation was not as good for high-grade MCT. Follow-up data that correlate cytologic grade with outcome assessment need to be done, as do validation studies of histopathology and cytology grading schemes. Grading via cytological criteria is subjective and should be done by experienced cytologists.

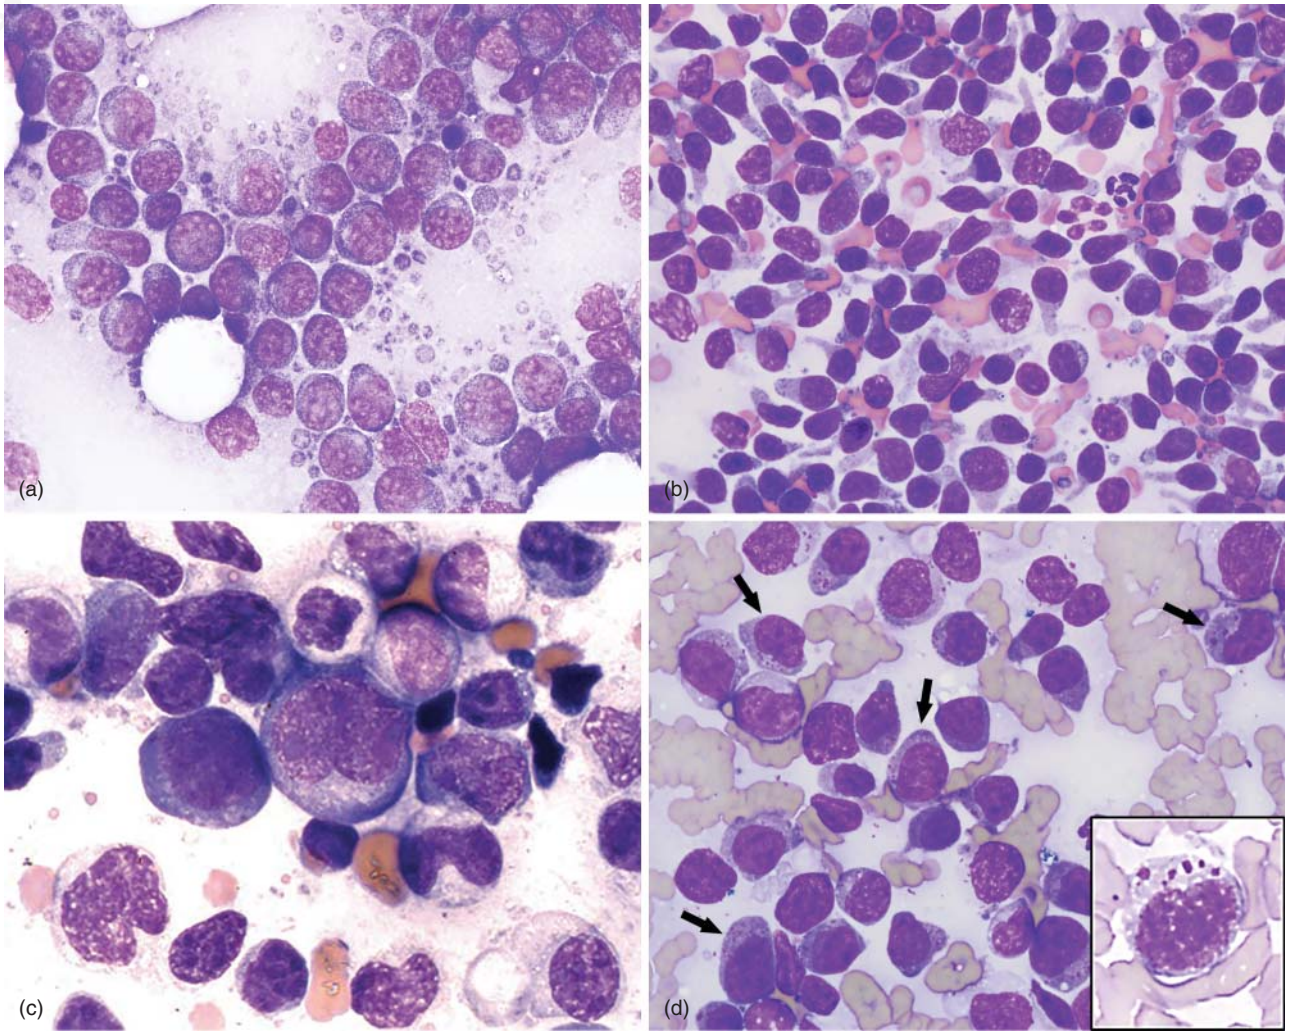

Figure 41.6 This collage is from different types of lymphomas. Most lymphomas are in lymph nodes or organs. (a) Lymph node aspirate from a dog. A monomorphic population of large lymphocytes with small amounts of cytoplasm and nuclei with stippled chromatin and prominent nucleoli indicate large-cell lymphoma; the most common cytologic type in dogs. The numerous fragments in the background with similar tinctorial properties to the cytoplasm of lymphocytes are lymphoglandular bodies. (b) T-zone lymphoma (TZL), aspirate from the submandibular lymph node, dog. The "hand mirror" appearance of the cytoplasm is readily apparent. The hand mirror feature is suggestive of TZL but not diagnostic and not present in all TZL. (c) Neoplastic lymphocytes from a dog with cutaneous epitheliotropic lymphoma. Nuclei of these tumors are often more pleomorphic with indentations, and a few horseshoe-shaped nuclei are present. (d) Large granular lymphocyte (LGL) lymphoma from a cat. Note the large lymphocytes with few cytoplasmic magenta granules (arrows and insert). This sample was from a liver aspirate. LGL lymphoma in cats is an aggressive tumor that arises from the small intestine. In advanced disease, many other organs can be affected. However, skin involvement is usually not seen. (a–c) Source: Meuten DJ Tumors in Domestic Animals Ed 5, Wiley Blackwell 2017 p. 953–960; p. 957–959. (a–d) 100× objective. Wright-Giemsa stain.

Approximately 85–90% of canine cutaneous MCT are low grade via histopathology and approximately 95% are benign: they will have STs greater than 4 years, and more than 95% are cured by complete surgical removal alone [5]. Between 75% and 90% of low-grade MCTs do not recur even if margins are incomplete or narrow (<1 mm) and 95% do not recur if margins are free of tumor cells. Dogs with higher-grade MCTs have STs of 6–12 months; however, the decisions to euthanize influence survival data, and the total number of dogs evaluated is small. Around one-third of high-grade MCTs will recur even if the histologic margins are free of tumor cells [1]. The histologic tumor-free margin distance that will prevent local recurrence of high-grade MCTs is not known and the majority of indolent MCTs will not recur even if tumor cells are at the margin [6]. It appears the biology of the MCT and/or host are more important predictors of recurrence than is margin evaluation. There is no grading scheme that provides 100% correlation with outcomes. Some MCTs that are predicted to behave in a benign or malignant manner will not behave as predicted and identifying these subsets of MCT is problematic [2]. Fortunately, this is a small percentage (estimate <5%) of canine cutaneous MCTs.

Lymph node evaluation for potential metastatic MCT

Cytology is used more frequently than histopathology to evaluate regional lymph nodes in dogs with MCT. However, no markers or cellular features distinguish neoplastic from non-neoplastic mast cells. Mast cells can be found throughout the body, including lymph nodes, bone marrow, buffy coats, and organs such as liver, spleen, and reproductive tract of normal dogs that do not have MCT. Therefore, the diagnosis of regional metastasis is based on numbers of mast cells seen and if the mast cells are aggregated. The subjective nature of this assessment means considerable experience is needed. Greater risk of lymph node metastasis is seen in high-grade MCT, tumors larger than 3 cm diameter, ulcerated tumors, tumors located on the digit, Shar-Pei dogs, and dogs with substage b disease (dogs are clinically ill) [2, 4, 7].

Diagnosis of MCT in regional lymph nodes can alter prognosis, treatments and staging [4, 7, 8]. If a patient with MCT has metastasis to a regional lymph node (regardless of grade), then further staging, including additional lymph node evaluation and abdominal ultrasound, is often recommended. The likelihood of additional lymph node or visceral metastasis in a patient with regional lymph node MCT metastasis ranges from 10% to 20%. In a series of 220 dogs with MCT who underwent complete staging, none of the dogs with nonmetastatic regional lymph nodes had clinically detectable metastasis in other areas [9]. All dogs with distant metastasis had metastasis in the regional lymph node; pulmonary metastases were not seen and are not expected in dogs with MCT. Approximately 30% had lymph node metastasis and 7% of dogs had distant metastases. MCTs rarely cause malignant cachexia. Euthanasia attributed to MCT is more likely due to recurrence, nursing care decisions, concurrent diseases and owners' elective choices than tumor metastases that erode health.

A study reported ST of approximately 8 months in dogs with cytologically confirmed lymph node metastasis (stage 2 disease) as compared to 6 years for dogs with normal or reactive lymph nodes [8]. However, once owners are informed that the prognosis is not as good due to regional node involvement, this information may influence decisions to treat, which in turn affects survival data (self-fulfilling prophecy). Additional studies examining treatment outcome in dogs with stage 2 MCT have reported prolonged ST. Long ST (years) and disease-free intervals can be seen in dogs with low-grade cutaneous or subcutaneous MCTs that have metastasized to a regional lymph node [2]. Multiple treatments can be offered.

Histiocytoma

Clinical features

The cell of origin is a dendritic cell in the epidermis, not a histiocyte or monocyte. These tumors are usually easy to diagnose because of the signalment (usually young), location of tumor (commonly on the ear, head, or neck), and appearance of tumor (one or more round, raised ulcerated hairless masses). However, they can occur in middle aged and geriatric dogs and can be located on parts of the body other than head and neck. The button-shaped mass is often "pink-tan colored," hairless and protrudes through the skin, may be ulcerated, and some tumors regress spontaneously.

Cytologic features

Histiocytoma cells do not exfoliate well, and therefore preparations are usually of low cellularity. Cells are round, individualized and have small amounts of lightly basophilic to blue-gray cytoplasm that may contain a few vacuoles (Figure 41.3). Cell borders are often distinct because of the basophilic proteinaceous material in the background of the slide (Figure 41.3). Tumor cells have round to oval nuclei that may be eccentric and have minimal anisocytosis (size variability). Nuclear chromatin condensation is variable, sometimes becoming ropey. There may be mature small lymphocytes or other inflammatory cells in low numbers admixed amongst the larger neoplastic cells. The lymphocytes are usually present in large numbers when the tumor is in the regression stage due to cellular immunity.

Differential cytologic diagnoses are lymphoma, TVT and plasmacytoma. Histiocytomas have more cytoplasm than lymphoid cells, the cytoplasm is less blue than lymphoma and inflammation is associated with histiocytoma. They can be difficult to differentiate from TVT without a history, although usually TVT cells have more abundant, more basophilic cytoplasm that contains many small discrete clear vacuoles, as well as more malignant nuclear features. TVTs typically exfoliate more cells than do histiocytomas. Although TVTs can be in many different locations on the body, if the tumor is found on the genitals and it is a round cell then TVT is the most likely diagnosis by far.

Transmissible venereal tumor (TVT)

Clinical features

TVTs, a tumor only seen in canids, are more common in areas where dogs run free and are not neutered, such as the Caribbean islands and in a few areas of the southern and midwest United States. The tumor cells contain 59 chromosomes, unlike the normal canine karyotype of 78 chromosomes [10]. The tumor cell has been shown to have been present in canids for at least 6000 years, during which time it has mutated approximately 38,000 times resulting in the marked difference in karyotype [10].

TVTs are usually located on the genitals of male or female dogs and less frequently on the skin, mucous membranes of the nose, mouth, and eyes, and more rarely in other areas such as lymph nodes, abdominal cavity, and brain, due to expansion into those tissues or metastasis [11]. It is

transplantable from dog to dog, and does so readily via social or sexual activity.

When on the vaginal wall or penis, the tumor begins as a nodule beneath the mucosa; they then break through the overlying mucosa where they appear as an ulcerated friable mass.

These tumors can appear cytologically similar to histiocytomas. They exfoliate easily and therefore numerous cells will be in the preparations. Location of the mass is usually helpful in making the correct diagnosis. In comparing TVT's to histiocytomas, the following features of TVTs can be used to differentiate the tumors: location, presence of many cells, abundant cytoplasm, a slightly more blue color than that of histiocytomas, and clear distinct discrete cytoplasmic vacuoles, which are much more common in TVTs (Figure 41.4). Nuclei of TVT cells tend to be larger, distinct and lightly basophilic as compared to histiocytomas. Nucleoli are usually readily visualized. In aspirates of histiocytomas the inflammatory cell component is mild, if present at all, although regressing tumors may contain numerous lymphocytes. Conversely, imprints of TVTs usually contain many inflammatory cells, predominantly neutrophils. TVTs are one of the few tumors for which imprints or swabs of the tumor surface are diagnostic.

The three primary differentials with which TVT can be confused are histiocytoma, plasmacytoma, and lymphoma. If the preparations appear similar to that of lymphoma but are from the vagina or penis, then the diagnosis is much more likely to be TVT. Lysozyme is a nonspecific cellular marker that positively stains most cases of TVT and approximately 60% of histiocytomas. When they are extra-genital or cytologically difficult, TVTs can be definitively diagnosed using polymerase chain reaction (PCR) to detect a unique long nuclear element upstream of the myc gene [12]. TVTs rarely spontaneously regress, but regression almost always occurs after therapy with vincristine.

Plasma cell tumor

Clinical features

Cutaneous plasma cell tumors are common in middle-aged dogs and are rare in cats. They can occur any place on the dog's skin/subcutaneous tissues and mucous membranes (oral, rectal). Plasma cell tumors appear as discrete nodules that are hairless and are often ulcerated. The majority are benign, and are not associated with bone marrow involvement and paraneoplastic syndromes (monoclonal gammopathy, hypercalcemia, amyloidosis) commonly associated with multiple myeloma, a separate and malignant entity (see Chapter 16).

Cytologic features

Diagnosis can usually be made from low magnification based on the presence of round cells with abundant deeply basophilic cytoplasm and a Golgi apparatus, which is a pale paranuclear zone visible in some cells (Figure 41.5). The nucleus is usually eccentrically located. The nuclear chromatin is condensed and aggregated. The classic "clock-face" or "spoke-wheel" pattern in the nuclear chromatin is only present in a minor population of the tumor cells and is much more visible on histopathology than on cytology. Some tumors contain neoplastic cells that have one or more intracytoplasmic globules that can be clear, pale blue or eosinophilic. These cells are called Mott cells; the cytoplasmic vacuoles are Russell bodies and they represent packets of immunoglobulin. If seen, they help confirm the diagnosis as plasma cell tumor, although Mott cells may be seen in non-neoplastic accumulations of plasma cells. A proteinaceous magenta or blue background color may be present due to the large amount of immunoglobulin that may be secreted by the tumor cells.

Some tumors produce a monomorphic population of round cells with very characteristic features of well-differentiated plasma cells that allow for a quick cytologic diagnosis (Figure 41.5a, b). Other tumors can be heterogenous and are predominated by more atypical cells with binucleation, multinucleation, lobated, bizarrely shaped nuclei; only on searching throughout the preparation can the more recognizable plasma cells be found (Figure 41.5c, d) that provide the clue to a correct diagnosis. Tumors with pleomorphic cellular and nuclear features as just described need to be differentiated from malignant histiocytosis.

Pleomorphic plasma cell tumors can be confused with histiocytic sarcoma, malignant histiocytosis (MH), histiocytoma, poorly stained MCT and osteosarcoma. Plasma cell tumors can usually be distinguished from these differential diagnoses by searching for well-differentiated plasma cells amongst all of the tumor cells. Examining the multinucleated or bizarre nuclei is interesting but does not help identify the cell of origin. Plasma cell tumors tend to be singular; malignant histiocytosis tends to have multiple tumors, may involve internal organs and/or joints, and has breed predispositions. The MH cells have more pleomorphic features than do plasma cells, are usually larger, and erythrophagocytosis is a characteristic, but sometimes difficult to find, cytologic feature.

Lymphoma

Clinical features

Although lymphoma is a common tumor in dogs and cats, it is uncommon in skin and therefore is the least common round cell tumor in skin or subcutaneous tissues. Lymphoma very rarely occurs as a solitary skin mass. If lymphoma is present in the skin it appears as multiple skin and subcutaneous lumps, or flat plaques located anywhere on the body; some have a mucocutaneous distribution (T-cell lymphoma). Regional or peripheral lymph nodes are often involved at presentation. Dogs are usually middle aged to

older and have weight loss. Cats often have weight loss, anemia, and are commonly feline leukemia virus (FeLV) positive with enlarged abdominal lymph nodes. It is rare for lymphoma to be confined to one system in the body; it is usually in multiple locations and lymph nodes (see Chapter 45).

Cytologic features

Lymphoid tissue exfoliates very well; aspirates of neoplastic lymphoid tissue are usually very cellular and may be too thick in some areas of the slide. The cells are round and discrete, often appearing close to each other due to the marked cellularity. The cells have uniform nuclei and typically a minimal amount of basophilic cytoplasm (Figure 41.6). The amount of cytoplasm will vary from a thin rim to a bulge, almost always off to one side. Distinct cytoplasmic protrusions, like mirror handles or cone heads are seen with a fairly indolent type of T-cell lymphoma (Figure 41.6b) [2]. The nucleus: cytoplasm ratio is high, usually 1 : 1, and rarely 1 : 2. The most characteristic cytologic feature of lymphoma is the uniformity and high nucleus: cytoplasm ratio. Many cytoplasmic fragments, commonly referred to as "lymphoglandular bodies," are usually present (Figure 41.6a). These cytoplasmic fragments may be confused with platelets. Nuclei usually have fine chromatin and nucleoli are often prominent. Intermediate (prolymphocytic) variants have nuclear chromatin that is clumped or marginated along the outer nuclear membrane. Cytoplasm is usually scant and moderately to deeply basophilic. For those lymphomas that differentiate toward the plasma cell line there is more cytoplasm, the cytoplasm is more basophilic and sometimes a pale perinuclear zone (Golgi apparatus) can be seen. Small-cell variants of lymphoma consist of well-differentiated normal-appearing lymphocytes and are very rarely, if ever, seen in the skin or subcutis. If large numbers of small lymphocytes are seen in a mass, it is likely normal lymphoid tissue or lymphocytic inflammation. The diagnosis of small-cell lymphoma should be confirmed by a pathologist. Most cases of cutaneous lymphoma consist of large cells with stippled chromatin and prominent nucleoli (features of immature cells) and are relatively easy to diagnose. All of the other round cell tumors will have more cytoplasm and nuclei will have more condensed chromatin than seen in lymphoma.

Cutaneous lymphoma can be further classified to subtype using immunophenotyping, flow cytometry, or PCR (see Chapter 15). There are numerous subtypes of lymphomas but one of the most important determinations for prognosis and treatment plans is to identify T vs. B immunophenotype. T-cell lymphoma is the most common immunophenotype for cutaneous lymphoma. Histopathology showing tissue architecture is required for the recognition of intraepithelial lymphomas (mycosis fungoides).

Epithelial cell tumors

Basal cell neoplasm (basilar epithelial neoplasm)

Clinical features

Basal cell neoplasm is one of the most common skin tumors of dogs and cats, and they are usually benign in behavior. They produce one or more bulging skin nodules, often located on the head and neck, and they are usually ulcerated.

Cytologic features

Although they are epithelial, they often exfoliate as round cells, individually or in groups, and can be confused with round cell tumors. Preparations are usually of low to moderate cellularity and consist of small individual cells as well as cells in clumps, aggregates, and ribbons (Figure 41.7a, b). Recognizing these patterns of cell organization is the key to the correct diagnosis of epithelial tumor. Inflammation is not present unless the tumor is ulcerated or is producing keratin, which can induce a neutrophilic or pyogranulomatous inflammatory response. Tumor cells are polygonal, oval or round with round to oval uniform nuclei; however, around the edges of the clumps some cells may be spindeloid. The amount of cytoplasm in basal cells is minimal to moderate and light blue to gray.

A pure basal cell neoplasm consists of just the polygonal/round cells that represent the basal epidermal cells. However, these tumors may differentiate toward secretory sebaceous cells and can have large areas that are pigmented. If cells are differentiating into sebaceous cells the cytoplasm can be abundant and vacuolated. Moderate numbers of vacuolated lipid-filled sebaceous cells and scattered melanin-laden cells may be present. Multicellular sheets composed of homogenous basal cells or a mixture of basal cells, sebaceous cells and melanin-filled basal epithelial cells may be present.

It is important to not confuse pigmented basal epithelial cells with melanocytes, as one could mistakenly make a diagnosis of melanoma.

Histopathology is usually necessary to definitively diagnose differentiated basal cell tumors, such as pigmented basal cell tumors, as well as determine malignant potential. The vast majority are benign. There are other groups of tumors that have a similar lineage such as trichoepithelioma, keratoacanthoma and calcifying epithelioma. These are recognized on histopathology based on how the cells are organized, what structures and products they produce. They cannot be classified as such on cytologic examination. They are all epithelial cell neoplasms that have a similar origin but different differentiation.

Sebaceous cell adenoma

Clinical features

Sebaceous cell adenoma is one of the most common skin tumors in dogs and is seen frequently in cats, as well. They

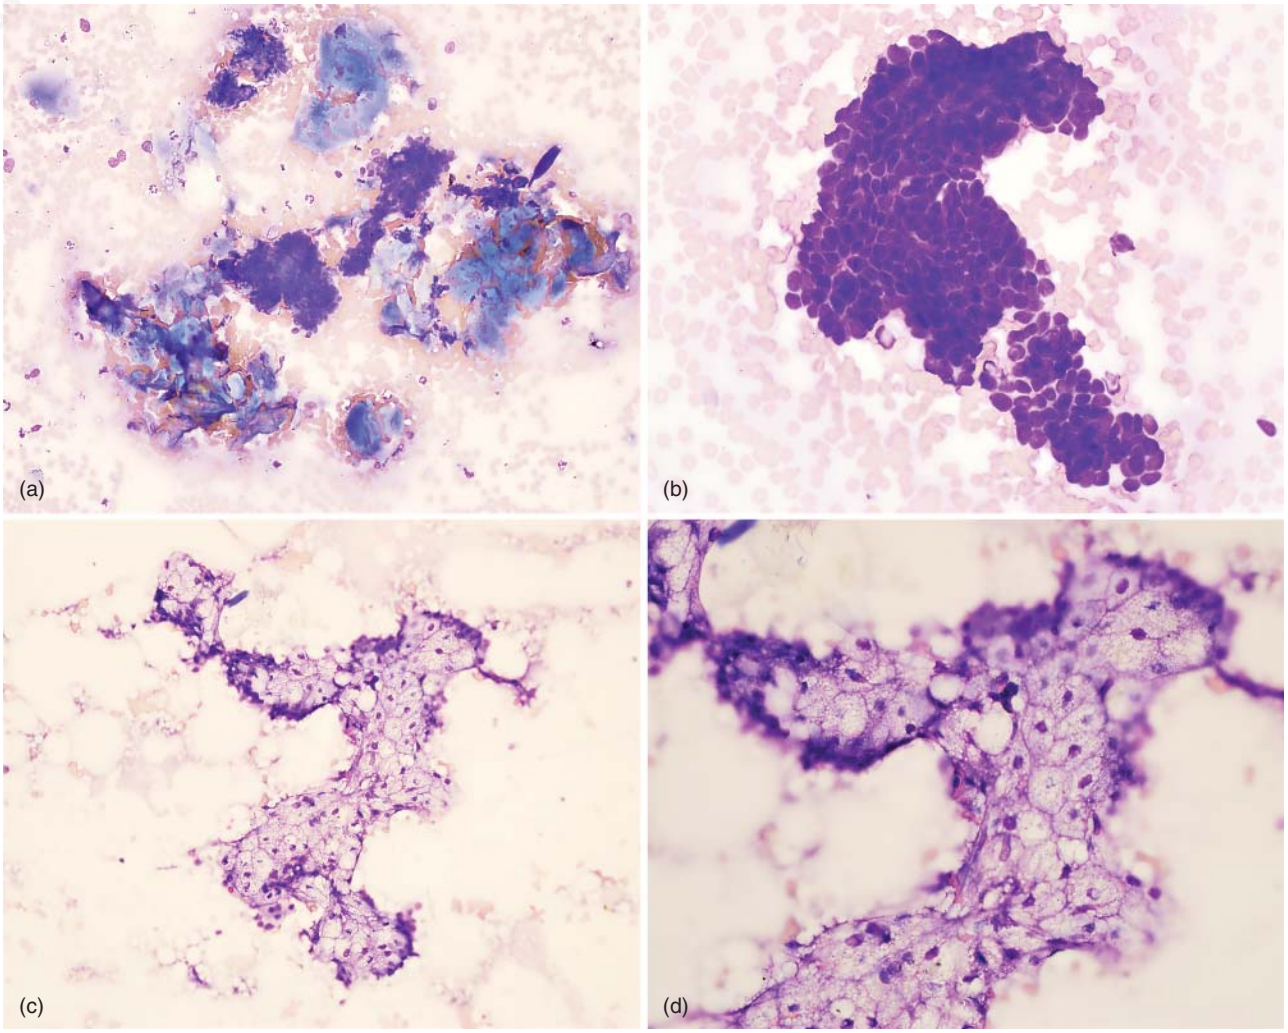

Figure 41.7 Cutaneous basilar cell tumor (a, b). Ribbons and clusters of uniform, cohesive epithelial cells with scant amount of cytoplasm, central round nuclei, and indistinct nucleoli. Some of these tumors can produce keratin (a). In addition to true basal cell tumors, trichoblastoma, trichoepithelioma, keratoacanthoma, and calcifying epithelioma can have the same basilar epithelial cell appearance on cytology, and their distinction would require histopathology. However, the vast majority of these tumors are benign. Sebaceous cell adenoma (c, d). Cohesive epithelial cells with marked amounts of vacuolated, foamy cytoplasm and a central round nucleus. Pleomorphism is absent. Sebaceous cell hyperplasia will look identical to an adenoma. However, their distinction is not clinically relevant. Basal cell and sebaceous cell tumors are easy to identify at medium magnifications due to cell-to-cell adhesions that form distinct clusters or aggregates. (a, c) 20× objective, (b) 50× objective, (d) 40× objective. Wright-Giemsa stain.

are overrepresented in cocker spaniels and poodles. These neoplasms are often on the head, neck, and especially the eyelids. Sebaceous adenomas may have a "wart-like" appearance on gross examination.

Cytologic features

Microscopically these tumors, and their hyperplastic counterparts, consist of numerous cells with a large amount of cytoplasm that is markedly vacuolated or foamy (Figure 41.7c, d). The cytoplasmic vacuoles vary in size; they are smaller than erythrocytes. Cells are usually in aggregates or groups that identify their epithelial heritage. Nuclei are usually positioned in the center or slightly eccentrically. They are benign in their appearance cytologically and benign in their biologic behavior. Sometimes they have numerous round cells scattered through them, which may be basal cells that are proliferating along with the sebaceous cells. Differentiation of sebaceous adenoma from sebaceous gland hyperplasia is clinically inconsequential.

Sebaceous cell carcinoma

Sebaceous cell carcinomas are uncommon. They resemble sebaceous adenomas but carcinomas have cellular and nuclear pleomorphism. The more differentiated tumors

resemble sebaceous adenomas and the more undifferentiated have marked variability in nuclear and cellular morphology. These tumors often shed cells individually and in clusters, adhered by desmosomes and hemidesmosomes. Some cells or groups of cells will have relatively little cytoplasm and the cytoplasm is basophilic due to the presence of increased RNA. Other cells will be much larger, the cytoplasm lighter, faintly blue or lightly eosinophilic and they will contain cytoplasmic vacuoles (lipid). Nuclei are often two to five times the size of neutrophils.

Liposarcoma is the primary differential diagnosis. Liposarcoma yields individual fat-laden cells (vacuolated) and sebaceous carcinoma produces fat-laden cells in clusters, aggregates or morulae. Liposarcoma is a rare tumor in animals; lipomas are common in dogs (see "Mesenchymal/Spindle Cell Tumors").

Squamous cell carcinoma (SCC)

Clinical features

Squamous cell carcinoma is a common tumor of the skin and epithelial tissue of older domestic animals and they occur in various locations including the nose, nasal cavity, ears (especially in white cats), gingivae of dogs and cats, tonsils of dogs, tongue of cats, stomach, vagina, prepuce, penis, and lungs.

Cytologic features

Touch imprints or FNA contain large cells, greater than 60 µm in diameter, with abundant basophilic to gray cytoplasm and central to eccentric round nuclei (Figure 41.8). Very few other neoplastic cells are as large as neoplastic squamous epithelial cells. SCCs are often so well differentiated that the diagnosis is relatively easy. Usually there are numerous neutrophils present because the tumors have an ulcerated

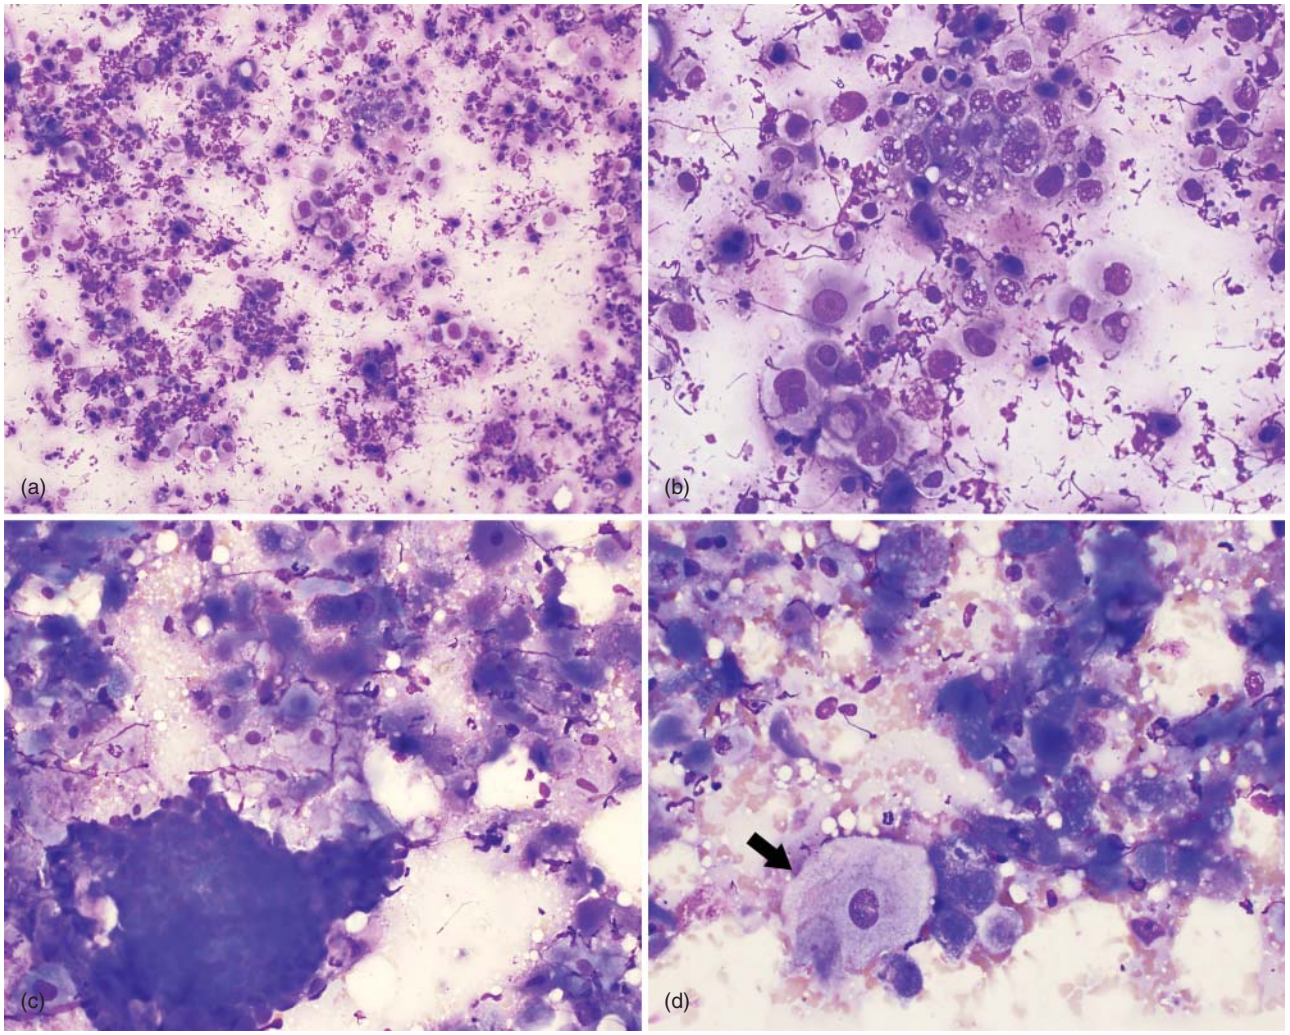

Figure 41.8 Squamous cell carcinoma from a cat (a, b) and a dog (c, d). Individualized cells and cells in large aggregates. Note the marked variation in cell size and shape. There are some very large squamous epithelial cells with angular cell borders and glassy, basophilic (keratinized) cytoplasm (d, arrow). Secondary inflammation is very common in these tumors, due to epidermal ulceration (a, b). (a) 20× objective, (c) 40× objective, (b, d) 50× objective. Wright-Giemsa stain.

surface, or because they produce keratin that induces an inflammatory response.

Some cells are individualized, and others are in cellular aggregates of 10–50 or more cells. Cell sizes and shapes are variable. Some cells are deeply basophilic, others lightly basophilic or gray and others pink due to keratinization. Nuclei and nucleoli are equally as pleomorphic. Nuclei are 2–10 times the size of neutrophils. Nucleoli will be variable in number and are prominent. Features that help make a diagnosis of SCC include characteristic location, gross appearance and marked variability in cellular clusters, cell size, nuclear size and nucleolar size.

Preparations made from non-neoplastic preputial exudates will contain numerous large well-differentiated squamous epithelial cells surrounded by many neutrophils. The cells will not be in clumps, and they will be uniform in morphology, a characteristic pattern of balanoposthitis and not SCC.

Perianal/circumanal gland tumors

Clinical features

Perianal gland tumors are very common tumors in the perineum of intact male dogs but can occur in castrated males and intact or spayed females. In male dogs they are hormonally (testosterone) responsive and regress, or at least decrease in size, after castration. If they occur in cats they are extremely rare. Circumanal glands are modified sebaceous glands. Adenomas and hyperplasia look similar cytologically and both are benign. These tumors rarely become malignant and there are no reliable criteria to recognize their malignant counterparts using cytology or histopathology of the primary lesion. The only way to be completely certain a malignant form is present is to find recognizable circumanal cells in a regional lymph node.

Cytologic features

Characteristic organization and cytologic features of individual tumor cells make this tumor easy to recognize at low and medium magnifications (Figure 41.9). Cells are individualized or in cohesive clusters of 8 to 50 or more cells. Large cells have abundant light blue, to blue-gray to lightly eosinophilic cytoplasm with a low N : C ratio of 1 : 3 to 1 : 5. The cells resemble hepatocytes and the nuclei are often central and completely encircled by cytoplasm. This cytologic feature has led to the nickname "hepatoid tumor" or "hepatoid cells." There is no associated inflammation. Higher magnification is not needed to confirm diagnosis.

No cytologic criterion predicts malignancy. However, if cells are smaller than usual, the N : C ratio is higher than usual (1 : 2) and there is variability in cellular and nuclear features, then the tumor may be malignant. Malignant circumanal tumors are rare. Female dogs are more likely to have a neoplasm arising from the apocrine gland adenocarcinoma (see next section).

Apocrine gland adenocarcinoma (AGAC) of anal sacs

Clinical features

Apocrine gland adenocarcinoma of anal sacs is the most common malignant tumor in the perineum of female and male dogs. It is more common in female dogs. Approximately half of the tumors bulge caudally and are readily visible. The other half are occult, lie beneath haired skin but are readily found on palpation of the perineum. The easiest way to diagnose this tumor is via rectal palpation and then FNA of the mass. Approximately 50–80% of these patients will have hypercalcemia and approximately one third of affected

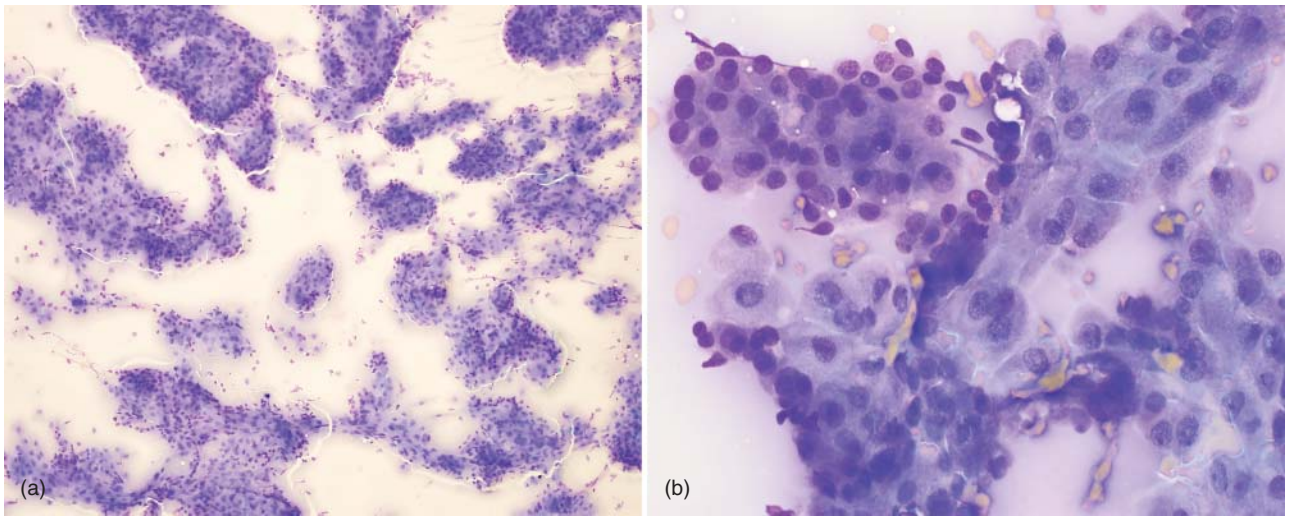

Figure 41.9 Perianal/circumanal ("hepatoid") gland tumor from a dog. (a) Clusters and morulae of uniform epithelial cells. (b) Large cells with abundant light blue to blue-gray to lightly eosinophilic (amphophilic) slightly granular cytoplasm with a low N : C ratio (lots of cytoplasm and a small nucleus). The cells resemble hepatocytes ("hepatoid"). Location in perineum is key to this diagnosis and for anal sac tumors, Figure 41.10. (a) 10× objective, (b) 50× objective. Wright-Giemsa stain.

dogs present for problems referable to their hypercalcemia, such as polyuria, polydipsia, lethargy, and weakness.

Cytologic features

These tumors exfoliate easily but the cells seldom remain intact. Therefore, numerous nuclei with a minimal amount of, or no, visible cytoplasm (naked nuclei) are usually present. Cells will be individualized and in clumps of various sizes indicating their epithelial origin (Figure 41.10). If cytoplasm is seen, it is a light blue-gray or lightly eosinophilic, and only a small amount is present, such that the N : C ratio is approximately 1 : 1 or 1 : 2 at the most (much less than that seen with circumanal tumors). The nuclei are characteristically uniform, round to oval and the chromatin pattern is usually fine with some visible nucleoli. Inflammation is not present.

The tumor cells have very few features of malignancy. However, almost all dogs who are diagnosed with these adenocarcinomas already have metastatic disease. Metastases occur first via direct extension into the pelvic vault, followed by systemic spread into sublumbar lymph nodes and, much later in the course, pulmonary and organ metastases. Sublumbar lymphadenopathy is a common finding on radiographs of the abdomen. Some dogs can survive for 1–2 years with repeated excisions of the primary and recurring masses. Removal of the tumor is followed by remission of hypercalcemia and hypophosphatemia; recurrence is followed by a return of the serum abnormalities (see case

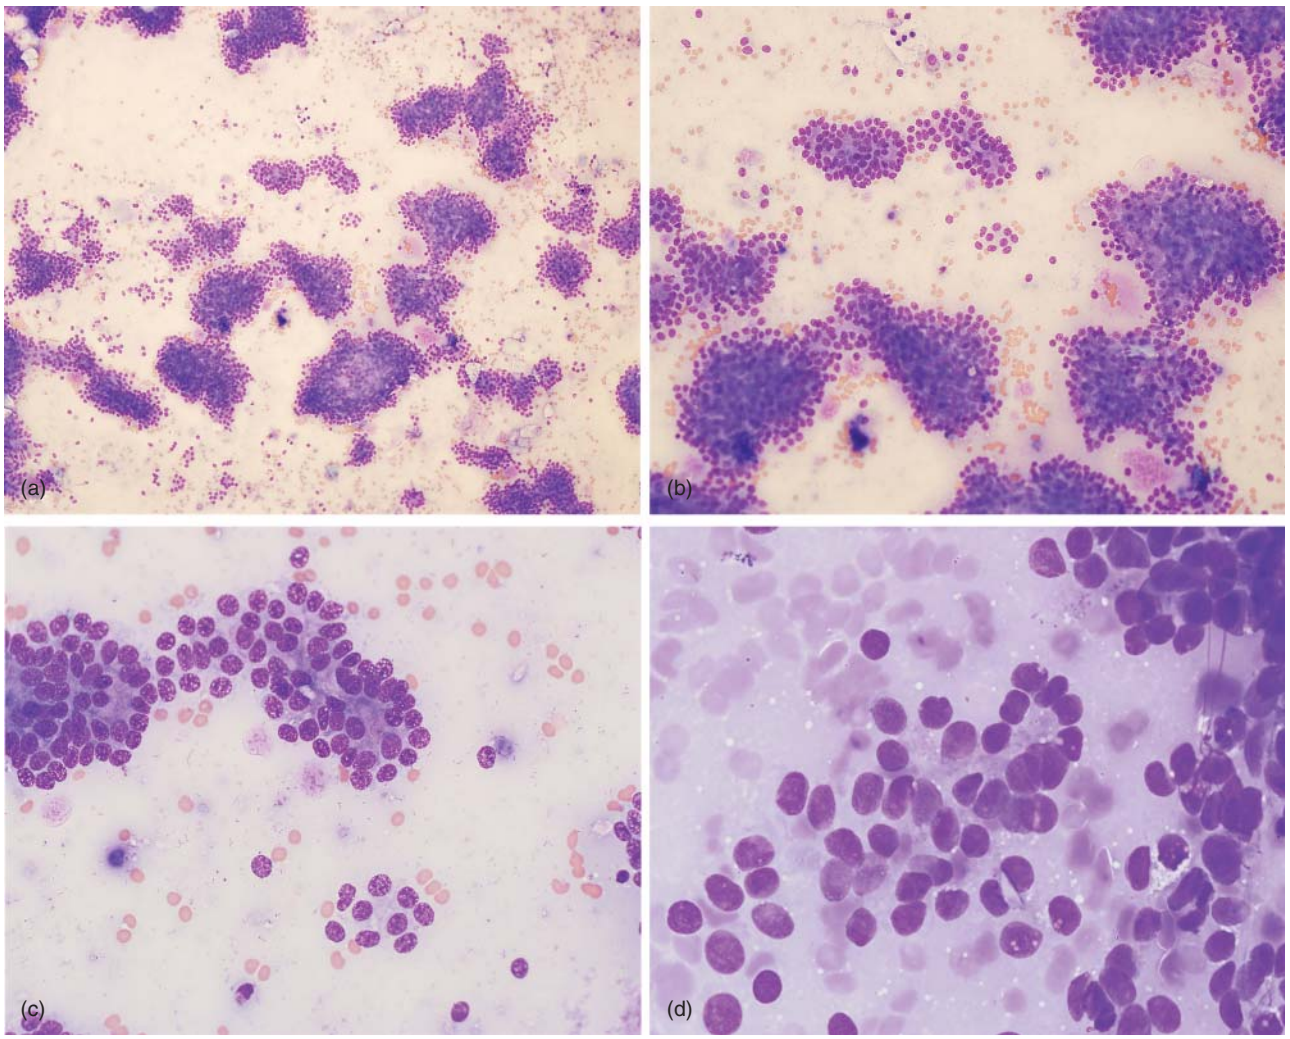

Figure 41.10 Anal sac apocrine gland adenocarcinoma from a dog. These tumors exfoliate easily and in high numbers, but the cells seldom remain intact. Therefore, numerous nuclei in a pool of cytoplasm or no visible cytoplasm (naked nuclei) is a common finding. The amount of cytoplasm and N : C ratio is much less than that seen with perianal gland tumors (Figure 41.9). Nuclei are uniform, round to oval in shape, with fine chromatin and some visible nucleoli. Despite the relatively uniform cytologic appearance, this is a malignant tumor with a high rate of metastasis to local lymph nodes at the time of diagnosis. More than 50% of dogs will also have paraneoplastic hypercalcemia. (a) 10× objective, (b) 20× objective, (c) 50× objective, (d) 100× objective. Wright-Giemsa stain.

example). Only primary hyperparathyroidism and hypercalcemia of malignancy are characterized by hypercalcemia and hypophosphatemia in dogs. If renal failure develops, often because of mineralization of the kidney, the serum phosphorus concentration will increase.

Diagnosis of this neoplasm may require integrating signalment, clinical signs, laboratory findings, and cytologic findings. For example, a female dog presenting with polyuria polydipsia, hypercalcemia, hypophosphatemia (unless there is concurrent decreased glomerular filtration rate), mass in the perineum, and aspirate consisting of the typical cytologic pattern described above would be relatively easy to diagnose.

Case example:

	Serum total Ca (mg/dL)	Serum P (mg/dL)n
Presentation	18.5	1.5
Removal of tumor	10.1	3.4
Recurrence (6 months)	16.2	2.0
Removal	9.0	4.2
Recurrence (16 months)	21	1.8

Postoperative hypocalcemia does not occur in these patients, unlike postoperative hypocalcemia associated with removal of a parathyroid adenoma. This is interesting in that the parathyroid glands are inactive to atrophic because of the prolonged hypercalcemia and therefore hypocalcemia would be expected.

Summary of expected features with circumanal tumors and AGAC:

	Circumanal tumor	AGAC
Sex	Male[a]	Female
Calcium	Within reference interval	Increased
Phosphorus	Within reference interval	Decreased
Perineum	Mass visible	Mass may be occult
Rectal	No masses in pelvic vault	Tumor in pelvic vault
Biologic behavior	Benign	Malignant

[a]These are generalities; certainly male dogs can develop AGAC and females can develop circumanal tumors.

Apocrine sweat gland tumors

Clinical features

Apocrine sweat gland tumors occur in dogs and cats but not as frequently as sebaceous gland or basal cell tumors. They can be benign or malignant.

Cytologic features

Cytologic features of apocrine sweat gland tumors overlap with those of sebaceous tumors, basal tumors and AGAC; thus they cannot be specifically identified via cytology. Nevertheless, cytology can be helpful in telling if it is an epithelial tumor and if it is more likely an adenoma or carcinoma.

Mammary gland tumors

The primary reason to perform FNA cytology of a mammary lump is to distinguish neoplasia from inflammation (mastitis). One should not use cytology to distinguish a benign from a malignant mammary tumor, although if the aspirate has many cytologic characteristics of malignancy, it is likely that the tumor is malignant. Once one has determined that the lesion is neoplastic, an excisional biopsy should be performed to determine the lesion's biologic behavior. Even with histopathology it can be difficult to distinguish benign from malignant tumors.

Mastitis, on the other hand, is characterized by nearly 100% neutrophils, and most neutrophils are degenerative. There is usually considerable extracellular, eosinophilic, amorphous material (milk) that prevents the formation of a good monolayer. Bacteria can often be identified intracellularly. Usually the animal is lactating and one or more glands are enlarged, red, tender, and inflamed.

Neoplastic lesions are predominated by mononuclear cells with few or no inflammatory cells. The cells vary greatly from case to case depending on the histologic type of tumor as well as the presence or absence of malignancy. Cells are individual and in groups, clusters, aggregates or acini to indicate their epithelial nature. Cells may contain one or more large cytoplasmic vacuoles. Cytoplasm is usually abundant with a high nucleus: cytoplasm ratio (up to 1 : 5). There can be considerable cellular and nuclear variability in terms of size and shape. Cells with markedly variable nuclear and cytologic features are more likely to be malignant. Aggregates of cells that pile together into disorganized, irregularly shaped morulae are more likely to be malignant. However, one should not rely on cytology alone to determine biologic behavior.

In dogs the ratio of benign to malignant mammary tumors is approximately 2.3 : 1 and in cats it is 0.25 : 1. In other words, mammary tumors are much more likely to be malignant in cats than in dogs. In summary, cytology is a useful tool to differentiate inflammation of the mammary gland from mammary gland neoplasia, but it is not very useful in determining degree of malignancy or tumor type.

Thyroid tumors

Clinical features

Around 80–90% of palpable thyroid masses in dogs are malignant and 98% of palpable thyroid lesions in cats are benign. Thyroid tumors tend to metastasize to the lungs before they spread to regional lymph nodes. Dogs with thyroid tumors are generally euthyroid, but thyroid tumors

in cats often cause hyperthyroidism. The clinical distinction of thyroid adenoma, hyperplastic nodules, and adenomatous hyperplasia is inconsequential in cats because they all have benign behavior. The clinical syndrome is usually seen in cats over 10 years of age and is distinctive. Some of the features are hyperactivity, weight loss, polyphagia, EKG abnormalities, increased serum alkaline phosphatase activity (70% of cats have a mild to moderate increase), increased serum alanine aminotransferase (ALT) activity, and polycythemia (20%) (see Chapter 33). Hyperthyroidism is uncommon in dogs.

The distinction of benign vs. malignant is better made by clinical criteria than cytologic criteria. All palpably enlarged thyroid nodules in dogs should be considered malignant even if the cytologic pattern appears benign, and thyroid masses in cats should be considered benign. In cats thyroid tumors are follicular but in dogs they can be follicular (multiple subtypes further classified) or medullary (C-cell). Follicular vs. medullary origin in dogs requires immunocytochemistry or immunohistochemistry to be certain of origin and should be considered as medullary tumors are less aggressive.

Cytologic features

Tumor aspirates yield few to numerous usually uniform cells that have distinct cell borders and round nuclei (Figure 41.11). Cells are in clumps or small rafts of 10–50 cells. Tumors with benign cytologic features have uniform cellular and nuclear characteristics. Cells are usually well-spaced and do not appear in piles or clumps. Cytoplasm is not abundant, is lightly eosinophilic to gray-blue, and on careful inspection at 400 or 1000× green-blue intracytoplasmic granules may be observed (Figure 41.11c, d). These granules stain for lipofuscin, although others have reported them to be thyroglobulin, or a thyroglobulin precursor (personal observations, confirmed with histochemistry). Their presence helps in the identification of thyroid cells if the tissue of origin is a ventral neck mass. Nuclei are uniformly round or slightly oval, central or basilar. Some cells may be organized in rows or clusters, and rarely are organized in acinar formation with colloid preserved. Cytoplasm is often missing, leaving free, round nuclei, a characteristic often associated with neuroendocrine tumors.

Tumors with more aggressive cytologic features are characterized by some of the above observations but coupled with moderate to marked cellular and nuclear variability, multinucleation, high nucleus: cytoplasm ratio, cytoplasmic vacuolation, and cellular piling.

Neuroendocrine tumors

Clinical features

The only neuroendocrine tumor of the skin, the Merkel cell tumor, is very rare. This diagnosis should not be made from cytologic examination of the aspirate alone. However, neuroendocrine tumors are common in other locations including the jugular groove (carotid body tumor), the base of the heart (aortic body tumors), or in the adrenal glands (cortical tumors or pheochromocytoma). Carotid body tumors can produce clinical problems and visible bulges from their location in the jugular groove at the ramus of the mandible in dogs. They are a differential diagnosis for a palpable mass in the ventral neck region of middle aged to older dogs. Brachycephalic breeds tend to have more carotid body tumors than other breeds. Biological behavior of these tumors varies with their location. Tumors in the carotid artery region rarely metastasize and aortic body tumors vary in their metastatic capability, but they may be lethal due to their location. Despite their somewhat benign cytologic appearance they are capable of invading blood vessels and metastasizing.

Cytologic features

Cytologically, neuroendocrine cells have uniform round nuclei with indistinct or no visible cytoplasm. Cytoplasm, if present, is lightly basophilic to dusty-gray. Nuclei and cells are individualized and rarely to never form true aggregates or clumps of cells. This pattern of uniform nuclei with little to no visible cytoplasm ("naked nuclei") is highly characteristic of neuroendocrine tumors (Figure 40.11; Figure 41.11). For unknown reasons these cells are fragile and rarely remain intact. A similar pattern is seen in apocrine gland tumors of the anal sac. Cells may have a "fried egg" appearance (centrally placed nucleus surrounded by cytoplasm) similar to MCT cells. Mild variation in nuclear size (anisokaryosis) may be noted at higher magnifications. Nuclear chromatin is fine, and a single nucleolus is often visible.

Neuroendocrine tumors can usually be diagnosed at lower magnifications because of the characteristic uniform appearance of numerous round nuclei and the clinical information of where the mass is located. Cytoplasmic neuroendocrine granules are not typically visible. There are no definitive cytologic criteria to differentiate malignant vs. benign tumors.

Mesenchymal/spindle cell tumors

Introduction

The mesenchymal tumors include fibroma, fibrosarcoma, hemangioma, hemangiosarcoma, hemangiopericytoma, neurofibroma, peripheral nerve sheath tumor, myxoma, myxosarcoma, rhabdomyoma, rhabdomyosarcoma, undifferentiated sarcoma, vaccine-induced sarcoma, and vaccine-induced lesion. Examples of this group of tumors are found in this chapter as Figures 41.12–41.14, and Figures 40.1 and 40.9.

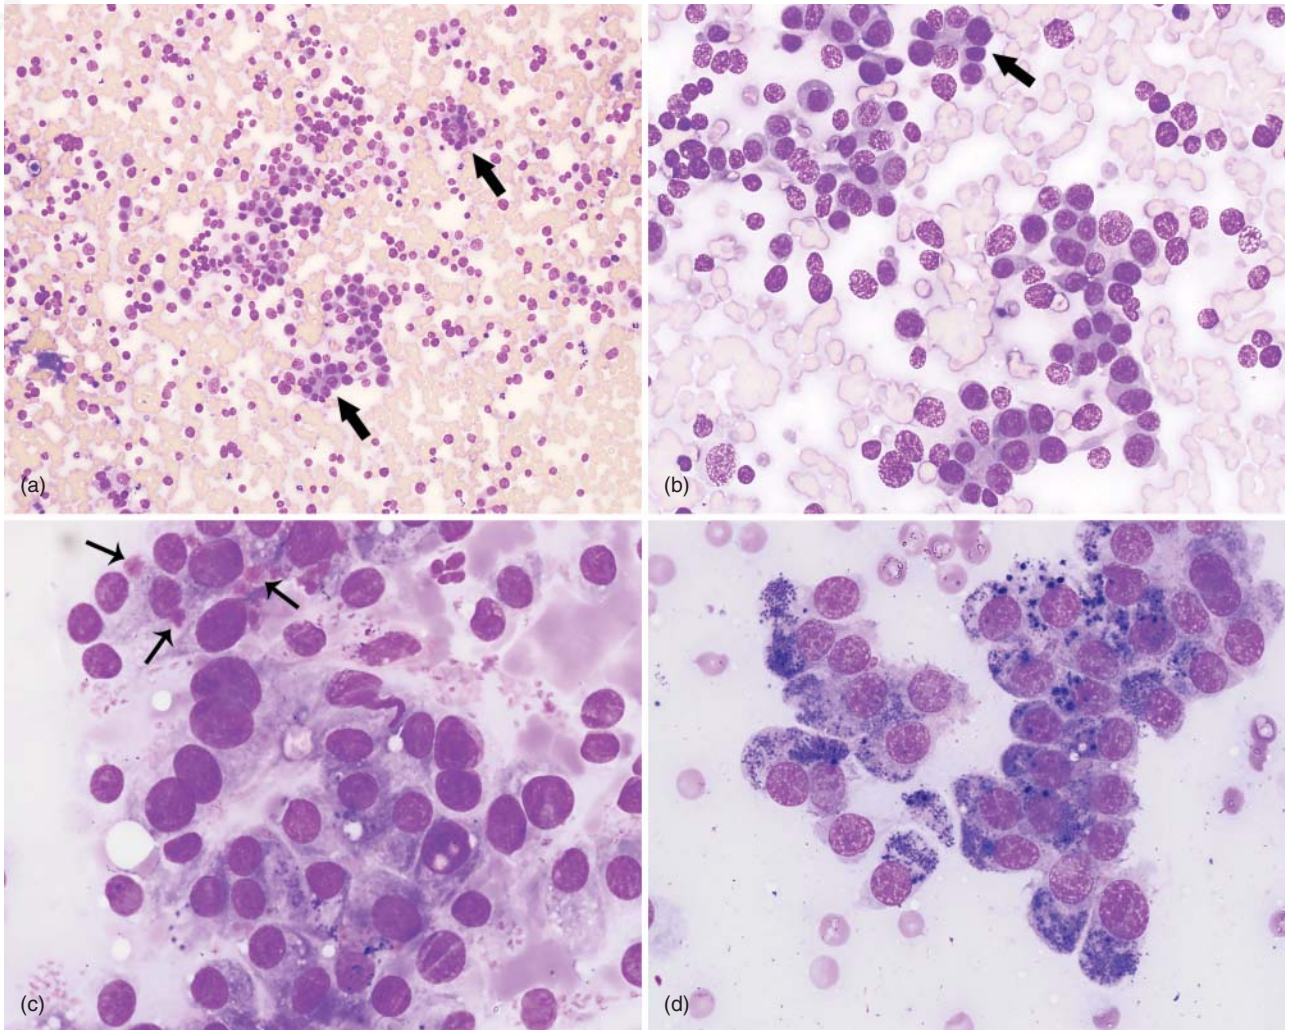

Figure 41.11 Thyroid tumor from dogs. Cells are organized in rows and clusters with acinar-like formation (a, b; arrows and Figure 40.11). Cytoplasm is often missing, leaving free, round nuclei (a, b). The small to moderate amount of cytoplasm stains lightly eosinophilic to grayish blue, and there may be green-blue intracytoplasmic granules consistent with lipofuscin (c, d). This lipofuscin pigment is positive to Schmorl's stain and is often mislabeled as thyroglobulin. Central or basilar nuclei are uniformly round or slightly oval. Colloid can be preserved between the cells (c, thin arrows). Despite their uniform appearance on cytology, all clinically detectable thyroid masses in dogs should be considered malignant. The tumor in (c) demonstrates more pleomorphic cytologic features characterized by variation in nuclear size and binucleation. The cells in (d) would be difficult to differentiate from normal thyroid cells, therefore look at many fields and use clinical data, e.g., mass is present in thyroid region. If a mass is palpable in the thyroid of a dog it is likely aggressive; the opposite is true for cats. (a) 20× objective, (b) 50× objective, (c, d) 100× objective. Wright-Giemsa stain.

Determining the exact identity of each of these tumors may not be possible using cytology. All available information should be considered when establishing a diagnosis. Tumors of mesenchymal origin tend to exfoliate poorly or at least yield fewer cells than do the round cell or epithelial tumors. This is attributed to their low cellularity and the presence of extracellular matrix that holds the cells together. However, less differentiated variants (more anaplastic) tend to have less extracellular matrix and more cells, and therefore may yield very cellular preparations. The key to placing cells in this category is to find cells or nuclei that are elongated. It is difficult to differentiate spindle cell tumors from fibroplasia (granulation tissue) with cytology alone. The quickest clue to identification is the absence of inflammatory cells and the predominance of oval or spindle-shaped nuclei. Several slides may need to be searched before enough cells can be found to evaluate. These tumors may require surgical excision and the "scrape" technique to produce enough cells to establish a diagnosis. The cells are individualized, and though they may be close together they do not form clusters, morulae or acini characteristic of epithelial cell tumors. When cells are closely opposed their true cell borders are rarely seen. Individual cells have distinct to barely discernible cell borders and their spindle shape is

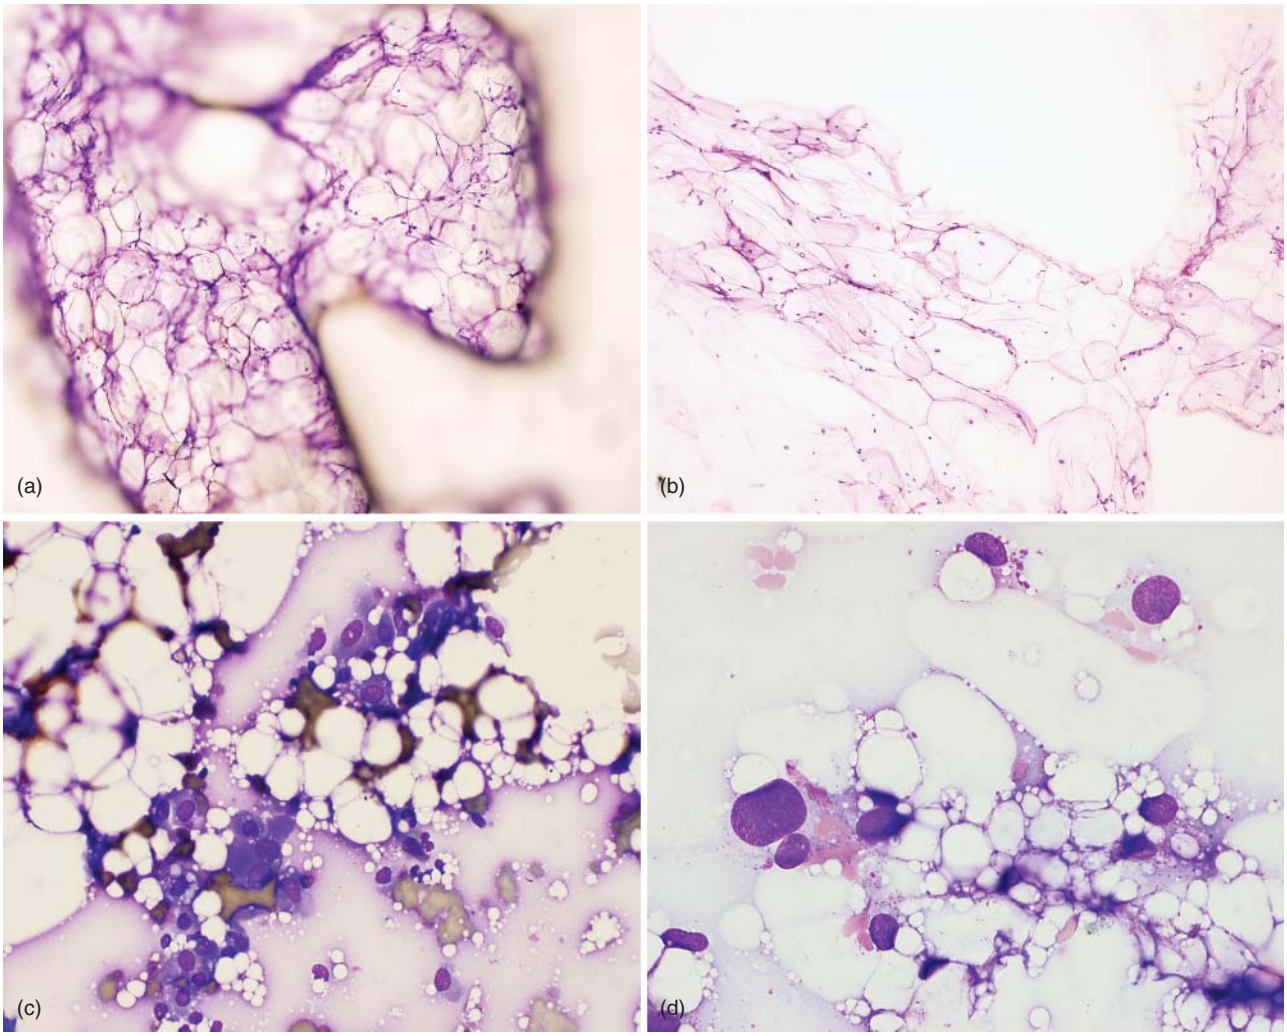

Figure 41.12 Lipoma (a, b) and liposarcoma (c, d) from dogs. (a, b) Lipoma: clumps of uniform adipocytes with large amount of cytoplasm and a small eccentric nucleus. Aspiration of subcutaneous fat will yield cells with a similar appearance. Therefore, the distinction must be made based on clinical findings, e.g., a mass is palpable in the subcutis. Histopathology is not needed to diagnose lipoma if the aspirate was taken from a soft subcutaneous mass. (c, d) Liposarcoma. This is a very rare tumor in animals yet is one of the most common soft-tissue mesenchymal (sarcoma) tumors in humans. The background contains numerous large and small, clear vacuoles of extracellular fat. Admixed are spindle cells with marked anisokaryosis, round to oval nuclei with finely stippled chromatin, and multiple, prominent nucleoli. There is no inflammation. (a, b) 10× objective, (c) 50× objective, (d): 100× objective. Wright-Giemsa stain.

usually easy to appreciate. The cytoplasm is light blue to gray or lightly eosinophilic; it follows the contour of the nucleus and therefore is elongated, oval-shaped, or streams at both ends to form points or a "tail." Sometimes the cells are plump with an angular, pointed cellular end that streams outward. Nuclear chromatin arrangement and nucleoli vary considerably. More cellular tumors tend to have multiple nuclei, multiple nucleoli and varying shapes and sizes to nuclei and nucleoli (features of malignancy). Multinucleation is a characteristic of more aggressive tumors.

Most of these tumors are relatively easy to classify as of mesenchymal origin but determination of malignant **vs.** benign is speculative as is their exact histologic origin. The following descriptions for the specific tumor types are subjective and are based on combining clinical and cytological features. Some cytologists believe lesions predominated by spindle cells should be described as "spindle cell tumor, spindle cell proliferation, fibroplasia or spindle cell tumor" and add the comment: "histopathology necessary for differentiation."

Histologic classifications of these tumors are in Table 41.1; however, as mentioned above, recognition of these individual types of tumors cannot be achieved with cytology. Histopathologic distinction of each of these tumors can also be difficult, requiring histochemical or immunohistochemical

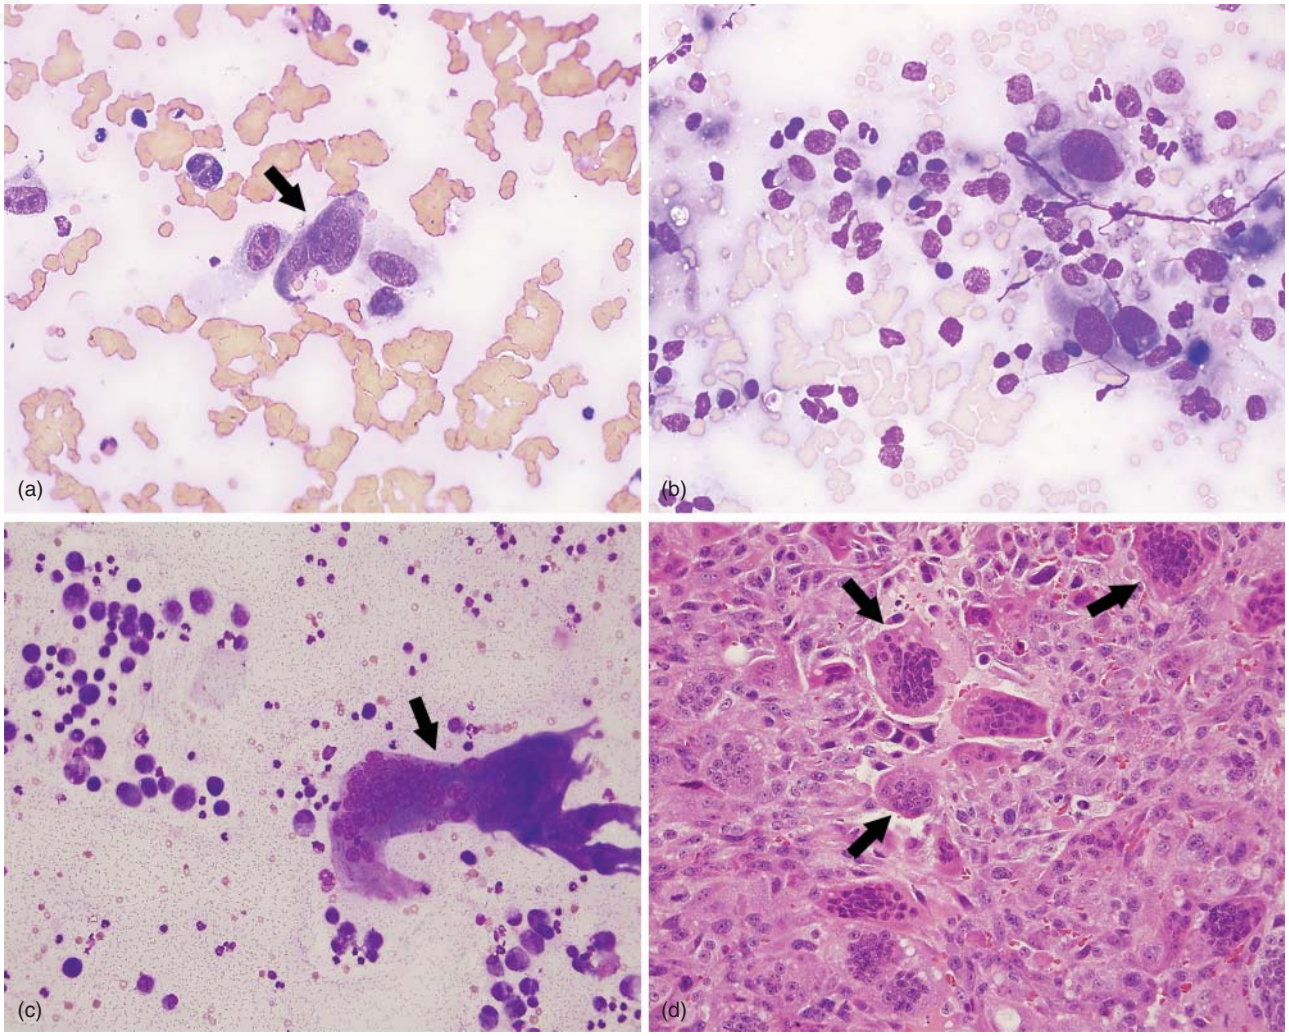

Figure 41.13 Fibrosarcoma (injection-site sarcoma) from cats. Note pleomorphic spindle cells exhibiting anisocytosis, anisokaryosis, and nuclei with multiple, large nucleoli. (a, c, d) These tumors can contain very large, multinucleated (>10–15 nuclei) cells (thick arrows). (b, c) Secondary inflammation, here indicated by the presence of lymphocytes, macrophages, and neutrophils, is a characteristic finding in these tumors. (a, b) 50× objective, (c, d) 40× objective. (a–c) Wright-Giemsa stain, (d) H&E stain.

stains [2, 6, 13]. Despite these generalizations some spindle tumors can be definitively diagnosed as far as subtype, and tumor behavior can be predicted. For example, lipomas are easy to recognize cytologically. Perivascular wall tumor (PWT, previously called hemangiopericytoma), is the most common spindle cell tumor in dogs and it has characteristic cytological features. Fibrosarcoma can also usually be diagnosed, especially in cats. All of the others can be categorized as spindle cell tumors, but recognition of the specific histologic type is not reliable. Therefore, a reasonable series of goals from cytologic evaluation of a mesenchymal tumor in the skin or subcutaneous tissues would be to first identify the process as neoplastic, then categorize it as spindle cell, then benign vs. malignant when possible, then a specific diagnosis (name of tumor), if possible.

Lipoma

Clinical features

Lipomas are very common subcutaneous tumors of middle aged to older dogs. They produce a bulging, nonulcerated mass in the subcutaneous tissues that is soft on palpation, although if they are in an area that is constricted by other tissue, they may feel firm. Tumors can be large, exceeding 12 cm in diameter and are often along the sides of thoracic and abdominal walls. They are uncommon to rare in cats.

A tentative diagnosis of lipoma can be made from how the mass palpates, and when material is squirted onto a glass slide numerous clear fat droplets can usually be observed.

Cytologic features

Initial interpretation at low magnification might be that nothing was aspirated as the slide appears devoid of cells.

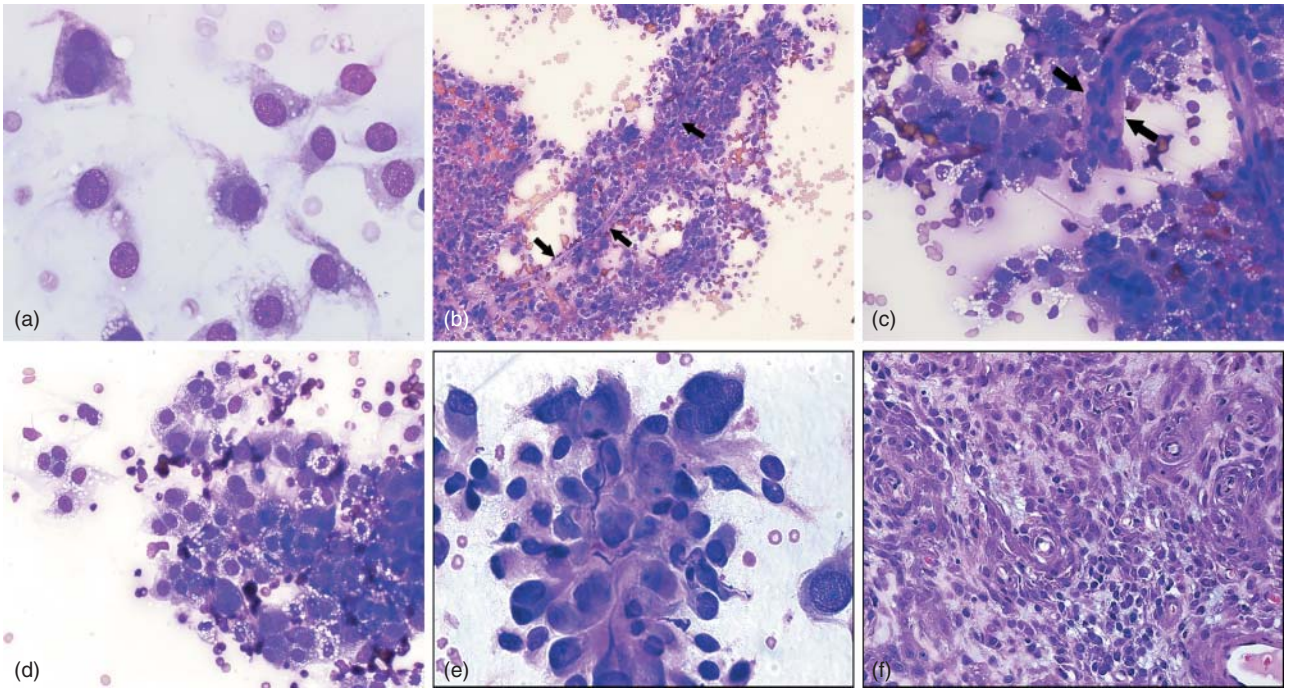

Figure 41.14 Soft-tissue mesenchymal tumors. (a–e) Fine-needle aspirates, (f) tissue biopsy and histopathology. (a) A spindle cell tumor from a subcutaneous mass from a dog. (b–f) Perivascular wall tumor (PWT). Unlike many other spindle cell tumors, fine-needle aspirates of these tumors yield very cellular preparations (b). Sometimes, vascular structures (capillaries) are aspirated as the tumor originates from cells lining the outer wall of blood vessels (arrows, b, c). Neoplastic spindle cells have long cytoplasmic "tails," often with "bipolar" pointed cellular ends (d, e). The cytoplasm can contain a few, small, discrete, clear lipid vacuoles (c, d). (f) Whorls of spindle-shaped cells are the most diagnostic feature of perivascular wall tumor (previously called hemangiopericytoma), best appreciated in biopsy specimens. (e) Source: Meuten DJ Tumors in Domestic Animals Ed 5, Wiley Blackwell 2017 p. 953–960; p. 957–959. (a, e) 100× objective, (b) 20× objective, (c, d) 50× objective, (f) 40× objective. Table 41.1 Benign and malignant (aggressive) mesenchymal (spindle cell) tumors.

Benign	Malignant
Lipoma	Liposarcoma
Fibroma	Fibrosarcoma
Perivascular wall tumor	
Hemangioma	Hemangiosarcoma
Myxoma	Myxosarcoma
Leiomyoma	Leiomyosarcoma
	Undifferentiated
[a]Nerve sheath tumors (NSTs)	

[a]Schwannoma, neurolemmoma, and neurofibroma are now lumped together as NST. Differentiation of these individual tumors is generally not needed and cannot be done cytologically or with routine histology.

By looking at areas that may look like debris, large vacuoles, and perhaps adipocytes may be observed. Adipocytes are very large cells with a nucleus that could be round or simply compressed over to the side of the cell and difficult to see (Figure 41.12a, b). In comparison to lipid-laden sebaceous cells (Figure 41.7c, d), the vacuoles in adipocytes are 5–20 times the size of the vacuoles in sebaceous adenoma cells. Adipocytes may appear as one large vacuole. Nuclei when seen are usually eccentric in adipocytes, unlike in sebaceous adenoma cells, where they are usually central in location. There is no inflammatory cell component with these tumors, although they sometimes contain numerous capillaries that are lined with cells that appear spindeloid. Histopathology is not needed for confirmation of the cytologic diagnosis, although if subcutaneous fat is aspirated, it can appear similar to a lipoma aspirate.

Liposarcoma

This is a rare tumor in all animals but one of the most common spindle cell sarcomas in humans. There are no unique clinical features.

Cytologic features

Numerous large and small clear lipid vacuoles within spindle-shaped cells are characteristic. Cell borders may not be readily discernible. Nuclei are round to oval to spindle-shaped. The cellularity is greater than that of a lipoma aspirate and nuclei have anaplastic feature (Figure 41.12c, d). Cytologic diagnosis of a liposarcoma should be confirmed

with histopathology. Differential cytologic diagnoses are sebaceous tumor or panniculitis. However, the tumor cells are not in clumps as is seen with sebaceous tumors, and there is no evidence of inflammation, as is seen with panniculitis.

Fibroma/fibrosarcoma

Fibromas exfoliate poorly and few cells will be on the slide. This is because the tumors do not contain many cells per unit area and those cells are firmly embedded in abundant collagenous matrix that connects the tumor cells. The cells are elongated, cytoplasm is light blue and nuclei are oval-shaped to round and are devoid of nucleoli (benign features). Aspirates of fibrosarcomas consist of numerous spindle cells with moderate to marked cellular and nuclear variability, including multinucleation. Fibrosarcoma aspirates are more cellular than aspirates of fibromas because the tumors do contain many cells per unit area and much less collagenous matrix. There may be a small amount of extracellular amorphous pink to eosinophilic material that resembles osteoid. This material is collagen (glycosaminoglycans). On careful inspection, eosinophilic to purple granules may be seen in a few cells.

Fibrosarcomas are more common in cats than dogs. They can be associated with injection sites as well as feline sarcoma virus in FeLV-positive cats.

Injection-site sarcoma/vaccine-induced lesion

Clinical features

Injection site sarcomas or lesions are recognized frequently in cats (Figures 40.9, 40.16, and 41.13). Originally, they were associated with vaccines but now are known to be associated with any injection, as well as chronic irritation and trauma. In fact, trauma-induced sarcomas have been reported in the eyes of cats. Most are in sites where injections are common, including the dorsum of the neck, between the shoulder blades, flank, rear limb, or chest wall.

Cytologic features

Lesions have a wide range of patterns that include pure inflammation to inflammation with preneoplastic changes, sarcoma, fibrosarcoma, and may or may not have accompanying inflammation (Figures 40.9c and Figure 41.13). When spindle cells with inflammatory cells are seen especially with extracellular, amorphous pink material that may be vaccine adjuvant, one should suspect a lesion of injection origin, with or without the historical information of location. The combination of anaplastic spindle-shaped cells, extracellular amorphous material, and location at the dorsum of the neck are very suspicious for this lesion.

Early lesions may contain only inflammatory cells with predominantly neutrophils but also numerous lymphocytes, plasma cells, macrophages and occasionally eosinophils; a few multinucleated giant cells and reactive fibroblasts may also be present. The lesions seem to then proceed through stages in which the inflammatory components decrease and the neoplastic changes increase, culminating in a clearly recognizable sarcoma. At the latter stage the lesions exfoliate numerous cells with a wide variety of cellular and nuclear abnormalities. Sometimes there are multinucleated giant cells with so many nuclei that they defy the pathologist's ability to count them all (hundreds in one extremely large cell) (Figure 41.13). Even at this latter state some inflammatory cells, especially lymphocytes and macrophages may remain (Figure 41.13b, c). The extracellular amorphous pink to purple, acellular material is interesting and highly suggestive of these vaccine-/injection-induced lesions. The composition of the extracellular material is unknown, but it may be of adjuvant origin. It is nonbirefringent and it resembles the cytologic appearance of ultrasound gel.

Predicting biologic behavior is best done by recognizing what the lesion is, and then relying on published case series that report they are deeply infiltrative, difficult to entirely excise and are notorious for recurrence but seldom metastasize to distant sites. Imaging studies sometimes demonstrate long fibrils that extend into deeper muscle layers and into vertebrae.

Hemangioma/hemangiosarcoma

FNA cytology of these lesions is frustrating as they tend to produce lots of blood and relatively few to no neoplastic cells (Figure 40.9d). If you are lucky to find any spindle-shaped cells it will be after carefully reviewing several slides and searching through a background of blood. The cells are spindle-shaped and plump but have no unique identifying features. Although these tumors are found in the skin, they are also commonly seen in the spleen and heart. Histopathology is a requirement for confirmation of this cytologic diagnosis.

Perivascular wall tumor/hemangiopericytoma/neurofibroma/peripheral nerve sheath tumors

These are different neoplasms that can be categorized under the terms *soft-tissue mesenchymal tumor (STMT)* or *soft-tissue sarcoma (STS)* (Figure 41.14). The latter term is popular but somewhat of a misnomer in that most tumors in this group are not aggressive and therefore are not sarcomas. Do not rely on cytology to distinguish these spindle cell tumors; even histopathology may require immunohistochemistry for definitive identification.

The most common canine STMT are the PVTs and 90% of these are not aggressive and do not metastasize [2, 6, 13]. They were previously diagnosed as hemangiopericytomas. They are found frequently on thoracic or pelvic limbs and occur in the subcutis on body walls. FNAs of these tumors yield preparations of relatively high cellularity, composed of distinctly spindle- or banana-shaped cells with long cytoplasmic "tails" (Figure 41.14b–e). They tend to have bipolar pointed cellular ends rather than only one pointed cellular

pole. They will be individual and in aggregates or whorls of 10–30 cells. Sometimes capillaries are aspirated as the tumor contains numerous blood vessels (Figure 41.14b, c). Whorls of spindle-shaped cells are the best diagnostic feature but are better appreciated in biopsy specimens (Figure 41.14f).

Cytology is very useful to establish a diagnosis of STMT and plan surgical removal. These tumors should be excised widely; they tend to recur but rarely metastasize. If treatment beyond surgical excision is planned or an estimate of survival is desired, then the excised tumors should be graded histologically. Excisional rather than core biopsy should be used for grading. However, the best predictors of behavior for PWT are size of tumor and depth of invasion of primary tumor. PWTs greater than 5 cm in diameter and/or tumors that have penetrated into deeper tissue layers are associated with more aggressive behavior, regardless of grade. Grading with histopathology uses mitotic count, percent necrosis and degree of differentiation to assign a grade of low or high. These grading schemes should be considered estimates of behavior as they are fraught with errors.

Low grade: recurrence rate of 25% after surgical excision, median ST of 118 weeks, 2% metastatic rate.

High grade: Recurrence rate of 62% after surgical excision, median ST of 49 weeks, 15% metastatic rate; however, the number of dogs in high-grade group with accurate follow-up information was very small [2].

Myxoma/myxosarcoma

These are uncommon tumors, found on the feet or legs of dogs. The best diagnostic feature is abundant background matrix (glycosaminoglycans or mucin) that is light blue, sometimes eosinophilic stippled (like joint fluid) or forming crescents and streams. The cellularity will be low and the cells may not spread into a monolayer due to the myxomatous stroma that adheres to the cells. This mucoid material may even cause the cells to align in rows (rowing). Rowing happens frequently in other viscous fluids such as normal synovial fluid or effusions due to feline infection peritonitis.

Differential diagnoses would include any of the other spindle cell neoplasms. Benign vs. malignant varieties cannot be determined cytologically and therefore should cytologic assessment should be confirmed with histopathology.

Rhabdomyoma/rhabdomyosarcoma

These are tumors of skeletal muscle, and occur on the legs, back and in somewhat other unusual locations including the dorsal laryngeal area, urinary bladder and tongue. Some tumors yield spindle-shaped cells and others have plump polyhedral cells that look epithelial or histiocytic. Rarely the tumor exfoliates elongated cells in which the cross-striations are still visible. Aspiration of normal skeletal muscle will produce broad muscle fibers in which cross-striations are seen easily. The nuclear density is less and the muscle fibers are wider in normal muscle. Benign vs. malignant behavior cannot be predicted cytologically and is difficult to impossible to accurately predict histologically. There are few long-term studies that have followed dogs with muscle tumors to determine their biologic behavior.

Undifferentiated sarcoma

This differential diagnosis is made frequently for STMT that are too undifferentiated to identify tissue of origin. Many of the features already described apply to this diagnosis. The preparations will vary from low to high cellularity, but the latter is more likely. The cells are individualized and in various shapes and forms, but some are clearly spindeloid. Plump cells that are polygonal, but with pointed streams of cytoplasm at one cellular pole, are enough for this designation. There will be moderate to marked cellular and nuclear variability or atypia. Binucleation and multinucleation are present, and various sizes, shapes and numbers of nuclei and nucleoli will further attest to the tumor's malignant nature.

Melanoma

Clinical features

Melanomas are common in the skin, toes, and oral cavity of dogs (Figure 41.15**)** and the perineum of gray Arabian horses. They are not as common in the skin of cats but are found with regularity in the eyes of cats. Most canine oral melanomas are malignant, but benign tumors, or at least tumors with low malignant potential, can be recognized with histopathology [14]. Skin melanomas in dogs and cats can be graded via histopathology to help predict malignancy and STs [15]:

	Canine melanoma		
Location	Skin	Skin	Oral
Mitotic count (MC)	<3	≥3	≥4
2-year survival	90%	25%	10%
Median survival	104 weeks	30 weeks	<4 months
Eventual death due to tumor	10%	45%	90%

MC was performed in 10 high-power fields (400× magnification but size of fields was not defined).

Cytologic features

Pigmented tumors are easy to diagnose; nonpigmented types are problematic. An interesting feature of melanomas is that they exfoliate in epithelial and mesenchymal patterns. If one sees both epithelial clusters and single spindle-shaped cells, or even round discrete cells, one should be suspicious of melanoma. If pigment is obvious the diagnosis is straight forward, and wide surgical excision with evaluation of margins via histopathology should be done. Pigment is intracellular

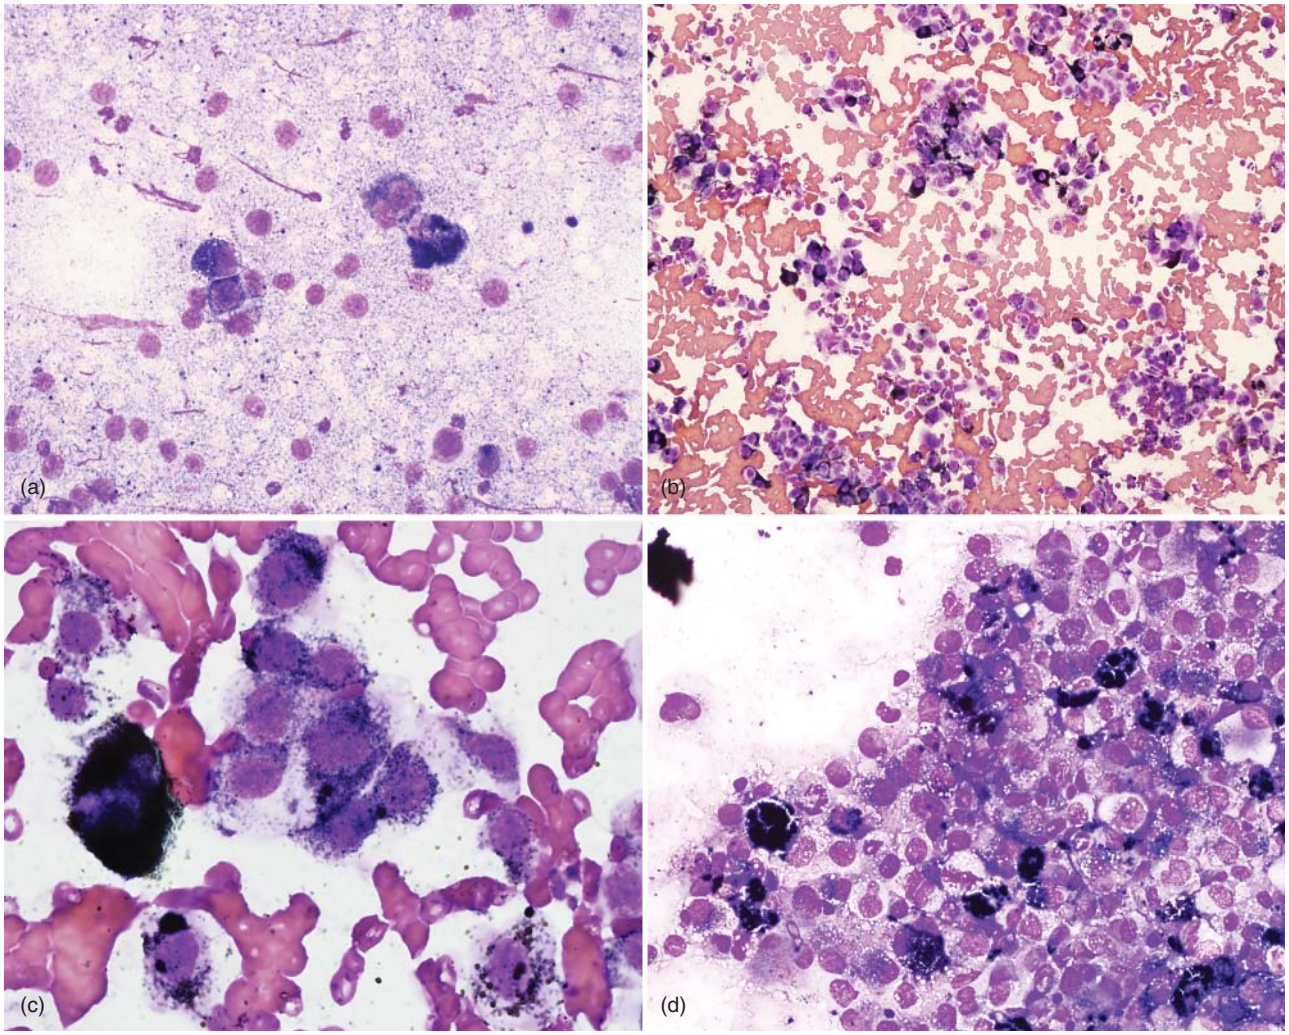

Figure 41.15 Canine melanocytic tumors, range of cytological patterns. (a) Cutaneous melanoma/melanocytoma, heavily pigmented individual cells, round nuclei; abundant pigment in background will make the slide black on gross inspection and the diagnosis easy. Histology is needed to assess biological behavior. (b, c) Digit melanoma, individual cells and aggregate of spindle-shaped cells with variable amounts of melanin pigment. (d) Metastasis in regional lymph node from an oral malignant melanoma; moderate to marked variability in cell and nuclear morphology; amount of pigment is highly variable (large black globules, small black granules, and some cells are devoid of pigment). (a) 50× objective, (b) 20× objective, (c) 100× objective, (d) 40× objective. Wright-Giemsa stain.

and is green to black (Figure 41.15). The granules can be uniform, small and needle like or can be globular and of variable sizes and shapes. If pigment is abundant it will also be extracellular. Tumors with abundant cytological pigment are usually black on gross inspection and the slides may be black. Hemangiomas may look red or black on gross examination as well. Place a cut surface of the tumor on a white paper towel and if the paper turns red it most likely is a hemangioma; if it turns black it is likely melanoma. True amelanotic melanomas are uncommon. Pigment can almost always be found but it may require diligent searching at higher magnifications 400× (40× objective) or with oil immersion (1000×). Poorly pigmented tumors will have a small amount or dusting of light green/yellow/brown pigment in a few tumor cells. Slides can be stained histochemically (Fontana Masson) and immunohistochemically (Melanin-A) at referral labs. If one sees large round cells with very large and distinct nucleoli ("owl eye" pattern) but no pigment, one should consider amelanotic melanoma and request special stains from the diagnostic lab.

Histiocytic sarcoma

This tumor is rare in cats; it can occur in any breed of dog, but Bernese mountain dogs, flat-coated retrievers, Rottweilers, and golden retrievers are breeds in which histiocytic sarcoma (HS) is most commonly seen [16] (see also Chapter 40).

There are molecular diagnostic tests for HS based on deletion of tumor suppressor genes CDKN2A/B, RB1, and PTEN [17]. Histiocytic sarcomas are a disease complex with multiple subtypes: malignant histiocytosis, systemic histiocytosis, disseminated histiocytosis, hemophagocytic syndrome, histiocytic sarcoma, etc. The majority of these tumors arise from interstitial dendritic cells that are present in perivascular tissues; however, hemophagocytic histiocytic tumors arise from splenic macrophages [11]. The distinctive microscopic feature for this subtype is the presence of erythrophagocytosis (Figure 40.12d, e). A unique location for this tumor is in joints. Many previous diagnoses of synovial sarcoma are likely to have been HS. Skin and subcutaneous are the most common sites and the tumor may be singular or multiple and occasionally is widely disseminated. These latter varieties are highly malignant. Some dogs will be hypercalcemic.

Although HS is a mesenchymal tumor, the tumor cells are not spindle-shaped; in fact, they look cytologically like a pleomorphic round cell tumor (Figure 40.12). Most HS are easy to diagnose because the tumor cells exfoliate in large numbers and the neoplastic cells have abundant cytoplasm that contains one to numerous nuclei. Multinucleated giant cells are characteristic. Nuclei and nucleoli are highly variable in number, size, and shape. Aggressive plasma cell tumor (Figure 41.5d) is a differential diagnosis but if giant cells, multinucleation, bizarre nuclei and nucleoli are numerous, then HS is more likely than plasma cell *tumor*. A definitive way to distinguish these two tumors is to request immunocytochemistry with antibody to MUM-1, which will stain plasma cells positively but not histiocytic cells [18]. Immunohistochemical stains that recognize histiocytic cells require special handling and expertise.

Non-neoplastic skin and subcutaneous lesions

Abscess

Aspirates of abscesses consist of predominantly neutrophils, and usually a few macrophages. Neutrophils are degenerative and, depending on the degree of sepsis, the bacteria may be infrequent or numerous, both intracellular and extracellular. Sometimes the degenerative features are so severe the neutrophils appear to be macrophages. The nuclei may be markedly swollen and round and cell and nuclear features are indistinct. Inflammatory lesions are discussed in detail in Chapter 39.

Hematoma and seroma

Clinical features

Hematomas present as a soft, fluctuant, nonpainful swelling in a location that is easily traumatized such as the ear. Aspirated fluid may be red, pink, orange, or yellow in color. Recent hematomas contain blood that appears similar to venous blood. As the blood in the hematoma is resorbed and the erythrocytes are phagocytized by macrophages, the color changes from red to yellow (seroma) and the transparency goes from cloudy to clear (seroma). The viscosity of the fluid increases as the hematoma is resorbed.

Cytologic features

The microscopic pattern varies as the lesion progresses from a hematoma into a seroma (Figure 41.16). Aspirates of recently formed hematomas appear similar to venous blood except that no platelets are seen and erythrophagocytosis by macrophages and occasionally neutrophils can be observed (Figure 41.16a, b). The platelets are activated during the bleeding process, are then incorporated into clot formation, and will not be visible cytologically. The presence of platelets, often found in clumps at the feathered edge of the film and lack of evidence of erythrophagocytosis indicates peripheral blood contamination, rather than a hematoma (Figure 41.16f). As the lesion ages, erythrophagocytosis will be more obvious, and the erythrocytes will be degraded. The iron complex (hemosiderin) resulting from the erythrocyte degradation appears as green, blue or yellow granules of varying sizes in the cytoplasm of the macrophages (Figure 41.16c). Hematoidin, a hemoglobin degradation product similar to unconjugated hemoglobin, forms later in the process and consists of intra- or extracellular yellow crystals that have a straight edge and are often in the shape of diamonds or rhomboids. Hematoidin is birefringent when viewed with polarized light and hemosiderin is not (Figure 41.16d, e). The nucleated cells will be a mixture of neutrophils and macrophages. Erythrophagocytosis can be in either cell but is predominantly in macrophages, especially in older hematomas.

As the lesion progresses into a seroma the gross color changes from red to yellow and it contains fewer cells. The macrophages may be inactive (blue gray cytoplasm with few to no vacuoles) or activated with increased amount of cytoplasm with foamy, vacuolated cytoplasm containing cellular debris. Seromas may develop independent of hematoma formation as a result of constant pressure. For example, seromas occur in dogs at sites subjected to constant bruising of tissues (elbow). The seroma fluid is high in protein and typically low in cell numbers. Macrophages are the principal nucleated cell found in seromas.

If the location, history and cytology are classic for a hematoma, such as on the ear, other differential diagnoses likely need not be considered. However, if you are suspicious that the cause of the hematoma could be neoplasia, then search for neoplastic cells, and consider excision or biopsy and histopathology.

Epidermal inclusion cyst (follicular cyst)

Clinical features

Epidermal inclusion cysts occur predominantly in dogs. The cysts arise from epidermal and adnexal structures. They vary

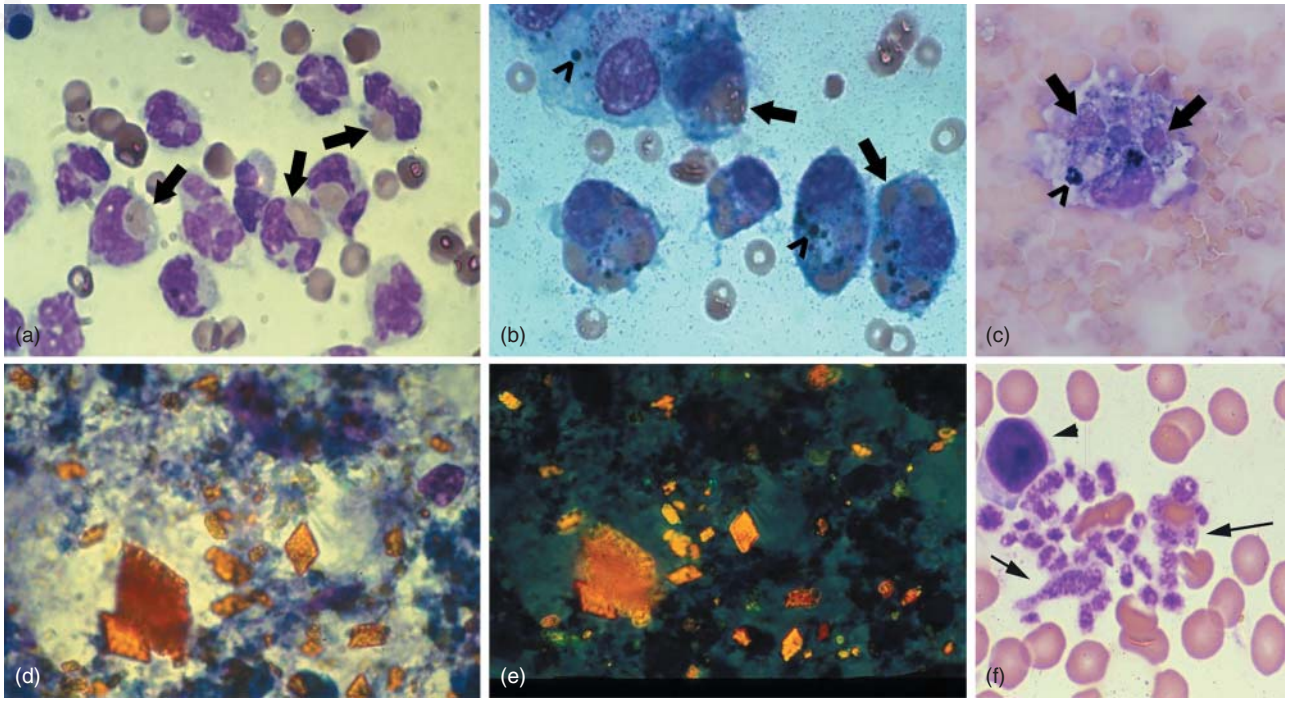

Figure 41.16 Hemorrhage (hematoma); early to later, starting with erythrophagocytosis (a–c, thick arrows) in neutrophils and monocytes in early lesions (a), followed by the presence of erythrophagia and hemosiderin (b, c; green-bluish globular pigment in macrophages, arrowheads). Hematoidin (d, e) forms after hemosiderin, and these golden, rhomboid crystals are birefringent when viewed with polarized light (e). Platelets (f, arrows) are *not* seen in hematomas, even in very early stages. They indicate aspiration of a blood vessel but not true hemorrhage. (a–f) 100× objective. Wright-Giemsa stain.

in size and consistency but often are 1–3 cm in diameter and are soft on palpation. Yellow-white to gray-tan "tooth-paste" like material oozes from them or can be expressed through a pore or can be aspirated into a syringe. Expressing the material through a pore may push the contents into the adjacent tissues resulting in an inflammatory reaction and causing the lesion to expand. The pasty and caseous accumulations range from white, gray to black in color, and may be oily in consistency. Lesions that are traumatized (spontaneous or iatrogenic) can be inflammatory and painful. The cysts are lined by squamous epithelium; the cells cornify, slough into the center and the lumen is filled with keratin (Figure 41.17). Pigmented epithelial cells cause the accumulations to become discolored, even black, like that of comedomes. The cyst fluid or cellular accumulations that degenerate are rich in lipids. Cholesterol crystal formation is common to these lesions (Figure 41.17).

Cytologic features

Cytologic samples from these lesions range from cellular to hypocellular. Key to the correct diagnosis is the recognition of cholesterol clefts and plates, accompanied by numerous keratin bars, squamous epithelial cells, and sometimes macrophages with hemosiderin or hematoidin. The keratin and cholesterol crystals in these preparations occasionally do not stain well but can be better visualized by reducing the size of the iris diaphragm or lowering the condenser. The cholesterol crystals are best seen using the 10 or 20× objectives; they appear as large, semiclear plates with straight edges. At 200 or 400× you will see numerous keratin bars or keratinocytes. These cells usually stain deeply blue but can be gray and vary in number from few to numerous. The cells have sharp, linear borders, are often folded and nuclei are not visible. Some nucleated, viable squamous epithelial cells may be present, with or without intracellular melanin. Macrophages with phagocytosed material and hemosiderin can also be present. Lesions that rupture may have numerous neutrophils but cysts that are still intact contain few or no neutrophils. Once these cysts rupture, they are associated with a moderate to marked pyogranulomatous cellulitis.

Sialocele/mucocoele

Clinical features

Sialoceles are soft swellings located where there are salivary glands or salivary drainage ducts such as the ramus of mandible, intermandibular space, or under the tongue, and are quite common in dogs. They are formed from saliva that has leaked into the adjacent tissues or accumulated as a result of a blocked salivary duct. The aspirated fluid is usually quite viscous.

Cytologic features

These lesions can be diagnosed at low magnification (4–10× objective) by observing fairly large amorphous areas of

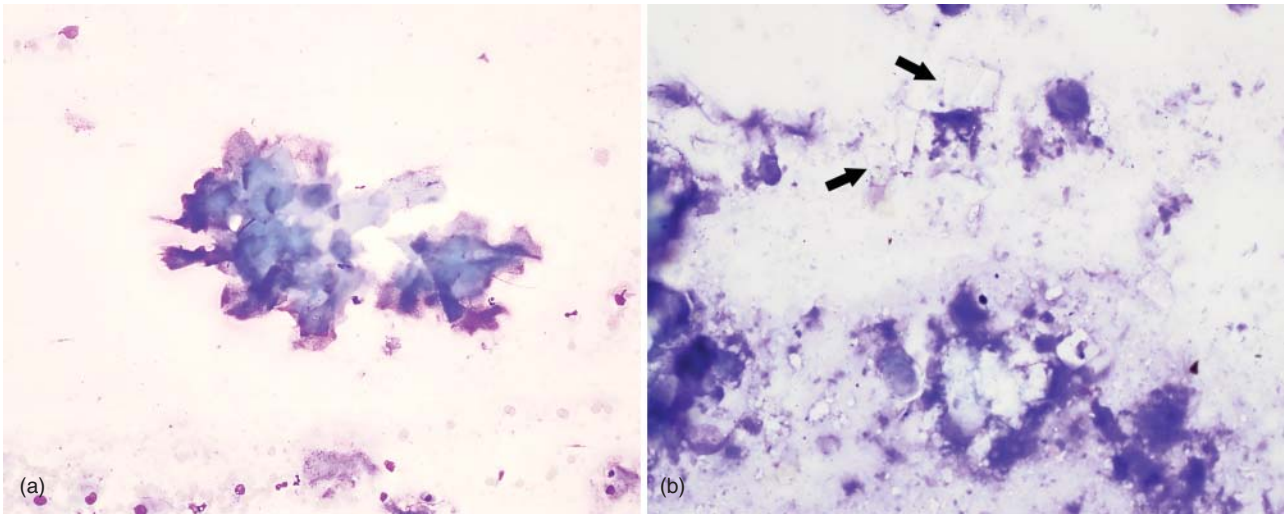

Figure 41.17 Epidermal inclusion cyst ("follicular cyst") from a dog. (a) Aggregates of superficial, anucleate squamous epithelial cells (keratinocytes, "keratin bars") are characteristic for these lesions. (b) Keratin is often accompanied by cholesterol crystals (arrows), which result from cellular degeneration. When these cysts rupture, they may stimulate granulomatous inflammation. (a) 20× objective, (b) 50× objective. Wright-Giemsa stain.

acellular, homogenous, pink to blue-gray material, sometimes having a cloud-like formation. These "clouds" likely consist of salivary fluid that has congealed. The presence of this background material should not be overlooked as it is helpful in making a diagnosis. The material is sometimes better visualized by reducing the iris diaphragm. The cellular response is typically modest to low and consists primarily of macrophages and mucin-containing epithelial cells, as well as a few erythrocytes and neutrophils (Figure 41.18a, b). The fluid stimulates a variable inflammatory response. Fluid may gravitate into unusual locations, including the mediastinum. The cells observed are usually macrophages exhibiting marked phagocytic activity. Salivary epithelial cells may resemble macrophages but will have more cytoplasm and no cytophagia. The high viscosity of the fluid may prevent cells from laying flat and therefore the neutrophils may appear as dense blue mononuclear cells. Examination of the preparation in thinner areas will help with the identification of neutrophils. The salivary epithelial cells have abundant cytoplasm with numerous clear vacuoles and variable numbers of distinct purple granules (mucous). The nucleus: cytoplasm ratio is low, often as low as 1 : 5. Macrophages are not as large, they are also vacuolated and often phagocytic, sometimes containing erythrocytes, neutrophils, or hemosiderin. Hematoidin crystals are products of intracellular digestion of rbcs that appear after hemosiderin and are commonly seen in aspirates of sialoceles (Figure 41.18b).

Sialodenosis

Clinical features

Sialodenosis is a clinical entity characterized by noninflammatory, non-neoplastic, idiopathic, usually bilateral enlargement of the mandibular salivary glands in dogs [19]. The salivary glands are sometimes clinically mistaken for enlarged lymph nodes. Clinical signs may include retching and gagging that is responsive to phenobarbital therapy.

Cytologic features

Aspirates of the enlarged salivary gland consist of normal-appearing salivary gland epithelial cells. The salivary epithelial cells are arranged in sheets, are very uniform, and have abundant vacuolated cytoplasm.

Salivary gland infarction

Clinical features

This is either an uncommon lesion or it is diagnosed incorrectly. Salivary gland infarction is more common in younger than older dogs.

Cytologic features

The glands will contain squamous cell metaplasia of the ducts, which has been misinterpreted as SCC. The squamous cells will be large and dysplastic and it is easy to assume they are part of a SCC. Invariably there will be considerable inflammation. Additionally, dead, necrotic material will be admixed with the viable squamous epithelial cells and neutrophils. The main differential is neoplasia; however, salivary gland neoplasia is not common in dogs and cats. Therefore, one should be certain the cellular changes are highly consistent with neoplasia before diagnosing a salivary gland SCC or salivary adenocarcinoma, as the lesion may actually be a salivary gland infarct with squamous metaplasia. The squamous cells in an infarct will be in clusters or sheets but the cells will not have the marked cellular and nuclear pleomorphism that characterize SCC. Many cells are

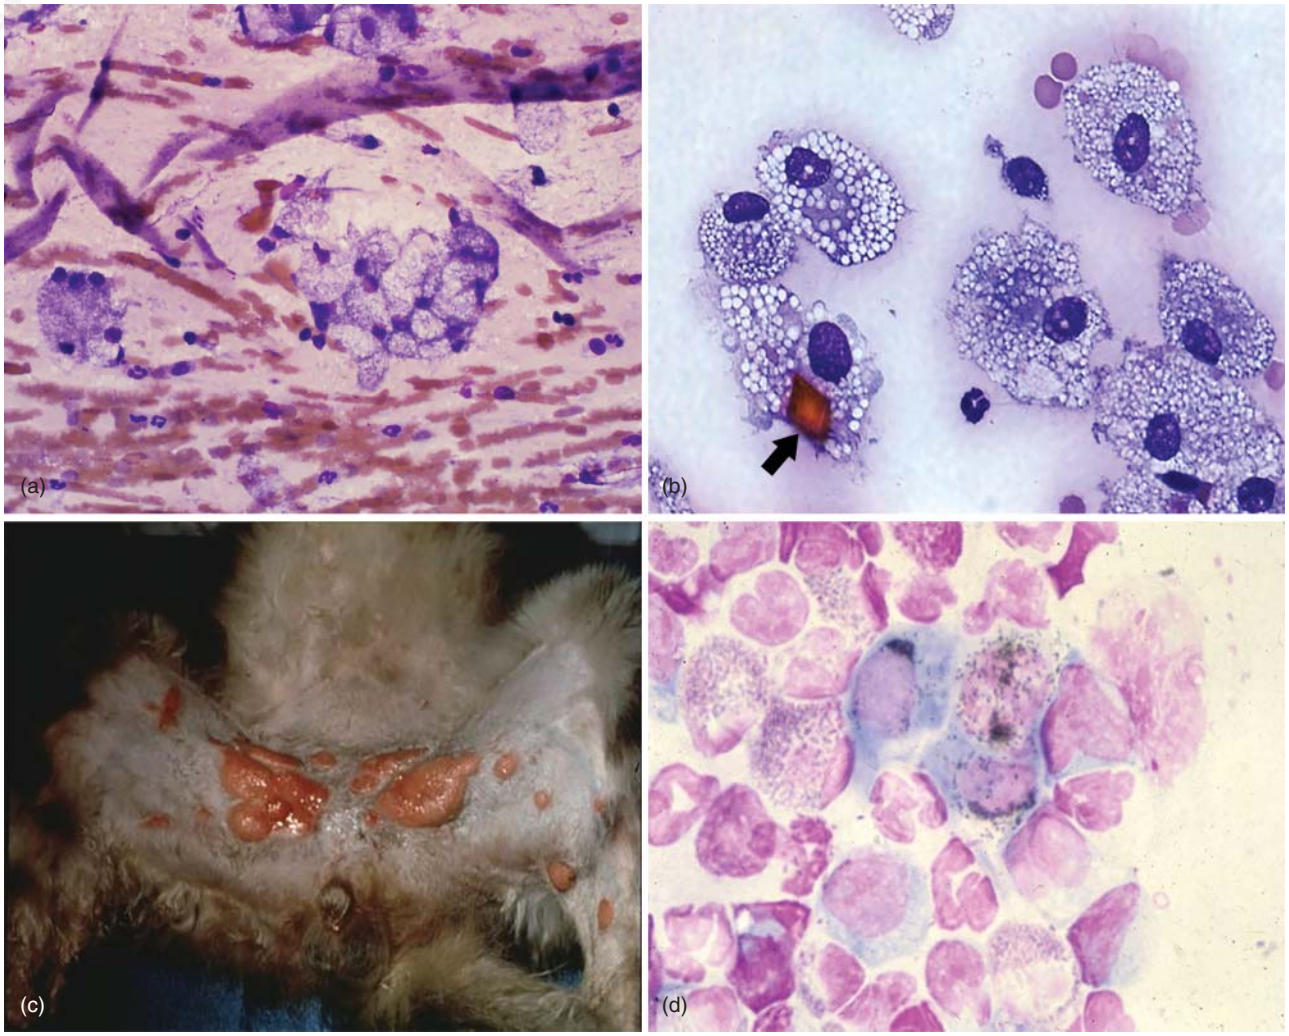

Figure 41.18 (a) Small clusters of uniform salivary gland epithelial cells from a dog with sialocele. Note the abundant, foamy cytoplasm of the epithelial cells, the pink stippled, mucinous background, and lining-up of erythrocytes ("rowing") indicating the presence of thick, viscous fluid (saliva in this case). Mildly increased numbers of neutrophils are consistent with inflammation. (b) Golden, rhomboid hematoidin crystal (arrow) in a macrophage is associated with prior hemorrhage and a frequent finding in sialoceles. (c, d) Cat with eosinophilic granuloma complex. Note the lavender granules within feline eosinophils (d) aspirated from the lesion in (c). Compare to green-black melanin pigment present in pigmented epithelial cells in the center of the image. (a) 50× objective, (b, d) 100× objective. Wright-Giemsa stain.

necrotic. Treatment is surgical excision; histopathology can be used to confirm the diagnosis.

Eosinophilic granuloma

Clinical features

Eosinophilic granulomas occur in the oral cavity and the skin of cats. They are most commonly located on the lips, abdomen, groin and along the pelvic limbs (Figure 41.18c). A similar oral lesion is seen in Siberian huskies.

Cytologic features

Eosinophils will make up greater than 25% of the nucleated cells and may predominate (Figure 41.18d). Mast cells can be numerous but will not be more common than eosinophils. Other cells present in smaller numbers include macrophages and lymphocytes. Fibroblasts may be present in low numbers and some may appear anaplastic. MCT is the main differential; however, eosinophils will not be as plentiful in MCT as they are in eosinophil granulomas (Figures 40.7 and 41.18d). Furthermore, eosinophils are not as prevalent in feline MCT as they are in canine MCT. Other differentials are hypersensitivity reactions secondary to insect bites/stings and parasites.

The diagnostic features of eosinophilic granuloma are that the patient is a cat, location of lesion, and numerous eosinophils present in cytologic preparations.

42 Cytology of Body Cavity Effusions

Robin W. Allison
Department of Veterinary Pathobiology, Oklahoma State University College of Veterinary Medicine, Stillwater, OK, USA

Effusions that develop in the peritoneal or pleural cavities are generally considered indicators of an underlying pathologic or physiologic process rather than a primary disease. Effusions are easily sampled, allowing for analysis that may provide a specific cause for the effusion or, more commonly, categorize the effusion such that a list of differentials can be prioritized. Healthy dogs and cats have a small amount of fluid present in the peritoneal and pleural cavities that is of insufficient quantity to sample. It is possible, however, to obtain a fluid sample from the peritoneal or pleural cavities of healthy horses and cattle.

Sample preparation

Fluid samples should be collected using aseptic technique and an aliquot placed into two tubes: a purple top blood collection tube containing EDTA and a sterile red top blood collection tube. Fluid from the EDTA tube is best for cytologic evaluation, obtaining nucleated cell counts and total protein estimation. Fluid from the sterile red top tube may be used for bacterial or fungal culture and ancillary biochemical testing, if needed. Slides should be prepared and the remaining fluid should be refrigerated if sample processing is not immediate.

Smears for cytologic evaluation should be made shortly after fluid collection. Slides should be air-dried completely, kept at room temperature, protected from formalin fumes, and stained within 3 days to prevent cell deterioration and staining artifacts. Direct smears are made from a well-mixed fluid sample using the same technique used for making blood films. Direct smears are usually adequate if the fluid has at least moderate cellularity (approximately 10,000 cells/μL); such fluid often appears cloudy. Fluids with low cellularity may be clear or hazy, in which case both a direct smear and a concentrated preparation should be evaluated. Many laboratories use a cytocentrifuge to concentrate fluid samples, but fluid samples can be processed in-clinic by centrifuging an aliquot of fluid in a conical tube, removing the supernatant, resuspending the cell pellet, and making a smear from the sediment (the same method used for processing urine samples). The concentrated preparation is best for evaluating various cell populations, while the direct smear is useful for estimating total nucleated cellularity.

Fluid analysis

Physical characteristics

The color and transparency of the fluid can be helpful to classify the effusion. For example, a clear, colorless sample typically has low nucleated cellularity and low total protein concentration, consistent with a transudate. Cloudy, red or pink samples frequently contain blood, which may indicate intracavitary hemorrhage or contamination during sampling. Opaque, tan or beige samples are generally highly cellular, often containing numerous inflammatory cells consistent with an exudate. Samples with a white or milky appearance may contain high concentrations of lipoproteins suggestive of chyle; these samples will continue to appear milky after centrifugation (Figure 42.1).

Total protein concentration

The fluid total protein concentration is used in conjunction with the total cell count to help classify the effusion as to potential etiology (Table 42.1). Fluids with low total protein concentrations and low nucleated cell counts are consistent with transudates, while exudates will have higher total protein concentrations and higher nucleated cell counts. Total protein is usually estimated using a refractometer. If the fluid is cloudy, the fluid should be centrifuged and the protein measured on the supernatant. Chylous effusions, containing high concentrations of lipoproteins that increase the refractive index, will often have artifactually increased total protein measurements.

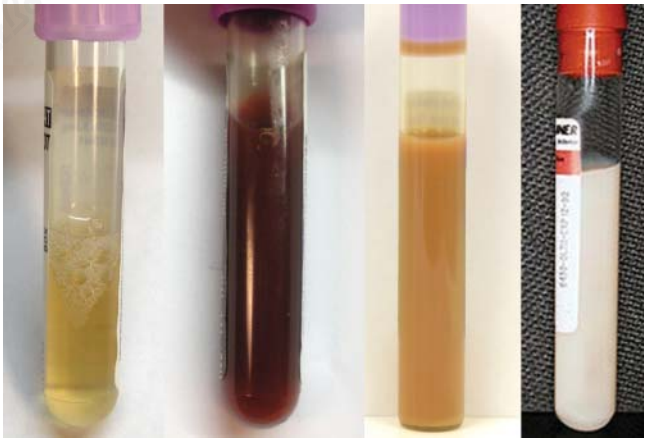

Figure 42.1 Physical characteristics of effusions may provide useful information. From the left, effusions shown here are (a) clear and pale yellow, consistent with a transudate; (b) cloudy and red, as seen with hemorrhage; (c) opaque and tan, consistent with an exudate; (d) milky white, suggestive of a chylous effusion.

Cell counts

Effusions may contain cells other than leukocytes, so it's preferable to refer to the nucleated cell count rather than leukocyte count. Nucleated cell concentrations can be determined with automated hematology instruments or by manual hemacytometer methods. If the fluid contains visible debris or clumped or clotted material, an automated method should not be used as tubing in the electronic cell counter may become clogged. Any clumping of cells will result in an artifactually decreased nucleated cell count. Often, however, estimation of nucleated cell numbers from microscopic evaluation of a direct smear is sufficient for clinical diagnostic interpretation. Erythrocyte concentrations will also be reported by automated analyzers, and a spun packed cell volume (PCV) is helpful to determine if a hemoabdomen or hemothorax is present.

Ancillary testing

In specific situations, additional tests can provide important diagnostic information. For example, if uroabdomen is suspected, creatinine and/or potassium concentrations can be measured in abdominal fluid and compared with serum concentrations. A summary of useful ancillary biochemical tests is provided in Table 42.2.

Cell types found in effusions

Mononuclear cells

This category includes macrophages, lymphocytes and mesothelial cells. These cell types are commonly present in low concentrations in cavitary effusions. Macrophages may appear quiescent, resembling large monocytes, or activated with abundant cytoplasmic vacuoles that may contain phagocytized cells, microorganisms or debris (Figure 42.2).

Table 42.1 Classification scheme for peritoneal and pleural effusions.

Classification	Total protein (g/dL)	Total nucleated cells/μL	Typical cell types	Comments
Transudate (protein-poor)	<2.5	<1500	Neutrophils, macrophages	Reactive mesothelial cells may be present.
Transudate (protein-rich)	>2.5	<5000	Neutrophils, macrophages	Reactive mesothelial cells may be present.
Exudate	>2.5	>5000 (dogs, cats) >10,000 (horses)	Neutrophils, macrophages, reactive mesothelial cells	Neutrophils may be degenerate. Microorganisms may be present. Mixed bacteria and plant material may be seen with gastrointestinal tract leakage.
Bile peritonitis	>2.5	>5000	Neutrophils, macrophages, reactive mesothelial cells	Bile pigment or mucinous material may be present.
FIP	>4	<5000	Neutrophils, macrophages	Prominent proteinaceous background present.
Chylous	>2.5	Variable	Small lymphocytes, finely vacuolated macrophages	Neutrophil numbers increase with time. Total protein often artifactually increased.
Uroperitoneum	<2.5	Variable	Neutrophils, macrophages, reactive mesothelial cells	Neutrophils may appear degenerate. Bacteria absent unless urinary tract infection exists.
Hemorrhagic	>2.5	Variable	Erythrocytes, leukocytes from peripheral blood	Platelets absent unless hemorrhage is acute or ongoing.
Neoplastic	Variable	Variable	Neoplastic cells (lymphocytes, mast cells, epithelial cells, mesothelial cells)	May have concurrent inflammation and reactive mesothelial cells.

Table 42.2 Selected ancillary tests for peritoneal and pleural effusions.

Parameter	Suspected condition	Expected results
α_1-acid glycoprotein (AGP)	FIP	Effusion AGP >1500 µg/mL
Albumin-globulin ratio (A : G)	FIP	Effusion A : G <0.9
Creatinine	Uroperitoneum	Effusion creatinine ≥2× serum creatinine
Potassium	Uroperitoneum	Effusion potassium >1.4× serum potassium
Total bilirubin	Bile peritonitis	Effusion bilirubin ≥2× serum bilirubin
Triglyceride	Chylous effusion	Effusion triglyceride > serum triglyceride Effusion triglyceride >100 mg/dL

Normal small to intermediate sized lymphocytes have a similar appearance to lymphocytes in peripheral blood, and are often the predominant cell type in chylous effusions. Reactive lymphocytes with more abundant deeply basophilic cytoplasm may be present as part of an inflammatory process. If lymphocytes are predominantly large cells containing nuclei with dispersed chromatin and nucleoli, lymphoma should be suspected (see Chapter 45).

Mesothelial cells, which line the peritoneal and pleural cavities and cover the viscera, frequently exfoliate into effusions. They are large round cells with a round nucleus and moderately abundant basophilic cytoplasm. Cytoplasmic borders may show a distinct pink fringe or cytoplasmic blebs

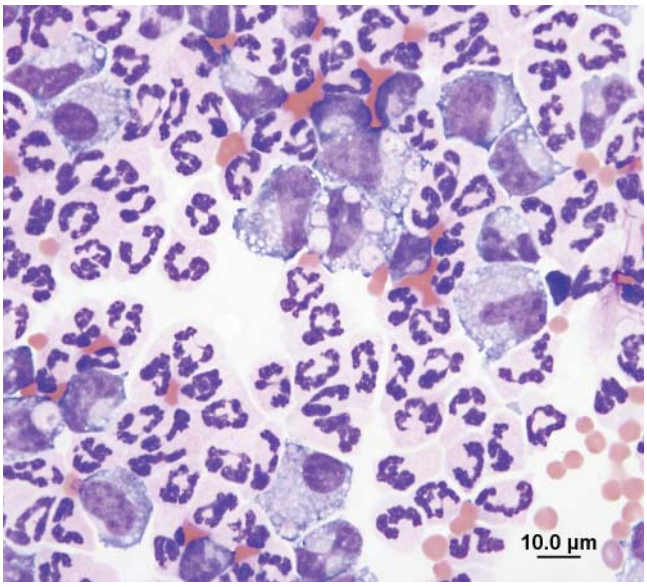

Figure 42.2 Nondegenerate neutrophils and macrophages, peritoneal effusion, horse (concentrated preparation). Neutrophils have dense chromatin and distinct segments; a few have become hypersegmented (an aging change). Macrophages have oval to indented nuclei with variable cytoplasmic vacuolation. Several macrophages contain phagocytized cell debris. Low numbers of erythrocytes are present in the background. Aqueous Romanowsky stain.

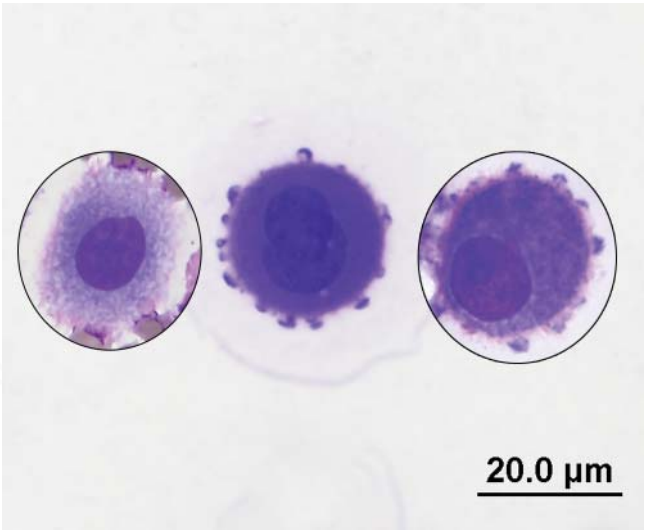

Figure 42.3 Mesothelial cells, pleural and peritoneal effusions, dog. Mesothelial cells have round to oval nuclei, may be binucleated, and often have a pink cytoplasmic fringe or cytoplasmic blebs. Aqueous Romanowsky stain.

(Figure 42.3). They are usually arranged individually or in small cohesive clusters. Mesothelial cells become hyperplastic and reactive whenever fluid accumulates in the pleural or peritoneal space, and especially when inflammation is present. Reactive mesothelial cells may be present in larger clusters and can sometimes be confused with neoplastic cells when they develop significant criteria of malignancy, including prominent nucleoli, deeply basophilic cytoplasm, anisocytosis, and anisokaryosis (Figure 42.4). Cells in mitosis may also be observed. Reactive mesothelial cells, when present in large numbers, may be difficult or impossible to distinguish from carcinoma or mesothelioma (discussed later). Fortunately, mesothelial cells are usually present in small numbers.

Neutrophils

A few neutrophils are often present in effusions, but the concentration can increase dramatically with inflammation.

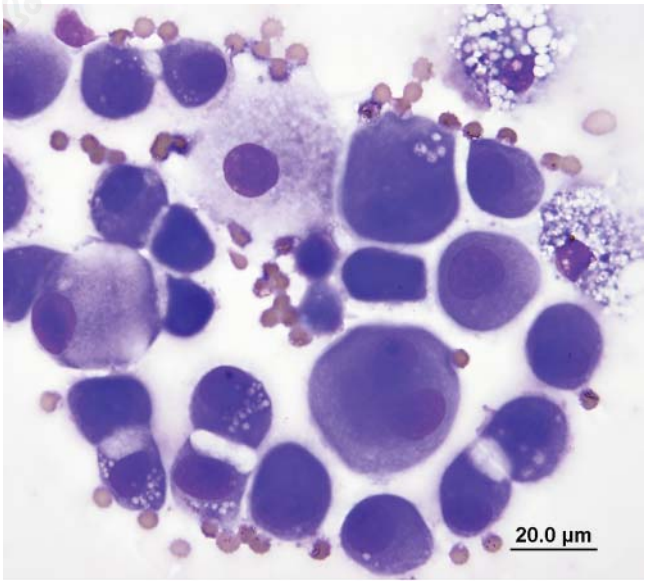

Figure 42.4 Reactive mesothelial cells, peritoneal effusion, dog (concentrated preparation). These reactive mesothelial cells are present individually and in small cohesive clusters. The cells have multiple criteria of malignancy including anisocytosis, anisokaryosis, and binucleation with prominent nucleoli, which raise suspicion for neoplasia. Two highly vacuolated activated macrophages are present in the upper right corner, and there are low numbers of erythrocytes in the background. Aqueous Romanowsky stain.

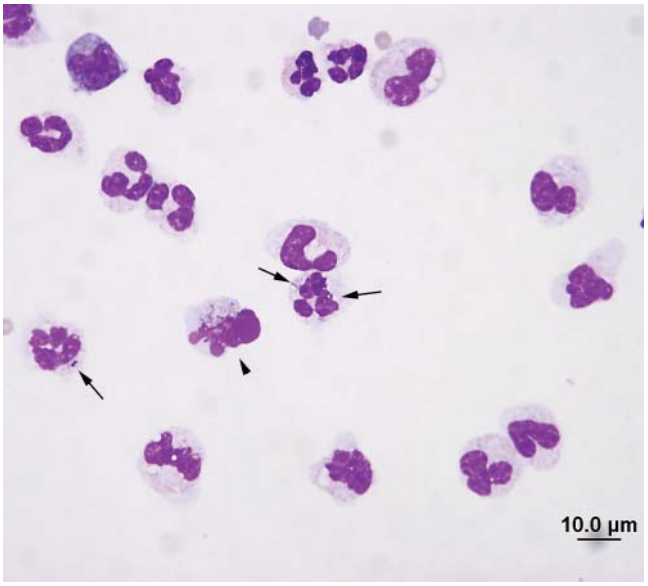

Figure 42.5 Degenerate neutrophils, peritoneal effusion, horse. Most of these neutrophils are degenerate with swollen nuclei that lack distinct segmentation. One nucleus has lysed (arrowhead). Two cells contain phagocytized bacteria (arrows), making this a septic exudate. Aqueous Romanowsky stain.

The morphology of normal, nondegenerate neutrophils in effusions is similar to that of neutrophils in peripheral blood. Nuclear chromatin is dense and segmentation is distinct (Figure 42.2). When neutrophils undergo normal aging within an effusion they become hypersegmented and pyknotic, and are eventually phagocytized by macrophages (cytophagia). Degenerate neutrophils have swollen nuclei that lose segmentation and stain pale pink; these cells may go on to disintegrate and become unrecognizable (Figure 42.5). Degenerate neutrophils suggest the presence of bacterial toxins. Neutrophils can also degenerate *in vitro*, and for this reason it is important to make smears of effusions prior to shipping to a diagnostic laboratory.

Eosinophils and mast cells

Eosinophils in effusions have the same morphology as those in peripheral blood and are usually few in number. The nuclei of aged eosinophils usually lose segmentations and become round. Increased eosinophil concentration (>10% of cells) may occur with a variety of underlying conditions including hypersensitivity disorders, parasitic infections, lung lobe torsion, heart failure, mast cell neoplasia, and some types of lymphoma (Figure 42.6) [1–3]. Mast cells have round nuclei and abundant cytoplasmic granules that stain dark purple with alcohol-based Romanowsky stains. Granules sometimes stain poorly or not at all with water-based (aqueous) Romanowsky stains (Figure 42.7) [4, 5]. Mast cells

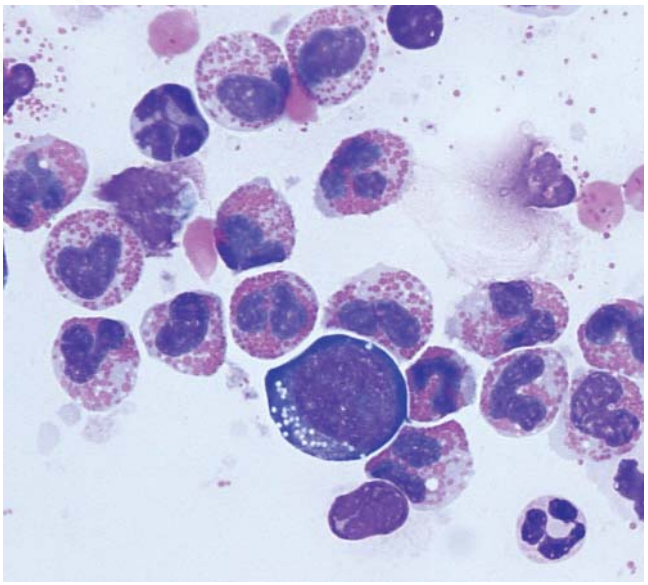

Figure 42.6 Eosinophils, peritoneal effusion, dog. Numerous eosinophils containing round, pink cytoplasmic granules are present. Granules are also seen free in the background, with few erythrocytes. A single large neoplastic lymphocyte contains a round nucleus with multiple nucleoli and has deeply basophilic cytoplasm containing a few vacuoles. This dog had lymphoma involving the mesenteric lymph nodes, liver, and intestine. Wright stain.

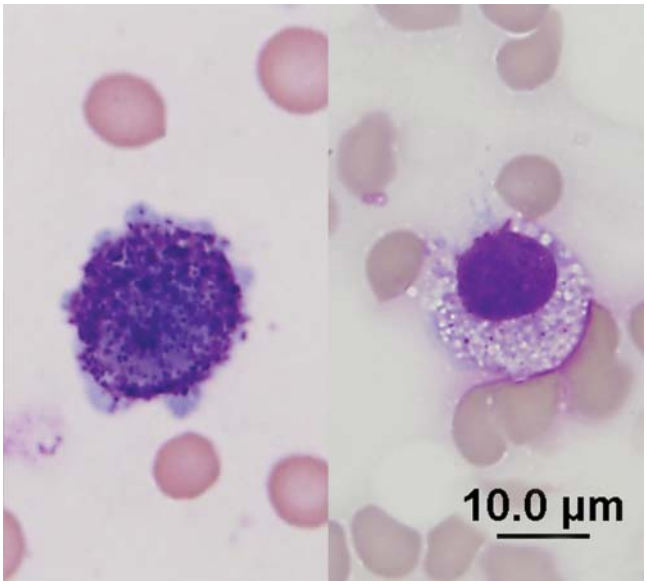

Figure 42.7 Mast cells, alcohol-based Romanowsky stain (left) and aqueous Romanowsky stain (right). Mast cells often contain abundant cytoplasmic granules that obscure the nucleus. These granules stain dark purple with alcohol-based Romanowsky stains but may stain poorly or not at all with aqueous Romanowsky stains.

may accompany many types of inflammatory conditions, but concentrations are generally low in effusions. Mast cell tumors within a body cavity can exfoliate large numbers of mast cells into an effusion, and cell morphology may be atypical (see Chapters 40 and 41).

Erythrocytes

Erythrocytes may be seen in large numbers whenever there is hemorrhage into a body cavity or when there is iatrogenic blood contamination at the time of sampling. Differentiating these situations is important and discussed in the section on hemorrhagic effusions. Inadvertent aspiration of the spleen will also result in a sample containing abundant blood.

Neoplastic cells

Tumors within the pleural or peritoneal cavities frequently cause effusions but do not always exfoliate neoplastic cells into the effusion. Tumor types most likely to exfoliate cells, and therefore be identified by cytologic evaluation, include lymphoma, mast cell tumor, carcinoma/adenocarcinoma, and mesothelioma. Details are discussed in the section on neoplastic effusions.

Effusion classifications and cytologic findings

Table 42.1 presents a classification scheme for peritoneal and pleural effusions that is based on total nucleated cell counts, total protein concentrations, and cytologic findings. Cutoff values used for total nucleated cell counts and total protein concentrations in the various categories of effusions vary by author [2, 6, 7]. Historically, the term "modified transudate" has been used to describe effusions that don't fit neatly into the transudate or exudate category based on nucleated cell counts and protein concentrations, but describing an effusion as a modified transudate has limited utility because of the wide variety of potential underlying disorders. It is preferable to use all of the effusion characteristics, including cytologic findings, to classify such effusions as specifically as possible.

Transudates

Transudates form secondary to decreased vascular oncotic pressure, increased hydrostatic pressure, or decreased lymphatic drainage [7]. Transudates can be further characterized as protein-poor or protein-rich.

- Protein-poor transudates (pure transudates): The most common cause is severe hypoalbuminemia, which may be associated with diseases such as protein-losing nephropathy or enteropathy and hepatic insufficiency or failure. Other potential causes include portal hypertension (presinusoidal or sinusoidal), portosystemic shunt and early cardiac insufficiency. Protein-poor transudates are clear and colorless with a low total protein concentration (<2.5 g/dL) and low total nucleated cell count (<1500/µL). Cytologically, the nucleated cells consist of mononuclear cells (macrophages, small lymphocytes, and mesothelial cells), and nondegenerate neutrophils. Mesothelial cells may become reactive if the effusion is long-standing.
- Protein-rich transudates: These effusions have also been referred to as modified transudates. They most commonly form secondary to congestive heart failure and portal hypertension (postsinusoidal). Increased hydrostatic pressure causes high-protein fluid to escape vessels in the lungs or liver. Protein-rich transudates may be clear to hazy with an increased total protein concentration (>2.5 g/dL) and low to moderate numbers of nucleated cells (<5000/µL) consisting of mononuclear cells and nondegenerate neutrophils. Mesothelial cells may be reactive.

Exudates

Exudative effusions form when inflammation alters capillary permeability. The underlying inflammation may be caused by infectious or noninfectious disorders such as bacterial, fungal, protozoal or viral infections, parasites such as *Mesocestoides*, pancreatitis, bowel or biliary tract rupture, organ necrosis and neoplasia. Exudates are hazy, cloudy or opaque with an increased total protein concentration (>2.5 mg/dL) and large numbers of nucleated cells (>5000/µL in dogs and cats or >10,000/µL in horses [8]). Nucleated cells are usually predominantly neutrophils, which may be degenerate, with variable numbers of macrophages and mesothelial cells (Figure 42.8). Cytology may allow differentiation of

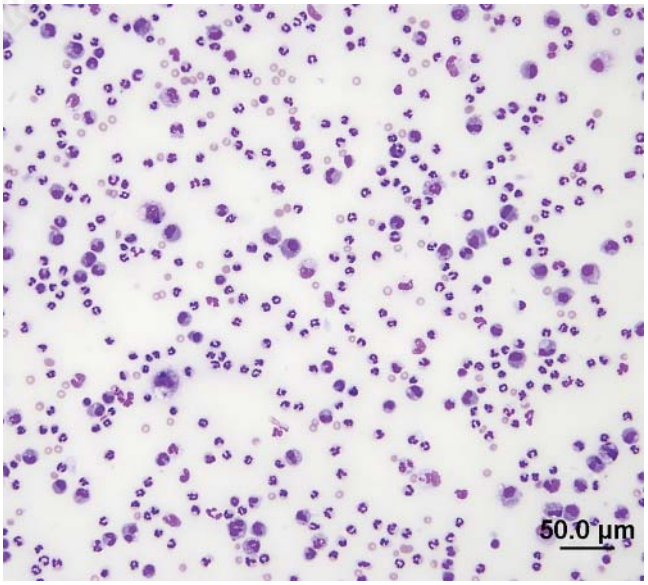

Figure 42.8 Exudate, pleural effusion, dog. This direct smear has high nucleated cellularity consisting predominantly of neutrophils with moderate numbers of macrophages, low numbers of small lymphocytes, and moderate numbers of erythrocytes. Some of the neutrophils are degenerate, so bacterial and fungal cultures would be recommended even in the absence of visible microorganisms. Aqueous Romanowsky stain.

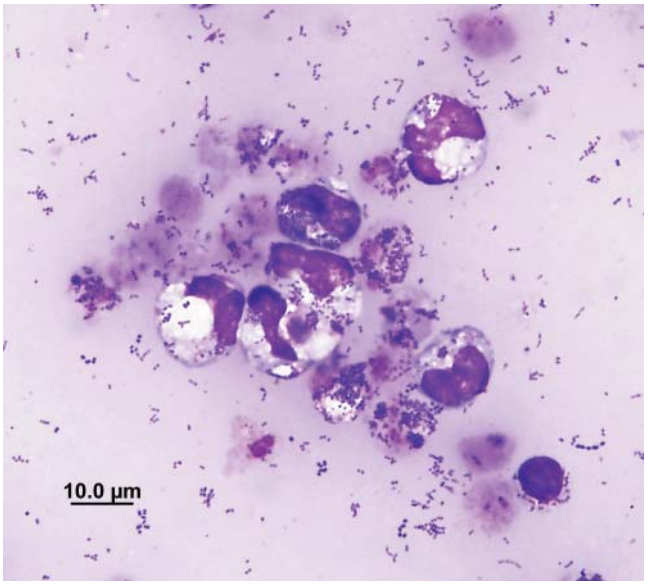

Figure 42.9 Septic exudate, pleural effusion, horse. Many bacteria are visible free in the background and phagocytized by leukocytes that are markedly degenerate (likely neutrophils). Bacterial culture identified two populations of bacteria (*Streptococcus zooepidemicus* and *Arcanobacterium pyogenes*). The nucleated cell count was 73,000/µL, and total protein was 5.5 g/dL. Aqueous Romanowsky stain.

specific types of exudates, discussed below. Bacterial and/or fungal cultures may be needed to identify specific infectious agents and may be useful to rule-out infectious causes when microorganisms are not visualized.

Septic exudates

Neutrophils are often degenerate, which should prompt close evaluation for the presence of microorganisms. In some cases, neutrophils may be so degenerate that most cells lyse, resulting in lower than expected total nucleated cell counts. Bacteria may be observed extracellularly or intracellularly, phagocytized by neutrophils and/or macrophages (Figure 42.9). Phagocytized bacteria must be seen in order to refer to an effusion as septic. In cases of infections secondary to penetrating foreign bodies or gastrointestinal leakage, a mixed population of bacteria (cocci, rods, spirochetes) may be evident. In addition to bacteria, other microorganisms that may be identified include yeast or fungi (such as *Histoplasma* spp., *Candida* spp., *Blastomyces* spp.) and protozoa (*Toxoplasma* spp., *Neospora* spp.) (see Chapter 39). Peritonitis related to *Candida* spp. has been recognized in dogs that had gastrointestinal or biliary tract leakage (Figure 42.10) [9]. In cases of gastrointestinal tract rupture or leakage, plant material (ingesta) and other fecal debris may be present in addition to a mixed bacterial population (Figures 42.11 and 42.12). Large ciliated protozoa (normal gastrointestinal tract flora) may be observed in peritoneal effusions from horses with gastrointestinal tract leakage (Figure 42.13).

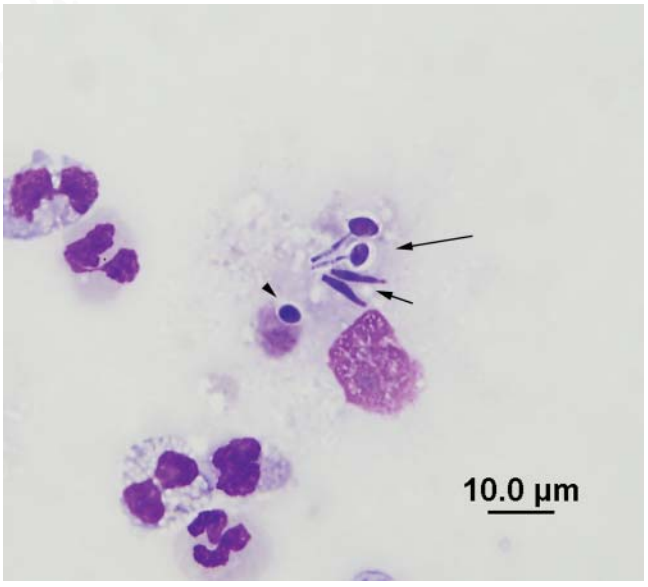

Figure 42.10 Fungal peritonitis, dog. Two hyphal structures (short arrow), two germ tubes emerging from yeast (long arrow), and one yeast form (arrowhead) are present extracellularly. Organisms were also seen phagocytized. Fungal culture grew *Candida albicans*, which was confirmed by polymerase chain reaction. This dog developed a fungal peritonitis following dehiscence of a previous intestinal resection site. Aqueous Romanowsky stain.

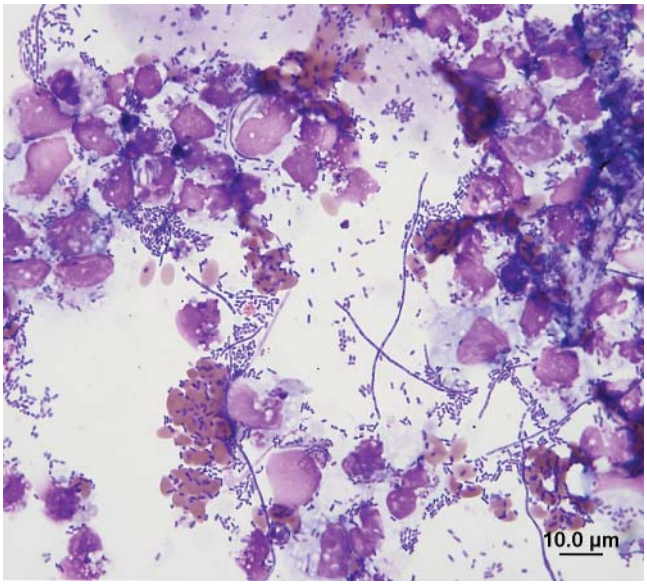

Figure 42.11 Septic exudate, peritoneal effusion, alpaca (concentrated preparation). Large numbers of mixed bacteria are present extracellularly and phagocytized by leukocytes. Leukocytes are degenerate and lysed, which makes them difficult to identify, but are most likely neutrophils. Low numbers of erythrocytes are present. The total protein was 2.7 g/dL, and the total nucleated cell count was 3000/µL, which is lower than expected likely because lysed neutrophils were not counted. This alpaca had an intestinal tract rupture resulting in septic peritonitis. Wright stain.

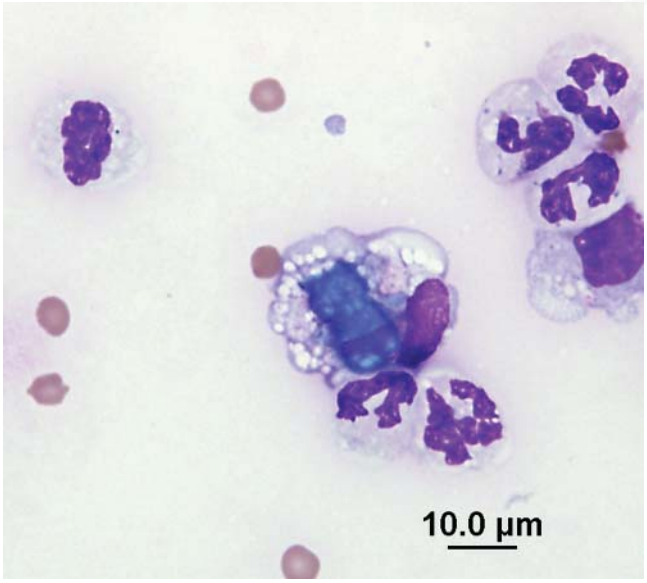

Figure 42.12 Plant material, peritoneal effusion, horse. The vacuolated macrophage in the center contains a large blue fragment of phagocytized plant material. Total nucleated cellularity was high, estimated at >200,000/µL from the direct smear. Neutrophils represented 74% of cells and were often degenerate. This horse had septic peritonitis caused by intestinal tract leakage. Aqueous Romanowsky stain.

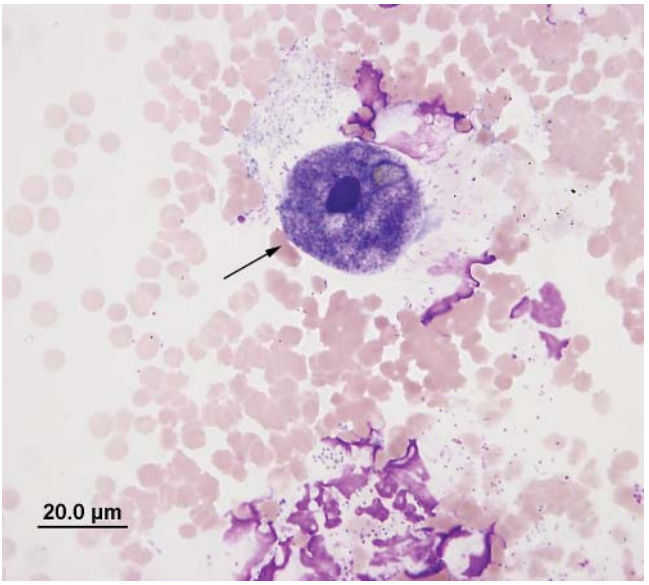

Figure 42.13 Ciliated protozoan, peritoneal effusion, horse (concentrated preparation). The arrow points to a large ciliated protozoal organism, which is a normal inhabitant of the intestinal tract. Neutrophils are degenerate and lysed, and there are numerous bacteria present intra- and extracellularly, with many erythrocytes in the background. These findings indicate septic peritonitis caused by intestinal tract leakage. The total protein was 4.7 g/dL, but the nucleated cell count was only 800/µL, probably because most of the neutrophils were lysed and couldn't be counted. Wright stain.

Accidental enterocentesis may also be a cause for the presence of mixed bacteria and ingesta in cytologic samples.

Bile peritonitis

Bile is a chemical irritant in the peritoneal cavity that causes inflammation. Bile leakage can occur because of damage to the gallbladder or bile duct, which may be secondary to underlying disorders such as bile duct obstruction, cholecystitis or cholangitis, mucocele formation, trauma, and biliary neoplasia. Grossly, the effusion may be orange, brown or green tinged from the bile pigments. Neutrophils are typically most numerous with variable numbers of macrophages. Bacteria or fungal organisms (*Candida* spp.) may also be present. Bile pigment may be visualized on cytologic preparations as amorphous blue-green to yellow-green extracellular material (Figure 42.14); such material may also be seen phagocytized by macrophages. Phagocytized bile pigment can be difficult to differentiate from hemosiderin in some cases. When bile peritonitis is suspected, measurement of effusion total bilirubin concentration may be useful; effusion total bilirubin concentration that is at least two times greater than the serum total bilirubin concentration supports biliary tract leakage (Table 42.2) [10, 11].

So-called "white bile" has been described in cases of biliary mucocele or bile duct ruptures [11]. This material is mucinous and does not contain the greenish bile pigment. Instead

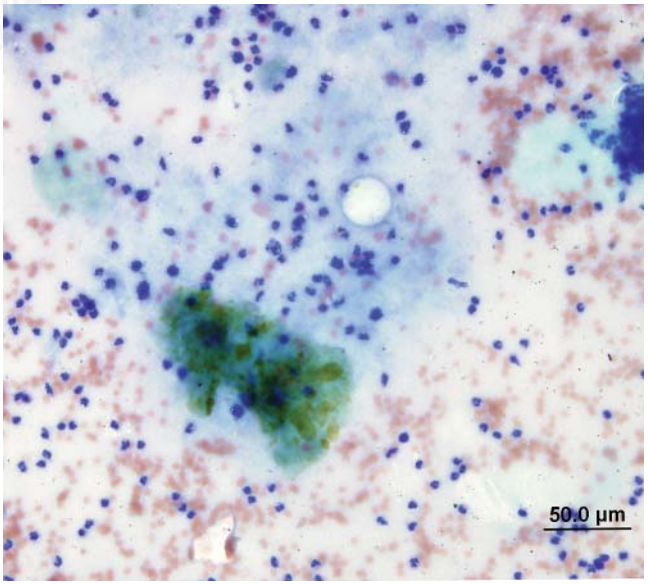

Figure 42.14 Bile peritonitis, dog. Nucleated cellularity is high and consists predominantly of neutrophils with many erythrocytes in the background. The green-yellow material is consistent with bile pigment, and the pale blue amorphous material is typical of mucinous "white bile." Aqueous Romanowsky stain.

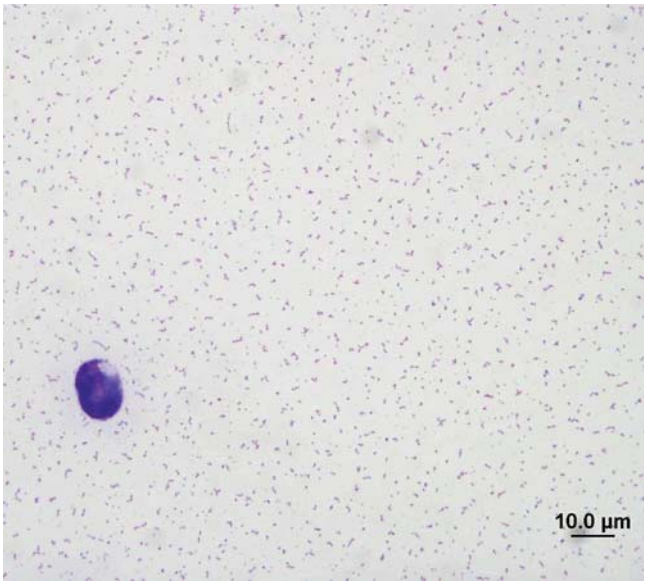

Figure 42.15 FIP, abdominal effusion, cat. One macrophage is present in a prominent pink, stippled background consistent with a high protein concentration. The pink protein precipitates should not be confused with bacteria, which stain blue with routine cytologic stains. The total nucleated cell count was 300/µL, the total protein was 6.0 g/dL, and the A : G ratio was 0.3. Aqueous Romanowsky stain.

it appears as lakes of pale basophilic amorphous material, usually seen in the background of the smear (Figure 42.14). The effusion is typically exudative, but effusion total bilirubin concentration is not always greater than the serum total bilirubin concentration. Measuring effusion bile acid concentration may still be helpful in these cases [12].

Feline infectious peritonitis (FIP)

Peritoneal and pleural effusions caused by FIP are somewhat unique. Grossly the effusion is usually yellow and clear to hazy, viscous, and may contain small flecks of fibrin. Although the effusion is caused by inflammation (vasculitis), nucleated cell counts are typically lower than the 5000/µL threshold for an exudate. Nucleated cells are a mixture of nondegenerate neutrophils and macrophages. Total protein concentration is high, frequently exceeding 4 g/dL [13]. These proteins are visible on cytologic preparations as pink, granular precipitates in the background (Figure 42.15). Measuring the effusion albumin and globulin concentrations may be useful (Table 42.2). Globulins are expected to dominate, so an albumin to globulin ratio (A : G) less than 0.9 is consistent with FIP [14]. Acute phase protein concentrations can also be measured in effusions and are expected to be high in cats with FIP. In one study, an effusion α_1-acid glycoprotein (AGP) concentration of >1550 µg/mL had a 93% sensitivity and specificity for diagnosing FIP [15]. The Rivalta test is a relatively simple in-clinic procedure that involves adding effusion fluid to a dilute acetic acid solution and observing if a white protein precipitate forms (positive test). Although it has long been popular for its low cost, the predictive value of a positive test is only 58.4%, and there is considerable subjectivity in determining a positive test result [16, 17].

Chylous effusions

Chylous effusions form when lymph containing a high concentration of chylomicrons leaks from lymphatic vessels, most often in the pleural cavity. Underlying causes for such leakage include trauma and many different disorders that may obstruct lymphatics, including heart disease, lung lobe torsion, diaphragmatic hernia, neoplastic masses, and other mass lesions such as granulomas. Some cases are idiopathic. Chylous effusions are usually milky white and opaque (Figure 42.1), and do not clear with centrifugation. Total protein concentration is artifactually increased by the presence of lipoproteins (chylomicrons), which increase the refractive index. Nucleated cell concentrations are variable but consist predominantly of small lymphocytes and macrophages; neutrophil concentrations may increase with chronicity because of inflammation associated with fluid accumulation or repeated thoracocentesis. Macrophages frequently contain numerous fine clear vacuoles consistent with lipid (Figure 42.16). Chylomicrons contain a high concentration of triglycerides, so comparing triglyceride concentrations with that of serum is helpful to confirm chylous effusion (Table 42.2). Chylous effusions will have higher triglyceride (typically >100 mg/dL) concentrations relative to serum [18, 19].

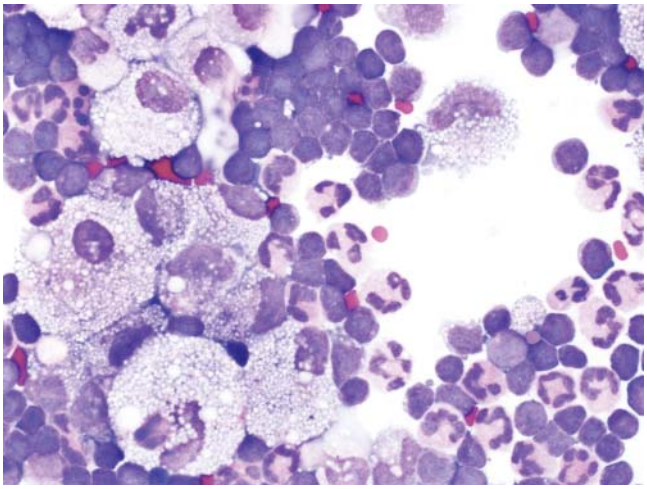

Figure 42.16 Chylous pleural effusion, cat (concentrated preparation). Lymphocytes, small to intermediate in size, predominate (77% of cells) with lower numbers of nondegenerate neutrophils (20%) and macrophages (3%). Macrophages contain numerous fine, distinct cytoplasmic granules suggestive of lipid. In chylous effusions, neutrophil numbers often increase with chronicity of the effusion. Wright stain.

Uroperitoneum

Urine may leak into the peritoneal cavity because of a variety of underlying disorders (such as trauma, neoplasia and urolithiasis) involving the urinary bladder, urethra, ureters, and kidneys. Urine is usually sterile unless there is a urinary tract infection, but urine acts as a chemical irritant causing inflammation. Nucleated cell concentrations and types of cells present will vary depending on duration of the effusion and the dilutional effect of the urine volume present, but cell concentrations are generally low to moderate and total protein concentration is low. Mononuclear cells predominate early and the neutrophil concentration increases with chronicity. Neutrophils may appear degenerate even in the absence of bacteria because of the inhospitable environment caused by urine. Occasionally, urinary crystals can be observed on the smear, confirming the diagnosis (Figure 42.17). When uroperitoneum is suspected, measuring creatinine or potassium concentration in the effusion and comparing to the serum concentration is helpful (Table 42.2). Creatinine is preferred to urea (BUN) because urea diffuses faster from the effusion back into blood. Generally, if uroperitoneum is present, the creatinine concentration in the effusion is expected to be greater than twice that of serum in samples obtained concurrently [20–22]. An abdominal fluid to serum potassium concentration ratio of >1.4 : 1 is also predictive of uroabdomen, with a sensitivity and specificity of 100% in one study [22]. However, stomach secretions are also high in potassium, and high abdominal fluid potassium concentration with a fluid to serum ratio of greater than 2.67 : 1 has been reported with gastric perforation [23].

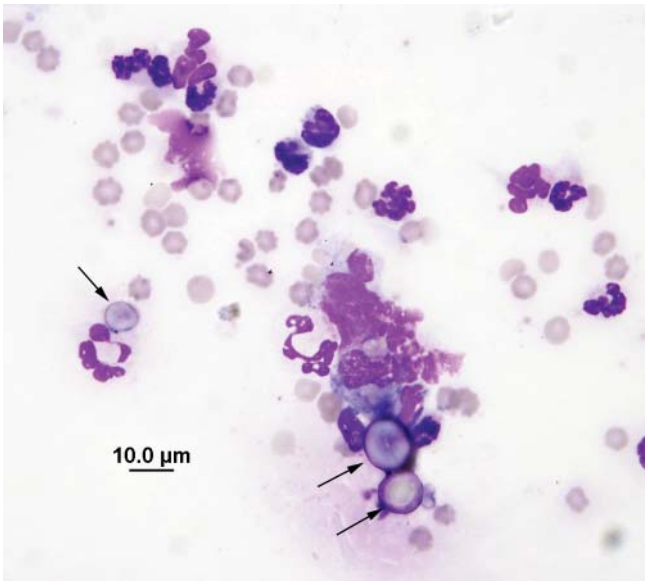

Figure 42.17 Uroperitoneum, horse (concentrated preparation). Arrows point to three crystalline structures that are consistent with calcium carbonate urinary crystals. Degenerate and nondegenerate neutrophils are present with few erythrocytes. The total nucleated cell count was 4300/µL, total protein was <2.5 mg/dL, and effusion creatinine concentration was 44 mg/dL. Wright stain.

Hemorrhagic effusions

Hemorrhagic effusions are caused by underlying disorders that result in bleeding into the thoracic or peritoneal cavities, such as trauma, neoplasia, and hemostatic defects. The effusion characteristics vary depending on the amount of blood present and the duration of hemorrhage, but a fluid PCV >3% suggests hemorrhage is contributory [7]. Total protein concentration is often >2.5 g/dL and nucleated cell numbers are low to moderate, consisting mainly of leukocytes, the distribution of which is reflective of peripheral blood. If neoplasia is the underlying cause, neoplastic cells may or may not be identified on the smear; hemangiosarcoma is frequently associated with hemorrhage but neoplastic cells are rarely recognized in the effusion. When hemorrhage is acute or ongoing, platelets may be present, but platelets rapidly aggregate and disappear from body cavities. Macrophages are frequently present and may contain phagocytized erythrocytes if the hemorrhage duration is greater than 24 hours. With chronicity, red cell breakdown products (hemosiderin, hematoidin) become evident within macrophages (Figures 42.18 and 42.19). Hemosiderin is usually blue-green but can be quite variable (yellow, green, blue) [24]. Since it contains iron, hemosiderin can be confirmed with an iron stain such as Prussian blue. Hematoidin does not contain iron but has a distinct golden yellow to amber crystalline appearance.

Iatrogenic hemorrhage during the sample collection process must be differentiated from true pathologic hemorrhage.

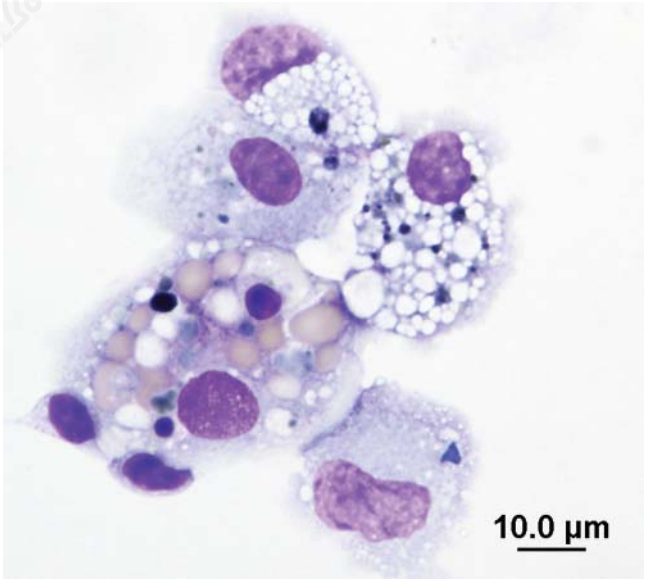

Figure 42.18 Evidence of previous hemorrhage, horse. Macrophages contain phagocytized erythrocytes (lower left) and/or dark blue-green globular pigment consistent with hemosiderin, a red-cell breakdown product containing iron. Aqueous Romanowsky stain.

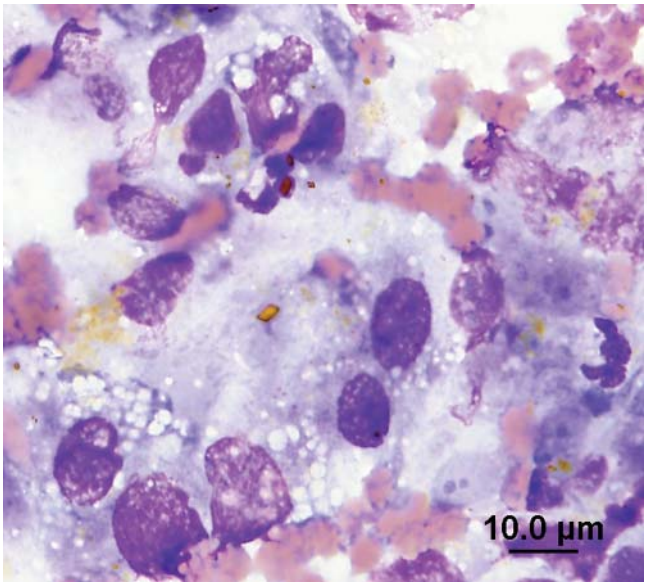

Figure 42.19 Evidence of previous hemorrhage, dog. Vacuolated macrophages contain crystalline golden to amber hematoidin, a red-cell breakdown product lacking iron. The amorphous yellow material is likely hemosiderin. Aqueous Romanowsky stain.

Many samples contain small numbers of erythrocytes as a result of minor contamination, and this does not cause a diagnostic challenge. When marked blood contamination is suspected, it is useful to consider presence or absence of platelets and red cell breakdown products as presented in Table 42.3. Inadvertent aspiration of the spleen may also result in a grossly bloody sample. In that case the effusion PCV may be greater than that of peripheral blood, platelets will be present, and hematopoietic precursors may be seen on the smear if extramedullary hematopoiesis is present in the spleen, which is common.

Neoplastic effusions

An effusion is characterized as neoplastic if there are identifiable neoplastic cells present. Many different types of tumors can exfoliate cells into an effusion, but in general, round cell tumors (such as lymphoma or mast cell tumor), carcinomas, and mesotheliomas do so much more readily than do mesenchymal tumors (sarcomas). Lack of identifiable neoplastic cells does not exclude neoplasia as the underlying cause of an effusion. Effusion characteristics are variable; there may be inflammation or hemorrhage present in addition to the neoplastic cells, which may be rare or numerous.

Neoplasia is easiest to recognize when there are large numbers of neoplastic cells with marked criteria of malignancy and there isn't concurrent inflammation or significant hemorrhage (see Chapter 40). Additionally, the presence of numerous reactive mesothelial cells may be confounding.

Lymphoma

Neoplastic lymphocytes in effusions look similar to those in other cytologic samples (see Chapter 45), and may be present individually in small to large numbers. Typically, neoplastic lymphocytes are larger than neutrophils, have high nucleus:cytoplasm ratios, and contain nuclei with a fine chromatin pattern (Figures 42.6 and 42.20). Nuclear outlines may be irregular, and large, prominent nucleoli are often evident. Lymphoma may involve large granular lymphocytes, which have distinct magenta cytoplasmic granules (Figure 42.21). Gastrointestinal lymphoma may cause a bowel perforation, in which case there may be a confusing mixture of inflammatory cells with phagocytized mixed bacteria (septic peritonitis) and variable numbers of neoplastic lymphocytes (Figure 42.22).

Mast cell tumor

Neoplastic mast cells may exfoliate from intracavitary mast cell tumors in large numbers. Mast cells have round nuclei and contain variable numbers of metachromatic (dark purple) cytoplasmic granules that can obscure the nucleus (see Chapter 41). In effusions, mast cell granules may have a packeted appearance in the cytoplasm. Cells from high grade tumors have more criteria of malignancy (anisokaryosis, karyomegaly, multinucleation) and may contain fewer granules (Figure 42.23) [25]. Mast cell granules may stain poorly or not at all with commonly used aqueous Romanowsky dip stains (Figure 42.7) [4, 5].

Carcinoma

Intracavitary carcinomas or adenocarcinomas may exfoliate neoplastic cells in small to large numbers. In contrast to lymphoma and mast cell tumors, neoplastic epithelial cells

Table 42.3 Distinguishing causes of hemorrhagic effusions.

Cytologic findings	Possible processes	Comments
Platelets present No erythrophagocytosis No hemosiderin, hematoidin	• Iatrogenic hemorrhage • Acute hemorrhage	Iatrogenic hemorrhage (blood contamination during sampling) is most common.
No platelets present Erythrophagocytosis and/or hemosiderin, hematoidin present	• Previous hemorrhage	Following hemorrhage, platelets disappear rapidly, erythrophagocytosis may occur within hours, hemosiderin or hematoidin may appear within a couple days.
Platelets present Erythrophagocytosis and/or hemosiderin, hematoidin present	• Ongoing hemorrhage • Previous hemorrhage combined with iatrogenic hemorrhage	Platelets are observed most often with blood contamination but may also be present if hemorrhage is acute or ongoing.

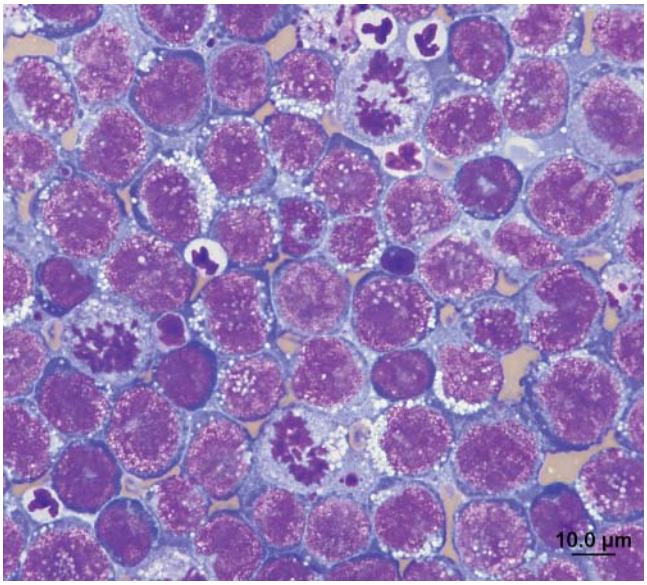

Figure 42.20 Neoplastic pleural effusion, lymphoma, dog (concentrated preparation). Neoplastic lymphocytes predominate and are large cells with high nucleus:cytoplasm ratios, dispersed chromatin, and prominent nucleoli. Nuclear outlines are irregular, and many mitotic figures are present. In this case, many of the lymphocytes have small cytoplasmic vacuoles. Few nondegenerate neutrophils and erythrocytes are also present. Aqueous Romanowsky stain.

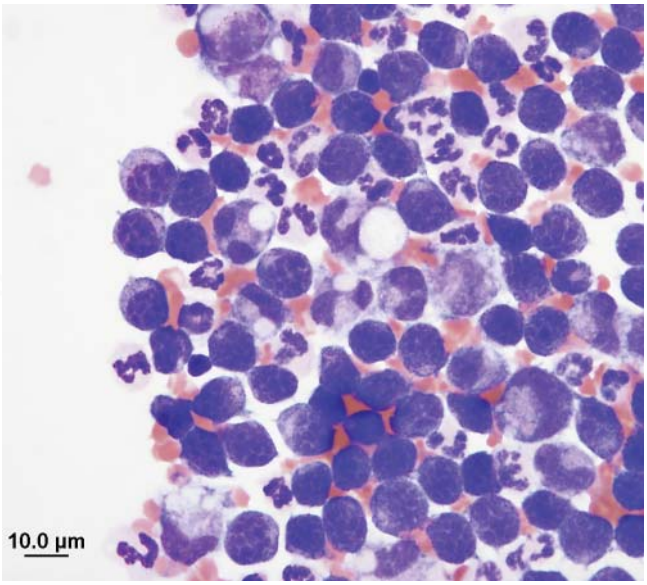

Figure 42.21 Neoplastic peritoneal effusion, large granular lymphocyte (LGL) lymphoma, horse (concentrated preparation). Most of the cells are large atypical lymphocytes containing coarse chromatin and distinct magenta cytoplasmic granules, consistent with LGLs. Other cells include nondegenerate neutrophils, macrophages, and erythrocytes. This horse had LGL lymphoma affecting the intestine. Aqueous Romanowsky stain.

tend to form cohesive clusters and are sometimes present in large sheets (Figures 42.24 and 42.25). Acinar structures may be recognized (Figure 42.26). Individualized cells may also be present and are typically large cells with rounded cell borders, easily confused with reactive mesothelial cells. Neoplastic epithelial cells often have marked nuclear criteria of malignancy including anisokaryosis, macrokaryosis, multinucleation, and coarse chromatin with large bizarre nucleoli (Figures 42.25 and 42.27). Mitotic figures and atypical mitoses may be observed (Figure 42.25). Cytoplasm is usually deeply basophilic and may be vacuolated or contain secretory material that pushes the nucleus to one side (Figures 42.25 and 42.28). There may be significant inflammation present concurrently. When carcinoma is suspected, differential diagnoses that should be considered include mesothelioma and markedly reactive mesothelial cells (discussed below).

Mesothelioma and reactive mesothelial cells

The distinction between reactive or hyperplastic mesothelial cells, mesothelioma and carcinoma is difficult and often

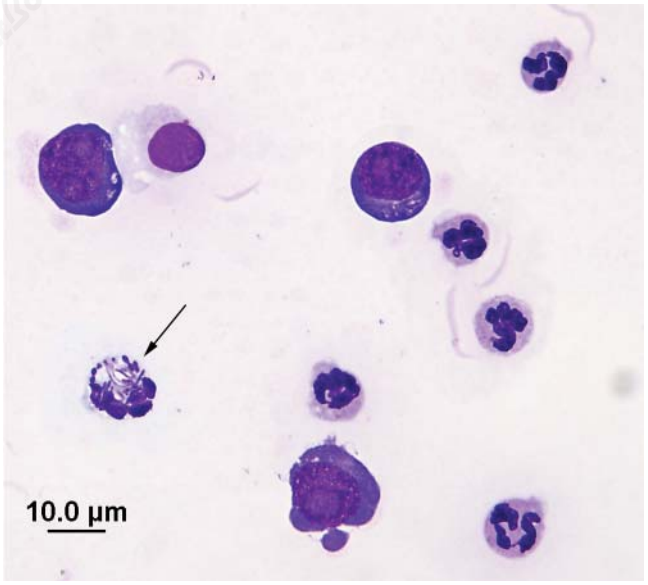

Figure 42.22 Neoplastic peritoneal effusion (lymphoma) with septic inflammation, cat. Three large neoplastic lymphocytes have dispersed chromatin with prominent nucleoli and deeply basophilic cytoplasm. Neutrophils are also present and one (arrow) contains phagocytized mixed bacteria. The nucleated cell count was 44,600/µL, with neutrophils predominating, and the total protein was 4.7 g/dL. This cat had intestinal lymphoma that caused an intestinal perforation and septic peritonitis. Aqueous Romanowsky stain.

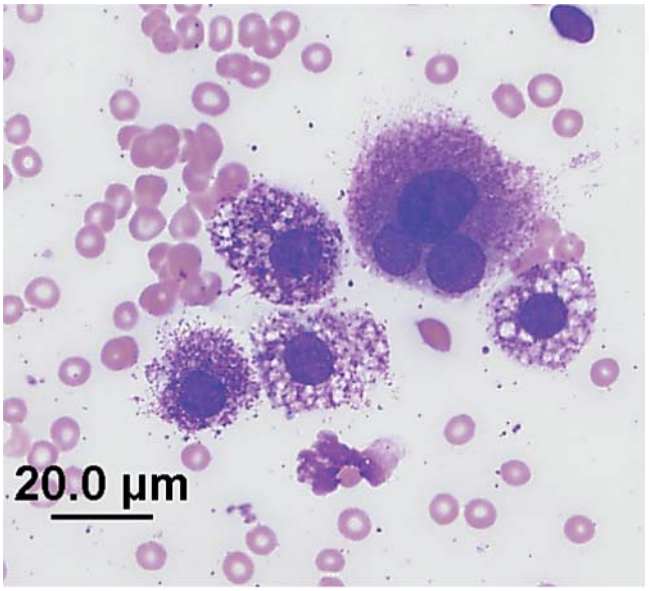

Figure 42.23 Neoplastic peritoneal effusion, mast cell tumor, dog. The neoplastic mast cells have variable cytoplasmic granulation, and one large trinucleated cell has anisokaryosis with large nucleoli. Free granules from lysed mast cells are seen in the background. There are numerous erythrocytes and platelets present, indicating either blood contamination during sampling or acute/ongoing hemorrhage. Aqueous Romanowsky stain.

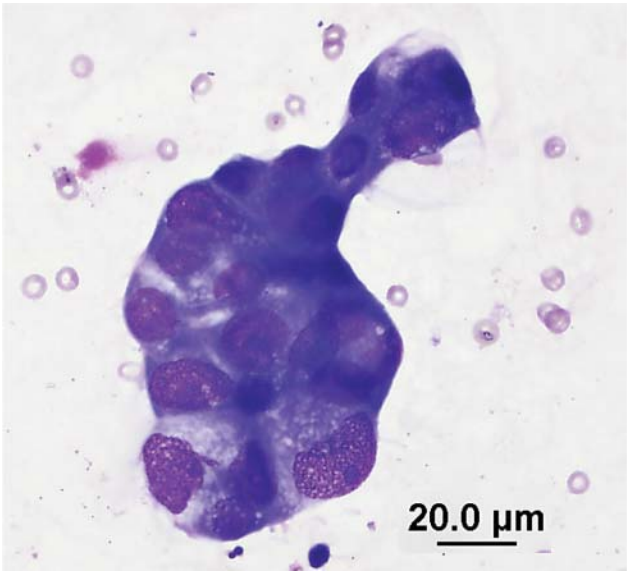

Figure 42.24 Neoplastic pleural effusion, carcinoma, dog. A tightly cohesive cluster of neoplastic epithelial cells have multiple criteria of malignancy including anisokaryosis, binucleation, coarse chromatin, and prominent nucleoli. The total nucleated cell count was 7500/µL and the total protein was 5 g/dL. This dog had a mammary gland anaplastic carcinoma that metastasized to the lungs. Aqueous Romanowsky stain.

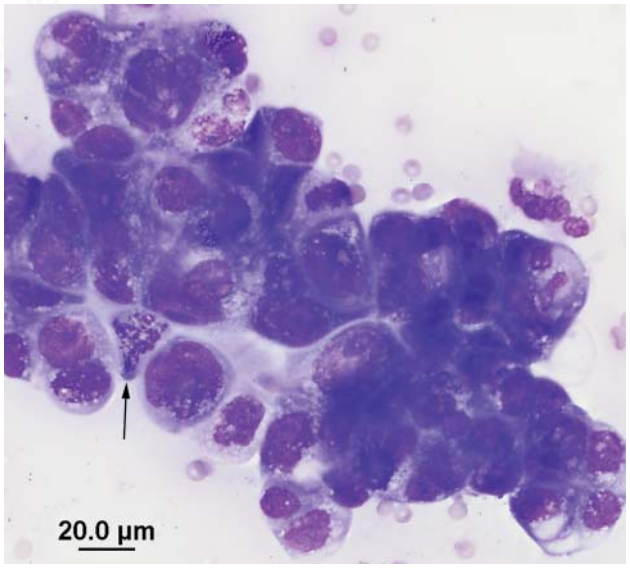

Figure 42.25 Neoplastic pleural effusion, carcinoma, dog. Same case as Figure 42.24. Many neoplastic epithelial cells are present in disorganized cohesive clusters. One abnormal mitotic figure is seen here (arrow). Cells have marked criteria of malignancy (anisokaryosis, binucleation, coarse chromatin with large, abnormal nucleoli), and some cells contain cytoplasmic vacuoles. Aqueous Romanowsky stain.

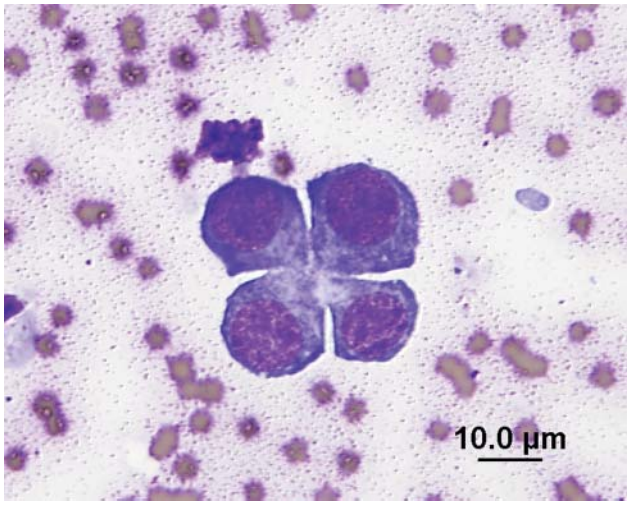

Figure 42.26 Acinar structure, adenocarcinoma, horse. The background contains protein precipitates and erythrocytes. Aqueous Romanowsky stain.

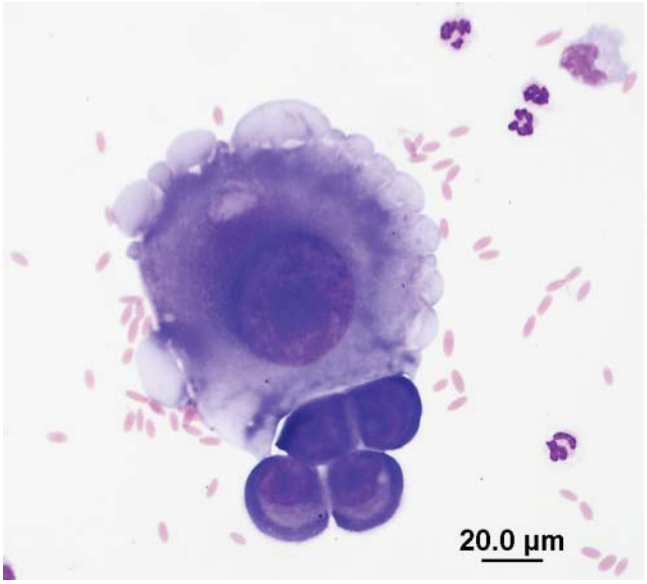

Figure 42.27 Neoplastic peritoneal effusion, carcinoma, llama. Five neoplastic epithelial cells are present; four smaller cells are deeply basophilic and appear cohesive. One karyomegalic cell has coarse nuclear chromatin and a huge, bizarre nucleolus. The total nucleated cell count was 500/µL, and the total protein was 2.7 g/dL. This llama had bicavitary neoplastic effusions secondary to metastatic mammary carcinoma. Wright stain.

impossible to make with cytology alone, even for experienced cytologists. In some cases, even histopathology may be inconclusive without the use of immunohistochemistry or ultrastructural studies [26]. Because mesothelial cells become reactive and exfoliate into any effusion, regardless of underlying cause, and frequently develop criteria of malignancy, extreme caution in interpretation is warranted, especially if there is concurrent inflammation (Figure 42.4).

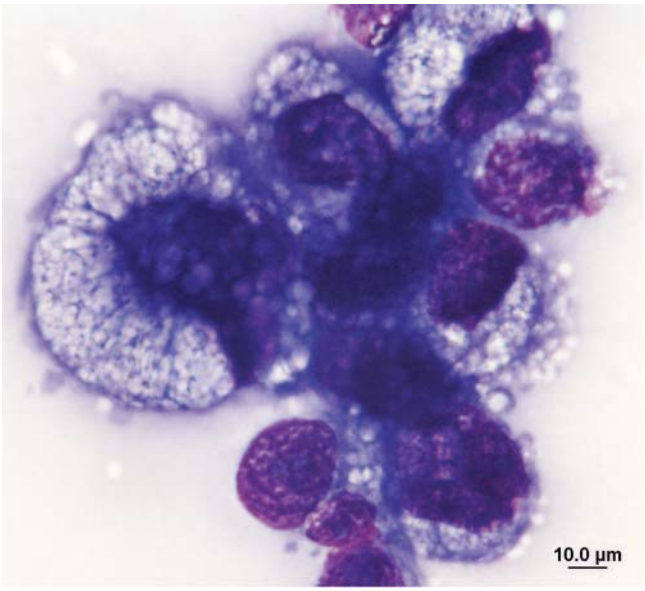

Figure 42.28 Neoplastic peritoneal effusion, adenocarcinoma, dog. Tightly cohesive neoplastic epithelial cells are vacuolated and have multiple criteria of malignancy (anisokaryosis, coarse chromatin, multiple large nucleoli). This dog had a pancreatic adenocarcinoma. Wright stain.

Cells from mesothelioma may develop the same criteria of malignancy as described for carcinomas, and are frequently present in large papillary clusters with irregular outlines (Figures 42.29 and 42.30) [27]. When an effusion contains

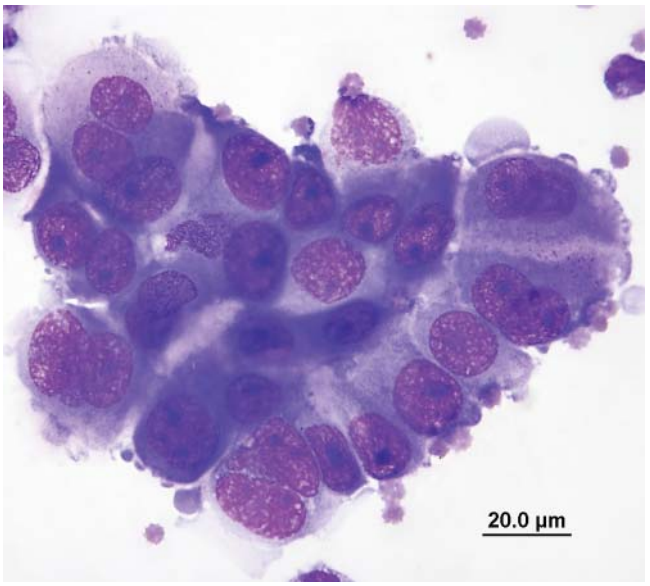

Figure 42.29 Neoplastic pleural effusion, mesothelioma, dog. A large cluster of cohesive neoplastic cells has marked criteria of malignancy including bi- and multinucleation, anisokaryosis, coarse chromatin, large prominent nucleoli, and nuclear molding. Cytologic differentials include carcinoma or mesothelioma. Histopathology confirmed mesothelioma in this case. Aqueous Romanowsky stain.

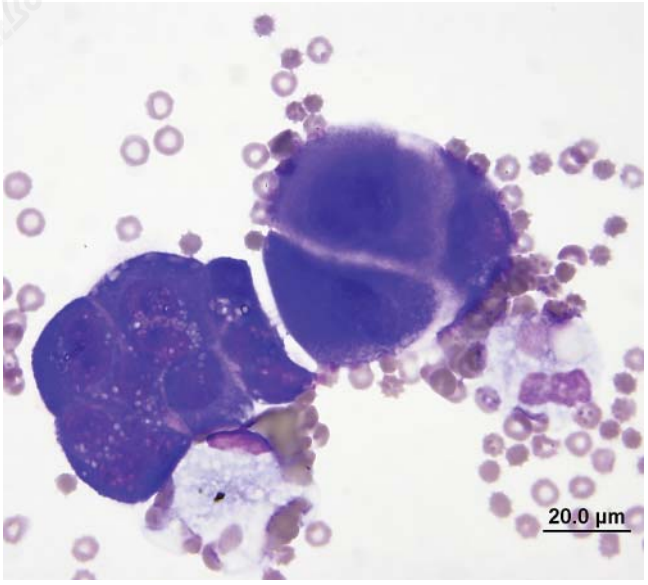

Figure 42.30 Neoplastic pleural effusion, mesothelioma, dog. Same case as Figure 42.29. Two clusters of cohesive neoplastic cells are present with two vacuolated macrophages and few erythrocytes. Criteria of malignancy include anisocytosis, anisokaryosis, binucleation, prominent nucleoli, deeply basophilic cytoplasm that is occasionally vacuolated. Aqueous Romanowsky stain.

many large clusters of markedly atypical cells, the abdominal or thoracic cavity should be evaluated thoroughly for mass lesions. In many cases, direct sampling of a mass for cytologic evaluation enables a more definitive interpretation.

Sarcomas

Sarcomas rarely exfoliate sufficient numbers of neoplastic cells into an effusion to allow diagnosis. Hemangiosarcoma, a common sarcoma of the spleen, is composed of neoplastic endothelial cells. These tumors frequently rupture and bleed, causing hemorrhagic effusions, but tumor cells are almost never seen on cytologic evaluation of the effusion.

43 Cytology of Synovial Fluid

James Meinkoth
Department of Veterinary Pathobiology, Oklahoma State University, Stillwater, OK, USA

Synovial fluid analysis is a fundamental part of the database in animals presenting with either monoarticular or polyarticular joint effusion. Additionally, it may provide useful information in animals with generalized lameness, generalized pain, or fever of unknown origin in an attempt to localize disease. The exact parameters measured and ancillary tests performed may vary between labs and will depend on the volume and nature of the sample acquired. However, the vast majority of clinically relevant information that can be derived from synovial fluid samples can be obtained by cytologic assessment of well-made, well-stained direct smears of synovial fluid. With experience, this can be performed in-clinic as long as the clinician has access to routine hematologic stains and a good-quality microscope. The results obtained can help determine the need for additional testing or direct treatment in a timelier manner than awaiting results from an outside lab.

There are a limited number of changes that can be seen in synovial fluid, despite a variety of potential disease processes. The downside to the clinician is that synovial fluid analysis rarely gives a definitive etiologic diagnosis. More often, it identifies a general process for which there are differential diagnoses. This must then be correlated with information from the history, physical exam findings, and additional tests to arrive at a specific diagnosis. The benefit to the clinician is that it is easier to gain competency in interpretation since, compared to other cytologic samples, the majority of synovial fluid samples have a very narrow spectrum of possible findings with which to become familiar. The main information to glean from examination of synovial fluid is to know the features of normal synovial fluid and then be able to identify and differentiate the following main processes:

1. *Inflammatory arthropathies:* These may also be termed *neutrophilic* or *suppurative* arthropathies and are usually the result of either infectious or immune-mediated diseases.

2. *Noninflammatory arthropathies:* These are also termed *degenerative joint diseases* (DJDs) and can result from a variety of congenital and acquired structural defects.

3. *Hemarthrosis:* This indicates hemorrhage into the joint space and must be differentiated from blood contamination during sample collection.

The goals of this chapter are to familiarize the reader with the various test results that may be received as part of synovial fluid analysis and their interpretation, optimal sample handling procedures (especially when limited sample is obtained), proper procedures to make and examine direct smears of synovial fluid, and the cytologic features of the above three main disease processes.

Parameters evaluated: normal and abnormal findings

Volume

The volume of joint fluid that can be obtained varies between species and the joint involved. Typically only a few drops to ~0.5 ml can be collected in dogs and up to 0.25 ml collected in cats [1, 2]. Several milliliters can be collected from normal joints in large animal species [3, 4]. Depending on the type of disease present, the volume may increase significantly. Increased volume of synovial fluid is best assessed by the person collecting the sample.

Physical properties

The color and relative viscosity of the sample should be noted. Normal synovial fluid is clear to pale yellow and extremely viscous [2, 5]. Viscosity can be assessed subjectively by the length of a strand that is formed before breaking if a drop of sample is gently expelled from the needle tip onto a slide and then the needle is slowly lifted away. Alternatively, a drop can be placed between the operator's fingers, which are then slowly pulled apart. Normal joint fluid should form a strand of a least 2.5 cm before breaking apart [2, 5]. Viscosity can be reduced with synovial effusion of any cause but is most significantly reduced in samples with a markedly increased concentration of neutrophils.

Normal synovial fluid does not clot as it lacks a significant concentration of fibrinogen, although it may gel to a semisolid state if left standing at room temperature. This property is termed *thixotropy*. This can be easily differentiated from clot formation since the sample will return to a fluid state with warming and mixing. Clotting may occur if there is either gross blood contamination or marked inflammation present. In these cases, if sufficient sample is obtained for cell counts, some should be placed into an anticoagulant tube to prevent clot formation. EDTA is the best anticoagulant to both prevent clot formation and to preserve cell morphology. Heparin can also be used if a mucin clot test is desired (discussed later); however, this is not a permanent anticoagulant and cell counts can decrease significantly in 24 hours [6].

Turbidity of the synovial fluid usually results from increased cellularity, which would be reflected either as an increased cell count, if measured, or as a subjective increase in cellularity of a well-made direct smear. A reddish tinge or grossly bloody color results from addition of blood, either through bleeding into the joint (hemarthrosis) or blood contamination of the sample during collection. The cytologic distinction between these two is discussed later in the section on hemorrhagic samples, but it is often best assessed by the person collecting the sample. True hemarthrosis is likely if the sample was equally discolored throughout collection. Conversely, with blood contamination during collection, the sample is often initially clear and then becomes discolored over time. In this event, collection should by stopped immediately to minimize further contamination of the sample.

If a hemodilute sample is suspected a small amount of the sample can be spun down to examine the color of the supernatant. If sample volume is limited, this can be done with a microhematocrit tube. A clear supernatant suggests either acute hemarthrosis or sample contamination during collection. With chronic hemarthrosis, the red cells are broken down and the hemoglobin is metabolized to pigments, which may impart a yellowish discoloration termed *xanthochromia*.

Mucin quality

The *mucin clot test* assesses the quality of hyaluronic acid in a sample and is performed by adding a small amount of synovial fluid to a tube of glacial acetic acid and assessing the quality of the clot that forms. Normal synovial fluid forms a tight, ropey clot, leaving the remainder of the acetic acid clear. With degradation of the hyaluronic acid in the sample, this clot becomes less tightly condensed or may fail to form altogether. The mucin clot test is typically subjectively graded as "good," "fair," or "poor". A mild decrease in quality of the mucin clot can be seen with any severe joint effusion due to dilution of hyaluronic acid. Marked decreases in mucin clot quality are most often seen with neutrophilic inflammation owing to the action of proteolytic enzymes present in neutrophils, which can degrade hyaluronic acid.

EDTA can break down polymerized hyaluronic acid, affecting results of this test. For this reason, the mucin clot test should be run on either a sample with no anticoagulant or on a sample collected in a lithium heparin tube.

The mucin clot test was historically used in the assessment of synovial fluid but is no longer run by most labs. The presence of inflammation within the joint is better assessed by cell count or simple direct examination of direct smears of synovial fluid.

Total nucleated cell count (TNCC)

Cellularity of synovial fluid, which is normally very low, is one of the major parameters assessed in determining the type of pathologic change present. The TNCC of synovial fluid can be determined by (i) use of an automated hematology analyzer, (ii) manual counts done on a hemocytometer, or (iii) subjective assessment of cellularity based on examination of direct smears. Several studies have shown good correlation between hemocytometer counts and those obtained from automated analyzers, supporting the use of automated methods for generating cell counts [7–10]. However, it should be noted that cell counts generated by either automated analyzers or hemocytometers can be falsely decreased due to cell clumping in the diluent due to the viscosity of the synovial fluid [7, 10]. With either method, more accurate cell counts may be obtained if the sample is pretreated with hyaluronidase to break down the viscosity of the sample and allow for more even distribution of the cells within the sample and analyzer diluent [7, 10]. Hyaluronidase treatment also reduces the incidence of error flags from automated analyzers and prevents clogging of the flow cells [8, 10]. Hyaluronidase treatment is not typically available for use with in-clinic analyzers and may not be available in many smaller reference laboratory settings. Therefore, clinicians must be aware that cell counts may suffer from this artifact. The TNCC obtained from either of these methods should be confirmed by comparing it to the subjective assessment of cellularity as determined by microscopic evaluation of direct smears. Often, subjective assessment of cellularity is the only parameter available when sample volume is scant, and it is usually sufficient for clinical assessment if done by experienced observers.

Cell counts of normal synovial fluid in all species are extremely low, typically less than 1000/μL [1, 4, 5]. In dogs, some joint may have cell counts as high as 3000/μL and there may be variability between joints [2].

In addition to pathologic increases in cellularity, TNCC may also be affected by gross hemodilution of the sample since the white blood cell (WBC) concentration of peripheral blood is much higher than that of normal synovial fluid. If the nucleated cell count is increased in a hemodilute sample, a subjective assessment should be made and reported as to whether

the increase in nucleated cells appears proportional to what would be expected for the amount of hemodilution or if there is likely an underlying pathologic process in addition to the hemodilution. This is best achieved by examining a direct smear and comparing the number and type of leukocytes present with what would be expected form peripheral blood contribution given the amount of erythrocytes present.

Erythrocyte concentrations are not typically reported other than a description of the sample color and a subjective comment on the amount of background blood on the smear.

Protein concentration

Protein concentration is most often estimated by refractometry. Published references list normal synovial fluid protein as assessed by refractometry to be less than ~2.5 g/dL [4, 5]. Increases in protein concentration are typically associated with inflammation. However, refractometry can significantly overestimate the protein concentration if an insufficient amount of sample is placed in an EDTA tube, as happens when there is limited sample obtained, because of the high refractive index of EDTA. Therefore, increased protein concentration alone should not be relied upon to determine inflammation in a sample and this should be confirmed by evaluating the cellularity and type of inflammatory cells seen on cytologic evaluation of direct smears.

A more accurate measurement of protein concentration would require a true protein to be determined using a colorimetric assay as is done on serum samples. However, this is not done for most routine diagnostic samples.

Cytologic evaluation

Cytologic examination of the specimen is the single most important part of synovial fluid analysis [5]. When sample volume is limited, cytologic examination of a direct smear is typically sufficient to obtain all clinically relevant information that can be obtained from the sample [11]. Conversely, without cytologic examination the interpretation of any other data is severely limited.

Preparation of cytologic slides

A direct smear will allow for both an estimation of the cellularity of the sample and a determination of the type of cells present [11]. If the cellularity of the sample is extremely low and sufficient sample is available, the preparation of either a cytocentrifuged sample (in a reference lab) or a sediment smear will yield a more cellular preparation and allow for assessment of a greater number of cells. However, when the cellularity of a synovial sample is this low there is generally little information to be gained from the cytomorphology of the cells. Most diagnostically important findings related to cellular morphology or presence of infectious organisms are associated with highly cellular samples.

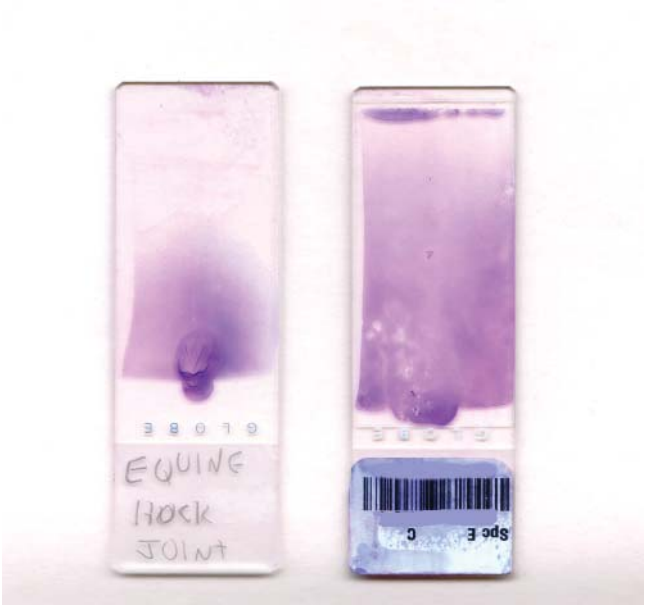

Figure 43.1 Two direct smears made from synovial fluid. The slide on the left has a feathered edge that will allow for visualization of cells in a well-spread-out area. On the slide on the right, the sample extends to the edge of the slide and has a thick abrupt end. This may not have a sufficiently thin area to evaluate.

Direct smears of synovial fluid are made by placing a small drop of well-mixed sample at one end of a glass slide. A second spreader slide is then used to spread out the sample similar to making a blood film [11]. Alternatively, if the sample is viscous and will not spread out along the spreader slide, a slide over slide preparation can be made similar to a standard cytology smear from a fine needle biopsy (see Chapter 39). The high viscosity of synovial fluid will often prevent cells from spreading out sufficiently to evaluate in thick portions of smears [12]. So, it is extremely important to have a thin area on the smear and thus a feathered edge should be present rather than allowing the sample to extend all of the way to the edge of the slide [11] (Figure 43.1). It is wise to make at least two to three slides per sample to ensure at least one diagnostic slide.

Estimation of cellularity

The cellularity of the sample can be estimated from a thin portion of the direct smear. Generally, only a few cells (0–5) will be seen per 20× objective field (200× magnification) *in thin areas* of smears from normal animals. As a general rule of thumb, the white cell count can be estimated by taking the average number of cells seen per 20× objective field and multiplying by 500. The goal is not to get a precise number of cells/μL but to differentiate normal cellularity, mildly increased cellularity and markedly increased cellularity. With practice, the cellularity can be estimated by "eyeballing" the number of leukocytes seen at low magnification and

comparing that to a comparable white cell concentration on a blood film with a known WBC count. Since cells are often unevenly distributed or may be present in clumps, evaluation of the entire smear including thinner portions may give a better overall assessment than counting the averaging the number of cells in a limited number of fields. Estimation does require experience and estimates can vary among observers but with practice can be done reliably [11, 12].

The number of cells seen per field will vary with the thickness of the smear made, and this can be quite variable due to the viscosity of synovial fluid. It is important to be in a thin area that would be equivalent to the monolayer of a blood film when estimating cellularity. This area can often be determined by the density of the background and by how well the individual leukocytes have spread out. In the thicker areas of the smear near where the sample was applied, the background if often diffusely proteinaceous with or without a stippled eosinophilic nature (Figure 43.2). In this area, the cells will not be well spread out and it is often not possible to clearly see the demarcation between the nucleus and the cytoplasm of the cell (Figure 43.2). As you move toward the feathered edge of the smear, the background will lighten and eventually the cells will spread out to where a clear demarcation can be seen between the border of the nucleus and the cytoplasm (Figure 43.3). In this area, the numbers of cells per field will be most representative of true cellularity of the sample and the estimate should be performed.

Estimation of viscosity/proteoglycan layer

The viscosity of the sample is typically assessed grossly by its physical properties. The viscosity of the sample and the quality of the hyaluronic acid may also be apparent on the cytologic preparation. If there are either erythrocytes or leukocytes present, these may be lined up in single file rows if the viscosity of the sample is high. This is termed *windrowing* and can be seen in normal synovial fluid as well as other viscous samples such as salivary aspirates (Figure 43.4). In addition, normal joint fluid often has a characteristic stippled eosinophilic background resulting from the presence of hyaluronic acid (Figure 43.5). It should

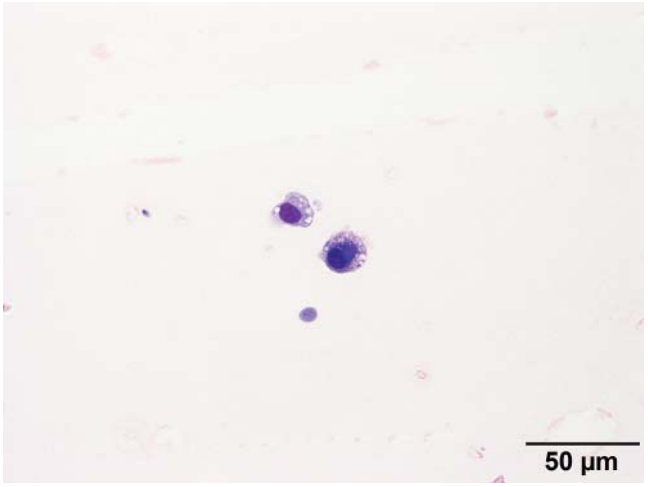

Figure 43.3 Thinner area of same smear. The background is clear. In this area, cells have spread out as evidenced by the demarcation between purple nucleus and basophilic cytoplasm being more distinct. This is the area where differential counts should be performed and where estimations of cellularity are likely to be more accurate. Aqueous Romanowsky stain.

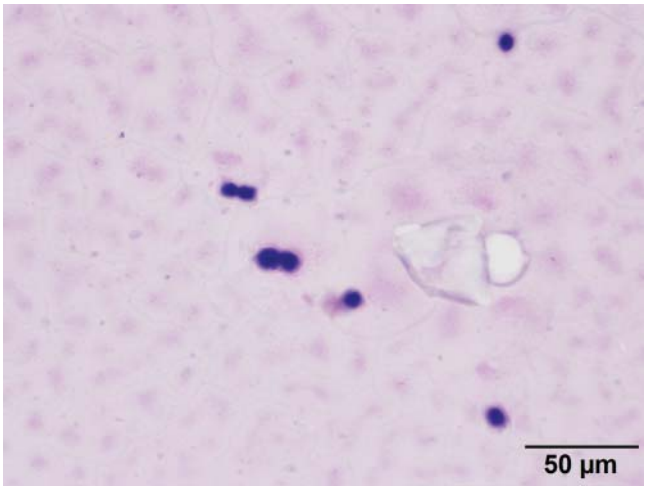

Figure 43.2 Thicker area of a direct smear shows a variably dense eosinophilic background. In this area, cells are not well spread out. Seven dark spheres representing nucleated cells can be seen, but cell type cannot be determined. In this area of the smear cellularity may appear artificially increased. Aqueous Romanowsky stain.

Figure 43.4 Low-magnification images of a direct smear of synovial fluid with blood contamination. The erythrocytes are lined up in a single-file manner termed "windrowing" typical of any highly viscous sample. There are a few neutrophils present, but they are in numbers that would be expected from peripheral blood contribution based on the amount of hemodilution present rather than suggesting inflammation. Aqueous Romanowsky stain.

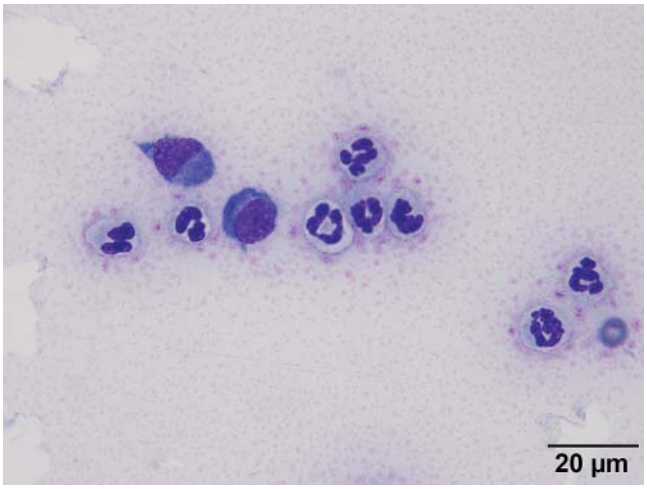

Figure 43.5 Direct smear of synovial fluid from a dog. Note the pink, stippled background, which is typical of synovial fluid. There is evidence of neutrophilic inflammation in this joint based on many neutrophils with no hemodilution. Aqueous Romanowsky stain.

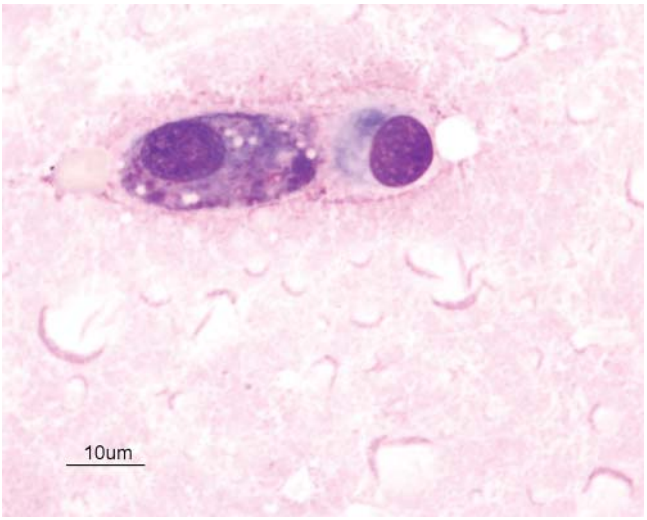

Figure 43.6 Two mononuclear cells in a direct smear of synovial fluid from a dog. The cell at the right is likely an unstimulated macrophage (also termed Type B synovial cell). The cell on the left, with the pink cytoplasmic granules, is likely a secretory or Type A synovial cell. Distinguishing between the various types of mononuclear cells in fluid is generally not of diagnostic significance. Wright-Giemsa stain.

be noted that this stippled background may be absent from some normal samples [1].

With marked neutrophilic inflammation, this stippled background may break down and be less prominent or absent, although this is not a consistent finding.

Differential count

In addition to a low nucleated cell count, normal synovial fluid is typically composed predominantly of various mononuclear cells and very few neutrophils. "Mononuclear" cells really refer to "mono*morpho*nuclear" cells rather than cells with one nucleus. This includes any cell without the nuclear segmentation characteristic of neutrophils, eosinophils and basophils. These can be small lymphocytes, macrophages or even synovial lining cells (Figure 43.6). The percentage of the different mononuclear cells present is variable and generally not of diagnostic significance, so they are all combined together and contrasted to the percentage of neutrophils present. Neutrophils (Figure 43.5) generally make up a low percentage of cells in synovial fluid, typically less than ~10% [1, 2, 4, 5]. Original publications report a slightly higher percentage of neutrophils in some samples [1]. However given the very low WBC counts of normal synovial fluid, consideration must be given to the potential effect that even a small amount of peripheral blood contamination could have on the differential count.

Most of the macrophages in normal synovial fluid do not have distended, vacuolated cytoplasm or show evidence of phagocytosis of other material [2]. Vacuolated macrophages may be present in a higher percentage in animals with inflammatory or degenerative arthropathies. However, this type of change may also occur in the tube if there is a delay between sample collection and preparation of cytologic slides. It is best to make smears immediately upon collection to avoid any artifacts associated with cellular aging.

With septic or immune-mediated arthropathies, there is typically a dramatic increase in both the absolute number and percentage of neutrophils present (Figure 43.7). Modest increases in neutrophils can be seen with inflammation resulting from trauma/inflammation of periarticular tissues, chronic hemarthrosis or secondary to intra-articular injections.

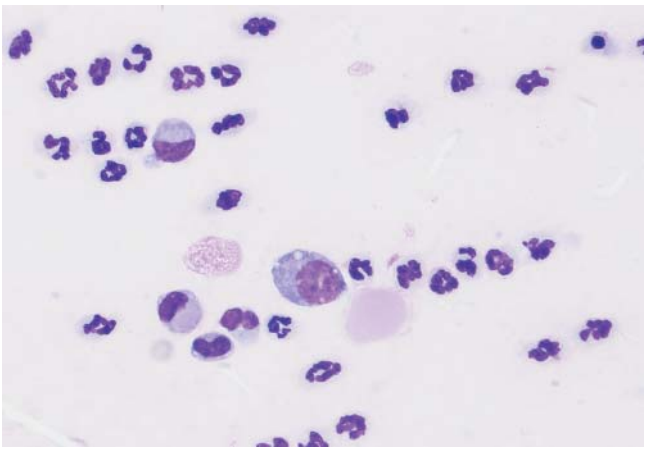

Figure 43.7 Direct smear of synovial fluid from a dog with septic arthritis. The cellularity is markedly increased with a predominance of neutrophils. The neutrophils appear nondegenerate despite a septic process. This is common with synovial fluid. Aqueous Romanowsky stain, 500× original magnification.

Any time there is significant blood contamination during sample collection, there is the potential for an increased percentage of neutrophils. The magnitude of this increase will depend on both the amount of contamination and the leukocyte count of the peripheral blood (more would be expected if the patient had a significant neutrophilia).

Samples submitted and triage of samples of limited volume

The amount of sample that can be collected is often limited, so it is important to consider which tests are most important to run given the suspected disease. Generally, the top priority is to make one or more well-made, thin, direct smears with a feathered edge. This is generally sufficient both to estimate the cellularity of the sample and then determine the cytologic abnormalities present, if any. Preparation of either cytocentrifuged or sediment smears uses significantly more sample, often does not add significant information, and should be done only if sufficient sample is available and other testing needs such as culture are met first.

If infectious joint disease is considered clinically likely, some sample should immediately be inoculated onto culture media or a culture transport system. Studies have shown improved recovery by using blood culture medium enrichment [13, 14]. Samples placed in EDTA are not appropriate for culture, since this anticoagulant can inhibit bacterial growth. Samples placed in sterile tubes may be used for culture, but organisms in these tubes may die during transit to the lab. Inoculation of microbial culture system is best done immediately after sample collection rather than after submission to the lab to maximize diagnostic yield.

If sufficient sample remains after making direct smears and inoculating culture systems (if needed), the remaining sample can be placed into either a serum tube (red top tube) or EDTA tube (purple top tube) that can be used to obtain a TNCC. Normal synovial fluid will not clot, so a cell count can often be obtained from a serum tube. However, if there is significant blood contamination or evidence of inflammation (turbid, less viscous sample) then synovial fluid should be placed into EDTA to prevent clot formation. The only limitations of an EDTA compared to a serum tube or other anticoagulant is that it may cause an artifactual increase in total protein (TP) as measured by refractometry if the tube is not adequately filled and it may alter the mucin clot test results. The former is not a problem if an appropriate sized EDTA tube is used considering the sample volume and the latter test is no longer run by most labs.

Heparin tubes can be used to obtain cell counts, and will not interfere with the mucin clot test. However, samples in heparin are not as stable as those in EDTA tubes. Significant decreases in cell counts can be seen by 24 hours when samples are collected in heparin [6]. So, unless cell counts can be obtained in a timely fashion, heparin is not the best choice.

Abnormal synovial fluid cytology

As previously described, normal synovial fluid will be clear to pale yellow and noted to be viscous when making direct smears. The cellularity is extremely low and nucleated cells present should be predominantly mononuclear cells. These can be a mixture of small lymphocytes, macrophages and synovial lining cells although the varying percentages of these is generally not clinically relevant. Relatively few (<10%) of the mononuclear cells should be highly vacuolated macrophages or contain phagocytized material [2]. Neutrophils should be less than ~10% of the nucleated cells. Departures from this appearance can generally be grouped into one of major categories below. Table 43.1 presents a summary of synovial fluid findings from both normal joints and each of the major classifications of abnormality.

Noninflammatory/degenerative arthropathies

This category encompasses a variety of conditions in which there are noninflammatory, degenerative changes to articular surfaces from a variety of underlying causes. These may be variably referred to in different publications as either *degenerative arthropathies*, *nonsuppurative arthropathies*, or *noninflammatory arthropathies*.

These conditions result in relatively mild changes in synovial fluid parameters [15–17]. There may be a mildly increased TNCC, typically not more than about ~5000 to 10,000/μL [5, 15, 17]. Nucleated cells still comprise >90% mononuclear cells with very few neutrophils. In some cases, there may be increased numbers of macrophages that appear "activated," having increased amounts of vacuolated cytoplasm and sometimes containing phagocytized material. If the articular damage is severe enough, multinucleated osteoclasts may be present. Because of the lack of neutrophilic inflammation, viscosity is normal to only mildly reduced and the normal stippled eosinophilic background is present. The mucin clot, if performed, is usually "fair" or "good."

This type of synovial fluid pattern can be seen with any form of osteoarthritis, which must be defined by clinical findings. Osteoarthritis can be either *primary* (due to a primary defect in articular cartilage) or *secondary* (resulting from an underlying joint disease leading to abnormal stresses on the articular surface) [18]. Secondary osteoarthritis may result from osteochondrosis, hip dysplasia, elbow dysplasia, joint trauma, or joint instability due to ligament damage (e.g., cruciate rupture).

Inflammatory (suppurative) arthropathies

Inflammatory arthropathies are also referred to as *suppurative arthropathies,* because they are usually characterized by a

Table 43.1 Summary of typical synovial fluid findings in various conditions.

Condition	Gross appearance	Viscosity	TNCC	Cytologic findings	Other considerations
Normal	Pale yellow	Highly viscous	Low <1000/μL <3000/μL in dogs	Predominantly mononuclear cells <10% nondegenerate neutrophils	Even mild hemodilution may affect differential count.
Degenerative arthropathy	Pale yellow	Normal to mildly decreased	Mildly increased (<~10,000/μL)	Predominantly mononuclear cells <10% neutrophils	May see increased % of vacuolated macrophages. May see osteoclasts if severe.
Inflammatory articular sepsis[a]	Turbid, opaque	Markedly decreased	Markedly increased (>~50,000/μL)	Marked predominance of neutrophils (>90%)	Bacteria often not evident or in very low numbers. Neutrophils often nondegenerate. Inoculate culture material directly upon collection. Typically monoarticular. May be oligo- to polyarticular in cases of hematogenous spread.
Inflammatory immune-mediated	Clear to turbid, depending on cellularity	Mildly to markedly decreased	Mildly to markedly increased	Neutrophils >10% but variable (20% to >90%)	LE cells may be present but rare. Typically polyarticular disease. Clinically normal joints may show inflammatory changes cytologically.
Hemarthrosis	Pink to dark red throughout collection	Mildly to markedly decreased	Normal to mildly increased	Many erythrocytes May see erythrophagia Neutrophils may be mildly increased disproportionately	May see erythrophagia. Platelets typically absent unless ongoing hemorrhage.
Iatrogenic blood contamination	Initially clear then bloody	Mildly to markedly decreased	Normal to mildly increased	Many erythrocytes Neutrophils increase in proportion to amount of blood No erythrophagia Platelets present	Erythrophagia may form *in vitro*. Make slides immediately. May still be possible to detect underlying inflammation if hemodilution is mild.

[a]Referring only to true infection of joint. Findings with infectious diseases of other tissues that result in immune-complex-mediated joint disease are similar to other immune-mediated diseases.

predominance of neutrophils in the synovial fluid. This type of response is most common with either infectious or immune-mediated disease. Often, the cytologic findings in these two classes of disease are virtually identical and they must be differentiated based on clinical findings and other tests results.

With inflammatory arthropathies, the TNCC typically is moderately to markedly increased, usually much higher than with degenerative arthropathies. Cell counts commonly range from ~20,000/μL to >100,000/μL [19–22]. A defining characteristic is that neutrophils comprise significantly more than 10% of the nucleated cells present. In most cases neutrophils are the predominant cell type (>50%) and it is not uncommon for them to comprise >90% of the nucleated cells present [19–22]. There may also be a concurrent increase in the absolute number of mononuclear cells and this may include large vacuolated macrophages. TP as assessed by refractometry is typically increased, ranging from 4.5–7.5 g/dL [19, 20, 22]. Because of the proteolytic enzymes released from these neutrophils, the viscosity of the sample is often markedly reduced, the typical stippled eosinophilic background may be absent and the mucin clot test, if performed, is often poor.

Infectious conditions

Pathogenesis

Infectious diseases can result in a suppurative arthropathy by one of two mechanisms. The first and most intuitive mechanism is true *septic arthritis* in which there is an infectious agent colonizing the articular tissues, which may be recoverable by culture. Such infectious arthritis can result from either direct inoculation of the joint (i.e., penetrating wound, surgical complication) or hematogenous spread. Direct inoculation will result in monoarticular disease while hematogenous spread may result in either monoarticular or polyarticular disease.

A second mechanism involves infectious diseases affecting distant tissues, often systemic infections. Not true "joint infections," these most likely result in suppurative arthritis via a Type III hypersensitivity reaction. Circulating immune complexes formed outside the joint are nonspecifically trapped within synovial membranes, similar to what happens with immune complex glomerular disease. Deposited immune complexes incite a suppurative response that in turn causes damage to the joint. This mechanism is essentially immune-mediated disease induced by an infectious agent (see later discussion of immune-mediated conditions).

Rhodococcus equi infection in foals most characteristically manifests as bronchopneumonia but affected foals may have many extrapulmonary disorders (EPD) as well. About one-third of the cases will show polyarticular joint swelling, which may be a prominent clinical finding [23–26]. Affected animals are not typically lame, joint swelling resolves with resolution of the pneumonia, and they have no lasting joint damage. Synovial fluid may show a neutrophilic inflammatory response without identifiable bacteria cytologically or by culture [25, 26]. However, some foals may have a true septic arthritis, osteomyelitis or both with organisms cultured from the joints [26]. Thus, the distinction between infectious arthritis and immune-mediated arthritis secondary to infectious disease is not clear cut in all cases.

Synovial fluid findings

Arthritis caused by infectious diseases typically results in a TNCC >50,000/μL and often >100,000/μL [19–22]. Septic arthritis of the joint itself is unlikely if the cell count is only mildly increased (<~20,000/μL), even if there is a neutrophilic predominance. The neutrophils in bacterial arthritis are often uncharacteristically nondegenerate because the viscosity of the synovial fluid is protective to cell morphology (Figure 43.7) [21, 22]. While not common, if degenerative change of the neutrophils is observed, then bacterial sepsis should be strongly suspected and a diligent search for infectious organisms on the slides should be performed (Figure 43.8).

If intracellular bacteria, or other infectious agents, can be found on cytology then septic arthritis is confirmed. However, in most cases bacteria are either not evident in the smears or are present in extremely low numbers, making direct visualization of bacteria in smear an insensitive method to confirm sepsis [19, 21]. If clinical and/or cytologic findings are suggestive of bacterial infection, culture should be performed by directly inoculating culture systems at the time of sample collection [27]. Even with properly performed culture, bacteria are not always isolated from cases of septic arthritis [27, 28]. Certain organisms, such as anaerobes and *Mycoplasma* spp., require specific culture conditions and the microbiology lab should be consulted for specific sample handling recommendations if these are suspected. *Mycoplasma* spp. is a significant cause of septic arthritis in cattle and specific culture should be considered in all cases of septic arthritis from this species [29].

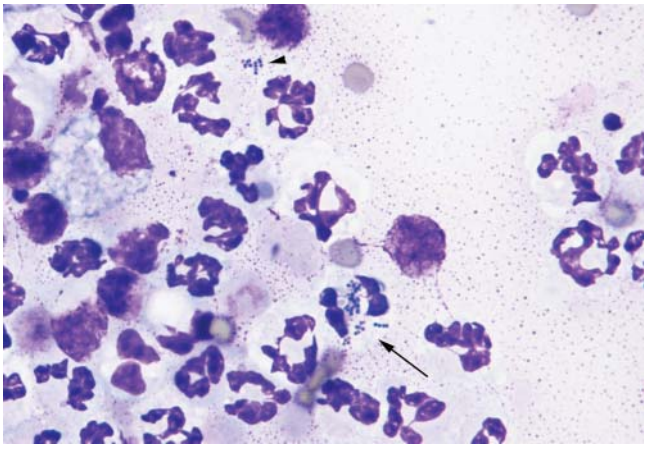

Figure 43.8 Direct smear of synovial fluid from a horse with septic arthritis. Bacterial rods are seen both within neutrophils (arrow) and extracellularly (arrowhead) in the presence of a marked suppurative response. Bacteria are often not present in cytologic preps in cases of septic arthritis, and culture should always be performed if clinical findings are suggestive. Aqueous Romanowsky stain, 1000× original magnification.

Various organisms involved in infectious arthritis

Bacteria are the most common infectious agents in septic arthritis in all species [27, 29–31]. In adult animals, these are usually monoarticular infections resulting from direct inoculation of the joint from a puncture wound or other traumatic injury. Polyarticular disease may occur secondary to septicemia, such as in cases of bacterial endocarditis in adults or navel infection in neonates. In some cases, the site of hematogenous spread is not apparent [32].

Certain rickettsial diseases commonly induce a neutrophilic polyarthritis. Lameness and neutrophilic polyarthritis are common findings in dogs infected with either *Ehrlichia ewingii* or *Anaplasma phagocytophilum* and should be considered in geographically endemic areas [33, 34]. Synovial fluid cell counts range from 15,000/μL to >100,000/μL. Neutrophils predominate and morulae are commonly found within neutrophils in acute infections (Figure 43.9). Unlike monocytic ehrlichiosis, morulae are often readily identifiable in neutrophils in the peripheral blood of acutely infected animals as well. Conversely, infection with *Ehrlichia canis* has not been reported to cause polyarthritis [35]. Early reports of such noted the morulae to be in neutrophils and likely represented infections with either *E. ewingii* or *A. phagocytophilum* prior to the characterization of these organisms. The inflammation seen with rickettsial organisms may be related to immune complex deposition rather than true infection of the joint. The presence of organisms within the synovial fluid may result simply because they are in peripheral blood neutrophils. Clinical signs of lameness and joint swelling are reported with cases of Rocky Mountain spotted fever in

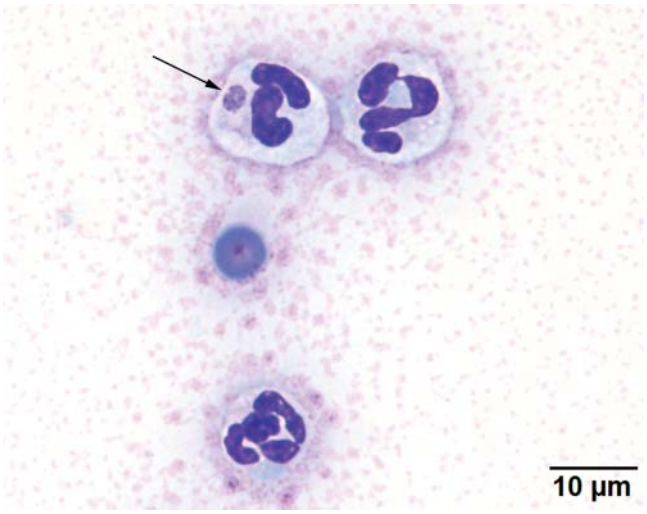

Figure 43.9 Direct smear of synovial fluid from a dog infected with *Ehrlichia ewingii*. Unlike monocytic ehrlichial (e.g., *Ehrlichia canis*) infections, morulae are often present within neutrophils (arrow) in either peripheral blood or synovial fluid in acute infections. Aqueous Romanowsky stain, 1000× original magnification.

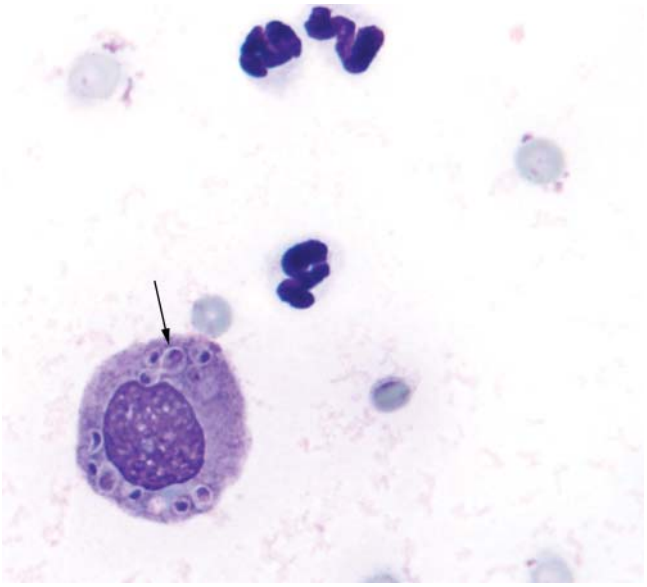

Figure 43.10 Direct smear of synovial fluid from a cat with histoplasmosis. Pyogranulomatous inflammation is typical. Organisms are seen within a macrophage (arrow). In some cases of feline histoplasmosis, lameness may be the primary, and sometimes sole, presenting complaint. Aqueous Romanowsky stain, 1000× original magnification.

dogs, but descriptions of synovial fluid analysis are lacking [27].

Arthritis involving one or several joints is a prominent finding in Lyme borreliosis in dogs. One or several joints are affected and the joint(s) affected may shift over time [36, 37]. Reports of synovial fluid analyses from experimentally affected animals showed an increase in TNCC that ranged from ~2500 to 40,000/µL with neutrophils comprising from ~20% to 90% of the total cells in affected joints of lame dogs [37]. Synovial fluid from unaffected joints in the same animal did not show significant changes.

Fungal diseases are rarely reported as causative agents of arthritis, typically occurring as an extension of fungal osteomyelitis [27]. One notable exception in endemic areas is erosive arthritis induced by histoplasmosis in cats (personal observations). In the author's experience, this is the most common cause of inflammatory joint disease in cats in Oklahoma. Organisms are found in synovial fluid cytology in many cases (Figure 43.10) but may be present in extremely low numbers. Diagnosis is often confirmed via urine antigen measurements. In people, infection of joints with *Candida* spp. has been reported in neonates, secondary to immunosuppression, and following joint implant surgery [38–40]. Rare cases have also been reported in veterinary medicine (Figure 43.11) [41, 42].

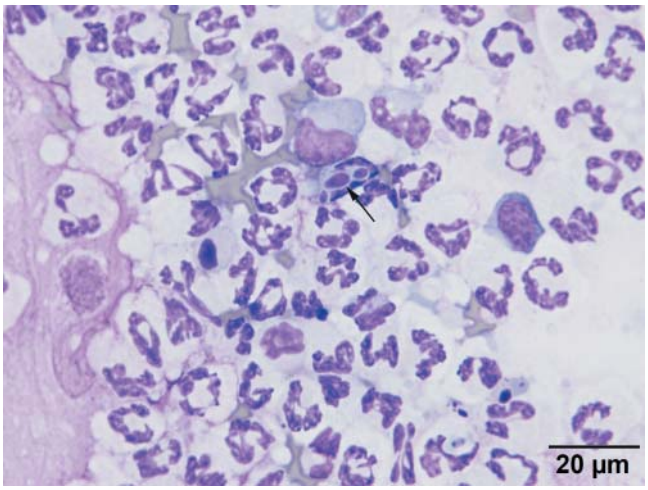

Figure 43.11 Direct smear of synovial fluid from a horse with fungal arthritis following joint surgery. Three fungal yeasts are seen in center (arrow). A thin clear halo is visible surrounding the organisms. *Candida tropicalis* was cultured from the fluid and confirmed via polymerase chain reaction of the isolate. Aqueous Romanowsky stain.

Immune-mediated conditions

Immune-mediated diseases are most common in dogs but have been reported in other species as well. They typically present as polyarticular disease. Different joints may be affected with varying severity and the joint(s) most affected may change over course of disease. In suspected cases it can be beneficial to sample multiple joints, even those that may not appear clinically affected, to confirm the polyarticular nature of the disease as a neutrophilic response is often detected in joints with minimal joint effusion.

The synovial fluid findings are generally similar, or identical to, those seen with arthropathy caused by infectious

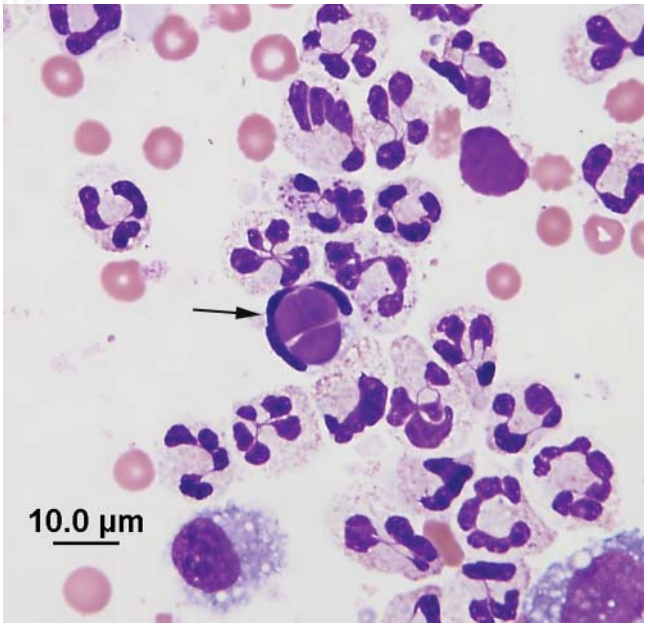

Figure 43.12 Direct smear of canine synovial fluid from a dog with immune-mediated polyarthritis. A lupus erythematosus cell (LE cell) is seen in the central neutrophil, which contains a single large, hyalinized, pink ("ground glass") inclusion (arrow) representing opsonized nuclear material from other cells that have lysed. This material displaces the nucleus of the neutrophil to the periphery. Aqueous Romanowsky stain. Source: Photo courtesy of Dr. Robin W Allison.

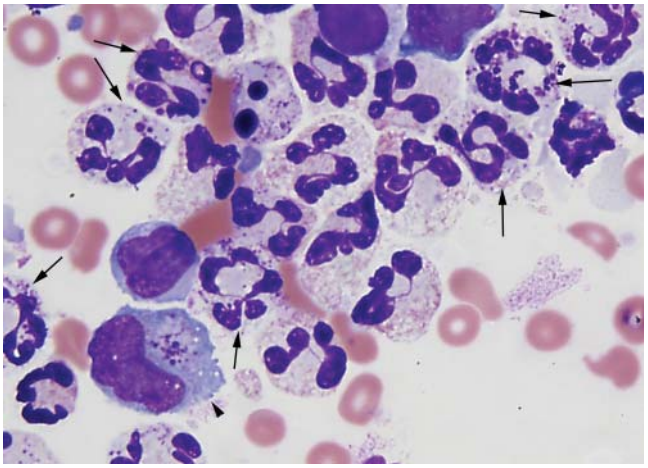

Figure 43.13 Cytospin preparation of synovial fluid from a dog. There is a suppurative inflammatory response present. Many of the neutrophils (arrows) and one macrophage (arrowhead) contain small, purple basophilic inclusions thought to be nuclear material. LE cells were seen in other fields along with these cells. These inclusions resemble bacteria in size and color but are generally more pleomorphic, lacking the distinct shape of bacterial rods or cocci. Aqueous Romanowsky stain, 1000× original magnification.

disease. TNCC may be mildly to markedly increased, depending on the joint sampled, and consist of a predominance of nondegenerate neutrophils. In rare cases, neutrophils may be found that have phagocytized opsonized nuclear material from other cells. These neutrophils are referred to as "LE cells" (lupus erythematosus cells). In the classic LE cell, the nucleus of the neutrophil is often displaced peripherally around a large mass of hyalinized, bright pink to pink-purple material (Figure 43.12). Oftentimes, neutrophils will contain smaller fragments of phagocytized material that stain dark purple, the more typical color of nuclear material. This material is thought to be phagocytized nuclear fragments and must be differentiated from neutrophils containing phagocytized bacteria (Figure 43.13). These cells have been termed "ragocytes," although this name is erroneous and should be discontinued. Finding these cells is suggestive of an immune-mediated pathogenesis, particularly systemic lupus erythematosus (SLE) (discussed later).

Since the cytologic findings in most immune-mediated diseases are similar, the differentiation of specific disease process present relies on clinical findings and additional testing. Table 43.2 lists the various reported conditions and a brief overview is given below. Immune-mediated diseases may be broadly categorized into erosive and nonerosive conditions based on presence of absence of bone lysis evident on imaging. Nonerosive conditions are more numerous, more common and generally associated with a better prognosis [27, 43].

Erosive immune-mediated conditions

The two erosive diseases described in veterinary medicine are rheumatoid arthritis (RA) and feline progressive polyarthritis.

RA has been described in both dogs and cats, although relatively infrequently compared to the incidence of this

disease in humans [43–45]. In people, clinical findings and rheumatoid factor (RF) testing are standard to define this disease. Compared to humans, only a low percentage of dogs suspected as having RA based on clinical findings are positive for RF, and then only at a low titer [43, 45]. Furthermore, positive RF tests are actually seen more frequently in animals with other immune-mediated diseases (SLE) and inflammatory conditions (heartworm disease, pyometra) than in animals with RA [45]. This has led to recommendations that RF not be relied on as a diagnostic test for this disease [27].

A chronic erosive polyarthritis of cats has been described as either *feline progressive polyarthritis* or *periosteal proliferative polyarthritis* [44, 46, 47]. Cats are mostly young to middle aged and the disease most commonly affects hocks and carpi, but any joint may be affected. In one report, about half the cats were euthanized and most others had persistent lameness despite continuous immunosuppressive therapy [44]. At our institution, we have seen a similar clinical presentation eventually attributed to histoplasmosis, with organisms identified in synovial fluid but sometimes not until after several months of immunosuppressive therapy.

Nonerosive immune-mediated conditions

Nonerosive polyarthritis is much more common in veterinary medicine than erosive arthritis. Of these, the majority of cases are idiopathic and this designation requires first excluding the other defined disorders, which are listed in Table 43.2 and briefly described below. Idiopathic immune-mediated polyarthritis (IMPA) itself has been classified into four subtypes. Type I, which is most common, occurs in patients in which there are no inflammatory or neoplastic conditions identified at other sites in the body. The other types are also referred to as *reactive polyarthritis* as they are associated with other conditions. Type II IMPA is defined as polyarthritis associated with an infectious process occurring in any distant tissue (i.e., not articular infections). Type III IMPA, also called *enteropathic*, is associated inflammatory disease of the gastrointestinal tract. Type IV IMPA is defined as polyarthritis associated with underlying neoplasia.

Polyarthritis can also be an uncommon complication of vaccination or administration of certain drugs. Polyarthritis associated with vaccination typically occurs within 5–7 days after inoculation and resolves spontaneously within 1–2 days. This is likely the result of transient circulating immune complex formation induced by the immunization [27]. A temporal association between onset of polyarthritis and administration of any drug therapy should prompt consideration of a causal relationship. Polyarthritis has been described in Doberman pinscher dogs following TMS therapy [48]. Clinical signs began between 10 and 21 days after initiation of treatment and rapid resolution was noted following withdrawal of the offending drug [48]. Repeated exposure to the drug resulted in relapse of signs.

Breed-specific polyarthritis has been reported in Shar Pei dogs associated with amyloidosis ("Shar Pei fever") and in young Akita dogs. In Shar Pei dogs, the hock joints are most commonly affected but carpal joints may also be involved. Usually only one or few joints are affected at a time, but joints affected can vary between episodes in a single individual. There are rare reports of synovial fluid findings [49, 50]. One dog showed a marked nonseptic, neutrophilic inflammation during acute disease, with normal joint fluid cytology seen during remission [49]. Another report demonstrated normal synovial fluid findings from several clinically affected as well as unaffected joints [50]. Joint pain and swelling is usually short-lived and resolves either without treatment or with administration of nonsteroidal anti-inflammatory drugs [49]. By contrast, Akita dogs seem to have a guarded prognosis and poor response despite treatment with immunosuppressive drugs [51]. Affected dogs usually first show clinical signs at a young age (<8 months) and have recurrent episodes of profound pain, which are often associated with fever and peripheral lymphadenopathy. Some affected dogs may also have suppurative meningitis [51].

Polyarthritis has also been associated with immune-mediated diseases concurrently affecting other tissues. Some dogs that present with steroid-responsive meningitis-arteritis (SMRA) also have IMPA [52]. Most cases are in young, medium- to large-breed dogs and clinical signs are often predominantly related to the meningitis, such as pain on flexion of neck. Lameness and joint effusion may not be evident despite inflammatory synovial fluid. Reported cases have responded well to immunosuppressive therapy. Polyarthritis has also been reported in association with polymyositis, predominantly in spaniel breeds [52, 53]. Myositis was confirmed on biopsy of at least two muscles in each case. Antinuclear antibody (ANA) testing was negative in all cases. The response to immunosuppressive therapy was more variable leading to the suggestion of worsened prognosis when polymyositis and arthritis occur concurrently compared to idiopathic IMPA alone [53].

SLE is a true autoimmune disease in which there is formation of antinuclear antibodies, in addition to autoantibodies against other cellular constituents [54]. Cases have been reported in both dogs and cats, although this disease is much less common than idiopathic IMPA. SLE should be considered when there are multiple, characteristic abnormalities present. Nonerosive polyarthritis is the most common clinical manifestation, but most affected animals also have glomerular protein loss and dermatologic lesions [54]. Immune-mediated cytopenias of any hematologic cell line may also be seen but are much less common than the previously mentioned features. Measurement of antinuclear antibodies is the most commonly performed "specific" test, although diagnosis of SLE is not based on any one finding or test result. One feature of note in some cases of SLE is identification of so-called "LE cells" (lupus erythematosus

cells) in synovial fluid or other body fluids (Figure 43.12). These cells form when neutrophils phagocytize opsonized nuclear material that has been released from other cells in the fluid. The neutrophil nucleus is displaced peripherally by the phagocytized material, which has a characteristic, hyalinized pink appearance. While these cells are uncommon, when seen they are strongly suggestive of SLE. In addition to the characteristic LE cells, neutrophils may also contain small, dark fragments of material presumed to also be phagocytized nuclear material. These often lack the characteristic, smooth, pink appearance of the material in LE cells and must be differentiated from bacteria (Figure 43.13).

Other causes of suppurative arthropathy

While immune-mediated and infectious disease are the most common causes of a neutrophilic arthropathy, other possibilities need to be considered.

Repeated arthrocentesis at 3-week intervals did not induce a significant increase in synovial fluid neutrophil numbers in nine healthy dogs [55]. Likewise, arthrocentesis repeated at either weekly or 10-day intervals in normal horses did not result in significant changes in TNCC or percentage of neutrophils [56]. However, a study of normal calves did show an increase in both TNCC (mean 14,000/μL) and absolute neutrophil count (mean 7920/μL) in repeat samples collected 24 hours after initial sample [57]. Similar increases in TNCC have been noted 24 hours after initial arthrocentesis in horses [58], so caution should be exercised in interpretation if repeated samples are collected in this short of a time interval.

Intra-articular injections (antibiotics, local anesthetics, corticosteroids) can often incite a rapid neutrophilic inflammatory response, the magnitude of which can vary depending on the degree of irritation incited by the injected agent [5]. TNCCs greater than 30,000/μL have been observed. Even lavage of the joint with saline can result in a moderate neutrophilic inflammatory response [58]. Marked inflammation of periarticular tissues may also be associated with a neutrophilic response within the synovial fluid itself [15]. Mild neutrophilic inflammatory response sometimes occurs following chronic hemarthrosis.

General considerations in differentiating infectious from immune-mediated arthropathies

If there is no history suggesting administration of intra-articular injections, lavage, or joint trauma in a case with suppurative arthritis, then a distinction between infectious and immune-mediated disease must be made.

The only potential relevant findings from the fluid cytology itself regarding this decision would be either the presence of (i) infectious organisms (bacteria, morulae, yeast) or markedly degenerate neutrophils, which would support infectious causes, or (ii) LE cells or neutrophils with other phagocytized nuclear material, which would support immune-mediated causes. These are uncommon to rare findings but should be specifically considered and searched for in such cases. Other factors to consider are the cell count and percentage of neutrophils present. Most cases of septic arthritis have markedly increased cell counts (typically >50,000/μL and often >100,000/μL). By contrast, with immune-mediated disease, including those induced by systemic infections resulting in immune-complex disease, TNCC may vary from mildly to markedly increased. Additionally, with true septic arthritis neutrophils usually comprise the vast majority (>90%) of the nucleated cells. By contrast, with immune-mediated diseases the neutrophil percentage may vary from 20% to >90% of all nucleated cells. Thus, in cases with only a mild increase in cellularity or percentage of neutrophils, immune-mediated disease is more likely. If there is a marked increase in cellularity and marked predominance of neutrophils, septic or immune-mediated are equally likely. It is important to realize that in many cases, the above findings will not differentiate the two processes and distinction must be made by the clinician based on other clinical considerations.

Monoarticular involvement is more likely to be related to an infectious cause since most immune-mediated diseases result in a polyarthropathy [21, 27]. Sampling of several joints may help detect polyarticular involvement even if joints are seemingly unaffected based on physical findings. Prior surgery, intra-articular injections, or a traumatic wound near the affected joint would be common potential sources of infection [21, 27].

Polyarthritis is typical of immune-mediated diseases but can also be seen with infectious disease resulting from hematogenous spread rather than a penetrating wound [27]. Immune-mediated disease is more common in dogs than in other species and is the most common cause of polyarthritis in that species. Hematogenous spread of bacteria is most common with neonatal sepsis or bacterial endocarditis [27]. Regionally endemic systemic infections appropriate for the species of the patient (e.g., neutrophilic ehrlichiosis in dogs, histoplasmosis in cats, post-*Rhodococcus* infection in foals) must also be considered and ruled out via infectious disease testing.

Hemorrhagic or hemodilute samples

Samples that are hemodilute result from either (i) true hemarthrosis, (ii) blood contamination during sample collection, or (iii) diapedesis of red cells (transmigration across intact capillaries) that is often seen in association with inflammatory arthropathies. These can typically be differentiated based on a combination of the characteristics noted during collection and the cytologic findings.

Hemarthrosis

In true hemarthrosis, the sample is typically noted to be bloody from the very beginning of collection rather than

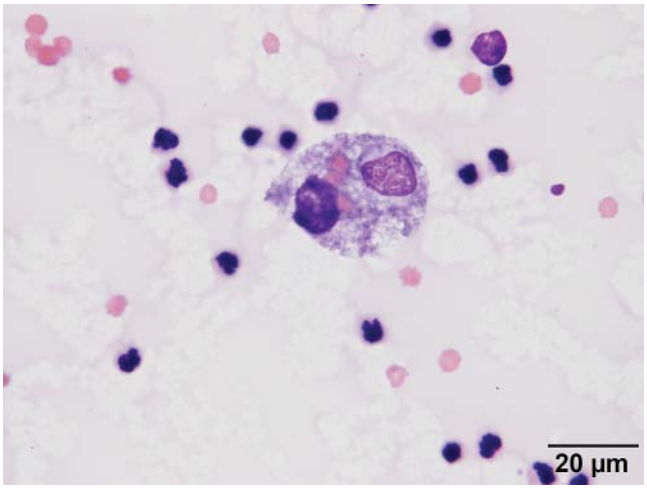

Figure 43.14 Direct smear of feline synovial fluid. A macrophage in the center displays phagocytosis or erythrocytes (erythrophagia). This finding suggests either hemarthrosis or diapedesis of erythrocytes secondary to inflammation rather than blood contamination during sample collection. In this case, there are many poorly spread out neutrophils surrounding the macrophage as well as relatively few erythrocytes, suggesting inflammation-induced diapedesis rather than frank intra-articular hemorrhage. Aqueous Romanowsky stain.

starting out clear. Cytologically, erythrocytes and leukocytes are generally present in numbers proportional to those seen in peripheral blood, after accounting for the patient's peripheral WBC count. This is subjectively assessed and is easy to do with experience. The sample may be compared to a blood film prepared from peripheral blood if there is any doubt.

With true hemarthrosis, macrophages may either display *erythrophagia* (phagocytosis of erythrocytes) or contain dark cytoplasmic pigment representing hemosiderin formed as a result of metabolism of erythrocyte hemoglobin (Figure 43.14). It is important to realize that erythrophagia is not found in every case since the amount of blood present may dilute out macrophages and make them difficult to find.

Even with blood contamination, *in vitro* erythrophagia may occur in the tube within a few hours. Therefore, direct smears should always be made immediately upon collection. Following bleeding into any body cavity such as the synovial space, platelets will aggregate and be removed. Thus, neither platelets nor platelet clumps will be seen unless the hemorrhage is active and ongoing. With chronic hemarthrosis, xanthochromia, a yellowish discoloration that forms from production of pigments from hemoglobin metabolism, may be noted in the supernatant formed following synovial fluid centrifugation.

Blood is cleared rapidly from the joint after a single bleeding event, at least in dogs. An *in vivo* study in dogs showed clearance of 71% of red cells at 24 hours and 96% at 48 hours [59]. The experimental hemorrhage was associated with an apparent inflammatory response as the TNCC increased from a baseline of <5000/µL to between ~5000 and 10,000/µL at 15 minutes and further increased to ~10,000 to 20,000/µL at 24 hours before returning to ~5000/µL at 48 hours. Unfortunately, differential leukocyte counts were not reported in this study. However, given the magnitude of the increase, this was likely a neutrophilic response. Experimental hemarthrosis in horses was noted to cause a "mild to moderate" increase in total WBC, neutrophils and mononuclear cells at 24 hours, which had resolved by 30 days, although the magnitude of the increases was not listed [60].

Hemarthrosis most often results from an acute traumatic injury to the joint. Recurrent hemarthrosis may also occur in animals with a hemostatic defect. Abnormalities of coagulation factors (hemophilia, vitamin K antagonism) are more likely to result in hemarthrosis than are platelet disorders such as thrombocytopenia. Intra-articular neoplasia is a much less common potential cause of hemarthrosis.

Contamination during collection

Blood contamination during sample collection can range from a minor increase in erythrocytes, only noted via microscopic examination, to a grossly blood sample. Compared to hemarthrosis, the collector may notice the sample be initially clear and then become bloody. Erythrophagia will be absent if smears were made immediately and platelets and/or platelet clumps will typically be found (Figure 43.15).

Direct smears should be examined even if there is blood contamination from sample collection to see if there is any evidence of leukocyte changes beyond what would be expected by the amount of hemorrhage. This is accomplished

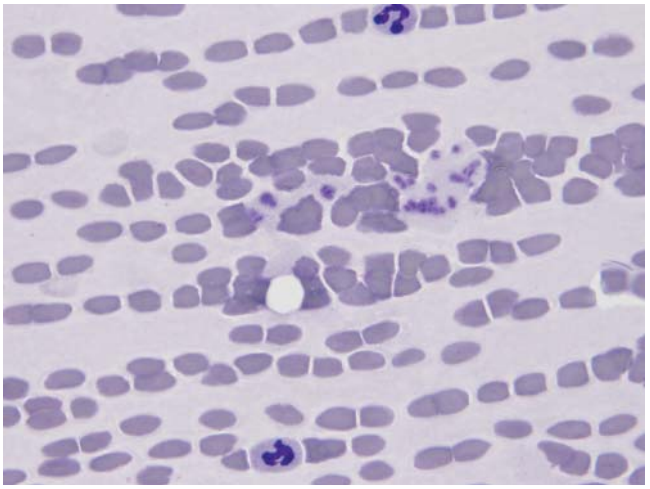

Figure 43.15 Iatrogenic blood contamination during sample collection in a direct smear of canine synovial fluid. Platelets are present in the center of the image amidst numerous erythrocytes exhibiting windrowing. Since platelets are removed quickly following intra-articular hemorrhage, this finding suggests either blood contamination during collection or ongoing hemorrhage. Aqueous Romanowsky stain, 500× original magnification.

by finding either (i) increased numbers of cells that would not be expected to come from peripheral blood (i.e., large, vacuolated macrophages) or (ii) a subjectively greater total number of neutrophils than would be expected from the amount of blood present. The former situation would suggest underlying degenerative joint disease. The latter situation may be seen in cases of infectious or immune-mediated joint disease. Since suppurative arthropathies are typically associated with dramatically increased neutrophil counts, detecting underlying inflammation may be possible despite significant blood contamination.

Blood contamination will have a significant effect on the *percentage* of neutrophils present, since normal synovial fluid has few neutrophils while neutrophils are the most prevalent leukocyte in peripheral blood. However, the effect on TNCC or TP is often minimal. One study examined the effects of blood contamination on synovial fluid results by adding autologous peripheral blood to normal synovial fluid *in vitro* in volumes up to 50% of the sample. While there were *statistically significant* increases in both TNCC and TP, the highest TNCC reported was 5000/μL and the highest TP found was 3.2 g/dL, even with addition of 50% blood [61]. Thus, even gross blood contamination is not likely to result in TNCCs suggestive of inflammatory arthropathies.

Hemorrhage/diapedesis secondary to DJD/inflammation

Minor hemorrhage or diapedesis of erythrocytes may occur secondary to either DJD or inflammatory arthropathies but is more common with inflammation. In these cases, the leukocyte changes related to the underlying condition are typically most prominent, but there may be mild to moderate increases in the numbers of erythrocytes in the background. Unless the sample is grossly discolored, the blood is unlikely to have a clinically significant effect on the TNCC. There may be an increased percentage of neutrophils present, especially if the baseline total cell count is low, since neutrophils will be the most common leukocyte added by the peripheral blood.

Neoplasia

Diagnosis of neoplasia via synovial fluid analysis is extremely rare. Certain primary neoplasms can involve the synovial membrane itself. The most common of these are synovial histiocytic sarcoma and synovial myxoma, but a variety of other sarcomas may less commonly arise from synovial tissue [62]. The histogenesis of the neoplasm previously termed "synovial cell sarcoma" is controversial. Many reported cases were likely misclassifications of histiocytic tumors prior to the widespread use of immunohistochemistry. The analogous tumor in humans is now thought to arise from a mesenchymal stem cell rather than truly being of synovial origin, even though the name has not changed [62]. Regardless, the diagnosis of these tumors is typically based on either histologic biopsy or fine needle aspiration biopsy of the lesion itself rather than from examination of synovial fluid.

Certain carcinomas have a propensity to metastasize to joint spaces. There are sporadic reports of patients presenting with a primary complaint of lameness and a diagnosis of metastatic carcinoma made by finding neoplastic cells via cytologic evaluation of synovial fluid (Figures 43.16 and 43.17) [63, 64].

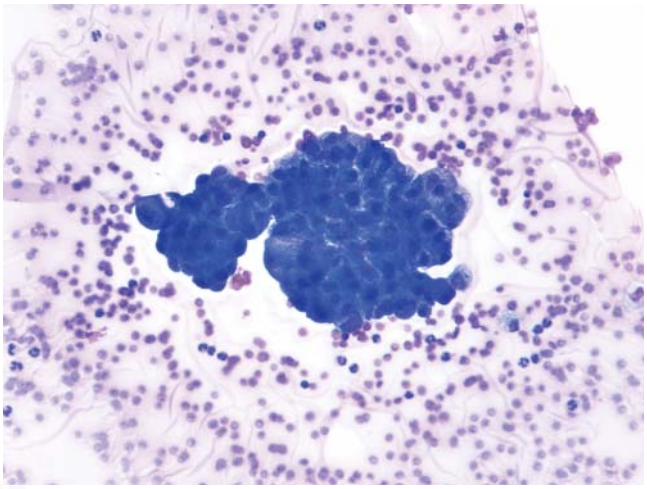

Figure 43.16 A large cluster of epithelial cells in a direct smear of synovial fluid of a dog with metastatic transitional cell carcinoma causing lameness. Epithelial cells are poorly spread out, which obscures cellular detail, but they are an atypical finding in synovial fluid. Aqueous Romanowsky stain, 200× original magnification.

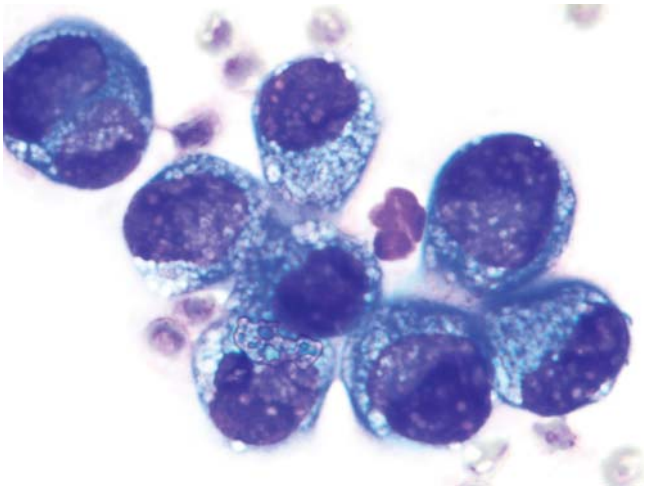

Figure 43.17 Higher magnification of cells from the same case as in Figure 43.16. Atypical epithelial cells are well spread out, allowing identification of cellular atypia. The cells have a high N : C ratio and significant anisokaryosis. Aqueous Romanowsky stain, 1000× original magnification.

44 Cytology of Abdominal Organs

Mary Anna Thrall[1] and Andrea A. Bohn[2]

[1]Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

[2]Department of Microbiology, Immunology and Pathology, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, CO, USA

This chapter is a relatively brief introduction to cytology of selected organs, with emphasis on the liver and spleen. The reader is referred to other books such as *Veterinary Cytology* edited by Sharkey et al. (Wiley-Blackwell, 2021) for more detailed information. Examination of cytologic material that has been aspirated from enlarged abdominal organs and abnormal masses within the abdominal cavity is commonly used as a diagnostic aid. While aspiration can sometimes be accomplished using palpation, ultrasonography is almost always utilized in localizing specific organs and masses. This diagnostic tool has introduced an artifact in cytologic preparations: the presence of ultrasound gel on the slide, which is amorphous and stains a magenta color (Figure 44.1). To avoid contamination of the slide with gel, a minimum amount should be used, and the gel should be wiped from the biopsy site with gauze and alcohol prior to aspiration and removed from fingers if present. An excellent review of preferred techniques for obtaining cytologic samples has been published (see Liffman and Courtman 2017 in "Suggested Reading" under "General").

The discussion below is categorized by organ. The general principles of cytology apply to the interpretation when examining material from any abdominal mass or organ. One is generally attempting to determine if the tissue is normal, and if not, if inflammation or neoplasia is present. If inflammation is present, one then tries to determine the cause of the inflammation. Non-neoplastic, noninflammatory lesions may also be diagnosed, such as cystic structures, and depending on the organ involved, other abnormalities may be detected. Examples of specific causes of abdominal organ enlargement not due to inflammation or neoplasia would include hepatic lipidosis, extramedullary hematopoiesis (EMH) in the spleen, etc.

Liver

Indications

Hepatomegaly and nodular lesions identified by ultrasonography are the primary reasons for liver aspiration. Other indications include the suspicion of neoplasia or inflammation within the liver, suspicion of hepatic lipidosis, and increases in liver enzyme activity and/or bile acids in blood. The primary contraindications are abnormal hemostasis, caused by either thrombocytopenia (<30,000/μL) or decreased coagulation factor activity, and the suspicion of hemangiosarcoma, which could potentially rupture if lacerated during aspiration. In dogs with normal or mild coagulation abnormalities, hemorrhage as evidenced by decreased packed cell volume occurred in 42% of dogs in which ultrasound-guided percutaneous liver biopsies were obtained (see Reece et al. 2020 in "Suggested Reading" under "Liver"). However, fine-needle aspiration is much less likely to result in hemorrhage, which is one of the advantages of fine-needle aspiration over biopsy. In general, if tissue architecture is needed for the diagnosis, a biopsy is indicated, as cytology will not be diagnostic.

Technique

Unguided liver aspirates are usually taken from the left side, with the animal in right lateral or dorsal recumbency or standing. More commonly, cytologic samples are taken using ultrasound guidance. More cellular samples with less blood contamination are obtained using a nonaspiration technique, in which a 22-gauge needle of varying length (2.5–8.9 cm) is attached to a 12-mL syringe via a 30-in. flexible extension line normally used for IV sets. The syringe is filled with air, then hung over the shoulder to keep it out

of the way, and the needle is held like a pen to enhance manipulation. Visualization of the needle point is enhanced by orienting the bevel toward the transducer. The transducer is pointed directly toward the target that is to be aspirated, and the needle is maintained in the center of the ultrasound beam. To avoid tissue trauma–induced clotting, the needle tip is positioned in the area to be aspirated within 10 seconds. Once within the target, the needle tip is moved rapidly back and forth 5–10 times without using negative pressure. The back-and-forth motion of the needle detaches cells, and the lack of negative pressure decreases the chance of blood contamination. The needle is removed from the animal, and the biopsy material within the lumen of the needle is expelled onto one or two glass slides using the syringe that was prefilled with air. The slides are then prepared using the pull technique described in Chapter 2, air dried, and stained. Three separate aspirates from different areas of the lesion should be obtained to improve the chances of making a correct cytologic diagnosis. This technique is described in more detail elsewhere (see Menard and Papageorges 1995 in "Suggested Reading" under "Liver"). When compared to aspirates using negative pressure, aspirates without negative pressure such as described above have greater cellularity, less blood contamination, and fewer broken cells (see Fleming et al. 2019 in "Suggested Reading" under "Liver").

Interpretation of liver aspirates

A significant amount of variability has been reported regarding the diagnostic accuracy of liver cytology when compared to histopathology. Quality of the samples and expertise and experience of the cytologists and histopathologists likely contribute to this reported variability. In general, cytology of focal lesions is more sensitive and has a higher positive predictive value for the diagnosis of vacuolar change and neoplasia, and is less sensitive and has a lower positive predictive value for the diagnosis of inflammation, necrosis, and hyperplasia (see Bahr et al. 2013 in "Suggested Reading" under "Liver"). Even though the cytologic findings may not exactly match those of histopathology, numerous liver diseases can often be accurately diagnosed using cytology, including (i) increased cytoplasmic vacuolation due to hydropic degeneration, accumulation of glycogen, or accumulation of lipid; (ii) increased copper in the cytoplasm; (iii) cholestasis; (iv) inflammation; (v) metastatic and primary liver neoplasia; and (vi) fibrosis. Cytologic descriptions of aspirates of normal and abnormal liver are presented below.

Normal

Normal hepatocytes are uniform, large, round cells with abundant amphophilic, somewhat granular cytoplasm. Cells contain a round centrally located nucleus with a single prominent pale blue to lavender nucleolus. Cells sometimes contain two nuclei. Normal hepatocytes often contain a small amount of dark blue-black pigment (Figure 44.2). This pigment is lipofuscin, a type of lipid within lysosomes that is commonly seen in older animals and typically is a slightly lighter and bluer color than is bile pigment or hemosiderin. The presence of lipofuscin can be confirmed by numerous lipid-staining methods such as Sudan III, oil red, and ferric ferricyanide (Schmori method I). Bile is rarely seen within hepatocytes and appears as dark green-blue or blue-black and can be identified with certainty by using a bile stain. Hemosiderin may also be seen within hepatocytes and is usually a more golden-brown to dark brown color and can be confirmed by an iron stain such as Prussian blue. Increased amounts of hemosiderin are seen in hepatocytes and macrophages of animals with hemolytic anemia.

Hepatocytes may occur singly or in clusters. Very infrequently, rectangular crystalline clear to pink-colored inclusions may be seen in the nuclei of some hepatocytes and are of no known significance (see Richter et al. 1965 in "Suggested Reading" under "Liver"). Biliary epithelial cells (cholangiocytes) may also be seen occasionally in normal

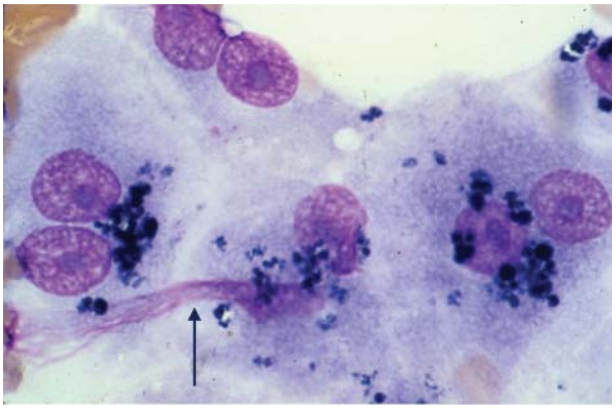

Figure 44.2 High magnification of normal binucleate hepatocytes. Note the single prominent nucleoli. One of the nuclei has ruptured and is streaming to the left (arrow). Lipofuscin granules within the hepatocytes are normal. Wright stain.

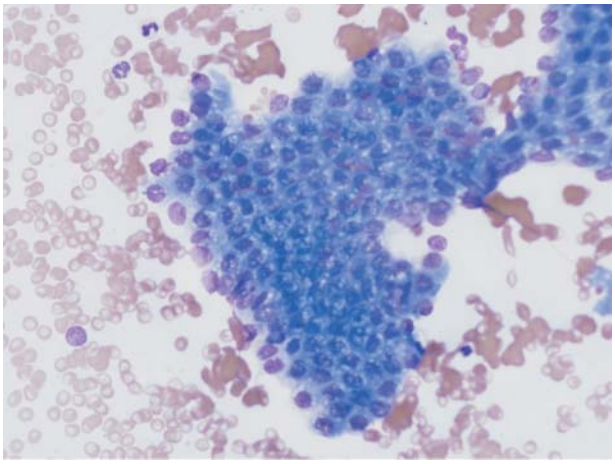

Figure 44.3 A cluster of biliary epithelial cells (cholangiocytes). Wright stain.

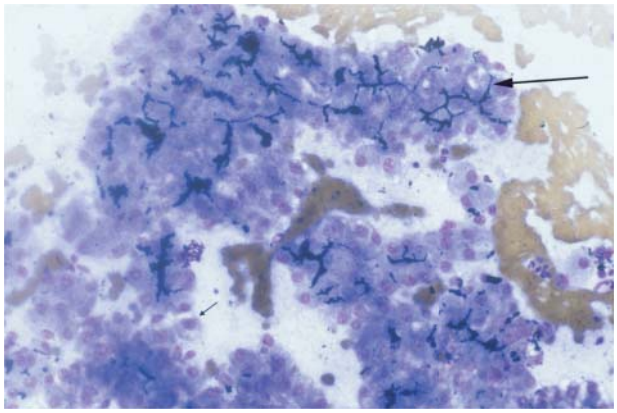

Figure 44.4 Aspirate of liver with marked cholestasis. Bile pigment is in canaliculi, exhibiting a linear appearance (large arrow). Most hepatocytes appear relatively normal, with a few showing vacuolar change (small arrow). Wright stain.

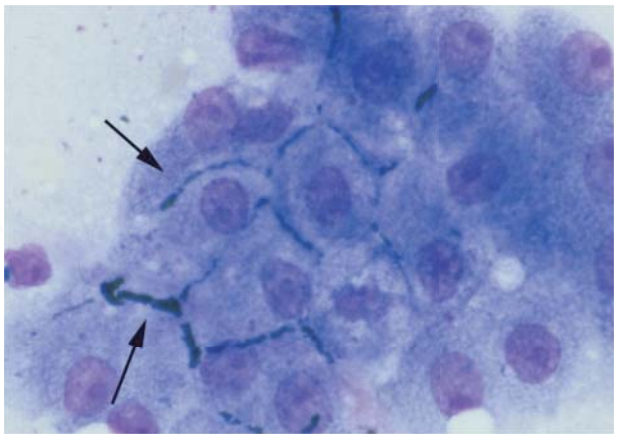

Figure 44.5 High magnification of bile pigment in canaliculi between hepatocytes (arrows). Wright stain.

aspirates. They are small and uniform in size with round nuclei and a relatively small amount of pale blue cytoplasm (Figure 44.3). Other cells occasionally observed in small numbers in aspirates from normal livers include mast cells, macrophages (Kupffer cells), lymphocytes, and neutrophils. Hepatic stellate cells (Ito cells) are rarely observed. They are round and contain clear globules of lipid within the cytoplasm. Mesothelial cells from the surface of the liver are occasionally seen in liver aspirates and should not be confused with neoplastic epithelial cells or fibroblasts. Occasionally hematopoietic precursors can be seen in aspirates of normal liver. Although aspirates of the liver of normal kittens are usually not indicated or performed, the hepatocytes of normal kittens often contain vacuoles that appear to be lipid.

Cholestasis

In animals with either intrahepatic or extrahepatic cholestasis, an increased amount of bile pigment may be observed within hepatocytes. Much more significantly, extracellular canalicular casts of bile, representative of the biliary tree, may be seen between hepatocytes (Figures 44.4 and 44.5).

Inflammation

Inflammation is evidenced by the presence of neutrophils, macrophages, lymphocytes or eosinophils, or some mixture of inflammatory cells. Inflammation may be suppurative (neutrophils) or nonsuppurative (lymphocytes or macrophages). The cytologic presence of inflammation should trigger biopsy and histologic examination, since the distribution of the inflammation cannot be determined unless an abscess visualized by ultrasonography was aspirated. The presence of inflammatory cells may indicate chronic hepatitis, acute hepatitis, cholangitis, cholangiohepatitis, or could accompany neoplasia. Liver inflammation in dogs is usually idiopathic or copper-related but can also be secondary to infectious diseases or neoplasia. In cats, cholangitis may be associated with the liver fluke *Platynosomum fastosum*, the incidence of which is very high in tropical and subtropical regions of the world such as the Caribbean and Brazil (Figure 44.6). In one study, eggs of *P. fastosum* were seen from 81% of stray cats in St. Kitts (see Krecek et al. 2010 in "Suggested Reading" under "Liver"). Centrilobular congestion, cholestasis, fibrosis, and liver failure may also be associated with this parasite, which is acquired by eating infected lizards.

Finding leukocytes within clusters of hepatocytes usually is indicative of hepatitis (Figures 44.7–44.10). Macrophagic inflammation may be indicative of an infectious disease that is typically associated with that type of inflammation, such as those caused by *Mycobacterium* spp., fungal diseases such as histoplasmosis, or protozoal diseases caused by *Leishmania* spp. or *Cytauxzoon* spp. (Figure 44.11). Ehrlichia morulae have been reported in lymphocytes within liver aspirates from a dog with hepatitis secondary to canine monocytic ehrlichiosis (see Mylonakis et al. 2010 in "Suggested

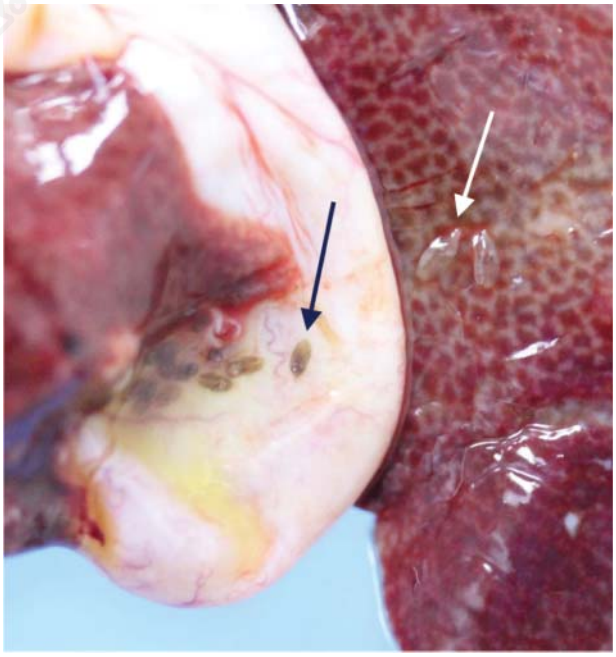

Figure 44.6 Cat liver fluke *Platynosomum fastosum* (arrows) on the surface of the liver after dissecting the gall bladder, bile ducts, and liver at autopsy of an adult St. Kitts cat. Note the enhanced reticular pattern of the liver due to congestion. The multiple lancet-shaped trematodes are approximately 5–12 mm long and 1 mm wide with a brown uterus and white vitellaria visible through the semitransparent tegument. Figure 44.7 Liver aspirate from a dog with mixed inflammation. Lymphocytes are indicated by dashed arrows and neutrophils by solid arrows. Note the vacuolar change in the hepatocytes. Wright stain.

Reading" under "Liver"). Rarely viral inclusions of canine infectious hepatitis may be seen in hepatocyte nuclei; they appear as magenta-colored bodies of various sizes, surrounded by chromatin. If neutrophils or lymphocytes are seen in a liver aspirate, one should consider if they are from blood contamination of the sample and check the complete blood count for the presence of neutrophilia or lymphocytosis.

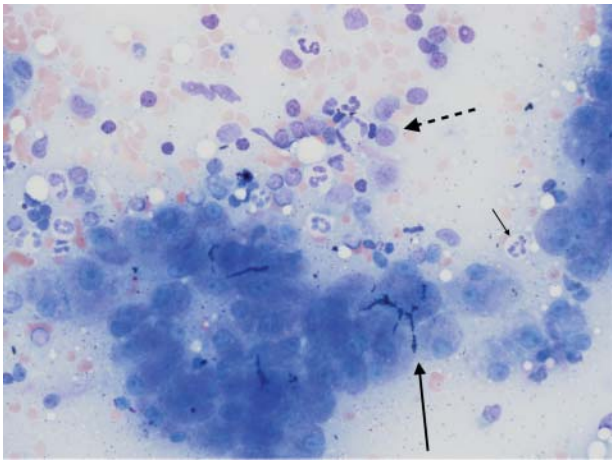

Figure 44.8 Liver aspirate from a dog with marked mixed inflammation. Many lymphocytes (dashed arrow) and neutrophils (small solid arrow) are present. Note the linear bile pigment within canaliculi between hepatocytes (large arrow) indicating cholestasis. Wright stain.

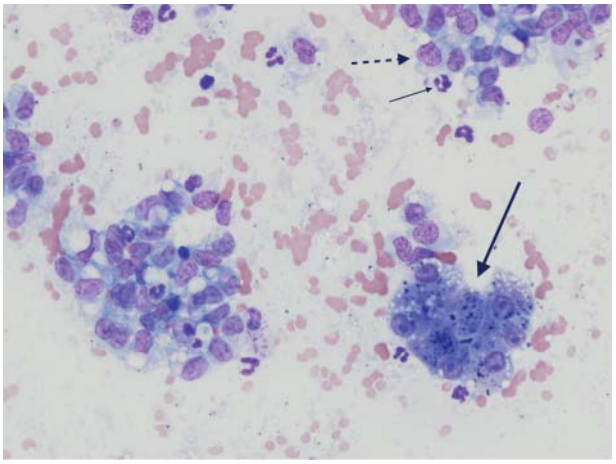

Figure 44.9 Liver aspirate from a cat with chronic inflammation of the liver. A cluster of hepatocytes (large arrow) with mild to moderate vacuolar change and pigment (likely lipofuscin) within the cytoplasm are shown in the center of the image. Neutrophils (small arrow) are scattered throughout, and an aggregate of macrophages is shown by the dashed arrow. Wright stain.

Vacuolar change

Vacuoles within the cytoplasm of hepatocytes are usually due to hepatic lipidosis, increased glycogen content, or hydropic degeneration. The presence of clear round discrete vacuoles is usually suggestive of lipid; the vacuoles may vary in size from small to large ballooning vesicles that distend hepatocytes, pushing the nucleus to the side, making them appear similar to small adipocytes (Figures 44.12 and 44.13). The clear staining areas are categorized by their size as either microvesicular or macrovesicular but on cytology often seem quite variable. Poorly delineated, light-colored, lacy-appearing areas in the cytoplasm are usually suggestive of increased glycogen content or hydropic degeneration (Figure 44.14). Special stains, such as periodic acid-Schiff (PAS) for glycogen or Sudan III for lipid, may be helpful

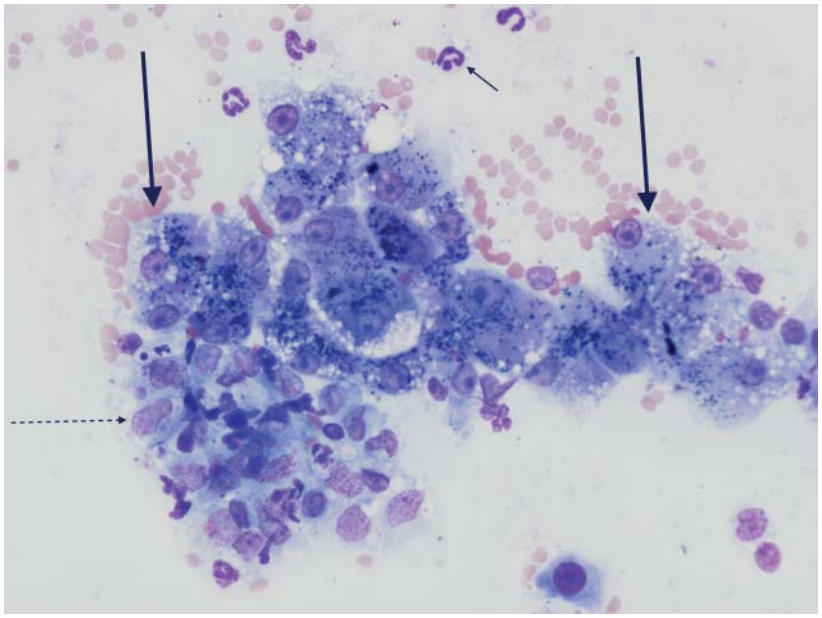

Figure 44.10 Same aspirate as shown in Figure 44.9. Large arrows indicate hepatocytes with vacuoles and lipofuscin, small arrow indicates neutrophil, and dashed arrow indicates macrophage. Wright stain.

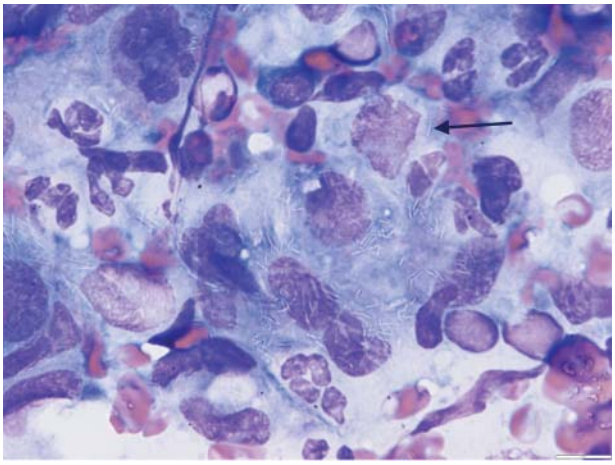

Figure 44.11 Aspirate of the liver of a dog. Pyogranulomatous inflammation is present as shown by the neutrophils and macrophages. Within the macrophages are clear nonstaining rods consistent with *Mycobacteria spp* (arrow). Wright stain.

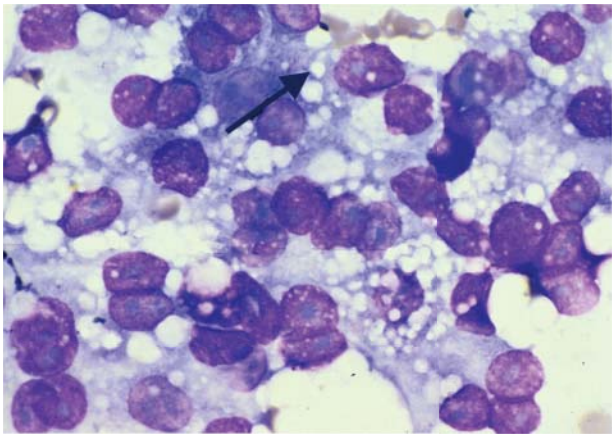

Figure 44.12 Aspirate of an enlarged liver from a patient with hepatic lipidosis. Note the numerous clear vacuoles within the cytoplasm of the hepatocytes (arrow). Wright stain.

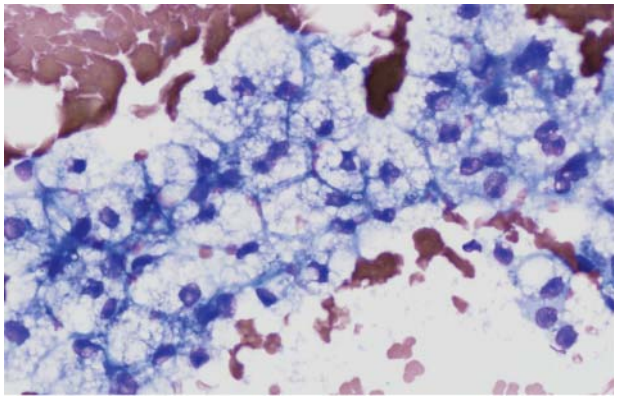

Figure 44.13 Aspirate of an enlarged liver from a patient with hepatic lipidosis. Hepatic vacuolization is marked, making the hepatocytes appear somewhat similar to adipocytes. Wright stain.

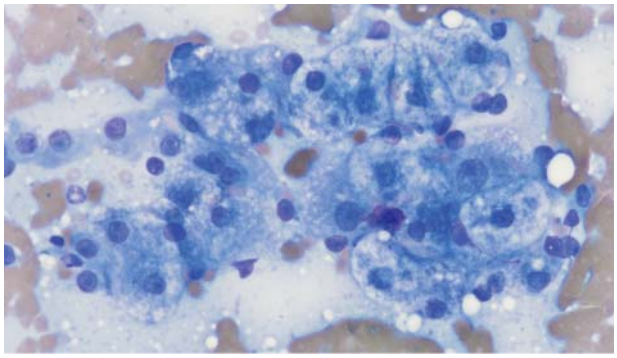

Figure 44.14 Aspirate of an enlarged liver from a dog with steroid hepatopathy. Note the lacy appearance of the cytoplasm compatible with increased glycogen. Wright stain.

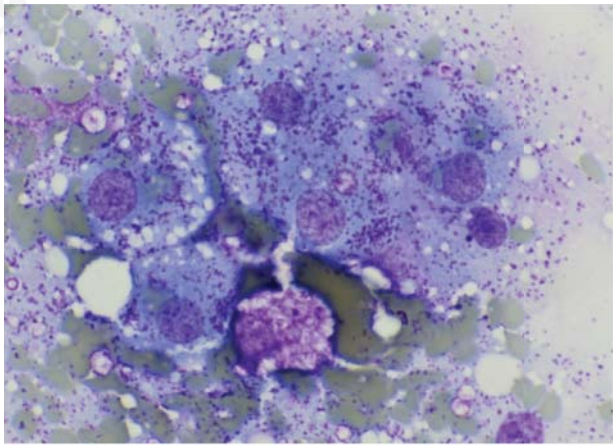

Figure 44.15 Liver aspirate from a cat with mucopolysaccharidosis VI. Note the numerous azurophilic granules within the cytoplasm and free in the background that consist of abnormally stored glycosaminoglycans (dermatan sulfate) resulting from inherited arylsulfatase B deficiency. Wright stain.

in differentiating the cause of vacuolar change. Hepatic lipidosis is more commonly seen in cats, whereas increased glycogen content and hydropic degeneration is more commonly seen in dogs. Steroid hepatopathy is a common cause of increased glycogen content. Although rare, lysosomal storage disorders may result in either granules (the mucopolysaccharidoses) (Figure 44.15) or vacuoles (lipid storage disorders) (Figure 44.16) in hepatocytes as a result of abnormal accumulation of substrate in lysosomes.

Nodular hyperplasia

Nodular hyperplasia is common in old dogs and may appear similar to primary or metastatic neoplasia by ultrasonography. Hyperplastic hepatocytes from these nodules usually appear much like normal hepatocytes. More binucleate hepatocytes may be observed, but the cells usually do not have features of malignancy. Cytologic abnormalities may include subtle increases in cell and nuclear size and slight variation in cell and nuclear size. Increased basophilia and vacuolization can also be seen.

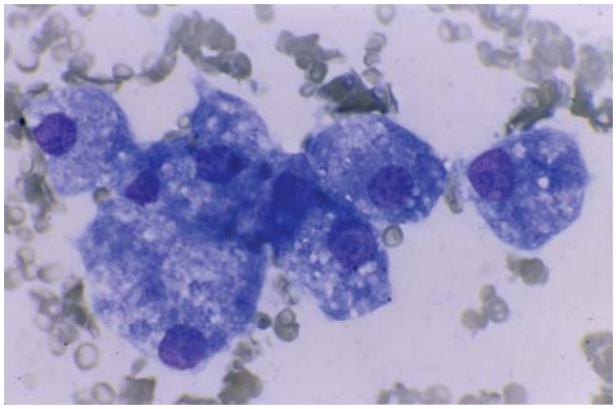

Figure 44.16 Liver aspirate from a cat with the lysosomal storage disease Niemann–Pick C, a cholesterol storage disorder. The vacuoles within the cytoplasm are representative of cholesterol. Wright stain.

Extramedullary hematopoiesis

EMH is commonly observed in liver aspirates of animals with increased hematopoiesis due to either inflammation, anemia, or hypoxia (Figure 44.17). Cells are those encountered in a bone marrow aspirate (erythroid and myeloid precursors and megakaryocytes). Progression of maturation is orderly, thus distinguishing EMH from a myeloproliferative disorder (Figure 44.18) (see Chapter 16).

Copper accumulation

Inherited copper-associated hepatopathy has been recognized in numerous breeds, including Bedlington terriers, West Highland white terriers, and Labrador retrievers. Increased copper in the liver can also be seen in Doberman pinschers with chronic hepatitis and may have a genetic predisposition. Increased copper in hepatocytes can also be seen in other breeds of dogs with cholestasis and inflammation. Copper is sometimes visible within the cytoplasm of hepatocytes and appears as pale green or turquoise crystalline granules with Wright stain (Figure 44.19). The presence of copper can be confirmed by staining for copper with rhodanine (Figure 44.20). De-staining cytology slides for special staining works well and is described in Marcos et al. 2009 in "Suggested Reading" under "General."

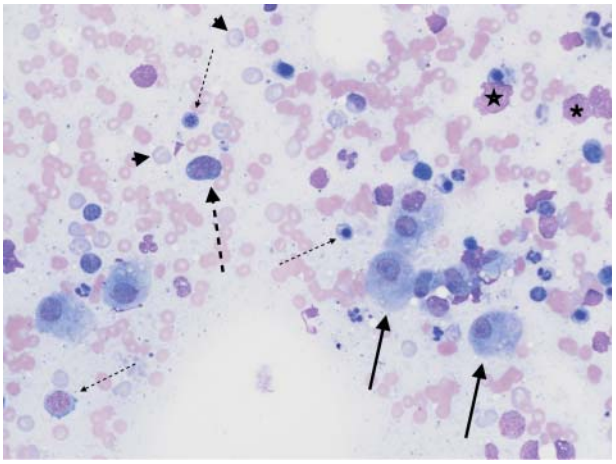

Figure 44.17 Liver aspirate from a dog with hepatomegaly, regenerative anemia, and marked extramedullary hematopoiesis with erythroid predominance. Maturation is orderly with marked polychromasia (arrowheads). Normal-appearing hepatocytes (large arrows), rubriblasts (large dashed arrow), and rubricytes and metarubricytes (small dashed arrows) are present. It is important not to confuse rubriblasts with lymphoblasts; the presence of more mature erythroid precursors helps differentiation. Broken nuclei likely from hepatocytes are indicated by stars. Wright stain.

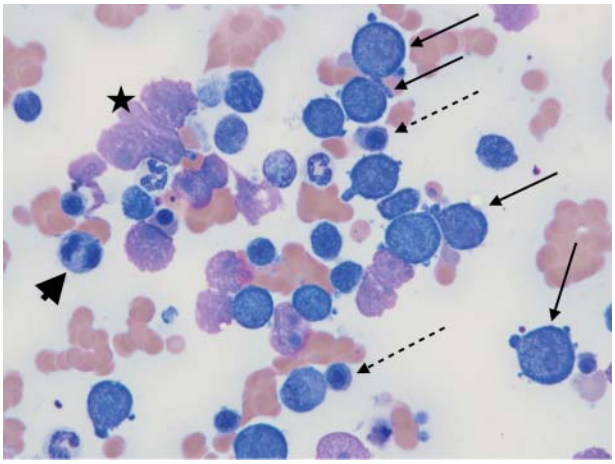

Figure 44.18 Liver aspirate from a cat with myeloproliferative disorder involving erythroid cell line (red cell leukemia). Note the disorderly maturation. Most of the erythroid precursors are rubriblasts (arrows). More mature metarubricytes are indicated by dashed arrows. An erythroid precursor in mitosis is also present (arrowhead). Broken cells are indicated by star. Wright stain.

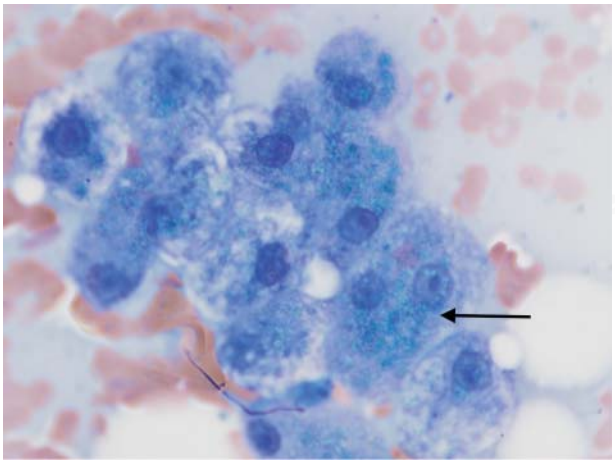

Figure 44.19 Liver aspirate from an 8-year-old dog with copper-associated hepatopathy. The alanine aminotransferase (ALT) activity in the serum was >1000 IU/L (normal = <125) on presentation, and alkaline phosphatase (ALP) activity was 549 IU/L (normal = <212). Note the turquoise-colored crystalline material within the cytoplasm of hepatocytes (arrow). Wright stain. Source: Courtesy Dr. Russell Moore, Colorado State University.

For additional information on copper-related hepatopathy, see Moore et al. 2016 and 2019 in "Suggested Reading" under "Liver."

Hepatic fibrosis

Hepatic fibrosis is a wound-healing response to chronic hepatitis, usually either idiopathic or copper-associated in the dog, that leads to deposition of fibrillar extracellular matrix components in the liver that are made of collagen. Fibrosis may lead to portal hypertension and acquired portosystemic shunts. Damaged hepatocytes and cytokines cause hepatic stellate cells (Ito cells) to transform into myofibroblasts that are thought to be the primary source of the matrix formation. Other cells that may play a role include resident fibroblasts, bone-marrow-derived fibrocytes, smooth muscle cells around vessels, and epithelial cells that transform to mesenchymal cells. Advanced fibrosis may lead to discrete nodule formation. Progressive replacement of hepatic parenchyma by fibrosis eventually results in hepatic synthetic failure, in which the liver fails to produce albumin, urea, cholesterol, and coagulation factors (see Chapter 27). Fibrosis can sometimes be diagnosed by aspiration cytology by the increase in spindle cells and mast cells, with at least 1 spindle cell per 10 hepatocytes and 4 mast cells per 100 hepatocytes considered increased enough to suggest fibrosis (see Masserdotti and Bertazzolo 2016 in "Suggested Reading" under "Liver"). However, for a definitive diagnosis, histologic examination of biopsy samples from several liver lobes is recommended, although in animals with liver failure secondary to fibrosis, biopsy could result in hemorrhage. A coagulation panel should be performed prior to biopsy.

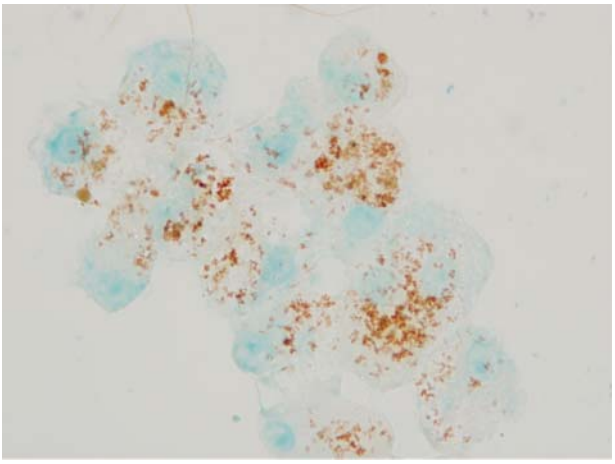

Figure 44.20 Same aspirate as shown in Figure 44.19. The presence of copper is confirmed by using a stain specific for copper, which stains an orange-brown color. Rhodanine stain. Source: Courtesy Dr. Russell Moore, Colorado State University.

Primary neoplasia

Hepatomegaly and increased bilirubin are common findings in dogs and cats with hepatobiliary neoplasia. Depending on the extensiveness of the neoplasia, other laboratory findings may include hypoalbuminemia, hyperglobulinemia, increased serum bile acids, and increased serum liver enzyme activity. Primary hepatocellular tumors are hepatocellular adenomas or carcinomas. Neoplasms of the liver can also originate from bile duct epithelium (biliary adenoma or carcinoma), cells of neuroendocrine origin (hepatic carcinoid), and mesenchymal cells (sarcoma).

Hepatocellular adenoma

Hepatocellular adenomas are more common in cats than dogs and are usually singular, often large tumors. They are difficult to distinguish from hyperplasia on cytology, as the hepatocytes usually appear quite normal. Cytologic features, however, may include mild anisocytosis, anisokaryosis, increased nucleus:cytoplasm ratio, and mild increased cytoplasmic vacuolation (Figure 44.21).

Hepatocellular carcinoma

Hepatocellular carcinomas are more common in dogs than in cats and are usually single large tumors, although they may be nodular or diffuse. Neoplastic hepatocytes often resemble normal hepatocytes to some extent, in that they typically have abundant basophilic cytoplasm. They usually have features of malignancy, however, such as cell crowding or piling, multiple nucleoli, variation in nuclear size, increased nucleus:cytoplasmic ratio, and variation in cell size, unless they are very well differentiated (Figure 44.22). Definitive diagnosis of well-differentiated hepatocellular carcinomas often requires large biopsies for histologic examination because hepatic structure is necessary to differentiate these tumors from hyperplasia or adenomas. Highly malignant hepatocytes are usually distinguishable from hyperplastic hepatocytes. Cytologic evidence of necrosis may also be present.

Occasionally hepatocellular carcinomas are so poorly differentiated that they cannot be distinguished from metastatic carcinoma (Figure 44.23).

Biliary adenoma and biliary cystadenoma

Biliary adenomas are rare, and whether biliary cystadenomas are neoplasms or a developmental anomaly is controversial. Biliary cystadenomas are more common in cats, can become large, and when aspirated, the material usually contains cyst contents and a scattering of normal-appearing biliary epithelial cells.

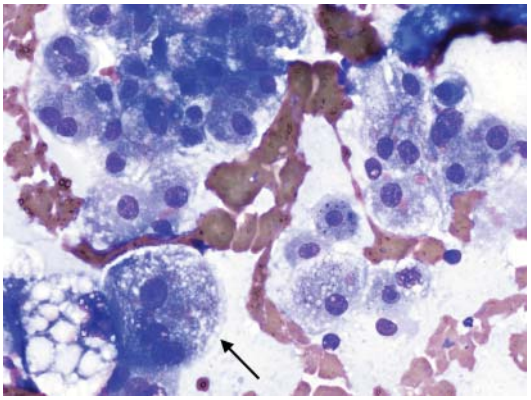

Figure 44.21 Liver aspirate from a dog with hepatocellular adenoma. Many of the hepatocytes appear relatively normal. Abnormal features include cytomegaly, increased vacuolation, and multinucleated hepatocytes (arrow). Wright stain.

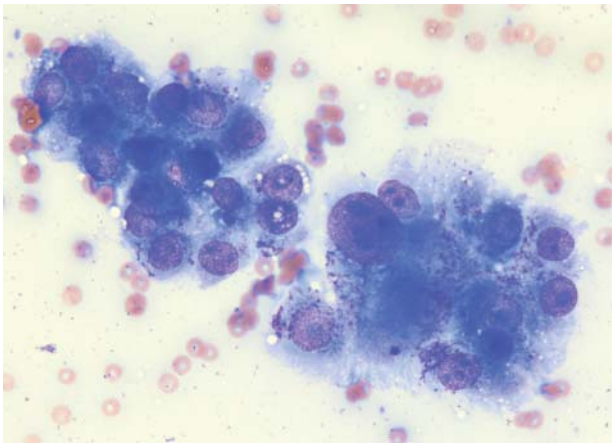

Figure 44.22 Liver aspirate from a dog with hepatocellular carcinoma. Note that the cells maintain some features of hepatocytes, but numerous criteria of malignancy are present including anisokaryosis, prominent large multiple nucleoli, and anisocytosis. Granules in the cytoplasm have been reported with hepatocellular carcinoma. Wright stain.

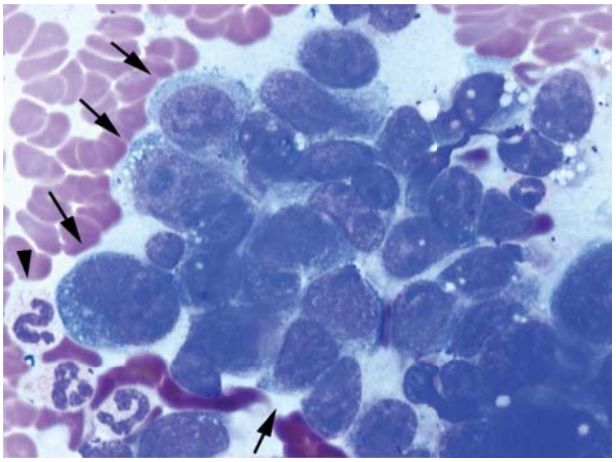

Figure 44.23 Liver aspirate from a dog with poorly differentiated hepatocellular carcinoma in which the neoplastic cells would be difficult to differentiate from a metastatic carcinoma by cytology. Note the numerous features of malignancy including high nucleus:cytoplasm ratio, multiple prominent nucleoli, and nuclear molding (arrows). A few neutrophils are present (arrowhead). Wright stain.

Biliary carcinoma (cholangiocarcinoma) and biliary cystadenocarcinoma

Biliary carcinomas are common liver tumors in cats and dogs and are typically aggressive with metastasis. Biliary carcinomas are tubular structures lined with cuboidal or columnar biliary epithelial cells. Biliary cystadenocarcinomas are similar but contain cysts. Malignant biliary epithelial cells have scant cytoplasm and may exhibit marked nuclear

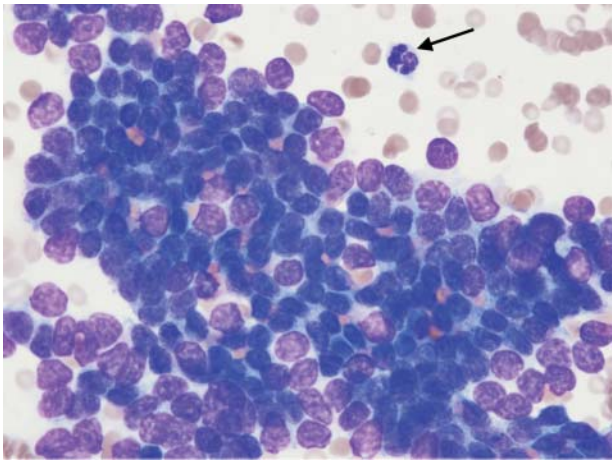

Figure 44.24 Liver aspirate from a dog with a well-differentiated cholangiocarcinoma. Note the cellular piling and mild anisocytosis. A neutrophil is indicated by the arrow, for size comparison. Wright stain.

atypia such as prominent nucleoli and clumped chromatin (Figure 44.24). Cells in mitosis may be seen.

Neuroendocrine tumors (carcinoids)

Intrahepatic neuroendocrine tumors are usually nodular or diffuse. These tumors are derived from the APUD (amine precursor uptake and decarboxylation) cells of the biliary system. The cells are similar to other neuroendocrine tumors and are usually quite fragile, thus numerous naked or bare nuclei are seen. Intact cells are small with round central nuclei. Chromatin is usually condensed, nucleoli are indistinct, and the cytoplasm is moderate to abundant and usually pale in color. Cytoplasmic vacuoles may be present. Cellularity is usually abundant in aspirates of these tumors, and they are difficult to differentiate from metastatic endocrine tumors.

Metastatic neoplasia

The liver is a common site for metastasis of tumors, which may occur as a single mass, multiple masses, or diffusely throughout the liver. These are briefly discussed in the following sections. Metastatic carcinomas could be from any epithelial tissue, including pancreas, gastrointestinal tract, bladder, mammary glands, etc. The most common metastatic sarcoma is hemangiosarcoma from the spleen. Metastatic round cell tumors include lymphoma, plasma cell neoplasia (usually multiple myeloma), mast cell neoplasia, and malignant histiocytic cells (histiocytic sarcoma or malignant histiocytosis).

Metastatic carcinoma and neuroendocrine and endocrine tumors

Metastatic carcinomas are detected cytologically by seeing epithelial cells that are not consistent with hepatocytes. Carcinoma cells usually can be recognized by their cell-to-cell relationship and commonly have malignant features, including large size, variability in cell size, variability in nuclear size, prominent nucleoli, basophilic cytoplasm, and perinuclear cytoplasmic vacuoles, especially in secretory cells (see Chapter 40). Commonly, the tissue of origin cannot be determined. Metastatic endocrine and neuroendocrine tumors appear as described above.

Sarcomas

Although sarcomas may originate in the liver, they are more commonly metastatic. Sarcoma cells are spindle-shaped with oval nuclei and prominent nucleoli (Figure 44.25). The cytoplasm is basophilic and may be vacuolated. They may be uniform or vary in size and shape. They may not exfoliate as readily as carcinoma cells, but they are readily observed on imprints of surgical biopsies. These cells should not be confused with fibroblasts, which may be present in animals with hepatic fibrosis. Hemangiosarcomas are the most common sarcomas and have usually metastasized from the spleen. Evidence of previous hemorrhage (erythrophagocytosis and hemosiderin-laden macrophages) and polychromatophilic erythrocytes may be observed, as may the abnormally shaped erythrocytes (acanthocytes) sometimes observed in blood films from dogs with hemangiosarcoma.

Lymphoma

Lymphoma is a relatively common neoplasm within the liver and is usually easily diagnosed by cytology. Neoplastic lymphocytes are usually diffusely distributed among normal-appearing hepatocytes (Figures 44.26 and 44.27). Liver aspirates containing large numbers of small lymphocytes can be more difficult to interpret, as the lymphoid population may be representative of an inflammatory process or small cell lymphoma. Surgical biopsy and histopathology,

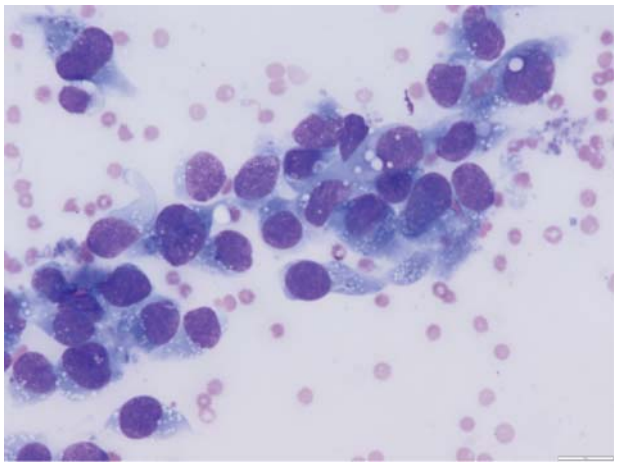

Figure 44.25 Liver aspirate from a dog with sarcoma in liver. Note the numerous spindle-shaped cells with punctate vacuoles within the cytoplasm. No hepatocytes are in this image. Wright stain.

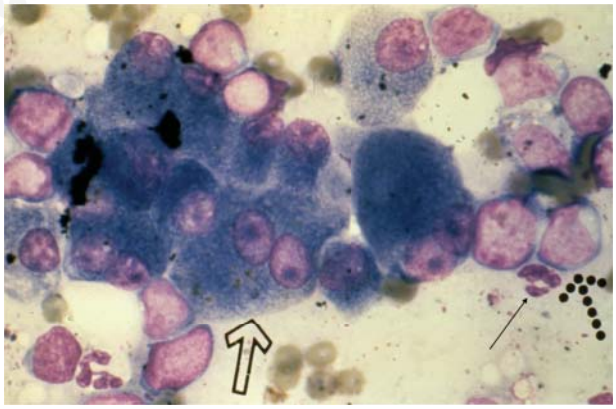

Figure 44.26 High magnification of a liver aspirate from a dog with disseminated lymphoma. Normal hepatocytes are indicated by open arrow, lymphoblasts by dotted arrow, and a neutrophil for size comparison by the small solid arrow. Wright stain.

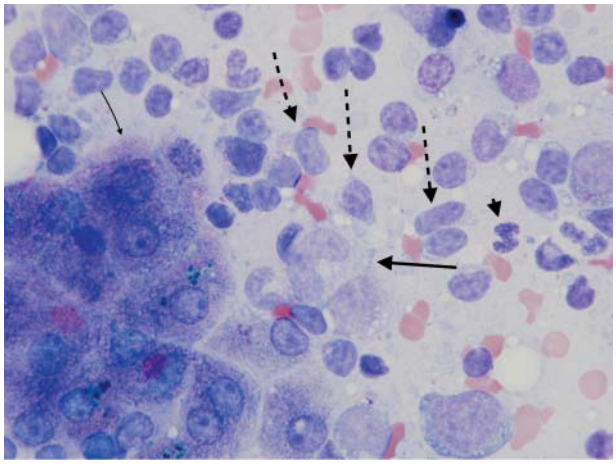

Figure 44.27 Liver aspirate from dog with large granular lymphocyte lymphoma (T-cell). Normal hepatocytes are indicated by small solid arrow, small to intermediate-sized large granular lymphocytes by dotted arrows, a neutrophil for size comparison by an arrowhead, and a probable myeloid precursor by the large solid arrow. Wright stain.

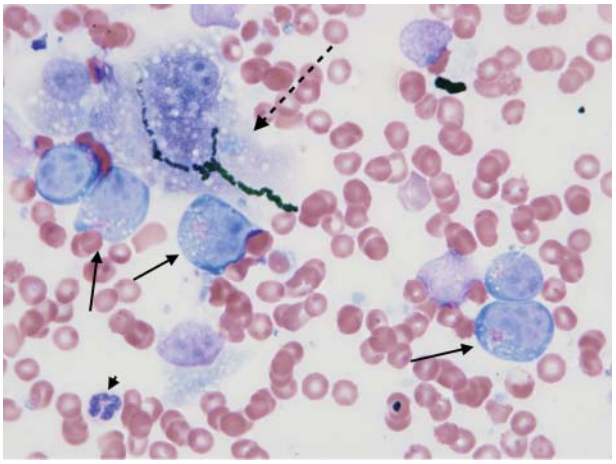

Figure 44.28 Liver aspirate from dog with large granular lymphocyte lymphoma (T-cell). Numerous immature T cells are indicated by arrows. Evidence of canalicular bile stasis around a normal hepatocyte is indicated by dashed arrow. Note neutrophil (arrowhead) for size comparison of lymphoid cells. Wright stain.

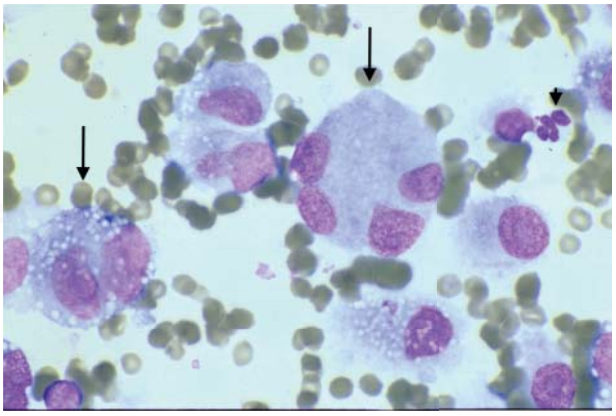

Figure 44.29 Liver aspirate from dog with disseminated histiocytic sarcoma. Numerous malignant histiocytes are present. Multinucleated cells are indicated by arrows. A neutrophil for size comparison is indicated by arrowhead. Wright stain.

as well as blood, bone marrow, lymph node cytology, immunophenotyping, and polymerase chain reaction (PCR) should distinguish the two processes. Lymphoma may originate in the liver or may metastasize from other areas. T-cell lymphoma that involves the liver in the absence of peripheral lymphadenopathy is usually either hepatosplenic T-cell lymphoma, which is very aggressive, or hepatocytotropic T-cell lymphoma (see Keller et al. 2013 in "Suggested Reading" under "Liver") (Figure 44.28). Hepatosplenic lymphoma is also discussed in the "Spleen" section of this chapter.

Disseminated histiocytic sarcoma

Disseminated histiocytic sarcoma, previously referred to as malignant histiocytosis, is often characterized by the systemic proliferation of large, pleomorphic, single and multinucleated histiocytes with moderate amounts of lightly basophilic vacuolated cytoplasm. Neoplastic histiocytic cells can appear fairly well differentiated but often exhibit marked cellular atypia. Features of malignancy include marked anisocytosis and anisokaryosis, prominent nucleoli, bizarre mitotic figures, and occasional phagocytosis of erythrocytes and leukocytes. The presence of multinucleated giant cells supports the diagnosis (Figure 44.29). Disseminated histiocytic sarcoma is a rapidly progressive, ultimately fatal, disorder that has been described in adult dogs, including Bernese mountain dogs; an increased incidence of the disorder is also seen in the golden retriever and flat-coated retriever breeds.

Myeloproliferative disease

Neoplastic myeloid cells commonly infiltrate the liver (see Chapter 16). If they are somewhat differentiated, recognizable progranulocytes with pink cytoplasmic granules will aid in the diagnosis. If they are undifferentiated, they may resemble lymphoblasts, and immunophenotyping may be necessary to accurately determine cell type.

Mast cell neoplasia

Large numbers of mast cells are present on the aspirate, and/or mast cells with atypical morphologic features are present. Although a few mast cells can be seen in normal liver, and increased mast cell numbers are seen with fibrosis, the number of mast cells with metastatic neoplasia is usually markedly increased, and they often appear in aggregates.

Gall bladder

Normal gall bladder aspirates are characterized by amorphous granular material and are usually acellular, although a few biliary epithelial cells may be seen (Figure 44.30). Bilirubin crystals may be seen and are usually needle-shaped and golden brown in color. In infected and/or inflamed gall bladders, bacteria may be seen and sometimes identified; however, culture should be performed for definitive identification. Inflammatory cells may include neutrophils, macrophages, and lymphocytes. Fluke eggs, yeast, and protozoa have been occasionally observed in aspirates. If the gall bladder is distended due to obstruction, or the wall is necrotic, gall bladder rupture may occur during aspiration, but this complication is very rare.

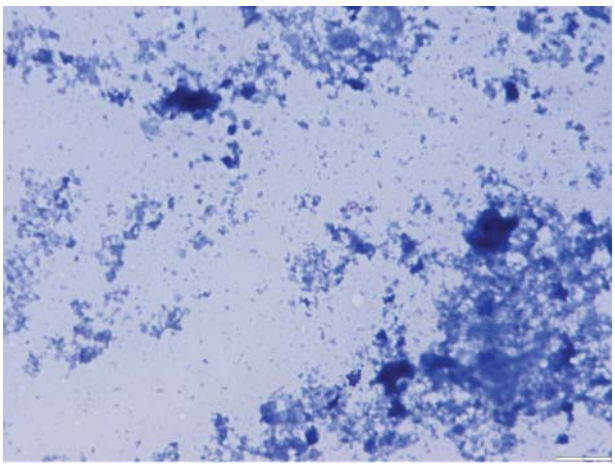

Figure 44.30 Aspirate of normal bile from the gall bladder of a dog. Note the granular amorphous material. No inflammatory cells or bacteria are present. Wright stain.

Spleen

Aspiration cytology of the spleen has been performed in humans since at least 1932. Splenomegaly, the presence of a splenic mass or nodule, an abnormal appearance on ultrasound examination, and staging of multicentric neoplasia, such as lymphoma or mast cell neoplasia, are the most common indications for aspiration of the spleen. In one study of 370 small dogs undergoing splenectomy for nodular splenic lesions, 44% of the lesions were benign and 56% were neoplastic, and the presence of hemoabdomen was usually associated with malignancy (see Fernandez et al. 2019 in "Suggested Reading" under "Spleen"). In another study of 105 dogs with incidentally detected nonruptured splenic masses, 70% of the lesions were benign, and 30% were malignant, the most common malignancy being hemangiosarcoma (see Cleveland and Casale 2016 in "Suggested Reading" under "Spleen").

As with liver, a nonaspiration technique is usually better than aspiration techniques. Nonaspiration techniques result in less blood contamination and higher cellularity. Also as with liver, if the diagnosis depends on architecture, cytology is not diagnostic.

In most studies, cytologic diagnoses correlated reasonably well with histologic diagnoses. Complications are rare, even in thrombocytopenic patients.

Normal

Specimens from normal spleen usually contain a large amount of blood since one of the functions of the spleen is to store blood. However, the presence of blood should not be considered diagnostic of a normal spleen, since blood can also be aspirated from tumors, hematomas, and congested spleens. Nucleated cells are primarily lymphoid cells, most of which are small lymphocytes. Small numbers of lymphoid cells are intermediate or large with nucleoli (see Chapter 45 for guidelines for lymphoid cell sizing). Numerous well-differentiated mast cells may be present, as well as small numbers of plasma cells and hematopoietic precursors. Splenic stromal tissue is commonly present, consisting of small uniform mesenchymal (spindle-shaped) cells. Numerous macrophages containing hemosiderin may also be seen.

Non-neoplastic lesions of the spleen

Non-neoplastic cytologic diagnoses of the spleen can include splenic hyperplasia, inflammation, EMH, and hemosiderosis.

Splenic hyperplasia

Splenic hyperplasia may be nodular or diffuse and is proliferation of the normal components of the spleen in response to antigenic stimulation, inflammation, or neoplasia. Hyperplasia may involve stromal elements and macrophages or

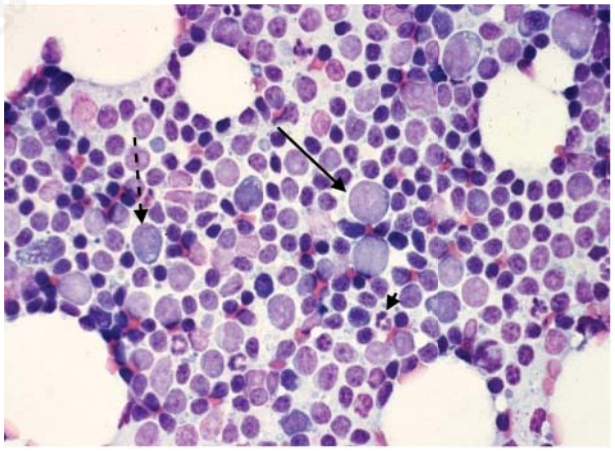

Figure 44.31 Aspirate of a spleen with lymphoid hyperplasia. Most of the cells are small lymphocytes. A large immature lymphoid cell is indicated by the arrow. An immature plasma cell is indicated by the dashed arrow, and a neutrophil for size comparison is indicated by the arrowhead. Wright stain.

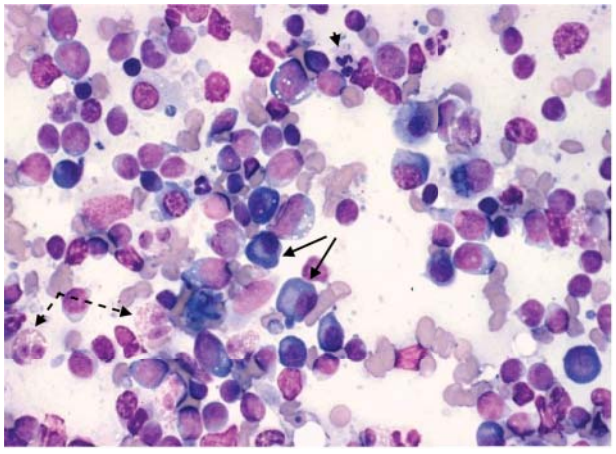

Figure 44.32 Spleen aspirate from a dog with evidence of antigenic stimulation. Normal-appearing plasma cells are increased in number (arrows). Also note the numerous eosinophils (dashed arrows). A neutrophil is indicated by an arrowhead. The majority of the cells are small normal-appearing lymphocytes. Wright stain.

consist of primarily lymphoid hyperplasia with increases in immature lymphoid cells and plasma cells. Cellularity is usually high (Figure 44.31). Increased splenic plasma cell concentration may be marked in some diseases associated with chronic antigenic stimulation (Figure 44.32). Canine splenic lymphoid nodules are typically classified as indolent lymphomas (marginal zone lymphoma [MZL] and mantle cell lymphoma [MCL], which are discussed in the lymphoma section below) or nodular lymphoid hyperplasia. Splenic hyperplasia involving the lymphoid component may be difficult to distinguish from lymphoid or plasma cell neoplasia, in which case flow cytometry or PCR for antigen receptor rearrangement (PARR) is usually helpful (see Chapter 14).

Macrophagic (histiocytic) hyperplasia may be seen in association with increased phagocytosis of abnormal erythrocytes, due to immune-mediated disease, Heinz body formation, or the presence of microorganisms in or on erythrocytes. Hemophagocytic syndrome, a benign histiocytic proliferative disorder that can occur in response to inflammation or neoplasia, primarily affects the bone marrow but may also involve the spleen and will also result in increased macrophages. With any type of histiocytic hyperplasia, numerous macrophages containing erythrocytes and hemosiderin are usually observed.

Inflammation (splenitis)

As with other organs and tissues, inflammation may be neutrophilic, macrophagic, eosinophilic, lymphocytic, plasmacytic, or mixed, and be septic or nonseptic. Examples of infectious organisms that may result in splenitis include fungi and yeasts such as *Cryptococcus* spp., *Candida albicans*, *Aspergillus* spp. and *Penicillium* spp. Protozoan organisms that have been reported in the spleen include *Neospora caninum*, *Hepatozoon canis*, *Leishmania* spp., *Trypanosoma cruzi*, and *Cytauxzoon felis*. Reported bacteria include organisms that cause anthrax (*Bacillus anthracis)*, listeriosis (*Listeria monocytogenes)*, tuberculosis (*Mycobacterium* spp.), salmonellosis, and tularemia. *Neorickettsia helminthoeca* and *Stellanchasmus falcatus* are neorickettsial organisms that may cause granulomatous or lymphoplasmacytic splenitis (see Chapters 39 and 45).

Hemosiderosis and siderotic nodules

Hemosiderosis, an increased amount of iron in the form of hemosiderin, can occur in the spleen resulting from excessive erythrophagocytosis associated with hemolytic anemia and with localized hemorrhage. Siderotic plaques and nodules have been associated with trauma, neoplasia, and advanced age. Aspirates of nodules contain macrophages, usually containing hemosiderin, as well as lymphocytes and hematopoietic precursors. Gamna-Gandy bodies, calcium–iron complexes, may be seen in areas of previous hemorrhage (see Ryseff et al. 2014 in "Suggested Reading" under "Spleen"). These complexes can be confused with fungal hyphae or other foreign material due to the formation of negative-staining, branching structures with septal-like divisions along the branches (Figure 44.33). Stains for iron or calcium are helpful in their identification.

Extramedullary hematopoiesis

A few hematopoietic precursors, including megakaryocytes, can be seen in normal splenic aspirates. When EMH is increased, often resulting from anemia-related hypoxia, it may be diffuse or nodular, and erythroid precursors usually predominate. The hematopoietic precursors appear identical to those found in the bone marrow (see Chapter 15).

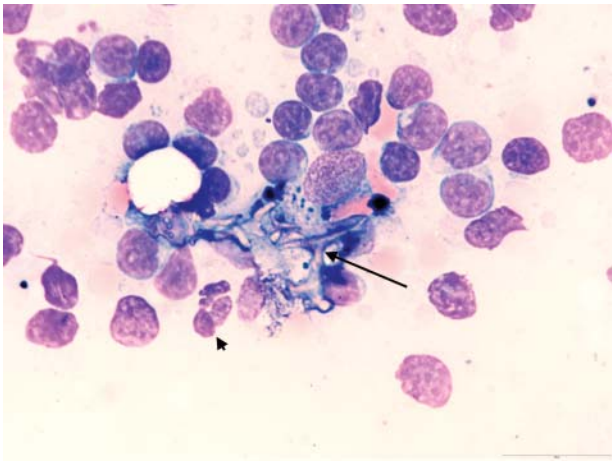

Figure 44.33 A Gamna-Gandy body in a splenic aspirate (arrow). Note the branching septate appearance, making it possible to confuse the calcium–iron complex with a fungal hypha. Most of the cells are small normal-appearing lymphocytes. Neutrophil indicated by arrowhead. Wright stain. Source: Courtesy Dr. Christina Jeffries, Colorado State University.

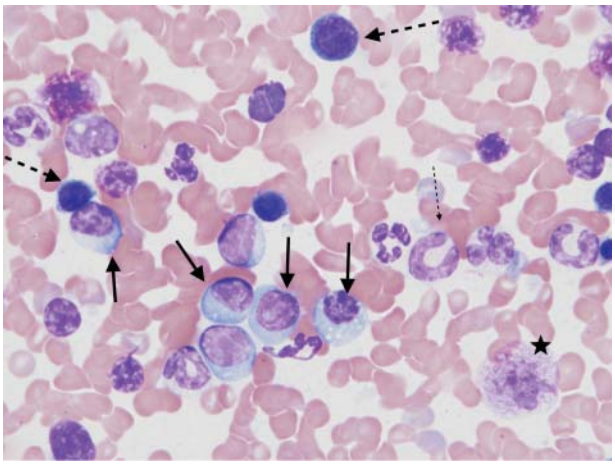

Figure 44.34 Aspirate of the spleen from a domestic ferret. Numerous plasma cells are present, indicated by arrows. Although plasma cells appear moderately well differentiated, the ferret had disseminated multiple myeloma. Extramedullary hematopoiesis is also present. Large dashed arrows indicate red cell precursors, and small dashed arrow indicates a band neutrophil. A broken nucleus is present (star). Wright stain.

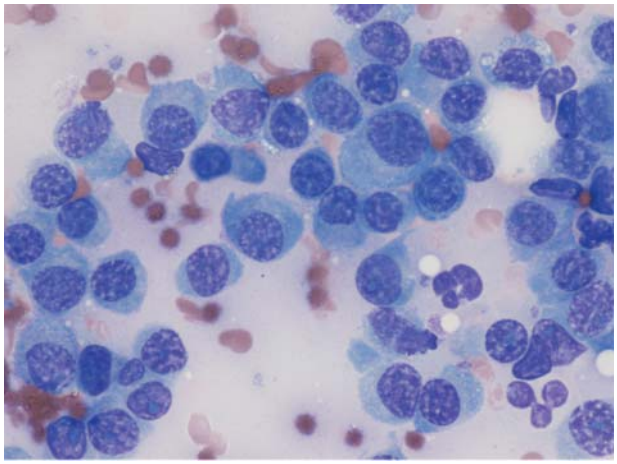

Figure 44.35 Disseminated plasma cell myeloma in the spleen. Numerous poorly differentiated plasma cells are seen. Wright stain.

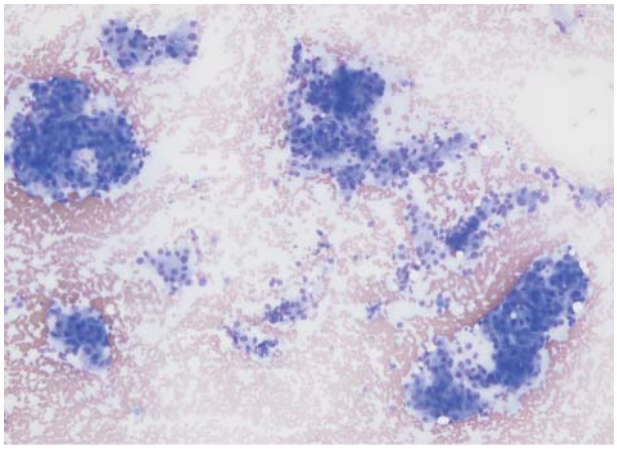

Figure 44.36 Splenic aspirate in a dog with metastatic apocrine gland anal sac adenocarcinoma. Note the abundant small, fairly uniform cohesive cells. No normal components of the spleen are present. Wright stain.

Splenic neoplasia

Neoplasia in the spleen may be primary or metastatic. Round cell tumors such as lymphoma, plasma cell neoplasia (Figures 44.34 and 44.35), and mast cell neoplasia, carcinomas, neuroendocrine tumors, and sarcomas may metastasize to the spleen (Figure 44.36). More common types of splenic neoplasia are discussed in the following section.

Lymphoma

Splenic lymphoma may be primary (arising in and confined to the spleen) or secondary (splenic involvement as part of multicentric disease) and is relatively common in dogs and cats. Multicentric lymphoma is also discussed in Chapters 40 and 45. As with lymph nodes, aspirates of spleens with lymphoma usually have greater than 40–50% large lymphoid cells containing nucleoli, although small cell lymphomas may also occur in the spleen. Three types of primary splenic lymphoma have been described in dogs. Two are indolent B-cell lymphomas and the third is hepatosplenic T-cell lymphoma; splenic MZL, MCL, and hepatosplenic lymphoma are described briefly below.

Splenic MZL (SMZL) is an uncommon form of lymphoma and is one of three subtypes of MZL (the others are nodal MZL and mucosal-associated). SMZL is an indolent small-cell B-cell lymphoma characterized by splenic infiltration and bone marrow involvement and little or no lymph node involvement. The majority of splenic MZL cases are solitary

splenic lesions identified on routine abdominal ultrasound examination.

MCL is an indolent B-cell lymphoma that is very rare in dogs, comprising approximately 1% of all cases of lymphoma. MCL primarily affects the spleen with occasional visceral node involvement. Peripheral node involvement is minimal if any, and bone marrow involvement is very uncommon. Mantle cells are in the cuff surrounding lymphoid follicles of the spleen. The neoplastic cells are small to intermediate in size and have a small amount of cytoplasm and inconspicuous nucleolus. For both types of indolent B-cell lymphoma, prognosis is good following splenectomy if the disease is confined to the spleen. Chemotherapy may not improve survival.

Hepatosplenic T-cell lymphoma has been described in humans and rarely in dogs, cats, and horses. Neoplastic lymphoid cells are intermediate to large with a moderate amount of pale blue cytoplasm, pink to magenta cytoplasmic granules, and prominent nucleoli. Peripheral lymph nodes are not involved. Clinical course is aggressive and response to therapy is poor. Neoplastic lymphoid cells occasionally are phagocytic (Figure 44.37).

Hemangioma and hemangiosarcoma

Hemangioma and hemangiosarcoma are connective tissue tumors arising from the vasculature (see Chapter 40). They are relatively common in dogs, especially large-breed dogs, and are the most common primary splenic tumor in dogs; they are relatively rare in cats. The spleen is a common site of occurrence in dogs; in one study of 370 small-breed dogs, 27% of splenic lesions were hemangiosarcomas (see Fernandez et al. 2019 in "Suggested Reading" under "Spleen"). Hemangiomas are significantly less common in dogs and are also uncommon in cats. Rupture of hemangiosarcoma may occur with aspiration but is quite uncommon. Because large areas of the tumor are filled with blood, one commonly only sees blood on aspirates of hemangiosarcomas, making the lesions difficult to distinguish from hematomas or hemangiomas. Evidence of previous hemorrhage (erythrophagocytosis and hemosiderin) is often present. Hemangiosarcoma cells are occasionally aspirated and are often spindle-shaped and usually show features of malignancy (Figure 44.38). It is not possible, based on cytology alone, to definitively differentiate hemangiosarcoma cells from other types of sarcomas that may have metastasized to the spleen (Figure 44.39).

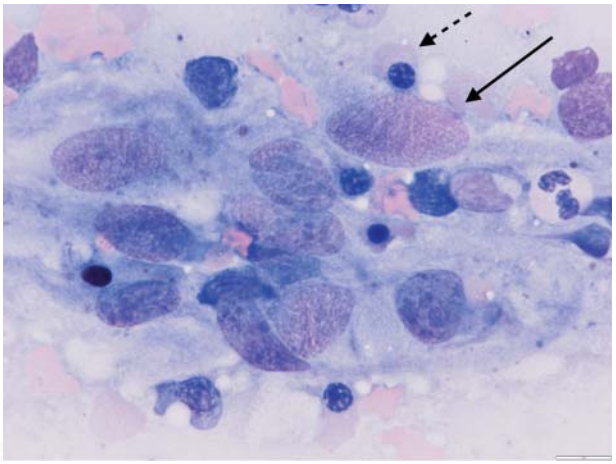

Figure 44.38 High magnification of a splenic aspirate from a dog with hemangiosarcoma. Note the large spindle-shaped sarcoma cells (arrow) that exhibit several criteria of malignancy, including nuclear molding and multiple prominent nucleoli. Extramedullary hematopoiesis is evidenced by the multiple erythroid precursors. A metarubricyte is indicated by the dashed arrow. Wright Stain.

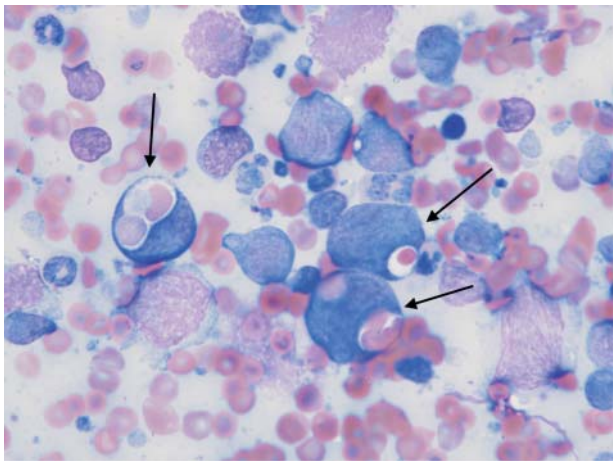

Figure 44.37 Aspirate of the spleen of a hedgehog with lymphoma. Neoplastic lymphoid cells have phagocytized erythrocytes (arrows). Wright stain.

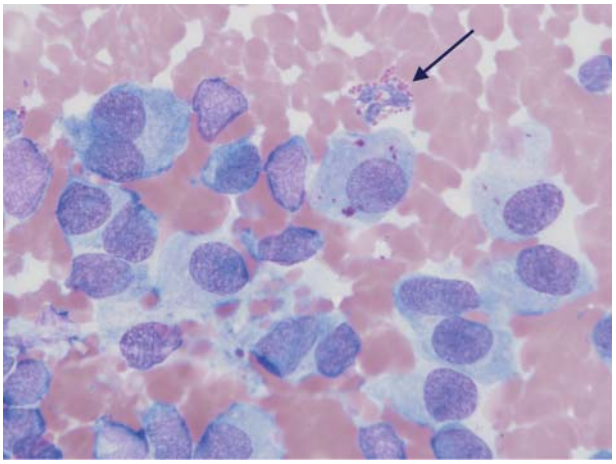

Figure 44.39 Splenic aspirate from a dog with metastatic osteosarcoma. Note the large spindle-shaped cells, a few of which have pink glycosaminoglycans in the cytoplasm. An eosinophil is indicated by the arrow, for size comparison. Wright stain.

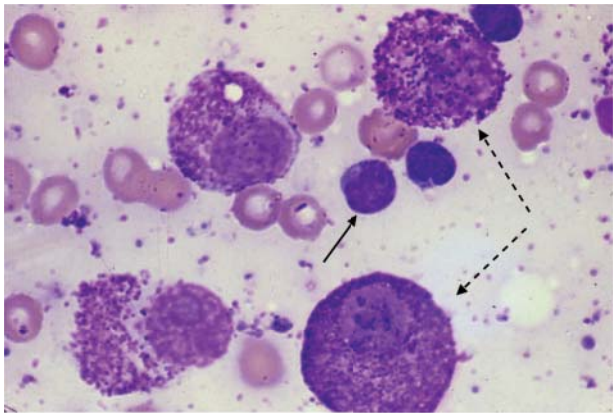

Figure 44.40 Splenic aspirate from dog with metastatic mast cell neoplasia. Mast cells are indicated by dashed arrows, and small normal-appearing lymphocyte by arrow. Note the numerous free mast cell granules in the background from broken mast cells. Wright stain.

Splenic mast cell neoplasia

Mast cell tumors are the most common splenic disorder of cats. Mast cell neoplasia of the spleen is much less common in dogs. Mast cells are round, discrete cells with numerous dark blue to purple cytoplasmic granules (Figure 44.40). Anaplastic mast cells tend to have fewer granules. However, occasionally mast cell granules do not stain with the quick Romanowsky stains, and these poorly staining cells (Figure 44.41) should not be confused with anaplastic mast cells. Because mast cells may be found in normal spleens, and increased numbers may be seen with reactive hyperplasia, benign mastocytosis may be difficult to differentiate from mast cell neoplasia. Mast cell tumors are also discussed in Chapters 40 and 41.

Histiocytic sarcoma

Histiocytic sarcoma is classified into three forms: localized, disseminated, and hemophagocytic histiocytic sarcoma.

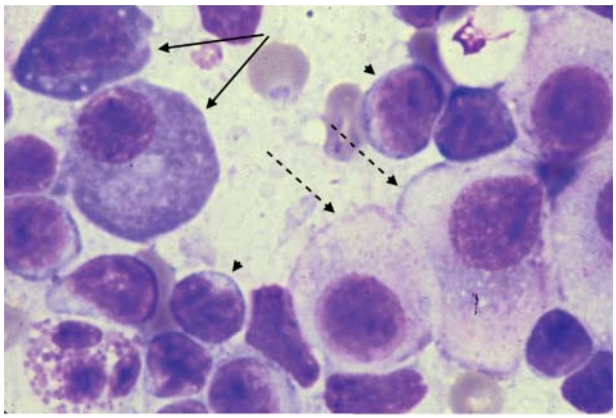

Figure 44.41 Mast cell tumor stained with a quick Romanowsky stain (Diff-Quik). Poorly staining mast cells are indicated by dashed arrows, plasma cells by arrows, and normal small lymphocytes by arrowheads. Wright stain.

Localized histiocytic sarcoma arises from dendritic cells and presents as discrete lesions in one tissue such as the spleen, skin, lymph nodes, joints, lung, and bone marrow. Disseminated histiocytic sarcoma, previously referred to as malignant histiocytosis, also arises primarily from dendritic cells and is characterized by multicentric disease. Hemophagocytic histiosarcoma is aggressive, primarily arises from splenic or bone marrow macrophages, and is characterized by neoplastic macrophages that exhibit erythrophagocytosis. Splenic histiocytic sarcoma can be any of the three subtypes. Splenic involvement is usually characterized by marked splenomegaly, often with numerous coalescing nodules. Cytological description of malignant histiocytes is discussed in this chapter under "Liver" and also discussed in Chapters 40 and 45. If localized to the spleen, splenectomy is indicated, and survival time can be longer than 1 year.

Myelolipoma

Myelolipomas are rare, benign tumors composed of adipose tissue and normal hematopoietic cells. Aspirates consist of well differentiated adipocytes and normal-appearing hematopoietic precursors.

Kidney

As with other organs, cytology is not useful if architecture is required to make a diagnosis. Suspected necrosis, inflammation, and neoplasia of the kidney are indications for cytology. Cytology of the kidney is particularly useful for diagnosing lymphoma. While diffuse lesions can be aspirated without ultrasound guidance, ultrasound-guided aspiration is recommended for focal lesions and to avoid puncturing major blood vessels. Detailed technique is discussed in other publications (see Borjesson 2003 and McAloney and Sharkey 2021 in "Suggested Reading" under "Kidney"). An excellent review of urinary tract cytology was published by Wycislo and Piech 2019 (see "Suggested Reading" under "Kidney").

Normal

As with other tissues, one needs to recognize the normal cytologic features to recognize abnormalities. The primary cells seen in renal cytologic samples are renal tubular epithelial cells, which exfoliate either individually or in small clusters. Cells are uniform, round to polygonal with abundant lightly basophilic cytoplasm. Dark blue to black granules may be seen occasionally in the cytoplasm, consistent with cells in the descending loop of Henle or distal tubules (Figure 44.42). In cats, the cytoplasm commonly contains clear lipid vacuoles (Figure 44.43). Occasionally glomerular tufts are aspirated.

Inflammation

Inflammatory lesions in the kidney are similar to those described for other tissues. Infectious agents such as bacteria, yeast, and fungi can usually be accurately identified.

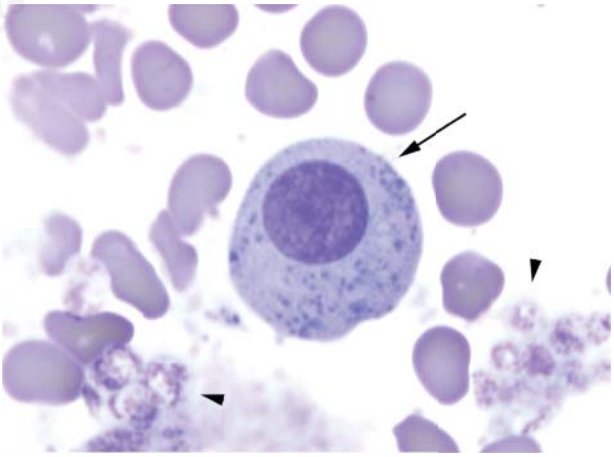

Figure 44.42 High magnification of a normal renal epithelial cell with granules in the cytoplasm, likely from the loop of Henle or distal tubule (arrow). Clumps of platelets from blood contamination are indicated by arrowheads. Wright stain.

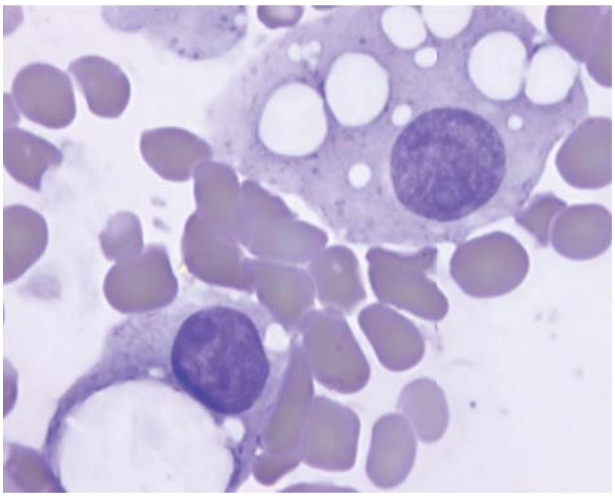

Figure 44.43 High magnification of a normal renal epithelial cell from a cat showing the common lipid vacuoles within the cytoplasm. Wright stain.

Renal toxicosis caused by ethylene glycol and melamine from contaminated pet food have been identified by the characteristic crystals in aspirates. Calcium oxalate crystals are usually the monohydrate form that are elongated with sharp edges (see Chapter 24).

Renal neoplasia

Renal neoplasms usually originate outside of the kidney and metastasize or extend to the kidney. Carcinomas, sarcomas, and nephroblastomas may originate in the kidney. Nephroblastoma cells have been described as large, round, sometimes cohesive cells with scant to moderate basophilic cytoplasm with round nuclei and associated matrix. In one case, the cohesiveness, presence of matrix, and absence of cytoplasmic fragments differentiated them from neoplastic lymphoid cells (see Michael et al. 2013 in "Suggested Reading" under "Kidney"). However, other reports show aspirates that could be easily confused with lymphoma (see Wycislo and Piech 2019 in "Suggested Reading" under "Kidney"). Metastatic tumors include lymphoma, melanoma, and hemangiosarcoma. Cytologic characteristics of these types of tumors are described in Chapter 40.

Pancreas

Pancreatic disease is difficult to definitively diagnose by laboratory evaluation or imaging. Cytology has been shown to be a safe and reasonably effective diagnostic tool. Indications include clinical and imaging findings that suggest the possibility of pancreatic disease, as well as nodular lesions that may be due to hyperplasia or neoplasia. Technique for aspiration is like that described for the liver, although some authors recommend using a smaller-gauge needle to minimize trauma. Several samples should be collected from different locations. Pancreatic cells are reported to exfoliate less readily than those of other organs such as the liver. Complications are reportedly rare compared to pancreatic surgical biopsy.

Normal

The exocrine pancreas is composed of acinar tissue and ducts that drain the acini. The endocrine pancreas is made up of islets within the exocrine pancreas; cells within the islets are morphologically similar, although they have varying functions. Cytology samples from normal pancreatic tissue have low cellularity and consist of epithelial cells that appear in clusters. They have a moderate amount of light blue cytoplasm containing fine pink granules, a round nucleus, and a single prominent nucleolus, similar to that of hepatocytes, although the cells have slightly less cytoplasm than hepatocytes (Figures 44.44 and 44.45).

Necrosis and inflammation

Necrotic pancreatic tissue appears as amorphous basophilic debris, similar to other types of necrotic tissue. Mineralization of the necrotic tissue is commonly seen and appears as colorless refractile small round crystaline material.

Pancreatic inflammation is like inflammation elsewhere and is usually classified as acute or chronic. Acute inflammation is usually neutrophilic, and chronic inflammation is typically mixed or lymphocytic. Granulomatous inflammation is uncommon. The inflammation is typically nonseptic, although bacteria may be seen in association with pancreatic abscesses.

Neoplasia

Benign neoplasia is rare. The most common malignant pancreatic tumor is acinar carcinoma, although ductal carcinoma also occurs. Typical malignant features of neoplastic epithelial cells are seen (see Chapter 40). Lymphoma of

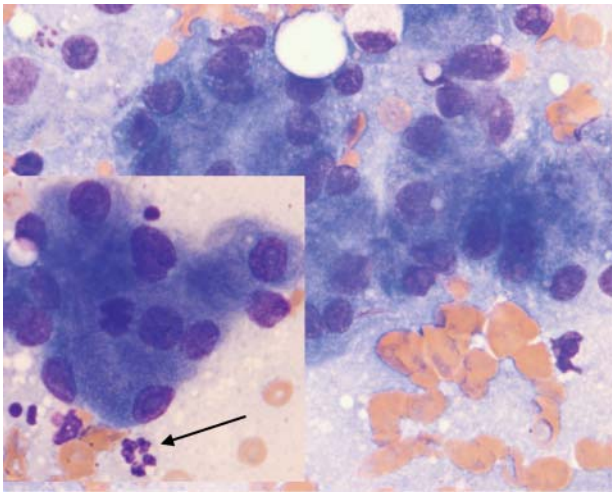

Figure 44.44 Aspirate of the pancreas showing normal pancreatic epithelial cells. Inset, lower left corner, shows a similar aspirate with a neutrophil (arrow) for size comparison. Wright stain.

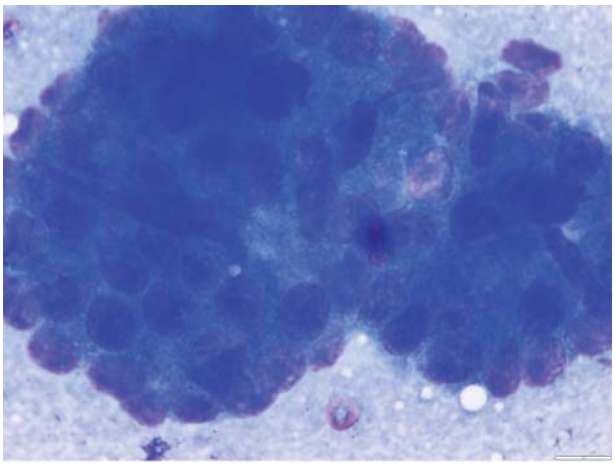

Figure 44.45 Aspirate of a pancreatic nodule from a 12-year-old English bulldog. The cells appear fairly well differentiated but the aspirate was very highly cellular with piling and increased nucleus:cytoplasm ratios, suggesting a possible well-differentiated carcinoma. Other differentials were benign neoplasia and hyperplasia. Histopathology was not performed. Wright stain.

the pancreas has been rarely reported. Insulinoma is the most common tumor of the endocrine pancreas. Cytologic features are those of any endocrine tumor and include many free round nuclei and relatively uniform cells with scant to moderate cytoplasm that may contain fine eosinophilic granules (Figures 44.46 and 44.47).

Adrenal gland

The adrenal glands are located near each kidney and are composed of the medulla and the cortex. Neuroendocrine

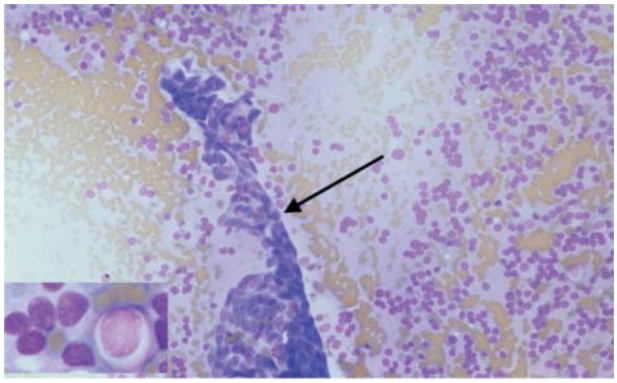

Figure 44.46 Aspirate of the pancreas of a dog with laboratory and clinical signs compatible with insulinoma. Inset in lower left corner shows higher magnification. Note the sheet of mesothelial cells in the center of the field (arrow). Wright stain.

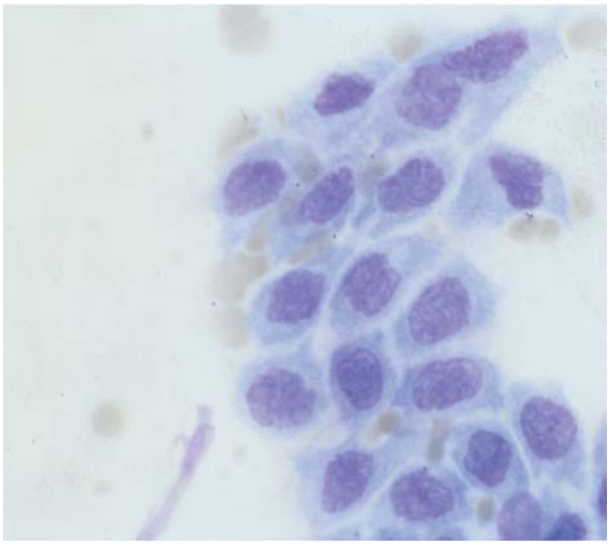

Figure 44.47 Higher magnification of the mesothelial cells that are shown in Figure 44.46. These are sometimes mistakenly confused with carcinoma or sarcoma cells or fibroplasia. Wright stain.

cells in the medulla produce catecholamines (epinephrine and norepinephrine). The cortex is made up of the glomerulosa, where aldosterone is made, and the fasciculata and reticularis, where cortisol and sex hormones are made. The most common indication for adrenal gland cytology is the detection of an adrenal mass by diagnostic imaging such as ultrasonography, computed tomography, or magnetic resonance imaging. In one study of 50 canine cases identified by imaging in which adrenal gland cytology was performed, the cytological analysis was conclusive in 77% and inconclusive in 23%, and the complication rate was very low, with hemorrhage being the most common complication. Diagnoses included pheochromocytoma (56%), carcinoma (14%), adenoma (12%), hyperplasia (7%), EMH (5%), and granulomatous inflammation from a migrating foreign body

(2%) (see Pey et al. 2020 in "Suggested Reading" under "Adrenal Gland").

Normal

Cortical cells have abundant lightly basophilic cytoplasm containing clear lipid vacuoles and a round central nucleus. Cells from the medulla have a typical neuroendocrine appearance with a small amount of lightly basophilic cytoplasm and a round central nucleus. Like other neuroendocrine cells, they easily lose their cytoplasm, and naked nuclei arranged in rows or rosettes are present.

Inflammation (adrenalitis)

Immune-mediated destruction of the adrenal gland is associated with lymphocytic or plasmacytic inflammation that results in hypoadrenocorticism, often in young dogs (see Section VII, Cases 108 and 109). The lymphocytes have been shown to be CD4+ T cells (see Friedenberg et al. 2018 in "Suggested Reading" under "Adrenal Gland"). While it would be theoretically possible to diagnose the presence of lymphocytic inflammation by cytology, most of these cases present due to clinical signs and laboratory findings associated with hypoadrenocorticism and are definitively diagnosed by baseline cortisol concentration and an adrenocorticotropic hormone (ACTH) stimulation test (see Chapter 33).

Neutrophilic and macrophagic inflammation can also occur in the adrenal glands, usually resulting from bacteria (including mycobacteria), fungi, and protozoa. Most of the organisms seen in cytologic samples have been reported in humans, rather than domestic animals. Eosinophilic infiltration of the adrenal gland has been reported in cats with hypereosinophilic syndrome.

Neoplasia

Primary adrenal neoplasia is common in dogs and ferrets and relatively uncommon in cats. Gonadectomy has been shown to induce sex-steroid-producing adrenocortical tumors in domestic ferrets. Neoplasms of the cortex (adrenocortical tumors) are adenomas or carcinomas, and neoplasms of the medulla are termed pheochromocytomas, a type of neuroendocrine tumor. Many adrenal tumors are functionally active. Adrenocortical tumors in dogs usually secrete cortisol and result in hyperadrenocorticism. Adrenocortical tumors in cats may cause hyperadrenocorticism or hyperaldosteronism. Pheochromocytomas from the medulla produce catecholamines; clinical signs include hypertension and tachycardia (see Chapter 33). The cells in neoplasms of the cortex (Figure 44.48) and medulla appear similar to those in normal adrenal glands and are described above. Whether the tumor is cortical or medullary in origin is usually easily determined by cytology, but because the cells do not exhibit much atypia, benign or hyperplastic tissue cannot usually be differentiated from malignant neoplasms by cytology

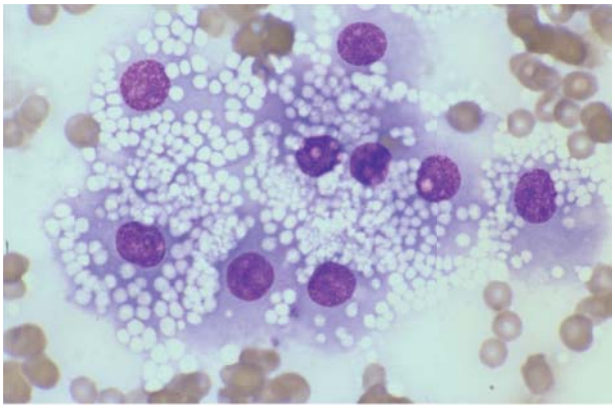

Figure 44.48 Aspirate of the adrenal gland from a dog with an adrenocortical tumor and laboratory evidence of Cushing's syndrome. Note the numerous discrete vacuoles within the cytoplasm. Wright stain.

(see Bertazzolo et al. 2014 in "Suggested Reading" under "Adrenal Gland"). EMH is sometimes seen in association with adrenocortical neoplasms and is reported to be more common in association with adenomas than carcinomas. Other rare primary adrenal neoplasms include myelolipomas, neuroblastomas, ganglioneuromas, and schwannomas.

Various types of neoplasms may metastasize to the adrenal gland and include carcinomas, hemangiosarcomas, and melanomas.

Intestine

The small intestine consists of the duodenum, jejunum, and ilium. Mucosal surface is lined by columnar epithelial cells with long microvilli and goblet cells that secrete mucus. Below the mucosal surface are smooth muscle layers. The large intestine contains more goblet cells. The rectum is lined by simple columnar epithelium. Aspiration of the intestine is typically performed with ultrasound guidance and is usually quite accurate, especially for lymphoma. However, samples can also be taken via endoscopy, usually using a brush passed through the endoscope to obtain samples. The accuracy of that technique is quite good as well and is described in detail in numerous reports (see Jergens et al. 1998 in "Suggested Reading" under "Intestine"). Rectal scrapings using a conjunctival scraper can also be performed to obtain cells (Figure 44.49). In one study of 167 dogs with clinical signs of chronic gastrointestinal disease in which endoscopic cytology was performed, cytologic diagnosis was in agreement with the histologic diagnosis in 81% of cases. For the differentiation between enteritis and lymphoma, endoscopic cytology had a sensitivity of 98.6%, a specificity of 73.5%, a positive predictive value of 72.3%, and a negative predictive value of 98.6%. The following diagnoses in this series of dogs were determined by histopathology: lymphocytic-plasmacytic enteritis in 93,

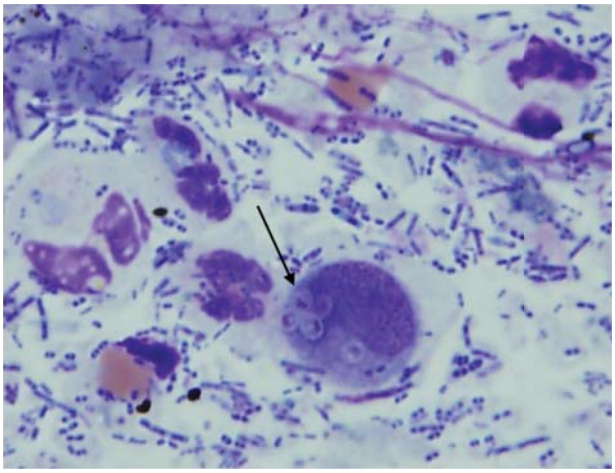

Figure 44.49 Rectal scraping from a dog with disseminated histoplasmosis. Note the multiple *Histoplasma* organisms in the macrophage (arrow). Wright stain.

eosinophilic enteritis in 5, small cell intestinal lymphoma in 45, and large cell intestinal lymphoma in 24 (see Maeda et al. 2017 in "Suggested Reading" under "Intestine").

Normal

Columnar epithelial cells are elongated with lightly basophilic cytoplasm and microvilli on the apical border. The nucleus is round and usually basilar, with an indistinct nucleolus. Goblet cells are also elongated and contain large purple mucin granules in the cytoplasm. Occasional eosinophils, lymphocytes, large granular lymphocytes, and plasma cells may be seen. If lymphoid follicles (Peyer's patches) are aspirated, numerous lymphocytes may be seen.

Inflammation

Inflammation of the intestine may be neutrophilic, lymphocytic-plasmacytic, or eosinophilic. Neutrophilic inflammation is usually caused by bacteria, including *Clostridium perfringens*, *Campylobacter jejuni*, *Salmonella* spp., and *Escherichia coli*. Neutrophils are destroyed rapidly in the lumen of the intestine. Evidence of overgrowth of these bacteria may be seen in fecal cytology, as well (Figures 44.50 and 44.51). Inflammation secondary to neoplasia can be difficult to differentiate from primary inflammatory processes if the aspirate is not fully representative of the lesion.

Lymphocytic-plasmacytic inflammation of the intestine in dogs is most commonly caused by hypersensitivity to food or gut microorganisms and can also be caused by lymphangiectasia and bacterial overgrowth. Differentiating lymphocytic inflammation from small cell lymphoma can be challenging in both dogs and cats. Flow cytometry and PAAR may be helpful in making the distinction (see Chapter 14).

Eosinophilic inflammation may be associated with hypersensitivity to food antigens, or with parasites, or be secondary to T-cell lymphoma or mast cell neoplasia.

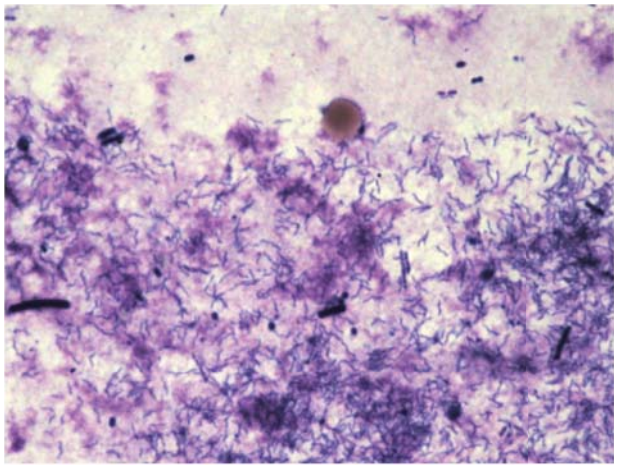

Figure 44.50 Fecal cytology from a dog with an overgrowth of *Campylobacter*. Note the "gull-wing" shaped organisms and the lack of diversity of bacteria. Wright stain.

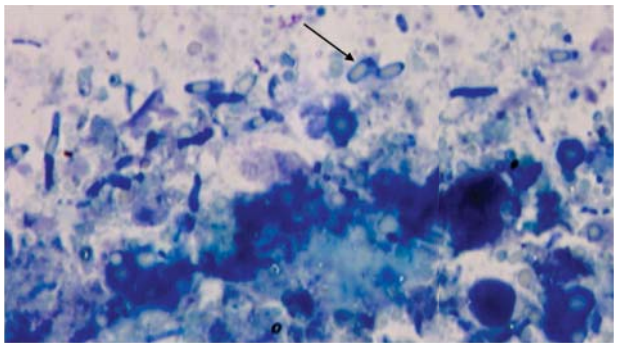

Figure 44.51 Fecal cytology from a dog with an overgrowth of *Clostridium*. Note the numerous safety-pin-shaped sporulated organisms (arrow). Wright stain.

Occasionally microorganisms such as *Giardia lamblia* may be seen on intestinal aspirates, particularly when the lumen of the duodenum is aspirated (Figure 44.52).

Neoplasia

Lymphoma of the gastrointestinal tract is the most common tumor of the intestine of dogs and cats, followed by adenocarcinoma and, least frequently, gastrointestinal stromal cell tumors and leiomyosarcomas. Mast cell tumors of the intestine in cats may also be seen.

Lymphoma

Intestinal lymphoma may be either nodular or diffuse. Intestinal lymphoma is the most common type of lymphoma in the cat but is a relatively rare type of lymphoma in dogs. Various subtypes of lymphoma occur in the intestine, just as in lymph nodes (see Chapter 45). In cats, lymphoma was traditionally classified as small cell or large cell and has more recently been classified as mucosal T cell that

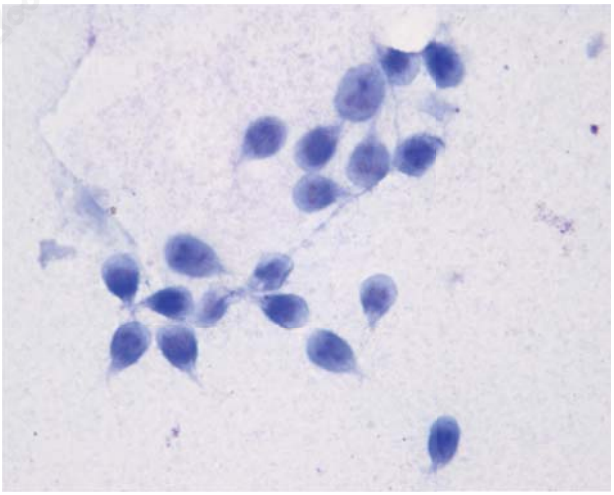

Figure 44.52 Aspirate of the intestine of a dog. The lumen was inadvertently aspirated and numerous *Giardia* organisms are seen. Note the pear-shaped organisms with two nuclei. The flagella are indistinct in this image. Wright stain.

has a relatively long survival time, transmural T-cell lymphoma (usually large granular cell lymphoma) that is less common, usually aggressive, and may be accompanied by leukemia (see Section VII, Case 13), and large B-cell lymphoma, which is also aggressive. Three histologic forms have been described in dogs: diffuse large B-cell lymphoma and enteropathy-associated T-cell lymphoma types 1 and 2, which are more common. Lymphomas that consist of large lymphoid cells with nucleoli are easy to recognize and have been described elsewhere (Figures 44.53 and 44.54). Small cell lymphomas are more common in cats and usually require histopathology or molecular methods to differentiate them from lymphocytic inflammation. Large granular lymphocyte lymphoma (T-cell lymphoma) is quite easy to

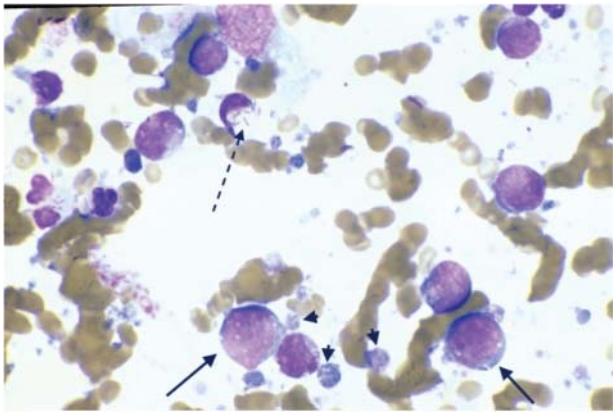

Figure 44.53 Aspirate of the intestine of a cat. Note the large immature lymphoid cells that are indicative of large cell lymphoma (arrows). The tumor had perforated the mucosa, and numerous neutrophils and bacteria can also be seen (dashed arrow). Cytoplasmic fragments indicating lymphoid origin are numerous (arrowheads). Wright stain.

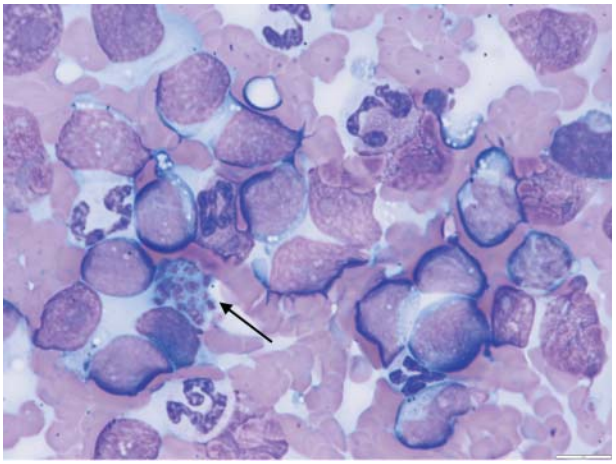

Figure 44.54 Aspirate of the stomach wall of a dog with gastric lymphoma. The numerous lymphoid cells are slightly larger than neutrophils. A platelet clump is indicated by the arrow. Wright stain.

diagnose cytologically and is described in Chapter 45. What were previously described as large globular leukocytes in the cat are now considered large granular lymphocytes.

Mast cell neoplasia

Mast cell tumors are the third-most-common tumor in the intestine of cats (after lymphoma and adenocarcinoma) and occur occasionally in dogs. Mast cell appearance has been described under "Spleen" in this chapter and elsewhere (see Chapter 40). In the intestine, they may be poorly granulated.

Carcinomas

Intestinal adenocarcinomas appear similar to other adenocarcinomas (see Chapter 40). Cellular piling and numerous other characteristics of malignancy such as anisocytosis and prominent nucleoli are usually present (Figure 44.55).

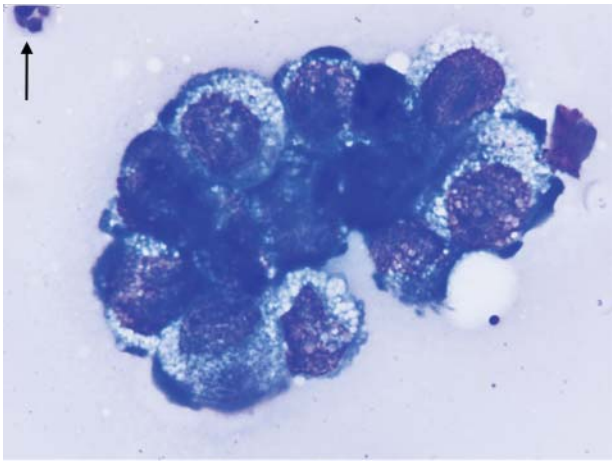

Figure 44.55 Aspirate of the intestine of a dog with intestinal adenocarcinoma. Note the cluster of very large vacuolated epithelial cells exhibiting prominent nucleoli and variability in size. A neutrophil is indicated by the arrow for size comparison. Wright stain.

Necrosis may be present. However, histopathology may be required since tissue architecture is often necessary for differentiating benign from malignant epithelial masses from the intestine.

Carcinoid

Carcinoids in the intestine are rare neuroendocrine tumors arising from enterochromaffin cells. They appear like other neuroendocrine cells and are uniform, in clusters and cord-like arrangements. Numerous naked nuclei are usually present.

Mesenchymal intestinal tumors

Connective tissue tumors of the intestine are referred to as gastrointestinal stromal cell tumors and were previously classified as either leiomyomas or leiomyosarcomas. Cells are spindle-shaped with wispy elongated cytoplasm and elongated nuclei with inconspicuous nucleoli. True leiomyosarcomas are likely less common than previously thought.

The function of lymph nodes includes filtering of particles and microorganisms, allowing antigens to come into contact with lymphocytes, resulting in subsequent activation of T and B lymphocytes. Lymph nodes were probably the first tissue to be studied by aspiration cytology. In 1904, the technique was used to search for organisms in human patients with trypanosomiasis (sleeping sickness). Aspiration cytology of lymph nodes has been increasingly advocated in both human and veterinary medicine because of the inexpensiveness, small amount of time required, and reasonably good sensitivity and specificity. In humans, cytology has a >90% sensitivity and specificity in differentiating a malignant process from reactive hyperplasia.

Lymph node enlargement, whether localized or generalized, is the primary indication for lymph node aspiration cytology (Figure 45.1). The differential diagnosis for an enlarged lymph node includes antigenic stimulation (reactive hyperplasia), lymphadenitis, lymphoma, and metastatic disease. Even if the node is not enlarged, lymph node cytology is occasionally helpful in determining if neoplastic metastasis to a lymph node has occurred.

Because cytology involves the study of aspirated cells, no architectural structures can be observed. However, it is worthwhile to review normal lymph node architecture to better understand the potential variability of the types of cells aspirated in normal and reactive nodes. B lymphocytes that matured in the bone marrow and T lymphocytes that matured in the thymus colonize lymph nodes. A normal node consists of a capsule, a cortex, a medulla, and sinuses (subcapsular, cortical, and medullary sinuses). The cortex contains follicles and parafollicular regions (Figure 45.2). Primary follicles contain primarily B lymphocytes. While T cells are also found in follicles, most are in parafollicular regions. Medullary cords consist of primarily B lymphocytes and plasma cells and are surrounded by sinusoids containing macrophages attached to reticular fibers (reticulum cells) and occasional mast cells. Lymph enters the node via afferent lymphatics and moves through the sinusoids, where antigens

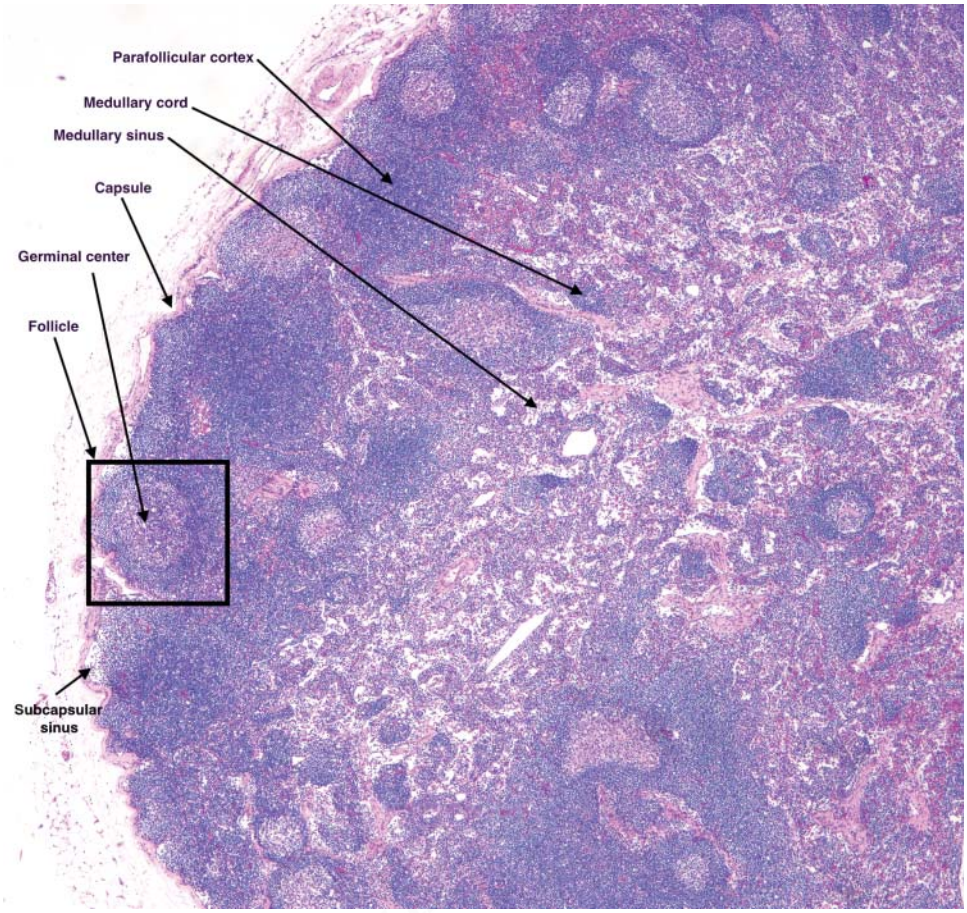

Figure 45.2 Normal lymph node from an African green monkey showing structures in the cortex and medulla. Within the cortex are follicles and parafollicular regions, as well as subcapsular sinuses. The medulla contains medullary cords made up of B lymphocytes and plasma cells, and sinuses containing macrophages. Different populations of cells may be aspirated from various areas of a lymph node. Hematoxylin and eosin (H&E) stain. Source: Courtesy of Dr. Pompei Bolfa, Ross University School of Veterinary Medicine.

are processed by reticulum cells and presented to T and B lymphocytes. Activated B cells enter primary follicles and become centroblasts that then migrate to the peripheral zone of the germinal center and become centrocytes. Centrocytes can reside in the mantle zone around the germinal center or form the marginal zone around the periphery of the mantle zone. Some centrocytes become plasma cells within the germinal centers. Macrophages containing phagocytized dying (apoptotic) B lymphocytes can be found within germinal centers and are sometimes called "tingible (stainable) body macrophages." Activated T lymphocytes in the parafollicular regions become T immunoblasts. Sinuses converge at the hilus of the node, and lymph then exits by the efferent lymphatics.

Technique

Selection of lymph nodes to be aspirated should be made on the basis of clinical findings. In animals with generalized lymphadenopathy, at least two nodes should be aspirated. Lymph nodes draining the oral cavity and gastrointestinal tract tend to be antigenically stimulated under normal conditions and should not be chosen if others are available. Superficial lymph nodes can be aspirated without using a local anesthetic, since the procedure is usually no more painful than venipuncture. Inflamed lymph nodes tend to be more painful than those affected with a neoplastic disorder. Lymph nodes within the thoracic or abdominal cavity should be aspirated using ultrasound guidance. A small-gauge needle (21–23 gauge) is redirected several times without withdrawing the needle from the skin. The needle is then attached to an air-filled syringe, and the material is expressed onto glass slides and "pull" films made, as is done when making films from bone marrow aspirates. One can also attach the needle to a syringe and apply gentle negative pressure to help obtain cells. Negative pressure should be released prior to withdrawing the needle from the tissue. Lymphoid cells, like bone marrow cells, are very fragile. Very little pressure should be placed on the spreader slide when

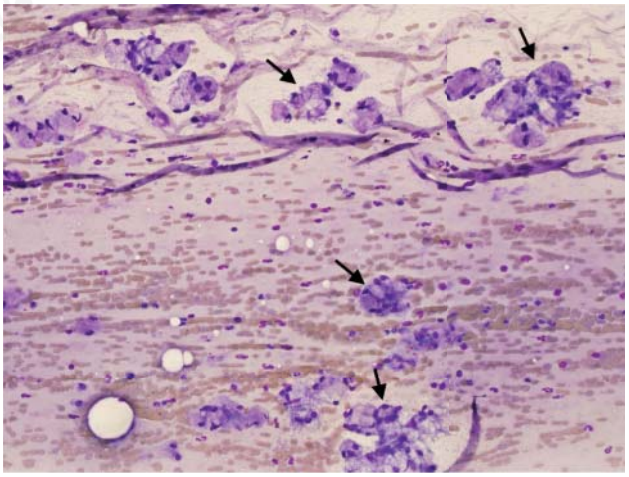

Figure 45.3 Salivary gland mistakenly aspirated when attempting to aspirate submandibular lymph node. Note the clusters of normal-appearing salivary gland epithelial cells (arrows). Background erythrocytes are arranged in a linear pattern ("windrowing") due to mucin within the salivary gland. Wright stain.

placing the material on the slide (see "Tissue Aspirates," Chapter 2). Imprints of biopsied nodes can also be made. Lymph node aspirates are often quite cellular, and additional staining time may be needed.

Nondiagnostic samples are usually due to a lack of cellularity or to the presence of many broken cells. Gentle spreading will usually prevent cells being broken. Aspirates of lymph nodes, like other tissue, tend to clot quickly, and if clotted they are nondiagnostic, as the cells are incorporated in the clot. Cells should be spread onto the slide within a few seconds of aspiration to prevent clotting. Sometimes perinodal fat is aspirated, rather than the lymph node itself, resulting in a nondiagnostic sample or a mistaken diagnosis of lipoma. Salivary glands are sometimes aspirated mistakenly when attempting to aspirate the mandibular lymph node, another reason to avoid aspirating that node if multiple nodes are enlarged (Figures 45.3 and 45.4). In some instances, aspiration of the salivary gland occurs because it is the salivary gland that is enlarged due to sialodenosis, and not the lymph node (see Chapter 41, "Sialodenosis").

Identification of cell types and other lymphoid elements

Small lymphocytes

Small lymphocytes are similar in appearance to the small lymphocytes found in blood. Small B and T lymphocytes cannot be distinguished from each other based on appearance. Because various subsets of lymphocytes in lymph nodes cannot be identified based on morphology, lymphoid cells are described according to size and the presence or absence of a visible nucleolus within the nucleus. Small lymphocytes are slightly smaller than a neutrophil (7–10 μm), and the nucleus is lightly larger than a red blood cell, with dense chromatin. A nucleolus is not visible within the nucleus, but chromatin clumps can be confused with nucleoli. The cytoplasm is generally scant and consists of a narrow rim around the nucleus (Figure 45.5). Some prefer to use nuclear size, rather than cell size, and consider a lymphocyte small if the nucleus is smaller than a neutrophil. The small lymphocyte is the primary cell type present in normal and hyperplastic nodes.

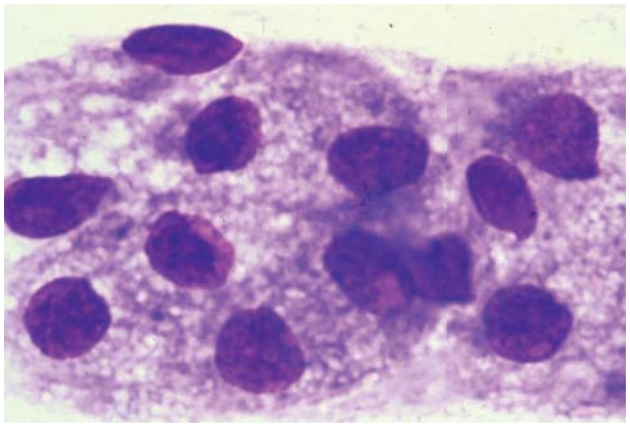

Figure 45.4 High magnification of aspirate of salivary gland from a dog. The enlarged salivary gland was originally thought to be the submandibular lymph node. Note the abundant vacuolated cytoplasm typical of secretory cells. Wright stain.

Intermediate lymphocytes

Intermediate lymphocytes have a nuclear diameter approximately equal to two red blood cells (9–15 μm), the nucleus is slightly larger than a neutrophil, and they have less densely packed nuclear chromatin (Figure 45.5). They are likely follicular centrocytes and marginal zone B cells.

Large immature lymphoid cells with apparent nucleoli (formerly called lymphoblasts)

The nuclear chromatin is fine and diffuse, and one or more nucleoli are observed in the nucleus. They are approximately 2–4 times the size of a small lymphocyte and 1.5–2 times the size of neutrophils. The nucleus is larger than a neutrophil. They may possess a broad or narrow rim of cytoplasm, but it is most commonly narrow (Figure 45.5). Large immature lymphoid cells are present in small numbers in normal nodes and usually do not exceed 20% of the total cell population in reactive lymph nodes. Lymphoid blasts are either follicular centroblasts or B or T immunoblasts from the paracortex and medullary cords and are difficult to classify as to type, based on cytologic appearance. Centroblasts have one to three peripheral nucleoli in the nucleus and scant cytoplasm, whereas immunoblasts have one centrally located nucleolus and a moderate amount of cytoplasm. Historically in veterinary medicine, the term "lymphoblast"

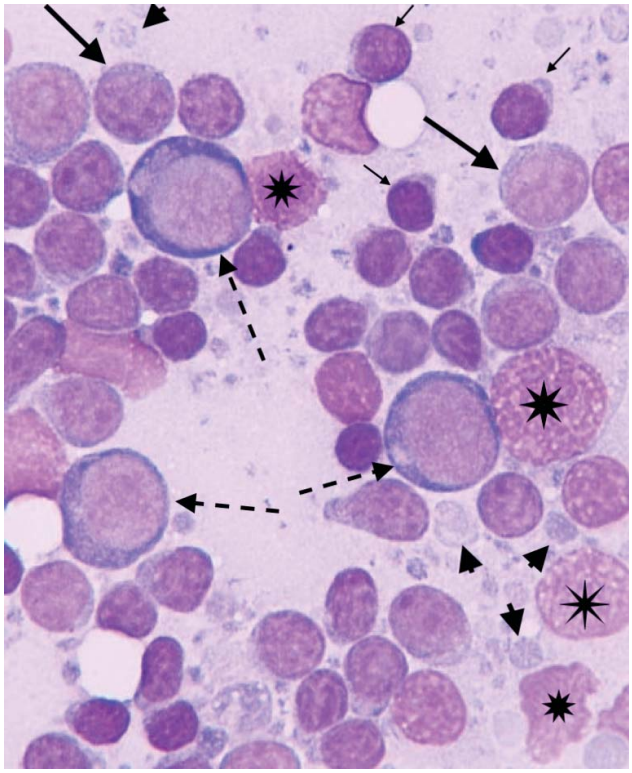

Figure 45.5 Lymph node aspirate from a dog with early antigenic stimulation. Small lymphocytes predominate (small arrows). Intermediate lymphoid cells are also present (large solid arrows). Large immature lymphoid cells are indicated by large dashed line arrows. Numerous cytoplasmic fragments are interspersed between cells (arrowheads). Broken nuclei are common to see in lymph node aspirates and are identified with asterisks. Wright stain.

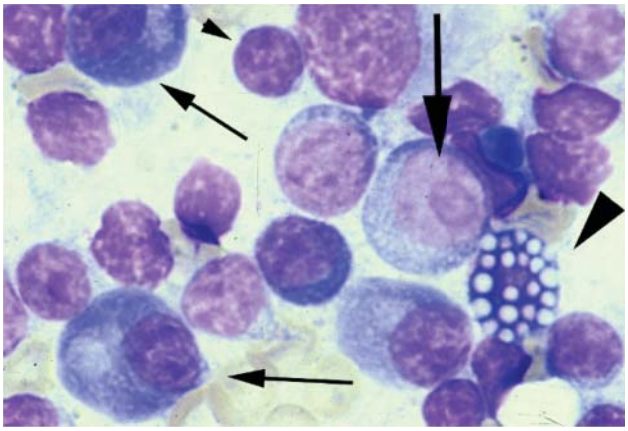

Figure 45.6 Reactive lymph node as evidenced by plasma cells (small arrows), a plasmablast (large arrow), and a Mott cell (large arrowhead). Small lymphocytes are also present (small arrowhead). Wright stain.

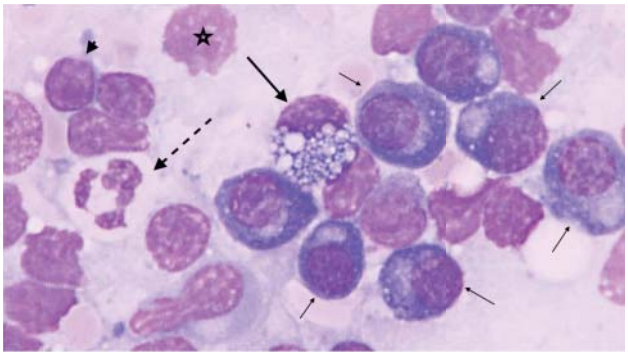

Figure 45.7 Aspirate of very reactive lymph node in a dog. Numerous plasma cells are present (small arrows), as well as a Mott cell (large arrow). The dashed line arrow indicates a neutrophil. Numerous cells are broken, with only nuclear material remaining (star). Wright strain.

was used for all immature lymphoid cells. According to the World Health Organization (WHO) classification of lymphoma, the term "lymphoblast" should only be used when describing specific precursor cells with defined morphologic features that are found in lymphoblastic lymphoma (LBL), a rare subtype of lymphoma arising from precursor cells that are uniform and small to medium in size, with round or convoluted nuclei not larger than the diameter of two erythrocytes and fine chromatin pattern and scant, sometimes vacuolated lightly basophilic cytoplasm. Nucleoli are small to inconspicuous and numerous cells in mitosis are seen; this subtype of lymphoma is discussed in more detail under the lymphoma section in this chapter. Some have suggested that when describing what have been traditionally called "lymphoblasts," the terms "immature large lymphoid cells with nucleoli," "lymphoid blasts," "centroblasts," or "immunoblasts" should now be used.

Plasma cells and plasmablasts

Plasma cells and plasmablasts are derived from antigenically stimulated B lymphocytes. The nucleus of plasma cells is eccentrically placed, the cytoplasm is generally quite basophilic, they may contain vacuoles, and a perinuclear clear area (Golgi zone) is commonly present. Plasma cells that contain many discrete packets of immunoglobulin (Russell bodies) are called Mott cells or Russell body cells and are commonly seen in reactive lymph nodes (Figures 45.6–45.8). Plasmablasts, B cells that have undergone blast transformation, are similar to other immature lymphoid blasts but usually have more cytoplasm that is basophilic and sometimes vacuolated, a Golgi zone may be apparent, and the nucleus may be more eccentric.

Neutrophils

Inflamed nodes will usually contain many neutrophils. These may appear healthy and intact whether the inflammatory process is septic or nonseptic (Figures 45.9 and 45.10), although degenerative changes may indicate septic inflammation. Karyolysis and karyorrhexis may be present. Bacteria are best observed within the cytoplasm of the neutrophils in thin portions of the preparation.

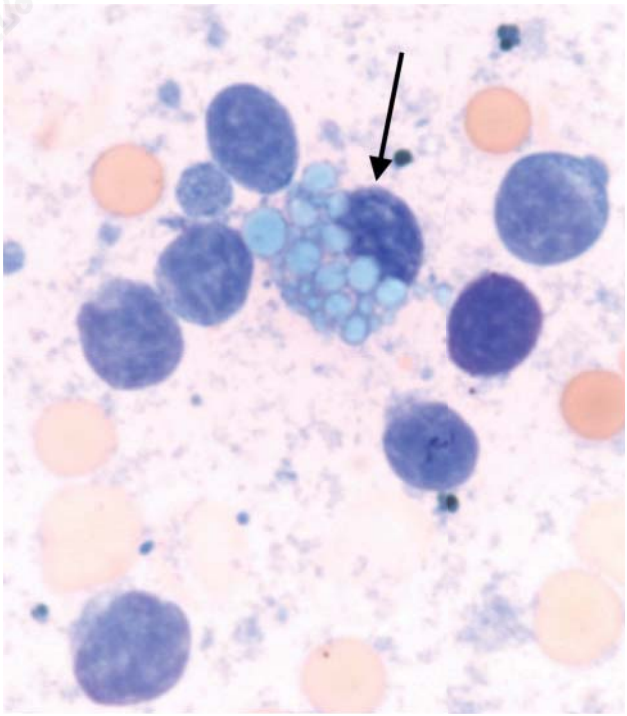

Figure 45.8 A Mott cell is indicated by the arrow. Russell bodies may not stain and appear clear, or the bodies may stain pink or light blue, as shown in this image. Wright stain.

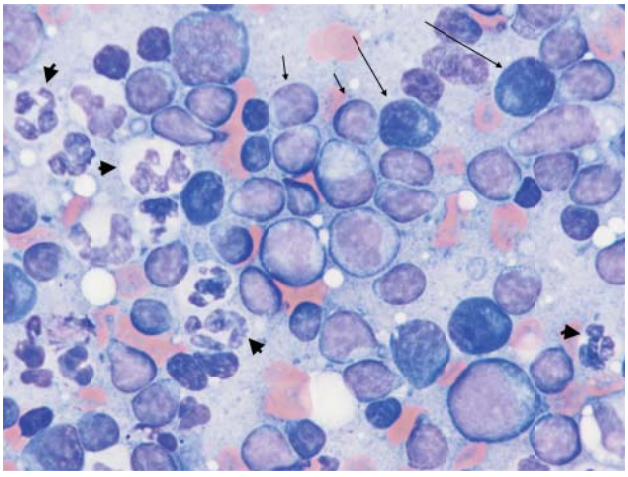

Figure 45.9 Aspirate of a submandibular lymph node of a dog that is both reactive and inflamed. Small lymphocytes are indicated by small arrows, plasma cells by long arrows, and neutrophils by arrowheads. Wright stain.

Macrophages

Macrophages may be observed in some inflammatory conditions. These cells are phagocytic, have abundant, usually vacuolated cytoplasm, and may contain cellular debris. Macrophages are sometimes multinucleated. When macrophages develop some of the characteristics of epithelial cells, such as abundant cytoplasm that lacks vacuoles, they are often referred to as epithelioid cells. Care should be taken not to confuse epithelioid cells with metastatic carcinoma cells (Figure 45.11).

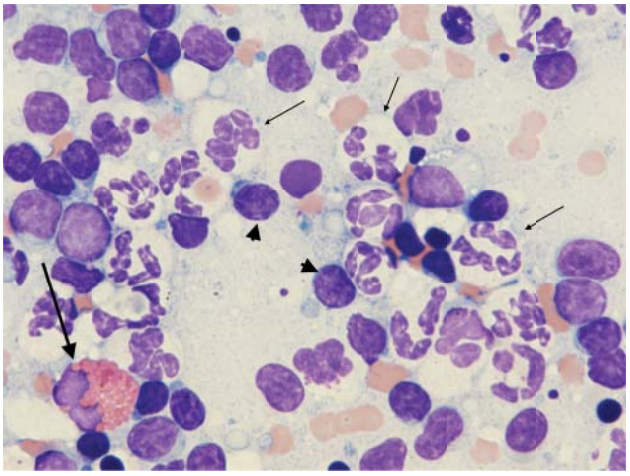

Figure 45.10 Suppurative lymphadenitis in a horse. Note the numerous neutrophils (small arrows), an eosinophil (large arrow), and small lymphocytes (arrowheads). The neutrophils are nondegenerate and no microorganisms are seen. Wright stain.

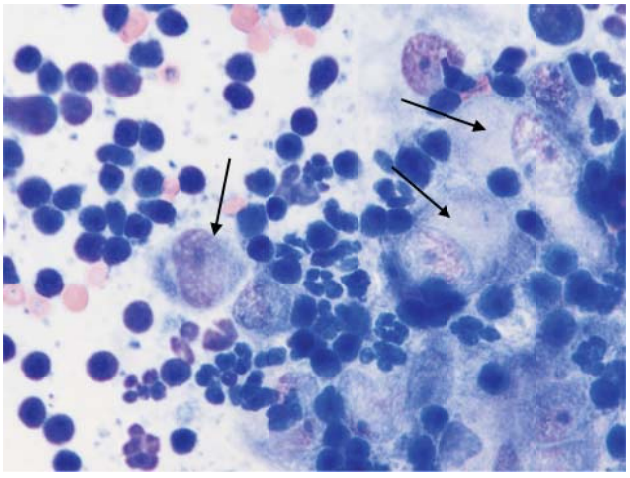

Figure 45.11 Pyogranulomatous lymphadenitis in a cat. Epithelioid macrophages are present in aggregates (arrows) and could be confused with epithelial cells. Numerous small lymphocytes and neutrophils are present as well. Wright stain.

Eosinophils

Eosinophils in lymph nodes appear similar to eosinophils in peripheral blood and are associated with allergic reactions, parasitic diseases, and neoplasms, including lymphoma and mast cell tumors. Eosinophilic inflammation of lymph nodes is commonly seen in patients with dermatitis or flea-bite allergy (Figure 45.12).

Mast cells

Mast cells are round cells with numerous basophilic granules in the cytoplasm. A few may be seen in normal lymph nodes.

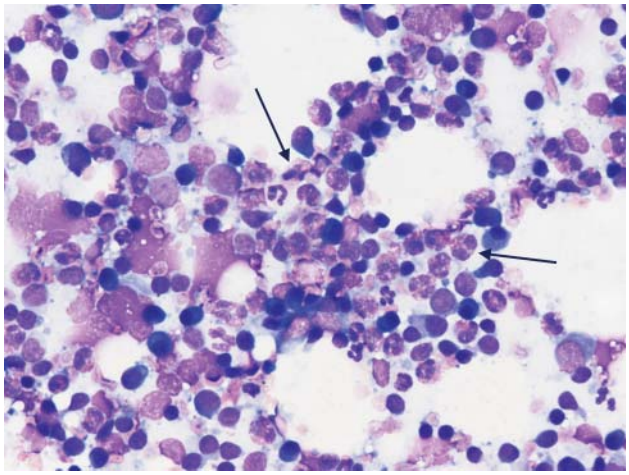

Figure 45.12 Eosinophilic lymphadenitis in a dog. Eosinophils are the predominant cell type (arrows). Numerous small lymphocytes and a few plasma cells are also present. Wright stain.

Lymph nodes draining skin lesions often have increased mast cells. The presence of many mast cells especially in aggregates is suggestive of mast cell neoplasia with metastatic involvement of the lymph node (Figure 45.13).

Neoplastic cells other than lymphoid cells

Neoplastic cells other than lymphoid cells, such as carcinoma cells, may be seen in lymph nodes to which neoplasms have metastasized (Figure 45.14). Cells not belonging to the normal population of the lymph node can usually be seen at low magnification. Malignant epithelial cells are usually quite pleomorphic and large, exhibiting numerous criteria of malignancy (Figure 45.15). Nuclei vary in size and shape and may exhibit nuclear molding. Nucleoli are often prominent and multiple. Occasional mitotic figures and multinucleated cells may be observed. The cytoplasm of malignant epithelial cells (carcinomas) commonly stains quite basophilic and may contain perinuclear vacuoles. Sarcomas metastasize to lymph nodes less frequently than carcinomas. Mast cell tumors commonly metastasize to lymph nodes and must be differentiated from normal mast cells that may be present in small numbers, particularly in inflamed lymph nodes. Malignant melanomas also commonly metastasize to lymph nodes. Metastatic disease in lymph nodes is discussed in more detail in a later section of this chapter.

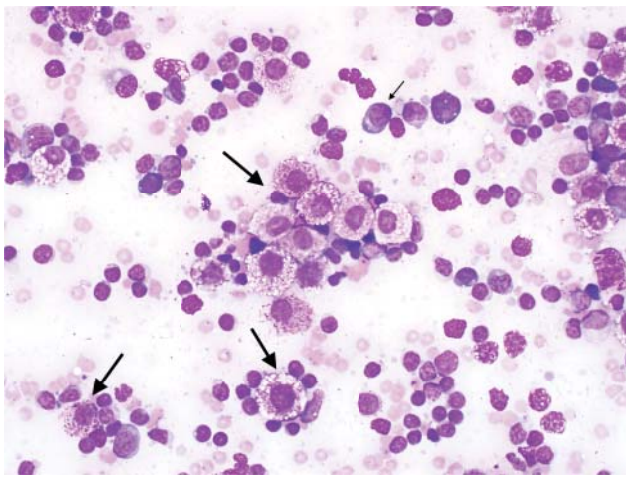

Figure 45.13 Metastatic mast cell tumor in a lymph node of the dog. Aggregates and single mast cells are scattered throughout (large arrows). The lymph node is also reactive (note plasma cell, small arrow). Small lymphocytes predominate, with some erythrocytes in the background. Wright stain.

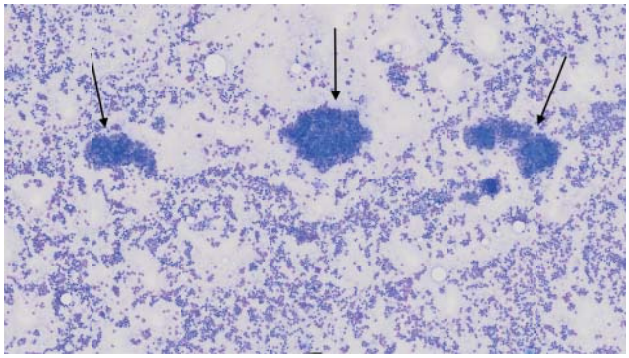

Figure 45.14 Low magnification of a lymph node with metastatic nasal carcinoma. Note the clusters of large cohesive epithelial cells (arrows) among the normal lymphoid population. Wright stain.

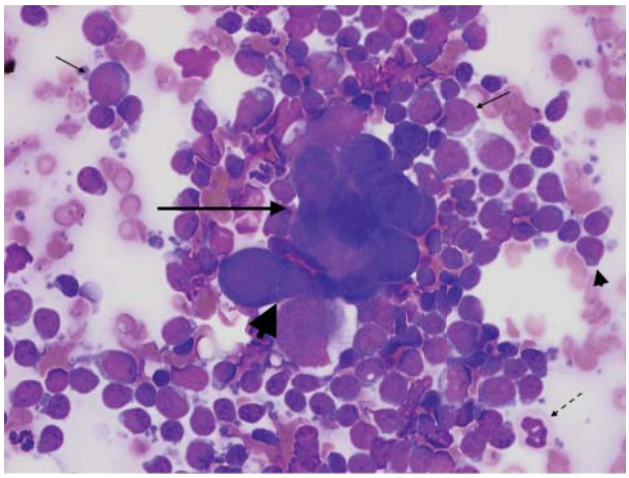

Figure 45.15 Metastatic nasal squamous cell carcinoma in a lymph node of a dog. A large cluster of neoplastic epithelial cells is indicated by the large arrow. Note the variability in size of the cells and the nuclear molding (large arrowhead). Small lymphocytes predominate (small arrowhead), with an occasional large immature lymphoid cell (small arrows), and neutrophils (dashed line arrow). Wright stain.

Cytoplasmic fragments and free nuclei

Small pieces of cytoplasm approximately 1–5 µm in diameter may be observed between cells (Figure 45.5). These fragments have been referred to as lymphoglandular bodies and are a characteristic feature of lymphoid tissue aspirates.

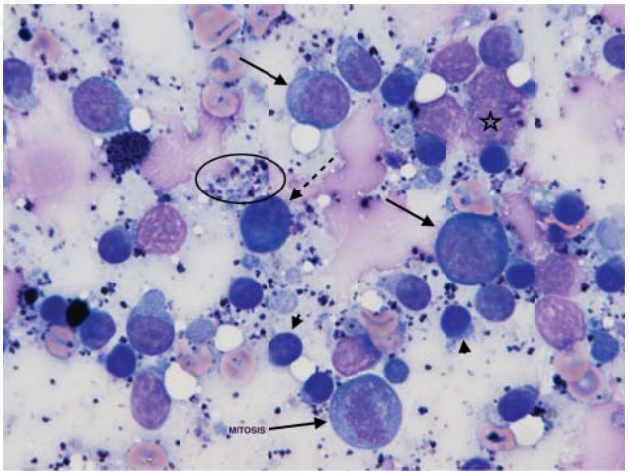

Figure 45.16 A large amount of hemosiderin (oval) is scattered throughout the preparation, indicating previous hemorrhage. The node is reactive, as indicated by plasma cells (dashed line arrow) and plasmablasts (arrows). One plasmablast appears to be in mitosis. Numerous cells are broken (star). A small lymphocyte is indicated by the arrowhead. Wright stain.

They should not be confused with platelets or organisms. Lymphoid cells are fragile and rupture easily, releasing nuclear material. Free nuclei are pink and swollen, and sometimes a light blue nucleolus can be seen within the broken nucleus (Figure 45.5). These broken cells with apparent nucleoli should not be confused with immature lymphoid cells containing nucleoli. If all of the cells are broken, the node should be reaspirated.

Pigment

Hemosiderin, a pigment resulting from red blood cell degradation by macrophages, is frequently seen in lymph nodes and may be intracellular or extracellular (Figure 45.16). Hemosiderin, the insoluble form of storage iron, stains blue-green to black with Wright stain and is usually within macrophages. Melanin is usually golden brown to black but may be confused with hemosiderin. If necessary, a Prussian blue stain can be used to confirm the presence of iron. Melanin may be present within macrophages in nodes draining pigmented lesions or may be seen in melanocytes with metastatic melanoma. It is sometimes difficult to differentiate macrophages that contain melanin from melanocytes; melanin within macrophages usually consists of homogeneous clumps within phagolysosomes, whereas melanin in melanocytes consists of individual melanin granules. Fontana Masson stain can be used to identify melanin.

Interpretation of cytologic findings

Normal lymph nodes

Small lymphocytes are the predominant cell type in normal nodes, comprising 85–90% of the cells observed. Very small numbers of macrophages, medium lymphocytes, large immature lymphoid cells containing nucleoli, plasma cells, and neutrophils may be present. One study of normal canine lymph node cytology reported a median percentage of neutrophils, eosinophils, and macrophages as 1.4%, 2.0%, and 1.4%, respectively. Plasma cells comprise less than 4% of cells in a normal canine lymph node. Intermediate lymphocytes are reported to make up 3–4% of cells in normal canine lymph nodes.

Reactive (hyperplastic) lymph nodes

The term "reactive lymphoid hyperplasia" describes the enlargement of the lymph node secondary to antigenic stimulation, the most common cause of lymph node enlargement. Hyperplasia may occur in follicles, interfollicular paracortical areas, medullary cords (plasma cell hyperplasia), and sinuses (histiocytosis). The cytologic features of antigen-stimulated lymph nodes is variable, depending on the area aspirated and the length of time since antigenic stimulation began. Small lymphocytes predominate in antigenically stimulated lymph nodes. Variable numbers of intermediate lymphocytes and large immature lymphoid cells may be observed. Mature and immature plasma cells are increased and are the key feature of a reactive lymph node (Figure 45.7). Rarely, plasma cells are the predominant cell in reactive lymph nodes, and in those cases, plasma cell neoplasia must be considered as a differential diagnosis. Macrophages, neutrophils, eosinophils, and mast cells may be slightly increased in number. Ultimately, inflammatory cells may be increased to the point that the node is classified as both inflamed and reactive. Aggregates or syncytia of macrophages may be seen and should not be confused with clusters of metastatic epithelial cells. Reactive nodes draining inflamed skin frequently contain increased numbers of eosinophils and mast cells. While some veterinary clinical pathologists distinguish hyperplastic lymph nodes from reactive lymph nodes based on the number of plasma cells present ("reactive" lymph nodes having more plasma cells), this is likely an artificial classification, since the number of plasma cells obtained will vary with the site within the lymph node from which the aspirate was taken. Caution must be taken not to confuse hyperplastic lymph nodes from small-cell variants of lymphoma. When nodes are enlarged and aspirates are very cellular, consisting of a uniform monomorphic population of small lymphocytes, a small-cell variant of lymphoma is more likely than hyperplasia (see lymphoma discussion later in chapter). The cause of the antigenic stimulation is usually not apparent in aspirates, although an exception is leishmaniasis, in which the typical nodal response is reactive hyperplasia, rather than inflammation, and organisms are commonly seen.

Ehrlichia canis

Ehrlichia canis morulae are rarely seen in lymph node aspirates of dogs with canine monocytic ehrlichiosis (CME).

Generalized lymphadenopathy due to antigenic stimulation is seen in the majority of dogs with ehrlichiosis. Increases in plasma cells, intermediate lymphocytes, and plasmablasts are typically seen.

Borrelia burgdorferi

Borrelia burgdorferi, a spirochete transmitted by *Ixodes* spp. ticks and the causative agent of Lyme disease, causes lymphadenopathy in humans and dogs in the acute stage of disease, particularly in the regional lymph node near the site of infection, but generalized lymphadenopathy is common. The lymphadenopathy is primarily due to reactive hyperplasia, and in dogs with experimental Lyme disease, it is characterized by proliferation of follicles, parafollicular B-cell proliferation, and increases in plasma cells in medullary cords. Macrophages, a few neutrophils, and sometimes eosinophils are found within medullary sinuses in variable numbers. Extracellular spirochetes are found persistently in the subcapsular sinus and superficial cortex of lymph nodes in experimentally infected mice. Lymphadenopathy is a hallmark of acute infection but the underlying causes and the functional consequences of this lymph node enlargement have not been revealed. Studies demonstrate that extracellular, live spirochetes accumulate in the cortical areas of lymph nodes following infection of mice with either host-adapted or tick-borne *B. burgdorferi* and that they, but not inactivated spirochetes, drive the lymphadenopathy. The ensuing lymph node response is characterized by strong, rapid extrafollicular B-cell proliferation and differentiation to plasma cells, while germinal center reactions have not been consistently observed.

Leishmaniasis

Leishmaniasis is an infectious cause of reactive lymph node hyperplasia in which the organisms are commonly seen in aspirates. The causal agent of canine leishmaniasis is the protozoan *Leishmania infantum* (also known as *L. chagasi*), which is quite common in Europe and other parts of the world. *Leishmania* is typically transmitted by sand flies and is also seen in the United States in dogs that have a travel history to endemic areas such as Spain. However, leishmaniasis also has been diagnosed in dogs that have no travel history, especially foxhounds in the eastern part of the United States, where the disease has become increasingly common. It is thought to be transmitted vertically or by dog-to-dog mechanisms in these states, because no vectors such as sand flies have been identified. The amastigote form of the parasite reproduces in macrophages, resulting in rupture and spread to numerous organs, including spleen, liver, bone marrow, and lymph node (Figure 45.17). The disease can take several forms, ranging from a mild cutaneous form to disseminated visceral leishmaniasis. Almost all dogs with clinical leishmaniasis have reactive lymph node hyperplasia, although a small percentage may also have a combination of reactive hyperplasia and histiocytic lymphadenitis or histiocytic lymphadenitis only. The amastigote is round with a light purple round nucleus and dark purple rod-shaped kinetoplast, as also shown in Figures 15.21 and 39.47.

Feline immunodeficiency virus

Feline immunodeficiency virus (*FIV*) infection in the early stages will commonly result in generalized lymphadenopathy due to antigenic stimulation. The lymph nodes appear reactive

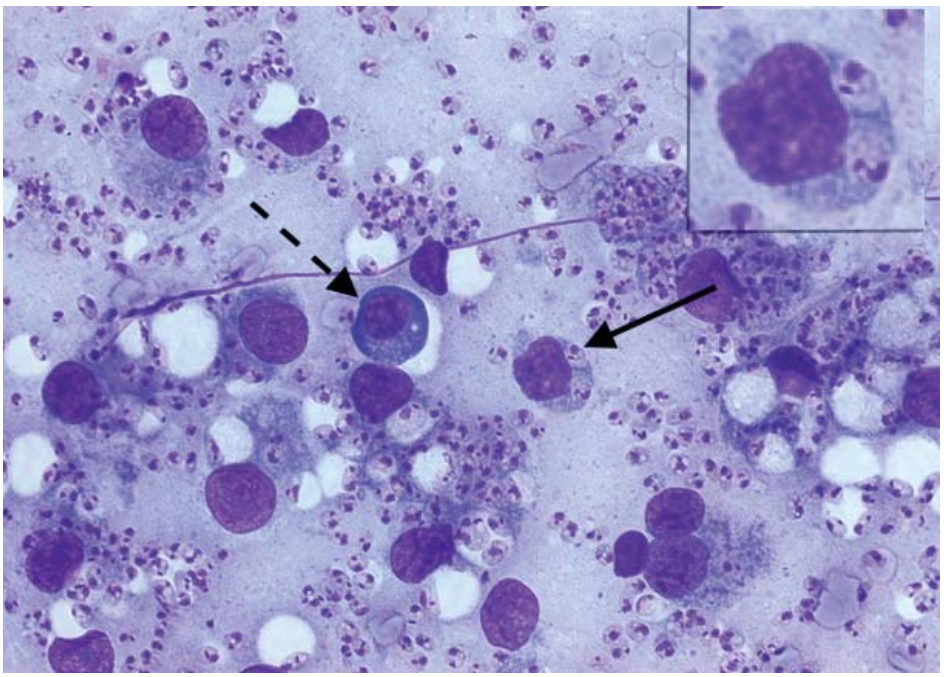

Figure 45.17 Lymph node aspirate from a dog with leishmaniasis. Note the "two-dot" organisms within the cytoplasm of cells (arrow). A plasma cell is indicated by the dashed arrow. Inset, right upper corner shows a higher magnification. Wright stain.

on cytology as a result of increased germinal centers and increased plasma cells in the medulla.

Phenobarbital hypersensitivity

Phenobarbital hypersensitivity is a rare idiosyncratic cause of reactive lymph nodes in dogs and cats. Cytology of the lymph nodes is consistent with reactive hyperplasia, and mixed inflammation is seen in spleen and liver aspirates. This well-recognized syndrome in humans is referred to as pseudolymphoma.

Lymphadenitis

The types of cells present in an inflamed lymph node are variable depending on the cause of inflammation; neutrophils, eosinophils or macrophages may predominate. If the most predominant cell is the neutrophil, the inflammation is classified as neutrophilic inflammation; "purulent" or "suppurative" are commonly used synonyms. If the predominant cell is the macrophage, the inflammatory response is classified as macrophagic, histiocytic, or granulomatous inflammation. Mixed inflammatory reactions may also be seen, in which some combination of inflammatory cells are present. If neutrophils and macrophages predominate, the inflammation is often referred to as pyogranulomatous. The required percentage of inflammatory cells present when describing a node as inflamed is subjective but has been reported to be >5% neutrophils for neutrophilic inflammation, >3% macrophages for macrophagic inflammation, and >3% eosinophils for eosinophilic inflammation. Inflamed lymph nodes may also be reactive, with increased numbers of plasma cells, intermediate lymphocytes, and large immature lymphoid cells containing nucleoli. Neutrophilic inflammation may become so severe that abscessation and necrosis occur, making it sometimes difficult to recognize that the origin of the abscess was a lymph node. Lymphadenitis may be due to multiple causes, but an immune-mediated or, more commonly, an infectious etiology must be considered when numerous neutrophils and/or macrophages are present.

Idiopathic pyogranulomatous lymphadenitis

Idiopathic pyogranulomatous lymphadenitis in dogs is assumed to be immune mediated since it is steroid responsive. It is most common in English springer spaniels. Clinical signs include pyrexia and lymphadenopathy, often accompanied by dermal lesions (nodular panniculitis), lethargy, hyporexia, and gastrointestinal and respiratory signs. Lymph node aspirates show mixed (pyogranulomatous) sterile inflammation. A very similar condition resulting in mandibular lymphadenopathy is *sterile granulomatous dermatitis and lymphadenopathy* (SGDL), also known in young dogs as juvenile cellulitis or puppy strangles, which occurs in both puppies and adult dogs, is reported in multiple breeds including Havanese, Australian shepherds, Irish setters, Dachshund, bichon frise, and Maltese, and is also steroid responsive and assumed to be immune mediated.

Infectious lymphadenitis

Microorganisms eliciting lymphadenitis include bacteria, protozoa, rickettsia, and fungal agents.

Bacterial lymphadenitis

Bacteria that may result in marked lymphadenitis include *Streptococcus equi*, *Yersinia pestis*, *Francisella tularensis*, *Mycobacterium* spp., *Bartonella henselae*, and various other bacteria that may cause regional lymphadenitis, such as *Salmonella*-related and *Listeria monocytogenes*–related mesenteric lymphadenitis, and *Rhodococcus equi*–related lymphadenitis, as shown in Figure 39.22.

- *Streptococcus equi* is the causative agent of "strangles" in horses, a frequently diagnosed infection that is characterized by neutrophilic lymphadenitis followed by abscessation of the lymph nodes of the head and neck. The cocci can be easily seen in lymph node aspirates, similar to what is shown in Figure 39.2. The disease was first described in 1251 and the causative agent was identified in 1888. *Streptococcus zooepidemicus*, a bacterium that is very closely related to *Streptococcus equi*, can also result in lymphadenopathy, appears identical to *Streptococcus equi*, as shown in Figures 39.12 and 39.13, but is less pathogenic and less contagious.
- *Yersinia pestis*, a Gram-negative coccobacillus with a bipolar safety-pin shape, is the causative agent of plague, a relatively rare zoonotic disease of historical significance in Europe (Black Death). The disease is more common in cats than dogs. In the United States, plague is more common in Colorado, California, and New Mexico. It also occurs in semi-arid parts of Asia, Europe, and Africa. Transmission occurs via flea bite or ingestion of infected rodents or rabbits. Cats commonly have bilateral mandibular lymphadenopathy;

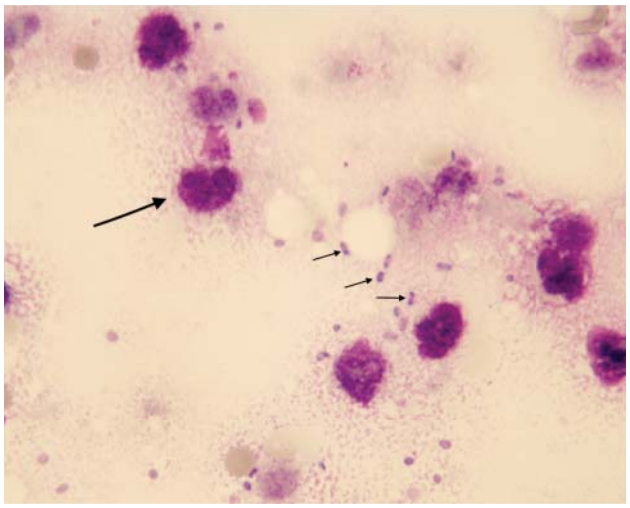

Figure 45.18 Submandibular lymph node aspirates from a Colorado cat with plague. Lymph nodes were abscessed, and neutrophils are very degenerate (large arrow), appearing as nuclear smudges. Numerous free *Yersinia pestis* organisms are present (small arrows). Wright stain. Source: Courtesy of Dr. Kyra Somers and Dr. Robin Allison.

lymphadenopathy is less common in infected dogs. Aspirates of nodes show neutrophilic inflammation as shown in Figure 39.15, and the coccobacilli are typically numerous (Figure 45.18). Neutrophilic lymphadenitis often evolves into abscessation and necrosis. Infected individuals may also develop pulmonary lesions and septicemia. Treatment of choice is gentamycin or doxycycline.

• *Francisella tularensis*, the causative agent of tularemia, also known as "rabbit fever," is a very virulent intracellular Gram-negative bacterium that is usually fatal in rabbits. Infection occurs in dogs and cats most commonly by contact with or ingestion of infected animals, usually rodents or rabbits, but can also be transmitted by arthropod vectors such as ticks or deer flies, inhalation of contaminated dust, or ingestion of contaminated food and water. The disease occurs in dogs, cats, humans, and many other mammalian, avian, piscine, reptilian and amphibian species in the Northern Hemisphere of the world. In the United States, it is most common in Arkansas, Missouri, South Dakota, Oklahoma, Kansas, and between the Rocky Mountains and the Sierra Nevada Mountains; it is reportable in some states. Tularemia is more severe, and probably more common, in cats than in dogs. Clinical signs are similar to those of plague and may include fever, lethargy, anorexia, lymphadenopathy, vomiting, diarrhea, mucopurulent oculonasal discharge, and occasionally skin lesions. Common laboratory findings in dogs include neutrophilia and thrombocytopenia. Lymphadenopathy associated with tularemia in humans is called "glandular tularemia." Lymphadenopathy occurs in approximately 20% of dogs with tularemia and is usually in the head and neck area. Cytologic findings range from reactive hyperplasia in acute disease, to suppurative or mixed inflammation, to necrosis. Lymph node aspirates are diagnostically useful as the organisms can sometimes be seen as well as cultured.

• *Bartonella henselae*, the causative agent of "cat scratch fever" in humans, is a very small (0.3–0.6 × 1.0–1.7 µm), pleomorphic Gram-negative rod. The organism is transmitted by the cat flea, and cats are typically asymptomatic when infected. Bartonellosis has been rarely associated with pyogranulomatous lymphadenitis in dogs. Both peripheral and visceral lymph nodes may be enlarged, and the pattern of inflammation is similar to what is seen in humans.

• *Mycobacterial* infections typically result in macrophagic or granulomatous lymphadenitis. Weight loss, lethargy, and generalized lymphadenopathy are the most common clinical signs. The majority of cells in infected lymph nodes are macrophages, and most macrophages contain nonstaining clear rods within the cytoplasm (Figure 45.19). Mycobacteria may also be seen within neutrophils and free between cells. Mycobacteria appear as nonstaining rods in Wright-stained preparations due to their lipid-rich cell wall that does not stain, as shown in Figures 39.23 and 39.24, but they stain pink with an acid-fast stain (Ziehl-Neelsen) (Figure 45.20). The most common species seen in dogs

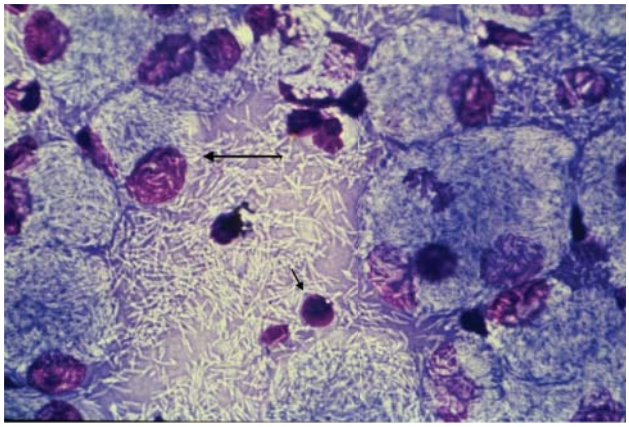

Figure 45.19 High magnification of an aspirate of a lymph node from a miniature schnauzer with generalized lymphadenopathy that was referred with an erroneous diagnosis of lymphoma and had been treated previously with glucocorticosteroids. Macrophages are the predominant cell (large arrow) and are filled with nonstaining large rods that were confirmed as *Mycobacterium avium*. Numerous organisms are also free in the background. A small lymphocyte is indicated by the small arrow. Wright stain.

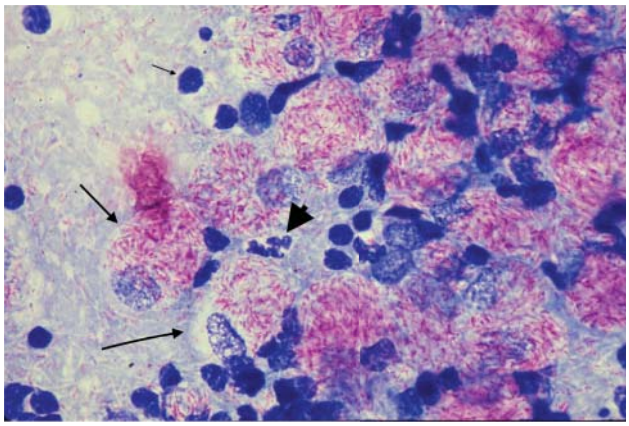

Figure 45.20 Aspirate of the same lymph node as shown in Figure 45.19, shown at a lower magnification and stained with an acid-fast stain. The mycobacteria stain pink. Macrophages predominate (large arrows), with numerous small lymphocytes (small arrow) and occasional neutrophils (arrowhead). Ziehl-Neelsen stain.

is *Mycobacterium avium*, an opportunistic non-tuberculous mycobacteria (NTM). The species *Mycobacterium avium* is currently divided into four subspecies including *avium* (MAA), *silvaticum* (MAS), *hominissuis* (MAH), and *paratuberculosis* (MAP). The subspecies *hominissuis* (MAH) is responsible for the majority of infections in dogs and is usually contracted from soil and water in the environment. The disease is usually systemic and commonly fatal, with mycobacteria in numerous locations in addition to lymph nodes, including the small and large intestine, spleen, liver, lungs, and bone marrow. While canine mycobacteriosis is relatively rare, a strong breed predisposition is seen in miniature schnauzers and basset hounds; dogs less than 5 years of age are most commonly affected. An autosomal

recessively inherited defect in the adaptor protein CARD9 (caspase recruitment domain-containing protein 9) has been shown to be responsible for the increased susceptibility in miniature schnauzers. All miniature schnauzers that are homozygous for the CARD9 variant gene develop mycobacteriosis due to *Mycobacterium avium* (see Ghielmetti and Giger 2020 in "Suggested Reading" under "Mycobacterial Lymphadenitis"). The CARD9 signaling pathway is essential in host defense against numerous fungal organisms and intracellular bacteria.

Rickettsial lymphadenopathy

Rickettsia that cause lymphadenomegaly include *Ehrlichia canis*, *Neorickettsia helminthoeca*, and *Stellanchasmus falcatus*. Lymphadenopathy associated with the rickettsial agent *Ehrlichia canis* is a result of reactive hyperplasia, rather than lymphadenitis, and is discussed in that section. *Neorickettsia helminthoeca* is an intracellular bacterium that causes salmon poisoning disease in dogs, primarily seen in the Northwest United States, Southern California, Western Canada, and Southern Brazil. However, dogs eating undercooked or raw trout or salmon from supermarkets in other areas can also be infected. The term "salmon poisoning" is a misnomer, since no poison is involved. *N. helminthoeca* is carried by the fluke *Nanophyetus salmincola*, the life cycle of which is complex and involves the snail *Juga plicifera* as the first intermediate host, salmonid fishes, primarily trout and salmon, as the second intermediate host, and fish-eating mammals as the definitive host. The ingested immature flukes (metacercaria) mature to adult flukes in the small intestine. Adult flukes begin producing eggs in approximately 1 week. Fluke eggs develop into miracidia that infect snails, thus completing the life cycle. The disease is fatal in approximately 90% of dogs that are not treated, usually within 1 week of showing clinical signs that include fever, weakness, anorexia, vomiting, diarrhea, dehydration, and lymphadenopathy. Histopathology shows granulomatous lymphadenitis, splenitis, enteritis, and hepatitis with necrosis. Diagnosis is made by recognition of clinical signs, the presence of fluke eggs in the feces, lymph node aspiration showing granulomatous inflammation and organisms, and serology or polymerase chain reaction (PCR) for *N. helminthoeca*. Histiocytic lymphadenitis, with numerous *N. helminthoeca* organisms within macrophages, is seen on lymph node aspirates. The rickettsia appear as small basophilic aggregates as shown in Figure 39.54, rather than distinct morulae. Doxycycline and supportive therapy are curative if given early in the course of the disease. A second closely related organism with similar transmission, *Stellanchasmus falcatus*, causes Elokomin fluke fever, a disease with similar clinical signs and outcome in bears but which typically only causes mild disease in dogs. However, *S. falcatus* has been reported to cause severe disease and death in a small number of dogs in the Pacific Northwest, with clinical signs and cytologic findings very similar to those seen in dogs infected with *N. helminthoeca*.

Protozoan lymphadenopathy

- *Leishmania* spp. usually results in reactive hyperplasia of lymph nodes and is discussed in that section. In some patients, however, macrophagic (histiocytic) lymphadenitis is seen, as shown in Figures 45.17 and 39.47.
- *Cytauxzoon felis*, a protozoan haemoparasite of the family *Theileriidae* that infects wild and domestic cats and causes cytauxzoonosis, is discussed in detail in Chapter 9 in the section on hemolytic anemia. This protozoan organism has two phases, one in macrophages (sporozoites and schizonts), and one in erythrocytes (merozoites/piroplasms). Sporozoites infect endothelial-associated macrophages and undergo asexual replication within the macrophages; sporozoites develop into large structures known as schizonts that occlude blood vessels in various organs, resulting in thrombosis, circulatory impairment, and an inflammatory response that leads to organ failure and death within a few weeks of infection. Merozoites are released from ruptured monocytes and macrophages and then infect erythrocytes. The organism can be identified not only within erythrocytes in the merozoite stage but also in lymph node, spleen, and liver aspirates, where schizonts can be observed, as shown in Figures 9.20, 39.44, and 39.45. The large macrophages often have prominent nucleoli, and the cytoplasm is distended with dark blue developing signet ring merozoites that are 1–2 μm in diameter.
- *Toxoplasma gondii* is another protozoan organism that can be found in lymph node aspirates of cats. It is an obligate intracellular coccidian parasite that can infect all mammals, but domestic and wild cats are the natural hosts. Transmission occurs vertically (transplacentally), by ingestion of infective oocysts or ingestion of infected tissue. Cats are usually infected by eating intermediate hosts, usually rodents, that are infected with tissue cysts. Bradyzoites are then released in the stomach and intestine from the tissue cysts and enter epithelial cells of the small intestine and form schizonts. Merozoites, formed and released from the schizonts, eventually form male and female gamonts. A wall is then formed around the fertilized macrogamont to form an oocyst. Oocysts, round to oval structures, 10×12 μm in diameter, are excreted in feces and are not infectious until after they sporulate, which takes 1–5 days. If infective oocysts are ingested, sporozoites hatch in the intestine and enter intestinal cells and form tachyzoites, which then multiply in almost any cell of the body, resulting in rupture of the cell and release of tachyzoites. Tachyzoites then infect additional cells and eventually encyst. Tissue cysts conform to the shape of the infected cell and range in size from 15 to 60 μm. On cytology, tachyzoites can be seen within cells or free, are falciform in shape (sickle or banana-shaped), have a small round nucleus, and are approximately 2×6 μm in diameter, as shown in Figures 15.20 and 39.46. Clinical signs are rare in infected cats, and when they occur are due to inflammation and tissue necrosis as a result of intracellular growth of tachyzoites. Diagnosis can be made by finding

the organism in fluids or macrophages of tissue aspirates, most commonly lymph nodes or bronchoalveolar lavage, or PCR to detect organism DNA. Treatment consists of oral clindamycin for 4 weeks.

• *Trypanosoma* spp. are protozoal organisms transmitted by biting flies and other insects that cause trypanosomiasis in domestic large and small animals, humans, and wildlife species worldwide. Lethargy due to anemia and/or central nervous system involvement and lymphadenopathy are common clinical signs. While they are commonly found in blood, they may also be seen in lymph node aspirates. As mentioned earlier in this chapter, lymph nodes were first aspirated in humans more than a century ago to diagnose trypanosomiasis. Trypomastigote forms of *Trypanosoma* spp. are fusiform in shape, contain a nucleus, a kinetoplast, and a flagellum, and are 16–26 µm in length. Cysts containing organisms can be seen in many tissues including muscle and brain.

Fungal lymphadenitis

Whenever a combination of neutrophils and macrophages (pyogranulomatous inflammation) is seen on a lymph node aspirate, fungal infection should be suspected and a search for organisms should be performed. Five dimorphic yeast organisms can cause systemic infections and include cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis. In addition, other fungal organisms with hyphae may be seen in lymph nodes. Some structures can be confused with fungal hyphae and are also briefly mentioned in this section.

• *Cryptococcosis* is a fungal disease that infects mammals, reptiles, and birds and is worldwide (see Chapter 39). Cats are more commonly affected than dogs. The asexual yeast phase of the organism in tissues reproduces by budding, which is very narrow-based. Cryptococcal organisms are round to oval, 4–6 µm in diameter, and surrounded by polysaccharide capsules that vary in size but can be up to 30 µm in diameter. The capsule aids in preventing phagocytosis by neutrophils and macrophages and also prevents neutrophil migration and cytokine production, thus decreasing T lymphocyte-mediated immune responses. The characteristic capsule is very helpful in identifying *Cryptococcus* in tissue aspirates, and because of capsule function, sometimes the organisms will be seen in the absence of any inflammatory cells. The capsule does not stain with Wright stain, giving a clear halo appearance around the organism, as shown in Figures 39.31 and 39.32. Wet mounts using new methylene blue or India ink are particularly useful in aspirates with few inflammatory cells and many cryptococcal organisms (Figures 45.21 and 45.22). When inflammation is associated with the organism, it is usually pyogranulomatous. If lymphadenopathy is present, usually lymph nodes of the head and neck are affected. The genus *Cryptococcus* includes over 37 species, the majority of which do not cause disease in mammals. The disease-producing species are referred to as the *C. neoformans–C. gattii* species complex, the most common of which are *C. neoformans* var. *neoformans, C. neoformans* var. *grubii*, and *C. gattii*. Virulence factors include the ability to grow at mammalian body temperature, the size of the capsule surrounding the organism, and the ability to resist oxidative damage.

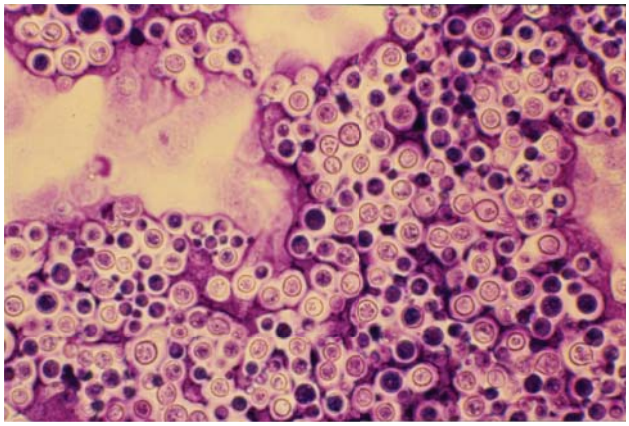

Figure 45.21 Imprint of an ulcer on a cat's paw showing numerous cryptococcal organisms, many of which are budding. Lymph node aspirates from this patient looked similar. Note the lack of inflammatory response. Wet mount using new methylene blue stain.

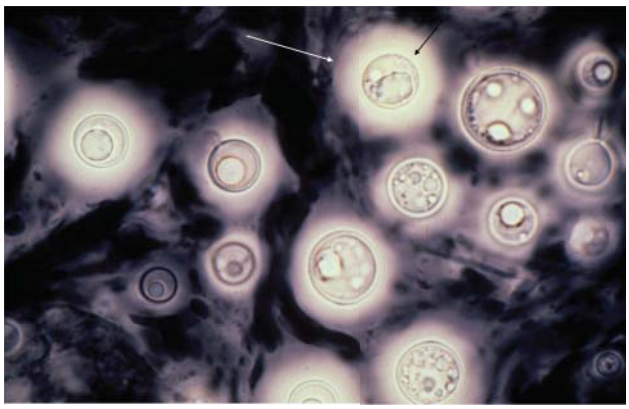

Figure 45.22 Very high magnification of aspirate of lymph node with many cryptococcal organisms and little inflammatory response. A wet mount was prepared by allowing the slide to air-dry, adding a drop of fountain pen ink (India ink is preferred), and placing a cover slip on top. The capsule does not allow the ink to permeate the organisms, producing a negative stain that allows good visualization of the capsule (white arrow), cell wall (black arrow), and cell contents.

• *Blastomyces dermatitidis* and other less common species (*B. gilchristii, B. helicus,* and *B. percursus)* are the causative agents of blastomycosis (see Chapter 39). *Blastomyces dermatitidis* is thick walled, 8–12 µm in diameter, does not have a capsule, and reproduces in tissue by broad-based budding (Figure 45.23). Blastomycosis is primarily seen in North America around the Great Lakes and the Ohio, Mississippi, Missouri, and St, Lawrence rivers. It is also

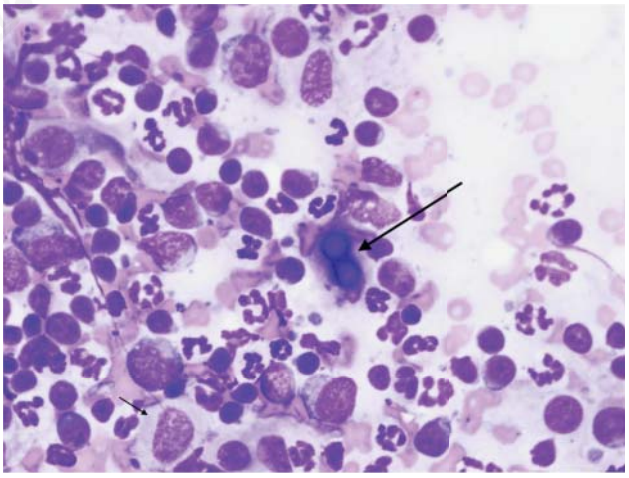

Figure 45.23 Lymph node aspirate from a dog with pyogranulomatous lymphadenitis due to blastomycosis. Note the budding organisms (large arrow). Small lymphocytes and neutrophils predominate, but occasional epithelioid macrophages are present (small arrow). Wright stain.

found throughout most of Africa and has been reported in India and the Middle East. *Blastomyces helicus* is smaller, similar in size to Histoplasma capsulatum, with which it is sometime confused, and is primarily found in western North America. The organism is in the environment and is usually associated with moist, acidic, sandy soils enriched with decaying organic matter and animal feces. Infections are most common in dogs and second most common in humans, but all mammals may be infected, including marine mammals. The conidia of the mold phase are inhaled; in the lungs, temperature-dependent transformation to the yeast phase occurs, and the yeast organisms are phagocytized by macrophages, where they are either eliminated or spread to various organs causing disseminated infection. Pulmonary disease is most common; disseminated infection manifests primarily as skin lesions and osteomyelitis, but many other organs including lymph nodes are commonly infected. Peripheral pyogranulomatous lymphadenitis is seen in approximately 50–60% of dogs with disseminated disease, and organisms are usually found in lymph node aspirates. A few cases of suppurative lymphadenitis and reactive hyperplasia have also been reported.

- *Histoplasma capsulatum* is also a dimorphic soil-borne fungus that is endemic in the Midwest and southern United States, especially along the Missouri, Mississippi, and Ohio River Valleys, and also has been reported in Central and South America, Africa, Asia, and Australia, and may infect all mammals but is most commonly reported in cats, dogs, and humans (see Chapter 39). Microconidia from the environment are inhaled or ingested and convert to the yeast form within the lungs or intestine, where they are either eliminated, cause local infection, or are disseminated within macrophages via the lymphatics and bloodstream to other organs, which may include the liver, spleen, bone marrow, oral cavity and gastrointestinal tract, eye, lymph nodes, skin, bone, and central nervous system. Clinical signs of histoplasmosis are nonspecific and may include fever, lethargy, anorexia, weight loss, respiratory or gastrointestinal signs, and lymphadenopathy. Histiocytic lymphadenitis with multinucleated macrophages and epithelioid cells is typical, and organisms are easily found phagocytized within macrophages, as shown in Figures 15.19, 39.25, 39.26, and 39.27. They are round to oval, surrounded by a narrow capsule, and are very small (2–4 μm) compared to the other dimorphic fungal organisms that cause systemic infections. Diagnosis is made by cytologic or histologic evidence of the characteristic organism, the presence of antigen in urine, or PCR. Treatment consists of long-term oral administration of antifungal agents such as itraconazole.
- *Coccidioides immitis and C. posadasii* are the largest of the pathogenic dimorphic fungi and are responsible for coccidioidomycosis (Valley fever), which is endemic in the southwestern United States and portions of Mexico and Central and South America in semiarid areas (see Chapter 39). The organisms occur in soil and air after soil disturbance, and as with the other potentially pathogenic dimorphic fungi, inhalation of arthroconidia leads to usually benign respiratory disease, but occasionally severe or fatal infections that are systemic. The morphology of *Coccidioides* spp. is dramatically different from *Histoplasma* and *Blastomyces*. Individual arthroconidia adopt a spherical form (spherules) that form an outer shell via synchronous internal division of their nuclei and cytoplasm, and the inner section fills with hundreds of individual (2–4 μm) endospores, as shown in Figure 39.33. Mature spherules are 20–100 μm in diameter and are too large to be phagocytized. When a spherule ruptures, it releases its endospores that then differentiate into new spherules. Dogs are the most severely affected species, with a susceptibility similar to that of humans. However, *Coccidioides immitis* can cause infection in many other species, including cats, horses, cattle, and other livestock. Osteomyelitis is the most common form of disseminated disease in the dog, while skin lesions predominate in the cat. While hilar lymphadenopathy is a common radiographic finding in dogs with coccidioidomycosis, peripheral lymphadenopathy is relatively uncommon in both cats and dogs. The lymphadenopathy is due to pyogranulomatous inflammation, and while infrequent organisms may be seen in lymph node aspirates, quite a bit of searching using low magnification is usually required (Figure 45.24).
- *Paracoccidioides brasiliensis* and *P. lutzii* are the causative agents of paracoccidioidomycosis, another dimorphic fungal infection that is relatively common in people in South America, particularly Brazil, and has also been reported in dogs, cats, and numerous wild mammals, especially armadillos, which are thought to harbor the fungus. Like the other dimorphic fungi, it grows in soil, and aerosolized conidia are inhaled, after which the infection may become systemic,

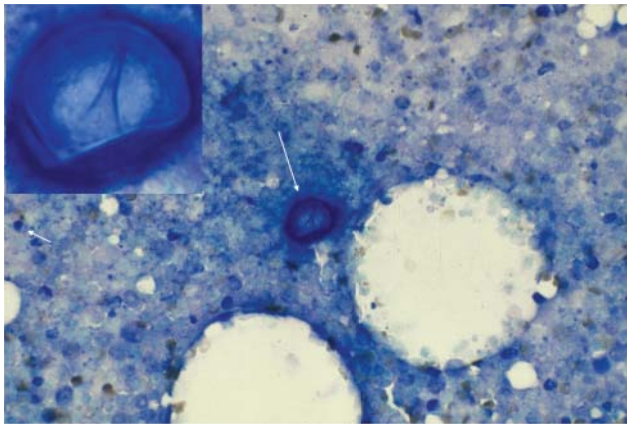

Figure 45.24 Low magnification of a lymph node aspirate from a dog with coccidioidomycosis. Only one *Coccidioidomyces* spherule was present on the entire slide (large arrow) and is in a very thick portion of the preparation. For size comparison, a small arrow is pointing at a plasma cell. Inset in left upper corner shows the spherule at high magnification. Wright stain.

primarily affecting skin, lymph nodes, lungs, and oral, nasal, and gastrointestinal mucous membranes and eliciting marked histiocytic inflammation. The systemic disease can be fatal if not treated. The yeast phase of the organism reproduces in tissue by multiple narrow based budding in which multiple buds will originate from the "mother" yeast, sometimes forming a "Mickey Mouse" appearance, with the mother yeast appearing as the head with two ear-like buds. The mother cells are 20–30 µm in diameter and can produce 10–12 daughter cells, each approximately 2–10 µm in diameter (Figure 45.25). Aspirates of lymph nodes show pyogranulomatous inflammation with numerous budding yeast organisms.

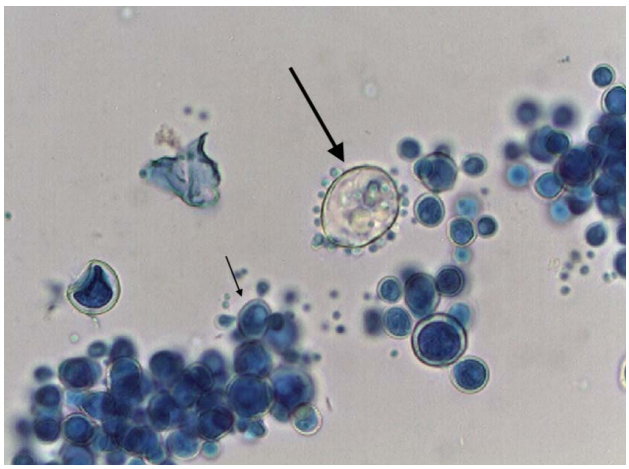

Figure 45.25 Yeast culture (37 °C) of *Paracoccidioides brasiliensis*. Note the "mother yeast cell" with multiple buds (large arrow) and the "Mickey Mouse" appearance of a cell with budding (small arrow). Organisms look similar on cytologic preparations. Wright stain. Source: Courtesy of Dr. Paulo Murillo Neufeld, Federal University of Rio de Janeiro, Brazil.

- *Other fungal organisms* that exist in the environment, such as *Paecilomyces*, *Penicillium*, *Aspergillus*, *Monocillium*, etc. can also cause localized or generalized lymphadenopathy, as shown in Figures 39.34–39.38. They typically elicit a histiocytic or pyogranulomatous lymphadenitis, and the hyphae and associated structures are usually evident in aspirates (see Chapter 39).
- *Pseudofungal structures: Gamna–Gandy bodies*, structures that may be seen in lymph node aspirates that look remarkably similar to fungal hyphae, form as a result of deposition of calcium and hemosiderin complexes on collagenous fibers, usually associated with previous hemorrhage within the lymph node (see Figure 44.33). Due to their similarity to fungal hyphae, periodic acid-Schiff (PAS) or Grocott-Gomori's methenamine silver staining is warranted to rule out fungal infection. Positive reaction with iron and calcium stains is needed for definitive identification.

Oomycosis lymphadenitis

Pythiosis and lagenidiosis are often fatal infectious diseases affecting animals that have exposure to lakes or ponds, primarily in the southeastern United States and other tropical and subtropical areas of the world such as Southeast Asia, eastern coastal Australia, and South America (see Chapter 39). These organisms are not true fungi but are aquatic pathogens in the class Oomycetes ("water mold"). They are more closely related to algae than fungi, but the appearance of the broad hyphae and the histiocytic inflammatory response is very similar to that of fungal infections, as shown in Figures 39.48–39.50. Cutaneous lesions are most common, but animals with systemic disease may have pyogranulomatous lymphadenitis, sometimes with an eosinophilic component; numerous broad hyphae are usually evident in aspirates. Definitive diagnosis can be made by culture or PCR. Treatment consists of early surgical excision of the granulomatous lesions and antifungal antibiotics, but animals are often unresponsive to therapy.

Lymphadenitis due to algae

Protothecosis, caused by members of the genus *Prototheca*, is a disease of humans and animals caused by infection with fungus-like, colorless microalgae that are no longer photosynthetic and have become parasitic. *Prototheca bovis*, *P. ciferrii*, *P. wickerhamii*, and *P. zopfii* are pathogenic in dogs and cats. *P wickerhamii* is often associated with cutaneous disease and has been isolated from all affected cats so far. *P bovis* is the most virulent variant and causes the majority of cases of bovine *Prototheca* mastitis cases, as well as most cases of disseminated protothecosis in dogs. Infection is acquired by ingestion or penetrating skin wounds. Clinical signs in dogs are often related to infection of the colon, and include colitis, severe diarrhea with mucus, and hematochezia. Systemic protothecosis may involve the central nervous system, lungs, spleen, liver, eyes, tongue, skin, and lymph nodes and is

more common in boxers and French bulldogs. In cats, the disease is limited to the skin and subcutis. Aspirates of lymph nodes show pyogranulomatous or histiocytic lymphadenitis, with numerous organisms phagocytized by macrophages or free. The organism has a thick wall, internal septations, and is 3–11 µm in diameter. The large sporangia form a morula, which has endospores that are radially arranged and molded to each other. Small endospores 1–2 µm in diameter may also be seen. Organisms stain deeply basophilic to magenta, sometimes with a clear halo (see Figure 39.51). Diagnosis is usually made by cytologic or histologic examination and confirmed by culture and/or PCR. Antifungal drugs are used to treat disseminated disease, and small lesions may be surgically excised. The prognosis in dogs with disseminated disease is very poor. *In vitro* testing has shown that ravuconazole (RVZ) has higher algaecide effect than other azoles tested against *Prototheca* species. An excellent review of protothecosis in dogs and cats has been published (see Masuda et al. 2021 in "Suggested Reading" under "Algae (Protothecosis)").

Neoplasia in lymph nodes

Lymph nodes are neoplastic either because of primary neoplasia of lymphoid cells or metastatic neoplasia in which other types of tumors are growing within lymph nodes. Primary neoplasia (lymphoma) is much more common than metastatic neoplasia. Cytology has variable sensitivity and specificity that is likely dependent on the expertise and experience of the person who is taking the aspirate, as well as the cytologist. In one study comparing cytology and histopathology findings in 367 canine and feline lymph nodes, of which 110 were neoplastic (including both lymphoma and metastatic neoplasia), cytology had a sensitivity of 66.6%, specificity of 91.5%, and accuracy of 77.2% for neoplasia. Likelihood of malignancy when a positive cytologic diagnosis of neoplasia was made was 93%. False negative findings were primarily found in mesenteric small T-cell lymphoma in cats, metastatic sarcomas, and metastatic mast cell tumors (see Ku et al. 2017 in "Suggested Reading" under "Lymph Node Metastasis"). Diagnostic utility of cytology for lymphoma and metastatic neoplasia is discussed in more detail in the following sections.

Primary lymphoid neoplasia (lymphoma, malignant lymphoma, lymphosarcoma)

Primary lymphoid neoplasia occurs in many species, but of the common domestic species, it occurs most frequently in dogs and is one of the most common types of neoplasia affecting dogs. Peripheral lymph nodes are usually involved in dogs, while this form of lymphoma is relatively rare in cats. Because most dogs with lymphoma present with enlargement of one or more peripheral lymph nodes due to the presence of many large neoplastic cells within the node, aspiration cytology of lymph nodes has very good diagnostic sensitivity and specificity and is much less expensive and invasive than lymph node biopsy and histopathology. A very simple approach to diagnosing primary lymphoid neoplasia is to consider the number of immature lymphoid cells present in the aspirate. Malignancy of lymphoid tissue is almost always characterized by a predominance of immature large lymphoid cells with apparent nucleoli (Figure 45.26), because large-cell lymphoma is by far the most common type of lymphoma. Numerous cells in mitosis may be present. Small lymphocytes and macrophages may be present in variable numbers. Plasma cells are usually quite few to absent, which aids in the differentiation between lymphoma and lymphoid hyperplasia. In general, the more plasma cells that are present, the less likely that lymphoma is the correct diagnosis. While it may be possible to aspirate numerous immature cells from a germinal center of a reactive node, plasma cells would almost always be increased as well. Redirecting the needle will help prevent aspiration of cells from one site in the node, and it is unusual to see more than 20% large immature cells in a reactive node. A mistaken positive diagnosis of lymphoma is very rare, and when erroneous diagnoses are made, it is usually a failure to confirm that lymphoma is present, sometimes due to excessive caution on the part of the cytologist. Infrequently, lymphoid tumors may be composed entirely of small lymphocytes. If an aspirate of an enlarged lymph node consists of a homogeneous population of small lymphocytes with no cytologic suggestion of reactive hyperplasia, a small-cell variant of lymphoma is likely. When a diagnosis of lymphoma cannot be confirmed by cytology, determination of clonality by PCR technology or immunophenotyping using flow cytometry is

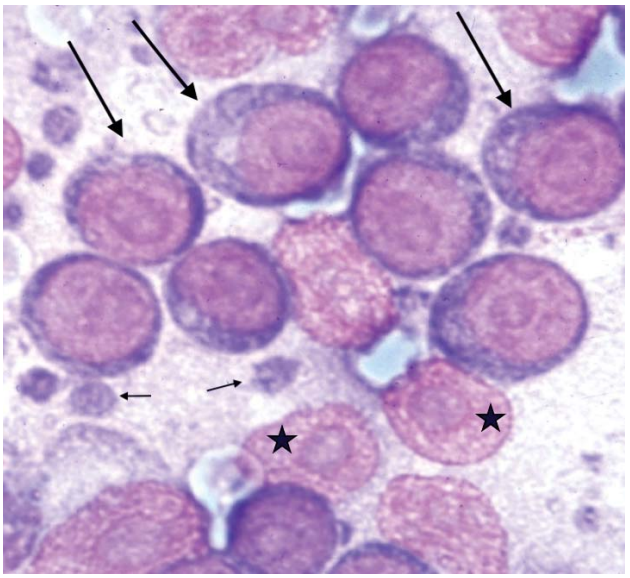

Figure 45.26 Lymph node aspirate from a dog with lymphoma. All cells are large immature lymphoid cells with a single large nucleolus (large arrows). Cytoplasmic fragments (lymphoglandular bodies) are indicated by small arrows. Broken cells with only no cytoplasmic borders are indicated by stars. Wright stain.

very helpful, since clonality is very characteristic of malignant cells, as they are derived from expansion of a single malignant cell. Molecular diagnostic techniques for diagnosis of hematologic malignancies including lymphoma are reviewed in Chapter 14.

Classification of lymphoma

A simple cytologic diagnosis of lymphoma is no longer adequate in many cases because biologic behavior, prognosis, and response to therapy can be quite variable, depending on the type of lymphoma present. Some types of lymphomas, especially T-zone lymphoma (TZL), common in golden retrievers, are very indolent with long survival times, and therapy is usually not indicated until the late stages of the disease. Correct classification of lymphoma is critical so that dogs with indolent lymphomas are not unnecessarily treated or euthanized. Lymphomas have been classified using cell morphology, tissue architecture, immunophenotyping, clinical features, and, in some cases, genetic analysis. These categorizations of lymphomas and other hematopoietic neoplasms are modeled on those already established in human medicine by the WHO, as discussed briefly in reference to leukemia classification in Chapter 16. The WHO classification of lymphoma was first adopted for use in dogs in 2002. Currently at least 20 subtypes of lymphoma in dogs and cats have been recognized, using the WHO classification (see Valli et al. 2011 in "Suggested Reading" under "Lymphoma – Dog").

- **Neoplastic lymphoid cell morphology.** Neoplastic lymphoid cell size is based on nuclear size compared to erythrocyte size when using histopathology, and cells are classified as small (nuclei approximately 1–1.25 times the diameter of an erythrocyte), intermediate (nuclei approximately 1.25–2 times the diameter of an erythrocyte), or large (nuclei same as or greater than 2.0 times the diameter of an erythrocyte). With cytology, lymphoid cell size is usually established by comparison to a neutrophil. Large cells are 1.5–2 times the size of a neutrophil, intermediate-sized cells are slightly larger than neutrophils, and small lymphoid cells are the same size or slightly smaller than neutrophils. Cytoplasmic volume and staining intensity and nuclear shape, chromatin pattern, and nucleolar features are also typically described (see "Identification of Cell Types and Other Lymphoid Elements" earlier in this chapter).
- **Lymphoma architecture.** Lymphomas are classified by histopathology as either diffuse or nodular/follicular. In diffuse lymphoma, lymph node architecture is effaced by the neoplastic infiltrate, whereas in nodular, the neoplastic infiltrate mimics or spares some portion of lymph node tissue.
- **Immunophenotyping of lymphoma.** For determination of immunophenotype, antibodies against lymphocyte markers (antigens called "cluster of differentiation" or "CD") are applied to tissue sections (immunohistochemistry), cytologic preparations (immunocytochemistry), or aspirated individual cells that have been placed in a fluid medium (flow cytometry). T-cell markers include CD3 (pan T), CD4 (helper T), and CD8 (cytotoxic T). B-cell markers are CD79a, CD20, and CD21, although some types of neoplastic T cells express CD21. Other cell markers that can be detected by flow cytometry are CD45, a common leukocyte antigen present in all hematopoietic cells except erythrocytes and plasma cells, the expression of which is sometimes lost in some types of neoplastic lymphoid cells, and CD34, an antigen on precursor cells. The presence or absence of major histocompatibility complex (MHC) class II peptides on lymphocytes is also typically reported when using flow cytometry for classification of lymphoma (see Chapter 14 for more detail).
- **Tumor behavior and prognosis.** Lymphomas are also classified as either indolent or aggressive, which helps predict survival time. Lymphomas with a slow rate of biologic progression are called indolent lymphomas. Many dogs with indolent lymphoma may have a normal lifespan without treatment and die of other disorders. Dogs with lymphoma classified as intermediate or high grade (more aggressive) usually respond better to chemotherapy but may go out of remission early.
- **Aspiration cytology for diagnosis of subtypes of lymphoma.** Although lymph node resection and histopathology in combination with immunophenotyping is the gold standard for classification and grading of lymphoma, aspiration cytology is more commonly used, due to the lack of invasiveness and lower expense. While aspiration cytology has numerous advantages, it is sometimes unsuccessful for certain subtypes of lymphoma, particularly small-cell variants, but when used in conjunction with flow cytometry, a definitive diagnosis of lymphoma, as well as subtype, can usually be made. Determination of lymphoma subtype using cytology alone is usually not possible and is highly dependent on the experience of the cytologist. In one study, agreement between the results of cytology alone and immunocytochemistry as to whether lymphoma was B cell or T cell was made in 90% of 70 cases in dogs (see Sapierzyński et al. 2012 in "Suggested Reading" under "Lymphoma – Dog"). However, cytologic appearance may sometimes be misleading. For example, sometimes T cells may have a plasmacytoid appearance that is usually associated with B cells, particularly in peripheral T-cell lymphoma (PTCL). In general, four broad categories of lymphoma in dogs can usually be determined based on cytology, sometimes with the help of flow cytometry: (i) diffuse large B-cell lymphoma; (ii) CD4+ T-cell lymphoma, including both PTCL and T-cell LBL, (iii) TZL; and (iv) large granular-cell lymphoma. Cytologic features of these types of lymphoma are discussed below. A study to determine if cytologic features were useful to predict survival time in dogs with aggressive lymphoma showed that relatively few cytologic features were useful, other than the presence of binucleated or multinucleated cells, which perhaps suggested a decreased survival time. Also noted

in this study was that the number of cells in mitosis was increased in aspirates made at time of relapse of remission, compared to those seen in aspirates at original diagnosis (see Munasinghe et al. 2015 in "Suggested Reading" under "Lymphoma – Dog").

Nodal lymphoma in cats is quite rare, and classification schemes that have been developed for dogs are lacking in cats. One study suggests that definitive cytologic diagnosis of lymphoma immunophenotype, using histopathology and immunocytochemistry as the gold standard, is likely not possible (see Gelain et al. 2021 in "Suggested Reading" under "Lymphoma – Cat"). Diagnostic accuracy in predicting nodal or mediastinal lymphoma immunophenotype varied from 35% to 75% of cases and did not appear to be correlated with the experience of the cytologists, likely because specific diagnostic criteria have been poorly described due to the low prevalence of this disease. In general, large granular lymphocyte (LGL) T-cell lymphoma in cats is almost always recognizable, B-cell lymphomas are more likely to have vacuolated cytoplasm, and B-cell lymphomas tend to have neoplastic cells that are large.

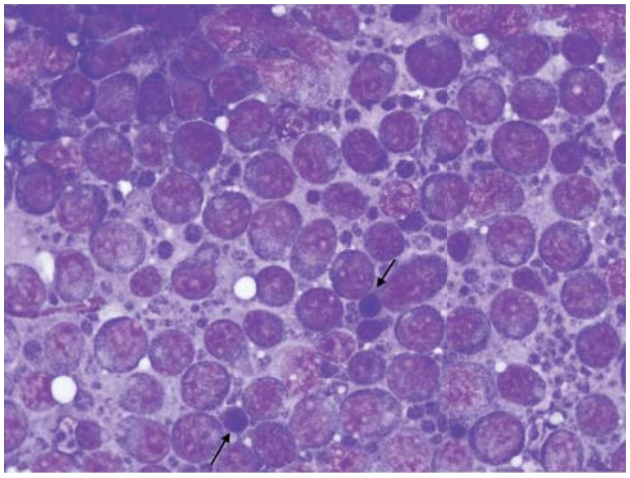

Figure 45.27 Lymph node aspirate from a dog with lymphoma that was confirmed to be diffuse B-cell lymphoma by flow cytometry. Almost all cells are large immature cells with multiple nucleoli. A few small lymphocytes are remaining (arrows). Wright stain.

Lymphoma subtypes in dogs and cats

The five most common types of canine lymphoma, listed in decreasing frequency, are diffuse large B-cell lymphoma (DLBCL), peripheral T-cell lymphoma not otherwise specified (PTCL-NOS), TZL, T-lymphoblastic lymphoma (also called precursor T-cell neoplasia), and marginal zone lymphoma (MZL), which is of B-cell linage. These classifications were established using histopathology and architecture, but as mentioned earlier, flow cytometry in conjunction with cytology can usually establish the type of lymphoma present as relates to cell type and size.

- *DLBCL* makes up about 50% of canine lymphoma cases and may be separated into two distinct subtypes, centroblastic, which is more common in dogs, and immunoblastic, which is more common in cats, although it may be difficult to differentiate the two types of blasts based on cytology. Centroblasts are medium to large (1.5 times the size of a neutrophil) and consist of moderately abundant blue cytoplasm with a round nucleus containing several prominent peripherally located nucleoli (Figure 45.27). Cytoplasm may contain punctate vacuoles. Medium-sized lymphocytes and residual small lymphocytes may be present. The immunoblastic form consists of large immunoblasts with scant darkly basophilic cytoplasm and a single central prominent nucleolus. Neoplastic cells are CD21, CD79a, and CD20 positive. Human DLBCL has been further subdivided into four subgroups according to genetic, immunophenotypic, and molecular findings. Genetic variation correlating with biologic behavior is also likely to exist in canine DLBCL and is currently being explored. Dogs with DLBCL usually present with rapidly progressive, generally painless nodal or extranodal disease and many have leukemia (stage V lymphoma) at the time of presentation. Flow cytometry is more accurate than blood film examination for determining peripheral blood involvement. Depending on the stage of disease at presentation, survival times of 12–24 months can be achieved with chemotherapy. Immunophenotypic characteristics are associated with prognosis. Large cell size and low MHC class II expression are predictive of decreased survival time. Rarely the cells express CD34 while retaining MHC class II expression, but this finding does not affect prognosis, and these cases should not be confused with B-cell LBL.
- *PTCL-NOS* is a relatively common, aggressive variant of lymphoma, often seen in golden retrievers, with a median survival time of 5–6 months, independent of treatment regimen. Cells are somewhat variable in size, ranging from 10 to 20 μm in diameter, with moderate amounts of pale blue cytoplasm that has no granules or vacuoles. Nuclei are variable in shape with fine chromatin, ranging from round to indented to multilobulated or cerebriform (flower-shaped). Nucleoli are multiple and variably prominent, and numerous cells in mitosis are usually seen (Figure 45.28). Few residual non-neoplastic lymphocytes are present, and rare plasma cells may be seen. Sometimes, the blasts may have a plasmacytoid appearance, and thus a plasma cell tumor or a B-cell lymphoma may be mistakenly diagnosed. They typically express CD4 and CD45 and express low amounts of class II MHC. This subtype exhibits a consistent gene expression profile with upregulation of phosphatidylinositol 3-kinase (PI3K) activity. PI3K plays a role in regulation of the cell cycle, leading to increased cell proliferation and survival.
- *TZL* is a relatively common type of indolent canine t-cell lymphoma characterized by clonal expansion of T-zone

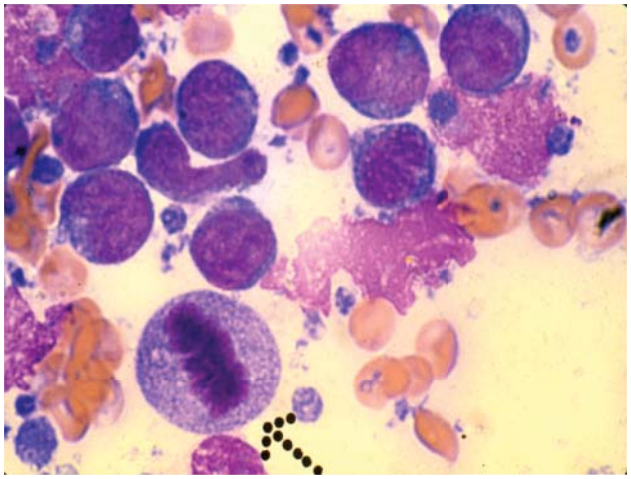

Figure 45.28 Lymph node aspirate from a dog with peripheral T-cell lymphoma. Note the cerebriform nuclei and cell in mitosis (dotted arrow). Wright stain.

lymphocytes that have a unique architectural and cytomorphologic pattern. Median age at onset is 8–10 years, and golden retriever and Shih Tzu breeds are most commonly affected. Mandibular lymph nodes are usually enlarged on presentation. Aspiration of lymph nodes shows predominantly intermediate-sized lymphocytes that range from 12 to 20 µm in diameter. The nuclei are small and round, and nucleoli are usually not evident. Cytoplasm is moderate to abundant and commonly forms unipolar cytoplasmic extensions or pseudopodia, sometimes referred to as "cone-heads" or "mirror-handles" (Figure 45.29). Very few, if any, cells in mitosis are seen. A few plasma cells may be present, as well as residual non-neoplastic lymphocytes, which sometimes

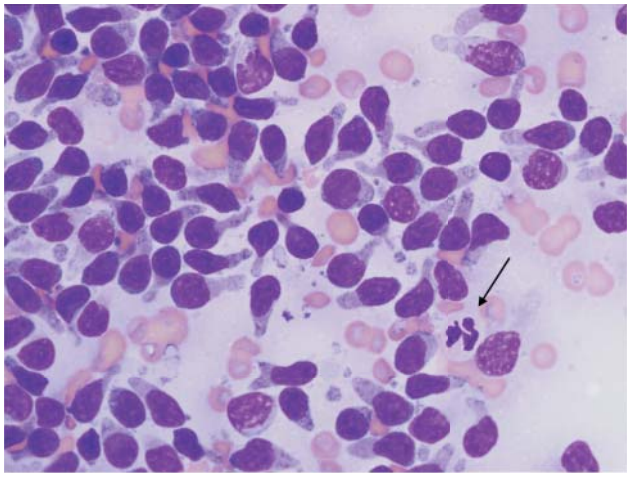

Figure 45.29 Lymph node aspirate from a dog with indolent T-zone lymphoma. Note the small size of the cells and the cytoplasmic extensions ("mirror-handles"). The neutrophil (arrow) is useful for size comparison. Wright stain.

results in cytologic misdiagnosis of these types of lymphoma as reactive hyperplasia or "inconclusive," especially when the cytoplasmic atypia is not present. Diagnosis can be confirmed by immunohistochemistry or flow cytometry, which show a unique loss of CD45 expression in the vast majority of cases, a high expression of class II MHC, and frequently an aberrant expression of CD21 (a B-cell antigen), as well as CD3 and CD5 positivity as expected for T cells. Expression of CD4 and CD8 is variable. Blood and bone marrow are infiltrated in 90% of cases, and about 50% of dogs have neoplastic lymphocytosis (leukemia). T-zone lymphocytes in peripheral blood are about the size of a neutrophil, have a round centrally located nucleus, slight to moderate amount of cytoplasm, and rarely a fairly indistinct nucleolus. Although canine TZL is incurable, it is considered indolent with a good prognosis, with or without treatment, with median survival times of 2–2.75 years. Therapy is not recommended until development of cytopenias or marked lymphocytosis, lymphadenopathy, or hepatosplenomegaly.

- LBL (*precursor neoplasia*) is quite rare, comprising 3–9% of cases of canine lymphoma. LBL and acute lymphoblastic leukemias (ALLs) are of B- or T-cell lineage and arise from precursors in the bone marrow or thymus, respectively. Whether classified as LBL or ALL depends on whether bone marrow or lymph node involvement is dominant. The biologic behavior and prognosis of LBL and ALL is similar, thus the primary tissue of origin is not significant, and both are now considered the same disease. Aspirates of either bone marrow or lymph nodes consist of a homogeneous population of cells that are small to intermediate in size with round to convoluted nuclei containing variable chromatin and faint to indistinct nucleoli and a small, often unipolar, cap of cytoplasm as shown in Figures 16.25 and 16.26. Numerous cells in mitosis may be seen. Despite the homogeneous population of relatively small cells without evident nucleoli, the disease is aggressive, with mean survival times of days to months. The T subtype is more common than the B subtype, occurs most commonly in the boxer breed, and is slightly less aggressive, with a mean survival time of 150 days. Studies have shown that 77% of boxers with lymphoma have the T-cell variant of LBL. The immunophenotype of the T subtype is similar to that of PTCL (CD45+, CD3+, CD4+, MHC II–). The lymphoblasts usually express the precursor marker CD34 when flow cytometry is used on viable cells, thus confirming their immaturity. On archived formalin-fixed tissues, CD34 is usually negative.
- *MZL* is a mature B-cell lymphoma that may affect lymph nodes, the spleen, or extranodal tissues. Cells originate from postfollicular memory lymphocytes of the marginal zone of either the spleen or lymph nodes. Splenic marginal zone lymphoma (SMZL) is an indolent, small-cell B-cell lymphoma characterized by splenic infiltration and bone marrow involvement, little or no lymph node involvement, good prognosis following splenectomy, and is discussed

briefly in the "Spleen" section of Chapter 44. Nodal marginal zone lymphoma (NMZL) accounts for approximately 6–10% of all canine lymphomas and almost always presents as generalized lymphadenopathy. The predominant cell on aspirates is intermediate in size, with round nuclei the size of two erythrocytes containing a large central nucleolus and a moderate amount of pale cytoplasm. Centroblasts and immunoblasts, as well as mitotic figures, are few in number. Few residual normal lymphocytes are usually present. Transformation of NMZL to DLBCL is thought to occur but may actually be a late stage of NMZL, in which the follicles are effaced, leading to a more diffuse appearance, with increased lymphoid blasts and more aggressive clinical disease. Median survival time for NMZL in one study was 259 days.

- *Mantle cell lymphoma* is an indolent B-cell lymphoma that is very rare in dogs, comprising approximately 1% of all cases. Mantle cell lymphoma primarily affects the spleen with occasional visceral node involvement. Peripheral node involvement is minimal, if any, and bone marrow involvement is very uncommon. The neoplastic cells are small to intermediate in size and have a small amount of cytoplasm.
- *Follicular lymphoma* is a mature B-cell lymphoma that is very rare in dogs, representing less than 1% of lymphoma cases. Complete effacement of the nodal architecture by neoplastic follicles of both peripheral and visceral nodes occurs. Distinguishing the neoplastic follicles from benign follicles in reactive hyperplasia may be difficult. Aspirates are composed of small cells that have pale and evenly dispersed chromatin and inconspicuous or small nucleoli. Few mitotic figures are seen. Cytologic diagnosis can be challenging, but numerous small cells, a few centroblasts, and the lack of plasma cells in an aspirate of a large node should trigger flow cytometry or PCR for antigen receptor rearrangement (PARR).
- *Large granular lymphocyte (LGL) lymphoma* is relatively rare and is more common in cats than in dogs. It has also been reported in horses, a cow, and goats. In dogs, LGL lymphoma usually involves the spleen and liver, and in cats the intestine is usually affected; LGL leukemia may be present (see Chapter 16 and Section VII, Case 13). LGL lymphoma has been associated with hemophagocytic syndrome, in which activated macrophages proliferate in various organs such as spleen and bone marrow and phagocytize erythrocytes, leukocytes, or platelets, as shown in Figures 15.16 and 15.17, resulting in pancytopenia or bicytopenia; the syndrome is difficult to distinguish from phagocytosis of cells due to primary immune-mediated disease. LGL lymphoma is rarely seen in peripheral lymph nodes, but mesenteric lymph node involvement is common in cats with intestinal LGL lymphoma. In one report of 109 cats with LGL lymphoma, 73 had abdominal lymph node involvement, 11 had thoracic lymph node involvement, and only two had peripheral lymph node involvement (see Finotello et al. 2018 in "Suggested Reading" under "Lymphoma – Cat"). The cells are intermediate to large in size, with moderate to abundant light blue cytoplasm containing azurophilic granules that are variable in size, ranging from very fine to large globular structures (Figures 45.30 and 45.31). The presence of the granules makes cytologic identification of this type of lymphoma quite easy, although the granules sometimes do not stain distinctly when the quick types of Wright stain are used. Nuclei are round to indented, have smooth to clumped chromatin, and have variably prominent nucleoli. LGLs are also described in Chapters 11 and 16 and shown in Figure 11.4 and Section VII, Case 13. Canine LGL lymphoma is usually composed of CD8+ cells. The disease is poorly responsive to therapy, and patients typically have a very short survival time.

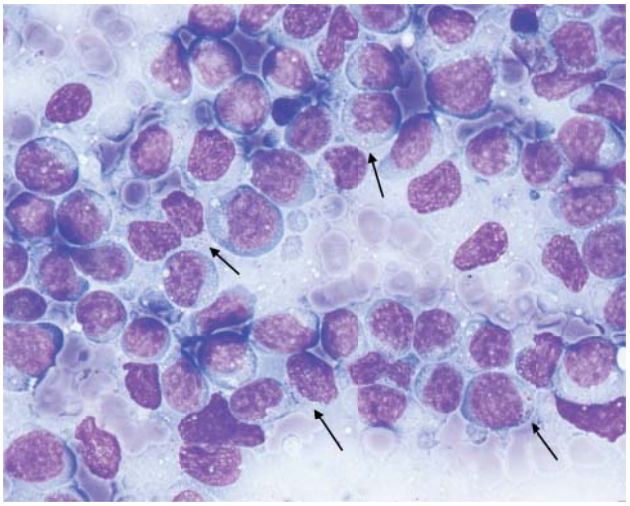

Figure 45.30 Mesenteric lymph node aspirate from a dog with T-cell lymphoma. Notice the very subtle large granular lymphocytes (arrows). Wright stain.

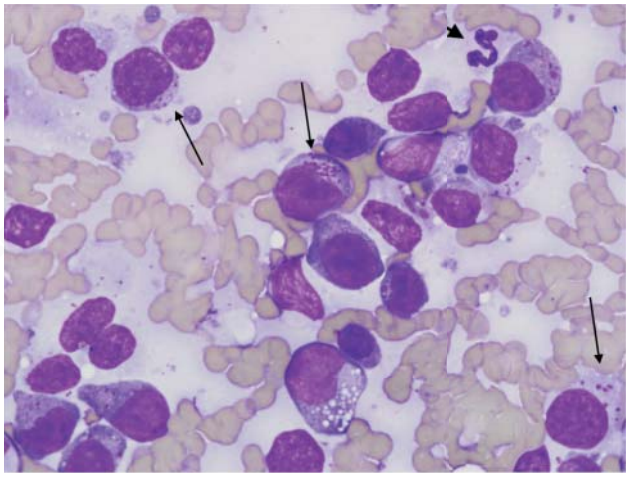

Figure 45.31 Mesenteric lymph node aspirate from a cat with large granular lymphocyte lymphoma. The azurophilic granules in the cytoplasm are quite large (arrows). Note the large size of the LGLs compared to the neutrophil (arrowhead). Wright stain.

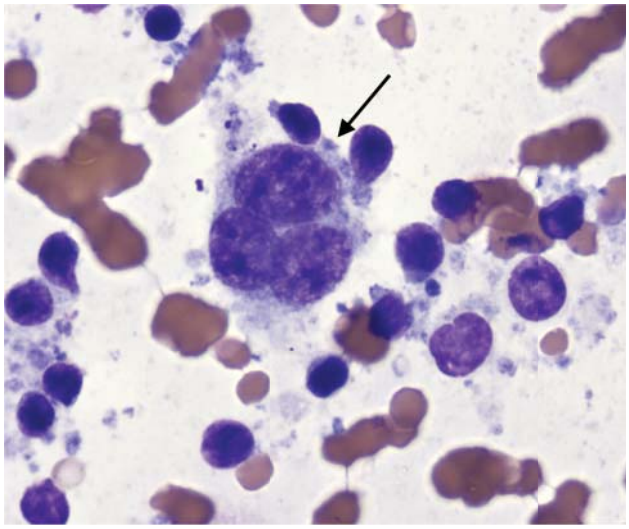

Figure 45.32 Lymph node aspirate from a cat with Hodgkin's-like lymphoma. Note the multinucleated Reed-Sternberg cell. Wright Stain. Source: Courtesy Dr. Jennifer Steinberg, Mid-Atlantic Veterinary Pathology, LLC.

Inset upper left: higher magnification of a Reed-Sternberg cell. H&E stain. Source: Courtesy Dr. Jennifer Steinberg, Mid-Atlantic Veterinary Pathology, LLC.

• *Hodgkin's-like lymphoma* is a rare form of lymphoma that has been reported most frequently in the cat and reported sporadically in the dog, ferret, whale, rat, and skunk. Hodgkin's lymphoma in people is very distinct from the other types of non-Hodgkin's lymphoma and is a common neoplasm in young adults that can be cured by chemotherapy and/or radiotherapy in approximately 85% or more cases. In people, it arises from transformed germinal-center or postgerminal center B cells and appears to be of B-cell origin in domestic animals. The tumor usually arises in a single lymph node or chain of lymph nodes and is usually slow growing in both people and cats. A classical diagnostic finding, in either cytologic or histopathologic biopsies, is the presence of the large and atypical malignant Reed-Sternberg cells, which constitute a minority of the cells present. Reed-Sternberg cells are very large (30–40 µm in diameter) and are typically binucleate with a "mirror-image" appearance (Figures 45.32 and 45.33). The other lymphoid population is usually mixed, with another population of large round cells, 20–30 µm in diameter with scant basophilic, sometimes vacuolated cytoplasm, and irregularly round nuclei with single large nucleoli. In addition, numerous small- and intermediate-sized lymphocytes and a few plasma cells and macrophages are usually present. A cytologic misdiagnosis of reactive hyperplasia is sometimes made unless Reed-Sternberg cells are recognized and not all aspirates contain them. Cervical lymph nodes are most commonly affected in cats, although extranodal sites have been reported. Most cats with Hodgkin's-like lymphoma have very long survival times, sometimes up to years, with or without surgical removal or chemotherapy. While affected lymph nodes are sometimes surgically removed in cats, surgical removal is not typically part of the therapeutic regime in humans. One reported cat with extranodal Hodgkin's-like lymphoma had complete remission following surgical incisional biopsy of the tumor.

Lymphoma in horses

Lymphoma is the most common type of malignant neoplasia seen in horses and is classified by anatomic distribution into multicentric, which is most common (41%), cutaneous (19%), and alimentary (11%). In one study, T-cell rich large B-cell lymphoma (TCRLBCL) was the most common histologic subtype seen in horses with lymphoma, and peripheral T-cell lymphoma and diffuse large B-cell lymphoma also were seen relatively frequently. Ages ranged from 2 months to 31 years (mean, 10.7 years). A total of 14 lymphoma subtypes in horses have been identified. Few descriptions of the cytologic appearance of lymph node aspirates have been published, but large B cells, intermediate T cells, small T cells, and LGL T cells have been described and are similar in appearance to those neoplastic cells in dogs.

Lymphoma in cattle

Two broad lymphoma syndromes have been recognized in cattle: enzootic bovine leukosis (EBL) and sporadic bovine leukosis (SBL). EBL is related to infection with *bovine leukemia virus* (BLV) and is a disease of mature cattle (see Chapter 16). Sporadic lymphoma is a disease of younger animals that are not infected with BLV and has been classified as calf, thymic, and cutaneous; the cutaneous form has two subsets, nonepitheliotropic (B cell) and epitheliotropic (T cell). EBL is a B-cell neoplasm, while SBL may originate

from either B or T lymphocytes. Lymph node involvement may be seen with either type of lymphoma syndrome, and aspirates typically consist of medium to large numbers of lymphoid blasts with scant basophilic cytoplasm and multiple distinct nucleoli.

Lymphoma in goats

One study in goats showed that the median age of disease was 3 years and that 73% had T-cell lymphoma and 27% had B-cell lymphoma. Multicentric distribution was most common. T-cell lymphoma usually involved the neck or thoracic cavity and was further classified as LBLs (27%), LGL lymphoma (9%), diffuse small lymphocytic lymphomas (27%), and PTCL not otherwise specified (36%). B-cell lymphomas were classified as diffuse large B-cell lymphoma (50%) or B-cell lymphocytic lymphoma intermediate type (50%). Only two cytologic descriptions of lymph node aspirates in goats with lymphoma were found in the literature. In a goat with B-cell lymphoma, the aspirate was described as consisting of a monomorphic population of large round cells with a large round nucleus, prominent multiple nucleoli, and a small amount of light blue cytoplasm intermixed with small lymphocytes, and in a goat with T-cell lymphoma, intermediate-sized T-cell lymphoblasts were described. Cell morphology of various subtypes of lymphoma on histopathology is similar to that of dogs.

Lymphoma in ferrets

Lymphoma is the second most common malignant neoplasm in domestic ferrets. Location of lymphoma, in order of decreasing frequency, is nodal, splenic, gastrointestinal, multicentric, and cutaneous. The cytologic appearance of malignant lymphoid cells appears to be similar to that seen in dogs and cats.

Metastatic neoplasia

Malignant tumors commonly metastasize via lymphatics, resulting in proliferation of neoplastic tissue in the lymph node. These neoplasms can often be diagnosed from lymph node aspirates. Diagnostic success is due to the ease with which alien tumor cells can be distinguished from the normal constituents of the node and depends on the degree of node involvement (Figure 45.34). Aspirates may yield only tumor cells, with complete displacement of normal lymphoid elements, when the node has been effaced by metastatic neoplastic cells. While metastasis may be detected by aspiration cytology in nodes that are not enlarged, the probability is decreased.

Some studies have shown that cytology is as accurate as histopathology in diagnosing carcinoma and sarcoma metastasis. However, both aspiration cytology and incisional or excisional biopsy may not always be successful in identifying metastasis. One problem is that the actual sentinel lymph node may not always be accurately identified. The sentinel lymph node is the first lymph node to which a cancer is likely to spread but may be different from the closest regional lymph node to the primary tumor, especially with tumors involving the head. In a study of 20 mast cell tumors in 17 dogs, the sentinel lymph node was different than the regional lymph node in 25% of cases, leading the authors to recommend indirect computed tomographic lymphangiography and sentinel lymph node excision and histopathology as a new standard of care in dogs with mast cell tumors, rather than regional lymph node cytology (see Lapsley et al. 2021 in "Suggested Reading" under "Lymph Node Metastasis").

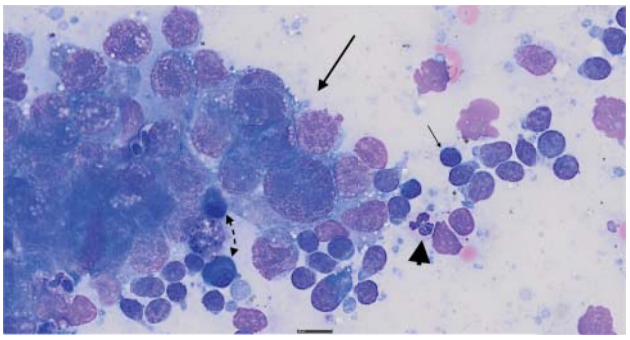

Figure 45.34 Aspirate of a lymph node with metastatic nasal carcinoma in a dog. A very large cluster of highly malignant-appearing epithelial cells is indicated by the large arrow. A normal population of lymphocytes (small arrow), as well as a few plasma cells (dashed line arrow) and neutrophils (arrowhead) are seen. Wright stain.

Also attributing to missed diagnoses of metastasis by both cytology and histopathology is that, in some cases, so few neoplastic cells may be in the lymph node at the time of aspiration or biopsy that they are not detectable by routine methods. Immunohistochemistry, using antibodies directed against the tumor cells, can detect very small numbers of neoplastic cells in aspirates or biopsies but is not routinely used in veterinary medicine.

Accurately predicting metastasis of mast cell tumors using cytology is more difficult than detecting neoplastic epithelial (carcinomas) or mesenchymal cells (sarcomas). Mast cells are commonly present in reactive lymph nodes. Thus, when very few neoplastic mast cells are present in a node, they can be mistaken for normal mast cells. Additionally, many lymph nodes with any type of metastasis are reactive. If the mast cells exhibit atypia, and if numerous mast cells are present in a node that is not inflamed as shown in Figure 45.13, the diagnosis of metastasis becomes less difficult.

Diagnosing melanoma metastasis can also be challenging for several reasons. The primary reason is that macrophages with phagocytized melanin (melanophages) are commonly seen in inflamed lymph nodes, as well as lymph nodes draining melanomas. Melanophages can sometimes be difficult to differentiate from melanocytes, although the melanin in lysosomes of macrophages is usually in aggregates, versus the fine granules seen in melanocytes. Melanocytes

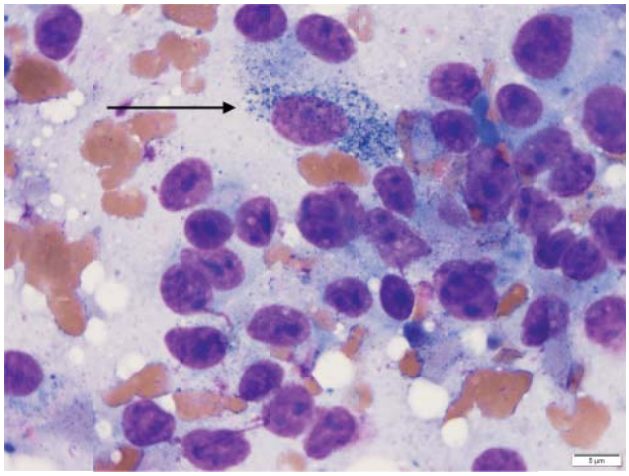

Figure 45.35 Lymph node aspirate from a dog previously diagnosed with a malignant melanoma on a digit. No lymphoid cells are present. Melanocytes without pigment predominate, but one melanocyte in this field contains fine melanin granules (arrow). Wright stain.

can be round, spindle-shaped, or epithelial in appearance (Figure 45.35) (see Chapter 41). Melanocytes from amelanotic melanomas that do not contain pigment can also be difficult to identify. Melanocytes sometimes are round and, if not pigmented, can be mistaken for immature lymphoid cells.

Very rarely, transmissible venereal tumors (TVTs) metastasize to lymph nodes and can be particularly difficult to distinguish from immature lymphoid cells with nucleoli, due to similar appearance and size. One distinguishing characteristic of TVT cells is their punctate vacuoles in moderately abundant cytoplasm, as shown in Figure 40.6e. Other hematopoietic tumors such as granulocytic leukemia may also spread from the bone marrow to such other tissues as lymph nodes, and if poorly differentiated, they are extremely difficult to distinguish from immature lymphoid cells based on cytology, as shown in Figure 16.2.

When attempting to aspirate the mandibular lymph node in the dog, the salivary gland may be mistakenly sampled. Normal salivary gland cells should not be confused with metastatic neoplastic epithelial cells. An extremely rare condition that might be mistaken for metastatic disease in a lymph node is the presence of a choristoma, a mass of normal tissue found in an abnormal location. Choristomas consisting of glandular epithelial tissue have been reported in lymph nodes from cattle, goats, and humans.

Clinical Case Presentations

Alex Mau
Department of Biomedical Sciences, Ross University School of Veterinary Medicine, Basseterre, Saint Kitts and Nevis

Introduction

This section presents a number of case studies taken from animal medical records. Each case is presented with its relevant clinicopathologic data. The cases are organized more or less by the primary disease or organ system involved in disease, with the understanding that many of them have multiple system abnormalities. For example, the first 17 cases focus on common primary hematologic disease. However, abnormal hematologic processes are dispersed throughout the remaining cases. The following is a directory of cases classified by the primary system abnormality or disease problem.

Clinical Case Presentations: Contents

Hematology

Case 1: Cat with hemolytic anemia due to *Mycoplasma haemofelis*, 780
Case 2: Dog with immune-mediated hemolytic anemia, 782
Case 3: Cat with myeloproliferative disorder, 784
Case 4: Cat with iron deficiency anemia, 785
Case 5: Dog with chronic inflammatory disease and iron deficiency, 786
Case 6: Dog with chronic external blood loss, iron deficiency anemia, 787
Case 7: Dog with iron deficiency anemia, 788
Case 8: Dog with iron deficiency anemia, 791
Case 9: Dog with hemangiosarcoma, acute blood loss, 795
Case 10: Dog with chronic ehrlichiosis and *Mycoplasma haemocanis*, 796
Case 11: Dogs with ehrlichiosis, 797
Case 12: Dog with lymphocytic leukemia, 801
Case 13: Cat with lymphoid leukemia, 802
Case 14: Dog with anemia of inflammatory disease and DIC, 804
Case 15: Dog with acute inflammatory disease and sepsis, 805
Case 16: Dog with immune-mediated thrombocytopenia, blood loss, 807
Case 17: Dog with hyperproteinemia and monoclonal gammopathy due to myeloma, 808
Case 18: Dog with bee envenomation, 810
Case 19: Foal with Rhodococcus, 812
Case 20: Dog with rattle snake envenomation, 814
Case 21: Cat with suspected antierythrocyte antibody, 817
Case 22: Dog with zinc toxicosis, 819
Case 23: Cow with postpartum hemoglobinuria, 821
Case 24: Parrot with lead poisoning, 823

Coagulation

Case 25: Disseminated intravascular coagulation (DIC), 824
Case 26: Dog with hemophilia A, 826
Case 27: Dog with vitamin K antagonist (rodenticide) toxicity, 827
Case 28: Horse with disseminated intravascular coagulation associated with pancreatitis, 828
Case 29: Dog with coagulopathy, 830

Renal Disease

Case 30: Dog with acute renal failure associated with heatstroke, 833
Case 31: Dog with end-stage renal disease, 835
Case 32: Dog with glomerular disease, amyloidosis, 837
Case 33: Cat with acute renal disease associated with thromboembolic disease, 839
Case 34: Dog with chronic renal failure associated with infiltrative neoplastic disease, 842
Case 35: Horse with hypercalcemic chronic renal failure and salmonellosis, 844
Case 36: Cat with kaliopenic polymyopathy/nephropathy syndrome, 847
Case 37: Dog with congenital Fanconi's syndrome, 849
Case 38: Dog with hypercalcemic nephropathy, 851

Case 39: Dog with polydipsia associated with hypercalcemia, 853
Case 40: Cat with renal disease and severe acidemia, 854
Case 41: Cat with acute renal failure due to ethylene glycol toxicity, 855
Case 42: Dog with ethylene glycol toxicity, 857
Case 43: Dog with atypical ethylene glycol toxicity, 859
Case 44: Foal with uroabdomen, 861
Case 45: Dog with leptospirosis, 863
Case 46: Dog with leptospirosis, 865
Case 47: Sheep with nephrotoxicity, 867
Case 48: Rhinoceros with renal failure, 869

Fluid and Electrolyte and Acid-Base Disturbances

Disorders of electrolytes and acid-base disturbances are not primary disease problems. Therefore, most electrolyte and acid-base disturbances are best considered with their primary disease process(es). For more broad exposure to this category, also see:

Electrolyte abnormalities

Cases 15, 26, 35, 36, 41, 42, 44, 45, 46, 50, 51, 58, 64, 65, 75, 76, 78, 79, 80, 83, 84, 89, 90, 91, 92, 93, 96, 97, 98, 99, 108, 109, 110

Acid-base disturbances

Cases 30, 40, 43, 49, 57, 76, 78, 79, 80, 83, 88, 93, 98

Case 49: Cat with compensated metabolic acidosis associated with diabetes, 872
Case 50: Cat with sodium chloride depletion due to meningomyelocele, 873
Case 51: Horse with colic, 875
Case 52: Cat with hyperkalemia due to soft-tissue injury, 877

Hepatic Disease

Case 53: Dog with cholangiohepatitis and cholestasis, 879
Case 54: Dog with hepatitis and cholestasis associated with steroid hepatopathy, 881
Case 55: Dog with chronic liver disease due to metastatic neoplasia, 883
Case 56: Dog with liver failure associated with chronic diaphragmatic hernia, 885
Case 57: Dog with liver failure associated with severe hepatic infiltrate with lymphoma, 887
Case 58: Dog with bile peritonitis, 889
Case 59: Dog with end-stage liver disease, cirrhosis, 891
Case 60: Dog with portosystemic shunt, 892
Case 61: Dog with portosystemic shunt, 894
Case 62: Dog with portocaval shunt, 895
Case 63: Dog with hepatocellular injury associated with trauma, 898
Case 64: Dog with cirrhosis and cholestasis, 900
Case 65: Dog with hepatic lipidosis and cellular injury associated with diabetes, 902
Case 66: Cat with hepatic lipidosis syndrome, 904
Case 67: Alpaca with hepatic lipidosis and serum lipid abnormalities, 905
Case 68: Dog with end-stage liver disease and hepatocutaneous syndrome, 907
Case 69: Dog with steroid-induced hepatopathy, 909
Case 70: Dog with presumptive Sago palm toxicity, 911
Case 71: Cow with hepatic dysfunction and photosensitization, 913
Case 72: Horse with hyperlipidemia, 915

Pancreatic and Gastrointestinal Disease and Glucose Metabolism

Case 73: Dog with hyperlipidemia syndrome, 917
Case 74: Dog with hyperlipidemia and pancreatitis, 919
Case 75: Cat with diabetic nonketotic hyperosmolar syndrome, 921
Case 76: Cat with diabetic ketoacidosis, 923
Case 77: Dog with hypoglycemia associated with insulin-secreting neoplasia, 925
Case 78: Calf with secretory diarrhea and hypotonic dehydration, 926
Case 79: Bull with upper gastrointestinal obstruction, 928
Case 80: Calf with nonsecretory diarrhea and hypertonic dehydration, 930
Case 81: Dog with protein losing enteropathy, 932
Case 82: Dog with exocrine pancreatic insufficiency, 934
Case 83: Dog with gastrointestinal obstruction, 936
Case 84: Dog with gastrointestinal obstruction, 938
Case 85: Dog with small intestinal bacterial overgrowth (SIBO), 940
Case 86: Dog with exocrine pancreatic insufficiency, 942
Case 87: Dog with intestinal lymphoma, 944
Case 88: Dog with exocrine pancreatic carcinoma, 946
Case 89: Horse with salmonella and PLE, 950
Case 90: Horse with panhypoproteinemia, 952
Case 91: Horse with coronavirus, 954
Case 92: Horse with Potomac horse fever, 956
Case 93: Cow with displaced abomasum, 958

Endocrine Disorders

Case 94: Dog with hypothyroidism, 960
Case 95: Dog with diabetes and secondary hypothyroidism, 961
Case 96: Dog with hypoadrenocorticism, 963
Case 97: Dog with hypoadrenocorticism, 965
Case 98: Dog with hypoadrenocorticism, 967
Case 99: Dog with hypoadrenocorticism, 969
Case 100: Dog with hyperadrenocorticism, 971
Case 101: Dog with iatrogenic Cushing's disease, 973
Case 102: Dog with pituitary adenoma secreting ACTH, 975
Case 103: Dog with pituitary-dependent hyperadrenocorticism, 977
Case 104: Dog with hyperparathyroidism, 979

Case 105: Dog with primary hyperparathyroidism, 981
Case 106: Dog with humoral hypercalcemia of malignancy, 983
Case 107: Dog with hypoparathyroidism, 985
Case 108: Dog with primary hypoadrenocorticism, 987
Case 109: Dog with primary hypoadrenocorticism, 989
Case 110: Dog with primary hypothyroidism, 991
Case 111: Dog with familial hyperlipidemia and diabetes, 993
Case 112: Mule with hyperparathyroidism and lymphoma, 995
Case 113: Parrot with diabetes, 997

Cytology

Case 114: Cat with FIP, 999
Case 115, Dog with urothelial carcinoma, 1001
Case 116, Dog with subungual squamous cell carcinoma, 1003
Case 117, Horse with equine multinodular pulmonary fibrosis, 1009

Perspective on Use of This Section

Interpretation of laboratory data is an art that is developed through accumulated experience. The interactions and patterns of data related to disease diagnosis are complex. One also must develop an appreciation for magnitudes of abnormality that influence interpretation of each measurement. This case discussion appendix is designed to provide the reader with both experience and guidance in beginning to learn the art of interpretation. This art is then continually cultivated through real-time experience in the clinical setting.

The laboratory data are presented for each case in a form that allows the reader to learn from making his or her own effort at describing and interpreting data. Please note the following formatting:

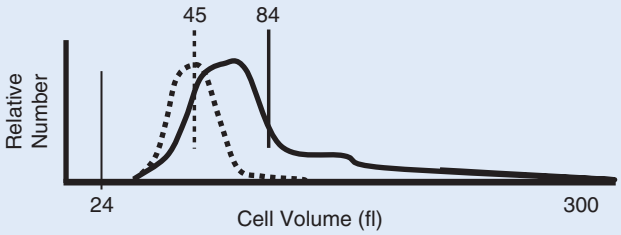
1. Data in the majority of the cases are presented in conventional units most commonly used in the United States. Data provided in some cases are in the International System of Units (SI), and in a few cases for which both types of units are provided, the SI units are in italics. Reference intervals vary between cases because the tests were performed at numerous laboratories.

2. Laboratory values that are abnormal and central to the interpretation are given in bold type.

Following each data set, an Interpretive discussion is presented. These narratives may be used by the reader for self-assessment of proficiency in interpretation of data.

List of Abbreviations

The following list of abbreviations identifies test results that are typically used in laboratory reports. The user should refer to these as needed while learning the content of laboratory reports.



Alb	Albumin
ALP	Alkaline phosphatase
ALT	Alanine aminotransferase
An. gap	Anion gap
aPTT	Activated partial thromboplastin time
AST	Aspartate aminotransferase
Bands	Band neutrophils
BUN	Blood urea nitrogen
Ca	Calcium
Calc. osmolality	Calculated osmolality
Chol	Cholesterol
CK	Creatine kinase
CL	Chloride
Creat	Creatinine
Eos	Eosinophils
Epith cells	Epithelial cells
GGT	Gamma glutamyltransferase
Glob	Globulin
Gluc	Glucose
Hgb	Hemoglobin
hpf	High-power fields
Lymphs	Lymphocytes
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean cell volume
Meas. osmolality	Measured osmolality
Metas	Metamyelocytes
Monos	Monocytes
Na	Sodium
NCC	Total nucleated cell count (also commonly called WBC for "white blood cell count")
PCV	Packed cell volume
Phos	Phosphorus
PT	Prothrombin time
RBCs	Red blood cells
Retics	Reticulocytes
SDH	Sorbitol dehydrogenase
Segs	Segmented neutrophils
Sp. gr.	Specific gravity
T. bili	Total bilirubin
TCO_2	Total CO_2
TP	Total protein
TP (P)	Total plasma protein
TP (S)	Total serum protein
Trig	Triglyceride
UN	Urea nitrogen (same as BUN)
WBCs	White blood cells
WRI	Within reference interval(s)

Case 1

Signalment and history: 11-year-old male cat. Lethargy and polydipsia. One month ago, PCV was 38%.

Hematology		Reference interval
PCV (%)	**13**	25–45
RBC ($\times 10^6/\mu L$)	**1.55**	5–11
Hgb (g/dL)	**4.0**	8–15
MCV (fL)	**84**	39–50
MCHC (g/dL)	31	33–37
Retics ($\times 10^3/\mu L$)	**155**	0–60
NCC ($\times 10^3/\mu L$)	**20.6**	5.5–19.5
Metas ($\times 10^3/\mu L$)	**0.4**	0
Bands ($\times 10^3/\mu L$)	**0.8**	0–0.3
Segs ($\times 10^3/\mu L$)	9.9	2.5–12.5
Lymphs ($\times 10^3/\mu L$)	**1.4**	1.5–7.0
Monos ($\times 10^3/\mu L$)	**3.1**	0–0.8
Eos ($\times 10^3/\mu L$)	0.2	0–1.5
Nucleated RBCs ($\times 10^3/\mu L$)	**4.8**	0
Platelets ($\times 10^3/\mu L$)	Adequate	150–700
TP (P) (g/dL)	**8.9**	6.0–8.5

Hemopathology: Many *Mycoplasma haemofelis* organisms on erythrocytes. Occasional reactive lymphocyte.

Histograms: Dashed histogram and vertical bar = normal
Solid histogram and vertical bar = patient

Histogram: Solid line = patient; dashed line = normal.

Biochemical profile		Reference interval
Gluc (mg/dL)	**249**	67–124
BUN (mg/dL)	**96**	17–32
Creat (mg/dL)	**6.6**	0.9–2.1
Ca (mg/dL)	10.2	8.5–11
Phos (mg/dL)	**7.9**	3.3–7.8

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: The cat is severely anemic; all measurements of red blood cell mass are decreased.

MCV: The mean cell volume is increased, which one would expect with a regenerative anemia. However, the increase is greater than can be accounted for by the reticulocytes, suggesting that agglutination is causing the increase, since doublets are being counted as one erythrocyte. This is confirmed by the histogram tailing to the right.

Reticulocytes are increased, indicating that the anemia is regenerative. Regenerative anemia is due to blood loss or blood destruction. The protein concentration suggests hemolysis and tends to rule out blood loss.

Nucleated RBCs are increased due to early marrow release, and are often present in a regenerative anemia.

Erythrocyte morphology: The presence of *Mycoplasma haemofelis* organisms explains the anemia (blood destruction). Agglutination is likely due to the presence of antibodies against the organisms.

Monocytosis and increased immature (band) neutrophils are indicative of an inflammatory leukogram.

Lymphopenia is indicative of a stress component in the leukogram.

Total protein: Total protein is increased. In this patient, it is due to hyperglobulinemia (see biochemical profile interpretation below).

Biochemical profile

The serum glucose concentration is moderately increased. This could be due to stress (glucocorticoid release), as the lymphopenia suggests, but could also be due to diabetes mellitus.

The BUN and serum creatinine concentrations are increased, and in the face of a urine specific gravity of only 1.020, is indicative of renal azotemia.

The serum phosphorus concentration is mildly increased, and is compatible with decreased glomerular filtration rate.

The serum total protein concentration is increased due to an increase in the globulin concentration. The increase in globulin should trigger protein electrophoresis to determine if gammopathy is monoclonal or polyclonal.

The serum cholesterol concentration is moderately increased. This may be due to metabolic disorders associated with diabetes mellitus.

Serum total CO_2 is decreased, suggesting metabolic acidosis.

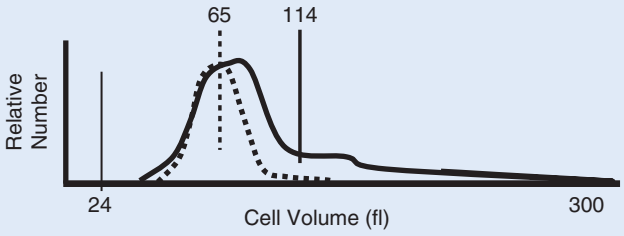
The increased calculated serum osmolality is primarily due to hyperglycemia and increased BUN.

Urinalysis

As evidenced by the relatively low urine specific gravity in the face of azotemia, the animal is not concentrating adequately, indicating renal dysfunction. The presence of glucose indicates that the renal threshold of glucose has been exceeded.

Summary

This animal had been previously diagnosed with diabetes mellitus and was not being controlled adequately. *Mycoplasma haemofelis* is often an opportunist in cats that are immunosuppressed. The hyperglobulinemia was polyclonal, indicating antigenic stimulation, possibly due to *Mycoplasma haemofelis*.



Case 2

Signalment: 5-year-old spayed female cocker spaniel
History: Acutely lethargic
Physical examination: Pale, slightly icteric mucous membranes

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: The dog is very anemic, as all measurement of red blood cells mass are decreased. The RBC count is likely erroneously decreased, due to erythrocyte agglutination, and groups of red blood cells being counted as one red blood cell.

MCV: The mean cell volume is erroneously increased due to agglutination. Although the anemia is regenerative, the MCV is much higher than can be accounted for by an increase in reticulocytes. As one can see on the histogram, erythrocytes that are agglutinated are being counted as one large erythrocyte (note histogram tailing to right).

Reticulocytes are increased, indicating that the anemia is regenerative, suggesting either blood loss or blood destruction. The protein and RBC morphology findings indicate hemolysis. The decreased MCHC may be attributed to regeneration.

Nucleated RBCs are increased, likely due to early release from bone marrow in response to marked anemia. However, it is also possible that the dog has decreased splenic function secondary to glucocorticosteroid administration.

Erythrocyte morphology: Presence of spherocytes and agglutination, in the absence of a previous blood transfusion, are indicative of immune-mediated hemolytic anemia.

Neutrophilia, increased immature neutrophils, and monocytosis are indicative of a markedly inflammatory leukogram. The absence of lymphocytes is suggestive of stress or corticosteroids. Inflammatory leukograms are commonly seen in association with immune-mediated hemolytic anemia.

Biochemical profile

Glucose is mildly increased. Considering the lymphopenia, this may be due to stress or steroids.

BUN is mildly increased, suggesting decreased GFR or bleeding into the GI tract. Since the creatinine is within the reference interval, and the dog is concentrating urine, this is likely prerenal azotemia, due to GI hemorrhage (high-protein diet) or decreased blood flow to the kidneys.

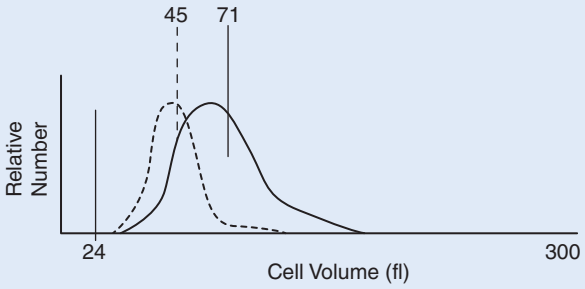
Bilirubin is increased, indicating either cholestasis or increased red blood cell destruction. Because the dog has immune-mediated hemolytic anemia, increased RBC destruction is most likely the cause.

Serum alkaline phosphatase activity is increased, which could be due to either cholestasis or previous treatment with corticosteroids.

Urinalysis

Bilirubinuria and the presence of bilirubin crystals reflect the increased serum bilirubin concentration. Conjugated bilirubin readily passes through glomeruli and is then excreted in the urine. Blood and protein may be present due to traumatic catheterization. The animal is concentrating, indicating that the increase in BUN is not due to renal dysfunction.

Summary



This is a typical case of immune-mediated hemolytic anemia. Dog was treated with prednisone and recovered. It had been previously treated with corticosteroids, accounting for the stress leukogram, hyperglycemia, and increased serum alkaline phosphatase activity.

Case 3

Signalment and history: 11-year-old DSH spayed female cat presented for anorexia and lethargy

Hematology		Reference interval
PCV (%)	**13**	25–45
RBC ($\times 10^6$/μL)	**1.84**	5–11
Hgb (g/dL)	**4.2**	8–15
MCV (fL)	**71**	39–50
MCHC (g/dL)	32	33–37
Retics ($\times 10^3$/μL)	7.4	0–60
Nucleated cells ($\times 10^3$/μL)	**71.3**	5.5–19.5
Metas ($\times 10^3$/μL)	**0.7**	0
Bands ($\times 10^3$/μL)	**2.1**	0–0.3
Segs ($\times 10^3$/μL)	**33.2**	2.5–12.5
Lymphs ($\times 10^3$/μL)	2.8	1.5–7.0
Monos ($\times 10^3$/μL)	**6.9**	0–0.8
NRBCs ($\times 10^3$/μL)	**24.9**	0
Blasts ($\times 10^3$/μL)	**0.7**	0
Platelets ($\times 10^3$/μL)	Adequate	150–700
TP (P) (g/dL)	8.0	6.0–8.5

Hemopathology: Blasts appear to be rubriblasts. Many prorubricytes and rubricytes also present.

Histogram: Solid line = patient; dashed line = normal.

Interpretive discussion

Hematology

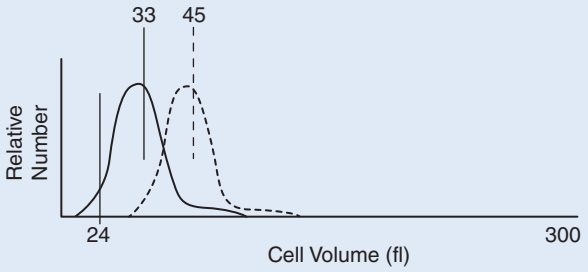
Packed cell volume, Hemoglobin, Red blood cell count: Cat is markedly anemic. Reticulocytes are not increased, indicating that the anemia is nonregenerative.

MCV is markedly increased, in the absence of reticulocytosis or agglutination. In a cat, this should trigger testing for feline leukemia virus, as the MCV may be increased as a result of viral-induced erythrodysplasia. Macrocytosis with widened histogram is often seen in FeLV positive cats with anemia.

Neutrophilia, increased band neutrophils and metamyelocytes, and monocytosis are indicative of inflammation.

Nucleated red blood cells are increased in the absence of reticulocytes. Moreover, many of these are quite immature, indicating that the cat has leukemia involving the erythrocytes.

Summary



Myeloproliferative disorder, red cell leukemia or M6(E).

Case 4

Signalment and history: 17-year-old male cat presented for lethargy and enlarged abdomen. Liver disease suspected, but biochemical profile normal.

Hematology		Reference interval
PCV (%)	**24**	25–45
MCV (fL)	**33**	39–50
MCHC (g/dL)	32	33–37
Retics ($\times 10^3/\mu L$)	ND	0–60,000
Nucleated cells ($\times 10^3/\mu L$)	13.2	5.5–19.5
Bands ($\times 10^3/\mu L$)	**4.5**	0–0.3
Segs ($\times 10^3/\mu L$)	6.6	2.5–12.5
Lymphs ($\times 10^3/\mu L$)	**0.5**	1.5–7.0
Monos ($\times 10^3/\mu L$)	0.5	0–0.8
Eos ($\times 10^3/\mu L$)	0.3	0–1.5
Basophils ($\times 10^3/\mu L$)	**0.8**	rare
Platelets ($\times 10^3/\mu L$)	Adequate	150–700
TP (P) (g/dL)	6.6	6.0–8.5

Hemopathology: Many keratocytes, schistocytes.

Histogram: Solid line = patient; dashed line = normal.

Interpretive discussion

Hematology

Packed cell volume: The cat is mildly anemic.

MCV: The mean cell volume is prominently decreased. Decreased mean cell volume is almost always caused by iron deficiency anemia, which in adults is almost always secondary to chronic external blood loss. The borderline decrease in MCHC is not important diagnostically.

Erythrocyte morphology: Keratocytes are commonly associated with iron deficiency anemia. Iron deficiency anemia is not as common in cats as in dogs, and the few cases we have seen did not have increased central pallor.

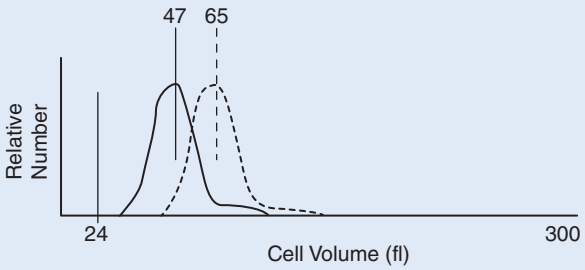
The total leukocyte count and the mature neutrophil concentration are within the reference interval, but the increase in band neutrophils is indicative of inflammation. Lymphopenia is indicative of stress or previous corticosteroid administration.

Total protein is within the reference interval. Although one might expect total protein to be decreased with chronic blood loss, animals often compensate for this chronic loss of protein.

Summary

Owner declined further diagnostic evaluation. Chronic GI blood loss secondary to an intestinal tumor would be the most likely diagnosis in this aged patient with iron deficiency anemia.

Case 5



Signalment: 1-year-old pointer

History: Treated for neck or back pain with corticosteroids by referring veterinarian. Dog was thought to have GI parasites due to occult blood in feces and was treated with anthelmintics. The dog returned 1 month later with a PCV of 15% and MCV of 40 fL. At that time the dog had an abdominal effusion.

Physical examination: Painful abdomen, pale mucous membranes

Hematology		Reference interval
PCV (%)	**18**	37–55
Hgb (g/dL)	**3.76**	12–18
RBC ($\times 10^6$/μL)	5.8	5.5–8.5
MCV (fL)	**47**	60–72
MCHC (g/dL)	33	33–38
Retics ($\times 10^3$/μL)	18	<60
NCC ($\times 10^3$/μL)	**40.1**	6–17
Segs ($\times 10^3$/μL)	**36.5**	3–11.5
Bands ($\times 10^3$/μL)	**0.4**	0–0.3
Metas ($\times 10^3$/μL)	**0.4**	0
Monos ($\times 10^3$/μL)	1.2	0.1–1.3
Lymphs ($\times 10^3$/μL)	1.2	1–4.8
Eos ($\times 10^3$/μL)	0.4	0.1–1.2
Platelets ($\times 10^3$/μL)	**623**	200–500
TP (P) (g/dL)	**5.9**	6–8

Hemopathology: Numerous keratocytes, few schistocytes, some RBCs appear hypochromic. Occasional lymphocyte with azurophilic granules.

Histogram: Solid line = patient; dashed line = normal:

Abdominal fluid analysis	
NCC (μL)	**90,000**
TP (g/dL)	**4.0**

Cytology: All cells are degenerate neutrophils. Bacteria of various types are present.

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin: Both are decreased, indicating that the dog is anemic. The red blood cell count is within the reference interval, suggesting erythrocytes are small.

MCV: The mean cell volume is decreased. Decreased mean cell volume is almost always caused by iron deficiency anemia, which in adults is almost always secondary to chronic external blood loss.

Reticulocytes are not increased, indicating that the anemia is nonregenerative. While uncomplicated iron deficiency anemia is usually regenerative, this anemia may be nonregenerative due to the presence of inflammation (note inflammatory leukogram).

Erythrocyte morphology: Keratocytes, erythrocyte fragmentation, and increased central pallor are commonly associated with iron deficiency anemia.

Neutrophilia and increased immature neutrophils are indicative of a marked inflammatory leukogram. The inflammatory leukogram is compatible with the presence of inflammation in the peritoneal cavity, although one would usually expect to see more band neutrophils in dogs with peritonitis. The presence of this inflammation may be the explanation for the lack of a regenerative response to the anemia, as an anemia of inflammatory disease may be superimposed on the iron deficiency anemia. The noted occasional granulated lymphocyte is interpreted as an incidental finding.

Platelets are increased. Approximately half of all animals with iron deficiency anemia have increased platelets, probably in response to cytokines and growth factors.

Total protein: Total protein is slightly decreased, probably as a result of chronic blood loss.

Histogram confirms the presence of a population of microcytic cells (normal histogram represented by dashed line).

Abdominal fluid analysis

Supportive septic inflammation. The presence of different types of bacteria suggests a GI source of bacteria.

Summary

The dog died, and on necropsy had an intestinal perforation secondary to an ulcer, chronic diffuse peritonitis, pyogranulomatous lymphadenitis and amyloidosis of the spleen, liver, and kidney. Presumably, the dog had been chronically bleeding from this ulcer, resulting in iron deficiency anemia.

Case 6

Signalment and history: 9-year-old female beagle presented for lethargy and pale mucous membranes. Owner reported that the dog occasionally had blood in feces.

Hematology		Reference interval
PCV (%)	**12**	37–55
RBC ($\times 10^6/\mu L$)	**2.76**	5.5–8.5
Hgb (g/dL)	**3.2**	12–18
MCV (fL)	**40**	60–72
MCHC (g/dL)	**29**	34–38
Retics ($\times 10^3/\mu L$)	**242**	0–60
Nucleated cells ($\times 10^3/\mu L$)	**33.4**	6.0–17.0
Metas ($\times 10^3/\mu L$)	–	0
Bands ($\times 10^3/\mu L$)	–	0–0.3
Segs ($\times 10^3/\mu L$)	**30.7**	3.0–11.5
Lymphs ($\times 10^3/\mu L$)	1.0	1.0–4.8
Monos ($\times 10^3/\mu L$)	1.0	0.2–1.4
Eos ($\times 10^3/\mu L$)	–	0.1–1.2
NRBCs ($\times 10^3/\mu L$)	**0.7**	0
Platelets ($\times 10^3/\mu L$)	Adequate	200–500
TP (P) (g/dL)	6.3	6.0–8.0

Hemopathology: Increased central pallor, occasional keratocyte, giant platelets.

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: The dog is markedly anemic; all measurements of red blood cell mass are decreased.

MCV: The mean cell volume is markedly decreased. Decreased mean cell volume is almost always caused by iron deficiency anemia, which in adults is almost always secondary to chronic external blood loss. The MCHC may be mildly decreased in iron deficiency as it is here. The reticulocytosis may also contribute to the decreased MCHC.

Reticulocytes are increased, indicating that the anemia is regenerative, suggesting blood loss or blood destruction. In this case, the decreased MCV strongly suggests iron deficiency anemia secondary to chronic blood loss. The presence of nucleated red blood cells is compatible with this degree of regenerative response.

Erythrocyte morphology: Keratocytes and increased central pallor are commonly associated with iron deficiency anemia.

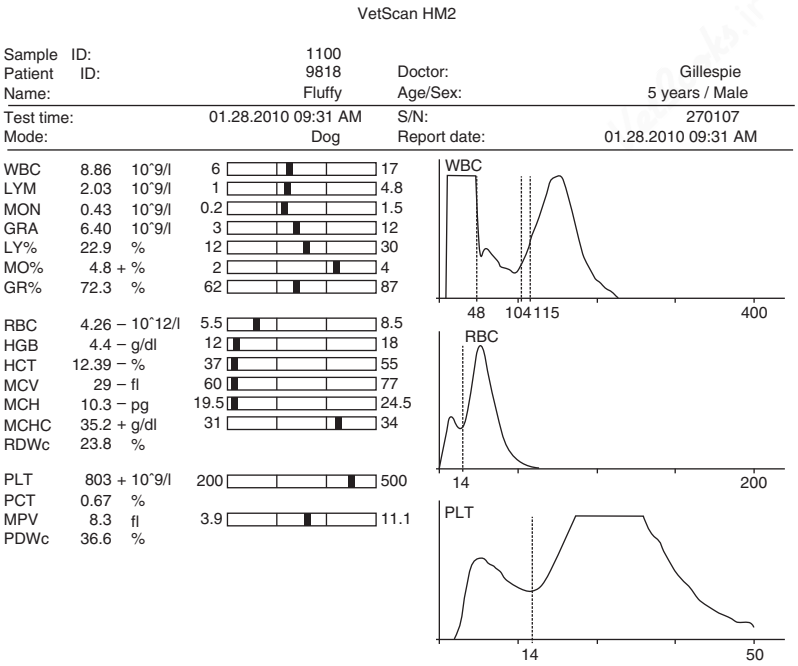
Neutrophilia is indicative of inflammation, even though no band neutrophils are present, since the neutrophil concentration is greater than twofold upper reference interval. The lymphocyte count is in the low normal range, indicating that there may be a stress or steroid component to the leukogram.

Total protein is within the reference interval. Although one might expect total protein to be decreased with chronic blood loss, animals often compensate for this chronic loss of protein.

Summary

GI barium series performed and jejunal mass seen. At surgery, a mass in the mid-jejunum was resected and determined to be a leiomyosarcoma with clean surgical margins. The regenerative response in this case is in contrast to the previous case to make the point that iron deficiency anemia may be either regenerative or nonregenerative.

Case 7



Signalment: 5-year-old mixed-breed dog
History: Lethargy
Physical examination: Lethargic, pale mucous membranes

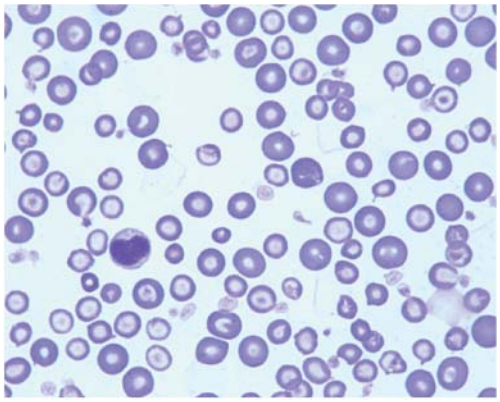
[a]Sample moderately lipemic.



1/20 histogram and blood film

1/28 histogram and blood film

Interpretive discussion

Hematology

PCV and Hematocrit: Decreased, indicating anemia. Note the marked discrepancy in the calculated hematocrit (HCT) and the spun packed cell volume (PCV). The HCT is calculated by the instrument using the following formula: (MCV × RBC)/10 = HCT(%). In the case of the sample from 1/28/10, the RBC count may be under-reporting the sample's RBC concentration since some small RBCs are likely appearing in the PLT channel. The lower reported RBC count is also likely due to the fact that two overlapping RBC peaks are now present in the RBC histogram from 1/28/10; the two overlapping peaks will be underestimated since the software expects only one RBC peak to be present and will not apply curve fitting algorithms here. Since the RBC count is underestimated, the HCT calculated here is lower than the reported PCV.

RBC

The RBCs are decreased as a result of anemia, but they are likely undercounted in this patient due to their small size, and are likely being counted in the platelet channel (see the platelet histogram below the erythrocyte histogram).

MCV

The decreased MCV indicates a severe microcytic anemia. The degree of microcytosis is illustrated by the RBC histogram on 1/20. The blood film contained many hypochromic erythrocytes, as well as keratocytes and schistocytes, erythrocyte shape changes and fragmentation that are very characteristic of iron deficient erythrocytes. The dog was treated with iron. Note that 1 week later on 1/28, the MCV increased, and the new normal-sized erythrocytes are evident in the erythrocyte histogram on 1/28. They are represented by the additional curve on the right side of the histogram as well as on the blood film made on 1/28.

MCHC

The MCHC is miscalculated to be high on 1/28 likely as a result of the undercounted RBCs. The MCHC is probably erroneously increased on 1/20 as well. The MCHC is calculated from the hemoglobin concentration and the HCT using the following formula: HGB (g/dL) divided by the HCT (%) × 100 = MCHC (g/dL). It provides an index for the quantity of hemoglobin relative to the volume of packed erythrocytes. It may be erroneously increased due to lipemia, hemolysis, or an erroneously low HCT. On 1/28, it is likely erroneously high due to the erroneously low HCT. On 1/20, it may also be erroneously high due to lipemia artifactually increasing the HGB.

RDW

The increased variation in erythrocyte size (anisocytosis) is represented by the increased red cell distribution width (RDW) on 1/28, a numerical expression (coefficient of variation) that correlates with the degree of anisocytosis and that the instrument determines by dividing the standard deviation of the red cell size by the MCV. Both iron deficient

microcytic erythrocytes and young macrocytic erythrocytes can also be seen on the blood film.

Platelets

The platelet concentration is markedly increased, as is often the case in patients with iron deficiency anemia. Some of the platelets are quite large. Also, some microcytic RBC are counted as PLT, falsely increasing the PLT concentration.

Reticulocytes

The reticulocyte concentration is increased, indicating a regenerative anemia.

Total protein

The total protein is slightly decreased on 1/20, likely due to chronic blood loss (protein is lost as well as erythrocytes).

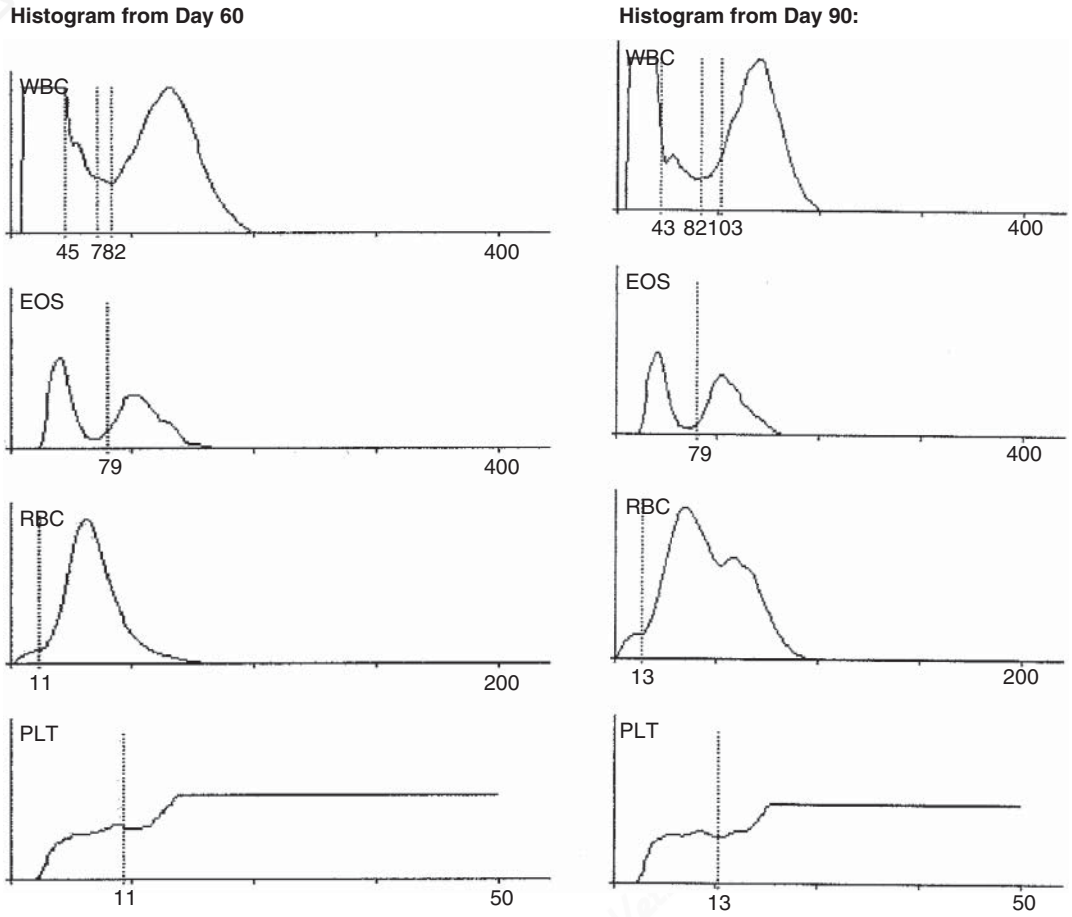
Summary

Iron deficiency anemia as indicated by marked microcytosis.

Outcome

The diagnosis of iron deficiency anemia was confirmed by measuring serum iron, which was 27 µg/dL (Reference interval = 98–220 µg/dL). The source of chronic blood loss is usually the gastrointestinal tract. An occult blood test was performed on the feces on multiple occasions, and was consistently negative. An examination of feces for the eggs of parasites such as hookworms was also negative. Further history revealed that the owner had given the dog an anthelmintic 2 weeks prior to presentation, presumably eliminating a hookworm infestation. The dog was treated with 15 mg/kg iron dextran IM, and the owner was instructed to give him 162.5 mg Ferrous sulfate orally once daily for 4 weeks. The hematocrit and MCV were normal at his follow-up examination 6 months later.

Case 8



Signalment: 5-month-old male Great Dane/Labrador retriever/mastiff cross weighing 23 kg

History: Lethargy, eating dirt (pica), vomited once and a small amount of blood was in vomitus, pruritic. Four of his five littermates died at 4–6 weeks of age. Hookworm eggs were seen on a fecal examination done at 7 weeks of age, and he also possibly had coccidiosis at that time and was treated for both. His sire is also his grandsire.

Physical examination: Pale mucous membranes, skin lesions present that appear to be pustular dermatitis

Plasma protein by refractometry(g/dL)	**5.2**	**5.4**	6.0	6.2	6.0–8.0

Hemopathology Day 1: Hypochromasia, microcytosis, keratocytes, schistocytes, marked polychromasia present, numerous macroplatelets present, some platelet clumping, platelet concentration appears adequate on blood film.
Hemopathology Day 60: Marked hypochromasia and microcytosis. Numerous large and giant platelets seen. Occasional schistocytes and keratocytes. Moderate polychromasia present.
Hemopathology Day 90: Occasional keratocyte seen.
Hemopathology Day 90: A few microcytic and hypochromic erythrocytes seen.

Additional tests

Biochemical profile

Abnormalities are shown below.

Phosphorus (mg/dL)	**7.5**	Reference interval: 2.9–6.6
Total protein (g/dL)	**4.9**	Reference interval: 5.4–8.2
Globulin (g/dL)	**1.4**	Reference interval: 2.3–5.2

PCR for babesia on Day 1– negative.

Fecal examination on Day 60 was negative for parasites, **positive for occult blood,** and **positive for Giardia antigen**.

Coagulation panel (aPTT and PT) on Day 60 was within normal limits.

Interpretive discussion

Hematology

Day 1: Marked anemia is present as evidenced by the decreased PCV, hemoglobin and erythrocyte count. The anemia is extremely microcytic (decreased MCV) and hypochromic (decreased MCHC), indicating iron deficiency anemia secondary to chronic blood loss. Microcytosis occurs with iron deficiency anemia because iron availability determines reticulocyte size. Under normal conditions, hemoglobin concentration in the rubricyte increases to a point that the concentration will trigger nuclear degeneration resulting in inability to undergo further mitosis. Hemoglobin synthesis is delayed when iron is limited, presumably resulting in extra rubricyte divisions and subsequent microcytosis.

Anemia is markedly regenerative as evidenced by the increased reticulocyte concentration. The red cell distribution width (RDW) is increased, indicating an increased variation in erythrocyte size (anisocytosis). The RDW is determined by the following calculation: Standard deviation of the MCV divided by the MCV × 100. RDW is consistently increased in patients with iron deficiency anemia, not only because of heterogenous volumes of erythrocytes but also because of the low MCV.

An inflammatory leukogram is present as evidenced by the increased band neutrophils.

The electronic platelet concentration is erroneously decreased, due to the presence of macroplatelets and platelet clumping.

The plasma protein is decreased, likely due to chronic blood loss or protein loss through the intestine (see below).

Examination of the blood film showed the presence of microcytosis and hypochromasia, which is compatible with the decreased MCV and MCHC. Keratocytes and schistocytes are often associated with iron deficiency anemia due to oxidative membrane changes. The polychromasia seen on the blood film is consistent with the increased reticulocyte concentration.

Day 60: The anemia is slightly less severe. Interestingly, the erythrocyte concentration is within the reference interval, even though the hemoglobin and PCV are decreased. This is likely explained by the fact that the erythrocytes are approximately half normal size, as shown by the MCV, which results in a decreased red cell mass and hemoglobin even though the red cell concentration is normal. Additionally, large platelets are being counted as erythrocytes, which would account for a slight increase in the erythrocyte concentration. Note that the red cell and platelet histograms show that there is no clear demarcation between the large platelets and the small red blood cells. The histogram is unimodal (i.e., all of the erythrocytes are one microcytic population). The anemia is regenerative, but less regenerative than on Day 1, suggesting that iron stores are further depleted. The RDW is still increased, indicating a variation in erythrocyte size. The electronic platelet count is slightly below the reference interval, likely due to large platelets being counted as erythrocytes rather than platelets.

Day 90: The patient is no longer anemic, and the erythrocyte concentration is above the reference interval. As on Day 60, this is likely due to the presence of increased numbers of small erythrocytes, so that the PCV and hemoglobin concentrations are discordant with the erythrocyte concentration. Additionally, large platelets are likely contributing at least slightly to this increased red cell concentration, as they are being counted as small red blood cells. The RDW is markedly increased, indicating a large variation in erythrocyte size. This variation is also evident in the bimodal red cell histogram, in which two distinct populations of red cells can be seen. The microcytic subpopulation consists of the residual cells produced during limited iron availability. There is also a new population of normal sized erythrocytes as a result of iron repletion that makes up approximately 30 to 40% of the erythrocyte population. A histogram from an iron deficient dog that received a blood transfusion of normal sized erythrocytes would look similar, but a transfusion was not given to this patient.

A reticulocyte count was not performed on Day 90, but it is likely that some of the erythrocytes are larger than normal. The MCV is still decreased due to the remaining microcytic cells, but it has increased by 6 fL since the previous CBC on Day 60.

Day 120. The only abnormalities are decreased MCV and increased RDW, due to the remaining microcytic erythrocytes. There is a discrepancy of 4% between the manual PCV and HCT, which is calculated by multiplying the MCV by the RBC count (in this case, $47 \times 8.17 = 38$). Erythrocytes from patients with iron deficiency anemia do not pack within the column of the hematocrit tube as completely as do normal erythrocytes. This may be due to their containing less hemoglobin, or possibly due to increased rigidity associated with membrane oxidation that occurs as a result of iron deficiency. The discrepancy is not as large when the patients are more anemic (see Day 1), because fewer erythrocytes are involved. These mild discrepancies should not alter interpretation or patient management.

Biochemical profile

The phosphorus is slightly increased, which is common in large-breed growing dogs. The total protein is decreased as a result of hypoglobulinemia. It is likely that the hypoglobulinemia was a result of loss of globulins through the inflamed GI tract (see below), although loss as a result of blood loss is likely contributing.

Summary and outcome

The dog was initially treated with oral iron (80 mg ferrous sulfate bid), famotidine, a histamine-2 receptor antagonist that decreases stomach acid, and sucralfate, a gastric protectant, with the assumption that the iron deficiency anemia was a result of chronic blood loss from an inflamed GI tract. He was also given an anthelmintic in case hookworm eggs had been missed on the fecal examination. The patient improved slightly but 2 months later developed obvious melena and was vomiting blood. Ultrasound examination and a duodenal and stomach biopsy by endoscopy were performed on Day 60. The duodenum appeared hyperemic but no ulceration was seen. Ultrasound showed a thickened hyperechoic gastric wall, and biopsies revealed severe eosinophilic plasmacytic lymphocytic gastritis and enteritis. A skin biopsy showing eosinophilic lymphocytic plasmacytic dermatitis was also likely due to hypersensitivity.

The patient was then treated with injectable iron on Day 60 (42 mg iron dextran IM) and every 2 weeks thereafter for the next 2 months. He also received dietary therapy for the inflammatory bowel disease (a digestive prescription diet) and benzimidazole, an anthelmintic with effectiveness against Giardia. Famotidine was discontinued, and omeprazole, a proton pump inhibitor, was initiated. By 90 days post–initial admission, the dog was no longer anemic, although his microcytosis persisted due to the relatively long lifespan of erythrocytes.

In summary, Iron deficiency anemia was a result of the chronic blood loss from the intestine. The most important keys to the diagnosis were the decreased MCV and increased RDW. The intestinal inflammation may have been secondary to giardiasis or a food allergy. An additional cause of iron deficiency anemia in patients with inflammatory bowel disease is decreased ability of enterocytes to absorb iron due to the presence of inflammation. The pathophysiology of this phenomenon is complex and is addressed by Kaitha et al. (see "Suggested Reading"). Additionally, both proton pump inhibitors and histamine 2 receptor antagonists can interfere with intestinal iron absorption. The patient's anemia did not significantly improve until injectable iron therapy was instituted. A serum iron was not performed until Day 60, at which time it was normal (146 µg; reference interval: 98–220), suggesting that oral iron had at least been effective in increasing serum iron. Presumably serum iron on Day 1 would have been found to be decreased, considering the severe microcytosis.

Case 9

Signalment: 10-year-old castrated male Labrador retriever

History: Four episodes of acute weakness over past 3 months. At time of wellness exam 4 months ago, dog had PCV of 44% and TP of 8.2 g/dL.

Physical examination: Pale mucous membranes, abdomen slightly distended

Hematology		Reference interval
PCV (%)	**16**	37–55
Hgb (g/dL)	**5.3**	12–18
RBC ($\times 10^6$/μL)	**2.48**	5.5–8.5
MCV (fL)	63	60–72
MCHC (g/dL)	34	34–38
Retics ($\times 10^3$/μL)	**342**	<60
NCC ($\times 10^3$/μL)	**39.1**	6–17
Segs ($\times 10^3$/μL)	**33.2**	3–11.5
Bands ($\times 10^3$/μL)	**1.2**	0–0.3
Monos ($\times 10^3$/μL)	**3.1**	0.1–1.3
Lymphs ($\times 10^3$/μL)	**0.4**	1–4.8
Eos ($\times 10^3$/μL)	0.4	0.1–1.2
NRBCs ($\times 10^3$/μL)	**0.8**	0
Platelets ($\times 10^3$/μL)	**130**	200–500
TP (P) (g/dL)	6.2	6–8

Hemopathology: Polychromasia increased, numerous acanthocytes and schistocytes. Numerous Howell-Jolly bodies.

Biochemical profile
No abnormalities

Abdominal fluid analysis	
PCV (%)	**24**
NCC ($\times 10^3$/μL)	**34**

Cytology: 95% nondegenerate neutrophils; 5% macrophages, many of which have phagocytized erythrocytes.

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: The dog is anemic; all measurements of red blood cell mass are decreased.

MCV: The mean cell volume is normal. However, it is surprising that it is not higher considering that the reticulocyte count is increased.

Reticulocytes are increased, indicating that the anemia is regenerative, and is thus due to blood loss or blood destruction. The borderline low plasma protein suggests blood loss is likely; this will be confirmed by additional findings. Nucleated RBCs are increased due to early marrow release as part of regeneration.

Erythrocyte morphology: Acanthocytes are commonly seen in dogs with hemangiosarcoma. The schistocytes are suggestive of microangiopathy, which may also be associated with hemangiosarcoma.

Neutrophilia, increased immature (band) neutrophils, and monocytosis are indicative of an inflammatory leukogram, although a component of the mature neutrophilia is likely due to stress or corticosteroids. Lymphopenia is indicative of stress.

Platelets are slightly decreased. Considering the presence of schistocytes, the animal may have DIC.

Total protein: Total protein is within the reference interval. However, considering that it was 8.2 g/dL 4 months previously, it is likely decreased due to blood loss within the abdominal cavity.

Abdominal fluid analysis

Hemoabdomen.

Summary

The signalment (large breed, older dog), history (episodes of weakness), regenerative anemia, erythrocyte morphology, and the hemoabdomen are all suggestive of hemangiosarcoma. An exploratory was performed, and the dog had hemangiosarcoma of the spleen and liver, which had ruptured. Previous episodes of weakness were likely due to previous ruptures of the tumor, which had subsequently sealed, then ruptured again.

Case 10

Signalment: 15-year-old Staffordshire terrier
History: Lethargic
Physical examination: Pale mucous membranes

Hematology	January	October	Reference interval

Hemopathology (January): Increased rouleaux, giant platelets, lymphs contain azurophilic granules.
Hemopathology (October): Increased rouleaux, lymphs contain azurophilic granules. Numerous *Mycoplasma haemocanis* organisms present.

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: The dog is anemic; all measurements of red blood cell mass are decreased.

Reticulocytes are increased in January, indicating that the anemia is regenerative, suggesting either blood loss or blood destruction. Although the PCV is further decreased in October, the anemia is no longer regenerative, suggesting bone marrow dysfunction.

Neutrophilic leukocytosis with left shift and monocytosis is indicative of an inflammatory leukogram (January).

Lymphocytosis in January is most suggestive of either lymphocytic leukemia or ehrlichiosis.

Platelets: The animal is markedly thrombocytopenic in October. The combination of thrombocytopenia and nonregenerative anemia should trigger a bone marrow aspirate examination and ehrlichia titer. Common causes of thrombocytopenia include ehrlichiosis, immune-mediated thrombocytopenia, and DIC.

Total protein: Total protein is increased. In this patient, it is due to hyperglobulinemia, which should trigger protein electrophoresis.

The presence of increased rouleaux is compatible with increased globulin. The presence of large granular lymphocytes is suggestive of certain types of antigenic stimulation, commonly ehrlichiosis, or a leukemia of LGL cells. The presence of *Mycoplasma haemocanis* organisms in October suggests either a previous splenectomy or splenic dysfunction, since the erythrocyte parasite is rarely seen in dogs with functional spleens. The anemia is no longer regenerative in the face of anemia and this erythrocyte parasite, suggesting marrow impairment of some type, and a bone marrow aspirate is indicated.

Summary

In January, the anemia was possibly due to blood loss associated with a large hematoma of the spleen, and the dog was splenectomized. The lymphocytosis, hyperglobulinemia, and presence of large granular lymphocytes should have triggered an ehrlichia titer but did not. The animal returned in October, severely anemic and thrombocytopenic. An ehrlichia titer was done at this time, and was strongly positive. The dog was treated for ehrlichiosis and hemoplasmosis, and recovered.

Case 11

Signalment: Three approximately 3-year-old adult intact dogs from St. Kitts that presented as strays

History: No history available

Physical examination: Poorly nourished, rough hair coats

Dog 1

Hematology				
	Day 1	**Day 60**	**Day 90**	**Ref range**

Total protein (g/dL)	**9.6**	5.3–7.2
Globulin (g/dL)	**6.2**	2.0–3.8

Serology and PCR

SNAP 4Dx positive and PCR positive for canine monocytic ehrlichiosis.

Fecal examination

Positive for hookworm eggs.

Dog 1

Interpretive discussion

Hematology

The dog has a mild microcytic anemia, suggesting iron deficiency anemia secondary to chronic blood loss. Serum iron was not measured. Leukocytosis due to lymphocytosis is present. Persistent lymphocytosis could be due to a neoplastic or benign expansion of lymphocytes, and considering that the dog is positive for ehrlichiosis, this is likely the cause of a benign lymphocytosis. A mild eosinophilia is present, likely due to parasitism, in this case hookworms (see fecal examination).

The electronic platelet count on Day 1 is erroneously low due to platelet clumping, which was observed on the blood film. When platelet clumping is present, the platelet concentration is difficult to estimate, and it is possible that the dog is thrombocytopenic or that the platelet concentration is actually normal. The total plasma protein by refractometry is persistently increased, likely due to hyperglobulinemia (see chemistry section). On Day 60, there is a discrepancy of 1.5 g/dL between the plasma protein estimate by refractometry and the protein concentration on the biochemical profile. Part of the difference is due to the presence of fibrinogen in the plasma, but the discrepancy is significant, and it is likely due to an error on the plasma protein estimate, possibly due to lipemia although that was not noted. On blood film examination, an increase in large granular lymphocytes was seen, which is a common finding in dogs with ehrlichiosis. Rouleaux was observed, which is associated with increased globulin concentration. Leukergy is also associated with high globulin concentrations. The top leukocyte histogram shows the lymphocytosis, and the bottom platelet histogram shows evidence of thrombocytopenia or platelet clumping (Figure 1). Clumped platelets can also be counted as lymphocytes on some hematology analyzers.

Chemistry

The only abnormalities are increased total protein concentration and increased globulin concentration. The hyperglobulinemia is likely due to chronic antigenic stimulation as a result of ehrlichiosis. A protein electrophoresis was not performed, but the gammopathy associated with ehrlichiosis is typically polyclonal.

Dog 2

Interpretive discussion

Hematology

The laboratory data are very similar to that of dog 1 (see above). One significant difference is that on Day 18, the dog had an inflammatory leukogram as evidenced by the neutrophilia and increased band neutrophils; toxicity of neutrophils was seen, which also indicates inflammation and early release of leukocytes, and a lymphocytosis was not present on that day. She had aborted a dead puppy the previous day, and the inflammatory leukogram is likely associated with inflammation in the uterus. The decrease in lymphocytes down to the reference interval is likely due to stress (cortisol) as a result of illness. As in dog 1, there is a significant discrepancy between the plasma protein estimate and the serum protein. The cause is not apparent, but again may have been due to the presence of lipemia if the dog was not fasted prior to sampling of blood.

Dog 3

Interpretive discussion

Hematology

The laboratory data are very similar to that of dog 1 (see above).

One significant difference is that the electronic platelet count is persistently decreased. The electronic count is erroneously low due to platelet clumping on Days 1, 60, and 90. However, the dog is also thrombocytopenic on Day 100 when no platelet clumping was observed. Ehrlichiosis commonly causes a mild to moderate thrombocytopenia, likely due to immune-mediated mechanisms.

Summary

Testing for canine monocytic ehrlichiosis is warranted in dogs with unexplained persistent lymphocytosis, particularly in endemic areas. The list of causes of persistent lymphocytosis in dogs is quite short and with few exceptions is due to either leukemia, thymoma, canine monocytic ehrlichiosis, hypoadrenocorticism, and very rarely, excitement. Gammopathy is also commonly associated with canine ehrlichiosis as seen in these three dogs, and is a result of an ineffective immune response to the organism. Although all dogs were treated with doxycycline for 2 months, the lymphocytosis and gammopathy persisted following therapy.

The gammopathy is typically polyclonal. Canine monocytic ehrlichiosis, first reported in 1935, is caused by *Ehrlichia canis*, a small, cocoid, intracellular Gram-negative bacteria transmitted by *Rhipicephalus sangineus*, a ubiquitous tick. Clinical signs and lesions of canine ehrlichiosis are related to the infection and immune response produced by the host, and frequently include thrombocytopenia and occasionally neutropenia. Anecdotal reports and the experience of some clinicians and clinical pathologists suggest that lymphocyte concentrations up to 30,000 cells/μL are possible in dogs with *E canis* infection. The lymphocyte response usually

consists of an increased percentage of cells with a large granular lymphocyte (LGL) phenotype, which have been shown to be CD8+ T cells. Therefore, an important differential for lymphocytosis in dogs is *E canis* infection, and unexplained lymphocytosis should prompt testing for ehrlichiosis. In our experience, approximately 15% of dogs with ehrlichiosis develop lymphocytosis.

Contributor: Dr. Mary Anna Thrall

Case 12

Signalment: 9-year-old male castrated beagle dog
History: Owner complaint of lethargy
Physical examination: Mildly enlarged peripheral lymph nodes, somewhat thin

Hematology		Reference interval
Plasma protein g/dl	7.3	6.0–8.0
PCV (%)	**32**	40–55
Hgb (g/dL)	**11.5**	13.0–20.0
RBC ($\times 10^6/\mu L$)	**4.80**	5.5–8.5
MCV (fL)	69	62–73
MCHC (g/dL)	35	33–36
Reticulocytes ($\times 10^3/\mu L$)	**49**	0–100
NCC ($\times 10^3/\mu L$)	**83.7**	4.5–15.0
Bands ($\times 10^3/\mu L$)	0	0–0.2
Neutrophils ($\times 10^3/\mu L$)	**16.7**	2.6–11.0
Lymphocytes ($\times 10^3/\mu L$)	**64.4**	1.0–4.8
Monocytes ($\times 10^3/\mu L$)	1.6	0.2–1.0
Eosinophils ($\times 10^3/\mu L$)	0.1	0.1–1.2
NRBC ($\times 10^3/\mu L$)	**0.8**	0
Platelets ($\times 10^3/\mu L$)	**139**	200–500
MPV (fL)	**11.4**	7.5–14.6

Hemopathology noted on blood film:
- Many of the lymphoid cells are large with fine chromatin and classified as prolymphocytes and lymphoblasts.
- No platelet clumps found.

Interpretive discussion

There is marked leukocytosis with the predominant abnormality being marked lymphocytosis. Further, the morphology indicates the presence of large lymphocyte forms. The magnitude of lymphocytosis is clearly interpreted as lymphocytic leukemia, with morphologic features of a blastic form that some would term "acute." There is a mild mature neutrophilia and monocytosis that is difficult to interpret. These could be related to steroid release, with neoplastic lymphocytosis masking the expected steroid-induced lymphopenia. Alternatively, there may be a compensated inflammatory stimulus. There is a disproportionate number of NRBC that may be related to either marrow and/or splenic injury associated with lymphoma/Leukemia.

The erythrocyte values indicate mild anemia. The anemia is poorly regenerative as indicated by the reticulocyte concentration. There is mild thrombocytopenia. The presence of two cell lines that potentially have decreased production along with evidence of leukemia suggests that marrow may be involved.

Summary

The pattern present is characteristic of lymphocytic leukemia. Cytometric analysis is recommended if treatment is considered.

Case 13

Signalment: 8-year-old DSH neutered female cat
History: Lethargy and anorexia for 3 days
Physical examination: Slightly dehydrated

CASES

Total bilirubin (mg/dL)	**1.1**	0–0.3

Interpretive discussion

Hematology

A leukocytosis is present due to lymphocytosis. The concentration of lymphocytes is very suggestive of leukemia, assuming that the cat was not excited. An excitement lymphocytosis can rarely result in a lymphocytosis of this magnitude. Examination of the blood film reveals that the lymphocytes range from 8 to 25 um in diameter and have scant to abundant pale to deep basophilic cytoplasm,

An image of the blood film is shown below (Figure 1).

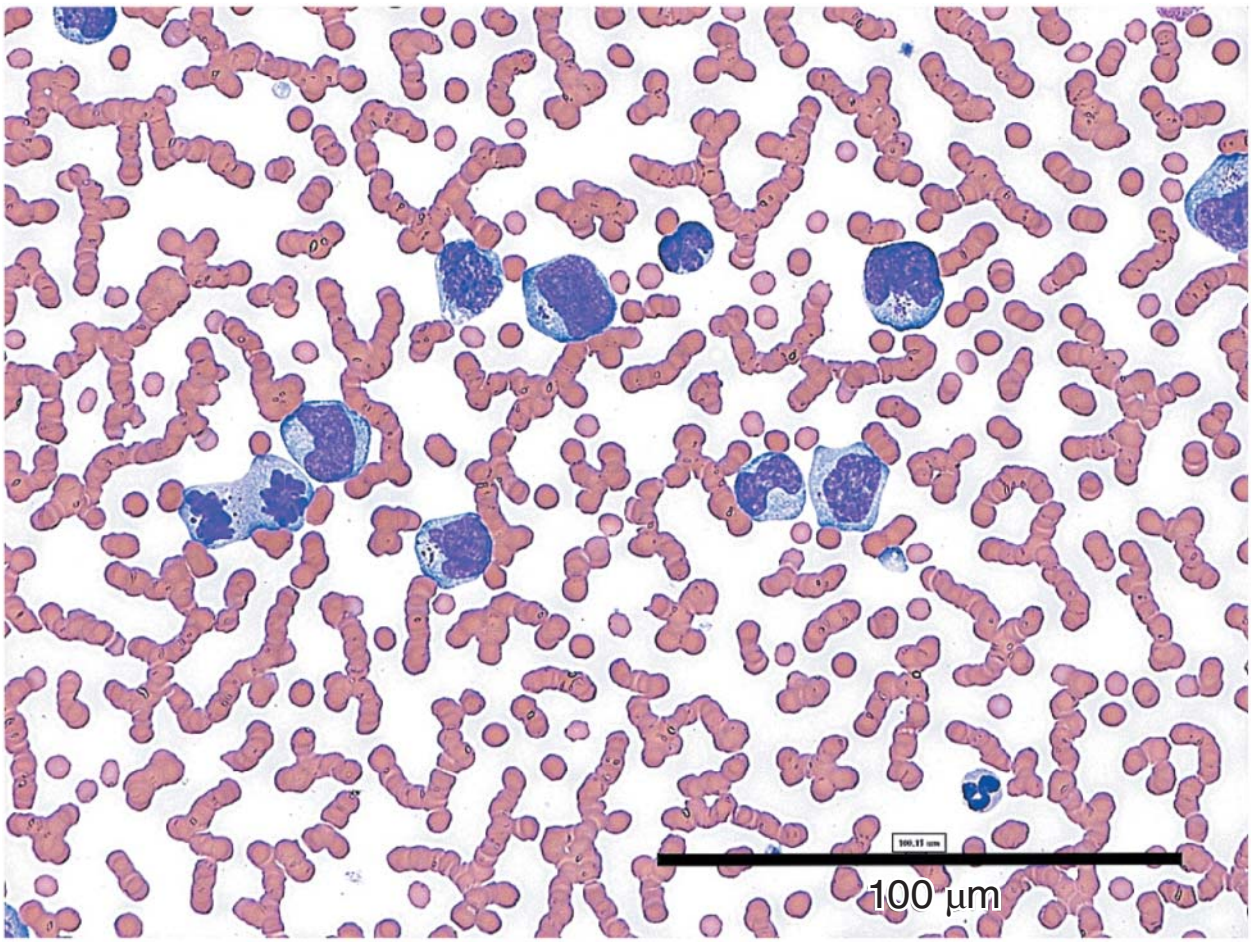

Figure 1 Almost all leukocytes are large granular lymphocytes. Note mitotic figure at left. Marked rouleaux is present.

containing round, small to large azurophilic, irregularly distributed granules, large pleomorphic nuclei with coarsely clumped chromatin and often prominent nucleoli. Cytoplasmic fragments containing azurophilic granules are occasionally observed as well as rare bizarre cells in mitoses. The granules in the lymphocytes are characteristic of those seen in large granular lymphocytes (LGLs).

Rouleaux is increased, which is typically due to increased globulin concentration, but the globulin concentration was normal in this cat.

Biochemical profile

The only abnormality was an increase in bilirubin. This is likely not due to increased erythrocyte destruction, as the PCV is normal. Liver disease or cholestasis remain as differentials, and without any other biochemical abnormalities, it would be difficult to determine which of these are resulting in the abnormality.

Summary and outcome

Flow cytometry of blood revealed that the neoplastic LGLs were CD3 and CD8 positive, indicating that they are T cells. Chemotherapy was instituted, and the lymphocyte concentration decreased for a period of time, followed by an increase to 64 000/μL, at which time severe anemia and thrombocytopenia were present. The patient's condition suddenly declined and the owner elected humane euthanasia. Autopsy was not performed.

Large granular lymphocytes (LGLs) are a morphologically distinct subset of lymphocytes characterized by intracytoplasmic azurophilic granules. LGLs are normally a minor component of blood lymphocytes but are the most common subset of lymphocytes in intestine. LGL expansion in dogs can be reactive and benign, such as seen with canine ehrlichiosis (see cases 10 and 11), or neoplastic, such as is seen in acute or chronic leukemias, and primary lymphomas. In cats, LGL neoplasia is usually aggressive, with a mean survival time of approximately 3 months. Almost all cats with LGL leukemia have neoplastic infiltrates in the intestine, most commonly the jejunum, and most also have infiltrates in the mesenteric lymph nodes and liver, and some have infiltrates in the spleen, kidneys, and bone marrow. The leukemia is usually secondary to the LGL intestinal lymphoma. Approximately 30% of intestinal lymphoma in cats have an LGL morphology, which may be missed on histopathology with H&E stains. The majority of cats with LGL lymphoma have increased serum bilirubin concentration, as did our patient, likely due to liver involvement.

Case 14

Signalment and history: 9-year-old male castrated dog presented for lethargy

Hematology		Reference interval
PCV (%)	**36**	37–55
RBC ($\times 10^6$/μL)	**5.42**	5.5–8.5
Hgb (g/dL)	13.2	12–18
MCV (fL)	66	60–72
MCHC (g/dL)	37	34–38
Retics ($\times 10^3$/μL)	0	0–60,000
NCC ($\times 10^3$/μL)	**96.4**	6.0–17.0
Metas ($\times 10^3$/μL)	–	0
Bands ($\times 10^3$/μL)	**7.7**	0–0.3
Segs ($\times 10^3$/μL)	**82.9**	3.0–11.5
Lymphs ($\times 10^3$/μL)	1.0	1.0–4.8
Monos ($\times 10^3$/μL)	**4.8**	0.2–1.4
Eos ($\times 10^3$/μL)	–	0.1–1.2
NRBCs ($\times 10^3$/μL)	–	0
Platelets ($\times 10^3$/μL)	**39**	200–500
TP (P) (g/dL)	6.2	6.0–8.0

Hemopathology: Decreased platelets, giant platelets, toxic neutrophils, numerous echinocytes, occasional schistocyte.

Interpretive discussion

Packed cell volume and hemoglobin are slightly decreased, indicating mild anemia.

Reticulocytes are not increased, indicating that the anemia is nonregenerative. Considering the inflammatory leukogram, this is most likely an anemia of inflammatory disease.

Marked neutrophilia with increased immature neutrophils and monocytosis is indicative of a chronic inflammatory leukogram.

Lymphopenia is indicative of a stress or steroid component to the leukogram.

Platelets are decreased. Thrombocytopenia is most commonly due to ehrlichiosis, immune-mediated thrombocytopenia or DIC. This should trigger other coagulation tests. The presence of giant platelets suggests that immature platelets are being released by the bone marrow, and the thrombocytopenia is not due to bone marrow dysfunction.

Summary

Anemia of inflammatory disease. Site of inflammation was a prostatic abscess. DIC was confirmed.

Case 15

Signalment: 4-year-old Doberman
History: Acutely ill, vomiting
Physical examination: Pendulous abdomen

[a] Had abdominal exploratory surgery the evening of Day 1; treated with fluids between Day 1 and Day 2.

Abdominal fluid analysis	
NCC (/μL)	**93 000**
TP (g/dL)	1.5

Cytology: 100% degenerate neutrophils; various types of bacteria phagocytized and extracellular.

CASES

Interpretive discussion

Hematology

Packed cell volume, Hemoglobin, Red blood cell count: Within or near reference intervals on Day 1, markedly decreased on Day 2 following blood loss that occurred at the time of surgery. Dog seemed to bleed excessively during the surgery, and given the breed, Von Willebrand disease should be investigated. Anemia may have also 'worsened' with aggressive fluid therapy resulting in hemodilution.

Reticulocytes are increased on Day 2, indicating that the anemia is regenerative. This regenerative response is earlier than is typically seen, in that reticulocytes do not usually increase until 24–72 hours following the onset of anemia.

Neutropenia is present on Day 1, with an increase in immature neutrophils, indicating in this case that the mature neutrophils are being consumed in an inflammatory process, and the marrow is not meeting the consumption demand. On Day 2, the mature neutrophils have increased, as have the immature neutrophils (bands and metamyelocytes). This indicates that the consumptive process has decreased (source of inflammation) or that the marrow has increased production, or both.

Lymphopenia is indicative of a stress or steroid component to the leukogram.

Platelets are mildly decreased on Day 1 and more markedly decreased on Day 2. While some platelets may have been consumed in clotting process secondary to surgery related blood loss, it is also possible that the animal has DIC, particularly with the history of excessive bleeding during surgery. This should trigger additional tests such as FDPs, PT, aPTT, and activated clotting time.

Total protein: Total protein is decreased on Day 1 and Day 2. In this patient, this is likely due to loss into the abdominal cavity on Day 1, compounded by blood loss on Day 2. Fluid administration may also be diluting the PCV and plasma protein on Day 2.

Biochemical profile

The serum glucose concentration is markedly decreased, both on Day 1 and Day 2. In this patient, considering the leukogram, this is most likely due to sepsis. Other differentials should include insulinoma, although this is a relatively young dog for an insulinoma.

The BUN is increased on both Day 1 and Day 2, and the serum creatinine is increased on Day 2. This may be either prerenal azotemia or renal azotemia. A urinalysis was not performed.

The serum calcium is decreased on both Days 1 and 2, due to the hypoalbuminemia.

The serum phosphorus concentration is increased on Day 2 and is compatible with decreased glomerular filtration rate.

The serum total protein concentration is decreased due to hypoalbuminemia on Day 1, and both hypoalbuminemia and hypoglobulinemia on Day 2 (see explanation above).

The serum bilirubin concentration is increased on Day 2, likely due to cholestasis related to septicemia.

The ALT and AST activity on Day 2 indicates hepatocellular injury, possibly related to anemia, shock, surgery, or septicemia.

The ALP activity is increased on Day 2, possibly related to endogenous corticosteroids or cholestasis.

Both sodium and chloride are decreased on Day 1, possibly due to loss of electrolytes into abdominal effusion, or loss due to vomiting.

Serum total CO_2 is decreased on Day 1, suggesting metabolic acidosis. This has been corrected by Day 2, likely due to fluid therapy.

The anion gap is increased on Day 1, likely due to lactic acid.

Abdominal fluid

The nucleated cell count is very high and all of the cells present are neutrophils, indicating suppurative inflammation or peritonitis. The total protein may be low because the serum protein is decreased, or it may he diluted in the large volume of fluid. The presence of different types of bacteria suggests that the source of bacteria is the gastrointestinal tract.

Summary

This dog had a consumptive inflammatory leukogram and hypoglycemia due to sepsis. On exploratory, the abdominal cavity contained 1400 ml of fluid, and a toothpick was found to have perforated the intestine. Dog died on the evening of Day 2 as a result of septic peritonitis.

Case 16

Signalment: 11-year-old female spayed border terrier dog

History: Owner noticed intermittent nose bleeds for a few days

Physical examination: Few petechial hemorrhages noted on mucous membranes, otherwise normal

Hematology		Reference interval
Plasma protein (g/dL)	**6.2**	6.0–8.0
PCV (%)	**24**	40–55
Hgb (g/dL)	**8.4**	12.0–18.0
RBC ($\times 10^6/\mu L$)	**3.34**	5.5–8.5
MCV (fL)	72	62–73
MCHC (g/dL)	35	33–36
Reticulocytes ($\times 10^3/\mu L$)	**149**	<60
NCC ($\times 10^3/\mu L$)	11.5	4.5–15.0
Bands ($\times 10^3/\mu L$)	0.1	0–0.2
Neutrophils ($\times 10^3/\mu L$)	9.0	2.6–11.0
Lymphocytes ($\times 10^3/\mu L$)	1.4	1.0–4.8
Monocytes ($\times 10^3/\mu L$)	0.7	0.2–1.0
Eosinophils ($\times 10^3/\mu L$)	0.1	0.1–1.2
NRBC ($\times 10^3/\mu L$)	0.2	0
Platelets ($\times 10^3/\mu L$)	**7**	200–500
MPV (fL)	**22**	7.5–14.6

Hemopathology noted on blood film:
- Moderate polychromasia.
- No platelet clumps found.
- Few macroplatelets on scanning.

Interpretive discussion

The erythrocyte values indicate moderate anemia. The anemia is regenerative as indicated by reticulocytosis, along with a few nucleated red cells. While the plasma protein concentration is seemingly normal, there is a reasonable probability it is decreased for this patient. The reason is that older dogs tend to have higher protein concentrations and 6.2 is regarded as low normal; the dog may have had a protein between 7 and 8 g/dL before bleeding occurred. The triad of anemia, regeneration, and decreasing protein is classical for blood loss.

The cause of the blood loss is thrombocytopenia. This magnitude of thrombocytopenia is expected to result in both petechial hemorrhages and blood loss that may not be physically visible.

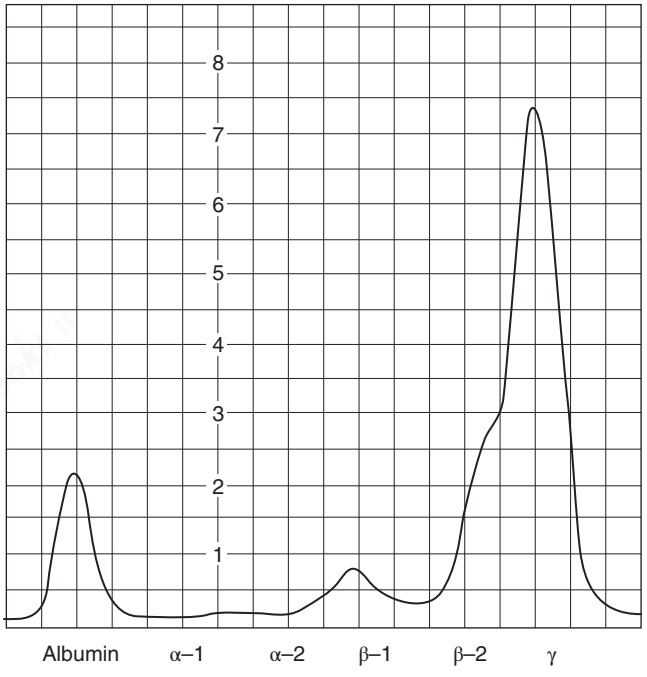
Examination of the data from the bone marrow perspective indicates that the marrow is producing erythrocytes (regeneration) and neutrophils appropriately. The thrombocytopenia present is therefore a selective, specific cytopenia. When present at this magnitude, typically less than $20 \cdot 10^3/\mu L$, immune-mediated thrombocytopenia is by far the most likely cause or diagnosis. Furthermore, the increased mean platelet volume (MPV) corroborated by macroplatelets on the blood film suggests accelerated marrow thrombopoiesis. This is the expected response to a consumptive thrombocytopenia.

Summary

The pattern present is characteristic of immune-mediated thrombocytopenia, with bone marrow response to hemorrhage.

Case 17

Signalment: 14-year-old castrated male mixed-breed dog
History: Polydipsia and polyuria, bloody diarrhea, weight loss
Physical examination: Lethargic, bilateral masses in perianal region



Hematology		Reference interval
Packed cell volume (%)	**33**	37–55
Hemoglobin (g/dL)	**11.1**	12–18
RBC (10^6/μL)	5.77	5.5–8.5

Serum protein electrophoresis tracing

Interpretive discussion

Hematology

There is a mild normochromic, microcytic anemia that appears nonregenerative (no increased polychromasia is noted on the blood film). A reticulocyte count should be done to confirm this. In a sick dog, anemia of chronic disease should be considered; however, anemia of chronic disease

is not usually microcytic. Given that the dog has bloody diarrhea, iron deficiency due to GI blood loss should also be considered as a cause of the microcytosis.

The lymphopenia suggests a stress/steroid response, although the expected neutrophilia is not observed. The slight thrombocytopenia is not clinically significant. Marked rouleaux seen on the blood film is related to the markedly increased plasma protein concentration (discussed further below).

Biochemical profile

The increased total protein concentration is due to marked hyperglobulinemia. This degree of hyperglobulinemia is usually caused by lymphoid neoplasia (such as multiple myeloma) but can also be seen with ehrlichiosis in dogs. A serum protein electrophoresis is indicated to evaluate for monoclonal versus polyclonal gammopathy (discussed later), and evaluation for tick-borne diseases should be pursued. The albumin concentration is moderately decreased, which may be from decreased production in response to the hyperglobulinemia. However, there is also evidence for urinary protein loss that may be contributing to the hypoalbuminemia.

The other significant abnormality present is hypercalcemia. Since this dog has palpable perianal masses and adenocarcinoma of the anal sac is a common cause of paraneoplastic hypercalcemia in dogs, aspiration cytology or biopsy of those masses should be performed. Hypercalcemia may also accompany lymphoid neoplasia, which is another possible differential in this dog based on the hyperglobulinemia. Ionized calcium could be measured to confirm the hypercalcemia but was not done in this case.

The slight increase in ALP suggests induction due to cholestasis or steroids. Decreased bicarbonate concentration with a normal anion gap is consistent with a secretional metabolic acidosis, and can be explained by the diarrhea (GI loss of bicarbonate).

Urinalysis

The urine is in the isosthenuric range, which can be explained by the hypercalcemia. Hypercalcemia interferes with ADH action in the renal tubules, preventing adequate urine concentration and causing polyuria with polydipsia. The pH is acid, consistent with the metabolic acidosis. The 3+ protein is significant given the urine specific gravity and inactive sediment. A urine protein: creatinine ratio could have been performed but was not in this case. Possibilities for the proteinuria include a prerenal proteinuria due to glomerular overload (paraproteinuria associated with multiple myeloma) or renal proteinuria due to glomerular disease.

Serum protein electrophoresis

There is a distinct monoclonal peak in the gamma region, suggestive of a neoplastic monoclonal gammopathy. However, some cases of canine ehrlichiosis have apparent monoclonal gammopathies, so further diagnostics are warranted to confirm lymphoid neoplasia.

Summary

The hypercalcemia was consistent with the clinical suspicion of anal sac adenocarcinoma, but the hyperglobulinemia suggested a second pathologic process. Fine needle aspirates of the perianal masses were consistent with anal sac adenocarcinoma, which was later confirmed by surgical removal and histopathology. Radiographs of the thoracic cavity showed no evidence of pulmonary metastases, however pathologic fracture of the right 6th rib was identified. Pending tickborne disease titers, a bone marrow aspirate was performed and was diagnostic for plasma cell myeloma (64% of marrow cells were plasma cells). An immunoelectrophoresis identified the paraprotein as IgA. Ehrlichial titers were negative. This dog was treated with melphalan and prednisone, and did well at home for about 1 year.

Case 18

Signalment: 14-month-old 23 kg male Belgian Malinois dog

History: Stung by approximately 200 honeybees 30 minutes prior to admission

Physical examination: Ataxia, vomiting, pruritis, and submandibular and ear edema on presentation. On Day 2 the dog exhibited severe ataxia, hematuria, hematemesis, and hematochezia.

Hematology	Day 1	Day 2	Day 4	Reference interval
Packed cell volume (%)	**60**	**36**	**14**	37–55

Plasma protein by refractometry (g/dL)	**8.5**	**5.2**	6.0	6.0–8.0

Plasma was red in color every day, indicating hemoglobinemia.
[a] Numerous degenerate neutrophils seen on blood film.
[b] Platelet clumping seen on blood film.

The only serum biochemical abnormality was an increased serum bilirubin on Day 2 (**0.8 mg/dL**; reference interval 0.1–0.6 mg/dL).

aPTT and PT were performed and were within normal limits.

Urinalysis (Day 2)

Color	**Red**
Transparency	**Opaque**
Sp. gr.	1.025
Protein	**2+**
Glucose	Neg
Bilirubin	Neg
Blood	**4+**
Sediment	Normal

Photomicrographs of blood films from Day 1 and 4 are shown in Figures 1 and 2.

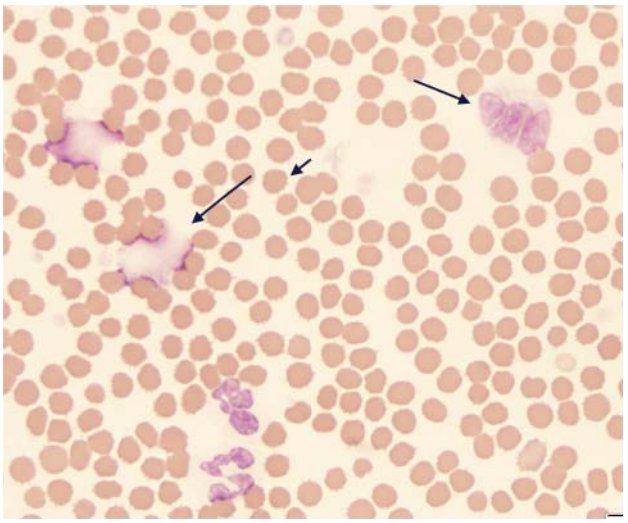

Figure 1 Blood film from Day 1. Note that all erythrocytes are echinospherocytes (small arrow). Degenerate neutrophils were numerous (large arrows).

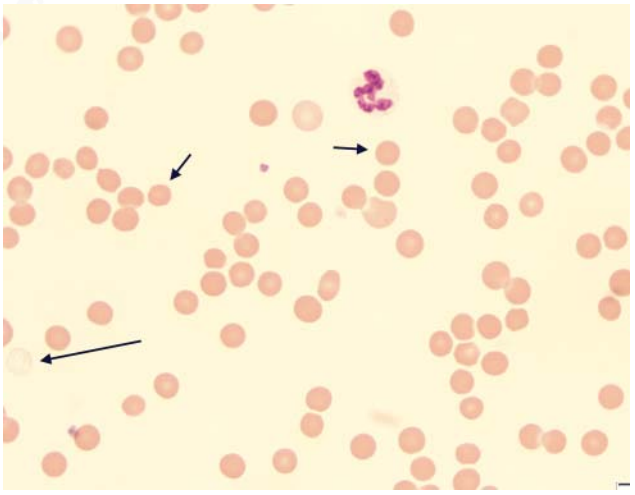

Figure 2 Blood film from Day 4. Note the lack of density of erythrocytes in the counting area, indicating severe anemia. Most erythrocytes are spherocytes (small arrows). Occasional lysed erythrocytes (ghost cells) are present (large arrow).

Interpretive discussion

CBC

The PCV is increased on admission, and echinospherocytes are present on the blood film. By Day 4, a marked hemolytic anemia is present, and spherocytes and lysed erythrocytes

are seen. Echinospherocyte and spherocyte formation has been reported with snake envenomation and bee envenomation. While spherocyte formation is usually associated with immune-mediated hemolytic anemia, it is likely that the spherocytosis and hemolysis associated with acute massive bee envenomation are not due to immune-mediated mechanisms. Two of the primary components of bee venom, melittin, and phospholipase A_2 (PLA_2), have been shown to induce hemolysis, both *in vivo* and *in vitro*, through a mechanism associated with echinocyte formation at low doses and spherocyte formation at higher doses. However, delayed hemolytic anemia could be due to antibody formation against altered erythrocyte membranes. The PLA_2 in bee venom is very similar to that found in snake venom and also causes type III echinocytosis and spherocytosis. The decreases in red blood count and hemoglobin concentration on Day 4 are also indicative of severe anemia.

The MCV is markedly increased on Day 1. Polychromasia was not present, suggesting that the increased MCV was due to erythrocyte swelling. The decreased MCV in our patient on Day 2 may have been due to the effects of melittin. In addition to spectrin stiffening, the changes in morphology could be due to leakage of ATP through melittin-induced pores; ATP depletion also triggers echinocytosis and spherocytosis.

The MCHC is erroneously increased on Day 4, likely due to hemolysis.

An inflammatory leukogram is present, as indicated by the neutrophilia on Days 1, 2, and 4, and presence of band neutrophils on Day 2 and 4 and metamyelocytes on Day 4. The monocytosis on Day 2 is also likely due to inflammation. A lymphocytosis is present on Day 2, possibly from antigenic stimulation.

The platelets are markedly decreased on Days 2 and 4. DIC was excluded as a cause based on the normal aPTT and PT. The thrombocytopenia may be immune mediated and has been previously described in dogs, horses, and humans with massive bee envenomation. However, it is also possible that platelet destruction occurs as a direct result of the cytotoxic effects of PLA_2 and melittin, both of which induce mitochondrial breakdown resulting in platelet apoptosis. Autoantibodies can be formed against altered platelet membranes, and an immune-mediated mechanism has been shown to be involved in the removal of apoptotic platelets. Thrombocytopenia is also often associated with rattlesnake envenomation.

The plasma protein is increased on Day 1, likely due to hemoconcentration. It is slightly below normal on Day 2 following fluid therapy.

Chemistry

The hyperbilirubinemia is compatible with increased erythrocyte destruction.

Urinalysis

Abnormalities include the present of protein and blood. Because of the normal sediment, and red coloration of plasma, the positive blood reading is due to hemoglobinuria.

Summary and outcome

Spherocytosis, hemolytic anemia and thrombocytopenia were associated with massive bee envenomation. Over 200 stingers were removed, and the dog was treated with IV fluids, glucocorticoids, antihistamine, a narcotic for pain, epinephrine, an H2 receptor antagonist, an antiemetic, and a cephalosporin antibiotic. The dog made a full recovery and the CBC was normal 1 month later.

Hematology

A marked anemia is present with no overt evidence of regeneration. Rather, the MCV is decreased and may be due to analyzer artifact due to the patient's hypo-osmolar state. More likely, the decreased MCV is due to iron deficiency commonly seen in neonates. Foals may remain microcytic up to 1 year of age [1]. An increased MCHC is not physiologically possible and reflects artifact, possibly due to hyperlipidemia. Causes for the anemia are not overt but concurrent hypoproteinemia could suggest blood loss, although a component of anemia of inflammatory disease, chronic renal failure or iron deficiency cannot be excluded. Serum iron is indicated.

An inflammatory leukogram is present and characterized by a marked neutrophilia with left-shift, toxic change and mild monocytosis. The marked neutrophilia is consistent with inflammation. Interestingly, the fibrinogen is within normal limits, which could indicate either excess consumption in DIC or decreased production with hepatic insufficiency, although there is minimal evidence of the latter.

Mild thrombocytopenia could reflect blood loss/hemorrhage or consumption due to severe inflammation (DIC). Consumption is also supported by the seemingly 'normal' fibrinogen considering severe inflammation, raising concern the fibrinogen along with platelets are being consumed in DIC.

Chemistry

A moderate azotemia is present and characterized by an increase in creatinine and disproportionate increase in BUN. This discrepancy may be due to decreased muscle mass (lower creatinine) or gastrointestinal bleeding (increased BUN). Notwithstanding, these changes indicate a decrease in GFR and could reflect prerenal (dehydration) or renal disease in this case. A urine specific gravity would be required to assess concentrating ability. Concurrent hyperphosphatemia is explained by decreased GFR but does not indicate the type of azotemia. Furthermore, in a growing animal such as this, increased phosphorus can be seen with bone growth.

The mild hypocalcemia is most likely due to decreased protein binding (hypoalbuminemia) and an ionized calcium is recommended to confirm this. If ionized calcium is also decreased, differentials to consider include sepsis and gastrointestinal or renal losses. The Ca × P product is calculated to be 99 mg/dL, indicating that soft-tissue mineralization may be occurring.

Hypoproteinemia is characterized by a hypoalbuminemia, which could be due to decreased production (negative acute phase protein), protein losing nephropathy or enteropathy, blood loss, and third spacing (effusions). A urinalysis with a urine protein to creatinine ratio may help rule in or out a protein losing nephropathy. A protein losing enteropathy is made less likely given the globulins are within normal limits, however, concurrent inflammation may be increasing the globulin into the reference range.

Decreased AST and GGT activities are unlikely to be significant. A very mild increase in CK activity is not clinically significant but could indicate mild muscle damage.

The most common cause of hypertriglyceridemia in horses, and the most likely in this case, is a negative energy balance leading to subsequent lipolysis and formation of VLDLs. While not mentioned in the history, this animal may have been anorexic in combination with the increased energy demand associated with massive inflammation.

The corrected chloride is calculated to be 96 mEq/l indicating a proportional hyponatremia and hypochloremia with differentials to consider including gastrointestinal losses (diarrhea), third spacing (cavitary effusion), or excessive free water gain (thirst response). Electrolyte losses through excessive sweating, while possible, are less likely given the potassium is within normal limits.

Decreased bicarbonate and an increased anion gap indicate a titrational metabolic acidosis with increased unmeasured anions. The most likely cause in this patient is accumulation of uremic acids and lactate. A lactate measurement is indicated.

Summary and outcome

Laboratory results reveal anemia, inflammation, possible renal disease and raises concern for DIC and sepsis. Additional testing in this patient should include a coagulation panel, urinalysis, blood gas and lactate measurement.

Despite medical management and aggressive fluid therapy, this patient failed to produce urine and died in hospital. Necropsy revealed necrotizing, suppurative pneumonia and enterocolitis. *Rhodococcus equi* was cultured from the lung abscess. Histopathology failed to reveal abnormalities in the kidneys; however, acute injury was still suspected.

Interpretive discussion

Hematology

A macrocytic hypochromic regenerative anemia present supported an increased reticulocyte count and the presence of anisocytosis and polychromasia on the blood film (Figure 1). In the presence of a regenerative anemia, the nucleated erythrocytes seen on the blood film are appropriate (i.e., consistent with a regenerative response). Differentials for a regenerative anemia include hemorrhage vs. hemolysis. Hemorrhage may be contributing to the hypoproteinemia in this case, although the hypoproteinemia is more severe than the anemia (see chemistry discussion). Additionally, there may be a hemolytic component in this patient with moderate icterus and only mild increases in ALP. Codocytes (aka. target cells) are increased in regenerative anemia in dogs. Transient echinocytosis occurs in dogs with envenomation of certain species of snakes (e.g., rattlesnake, coral snake, water moccasin, and asp vipers) secondary to the presence of phospholipases in the venom that causes ATP depletion. Other differentials not pertinent in this case include marked electrolyte abnormalities, marked uremia, glomerulonephritis, and some neoplasms.

An inflammatory leukogram is present characterized by a moderate neutrophilia with a regenerative left shift and toxic change. A moderate thrombocytopenia is present. As only a few small platelet clumps are observed, the platelet count is likely mildly to moderately decreased. The presence of a few giant platelets suggests a regenerative bone marrow response. Differentials include vasculitis, phospholipase-mediated aggregation and sequestration in the edematous limb, venom-induced consumptive coagulopathy (VICC), and disseminated intravascular coagulopathy (DIC).

Coagulation

The prolonged prothrombin and partial thromboplastin time in this case may be due to factor consumption secondary to venom-induced consumptive coagulopathy. In VICC the procoagulant clotting pathway is initiated by snake venoms at various places in the pathway (varies by venom), not tissue factor [1]. Additionally, it is not associated with systemic microthrombi and end-organ failure seen in DIC [1]. Thus, IVCC has a pathogenesis, mechanism of initiation, and outcome that is different than what is seen with DIC [1]. It should be noted that there are many hemostatically active toxins in snake venoms, and an individual snake's venom often contains many different toxins [1]. Some toxins are pro-coagulative and others anticoagulative, resulting in complex hematologic changes that may cause hemorrhagic diathesis and/or formation of macro- or microthrombosis that result in end-organ failure [1].

Biochemical profile and additional diagnostics

A severe panhypoproteinemia is present with relatively proportional decreases in both the albumin and globulin fractions. Differentials include hemorrhage, loss of plasma (vasculitis), hemodilution (overzealous IVF administration, use of plasma expanders, edematous disorders such as heart failure).

There is a marked increase in creatine kinase consistent with muscle injury and supports the clinical finding of puncture wounds with limb edema (i.e., recent trauma). Other potential contributors would include myositis and myonecrosis that are sometimes associated with rattlesnake envenomation [1].

A mild hypocalcemia is present and is consistent with hypoalbuminemia, and a mild hyperphosphatemia is present. This pattern has been associated with massive cellular lysis (e.g., myonecrosis, tumor lysis syndrome). The release of intracellular phosphorus drives the hyperphosphatemia. The extracellular phosphorus then binds to calcium, resulting in the pattern of hypocalcemia and hyperphosphatemia. An ionized calcium would be required to determine if a true hypocalcemia is present.

A marked hypocholesterolemia is present in this patient. It is an interesting finding that is associated with rattlesnake envenomation [1]. The mechanism is unknown; however, there are several speculations include lipoprotein leakage through capillaries, changes in lipoprotein transport, and increased lipoprotein metabolism caused by phospholipase activity [1].

There is a mild mixed hepatocellular pattern. The mildly ALT is increased by approximately 2.5× the upper reference interval (URI) indicating hepatocellular damage. In this case, the primary differential is hypoxic injury secondary to anemia. Additionally, a skeletal injury component should also be considered in this case, as the half-life of ALT is approximately 2–3 days in dogs. The ALP is approximately 1.5× the URI and in the presence of a moderate hyperbilirubinemia suggests a cholestatic pattern. The hyperbilirubinemia subjectively seems higher than expected with only mild increases in ALT. In this case, a prehepatic etiology (e.g., hemolysis) is a reasonable differential, especially as some snake venoms include hemolysins.

A mild azotemia is present characterized by a mild increase in BUN. This may represent resolving dehydration, or potentially a mild upper GI bleed.

The mild hypernatremia and hyperchloremia suggests free water loss (panting/hyperventilation, pyrexia), and/or iatrogenic (hypertonic saline administration).

The mild hyperglycemia is likely a glucocorticoid-mediated response to stress (in this case, likely pain).

Ancillary Testing

The marked increase in cardiac troponin-I (cTnI) is a sensitive and specific marker of myocardial injury and necrosis. The marked increase is consistent with myocardial injury. There are two proposed mechanisms, venom-induced myocardial injury (i.e., specific cardiotoxins) and myocardial injury occurring secondary to systemic inflammation [2].

Summary

The patient was admitted into the ICU and received IVF resuscitation (including hypertonic saline administration), multiple doses of antivenom, aggressive analgesia, antibiotics, and multiple transfusions (packed RBCs, fresh frozen plasma, and albumin). Shortly after this bloodwork was collected, the patient had a right forelimb amputation performed. He continued to be hospitalized with aggressive supportive care. Sadly, the dog went into cardiopulmonary arrest and died.

Case 21

Signalment: 14-year-old male-neutered domestic short-haired feline

History: Presented for investigation of persistent pancytopenia and progressive anemia. Had received two whole blood transfusions 3 weeks ago and immunosuppressive therapy. PCV initially responded but declined 2–3 days after, and the patient was discharged on symptomatic therapy. A probable hematopoietic (possibly histiocytic based on negative PARR and faint CD204 immunocytochemistry) neoplasm was diagnosed. A two-unit cross-match was performed prior to receiving an additional required transfusion. Both the patient (A) and donors (X and Y) were supposedly Type A.

Interpretive discussion

The results of the two-unit cross-match (Table 1) show compatibility between the recipient (A) and donor X, but not donor Y. Major cross-matching results indicate the recipient's serum does not contain antibodies against the donors' erythrocytes, however, minor cross-matching results between the recipient (A) and donor Y, suggest the presence of preformed antibodies in the serum of donor Y against the recipient's erythrocytes.

The history of prior transfusions is not responsible for this result. Since the major cross-matches were performed several weeks after the first transfusions and results against both donors were negative, the patient was probably not sensitized by prior transfusions. Furthermore, auto agglutination interference is ruled out based on a negative Auto Control result.

Despite the recipients and donors being previously reported as Type A, mis-typings can occur. However, since approximately 30% of Type A cats can have naturally occurring Anti-B antibodies and these tend to be weaker antibodies, the weak positive minor cross-match might suggest the donor Y is Type A and that the other donor, X, and the recipient are Type B. This is an unlikely scenario given the low frequency of Type B cats (<1% in DSH/DLH) [1]. In addition, all Type B cats have strong Anti-A antibodies by the time they are about 3 months old, so one would expect a very strong major cross-match reaction against donor Y.

Assessing both Tables 1 and 2 in conjunction, it is apparent that Donor Y is the animal of concern since there are

Table 1 Two-unit cross-matching results for recipient in question (A) and potential donors (X and Y).

Patient	Donor		Result (Macro)[a]	Result (Micro)[b]	Interpretation	Auto QC
A	X	**Major**[c]	Neg	Neg	Compatible	Neg
		Minor[d]	Neg	Neg	Compatible	
A	Y	**Major**	Neg	Neg	Compatible	
		Minor	Neg	3+	**Incompatible**	

Key:
[a]Macroscopic agglutination reaction.
[b]Microscopic agglutination reaction.
[c]Major cross-match.
[d]Minor cross-match.

Table 2 Historical cross-matching results for unrelated recipients (B and C) and potential donors (X, Y, Z).

Patient	Donor		Result (Macro)	Result (Micro)	Interpretation	Auto QC
B	Z	**Major**	Neg	Neg	Compatible	Neg
		Minor	Neg	Neg	Compatible	
B	Y	**Major**	Neg	Neg	Compatible	
		Minor	1+	2+	**Incompatible**	
C	X	**Major**	Neg	Neg	Compatible	Neg
		Minor	Neg	Neg	Compatible	
C	Y	**Major**	Neg	Neg	Compatible	
		Minor	2+	4+	**Incompatible**	

three different patients cross-matched against donor Y, and minor-side reactions occurred in each of them. The primary differential for this case is the presence of an antibody in the donor's serum against an antigen present on the patient's erythrocytes, such as Mik [2]. The other negative cross-match reactions make a common reagent issue, e.g., phosphate buffered saline (PBS), unlikely. Typing the donor and/or patient for the Mik antigen is no longer available. Human error in this case was unlikely as two different testers obtained similar results when cross-matching against donor Y.

Although donor Y was only minor cross-match incompatible, plasma is still present that might contain sufficient antibodies to agglutinate the patient's RBCs. The *in vitro* reaction was only at the microscopic level so it is not clear if this is strong enough to be clinically significant, however, historical minor cross-matching results did show microagglutination in recipients B and C (Table 1).

Outcome

The recipient received pRBC from donor X and initially tolerated this well but toward the end of the transfusion became febrile and lethargic. The transfusion was discontinued, and fluid therapy was reinstated along with administration of antihistamine. The cat become progressively hypotensive, hypoglycemic and pancytopenic. He also developed hyperbilirubinemia (1.2, then 3.1 mg/dL). Despite supportive care, patient continued to decline and was humanely euthanized 4 days later.

A transfusion reaction may have occurred and laboratory testing to assess this should include checking for data entry errors, examination of patient serum for increased hemolysis and serum icterus index or bilirubin over pretransfusion levels, Coombs testing on a fresh post-transfusion sample, and possibly re-typing and re-cross-matching.

Interpretive discussion

Hematology

The PCV decreased rapidly, and that in conjunction with hemolyzed plasma, suggests a hemolytic anemia. A blood film was not examined until later, at which time numerous Heinz bodies and a few spherocytes were seen, explaining the cause of the hemolysis. A Coombs test was performed because a differential at the time was Immune-mediated hemolytic anemia.

The increase in band neutrophils is indicative of an inflammatory leukogram, and the lymphopenia is indicative of a stress or cortisol leukogram. The neutrophilia may be due to both inflammation and stress.

Chemistry

Increased BUN and normal creatinine suggest decreased glomerular filtration rate (GFR) due to prerenal azotemia secondary to dehydration, or the increase could be due to bleeding into the GI tract. A third possibility is that the increase in BUN could be indicative of early kidney damage. A urine analysis was not performed.

Total bilirubin is increased, likely due to increased erythrocyte destruction, but liver disease and/or cholestasis could also be present.

The AST activity is slightly increased, which could be due to hepatic damage or muscle damage. The ALT is normal, suggesting that it is not due to hepatic damage, and the CK activity is not increased, suggesting it is not due to muscle damage. In this case, the increase is likely due to hemolysis, since AST is present within erythrocytes.

Alkaline phosphatase and GGT activities are increased, suggesting cholestasis since the bilirubin is increased, although most of the bilirubin increase is likely due to increased erythrocyte destruction. The cholestasis could be secondary to pancreatitis (see below).

Amylase and lipase activity are both markedly increased, and this increase is likely due to pancreatitis. Although both amylase and lipase are commonly increased in patients that are azotemic, this dog is only mildly azotemic, and the decreased GFR if likely not contributing significantly to the increases. Pancreatic lipase immunoreactivity was not performed in this patient.

Radiographs were taken on Day 2 (Figure 1).

Radiology

In a survey lateral abdominal radiograph there was a round metallic foreign body in the stomach. There is mild gaseous

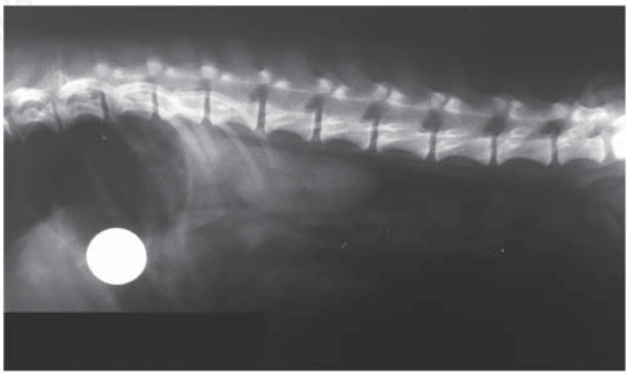

Figure 1 Lateral abdominal radiograph. Note the metallic foreign body in the stomach. Source: Image courtesy of Dr. Krystal Blair.

Figure 2 A corroded penny adhered to a dime; this was the origin of the metallic foreign body discovered in the abdominal radiograph. Note the erosion of the penny due to the action of gastric hydrochloric acid. Source: Images courtesy of Dr. Krystal Blair.

distension of the stomach but the degree of distension is not concerning for an obstruction without more fluid accumulation. From one view, it is not possible to determine whether this is a disc, such as a coin, or a sphere, such as a ball bearing. If the foreign body is discoid, a coin is the most likely identity. In DICOM images that are calibrated, it is possible to measure the diameter of a foreign body using the calipers of the viewing software. The approximate diameter of the most commonly used US coins, from small to large, is as follows: 10 cent – 17.9 mm; 1 cent – 19.1 mm; 5 cent – 21.2 mm; 25 cent – 24.3 mm. Measurement can assist in estimating whether the coin is likely to be a one cent piece, under which circumstance removal may be more urgent if the coin is in the stomach. In this dog, it was not possible to measure the coin preoperatively.

Summary and outcome

A penny and dime were surgically removed from the patient's stomach on Day 2 (Figure 2). Since 1983, United States Lincoln pennies are composed primarily of zinc (approximately 2440 mg of elemental zinc per coin) [1]. The LD_{50} of zinc is approximately 100 mg/kg. Acid in the stomach causes the release of free zinc, which is distributed to the liver, kidneys, muscle, bone and pancreas, where it has a direct corrosive effect on tissues. Pancreatitis is present in this patient and has been previously reported in dogs with zinc toxicosis [2]. Zinc has been shown to concentrate in the pancreas and be eliminated in pancreatic secretions. The necrosis and inflammation may be due to activation of intrapancreatic trypsinogen by zinc [3].

The cause of the Heinz body formation is theoretically due to zinc interference with glutathione reductase. Spherocyte formation can also be seen with zinc toxicosis, possibly due to altered antigenicity of erythrocyte membranes, or more likely due to direct damage of erythrocyte membranes by zinc. Zinc has also been reported to interfere with coagulation factor synthesis. An aPTT and PT were not performed in this patient.

Major histopathologic findings include hepatocellular centrilobular necrosis with hemosiderosis and vacuolar degeneration, renal tubular necrosis with hemoglobin casts, and pancreatic duct necrosis with fibrosis of the interlobular fat.

The patient required intermittent hospitalization and IV fluids for several weeks, and eventually made a full recovery. Prognosis for patients with zinc toxicosis is good if a prompt diagnosis is made, the source of zinc is removed immediately, and supportive therapy is instituted. In one series of 19 cases, 89% survived to discharge [4].

After saturation with ammonium sulfate solution the urine became clear.

Rothera test in urine: positive ++

Interpretive discussion

Hematology

The cow is moderately anemic, with macrocytosis and high MCHC concentration. While no reticulocyte count is available, macrocytosis due to acceleration of erythropoiesis and a regenerative anemia are likely in this case. Considering the increased MCHC, which may be falsely increased due to a false increase in hemoglobin due to the presence of free hemoglobin, one should suspect an intravascular hemolytic anemia.

Neutropenia along with hyperfibrinogenemia in a ruminant suggests acute inflammation, as neutrophils are being consumed in the inflammatory process and fibrinogen is an acute phase protein.

Chemistry

Increased NEFA and BHB, indicating negative energy balance and lipid mobilization, which is a frequently observed during the transition period (less than 21 days before calving until 21 days after calving) of high producing dairy cows. BHB measurement in blood is the gold standard test for diagnosing ketosis and the observed value (1.2) indicates a subclinical ketosis (values within 1.0–2.4 are considered to be subclinical ketosis). Subclinical ketosis is related to decreased milk yields, mastitis, and metritis in dairy cows.

Hypocholesterolemia during the transition period is frequently associated to low dry matter intake, although it can also be related to a liver dysfunction.

Hyperproteinemia due to hyperglobulinemia suggests inflammation and/or active immune response to antigenic stimulation. Hypoalbuminemia is likely related to this protein being a negative acute phase protein, which decreases during inflammation. Hypoalbuminemia can also be observed during the early stages of lactation due to mobilization for milk production.

Blood urea nitrogen increase in dairy cows is frequently associated to negative energy balance, rather than due to decreased glomerular filtration. BUN is part of the rumen degradable protein (RDP) that is digested by the rumen microbiota. Lack of energy prevents the rumen microbiota from digesting the RDP, and consequently the excess of BUN is directed to the blood and milk. An increased BUN in a dairy cow presenting with increased NEFA and BHB should be interpreted as negative energy balance.

Hypophosphatemia is frequently associated with the high demands during lactation in high producing dairy cows, especially if the dietary phosphorus supplementation is not adequate. Phosphate is an essential component of ATP, the energy source of the cell. ATP is required for normal red blood cell membrane integrity. An intravascular hemolysis is the most severe side-effect of hypophosphatemia and occurs when serum concentrations of phosphate are severely decreased, as observed in this case.

The low GPX activity indicates Selenium (Se) deficiency, likely related to insufficient supplementation on the diet. Selenium is found in the soil and taken up by plants at different levels. A continual dietary supply of Se in cattle is essential in areas where the soil is deficient. Se is an antioxidant and a component of the GPX enzyme that inhibits

and destroys naturally occurring peroxides that cause cell damage. Se deficiency can predispose to hemolysis and white muscle disease, among other syndromes in cows. Se deficiency is also related to decreased milk production, as observed in this case.

The GDH activity increase is likely related to liver injury due to overload, which is a common finding in high producing dairy cows during the early lactation.

Urinalysis

Brown colored urine can be observed due to hematuria, hemoglobinuria or myoglobinuria. Absence of color change after centrifugation suggests hemoglobinuria or myoglobinuria. The clearance of the brown color after saturation with 80% of ammonium sulfate confirms the presence of hemoglobinuria, as the reaction precipitates the hemoglobin.

A positive result in the Rothera qualitative test in urine indicates the presence of acetone and acetoacetate (ketone bodies), confirming the subclinical ketosis.

Summary

A postparturient hemoglobinuria with intravascular hemolytic anemia due to hypophosphatemia was diagnosed in this dairy cow. The syndrome has been recognized in a few high-producing dairy cows fed low phosphate rations. It is observed sporadically in dairy cows up to 6 weeks postpartum associated with high milk production. It is characterized by an acute intravascular hemolytic anemia with hemoglobinuria. The first sign of the disease is seen when affected animals present a red to brown urine. Its presentation has been associated to diets with low content of phosphorus, although in this case the low concentration of selenium could have worsen the clinical scenario. Deficiency of selenium or copper can also trigger postparturient hemoglobinuria in cows.

Furthermore, some plants have been incriminated on causing postparturient hemoglobinuria, and those include (i) sugar beet roots (mangels) and leaves, (ii) field crops such as green oats, perennial ryegrass, Egyptian clover, and alfalfa, and (iii) members of the genus *Brassica*, often referred to as cruciferous plants. In addition to their low phosphorus content (<0.4% dry matter) or high calcium to phosphorus ratio (>2 : 1), some feeds (e.g., rape, sugar beet, and kale) contain hemolytic substances. Hemolytic saponins from sugar beets or alfalfa may interact with a low serum phosphorus concentration to produce postparturient hemoglobinuria. It has also been postulated that phosphorus deficiency was a necessary predisposing factor and that feeding cruciferous plants precipitated the hemolytic crisis.

Differential diagnosis of hemolytic anemia in ruminants should include infectious causes such as *Babesia* spp., *Theileria* spp., *Anaplasma maginale*, and *Leptospira* spp.

Additionally, this cow presented with subclinical ketosis and liver injury frequently described in high producing dairy cows during the transition period. An acute inflammation is observed and could be a consequence of the hemolytic anemia, the negative energy balance and/or liver injury.

Suggested decision levels when reference values are unavailable or to offer another set of values are in parentheses.

Interpretive discussion

Hematology

The bird has a normal packed cell volume with the normal expected number of polychromatic erythrocytes; however, there is an increased number of immature erythrocytes (rubricytes). An inappropriate release of rubricytes in a nonanemic bird in the absence of a significant polychromasia is suggestive of lead poisoning, myeloproliferation, or myelodysplasia.

Chemistry

The plasma creatine kinase (CK) activity is markedly increased, indicating skeletal muscle injury or exertion. The degree of increased plasma aspartate aminotransferase (AST) activity is also likely associated with skeletal muscle involvement rather than hepatocellular disease. A much higher degree of AST activity would be expected with hepatocellular disease: however, one cannot completely rule out coexisting hepatocellular disease based on plasma CK and AST activities alone.

Whole body radiographs revealed multiple small mineral and metallic objects in the ventriculus. Blood heavy metal analysis revealed a whole blood lead concentration of 1.5 ppm with an expected normal <0.2 ppm and zinc concentration of 0.39 ppm with an expected normal <2.0 ppm. These findings were indicative of lead poisoning and the cause of the inappropriate release of immature erythrocytes in the peripheral blood as well as hematuria, a common finding on physical examination of psittacine birds with lead poisoning.

Chelation therapy for lead poisoning was performed (CaEDTA treatments on 5 days on, 5 days off cycle). Following two treatments the bird's strength returned and it was no longer exhibiting ataxia. After 21 days, the bird's blood profile was normal, and no hematuria was seen.

Heavy metal poisoning is a common disorder of pet birds. Sources of the heavy metals include paint, stained glass, soldered metals, curtain weights, fishing weights, cages (antique, homemade, imported), wine foil, metal pipes, and hardware, such as nuts, bolts, and screws. Clinical signs of acute heavy metal toxicity include weakness, depression, hematuria, abnormal droppings, and central nervous system disorders, such as seizures and ataxia. Clinical signs of chronic heavy metal toxicity include weakness, weight loss, vomiting, hematuria, and central nervous system disorders, such as seizures and ataxia.

Interpretative discussion

Hematology

There is anemia that is regenerative as evidenced by the significant reticulocytosis and polychromasia. Anemia in combination with low total protein suggests that the cause is blood loss. There is a mixed inflammatory and stress (steroid) leukogram evidenced by the neutrophilia with band neutrophils, monocytosis, and absence of lymphocytes and eosinophils. The thrombocytopenia in conjunction with the large platelets suggests increased consumption and production of platelets.

Biochemical profile

Hypocalcemia corrects into the normal range, and thus is due to hypoalbuminemia. Hypoproteinemia is due to blood loss. The hyperbilirubinemia may result from increased erythrocyte destruction or cholestasis. Increased alkaline phosphatase activity supports cholestasis. Very mild hyponatremia and hyperkalemia are probably insignificant in this case.

Urinalysis

The urine specific gravity is isosthenuric, but the urea nitrogen is normal, so the specific gravity may not be significant. Water deprivation and ensuing specific gravity would determine renal function reserve. Hyperbilirubinuria is a consequence of hyperbilirubinemia.

Coagulation data

Decreased platelets, prolonged ACT, PT, aPTT, and increased FDPs support disseminated intravascular coagulation. Erythrocytes may be destroyed during disseminated intravascular coagulation, thus contributing to elevated total bilirubin.

Summary

The mass was diagnosed as malignant histiocytosis, with nodules in the liver, spleen, mediastinum, and peripheral lymph nodes at necropsy. A likely scenario is that extensive tumor mass developed necrosis and/or inflammation that triggered hypercoagulability leading to disseminated intravascular coagulation. Involvement of liver likely explains the hypoalbuminemia and other liver changes.

Case 26

Signalment: 5-month-old female dog

History: The puppy bleeds excessively when it loses teeth

Physical examination: The mucous membranes were pale. There is moderate bleeding evident at the site of a recent tooth loss.

aPTT (seconds)	>**120**	9–11
Fibrinogen (mg/dL)	200	100–400
Bleeding time (minutes)	3	1–5

Interpretative Discussion

Hematology

The anemia is regenerative as the reticulocyte count is increased and there is polychromasia and anisocytosis on the blood film. The cause of anemia is not determined but is likely due to hemolysis or blood loss since it is regenerative. The clinical findings of hemorrhage suggest that blood loss is the cause. Thrombocytosis is common in iron deficiency anemia. Microcytosis is evident in chronic iron deficiency, and may contribute to anisocytosis. Size of erythrocytes is not known, since the MCV is not provided. Serum iron and iron binding capacity would be useful in determination of the cause of anemia. The neutrophilia, left shift, and monocytosis indicate an inflammatory leukogram. Lymphopenia is indicative of a concurrent stress/steroid mediated response.

Coagulation data

The coagulation profile suggests a deficiency of one or multiple coagulation factors in the intrinsic pathway. Platelet concentration is increased in number, and no large forms are seen in peripheral blood. Bleeding time is normal, and in the face of adequate platelet concentration, indicates that platelet function is normal. The most common cause of a severe coagulopathy with normal platelet concentration, normal hepatic enzyme activity, and a prolongation of the aPTT with normal PT is factor 8 deficiency. The occurrence is less common in females, and to have an affected female requires that the sire also be affected.

Summary

This dog was tested for factor 8 plasma activity and was found to have 21% of normal activity, which is diagnostic for factor 8 deficiency or hemophilia A. This is compatible with the major abnormalities in the ACT and aPTT and the clinical description of bleeding in a young dog.

Case 27

Signalment: 7-year-old female Walker hound

History: The owner noticed a swelling on the right front leg on the day of admission

Physical examination: The mucous membranes were pale. There was a subcutaneous swelling in the right ventral thoracic area, with some dried blood on all four legs.

CASES

Interpretive discussion

Hematology

The anemia is nonregenerative as the erythrocyte indices are normal and the reticulocyte count is normal. The plasma and serum protein are low, with equal deficiency of globulin and albumin, suggesting blood loss as the cause of anemia. The anemia is likely too acute for there to be a regenerative response. Aspiration of the subcutaneous mass confirmed the presence of blood. Mild neutrophilia, monocytosis, and lymphopenia are indicative of a stress leukogram.

Biochemical profile

The protein changes discussed above indicate subacute blood loss, with fluid shifting and dilution of plasma protein resulting in anemia and hypoproteinemia. The mild decrease in sodium and potassium are insignificant.

Coagulation data

The coagulation data indicates either a deficiency of multiple coagulation factors, or a single factor deficiency of the common pathway. Platelets are normal in number, and, no large forms are seen in peripheral blood. Bleeding time is normal and in the face of normal platelet concentration, indicates that platelet function is also normal. The most common cause of a severe coagulopathy with normal platelets and normal hepatic enzyme activities is vitamin K antagonism.

Summary

This dog was exposed to diphacinone, a rodenticide that is a vitamin K antagonist; coagulation times returned to normal following administration of vitamin K.

Case 28

Signalment: 2-month-old female horse
History: Off feed
Physical examination: Depressed, evidence of diarrhea

Interpretive discussion

Hematology

There is a marked anemia. While it is not unusual for neonatal animals to have a "congenital anemia" due to iron deficiency, the PCV is much lower than is typically encountered by this physiological change. The presence of anisocytosis leads one to suspect that there may be a regenerative response, for which evaluation of the MCV and RBC histogram would be useful. The presence of nucleated erythrocytes in the peripheral blood is uncommon in horses but occasionally seen in foals with profound regenerative responses, or with damage to the bone marrow endothelium, as might occur with sepsis. Combined decreases in PCV and serum proteins may indicate hemorrhage. There is a marked thrombocytopenia, which may be due to decreased production or increased consumption; thrombocytopenia

is severe enough to be resulting in blood loss. Refer to the discussion of the coagulation profile for more on this matter.

Biochemical profile

The BUN, serum creatinine, and phosphorus concentrations are increased, but the nature of this azotemia cannot be definitively differentiated without a urinalysis.

There is hypocalcemia and hyperphosphatemia. This combination of mineral abnormalities may be seen in nutritional secondary hyperparathyroidism due to excessive dietary phosphorus. However, higher serum phosphorus concentrations are commonly observed in growing animals, and hypocalcemia may also be due to uptake by widespread damaged tissues, decreased intake with anorexia, or to an apparent decrease due to hypoalbuminemia.

Serum total protein concentration is decreased, including both hypoalbuminemia and hypoglobulinemia. Low serum albumin may be hepatocellular dysfunction or cachexia and decreased albumin synthesis. Alternatively, there may be pathologic albumin loss due to gastrointestinal or renal disease. Low serum globulin in a 2-month-old foal is not due to failure of passive transfer but may be due to decreased production, malnutrition, or pathologic loss. Loss of all proteins would be expected with hemorrhage, which could also account for the profound anemia. This is the most likely cause.

The serum total bilirubin concentration is increased, with only a mild increase in serum GGT activity. This may reflect hyperbilirubinemia of fasting in an equine anorexic patient. However, SDH activity is increased, indicating hepatocellular damage.

Serum sodium and chloride concentrations are decreased. This is commonly observed in young animals with an enterotoxigenic or secretory diarrhea. This may also be due to gastrointestinal stasis, a third space accumulation in the abdominal cavity, as well as to decreased intake. One would typically expect a hyperkalemia to occur in secretory diarrhea, owing to acidosis-induced intercompartmental exchange. Hypokalemia may be expected in third space syndromes, owing to potassium loss and renal decompensation. It is possible to observe normokalemia with concomitant potassium loss and metabolic acidosis, wherein redistribution of potassium from the intracellular to the extracellular fluid compartment obscures the whole-body potassium deficit. There is evidence in support of abdominal hemorrhage and third spacing due either to acute pancreatitis or a gastric ulcer (see below).

Marked lipemia is often seen in ponies with starvation and metabolic disease but is unusual in horses. In other species, hyperlipidemia may occur due to impaired triglyceride clearance associated with endotoxemia. One should consider other potential causes of hyperlipidemia such as pancreatitis. In this case, serum amylase activity is normal, but lipase activity may be increased. There is evidence of recent hemorrhage into the abdominal cavity, which could be related to acute pancreatitis, but is more often due, in diseased foals, to a bleeding gastric ulcer. The low calculated osmolality would be expected, given the hyponatremia and hypochloremia.

Blood gas data

There is an increased anion gap metabolic acidosis with respiratory compensation. This is consistent with a secretory diarrhea, complicated by hypovolemia and/or sepsis. If there were gastrointestinal stasis, one might expect an alkalosis. If there were a ruptured urinary bladder, one might expect a metabolic acidosis with hyperkalemia. The increased anion gap may result from sepsis, with hypovolemia and lactic acidosis due to reduced tissue perfusion and/or the metabolic effects of endotoxemia. The decreased oxygen tension may indicate respiratory compromise as well.

Coagulation data

The prothrombin time is prolonged slightly, the activated partial thromboplastin time is normal, and the FDP concentration is in an intermediate range. These findings may indicate disseminated intravascular coagulation, particularly in light of the severe thrombocytopenia, wherein Factor VII levels are becoming depleted, thereby prolonging the PT, but other coagulation factor concentrations are adequate to maintain a normal aPTT. The concurrent observation of thrombocytopenia and findings consistent with blood loss anemia support a diagnosis of DIC with pathologic hemorrhage.

Summary

Enterotoxigenic *E. coli* diarrhea, pancreatitis, hepatitis, and DIC were findings confirmed at necropsy. On necropsy, the pancreas was 5 to 6 times normal size and the liver was swollen. Histopathology showed necrosis and inflammation of the pancreas, diffuse mesenteric steatitis, fat necrosis and fat saponification, inflammation of the liver with thrombi in central veins and associated focal ischemic necrosis. Inflammatory disease is often not reflected in equine leukograms.

Case 29

Signalment: 9-year-old 14 kg male Welsh corgi mix from Wisconsin

History: Stiff joints, shifting leg lameness for 1-week duration, severe pain over shoulder area, anorexia for 1 day

Physical examination: Pale mucous membranes, labored breathing. When sedated for radiographs, hematoma under tongue (see Figure 1) and bruising in axillary region were noted.

Interpretive discussion

Hematology

The dog has a normocytic normochromic regenerative anemic on Days 1 and 2, likely due to blood loss. On Day 2, the anemia is extremely regenerative as evidenced by the marked reticulocytosis. All measures of red cell mass are decreased.

An inflammatory leukogram is present, as indicated by the marked neutrophilia and presence of band neutrophils on Days 1 and 2. The monocytosis on Day 1 is also likely due to inflammation. A lymphocytosis is present on Day 2, possibly due to antigenic stimulation.

The thrombocytopenia may be partially due to blood loss, but blood loss would not account for this magnitude of thrombocytopenia. Other considerations should include disseminated intravascular coagulopathy (DIC), since aPTT and PT are prolonged. The dog is antibody positive for Lyme disease, which has infrequently been associated with thrombocytopenia in dogs. Other differentials should include immune-mediated thrombocytopenia. A lack of production of platelets is not likely, considering the bone marrow is functional as indicated by the regenerative anemia and neutrophilia. Warfarin toxicosis (see below) has been associated with mild to marked thrombocytopenia in dogs. The mechanism is not known but is apparently not due to DIC [1].

The plasma protein estimate is slightly decreased on Day 1, likely due to blood loss.

Serology

The dog had antibodies to *Borrelia burgdorferi*. Lyme disease has infrequently been associated with thrombocytopenia and arthropathy [2, 3], and because the dog was from an endemic area, an initial tentative diagnosis of Lyme disease was made. However, the majority of dogs from endemic areas are antibody positive, with a small percentage having active infections [3].

Chemistry

The only abnormalities present were a decreased total protein and albumin, likely due to blood loss in this case. However, proteinuria, while likely from hematuria, could be the cause of the hypoalbuminemia, and a urine protein:creatinine ratio should be considered.

Urinalysis

The urine contains 4+ blood as measured on the dipstick. Erythrocytes were seen on urine sediment, but not as many as would be suggested by the 4+ blood. Proteinuria may be associated with hematuria. Bilirubin and bilirubin crystals were present, more than usual with a serum bilirubin in the reference range. Bilirubin is likely from increased extracellular erythrocyte destruction following hemorrhage into tissues. Hematuria is consistent with bleeding in other areas, such as under the tongue.

Coagulation panel

The aPTT and PT are both prolonged on Day 1, and the PT is markedly prolonged on Days 1 and 2; PT is still slightly prolonged on Day 23. Differentials for prolongation of both the aPTT and PT, indicating defects in both the intrinsic and extrinsic and/or common coagulation pathways, include DIC, liver failure, and a lack of vitamin K dependent factors (II, VII, IX, X). The thrombocytopenia in conjunction with prolonged aPTT and PT could suggest DIC, and additional tests, such as D-dimers or fibrin degradation products, are indicated but were not performed. Liver failure was excluded as a differential because cholesterol, BUN, and bile acids were within the reference interval. Warfarin toxicosis remained a top differential, as it blocks vitamin K epoxide reductase that reactivates vitamin K_1. Without active vitamin K_1, factors II, VII, IX, and X have decreased clotting ability. The PIVKA (proteins induced by vitamin k absence or antagonism) test is sometimes used to confirm warfarin toxicosis [4] but was not performed in this case.

The aPTT and PT are both prolonged on Day 1, and the PT is markedly prolonged on Days 1 and 2; PT is still slightly prolonged on Day 23. Differentials for prolongation of both the aPTT and PT, indicating defects in both the intrinsic and extrinsic and/or common coagulation pathways, include DIC, liver failure, and a lack of vitamin K dependent factors (II, VII, IX, X). The thrombocytopenia in conjunction with prolonged aPTT and PT could suggest DIC, and additional tests, such as D-dimers or fibrin degradation products, are indicated but were not performed. Without active vitamin K_1, factors II, VII, IX, and X have decreased clotting ability. The PIVKA (proteins induced by vitamin k absence or antagonism) test is sometimes used to confirm warfarin toxicosis [4] but was not performed in this case.

Radiology

There is a lobular mass in the pharynx, dorsal to the hyoid apparatus (Figure 2). This in nonspecific, and also unusual, and the considerations would normally be a neoplasm or an inflammatory mass, but in this patient, this was a hematoma. There is also poorly defined swelling in the submandibular region and in the ventral aspect of the neck. These too are nonspecific, and the considerations are cellulitis/abscess and diffuse tumor, such as mast cell tumor, but in this patient, hematomas have to be considered. This is a very unusual distribution of hemorrhage due to a coagulopathy but illustrates that variation is commonly observed.

Summary and outcome

Additional history revealed that the dog had been exposed to diphacinone, a long-acting warfarin rodenticide, and had a previous history of diphacinone toxicosis. The dog was treated with 5 mg/kg vitamin K1 daily, divided in two doses, for 30 days, and recovered uneventfully. He was also treated with doxycycline for 1 month for Lyme disease, although probably unnecessarily. Aspiration to confirm the presence of blood in the joints would have been diagnostically useful to possibly explain the shifting leg lameness, which resolved following vitamin K1 therapy. Bleeding into joints in humans, as a result of warfarin therapy or inherited coagulopathies, has been reported to induce inflammation and joint pain [5, 6].

While an explanation for the marked inflammatory leukogram was not readily apparent, warfarin toxicosis has been reported to cause a leukocytosis and neutrophilia, possibly related to hemorrhage within tissues and resultant inflammation, but in some cases simply due to a stress leukogram [7, 8].

Interpretive discussion

Hematology

Hemoconcentration is indicated by the increased PCV and physical signs of dehydration. Mild neutrophilia, monocytosis, and borderline lymphopenia is interpreted as a stress leukogram.

Biochemical profile

There is a mild hyperglycemia, which may be due to a catecholaminergic or steroid stress response.

The BUN and serum creatinine concentrations are increased. See discussion of urinalysis below to explain whether the azotemia is likely prerenal, renal, or postrenal.

Hyperalbuminemia with hyperproteinemia indicates dehydration. In this case, hyperglobulinemia is also likely caused by dehydration.

There is a mild hypocalcemia in the face of hyperalbuminemia due to dehydration. Thus, serum calcium concentration is truly decreased. This is often seen in heat-stressed animals, subsequent to widespread tissue damage and precipitation of calcium salts in ischemic areas.

The small increase in serum ALT activity may not be significant, or may reflect some hepatocellular damage.

The hypernatremia, in concert with other signs of dehydration, indicates a hypertonic dehydration. This is commonly seen in heat-stressed dogs owing to increased insensible losses of water, in excess of solute, due to hyperventilatory evaporation.

The measured and calculated osmolality values are increased, consistent with hypertonic dehydration. However, the osmol gap is also increased, indicating the accumulation of unmeasured osmotically active solutes in the blood. The anion gap is likewise increased, and given the dehydration and probable tissue hypoperfusion, some degree of lactic acidosis is likely.

Blood gas data

There is a combined metabolic (decreased bicarbonate) and respiratory (increased pCO_2) acidosis. The metabolic acidosis results from lactic acidosis due to tissue hypoperfusion. The respiratory acidosis suggests compromised pulmonary function.

Urinalysis

The presence of 1+ proteinuria with a specific gravity of 1.011 indicates significant urinary protein loss. The fine granular casts indicate tubular epithelial damage. The isosthenuric specific gravity in the face of dehydration and azotemia, yet in the absence of electrolyte depletion, suggests renal disease as well. This is likely a case of acute renal failure secondary to heat stress. The presence of calcium oxalate crystals may have no importance, or may represent one potential route of calcium loss due to renal tubular damage associated with the hypocalcemia.

Summary

Heat stress, hypertonic dehydration, and acute renal failure. If one did not have the history given, or doubted its veracity, laboratory findings like these would strongly suggest antifreeze intoxication. One could analyze serum for ethylene glycol concentration to definitively rule this possibility in or out.

Interpretive discussion

Hematology

The nonregenerative anemia is secondary to chronic renal disease. Decreased erythropoietin production by the kidneys is a major factor leading to anemia in animals with chronic renal disease. The severity of anemia is unusual for chronic renal disease. Such anemias are typically of mild to moderate severity. Other causes of nonregenerative anemia should also be considered in this case.

The cause of the lymphopenia is increased blood steroid concentration associated with stress. The leukocyte response in not a typical steroid-mediated response in that a mature neutrophilia typically accompanies lymphopenia. It is likely that the animal's resting neutrophil concentration was low normal and it has approximately doubled due to the steroid influence.

Biochemical profile

The triad of BUN, creatinine, and phosphorus concentrations is markedly increased indicating decreased glomerular filtration. These products are passively filtered by the glomerulus, and any cause of decreased glomerular filtration will result in retention of these analytes in the blood. In light of the urine specific gravity in the isosthenuric range, primary renal azotemia is interpreted.

At least two mechanisms have played a role in causing the hypocalcemia. The phosphorus concentration is markedly increased, and the Ca · P product is 141. When this product exceeds 70, calcium and phosphorus precipitate in soft tissues, decreasing the serum calcium concentration. In addition, chronic renal disease may result in decreased activation of vitamin D by the kidneys (i.e., conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferoL). Decreased activated vita-

min D results in decreased absorption of calcium from the intestinal tract.

Urinalysis

A urine specific gravity in the isosthenuric range in an azotemic animal suggests an inability to concentrate urine. Animals with prerenal azotemia due to decreased renal perfusion (e.g., dehydration, cardiac insufficiency, circulatory shock) should be conserving water and concentrating urine. The urine specific gravity is a key to properly interpreting the cause of the azotemia in this case.

Urine sediment—Small numbers of leukocytes and erythrocytes are normal in urine. These numbers must be interpreted in light of the urine concentration and the technique used to concentrate the sediment. Leukocyte numbers may be slightly increased in this case, suggesting minimal inflammation in the urinary tract.

Summary

These data indicate chronic renal failure. Chronicity is suggested by the nonregenerative anemia, which would not be present with acute renal failure. Postmortem diagnosis in this case was chronic interstitial nephritis or end-stage renal disease. No lesions suggesting suppurative inflammation in the urinary tract were found.

Case 32

Signalment: 9-year-old intact female dog

Interpretive discussion

Hematology

A mild nonregenerative anemia (reticulocyte count is in the normal range) is present. This should prompt an evaluation for endocrine disease, renal disease, and chronic inflammatory disease as potential causes. In this case, chronic renal disease is probably the underlying cause. There is no evidence of inflammatory disease in the leukogram.

Biochemical profile

The azotemia indicated by increased concentrations of BUN, creatinine, and phosphorus should be classified as renal since urine concentration is not adequate (i.e., <1.030), suggesting a loss of renal concentrating ability.

The hypocalcemia is probably due to two factors. The calcium · phosphorus product is 75. When this product exceeds 70, precipitation of calcium and phosphorus in soft tissues can occur, and decreased serum calcium concentrations may result. In addition, activation of vitamin D by the kidney is decreased in chronic renal disease, resulting in decreased absorption of calcium from the small intestine.

The hyperphosphatemia is due to decreased glomerular filtration rate (GFR). In this case, glomerular disease has caused decreased GFR and subsequent hyperphosphatemia.

In light of the marked proteinuria, the most likely cause of the hypoproteinemia and hypoalbuminemia is renal protein loss, due to glomerular disease. The hyperglobulinemia most likely resulted from chronic antigenic stimulation. History of a previous abscess and subsequent lymph node enlargement are compatible with such antigenic stimulation (i.e., the original infection may not have been completely eliminated, resulting in chronic antigenic stimulation and hyperplasia in lymphoid tissue). Such chronic antigenic stimulation can predispose to some forms of glomerular disease.

Hypercholesterolemia is interpreted as a component of nephrotic syndrome. Nephrotic syndrome, a group of abnormalities that may be associated with serious glomerular disease, includes hypoalbuminemia, proteinuria, hypercholesterolemia and edema. In this case, edema was not observed; however, presence of the other three components is still suggestive of this syndrome. Edema is not likely to occur until the albumin is below 1.0 g/dl. The mechanism causing hypercholesterolemia in this syndrome has not been identified.

The cause of mild hyponatremia is not certain in this case. Renal Na loss is a possible cause. If edema were present, it is possible that dilution of extracellular Na in this fluid (third-spacing) could result in decreased serum Na concentration. Edema was, however, not evident in this case, and, even in animals with edema, hyponatremia is not common.

Serum amylase and lipase activities are commonly increased in animals with decreased GFR. Although other causes of increased activities such as pancreatitis could be considered in this case, the clinical presentation and other laboratory data are more compatible with decreased GFR resulting in mildly increased amylase and lipase activities.

Urinalysis

Urine concentrating ability is inadequate. If the azotemia in this dog were due to prerenal causes such as dehydration, cardiac insufficiency, or circulatory shock, urine specific gravity should be >1.030. The specific gravity suggests inadequate concentrating ability and primary renal azotemia. Postrenal azotemia is ruled out by the demonstration of a patent urethra via catheterization and by the absence of evidence of urine leakage into tissues or the abdomen. Lack of concentrating ability results from loss of nephrons and/or tubular damage. Both of these alterations are probably occurring in this dog. Although the disease is primarily glomerular, severe damage to glomeruli results in secondary tubular damage and in loss of nephrons.

A 4+ protein in a moderately dilute urine and a urine protein/creatinine ratio (UPC) of 5.4 are evidence of severe proteinuria. In the absence of evidence of hemorrhage or inflammation (i.e., increased erythrocyte or leukocyte numbers in the urine sediment), a UPC >1.0 is abnormal in the dog, and a UPC >5.0 is indicative of glomerular disease. A UPC of >15 is diagnostic for glomerular disease.

Summary

Renal biopsy revealed amyloidosis. Chronic infection resulting in chronic antigenic stimulation probably predisposed the dog to this disease. The lymph node enlargement was most likely due to hyperplasia secondary to chronic antigenic stimulation. The combination of hypoalbuminemia, proteinuria, and hypercholesterolemia suggest imminent onset of nephrotic syndrome.

Interpretive discussion

Hematology

In light of normal values for other erythrocyte measurements, the slightly decreased MCHC is not significant. Mature neutrophilia and lymphopenia are typical of a stress leukogram. The basophils are not significant. Occasionally, nucleated RBCs may be found in the blood of normal animals. In the absence of anemia or other erythrocyte abnormalities, the few nucleated RBCs noted in this cat are not important.

Biochemical profile

The cat is hyperglycemic on Days 1 and 3. This abnormality could be due to severe excitement or stress with resulting increased epinephrine or corticosteroid levels, respectively. The leukogram is suggestive of stress. The presence of ketonuria on Day 1 suggests that diabetes mellitus should also be considered. Although this cat's blood glucose concentration on Day 1 is not above the renal threshold, detection of glucosuria on this day suggests that the cat may have had periods with higher blood glucose concentrations or that this cat has an abnormally low renal threshold for glucose.

The cat has an azotemia that progresses from mild to severe. Since urine specific gravity is high on Day 1, the azotemia on that day appears to be prerenal. Urine specific gravity is in the isosthenuric range on Day 3 and may be of renal origin; however, the cat had received fluid therapy, and this, rather than renal failure, likely caused the low urine specific gravity on this day.

Hypocalcemia progresses from mild on Day 1 to marked on Day 3. While ethylene glycol toxicosis may result in hypocalcemia and causes severe azotemia, rear leg paralysis and increased CK activity are not associated with ethylene glycol toxicosis. The Ca · P product on Day 1 is 67 on Day 1 and 79 by Day 3. Precipitation of Ca and P in the tissues may, therefore, be occurring on Day 3 and may, in part, explain the decreasing Ca concentration. Massive muscle tissue destruction, as evidenced by increased CK activity, may have resulted in calcium precipitation in damaged tissues and subsequent hypocalcemia.

Hyperphosphatemia resulted from decreased glomerular filtration rate. Maintenance of normal serum P concentration depends on normal glomerular clearance of P.

Total serum protein concentration was normal on Day 1 but decreased by Day 3. Although both albumin and globulin concentrations remained within reference intervals, concentrations of both of these proteins decreased due to fluid therapy and subsequent expansion of blood volume. In light of normal serum albumin and globulin concentrations, the significance of the hypoproteinemia is borderline.

Increased serum ALT activity suggests mild hepatocyte injury that progressed to moderate.

The combination of increased serum AST and CK activities indicates muscle injury. Since CK has a short half-life (less than 4 hours), the extremely high CK activity implies active muscle damage. AST is also present in hepatocytes, and hepatic injury is an alternate explanation for the increased serum AST activity, but, in light of the increased serum CK activity, muscle origin is most likely.

Hyponatremia on Day 3 may be due to renal loss (see fractional excretion results). Since hypochloremia is also evident, vomiting could also be a cause of Na loss. Hypochloremia on Day 3 may be due to both renal loss and vomiting.

Hyperkalemia on Day 3 may be due to several different causes. Since the cat is in renal failure, kidneys may not be excreting K normally. This cat also had a significant degree of tissue necrosis that could have resulted in release of K from dead or dying cells.

The increased anion gap suggests increased concentrations of anions such as ketones, uremic acids, phosphate, sulfate, or lactate. Ketones are not present in the urine of this cat on Day 3, and a significant ketosis is, therefore, not likely. Since the cat is severely azotemic, concentrations of uremic acids are probably increased. Serum phosphorus concentration confirms that increased phosphate is contributing to the anion gap. The final diagnosis suggested that this cat had significant tissue damage, and this probably increased serum sulfate concentrations. Hypoxia was also a component of this cat's disease; therefore, lactic acidosis was also occurring.

Urinalysis

The implications of the urine specific gravities were discussed in the interpretation of this cat's azotemia. The cat has proteinuria and hematuria on both days and pyuria on Day 1. These abnormalities suggest urinary tract inflammation. Cystitis or pyelonephritis are possible causes of this inflammation. The protein concentration decreased between Days 1 and 3, but this probably reflects the change in the concentration of the urine with more dilution of protein on Day 3. Both pyuria and hematuria probably contributed to the proteinuria. Other causes of proteinuria such as glomerular or tubular disease cannot be eliminated. The dipstick test for blood was equally increased on Days 1 and 3, but the RBC concentration decreased markedly between these days. This suggests that the positive test is due to either hemoglobinuria or myoglobinuria. In light of the apparent muscle injury (increased CK), myoglobinuria is most likely.

Glucosuria is marked on both days. On Day 3, this reflects a blood glucose concentration that exceeds the renal threshold. The glucosuria is more difficult to explain on Day 1, when the blood glucose is below the renal threshold. While it is possible that this cat has a lowered renal threshold, it is also possible blood glucose concentrations were fluctuating on Day 1 with periods above the renal threshold occurring.

Presence of a few granular cast suggests tubular damage.

The significance of the positive urine ketone reaction is considered in the discussion of hyperglycemia.

Fractional excretions of Na, K, P, and Ca are increased. This indicates abnormal reabsorption of these electrolytes and, in this case, is probably due to acute renal damage.

Coagulation data

The activated partial thromboplastin time (aPTT) is slightly decreased on Day 1 and probably reflects this cat's hypercoagulable condition. The mechanism of this change is not known but may be related to this cat's cardiac problem (see summary). This cat was treated with streptokinase between Days 1 and 3, and this treatment increases aPTT and PT, and return of aPTT to within the reference interval on Day 3 may

have resulted from this treatment; however, the absence of a longer PT on Day 1 as compared to Day 3 makes a significant effect of streptokinase treatment less certain.

Summary

Clinical diagnosis was restrictive cardiomyopathy with aortic thromboemboli (saddle and renal thrombosis and pulmonary thromboembolism). Restrictive cardiomyopathy predisposes to thrombosis. In this case, the thrombotic disease involved the kidneys and resulted in acute renal failure. In addition, hypoxia occurred in other tissues including the muscles of the rear legs. This resulted in increased serum activities of AST and CK. Necropsy examination was not performed.

Case 34

Signalment: 11-year-old FS canine
History: Weight loss and polyuria
Physical examination: Thin, slightly dehydrated

Interpretive discussion

Hematology

The PCV is marginally decreased, but without reticulocyte count it is difficult to classify the regenerative response. A marginal normocytic, normochromic anemia is observed in renal failure, for which there are other indications in the laboratory data.

The lymphopenia indicates a steroid response.

Biochemical profile

The serum glucose concentration is normal.

The BUN, serum creatinine, and serum phosphorus values are markedly increased. These findings are consistent with decreased glomerular filtration rate. However, one cannot differentiate the nature of the azotemia (prerenal, renal, or postrenal) based on these findings alone. Refer to the discussion of urinalysis results for further interpretation.

Serum total calcium is mildly increased, for which one should consider hypercalcemia of malignancy, hypoadrenocorticism, renal failure, vitamin D toxicosis, or primary hyperparathyroidism.

A significant increase in serum ALP activity and mild increase in GGT activity is consistent with cholestasis. Because AST and ALT activities are normal, there is not likely any hepatocellular damage. ALP and GGT activities may also be increased by corticosteroids.

Serum Na and Cl are decreased in concentration, while serum K is increased. The Na: K ratio is 23.2, which may indicate hypoadrenocorticism. Alternatively, renal disease may result in a functional hypoadrenocorticism due to

inability of the damaged renal tubules to respond appropriately to mineralocorticoids or may be due to a simple loss of sodium and retention of potassium because of renal disease and oliguria. The serum total CO_2 is decreased, indicating a metabolic acidosis, while the anion gap is increased, indicating the accumulation of organic anions. Acidosis may result in hyperkalemia as well.

The serum calculated osmolality is increased, predominantly because of the profound azotemia. Likewise, the increased anion gap is due to retention of urinary metabolic products.

Serum amylase and lipase activities are normal, and while not definitive, lessen the probability for pancreatitis.

Urinalysis

The urinary specific gravity is in the isosthenuric range, and there is 3+ proteinuria in the absence of significant hematuria or pyuria. The urinary protein: creatinine ratio is 11.1, which is significantly increased. The mild bilirubinuria is likely significant considering the low specific gravity. The coarse granular and waxy casts also definitively indicate renal tubular damage. Together with the marked azotemia, these findings support a diagnosis of renal disease.

Summary

Malignant fibrous histiocytoma of both kidneys identified at postmortem examination. This accounted for chronic renal failure.

Case 35

Signalment: 12-year-old quarter horse gelding
History: Losing weight and recently has loose stools
Physical examination: Thin to poor body condition, mild dependent edema all four limbs. Horse developed watery diarrhea during hospitalization.

Interpretive discussion

Hematology

The PCV, hemoglobin, and total RBC count are decreased, indicating a moderate anemia is present. It cannot be determined if the anemia is regenerative because reticulocytes are not released from marrow in the horse. Given the biochemistry profile the anemia is likely due to chronic renal failure (CRF). The mild to moderate degree of anemia fits with CRF as severe anemia is not seen with renal failure unless there is a second problem, e.g., blood loss. If this horse is dehydrated the anemia is more severe as are the protein losses. The plasma protein is markedly decreased, likely due to diarrhea and GI loss. There is severe, life-threatening leukopenia, neutropenia with a left shift and toxic changes in neutrophils. This is seen with acute diarrheal disease in horses due to endotoxemia and/or overwhelming sepsis. The bone marrow cannot meet demands and a likely source of the problem is enteric salmonellosis with or without septicemia.

Biochemistry profile

This horse has GI and renal disease, both appear to be severe. Marked azotemia, isosthenuria and hypercalcemia with hypophosphatemia are diagnostic for renal failure in the horse. Suspect chronic renal failure due to poor body condition, history, anemia, hypoalbuminemia, electrolyte abnormalities and an inactive urine sediment. Additionally, chronic renal failure is more common than acute renal failure in horses. UN and Ct are about as high as possible in a living patient; clearly this is not due to a prerenal cause. Isosthenuria confirms renal and postrenal is rare in an adult horse, especially one that is urinating, perhaps even with an increased volume of urine. Lesion in the kidneys is likely to be end-stage, small shrunken kidneys with fibrosis and little

to no chance of regeneration or long-term survival. Lesion may have started as glomerulonephritis or amyloidosis as hypoalbuminemia is moderate, but it can also be seen in severe chronic renal failure from any cause that compromises glomerular function. Peripheral edema is attributed to hypoalbuminemia and decreased colloidal osmotic pressure. Horses tend to develop peripheral edema rather than ascites with hypoalbuminemia.

Hypercalcemia and hypophosphatemia are only seen with renal failure in Equidae, all other species develop hyperphosphatemia even if hypercalcemia is present. The only other differentials for hypercalcemia and hypophosphatemia are a malignancy and primary hyperparathyroidism. Hypercalcemia of malignancy (HHM) is uncommon in horses but has been reported in horses with gastric carcinoma and lymphoma. Primary hyperparathyroidism is very rare in horses and would only be pursued if renal failure and HHM are ruled out first. All three differentials are associated with dilute urine due to inhibition of ADH by hypercalcemia. If mild or moderate azotemia is present with dilute urine in a horse with hypercalcemia and hypophosphatemia it can be difficult to distinguish HHM and chronic renal failure. The easiest diagnostic tests are to first search for cancer (enlarged lymph nodes and endoscopy to look for gastric SCC), rectal and/or ultrasound examination of kidneys to determine if they are small and shrunken. If this does not clarify, then consider protein creatinine ratio and/or fractional excretion of sodium, if <1% rule out renal, if >1% rule in renal. Always favor renal failure over HHM in horses.

Hyponatremia and hypochloremia can be attributed to chronic renal failure and/or GI loss; the latter is more likely. The hyperkalemia is severe and life threatening. This is unusual as adult horses tend to develop hypokalemia with GI disease but young horses with diarrhea will have hyperkalemia. The most likely explanation is metabolic acidosis even though it does not appear that severe in this horse. The pattern of hyponatremia and hyperkalemia can be seen with renal failure, urinary bladder rupture and hypoadrenocorticism. Decreased bicarbonate (TCO_2) is due to GI and/or renal loss. Increased anion gap is due to retained uremic acids, shock and anaerobic glycolysis with accumulation of lactic acid. Horses with diarrheal diseases usually have a metabolic acidosis as does this horse. Hypoalbuminemia and concurrent decreased serum globulin are due to GI disease, suspect salmonellosis. Hypoalbuminemia is moderate and more severe than the decrease in globulins, which may be due to renal loss of albumin in addition to the loss in GI tract. Proteinuria without blood is present in the urine and supports renal loss of albumin. Increased bilirubin is due to anorexia, which is the most common cause of icterus in horses. Although hepatic disease and cholestasis are possible explanations, they are too unlikely given all of the clinical and biochemistry data (liver enzymes WRI). The mild increase in GGT may be spurious rather than a true indicator of liver issues. GGT seems to increase in horses easily and is not reliable indicator of hepatic problems if increased without any increases in other hepatic parameters.

Increase in CPK is mild for a horse and is due to recumbency, it is too low to consider a primary muscle disease. The AST is WRI so it is not a muscle problem in which the CPK is decreasing while the AST is still increased. The urine is yellow, no evidence of brown color or blood, rule out myoglobin-induced renal damage with these values. Urine is not concentrated; a second check to confirm isosthenuria is usually recommended but in this case is not needed. Proteinuria with no evidence of hemorrhage or active sediment in an animal with hypoalbuminemia is due to renal loss. The proteinuria is more severe than 2+ since the urine is dilute. A protein to creatinine ratio could help assess the degree of severity but is not needed in this case, given all of the data. The few white and red blood cells are inconsequential, may be due to voided urine and the calcium carbonate crystals are normal for a horse.

Summary

Marked chronic renal failure and salmonellosis

Outcome

Horse was euthanized and chronic renal failure and salmonellosis were confirmed at autopsy. Initially the horse presented primarily for weight loss, while it was being evaluated it developed profuse diarrhea in the hospital. The horse was sick and stressed and likely had a recrudescence of salmonella. The horse may have been a carrier of salmonella.

Both kidneys were small, knobby and looked like irregular bovine kidneys due to marked fibrosis. Microscopically there was severe glomerulonephritis, chronic interstitial nephritis and even oxalate crystals in many tubules. The oxalate crystals were attributed to either being a horse or endogenous formation of oxalates, which happens in chronic renal failure in dogs and other species as well. It was not ethylene glycol toxicity. Glomerulonephritis was considered the primary lesion but it was difficult to determine if it preceded the interstitial nephritis. Pulmonary thrombi were present and one large thrombus was present in the pulmonary artery. These thrombi were likely due to hypoalbuminemia and decreased AT III (not measured), which lead to a state of increased coagulability. Pulmonary thrombosis associated with decreased AT III and glomerular lesions is seen most frequently, or documented most frequently in dogs.

Hypercalcemia and hypophosphatemia are present in some horses with renal failure, empirically, perhaps about one third. The pathogenesis is not known and multiple theories are postulated. These electrolyte changes will even occur with nephrectomy in the horse. Some horses may excrete excess dietary calcium (from alfalfa-rich diet) in the urine and retain phosphorus. Hypercalcemia is then

attributed to decreased excretion by the failing kidneys and hypophosphatemia to increased excretion. However, if the kidneys are removed it seems impossible to explain how they would develop hypophosphatemia. Certainly there cannot be increased renal loss because the kidneys have been removed, so it must be increased GI loss, but this is unproven. Many horses with chronic renal failure will have hyperphosphatemia and normo or hypocalcemia, similar to other species.

Case 36

Signalment: 6-year-old MC feline DSH

History: Approximately 1-month duration of intermittent weakness, exercise intolerance, poor hair coat

Physical examination: Cat is near collapse and approximately 10% dehydrated. There is definite cervical ventroflexion.

Interpretive discussion

Hematology

There is a mature neutrophilia and lymphopenia, indicating a stress leukogram. Other components of the hemogram are normal.

Biochemical profile

The BUN and serum creatinine concentrations are mildly increased. These findings are consistent with decreased glomerular filtration rate. However, one cannot differentiate the nature of the azotemia (prerenal, renal, or postrenal) based on these findings alone. Refer to the discussion of urinalysis results for further interpretation. The normal serum phosphorus and total calcium concentrations do not contribute to the characterization of renal disease.

Serum total protein and albumin concentrations are increased; this documents marked dehydration or hemoconcentration.

Serum CK activity is increased significantly and is indicative of muscle damage.

Serum Na and Cl concentrations are normal, but serum K concentration is markedly decreased. This is especially significant in light of the acidosis, which results in a shift of potassium from within cells to extracellular fluid and suggests a marked potassium deficit.

Blood gas data

There is prominent acidosis. This is due to a combined metabolic (decreased HCO_3) and respiratory (increased pCO_2) acidosis, with an increased anion gap. It would not be unusual for this degree of dehydration to lead to hypovolemia-induced lactic acidosis. It is also possible that this degree of hypokalemia may have caused sufficient respiratory muscle dysfunction to impair normal ventilation.

Urinalysis

The urinary specific gravity is in the isosthenuric range. Given the azotemia and normal serum Na and Cl concentrations, this indicates probable renal disease. However, hypokalemia can also impair ADH responsiveness by the kidneys, so that urine concentration should be evaluated following rehydration and K repletion.

The urinary FE_{Na} is 0.55%, which speaks against a generalized renal tubular disease. However, the. FE_K is 37.7%, which is markedly increased, especially for a cat with this degree of hypokalemia.

Summary

The combined observations of azotemia, hypokalemia, acidosis, and hyperkaluria in a cat with cervical ventroflexion and evidence of widespread muscle damage support a diagnosis of feline kaliopenic polymyopathy/nephropathy syndrome. In this case, it was completely corrected by dietary change (nonacidifying, higher K diet). This syndrome is no longer seen, as dietary imbalances in commercial cat food were corrected.

Interpretive discussion

Hematology

The packed cell volume, erythrocyte count, and hemoglobin concentration are decreased, indicating an anemia. Observed red blood cell morphologic abnormalities include acanthocytes and schistocytes. These may be observed when there is erythrocytic membrane damage due to free radical or lipid metabolic abnormalities, or when there is microangiopathic pathology due to vascular disease or neoplasia. Although a reticulocyte count has not been provided, the increased erythrocyte MCV and nucleated erythrocytes are consistent with a regenerative response. There are no other hematologic abnormalities.

Biochemical profile

Serum glucose concentration is normal, and its importance in the interpretation of the glucosuria is discussed below.

The BUN and serum creatinine concentrations are increased, while the serum phosphorus value is at the upper limit of the reference interval. These findings are consistent with decreased glomerular filtration rate. However, one cannot differentiate the nature of the azotemia (prerenal, renal, or postrenal) based on these findings alone. Refer to the discussion of urinalysis results for further interpretation.

The serum total calcium concentration is decreased. The ionized calcium concentration reported with the blood gas panel is likewise less than normal, indicating a true hypocalcemia. In this case, excessive loss of calcium in the urine is the likely cause (see urinalysis discussion).

Serum total protein, albumin, and globulin concentrations are within the reference interval. This observation suggests that there is not hemoconcentration due to dehydration, although a concurrent protein losing disorder might exist. Thus, the azotemia noted above is less likely due to dehydration, and more likely renal in origin.

Serum cholesterol is increased, whereas other indices of hepatic function are normal. There are no other indicators of a primary metabolic disease like diabetes mellitus, but it is possible, nevertheless, that this dog has hypothyroidism or hyperadrenocorticism.

The serum sodium and chloride concentrations are normal, yet there is hypokalemia. Possible causes in this case might include hyperadrenocorticism, chronic renal disease, or urinary potassium wasting associated with diuresis. Calculated serum osmolality is mildly increased due to the azotemia.

Blood gas data

Indices of acid-base metabolism (pH, pCO_2, HCO_3, and anion gap) are normal.

Urinalysis

Although the urinary specific gravity indicates some concentrating ability, one would expect this to be greater if the azotemia were prerenal in origin. It is also possible for the specific gravity to be increased by the presence of solutes, which do not contribute to renal concentration capacity (glucose, protein, amino acids). Concomitant determination of urinary. Osmolality (358 mOsm/L) confirms that the urine is not being adequately concentrated relative to the calculated osmolality of the serum. Inability to concentrate the urine may be due to central diabetes insipidus (a defect in hypothalamic/pituitary antidiuretic hormone release), or nephrogenic diabetes insipidus (ADH is released, but the kidney is unable to respond). The latter may be caused by anatomic pathology or functional impairment of renal tubular actions necessary to maintain a medullary concentration gradient and water reabsorption. This finding may indicate that the observed azotemia is renal in origin.

The presence of proteinuria on the dipstick was followed by a chemical determination of urinary protein concentration. When indexed to the urinary creatinine value, the urinary protein: creatinine ratio is 1.75. While this value is probably abnormal, it is not sufficiently high to indicate glomerular protein loss. Values in the range of 1.0 to 2.0 have been associated epidemiologically with tubular or inflammatory causes of proteinuria. The absence of significant numbers of leukocytes suggests there is no inflammatory disease. The presence of fine granular casts is indicative of renal tubular damage, and may explain the proteinuria.

Glucosuria concomitant to euglycemia may be explained by three mechanisms. (i) There is a Fanconi's-type syndrome wherein tubular malfunction leads to loss of glucose, protein, and other solutes that would otherwise be reabsorbed from the glomerular filtrate. This is supported by the findings of modest proteinuria and increased urinary fractional excretion of electrolytes. Fanconi's syndromes may be inherited (as reported in Basenjis and Whippets) or acquired (as reported following exposure to nephrotoxicants, including aminoglycoside antibiotics and heavy metals). (ii) There was an earlier episode of hyperglycemia that exceeded the renal threshold for glucose reabsorption, during which time the urine analyzed was produced. Depending on the rate of urine formation, a single void may represent blood chemistry-related changes for many hours prior to specimen collection. (iii) A laboratory error was made in the determination of either the serum glucose (improper preservation of the blood sample or analytical error) or the urinary glucose (cross-contamination of dipstick reaction squares by excess urine or operator error in interpreting the color change).

The FE_{Na} is 1.62%. This may be indicative of renal tubular disease or dysfunction due to mineralocorticoid deficiency or transport malfunction. The FE_{Ca} is 7.47%. This is particularly inappropriate given the hypocalcemia, and may well be the cause of calcium loss from the body. This may be indicative of renal tubular disease or dysfunction due to parathyroid hormone deficiency or transport malfunction. Increased urinary excretion of both of these electrolytes may be observed in renal failure (consider the azotemia and impaired urinary concentrating ability) or in Fanconi's syndrome, wherein proximal renal tubule reabsorptive function is impaired (consider the euglycemic glucosuria).

Summary

This is a case of congenital Fanconi's syndrome that did not resolve following supportive treatment for renal failure. Other tests one should perform include those that evaluate the parathyroid gland.

Interpretive discussion

Hematology

The nucleated cell count is mildly increased, but there is a neutropenia and marked lymphocytosis. Other hematologic parameters, including cell morphology, are normal. However, the concurrent observation of marked lymphocytosis and neutropenia should alert one to the possibility of lymphocytic leukemia, lymphoma with bone marrow involvement, or ehrlichiosis. The concurrent observation of marked lymphocytosis and hypercalcemia should likewise lead to consideration of lymphoma and humoral hypercalcemia of malignancy.

Biochemical profile

The BUN, creatinine, and phosphorus concentrations are mildly increased. These findings are consistent with decreased glomerular filtration rate. However, one cannot differentiate the nature of the azotemia (prerenal, renal, or postrenal) based on these findings alone. Refer to the

discussion of urinalysis results for further interpretation.

The serum total calcium concentration is markedly increased. In light of the lymphocytosis, humoral hypercalcemia of malignancy is most likely. PTH-rp could be measured to support this interpretation. The Ca · P product is increased at 109, indicating likely soft-tissue mineralization.

The serum total protein and globulin concentrations are slightly increased. Increased globulin concentration may occur in dogs with lymphoproliferative disorders.

The total bilirubin concentration is increased, as are the serum ALP and GGT activities. These findings are evidence of cholestasis. There are mild increases in the serum activities of ALT and AST, so there may be some hepatocellular damage as well.

The increase in serum potassium is probably due to redistribution of intracellular potassium to the extracellular space secondary to acidosis. The serum total CO_2 concentration is mildly decreased, indicating a metabolic acidosis. A complete blood gas panel is required to completely evaluate acid-base status.

Urinalysis

The urine specific gravity is in the isosthenuric range. The dog does not appear to be dehydrated, and it is possible for a normal dog to produce urine with a specific gravity in this range. However, this dog is azotemic. Dilute urine in the face of azotemia usually indicates renal disease, but hypercalcemia interferes with concentrating ability by antagonizing the actions of ADH. Hypercalcemia may also cause damage to the kidney, especially when phosphorus is concurrently increased. There is significant proteinuria of 2+ on the dipstick, and a UPC of 2.6. In the absence of significant sediment changes, this is indicative of renal protein loss, probably glomerular in origin. The FE_{Na} is 1.73%, indicating tubular dysfunction. Increased fractional excretion of Ca is expected given the hypercalcemia.

Summary

This is a case of lymphoma with hypercalcemia of malignancy and hypercalcemic nephropathy.

Case 39

Signalment: 9-year-old female dog
History: Polydipsia, polyuria
Physical examination: Mass in pelvic inlet

Biochemical profile		Reference interval
Gluc (mg/dL)	106	65–122
BUN (mg/dL)	8	7–28

Urinalysis	
Specific gravity	**1.014**

Interpretive discussion

Biochemical profile

Hyperproteinemia is due to hyperalbuminemia, indicating dehydration. There is marked hypercalcemia and this magnitude of increase is suggestive of hypercalcemia of malignancy or primary hyperparathyroidism. Hypercalcemia of this magnitude may result in renal injury leading to azotemia and loss of concentrating ability. A dehydrated animal should be maximally concentrating its urine, and this dog's urine is nearly isosthenuric. This could be consistent with renal disease (early, prior to development of azotemia), but hypercalcemia alone is sufficient to explain this abnormality (due to antagonism of ADH at the renal tubules).

A slight increase in alkaline phosphatase activity (ALP) suggests cholestasis or drug induction (corticosteroids, anticonvulsants). If cholestasis is present it is not of sufficient magnitude to affect the serum bilirubin. A more likely explanation for the increased alkaline phosphatase is increased bone turnover secondary to increased serum concentration of PTH or PTH-rp, which could be measured.

Summary

The mass in the pelvis was aspirated, and appeared neuroendocrine, rather than lymphoid. The mass was surgically removed and confirmed by histopathology to be an apocrine gland adenocarcinoma of the anal sac. Following surgery, the calcium normalized, but later metastasis to the lungs resulted in return of hypercalcemia. In contrast to the previous case, the hypercalcemia has not resulted in sufficient renal injury to cause azotemia.

Case 40

Interpretive discussion

Hematology

There is a stress leukogram indicated by mature neutrophilia and lymphopenia.

Biochemical profile

Increased glucose is compatible with stress identified in the leukogram. The BUN and creatinine are mildly increased, indicating azotemia. The urine specific gravity is less than what one would expect in a cat with prerenal azotemia, therefore renal azotemia should be considered. However, hypercalcemia alone can interfere with normal concentrating ability. With a calcium of 18 mg/dl, renal dysfunction is likely occurring due to soft-tissue mineralization. The total protein and albumin are increased, particularly for a young cat, indicating dehydration.

The calcium is markedly increased. Primary causes of this degree of hypercalcemia are hypercalcemia of malignancy, primary hyperparathyroidism, and hypervitaminosis D. Vitamin D toxicosis should be very high on the differential list, due to the age of the cat and the acute onset. Because of acidosis, ionized calcium is likely very high. Phosphorus is mildly increased. This could be in part due to the young age of the cat or may be due to decreased GFR. It is also seen with hypervitaminosis D. The Ca · P product is markedly increased at 171, which will result in calcification of renal tubules, lungs and other soft tissues.

Potassium is increased. This may be due to acidosis and an associated shift of K out of cells or the animal may be becoming oliguric. Increased anion gap indicates increase in unmeasured anions. Possible unmeasured anions are lactic acid or uremic acids. Increased phosphates are also adding to the anion gap.

Blood gas data

The pH is extremely decreased indicating severe acidemia. The pCO_2 is the major abnormality in the balance between bicarbonate and CO_2. Therefore, respiratory acidosis is the major component of the acidosis. The bicarbonate is also decreased indicating a component of metabolic acidosis is superimposed. Hypoxemia is also present. The combined hypoxemia and retention of CO_2 indicate a severe ventilation abnormality, probably due to calcification of lungs. The metabolic acidosis is probably a result of renal failure.

Summary

The cat was diagnosed with renal disease with severe acidemia, both metabolic and respiratory. The respiratory component may be due to calcification of lungs. Cholecalciferol toxicosis was diagnosed, as the cat had an opportunity to ingest a rodenticide containing cholecalciferol.

Case 41

Signalment: 3-year-old male cat
History: Acute lethargy, vomiting, and anorexia
Physical examination: Obese, almost comatose

Hematology		Reference interval

pH	5.0		

Interpretive discussion

Hematology

PCV is slightly increased. This is likely due to dehydration, considering that the albumin is also increased. The mature neutrophilia and lymphopenia are suggestive of a stress or corticosteroid leukogram.

Biochemical profile

The serum glucose concentration is increased. Differentials should include stress or corticosteroids, excitement and diabetes mellitus. Excitement is less likely than the others, since the cat does not have an excitement leukogram and there is glucosuria. (See summary for further discussion of hyperglycemia.)

The BUN and creatinine are increased, and considering that the cat is not concentrating its urine, this is most likely a renal azotemia. Since the cat is dehydrated, a prerenal component to the azotemia may be present as well. Because the cat is not anemic, is obese, and the history is acute, this is most likely acute renal failure. Phosphorus is increased due to decreased glomerular filtration rate.

The serum calcium is decreased. Considering that the cat likely has acute renal failure, the most likely cause of the hypocalcemia is formation of calcium oxalate crystals associated with ethylene glycol toxicosis. Oxalate is one of the metabolites of ethylene glycol and combines with calcium to form calcium oxalate crystals.

Hyperproteinemia is due to hyperalbuminemia, indicating dehydration.

The sodium is increased, likely due to dehydration. Chloride would be expected to increase with sodium but is selectively decreased in this case, probably due to vomiting of gastric HCl. This causes a hypochloremic alkalosis. However, TCO_2 is decreased and the anion gap is increased, suggesting concurrent metabolic acidosis and a mixed acid–base disorder. A blood gas would more fully characterize the acid–base status.

The increased anion gap indicates increased concentrations of anions other than those used in the formula to calculate the anion gap (chloride and HCO_3^-). In this case, uremic acids, phosphate, albumin, and most importantly, metabolites of ethylene glycol are probably contributing to the anion gap and a high-gap metabolic acidosis.

The calculated osmolality is increased, since the substances that are included in the formula to calculate osmolality are increased (glucose, urea, sodium, potassium). However, the measured plasma osmolality is much higher than the calculated osmolality, since a substance is present in the blood that is not used in the formula to calculate osmolality. The most

common cause of an increased osmole gap is the presence of ethylene glycol, which contributes to plasma osmolality due to its low molecular weight.

Urinalysis

The urine specific gravity of 1.016 in an azotemic dehydrated cat indicates that the cat is not capable of concentrating urine, and that renal dysfunction is present. The presence of calcium oxalate monohydrate crystals in a cat with acute renal failure is very suggestive of ethylene glycol toxicosis. The renal threshold for glucose has been exceeded, resulting in glucosuria. The 1+ proteinuria is probably significant in light of the low urine specific gravity and probably resulted from tubular damage.

Summary

The cat died, and necropsy revealed renal tubular necrosis and the presence of calcium oxalate crystals in the tubules due to ethylene glycol toxicosis. The cat had access to antifreeze shortly before it became ill. Approximately 50% of dogs and cats with ethylene glycol-induced renal failure have hyperglycemia, probably due to a combination of stress and the formation of aldehyde, a metabolite of ethylene glycol that interferes with glucose metabolism. While diabetes mellitus could cause hyperglycemia and metabolic acidosis, the presence of acute renal failure and calcium oxalate crystalluria should prompt consideration of ethylene glycol toxicosis.

Case 42

Signalment: 9-year-old intact male mixed-breed dog

History: Two-hour history of tremors and seizure-like activity, unable to stand; previously healthy; free-roaming dog

Physical examination: Recumbent, unable to stand, tacky mucus membranes, CRT <2 seconds

Hematology		Reference range

iCa (mmol/L)	**0.53**	(1.12–1.4)
Urine specific gravity	1.009	

Urine sediment: Many calcium oxalate monohydrate crystals.

Interpretive discussion

Hematology

The erythrocyte indices on the CBC and the appearance of the RBCs on the blood film appear within normal limits. There is a mild decrease in the MCHC, which is likely spurious (normal variant). A mild leukocytosis due to a mild neutrophilia with toxic change is consistent with inflammation. The lymphopenia and eosinopenia are likely due to increased endogenous glucocorticoids and are consistent with a stress component to the leukogram. While the mild neutrophilia may be also due to glucocorticoids, the toxic change suggests inflammation. The platelet count is within reference limits and likely slightly higher than the reported value, as a few platelet clumps are seen.

Biochemical profile and additional diagnostics

A severe azotemia due to a marked increase in serum creatinine and BUN is present, alongside poorly concentrated urine (isosthenuria) indicating a renal azotemia. Considering the history and the lack of anemia of renal disease, this is likely due to acute kidney injury (toxins, infectious organisms, ischemic injury). Additionally, it is likely the renal azotemia has a prerenal component. Most animals with isosthenuria are dehydrated as they cannot keep up with renal water losses. Dehydration is further supported by tacky mucus membranes noted on physical exam. The albumin is at the lower end of the reference interval in a dehydrated and may decrease below the reference interval with rehydration therapy. The most common cause of a mild hypoalbuminemia is acute inflammation (albumin is a negative acute phase protein).

A hyperphosphatemia and hypermagnesemia are also present. In the face of a renal azotemia, this is most likely due to a decreased GFR. In this particular case, the hyperphosphatemia may be also due to phosphate rust inhibitors found in antifreeze. A marked total hypocalcemia is noted on the chemistry and confirmed with an ionized calcium. Hypocalcemia has been reported in dogs with kidney disease due to renal loss. Additionally, calcium is being bound to oxalic acid, a metabolite of ethylene glycol, and excreted in the calcium oxalate monohydrate crystals found on urine sediment. The primary differential for calcium oxalate

monohydrate crystals in the presence of azotemia and hypocalcemia is ethylene glycol toxicosis.

The patient has a mixed acid-base status. A severe acidemia is noted on venous blood gas. There is a titration metabolic acidosis characterized by a low bicarbonate (metabolic acidosis) with a markedly increased anion gap (unmeasured ions). Common causes of an increased anion gap include lactate, uremic ions, ketones, and ethylene glycol toxicosis. In this particular case, uremic ions are likely a contributing factor; however, this is a substantially high anion gap to assign to kidney insufficiency alone. Ethylene glycol metabolites are probably contributing to the acidosis. Additionally, there is a disproportionate hypochloremia, consistent with a hypochloremic metabolic alkalosis. In dogs, this is commonly associated with gastric vomiting.

A mild hypoglycemia is present, which is unusual in patients with ethylene glycol toxicosis. Approximately 50% of dogs and cats with ethylene glycol toxicosis are hyperglycemic secondary to ethylene glycol metabolites interfering with glucose metabolism. Based on the physical exam findings, and the potential for somewhat prolonged seizure-like activity, an increased metabolic rate (i.e., increased glucose consumption) may be causing the hypoglycemia. Another consideration would be delayed sample separation and processing, as glucose continues to be metabolized by the cellular components of blood.

The mild increase in creatine kinase is reflective of mild muscle injury. In this case, it is likely due to seizure-like activity and tremors, or potentially in-hospital treatments (intra-muscular injection or inadvertent muscle penetration during venipuncture).

Summary

The patient was stabilized with intravenous fluid therapy and a calcium gluconate infusion. Based on the strong clinical suspicion of ethylene glycol toxicosis and an associated poor prognosis, owners elected humane euthanasia.

Interpretive discussion

Biochemical profile

The serum glucose concentration is slightly increased. This may be due to stress, although the leukogram is normal. Aldehydes, a metabolite of ethylene glycol (see later discussion), are reported to interfere with glucose metabolism.

The BUN and creatinine are normal in this dog that has a high serum ethylene glycol concentration. In dogs, azotemia begins between 24 and 36 hours following ingestion. The history suggests that this dog ingested antifreeze approximately 5 hours prior to the time of these laboratory data.

Phosphorus is markedly increased. Hyperphosphatemia may be due to the young age of the dog but is somewhat high for this. In this case the serum phosphorus increase was likely due to phosphate rust inhibitors present in most commercial antifreeze.

Serum alkaline phosphatase activity is mildly increased, likely due to the bone isoform that is increased in growing dogs.

The anion gap is increased, likely due to either phosphates or metabolites of ethylene glycol, which are anions. The calculated osmolality is slightly increased. However, the actual (measured) plasma osmolality is much higher than the calculated osmolality, resulting in a large osmole gap, since a substance is present in the blood that is not used in the formula to calculate osmolality. The most common cause of an increased osmole gap is the presence of ethylene glycol, which contributes to plasma osmolality due to its low molecular weight. This was confirmed by measuring serum ethylene glycol concentration.

Blood gas data

The blood pH is slightly low and HCO_3 is decreased, indicating metabolic acidosis. Metabolites of ethylene glycol are acids. Decreased pCO_2 is consistent with a compensatory respiratory alkalosis. The blood gases were determined about 1 hour following the biochemical profile, which probably accounts for the discrepancy between the HCO_3 determined on the biochemical panel, and that from the blood gas machine.

Urinalysis

The urine specific gravity of 1.012 in this patient is likely due to ethylene glycol causing osmotic diuresis. It is also possible

that concentrating ability has been impaired, but the animal is not yet azotemic.

Summary

The dog was treated with fomepizole, an alcohol dehydrogenase inhibitor, approximately 7–8 hours following antifreeze ingestion, and did not become azotemic. In contrast to the previous case, the biochemical profile is often not diagnostic in acute ethylene glycol poisoning, and other tests, such as serum ethylene glycol concentration or measured osmolality must be used to confirm the diagnosis. The acute onset of stumbling and stupor triggered suspicion of ethylene glycol toxicosis.

Case 44

Signalment: 5-day-old male foal
History: Foal was fine at birth, now will not eat
Physical examination: Acts colicky, seems constipated

Interpretive discussion

Hematology

There is a mild decrease in plasma proteins; concerned about failure of passive transfer of colostrum but globulins on chemistry panel are adequate.

Biochemical profile

Azotemia is present but there is no urine specific gravity to help determine if this is prerenal or renal azotemia. Recommend catheterization to collect urine and determine if the foal can urinate on its own. UN is mildly increased but creatinine (Ct) is moderately increased, the ratio of UN/Ct is 6. This can happen with recent fluid therapy and a more rapid decrease in UN than Ct, but no fluids have been administered. It could happen with a hepatic shunt and decreased synthesis of UN and with noncreatinine chromogens in horses and cattle. The latter is more likely but confuses the interpretation of the severity of the azotemia. The increase in phosphorus is consistent with a decreased GFR; prerenal, renal, or postrenal causes can do this.

The key abnormalities are the hyponatremia, hyperkalemia and hypochloremia. The Na:K ratio is low at 16 (see comments section). In a foal the most likely differentials are diarrhea, ruptured urinary bladder, renal failure, and hypoadrenocorticism due to a septicemia. There is no evidence of diarrhea at this time; renal failure is a possible explanation. To evaluate uroabdomen recommend abdominocentesis and determination of Ct (and/or UN) on the abdominal fluid and in a concurrent serum sample to compare Ct in abdominal fluid to serum; they should be equal if the bladder wall is intact. Ct (and/or UN) will be higher in abdominal fluid than serum if bladder has ruptured. Hypoadrenocorticism is unlikely; only pursue if other differentials are ruled out. Bicarbonate (TCO_2) is decreased, AG is high end of reference interval, and there likely is a metabolic acidosis, possibly due to dehydration and decreased tissue perfusion. ALP is mildly increased probably due to bone (growth) or liver source; does not seem important to pursue at this time. The bilirubin is increased, which could be due to a liver problem, but anorexia is the more likely cause (anorexia is the number one reason for hyperbilirubinemia in horses).

Abdominocentesis	
Clear, slight yellow color	
TNCC 8500/μL 50 : 50 neutrophils and mononuclear cells	
Total protein (refractive index) 2.8 g/dl	
Creatinine (mg/dL)	
Abdominal fluid	9.2
Serum	4.8

Summary and comment

Uroabdomen. There was a hole in the dorsal aspect of the urinary bladder. It was surgically repaired and the bladder wall appeared healthy at surgery. The foal recovered.

Rupture of the urinary bladder is usually caused by an obstruction (calculi) in males or excessive trauma (hit by car) in all species except horses. Typically, the problem is seen in male foals that appeared fine at birth but gradually develop anorexia and other problems. The male urethral lumen is small and apparently does not allow expulsion of urine easily enough during birth, and the back pressure caused by the mare's strong contractions during parturition causes the bladder to rupture. There are no calculi obstructing outflow. Usually there is a history of dribbling urine or that the foal

was seen to urinate. The hole is almost always located dorsally due to the musculature of the bladder wall and therefore patients may still urinate. If contrast dyes are used to determine bladder integrity, the dye may still be retained for the same reason. Comparison of abdominal Ct concentration to serum Ct is the diagnostic test of choice. Abdominal Ct does not have to be twice as great as serum Ct to rule in a ruptured bladder, it just needs to be several mg/dl higher than the serum Ct. If the bladder wall is intact the serum and abdominal Ct will be similar or identical. If the patient is not azotemic, then both samples will have Ct concentrations WRI, if the bladder wall is intact. If the patient has renal failure and is azotemic than the abdominal Ct concentration will be increased to a comparable value, if the bladder wall is intact.

The serum electrolytes and Na:K ratio of less than 20 are key to consider this differential diagnosis. In dogs the following are the four most likely differentials and the tests to rule in or rule out each differential for this electrolyte pattern:

Diagnosis	Test of choice
Hypoadrenocorticism	Basal cortisol; ACTH stim
Renal failure	Fluid therapy; complete UA; fractional excretion of Na
Uroabdomen	Compare abdominal and serum Ct concentrations
GI – whipworms, *Salmonella*	Fecal floatation; fecal culture

Case 45

Signalment: 7-year-old male intact mixed-breed canine
History: Presents for icterus, vomiting, diarrhea, and lethargy
Physical examination: Dull but responsive, markedly icteric, and 10–12% dehydrated

Sediment: Low numbers of erythrocytes, leukocytes, occasional squamous cells and the rare granular cast.

Interpretive discussion

Hematology

A mild microcytosis and hyperchromasia is indicated by the hematology analyzer and is most likely an artifact secondary to hyponatremia or hypochloridemia. The patient is not anemic making iron-deficiency unlikely. A falsely decreased MCV is an artifact of the Sysmex (and potentially other) analyzers, that is caused by a hypo-osmolar environment *in vivo* (hyponatremia) to which red cells adjust by increasing cytoplasmic water content. When put in a diluent, osmosis results in water loss, causing cell shrinkage (low MCV and high MCHC).

Low numbers of codocytes (target cells) are usually a nonspecific finding. They have been reported with liver disease and is the most likely cause in this case with unrelated differentials being iron deficiency, regenerative anemia, and congenital dyserythropoiesis, although target cells can be seen in many conditions, including health.

A mild leukocytosis characterized by a mature neutrophilia, low-normal lymphocyte count, monocytosis and eosinopenia is consistent with a stress response. There is also a likely component of inflammation that is supported by the degree of monocytosis, the presence of reactive lymphocytes, and the mild hyperglobulinemia noted in the chemistry (see below).

The platelet count is within the reference interval; however, a few giant platelets are observed and are suggestive of bone marrow stimulation.

Mild hyperproteinemia by refractometry is discrepant with the biochemistry analyzer and likely secondary to the increased BUN. Proteins will be further discussed in the chemistry. Moderately icteric serum supported by the hyperbilirubinemia is unlikely to be secondary to severe hemolysis as the patient is not anemic.

Chemistry

A mild hyperproteinemia characterized by a mild hyperglobulinemia is present. If the patient is clinically dehydrated, the protein concentration may decrease after restoring fluid balance. Hyperglobulinemia in an adult dog is suggestive of either an inflammatory or neoplastic (lymphoma, multiple myeloma) etiology.

Marked increase in ALT (~10× the upper reference interval) is indicative of hepatocellular injury and differentials to consider include:

- Infectious agents. Leptospirosis is the primary differential in the presence of renal insufficiency. Other potential infectious agents include canine adenovirus-1 (CAV-1), which is typically seen in unvaccinated dogs under the age of 1.
- Hepatotoxins such as NSAIDs, amanita phalloides ("death cap"), psago palm, blue-green algae, aflatoxins, xylitol, etc.
- Hypoxic injury; ischemia secondary to thrombi, congestion.
- Neoplasia.

There is a concurrent marked increase in ALP (~10× over upper reference internal) and moderate-to-marked increase in GGT, which most likely reflects biliary tract disease. Elevation in GGT activity can also be attributed to renal insufficiency as the enzyme is excreted in urine.

The is a marked hyperbilirubinemia with an associated bilirubinuria. Typical pathomechanisms to consider are hepatic and posthepatic causes of icterus with prehepatic

being unlikely in the absence of anemia. Given the increased ALT activity, hepatic jaundice is most likely and may be due to defective uptake of unconjugated bilirubin or impaired excretion.

A marked azotemia with inadequately concentrated urine (<1.030) is suggestive of renal azotemia, although a prerenal (dehydration) component is also likely. The marked hyperphosphatemia and a mild hypermagnesemia is consistent with a decreased GFR. Hemolysis may be a minor contributing factor. Mild hypocalcemia may be due to sepsis, decreased vitamin D production, increased renal excretion or tissue mineralization. The Ca × P product is 218 (well above 70) meaning that mineralization of tissues is occurring. Renal injury is also supported by the presence of rare granular casts in the urinalysis. Given the RBC concentration is within reference limits (absence of anemia), acute renal injury is more likely than chronic. Differentials to consider for the acute renal injury include infectious agents (leptospirosis), toxins (NSAIDs, ethylene glycol) and ischemic injury.

There is a hyponatremia and marked hypochloremia that may be due to both renal and gastrointestinal losses. The corrected chloride is 76.7 mmol/l and indicates selective chloride loss due to vomiting in this case. Bicarbonate is within the reference interval; however, there is a markedly increased anion gap consistent with titration acidosis and most like due to uremic ions or lactate. In the presence of diarrhea, loss of bicarbonate may also be contributing to metabolic acidosis. While the potassium is within reference intervals, there may be transcellular shifts out of cells (inorganic acidosis) and into cells (metabolic alkalosis) as well as renal and gastrointestinal losses that are masked by the complex acid-base disturbances.

A mild hyperglycemia is present and could reflect stress (epinephrine or cortisol mediated) or acute pancreatitis.

Urinalysis

Urine specific gravity is inadequately concentrated and is suggestive of renal insufficiency (discussed in chemistry). The aciduria (pH 5.5) in this case is paradoxical (given the hypochloremic alkalosis) and can occur when severe dehydration is present. There is marked bilirubinuria, particularly given the relatively dilute urine and this secondary to hyperbilirubinemia (although bilirubinuria typically precedes hyperbilirubinemia).

The 2+ Heme result in combination with the observed erythrocytes is indicative of hematuria. Differentials to consider include acute hemorrhagic renal injury, inflammation or iatrogenic causes.

A true proteinuria is present and is unlikely to be explained solely by the 2+ Heme result. Typical pathomechanisms to consider for proteinuria are prerenal (hypertension, pyrexia), renal (nephropathy, glomerulopathy), and postrenal (cystitis).

Summary

This patient had a leptospirosis SNAP test, which was negative. Further testing for leptospirosis may have included a microscopic agglutination test (MAT) or PCR.

He was hospitalized with IVF and supportive care for 24 hours and discharged from the hospital with a presumptive diagnosis of leptospirosis.

Interpretive discussion

Hematology

The packed cell volume, hemoglobin, and red blood cell concentration are all proportionally decreased consistent with a moderate anemia. The low-normal MCV and lack of polychromatophilia is consistent with a nonregenerative or preregenerative anemia, despite the mildly decreased MCH and MCHC. The mildly decreased MCH and MCHC is suspected to be a spurious finding in this case. The leukogram is overall unremarkable. There is a marked thrombocytopenia that is supported by findings on the blood film. Differentials include a consumptive process (e.g., DIC, vasculitis), platelet destruction (e.g., ITP), or potentially bone marrow disease as a nonregenerative anemia is also present.

Biochemical profile

There is a marked azotemia characterized by a marked increase in BUN and a moderate increase in creatinine. Although a urine specific gravity is not available, the azotemia is severe enough to be a renal azotemia. Additionally, the BUN is disproportionately increased with respect to the creatinine, suggesting a prerenal component (dehydration). The other potential consideration would be poor muscle mass, which may mask the severity of increase in creatinine.

A marked hyperphosphatemia is present, likely representing a decreased glomerular filtration rate (GFR) in this patient. This marked increase is roughly proportional to the increase in BUN, further supporting the diagnosis of renal disease. The calcium is within reference limits; however, the product of the calcium and phosphorus exceeds 100; therefore, soft-tissue mineralization is occurring and likely accelerating the kidney injury. A marked hyperkalemia

is present, and most likely secondary to decreased renal excretion (oliguria or anuria). Puppies have mildly increased phosphorus concentration due to increased growth hormone; however, this is likely only a minor contribution to the marked hyperphosphatemia.

An approximately threefold increase in the ALP enzyme activity alongside a moderate increase in the total bilirubin concentration consistent with cholestasis. A small portion of the increase in ALP is likely due to the bone isoenzyme as this is a young growing animal. Increases in bALP do not cause a hyperbilirubinemia.

A mild hyperglycemia is present. Puppies tend to have higher glucose concentrations, and this result falls comfortably into that general reference range.

There is a mild hypoproteinemia due to a mild hypoalbuminemia. Considering the patient is likely dehydrated, these values will likely mildly decrease with rehydration therapy. It is important to remember that puppies, in general, tend to have lower protein concentrations than adult dogs. This is likely contributing to the hypoalbuminemia. Additional considerations in this case include inflammation (negative acute phase protein), renal loss, or liver insufficiency. A urinalysis would be helpful in assessing if protein is being lost in the urine. The globulin fraction is within the low-end of the adult reference interval, and in the presence of vomiting and diarrhea, GI loss of both albumin globulin cannot be ruled out.

Abdominal fluid analysis

A transudate effusion (TNCC <5000 cells/μL, TP <2.5 g/dL) is present in this patient. Hypoalbuminemia is the classic cause of transudate effusion; however, the albumin is only mildly decreased and probably only a mild contributor. An underlying cause of increased hydrostatic pressure was not identified in this case, so the underlying cause of the effusion is unclear. A vasculitis is a possibility; however, these effusions typically result in a high-protein (modified) transudate or exudate.

Summary

Serum antibody titers for canine leptospirosis were positive. The nonregenerative anemia and thrombocytopenia are common CBC findings in canine leptospirosis. The nonregenerative anemia is likely related to renal injury and possible anemia of inflammatory disease. A thrombocytopenia has been reported in up to 50% of dogs with leptospirosis, and is likely due to vasculitis and/or DIC. The most common biochemical changes are associated with acute kidney injury (AKI) and include azotemia and hyperphosphatemia. Increased serum liver enzyme activity is reported some dogs, and rarely seen without azotemia. Increases in serum ALP activity and total bilirubin, seen in this case, are more common than increases in serum ALT activity. The hyperkalemia is likely caused by decreased renal excretion (oliguria/anuria) and extracellular shifts in response to an inorganic titration acidosis due to uremic ions. Hypoalbuminemia is reported in some cases, and occasionally associated with an effusion.

The clinicians suspected leptospirosis and treated accordingly; however, the patient quickly progressed to anuric renal failure. A positive *Leptospira* spp. PCR and direct florescent antibody test confirmed the clinical suspicion. Findings on necropsy included: marked icterus; multifocal and subcutaneous hematoma; severe multifocal-to-coalescing lymphoplasmacytic interstitial nephritis; hemorrhaging and lymphoplasmacytic cystitis; diffuse hepatopathy with scattered individual hepatocyte necrosis and hepatocellular dissociation. The renal and hepatic findings, icterus, and lesions related to bleeding diathesis (hemorrhagic cystitis and cutaneous hematomas) are classical lesions for the subacute state of leptospirosis.

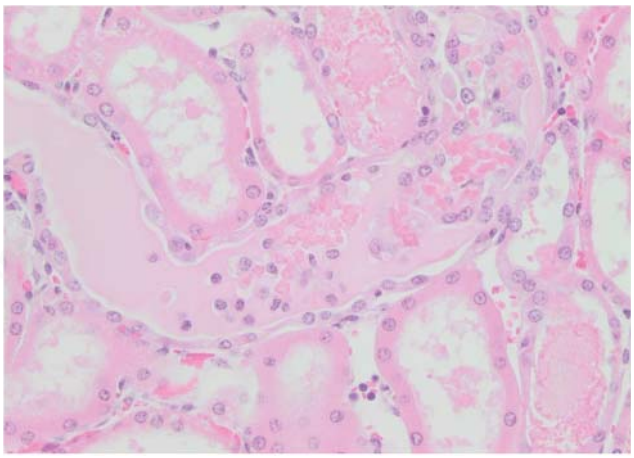

Figure 2 Histological section of the renal tubules, showing shed epithelial cells and debris and the early formation of a cast.

Interpretive discussion

Hematology

The increased PCV and total protein in sheep 2 is suggestive of relative polycythemia (dehydration). Protein will be discussed in the section below.

Chemistry and urinalysis

Both sheep are hyperglycemic, and this is likely a stress (corticosteroid) response.

Azotemia in both sheep is severe and characterized by a marked increase in BUN and creatinine. A prerenal component may be present considering the likely dehydration, but

an inadequate USG of 1.016 is supportive of renal dysfunction. Decreased GFR and renal insufficiency also explains the hyperphosphatemia and hypermagnesemia.

Sheep 2 has a hyperproteinemia characterized by a hyperglobulinemia and high-normal albumin, suggestive of dehydration. Increased globulins could also be due to inflammation, although the lack of an inflammatory leukogram makes this less likely.

An ionized calcium is strongly recommended to further characterize the nature of the hypercalcemia present in both sheep. Dehydration and relatively increased albumin binding may be a contributing factor; however, renal disease is also possible as evidenced by the azotemia and USG.

Increased GLDH activity is suggestive of mild hepatocellular injury. The mild increase in GGT observed in sheep 1 may be clinically insignificant, but the possibility of biliary disease should be considered.

An increase in CK activity is indicative of muscle injury and probably due to prolonged recumbency.

A metabolic acidosis is present as evidenced by the moderately decreased bicarbonate. The anion gap for sheep 2 is calculated at 48, indicating the presence of a titration/consumption acidosis. The unmeasured anions present are most likely uremic acids or lactate. Both acidosis (transcellular shifting of potassium) and the likely anuric/oligouric renal failure are likely contributors to the hyperkalemia.

Azotemia and inadequately concentrated urine are strongly suggestive of renal disease. The finding of cellular cast within the urine in this number in these animals is pathognomonic for renal tubular necrosis. Increased numbers of RBCs and WBCs could be an indication of inflammation or hematuria. The acidic pH is secondary to the metabolic acidosis.

Summary and outcome

The clinical pathology findings indicated acute renal tubular necrosis as the likely cause of the renal failure, and the farmer was advised to move the sheep. Necropsy and subsequent histopathology confirmed severe acute tubular necrosis as the cause of renal failure in the affected sheep (Figures 1 and 2). Further investigation of the pasture revealed very little green feed and the presence of Amaranthus spp., commonly referred to as "pigweed," a toxic weed known to cause toxic nephrosis in livestock. The affected sheep were pregnant at the time of intoxication, and in those that survived the subsequent lambing percentage was markedly decreased when compared to unaffected cohorts on the same property. This likely indicates loss of pregnancy in affected sheep secondary to the intoxication.

Interpretive discussion

Hematology

The neutrophilia and concurrent hyperfibrinogenemia are suggestive of inflammation.

MCHC is calculated to be 38 g/dl (RI: 32–41 g/dL) and Hgb appears disproportionately high for this HCT. This may be insignificant, but intravascular hemolysis and Heinz bodies should be excluded as possible causes of an erroneous increase in hemoglobin concentration. The severe hypophosphatemia in this patient could also be responsible for intravascular hemolysis.

Chemistry and additional tests

Mild hyperglycemia is likely due to stress (cortisol or epinephrine induced).

Azotemia is present and characterized by mild increased urea nitrogen and creatinine, which combined with isosthenuria, indicates renal insufficiency. The hypercalcemia is a confounder in that it may be the cause or contributing factor for apparent inability to concentrate urine.

BUN/Creatinine ratio is 10; BUN is only mildly increased while creatinine is disproportionately higher, suggesting there may be a decrease in urea synthesis, potentially due to chronic liver failure, which is also supported by the hypoalbuminemia. Alternatively, creatinine may be falsely increased due to noncreatinine chromogens such as vitamin C, bilirubin, and carotene.

Causes of hypercalcemia in rhinoceroses are not widely reported in the literature. Like other mammals, differential diagnoses to consider in this animal include paraneoplastic hypercalcemia, primary hyperparathyroidism, renal disease, granulomatous inflammation, and vitamin D toxicosis. However, phosphorus is markedly decreased and the three differentials for hypercalcemia **and** hypophosphatemia are primary hyperparathyroidism, humoral hypercalcemia of malignancy (HMM), and renal failure in horses. While renal failure usually results in hypocalcemia and hyperphosphatemia, the opposite occurs in some horses. Hypophosphatemia is a more important diagnostic clue in this patient than is hypercalcemia, as there are so many causes of hypercalcemia.

Undetectable levels of PTH make hyperparathyroidism very unlikely. However, it is also possible that the PTH was falsely decreased due to either the lack of cross-reactivity with antibodies, since the test was designed for use in human patients, or improper preservation of the serum sample. Poor preservation may occur if the sample is not frozen **or** if repeatedly freeze-thawed, resulting in denaturation of proteins. With renal failure, a marked increase in PTH is expected and is due to secondary hyperparathyroidism and decreased PTH clearance by the kidneys. PTH-rp was not performed and is needed to rule out HMM. Any animal of this age could possibly have a tumor, such as lymphoma, and HHM is much more common than primary hyperparathyroidism in all domestic animals. There is no indication of enlarged lymph nodes to support lymphoma but a thorough search for concurrent malignant neoplasia such as lymphoma or carcinoma is recommended. PTH and PTH-rp should always be performed simultaneously so a situation just like this does not have to be interpreted. The only time these hormones are needed is when an obvious cause of hypercalcemia and hypophosphatemia cannot be found.

Chronic renal failure leading to hypercalcemia and concurrent hypophosphatemia is a phenomenon observed commonly in horses, contrary to the hypocalcemia and hyperphosphatemia seen in other domestic species. In a retrospective study of chronic renal failure in 99 horses, hypercalcemia and hypophosphatemia was observed in 67% and 47% of cases, respectively. Hypercalcemia due to renal failure can occasionally be seen in other species such as the dog and the cat, but they exhibit hyperphosphatemia with CRF; the concurrent hypophosphatemia with azotemia is rare and only seen in horses. (More typically, dogs and cats with renal failure and hypercalcemia have hypercalcemia due to some other cause, and the renal failure is caused by mineralization of the kidneys.) Interestingly, horses, rhinoceroses and other odd-toed ungulates are taxonomically related, and this could explain physiological similarities. Anorexia and decreased intake may also be contributing to hypophosphatemia.

CPK is 590 IU/L, which could be mildly increased but certainly is not in the range expected for rhabdomyolysis and secondary renal failure. The history of chronic weight loss, combined with proteinuria without evidence of inflammation in UA, and mild azotemia make acute nephrotoxicity unlikely and all point to CRF, especially due to glomerulonephritis.

Hypoalbuminemia is likely multifactorial in this case and the result of inflammation (negative acute phase protein), decreased intake (anorexia) and a protein losing nephropathy. The proteinuria supports the latter, and although guidelines for the interpretation of urine protein: creatinine ratios in rhinoceroses have not been published, a value >2.0 is suggestive of glomerular disease in other species. There is no evidence of inflammation in the urine sediment, suggesting that the proteinuria is not associated with inflammation. The significance of the hypoglobulinemia is uncertain but could reflect a protein losing enteropathy given that blood loss is unlikely. One would expect cholesterol to also be decreased (see below). Decreased albumin and globulin are usually associated with protein losing enteropathy; other causes of hypoalbuminemia being glomerulonephropathy, liver failure, and blood loss. End-stage liver disease is usually associated with hypoalbuminemia and hyperglobulinemia, possibly due to decreased Kupffer cell function, with antigens from the GI tract then gaining access to the immune system.

Hypercholesterolemia in this case is possibly due to nephrotic syndrome since the patient has hypoalbuminemia and proteinuria; hypercholesterolemia is postulated to occur as an attempt to restore oncotic pressure lost due to hypoalbuminemia. Anorexia and subsequent development of a negative energy balance leading to lipolysis may also be factor. Cholestasis is unlikely given that bilirubin and liver enzyme activities are within reference range. It is also important to note that **decreased** cholesterol is typically observed with protein losing enteropathies, making this a less likely differential for protein abnormalities.

On biochemical profiles, bicarbonate is calculated by measuring TCO_2 and as such, an increased bicarbonate is indicative of a metabolic alkalosis. A cause for the increased bicarbonate is not evident in this case, as a corrected chloride of 94 mEqv/L makes alkalosis secondary to H+ loss unlikely. If this animal was receiving fluid therapy, added bicarbonate or lactate in commercially available fluid solutions should be considered. Ultimately, this animal requires a blood gas analysis to assess pH. A urine pH of 8.5 is typical for herbivores

in health but having alkaline urine may further evidence the alkalosis, possibly reflecting an increased serum pH.

A mild hyponatremia and proportionately decreased serum chloride may indicate gastrointestinal (diarrhea) or renal losses, or an increase in water intake with fluid therapy or excessive drinking.

A urine specific gravity of 1.010 is likely attributed to CRF. However, increased serum Ca interferes with the action of ADH on tubules and therefore is a likely contributor to isosthenuria. Hydration status is not reported, and interpretation of USG should take this into consideration. If the animal is receiving fluid therapy at the time of urinalysis, the USG is not meaningful. If the animal is dehydrated, and not concentrating urine, it is likely not capable of concentrating. An alkaline urine of pH 8.5 is common with many herbivores and horses, as is the presence of calcium carbonate crystalluria in horses, further implying the physiological similarities between the rhinoceros and the horse.

Summary and outcome

This animal decompensated and was found dead. Postmortem and histopathology revealed: severe interstitial nephritis and chronic glomerulonephritis periglomerular sclerosis (chronic kidney disease). There was no evidence of neoplasia such as lymphoma or gastric squamous cell carcinoma, both of which are associated with humoral hypercalcemia of malignancy in horses. The parathyroid glands were not assessed histologically so primary hyperparathyroidism remains a possibility, however the undetectable concentration of PTH makes this unlikely. Concurrent hypercalcemia, hypophosphatemia, azotemia and isosthenuria all suggest CRF and a pathogenesis of hypercalcemia similar to that seen in horses.

In horses, the kidneys are a major route of excretion for calcium and anything that causes a decreased in GFR, including CRF, can result in hypercalcemia. Many horses in renal failure have calcium and phosphorus concentrations similar to other species, most notably hyperphosphatemia, although some horses have hypercalcemia and hypophosphatemia. Perissodactyla is an order of odd-toed ungulates that includes Equidae (horses, zebras), Rhinocerotidae (rhinoceroses), and Tapiridae (tapirs). Literature regarding the renal physiology of rhinoceroses is sparse, but given the common ancestry and taxonomical relationship between rhinoceroses and horses, it is possible that they share similarities, maybe explaining the hypercalcemia and hypophosphatemia in this case and perhaps the calcium carbonate crystalluria.

The cause of the panhypoproteinemia remains uncertain as there was no evidence of a protein losing enteropathy at postmortem, although autolysis was preset and the small intestine was not closely examined. The cause of the hypoalbuminemia was renal loss but the hypoglobulinemia remains unexplained.

Case 49

Signalment: 10-year-old castrated male domestic short hair cat
History: Anorexia, lethargy
Physical examination: Dehydrated

Miscellaneous tests		Reference interval
Plasma glucose (mg/dL)	**328**	67–124
Urinalysis dipstick abnormalities	Glucosuria and ketonuria	
Na (mEq/L)	**130**	146–160
K (mEq/L)	**2.2**	3.7–5.4
CL (mEq/L)	**74**	112–129
pH	**7.28**	7.33–7.44
HCO_3 (mEq/L)	**9.2**	16–20
pCO_2 (mmHg)	**20**	28–34

Interpretive discussion

There is moderate hyperglycemia that exceeds the renal glucose threshold. There is resultant glucosuria. Ketonuria indicates impaired glucose utilization by tissues suggesting insulin deficiency. This establishes a working diagnosis of diabetes mellitus.

There is marked hypokalemia in the face of acidosis (see blood gas discussion), which would be expected to increase potassium due to an intracellular to extracellular shift. It would be suspected that total body potassium is depleted and there should be caution in insulin administration that would drive potassium into cells, resulting in weakness due to even more severe hypokalemia. There is also hyponatremia and disproportionate hypochloremia. The hyponatremia may be due to a combination of urinary and gastrointestinal loss. The disproportionate hypochloremia is of a magnitude that suggests upper gastrointestinal chloride loss due to vomiting.

The acid-base data show a low pH and decreased bicarbonate, consistent with a metabolic acidosis. The decreased pCO_2 is a compensatory response (respiratory alkalosis). There is also a likely hidden component of metabolic alkalosis (hypochloremic alkalosis), resulting in a mixed acid-base disorder. The loss of HCl in gastric fluid will metabolically generate bicarbonate. The generation of ketoacids that require buffering by bicarbonate is judged to be more severe in the balance between bicarbonate utilization and production.

Summary

Diabetic ketoacidosis pattern, largely compensated.

Case 50

Signalment: 5-year-old spayed female Manx cat

History: Decreased appetite of approximately 2 weeks' duration. Fluid draining from a fistula over the terminal coccygeal vertebrae of 8 months' duration.

Physical examination: Approximately 6% dehydrated. Coccygeal vertebrae were noted to terminate cranial to the anal sphincter. The fistula was noninflamed and draining a clear, colorless fluid.

CASES

Interpretive discussion

Hematology

The increased PCV is consistent with hemoconcentration due to dehydration. Other data are unremarkable.

Biochemical profile

The azotemia (increased BUN and serum creatinine concentrations) may be prerenal and/or renal. Refer to the discussion of urinalysis below.

There is hypocalcemia, despite hyperproteinemia due to hemoconcentration, suggesting that serum calcium concentration may be truly decreased. An ionized calcium could be measured for confirmation. Hypocalcemia could have occurred secondary to chloride depletion and loss of the electrochemical gradient needed to support calcium absorption from the glomerular filtrate in the Loop of Henle of the renal tubules.

Serum sodium and chloride are decreased in concentration. This usually reflects increased loss, compounded by reduced intake in sick, anorexic patients. In this case, there is physical evidence of cerebrospinal fluid loss from a draining meningomyelocele. Cerebrospinal fluid contains higher sodium and chloride concentrations than the blood, owing to the active chloride transport mechanism employed by the choroid plexus for secretion. Draining CSF from the body will create electrolyte depletion in excess of water, an otherwise classic scenario for hypotonic dehydration. Although this cat had been losing CSF for some time, the development of anorexia probably precipitated an imbalance between these pathologic losses and replacement of the electrolytes, resulting in the clinical presentation.

Urinalysis

The urinary fractional excretion values for sodium and chloride were well within the normal reference interval, thereby ruling out renal loss as a cause for the electrolyte depletion. The only significant abnormality is a urine specific gravity of 1.015. Dehydration should stimulate antidiuretic hormone release from the hypothalamus, and increased

water reclamation by the renal tubules. However, electrolyte loss in this type of hypotonic dehydration often leads to medullary solute depletion and a loss of the renal concentration gradient. Another alternative is that there is renal disease, due to renal hypoperfusion, sepsis, etc., resulting in both azotemia and loss of concentrating ability.

Summary

Sodium chloride depletion in a Manx cat with a fistulated meningomyelocele (Hall JA, MJ Fettman, JT Ingram. Sodium chloride depletion in a cat with fistulated meningomyelocele. J Am Vet Med Assoc 1988;192:1445–1448).

Interpretive discussion

Hematology

There is a neutrophilic leukocytosis with low normal lymphocyte numbers, which most likely reflects stress, rather than inflammation. The fibrinogen is within normal limits. The PCV is at the top of the reference interval and serum proteins are normal, suggesting possible splenic contraction.

Abdominal fluid analysis	
Fluid color	Straw
Fluid clarity	Hazy
Supernatant color	Straw
Supernatant clarity	Clear
TP (g/dL)	1.3
NCC (/μL)	300

Cytology: There are approximately equal numbers of neutrophils and large mononuclear cells. Although the overall cellularity and protein are low, some of the neutrophils are degenerate and bacteria are seen extracellularly, predominantly rods. Some of the macrophages and neutrophils contain cytoplasmic material suggestive of bacterial remnants. There are moderate numbers of lymphocytes and rare mast cells seen. There is debris present in the background.

Biochemical profile

There is a mild hyperglycemia, which is consistent with stress. The increases in serum creatinine and serum phosphorus are likely the result of decreased glomerular filtration rate. Creatinine is a more sensitive marker for decreased GFR in horses because of their ability to excrete urea into the GI tract. A urinalysis might help differentiate prerenal from renal azotemia, but the low chloride (discussed later) might affect urinary concentrating ability. There may be a prerenal component (dehydration) to the azotemia since the PCV is at the top of the reference interval. However, the normal albumin does not support dehydration, and there does not appear to be much protein loss into the abdominal effusion (which would lower the serum albumin).

There is a slight hypocalcemia, which may be due to deposition in injured tissue.

VetBooks.ir

Increased CK activity indicates muscle cell damage. The increased SDH activity is specific for hepatocellular injury. The slight increase in AST activity could be from muscle or hepatocellular injury.

There is a selective hypochloremia, indicating a hypochloremic alkalosis. Selective chloride loss can result from upper GI loss or sequestration of CL and excessive sweating in horses. In addition, the decreased TCO_2 and increased anion gap indicates a high-gap metabolic acidosis; thus, there is a mixed acid-base disorder. Uremic acids and lactic acid, secondary to hypoperfusion, are likely contributors to the anion gap. A blood gas profile is needed to fully assess acid-base status in this horse.

Abdominal fluid analysis

Although the quantitative indices are all within normal limits, the presence of degenerate inflammatory cells, bacteria, and debris are all consistent with an acute rupture of the intestinal tract.

Summary

This mare experienced intestinal colic, followed by acute rupture of the involved strangulated intestine. There had not been time for an inflammatory leukogram to develop.

Case 52

Signalment: 7-year-old spayed female DLH cat
History: Attacked by dog in same household
Physical examination: Dehydration, tachypnea, marked bruising, and several small bite wounds on the back of the neck

Interpretive discussion

Hematology

On Day 1, although erythrocytosis is not observed, the PCV is shifted towards the upper reference interval, possibly due to a combination of dehydration and an epinephrine-mediated response. On Days 4 and 7 the cat has developed a mild anemia. A decreasing PCV combined with increased bilirubin concentration should raise concerns of hemolytic disease. However, given the history and presentation of this case, a combination of inflammatory disease and blood loss from the attack offers a most likely explanation. The slightly increased reticulocyte concentration on Day 7 is indicative of an initial regenerative response.

Even though it is not accompanied by neutrophilia, the mild lymphocytosis observed on Day 1 is most likely the result of an excitement response caused by epinephrine release from being attacked by the dog. On Day 4, a left shift without neutrophilia, and lymphopenia are appreciated, and attributable to inflammation. On Day 7 the left shift still present but the total number of band neutrophils has decreased significantly, indicating that the inflammation is subsiding.

Thrombocytopenia is observed on Days 4 and 7. Excessive consumption/Loss associated with blood loss is a potential explanation. A declining platelet count on a trauma patient could raise concerns of DIC, however, coagulation profiles were within reference intervals in this patient.

Chemistry

Marked hyperkalemia is present on Day 1. Considering the lack of azotemia and the urinalysis results, causes other than lack of renal excretion should be considered. Potassium shifting from the intracellular to the extracellular fluid is a likely explanation, with both tissue necrosis (damage from the trauma) and metabolic acidosis (lactic acidosis induced by the struggle with the dog) being potential contributors to hyperkalemia. Mild hyperkalemia persists on Day 4 and potassium concentration has returned to the reference interval on Day 7.

Hypophosphatemia, observed on Day 1, is not a frequent finding in cats. In this case, it is likely a consequence of hyperventilation inducing respiratory alkalosis, leading to changes in cellular pH that stimulate glycolysis and ATP production depleting serum phosphate concentration.

Total bilirubin and ALT activity were increased on all exams.

ALT is fairly liver-specific and usually associated with hepatocellular damage. However, the history of trauma and other laboratory findings suggests a potential muscle origin for the increased ALT activity.

Hyperbilirubinemia is normally associated with cholestasis and /or hemolytic disease. However, there was no evidence of cholestasis on imaging exams, and although hemolysis cannot be excluded it is more likely that the increased bilirubin concentration is caused by the breakdown of hemoglobin within the hematomas, as well as some contribution of nonblood heme (i.e., myoglobin). CK and AST activities could help to assert if muscle damage was indeed a contributor to these findings. Unfortunately, they were not performed.

Hypoalbuminemia is observed on Days 4 and 7. This is likely an acute phase response to inflammation, as evidenced by the left shift and the increase in the globulin concentration, albeit still within the reference interval, in comparison with Day 1. Blood loss could also have contributed to the hypoalbuminemia.

Urinalysis

Brown-colored urine with a 4+ dipstick result for blood in the absence of compatible hematuria indicates pigmenturia. The dipstick is not capable of differentiating between hemoglobinuria and myoglobinuria. Proteinuria is also observed. Although the dipstick is more sensitive to albumin, it is impossible to rule out the interference of hemoglobin and/or myoglobulin in this result.

The presence of casts is indicative of acute tubular injury, which can be due to ischemic lesions and nephrotoxic substances, such as myoglobin and hemoglobin, among other causes. Although their presence can be suggestive of renal disease, it isn't a reliable indicator of prognosis as it doesn't necessarily correlate with the extent and reversibility of the injury. Although no further urinalysis was performed, gross appearance of the urine was normal on Day 2.

Summary and outcome

The cat suffered severe soft-tissue trauma to the neck, which likely led to muscle injury and local inflammation. Blood loss from the injuries was not considered to be major but it seemed to have contributed to the anemia along with the inflammatory disease. The cat was severely ataxic for the first few days but clinical improvement was observed during the 8 days of hospitalization before being discharged. Follow-up CBC and chemistry panel performed on Day 15 were all within reference intervals and the patient was fully recovered within 3 weeks following the incident.

Hematology

The PCV, hemoglobin concentration, and RBC count are at the lower end of the reference interval, and it is possible that an anemia has been masked by dehydration. With a history of vomiting and diarrhea and an increased plasma protein concentration, it is possible that this animal is dehydrated. However, we have no additional support for dehydration in these data. Because the serum is lipemic, a likely explanation for the high total plasma protein as measured by refractometry is the presence of lipids, which interfere with the reading. The presence of moderate polychromasia suggests a regenerative response. Blood loss may have caused a regenerative anemia in this dog (see summary).

Neutrophilia with a left shift indicates an inflammatory leukogram.

Biochemical profile

The BUN concentration is only mildly increased and the serum creatinine concentration is normal. Urine specific gravity indicates inadequate urine concentrating ability in the face of possible dehydration (if present) and azotemia, suggesting possible renal disease. Increased BUN with normal creatinine also prompts consideration of prerenal azotemia secondary to GI tract hemorrhage (which acts as a high-protein meal).

Both plasma and serum protein concentrations are increased, but the plasma protein concentration is much higher than the serum protein concentration. Because fibrinogen is present in plasma but not in serum, one would expect the plasma protein concentration to be 0.2 to 0.4 g/dl higher than that of serum. However, the difference is often greater because plasma protein concentration is estimated

using a refractometer, while serum protein is measured spectrophotometrically. Increased plasma concentration of lipids may falsely increase the protein estimate determined by a refractometer. The increased difference between these protein concentrations in this case is likely due to lipemia.

The hyperglobulinemia may be the result of chronic antigenic stimulation with subsequent increase in antibody production.

The combination of hyperbilirubinemia and increased serum ALP activity is typical of cholestasis. The increased bilirubin concentration in the urine reflects the hyperbilirubinemia; conjugated bilirubin is cleared by the glomerulus and excreted in the urine. Although hypercholesterolemia is a nonspecific problem, cholestasis is a common cause of this abnormality and may be an explanation in this case. The magnitude of the hypercholesterolemia is unusual for cholestasis alone. Since this dog is a miniature schnauzer, and the serum is lipemic, suggesting hypertriglyceridemia and/or chylomicronemia, idiopathic hyperlipidemia is likely.

Increased serum AST and ALT activities indicate hepatocyte injury. Both of these enzymes are leakage enzymes and are present in significant concentrations in hepatocytes. AST is also present in high concentrations and ALT in low concentrations in muscle, but muscle is an unlikely source of these enzymes in this case. In light of the evidence for cholestasis, hepatic origin is most likely for these enzymes in this dog.

Urinalysis

Proteinuria, pyuria, and bacteriuria suggest inflammation in the urinary tract. Since these are found in a voided urine sample, reproductive tract origin must also be considered. Bacteria in a voided urine sample may be contaminants but are more significant when accompanied by pyuria. Culture of this urine sample is indicated.

Summary

This dog had a suppurative cholangiohepatitis, a duodenal ulcer, and pyelonephritis. The cholangiohepatitis resulted in the cholestasis and damage to hepatocytes. The chronic antigenic stimulation caused by both cholangiohepatitis and pyelonephritis resulted in hyperglobulinemia. The mild azotemia could have resulted from pyelonephritis or GI hemorrhage secondary to the duodenal ulcer.

Interpretive discussion

Hematology

There is a moderate leukocytosis characterized by a mature neutrophilia, lymphopenia, and monocytosis. This is most consistent with a steroid/stress leukogram, which is expected given the history of prednisone administration. The magnitude of the mature neutrophilia is slightly greater than that usually seen with a stress response alone, so chronic inflammation should also be considered.

Although there is no anemia present there are significant erythrocyte membrane changes observed. Acanthocytes may be seen with liver disease and hemangiosarcoma. Keratocytes and schistocytes suggest there is some red cell fragmentation occurring.

Biochemical profile

The most significant abnormalities relate to the liver. Increased activities of the leakage enzymes ALT and AST indicate there has been hepatocellular injury. Increased activities of the inducible enzymes ALP and GGT may be due to cholestasis and/or drug induction, given the history of steroid administration. The increased total bilirubin concentration supports cholestasis, since there is no indication of hemolysis, and indicates that hepatic function has been compromised.

Albumin is slightly decreased, most likely due to the ongoing inflammatory bowel disease. Decreased production due to liver failure is less likely since glucose, BUN, and cholesterol are normal. The mild decrease in calcium is likely due to a decrease in protein-bound calcium secondary to hypoalbuminemia. An ionized calcium could be measured to confirm this.

Summary

There is laboratory evidence for hepatocellular injury and cholestasis severe enough to affect hepatic function. Given the history of prednisone administration, a steroid hepatopathy is most likely. Red cell membrane changes may

be due to hepatic disease or potentially hemangiosarcoma. A liver aspirate was performed and revealed marked indistinct hepatic vacuolization consistent with glycogen, and numerous bile casts indicating cholestasis. These findings were confirmed on a liver biopsy; there was no evidence of neoplasia or inflammation. Biopsies of the skin lesions revealed pyogranulomatous dermatitis with intralesional pigmented fungal hyphae. Presumably immune suppression due to the prolonged steroid administration predisposed to the fungal infection.

Case 55

Signalment: 5-year-old FS canine

History: On phenobarbital to control seizures for 2.5 years. Vomiting daily and lethargic for about 1 month.

Physical examination: Lethargic, icteric, pendulous abdomen; arthritic, and appears older than stated age

Interpretive discussion

Hematology

There is a moderate neutrophilia with a mild left shift, monocytosis, and slightly toxic neutrophils were observed in the blood film. This is an inflammatory leukogram, but the lymphopenia indicates a concurrent steroid-induced component. Monocytosis is consistent with the combined leukocyte response.

Biochemical profile

The serum glucose concentration is at the low end of the reference interval and the BUN is decreased. These findings may indicate hepatic functional impairment, particularly in light of the observation of a potential stress leukogram (stress would be expected to increase the glucose concentration). See discussion of serum protein below. Decreased creatinine likely reflects decreased muscle mass.

The serum total protein and albumin concentrations are decreased. Considerations in this case include renal loss (see urinalysis discussion) and, more likely, decreased production secondary to hepatic disease (discussed more later).

There is a mild hypocalcemia that is likely secondary to hypoalbuminemia, and therefore not clinically significant. An ionized calcium could be measured to confirm this.

Serum cholesterol is decreased. While one should not overinterpret decreases in some analytes, this is commonly observed in end-stage liver disease, owing to impaired

hepatic lipid synthesis. This is particularly notable given the degree of hyperbilirubinemia and increases in enzyme activities indicative of cholestasis (ALP and GGT). The magnitude of increase in serum ALP activity is large enough to warrant consideration of corticosteroid induction. Likewise, the degree of increase in GGT activity may be related to steroid induction rather than cholestasis alone. The serum ALT and AST activities are moderately increased, indicating hepatocellular damage. Phenobarbital may induce increased production of several liver enzymes.

The serum sodium and potassium are decreased, and one should consider typical causes for electrolyte depletion, including pathologic losses from the gastrointestinal and urinary systems, as well as third space syndromes. Hypokalemia is a frequent observation in hepatic disease, often due to anorexia and vomiting.

Coagulation data

The aPTT and PT are normal. If hepatic disease or end-stage liver failure has progressed sufficiently, as suggested by even lower values for glucose, BUN, albumin, and cholesterol, one might expect these indices of coagulation factor synthesis to become abnormal as well.

Urinalysis

The urinary specific gravity indicates the urine is poorly concentrated and may reflect impaired concentrating ability. This may be due to the decreased BUN, since urea also plays a role in urine concentration. The concentrations of protein, ketones, bilirubin, and blood are particularly notable given this weak urine concentration. The proteinuria is explained by the urinary tract inflammation/infection as indicated by the significant pyuria, bacteriuria, and presence of marked occult blood. The presence of bilirubin is not surprising given the degree of hyperbilirubinemia. The presence of ketonuria in the absence of glucosuria is unusual. Ketosis is a possible sequela to impaired oxidative lipid metabolism by the diseased liver, especially when triglyceride absorption from the GI tract or mobilization from peripheral stores is greater than hepatic functional capacity for processing.

Summary

There is biochemical evidence of chronic liver failure, cholestasis, and hepatocellular injury. Phenobarbital-induced hepatopathy was considered. Ultrasound of the liver showed an enlarged liver with numerous well-defined hypoechoic foci throughout. Masses throughout the cranial mid-abdomen had similar echogenicity as masses within liver. Cytology of a liver aspirate showed vacuolated hepatocytes, bile stasis, and a population of nonhepatic cells with a high nucleus: cytoplasm ratio, most of which were broken. Numerous cells in mitosis were observed, and neoplasia was diagnosed. Biopsy of liver revealed adenocarcinoma that effaced and replaced hepatic parenchyma and glucocorticoid hepatopathy with severe bile stasis. The neoplasm had a neuroendocrine (potentially adrenal) pattern, and was possibly causing the steroid hepatopathy. Endocrine panel was not performed. Dog was euthanized; necropsy was not allowed.

Case 56

Signalment: 6-year-old spayed female dog
History: Struck by car 1 month ago. Not taken to veterinarian. Dyspnea since accident. Anorexia.
Physical examination: Emaciated and lethargic. Intestinal sounds auscultated in thorax.

Interpretive discussion

Hematology

This dog's erythrocyte measurements are near the lower end of their reference intervals, and there is no evidence of a regenerative response. This may be normal for this dog, or it is possible that this dog is developing a nonregenerative anemia secondary to chronic disease.

Leukocyte abnormalities are a mature neutrophilia and lymphopenia, typical of a corticosteroid-mediated leukogram.

Biochemical profile

Decreased BUN concentration can be caused by hepatic failure, diuresis, decreased protein intake, or treatment with anabolic steroids. BUN concentration below the reference interval can also occur in normal animals. In light of other laboratory findings in this case, the decreased BUN concentration is probably due to hepatic failure and resulting failure of hepatocytes to synthesize urea. Anorexia resulting in decreased protein intake may have also contributed to this abnormality.

This dog has hypocalcemia; however, it also has severe hypoalbuminemia. Hypoalbuminemia, and resultant decreased protein-bound calcium, may be the cause for the hypocalcemia, in which case it is not clinically significant. Ionized calcium could be measured to confirm this. While not always necessary, determining the ionized calcium would be recommended in this case because of the magnitude of the hypocalcemia and the critical condition of the patient.

Both plasma and serum protein concentrations are decreased. These decreases are a result of hypoalbuminemia. When interpreted in combination with other laboratory data, this abnormality is probably due to decreased albumin

synthesis by the liver. Decreased protein intake can result in hypoalbuminemia and may also have played a role in this case. The albumin concentration is low enough to lead to ascites; however, ascites was not noted in this animal.

In dogs, hyperbilirubinemia can result from hemolysis, failure of hepatocyte uptake and metabolism of bilirubin, or failure to excrete bilirubin due to cholestasis or other disruption of bile flow. In this case, failure of hepatic uptake and metabolism of bilirubin is probably the major abnormality leading to hyperbilirubinemia. It is also probable the bile duct is partially blocked and cholestasis is playing a role in producing this abnormality. The increased serum ALP activity suggests cholestasis is present in this dog.

Hypocholesterolemia is probably another result of hepatic failure. The liver is a major site of cholesterol synthesis and excretion. Abnormalities of these two processes have opposite effects on serum cholesterol concentrations. In this case, synthetic failure is apparently more severe than failure to excrete cholesterol.

Both serum ALT and AST activities are mildly increased. These enzymes leak from injured hepatocytes, and liver injury is the appropriate interpretation in this case. AST is also present in muscle cells, and muscle injury cannot be ruled out, but the mild increase of AST activity in conjunction with the increased ALT activity suggests the AST has leaked from the liver in this case.

Increased ALP activity most often results from either cholestasis or increased blood corticosteroid concentrations. In combination with other laboratory data suggesting hepatic disease, cholestasis is the most important cause of the increased ALP in this case. This dog probably had an increased blood corticosteroid concentration as suggested by the leukogram, and this may have also played a role in increasing the serum ALP activity.

Hyperkalemia may be a result of metabolic acidosis-induced shifting of potassium from within cells to extracellular fluid. In animals with metabolic acidosis, hydrogen ions enter cells in an attempt to equalize their concentrations in the intracellular and extracellular compartments. In order to maintain electrical neutrality, potassium ions must leave the cells. The net result is increased extracellular and, therefore, serum potassium concentrations.

The cause of the decreased total CO_2 is not certain. Since this animal has a compromised respiratory system, it is reasonable to assume that it has a respiratory acidosis. However, the total CO_2 concentration would be expected to increase in compensation for the respiratory acidosis. Since this concentration decreased rather than increased, it is reasonable to assume the dog has another abnormality causing metabolic acidosis. Although the anion gap is normal, the markedly low albumin may be masking an increase in unmeasured anions, thus there could be a hidden high-gap acidosis. Abnormal renal regulation of acid-base balance is another possible cause of decreased total CO_2, but there is no evidence of renal dysfunction in this case. A blood gas analysis would be helpful to further evaluate this dog's acid-base status.

The hyperammonemia is a result of hepatic failure. Ammonia is normally absorbed from the digestive tract and transported to the liver by the portal circulation. The liver is responsible for removing and metabolizing this ammonia. Alterations in blood flow to the liver and/or markedly decreased numbers of functional hepatocytes can result in increased blood ammonia concentrations.

Urinalysis

Bilirubinuria and the presence of bilirubin crystals are the only abnormalities in the urine. These changes reflect the increased serum bilirubin concentration. Conjugated bilirubin readily passes through glomeruli and is then excreted in the urine. The very mild increase in urine bilirubin suggests that most of the serum bilirubin is unconjugated. Interestingly, this dog is concentrating urine in the face of a very low bun.

Summary

Exploratory surgery revealed a diaphragmatic hernia through which the liver and a portion of the GI tract had passed. The liver was decreased in size and firm. Many fibrous adhesions were present. On the surgeon's recommendation, the dog was euthanized.

This dog had hepatic failure due to chronically decreased blood supply to the liver. Decreased BUN, albumin, and cholesterol concentrations suggested decreased synthetic function by the liver. Increased bilirubin and ammonia concentrations resulted from decreased delivery of these substances to the liver and, therefore, decreased removal from the blood as well as due to decreased functional hepatic mass. Cholestasis resulting from partial occlusion of the bile duct also contributed to hyperbilirubinemia. Since this was an end-stage liver disease, leakage of ALT and AST from hepatocytes was minimal due to the small number of hepatocytes remaining, and serum activities of ALT and AST were, therefore, only slightly increased.

Case 57

Signalment: 10-year-old spayed female Doberman dog
History: Lethargy, weight loss, diarrhea, and poor appetite
Physical examination: Depressed, dehydrated, hypotensive, and icteric

Hematology		Reference interval
TP (P) (g/dL)	**4.7**	6.0–8.0

Interpretive discussion

Hematology

The hematocrit is low normal, but some degree of anemia is probable given physical dehydration; the baseline hematocrit is not known.

There is moderate hypoproteinemia, to be considered in chemistry interpretation.

The leukogram indicates moderate lymphocytosis. The presence of mostly abnormal lymphocyte forms indicates lymphoproliferative disease that is leukemic. The left shift with mild neutrophilia indicates concurrent inflammatory stimulus. Minimal monocytosis accompanies the inflammatory pattern.

There is thrombocytopenia with some giant platelets, indicating active thrombopoiesis. A consumptive process should be considered.

Chemistry

Renal analytes

The following processes are identified:
- Moderate azotemia indicated by BUN and prominent hyperphosphatemia. The creatinine has likely increased in this individual, within the reference interval. Increased magnesium is due to decreased GFR.
- Likely a prerenal component given dehydration and other evidence of poor perfusion such as lactic acidosis (later). A urinalysis, especially specific gravity, would be helpful.
- Possible renal component requires urinalysis for further characterization.
- The Ca · P is 124 indicating calcification will be occurring.

Liver

The following processes are identified:
- There is hepatocellular injury indicated by increased activities of ALT/AST.
- There is evidence of liver function failure in the form of probable decreased cholesterol synthesis and marked hyperbilirubinemia in the face of near normal HCT.
- Cholestasis and/or steroid-induced ALP are considerations given the ALP magnitude; cholestasis is a likely contributing factor to the hyperbilirubinemia.

• Mild hypoglycemia and hypoalbuminemia may also be related in part to function failure.

Protein

There is marked hypoproteinemia due to panhypoproteinemia. All potential causes of loss should be evaluated, particularly GI given the observation of diarrhea.

Acid-base/electrolyte

The following processes are identified:

• There is severe, life-threatening acidemia. This is a mixed acidosis of two processes.

• There is metabolic acidosis indicated by decreased bicarbonate. This is most likely related to poor tissue perfusion and development of lactate acidemia, as well as uremic acids.

• There is also a component of respiratory acidosis indicated by the prominent increase in pCO_2. The respiratory component is likely related to terminal respiratory failure; this would prompt evaluation of cardiopulmonary function.

• Both the pCO_2 and bicarbonate are counter to any detectable compensation.

• The increased anion gap is attributable to retention of renal-excreted anions such as phosphate and sulfate, and lactate is a contributing factor.

Summary

• Biochemical evidence of liver function failure, with hepatocellular injury and cholestasis. Hepatic infiltrate with lymphoma should be considered given that there is blood evidence of lymphoproliferative disease.

• Azotemia likely prerenal; kidneys should be investigated further.

• Severe mixed acidemia compatible with multiple causes of metabolic acid and respiratory acid formation.

• Lymphoproliferative disorder.

• Marked panhypoproteinemia.

Recommendations for further characterization would include:

• Urinalysis.

• Evaluation of liver and kidney size with sampling for possible infiltrative disease (lymphoma).

• Bone marrow for possible infiltrate.

• Cytometric analysis of blood leukocytes if treatment is contemplated.

As follow-up, the dog was euthanized. Necropsy findings included splenomegaly, hepatomegaly, lymphadenopathy with marked involvement with lymphoma. The severity of this change in liver would explain the biochemical evidence of function failure.

TP (g/dL)	**3.8**	Lymphs	5%
NCC (/µL)	**8800**	Macrophages	21%

Other observations: Neutrophils are nondegenerate. Lymphocytes are uniformly small. Large mononuclear cells are a mixture of reactive mesothelial cells and macrophages. Macrophages contain large amounts of blue-green pigment, suggestive of bile. No micro-organisms are evident. Moderate numbers of erythrocytes are present.

Interpretive discussion

Hematology

This dog has a nonregenerative anemia. The indices reveal that this anemia is microcytic and borderline hypochromic. These abnormalities, in combination with the presence of hypochromasia and keratocytes observed on the blood film, indicate iron deficiency. Serum iron concentration should be measured in this dog. Although the most common cause of iron deficiency is chronic blood loss, there is no history of such blood loss in this case. In most such cases, examination of feces will reveal the presence of blood. GI parasites such as hookworms, should also be considered.

Borderline neutrophilia with a slight left shift suggests a mild tissue demand for neutrophils, and, therefore, a mild inflammatory process. It is likely that the anemia is nonregenerative due to the presence of inflammation (anemia of inflammatory disease).

Biochemical profile

The blood glucose concentration is at the bottom of the reference interval. Decreased carbohydrate intake or decreased hepatic production are possible causes. Since there is little evidence of hepatic failure in this case, decreased intake appears to be the most likely explanation. Alternatively, it may be normal for this dog.

The hypocalcemia may be a result of hypoalbuminemia, in which case it is not clinically significant. An ionized calcium could be measured to confirm this.

The mild hypoalbuminemia is probably due to decreased protein intake or decreased amino acid absorption from the GI tract. Evidence of hepatic failure is not present, and urine protein concentration is normal; therefore, decreased albumin production by the liver and increased albumin loss through the kidneys are unlikely. In light of the anemia and the evidence of iron deficiency, chronic blood loss should be considered as a cause of hypoalbuminemia in this case; however, globulin concentration usually decreases proportionally with albumin concentration during blood loss. The globulin concentration may, however, have been increased in this dog due to chronic antigenic stimulation, and this would explain a normal globulin concentration despite blood loss severe enough to result in hypoalbuminemia.

The combination of increased serum and urine bilirubin concentrations suggests disruption in the hepatic excretion of conjugated bilirubin. The serum bilirubin concentration, while increased, appears inappropriately low in light of the marked increase in urine bilirubin concentration. Dogs have a low renal threshold for bilirubin, and, in dogs with abnormalities of hepatic conjugated bilirubin excretion, urine bilirubin concentration may increase prior to increases in serum bilirubin concentration, or urine bilirubin concentration may be markedly increased while serum bilirubin concentration is only mildly increased.

Hyponatremia and hypochloremia were probably caused by dilution of these electrolytes in an increased volume of extracellular fluid. This increased fluid volume is a result of accumulation of fluid in the peritoneal cavity. This "third-spacing" phenomenon commonly results in hyponatremia and hypochloremia.

Urinalysis

Marked bilirubinuria and presence of bilirubin crystals are the only abnormalities in the urinalysis. These changes probably resulted from increased passage of conjugated bilirubin into the blood with subsequent renal excretion. Either cholestasis or rupture of the bile duct or gall bladder could be an underlying cause.

Abdominal fluid analysis

Based on the total nucleated cell count and on the predominance of neutrophils, the peritoneal fluid should be classified as an exudate. Since neutrophils are nondegenerate and bacteria are absent, this is probably a nonseptic exudate. The pigment noted in macrophages is suggestive of bile and, therefore, gall bladder or bile duct rupture are likely.

Summary

Exploratory surgery revealed a ruptured gall bladder. Due to severe adhesions throughout the peritoneal cavity, the owner was offered a guarded prognosis. The owner opted for euthanasia.

Bilirubin leaking with bile into this dog's peritoneal cavity was reabsorbed through the peritoneal wall. The bilirubin entered the blood and was efficiently excreted by the kidneys. As a result, serum bilirubin concentration increased only slightly while urine bilirubin concentration increased markedly. Serum activities of the hepatic leakage enzymes, ALT and AST, did not increase since there was no direct liver injury. Serum activity of ALP did not increase since there was no cholestasis.

Case 59

Signalment: 2-year-old male mixed-breed dog
History: Weight loss, lethargy
Physical examination: Thin dog, pendulous abdomen
Hematology: Unremarkable

NCC (/μL)	1500
Segs (%)	60
Lymphs (%)	22
Macrophages (%)	18

Morphology: Neutrophils nondegenerate

Interpretive discussion

Biochemical profile

A number of factors in the profile suggest liver failure. These include a borderline low glucose, low BUN, hypoproteinemia characterized by severe hypoalbuminemia, and a markedly low cholesterol concentration. Hepatic enzymes are often normal with end-stage liver disease. An alternative, but less likely, possibility for this pattern is severe starvation. The increased bile acids indicate decreased liver function and help confirm end-stage liver disease.

Hypocalcemia may be due to hypoalbuminemia, in which case it is clinically insignificant. An ionized calcium could be measured to confirm this.

Body fluid analysis

The abdominal fluid has the typical features of a transudate. With end-stage liver disease this is due to a combination of hypoalbuminemia and increased portal blood pressure resulting in transudation of fluid into the cavity.

Summary

Hepatic cirrhosis; end-stage liver disease.

Case 60

Signalment: 3-month-old intact female dog

History: Anorexia, depression, and diarrhea of 1-week duration. Poor growth rate.

Physical examination: Severe, diffuse dermatitis with multifocal ulcerative lesions

Interpretive discussion

Hematology

This dog has a severe nonregenerative anemia. The anemia in this dog is microcytic, and the serum iron concentration is decreased, suggesting iron deficiency secondary to chronic blood loss. Alternately, microcytic anemia is also seen in dogs with portosystemic shunt, in which case serum iron may or may not be decreased, and anemia may be secondary to other abnormalities in iron metabolism. Red blood cell fragmentation is a typical finding in iron deficiency anemia. While iron deficiency anemia may be regenerative, this dog's bone marrow is not adequately responding, perhaps due to viral damage or concurrent anemia of chronic disease.

Severe leukopenia has resulted from a combination of neutropenia and lymphopenia. In a young dog with diarrhea as well as neutropenia and lymphopenia, parvovirus infection with virus-induced bone marrow damage should be a strong consideration. Acute bacterial enteritis resulting in endotoxemia may result in a similar leukogram. The presence of toxic neutrophils suggests that the bone marrow is rapidly producing neutrophils, and this may signal early recovery of previously suppressed neutrophil production, or may be a response to loss of neutrophils due to rapid, destruction or emigration into tissues as would occur with endotoxemia or overwhelming tissue demand for neutrophils, respectively.

Platelets are adequate, indicating chronic marrow failure is not present.

Biochemical profile

Hypoglycemia probably resulted from decreased hepatic glucose production. Numerous diseases can result in hypoglycemia, but, in light of other laboratory data, hepatic failure is the most likely cause of hypoglycemia in this dog. The decreased blood supply to the liver that occurs with

portosystemic shunts can result in liver atrophy. Such a liver cannot play its normal role in maintenance of blood glucose concentrations. A second possibility, in light of the decreased neutrophil concentration, is that the dog has bacteremia or endotoxemia that may result in hypoglycemia. A third possibility is that glucose is being lost through the urinary tract (see discussion of glucosuria).

Both the BUN and serum creatinine concentrations are decreased. Since there is evidence of hepatic failure, it is likely that the decreased BUN concentration resulted from decreased liver production of urea. Decreased creatinine reflects decreased muscle mass.

This dog has both hypocalcemia and hypoalbuminemia. The hypocalcemia may be caused by decreased protein-bound calcium secondary to the hypoalbuminemia, in which case it is clinically insignificant. An ionized calcium could be measured to confirm this.

Hypophosphatemia occurs most commonly in hypercalcemic disorders such as primary hyperparathyroidism and pseudohyperparathyroidism, but these are unlikely in a 3-month-old dog. Other causes include dietary phosphate or vitamin D deficiency, malabsorption syndrome, diabetes mellitus, and canine Fanconi-like syndrome. This dog appears to have a renal tubular defect (see discussion of glucosuria), and it is possible that this defect is part of a canine Fanconi-like syndrome. In such a syndrome, inadequate tubular reabsorption of phosphate results in excessive loss of phosphate in the urine.

The hypoproteinemia is the result of both hypoalbuminemia and hypoglobulinemia. These abnormalities, in combination with anemia, indicate that blood loss should be considered. In this case, it is likely that chronic liver disease is also contributing to hypoalbuminemia.

This dog's serum bilirubin concentration, serum alkaline phosphatase (ALP) activity, and gamma glutamyltransferase (GGT) activity are normal, suggesting that cholestasis is not occurring. While most forms of liver failure result in some degree of cholestasis, liver failure resulting from a portosystemic shunt usually does not. These normal values, in combination with the history and other laboratory abnormalities, suggest that a portosystemic shunt is likely. Since this is a young dog, a slight increase in ALP of bone origin would not have been unusual. Despite evidence of hepatic disease, serum ALT and AST activities are normal. Serum activities of hepatic leakage enzymes such as ALT and AST may be normal to increased in dogs with portosystemic shunts.

The hyponatremia and hypokalemia may have resulted from diuresis induced by glucosuria, or losses associated with diarrhea. It is also possible this dog's tubular function defect includes abnormal reabsorption of Na and K. Decreased intake likely contributed to the hypokalemia.

Markedly increased fasting bile acid concentration can result from decreased hepatic blood flow, hepatic failure, or cholestasis. In this case, decreased hepatic blood flow and subsequent hepatic failure are the most likely explanations.

Blood loss is the most common cause of decreased serum iron concentration in animals, although nursing animals have low serum iron due to inadequate dietary intake. In this case, however, the decreased serum iron concentration is probably due to the presence of a portosystemic shunt. Decreased serum iron concentration does not always occur in dogs with portosystemic shunts and the cause is not known, but it appears to be related to iron sequestration in tissues such as liver and/or defects in the transport of iron. Some cases also have intermittent gastrointestinal bleeding associated with pica.

Urinalysis

Moderate glucosuria in an animal with a low or normal blood glucose suggests a lowered renal threshold for glucose and, therefore, a renal tubular absorption defect. Such a defect may be confined to glucose absorption only, or may include defective absorption of several substances. As previously noted, this dog may also have defective absorption of phosphate, sodium, and potassium. If this is the case, this is probably a form of canine Fanconi-like syndrome. Measurement of the fractional excretion of phosphate, sodium, and potassium would have helped in assessing this possibility.

Summary

This dog had a portosystemic shunt. Hypoglycemia, decreased BUN concentration, hypoalbuminemia, and increased serum bile acid concentrations resulted from decreased hepatic blood flow and subsequent hepatic failure. Microcytosis has been reported as common in dogs with portosystemic shunts. This dog also has a renal tubular defect. Glucosuria in the presence of hypoglycemia, hypophosphatemia, hyponatremia, and hypokalemia are probably a result of defective tubular reabsorption of these substances. This defect is probably a canine Fanconi-like syndrome. Neutropenia does not typically occur in either portosystemic shunts or canine Fanconi-like syndrome, and this dog may have a concurrent enteric infection, most likely caused by parvovirus or endotoxin-producing bacteria, resulting in this abnormality.

Serum iron (µg/dL)	**22**	60–100

Interpretive discussion

Hematology

The dog has mild anemia that is not characterized by a reticulocyte count. The anemia is microcytic suggesting iron deficiency. Microcytosis should also prompt consideration of a portosystemic shunt in a young dog. Although some dogs with portosystemic shunt will have low serum iron concentrations, marked hypoferremia suggests iron deficiency is the cause of the microcytosis. There is a marked leukocytosis characterized by neutrophilia with a left shift; this is interpreted as an inflammatory leukogram.

Biochemical profile

The decreased BUN suggests reduced biosynthesis of urea by the liver. The same may be interpreted for cholesterol and albumin. There is a slight increase in ALT suggesting a mild degree of hepatocellular injury. The markedly increased bile acid concentration confirms a defect in hepatic function. The bilirubin and ALP do not indicate cholestasis. The slight increase in GGT is of questionable significance.

Hypocalcemia may be due to hypoalbuminemia, in which case it is clinically insignificant. An ionized calcium could be measured to confirm this.

Decreased creatinine reflects decreased muscle mass.

Summary

The findings of reduced hepatic biosynthesis with retention of bile acids in a young dog are highly suggestive of portosystemic shunt.

Case 62

Signalment: 10-year-old Yorkshire terrier

History: Disoriented and vomiting. The referring veterinarian (rDVM) performed a biochemical profile and urine analysis and referred the patient to a specialty hospital, where additional laboratory data were obtained.

Physical examination: Extremely small, even for breed, and very thin.

Initial laboratory data (provided by rDVM)		Reference interval
Glucose (mg/dL)	**45**	(75–130)
ALT (IU/L)	**313**	(<100)
ALP (IU/L)	**312**	(<100)
Urine specific gravity	1.023	
Urine glucose (mg/dL)	**Trace = 50**	(0)

Epithelial cells (hpf)	0–5
Fat droplets	Many
Bilirubin crystals	Rare

Imaging

Initial radiographs and ultrasound findings were normal, without evidence of a portosystemic shunt. The presence of an extrahepatic portosystemic shunt was determined by computed tomography angiography. Areas of hypoperfusion with possible necrosis were seen in the liver. A splenophrenic portosystemic shunt was identified as evidenced by an anomalous vessel that has a leftward and dorsal course after the splenic vein joins the portal vein; it then has a tortuous course before joining the vena cava along the diaphragm. Bilateral renal mineralization and cortical cysts were also observed.

Interpretive discussion

Hematology

The only abnormality in the CBC was leukocytosis due to neutrophilia. The mature neutrophilia may be due to inflammation or possibly stress, since the lymphocyte concentration is toward the lower end of the reference interval.

Most dogs with portosystemic shunts are microcytic; the MCV in this patient is within the reference interval.

Chemistry

Persistent hypoglycemia is present. Hypoglycemia in an older dog is usually a result of an insulinoma, which in this case was excluded as a diagnosis by measuring serum insulin. If an insulinoma were present, insulin concentration would be increased, rather than decreased. The decrease is appropriate in light of the hypoglycemia. The probable cause of hypoglycemia in this patient is severe, possibly end-stage liver disease, as evidenced by the pre- and postprandial increase in bile acids, and the high blood ammonia concentration as a result of a shunt. However, hypoglycemia may also be a result of the loss of glucose in the urine (see below).

The BUN is at the low end of the reference interval, which may be significant, considering the other evidence of severe liver dysfunction. The creatinine is below the reference interval and in this case is likely due to muscle wasting or small muscle mass.

Hypocalcemia is present, and can be primarily explained by the hypoalbuminemia, since approximately half of calcium is bound to albumin. However, other causes of hypocalcemia should be considered, such as hypovitaminosis D or hypoparathyroidism. Ionized calcium, vitamin D concentrations and PTH were not measured. Another possibility, considering the glucosuria in the face of hypoglycemia, is the possibility that the dog has a proximal tubular defect that is resulting in the loss of calcium through the urine. Phosphorus is within the reference interval, and would be expected to be decreased with hypovitaminosis D and likely increased with hypoparathyroidism. Additionally, if a proximal tubular defect is responsible for a loss of calcium in the urine, one would also expect a loss of phosphorus and electrolytes.

Total protein is decreased due to hypoalbuminemia, which in this case is likely due to a lack of production of albumin by the liver. Proteinuria is present, which may be another possible cause of hypoalbuminemia in this patient. A protein:creatinine ratio was not performed.

Serum ALT activity is increased, indicating hepatocellular damage. AST activity is also increased, which may be coming from the liver or from muscle. ALP and GGT activities are moderately increased, indicating cholestasis or induction by glucocorticoids or other drugs. However, bilirubin is not increased, suggesting that cholestasis is not present. CK activity is moderately increased, indicating muscle damage, which could be a result of trauma or intramuscular injections in this small dog.

The marked bile acid increase is indicative of liver disease, and when postprandial bile acids are increased to this magnitude, a portosystemic shunt should be strongly suspected. Imaging confirmed that the dog had a shunt (see below).

Blood ammonia increase is indicative of severe liver dysfunction, since ammonia is cleared from the portal circulation by the liver and converted to urea (see low normal BUN concentration discussion above). The increased ammonia concentration is likely causing the disorientation that the dog is experiencing, since ammonia is toxic to the central nervous system.

Urinalysis

Proteinuria is present, and should trigger a protein:creatinine ratio, which was not performed.

Glucosuria in the face of hypoglycemia is the most significant of the abnormal findings, and indicates a proximal tubular defect in the kidney. Ketonuria is also present and is likely due to hypoglycemia, and resultant mobilization of fat for energy. It also may be due to a lack of tubular resorption of acetoacetic acid. To confirm a Fanconi-like syndrome, fractional excretion of sodium, potassium, calcium and phosphorus can be performed, as well as measurement of amino acids in the urine, which are also not resorbed. The cause of the glucosuria and hypoglycemia was not pursued in this patient, and additional tests were not performed to confirm Fanconi syndrome. One confounding aspect of the case is that the dog received IV glucose to treat the hypoglycemia at some time prior to urinalysis, and it is possible that the renal threshold of glucose was exceeded as a result of glucose therapy. It could not be confirmed whether or not the dog had received IV glucose prior to the urinalysis performed by the rDVM.

It is unusual that the dog did not have ammonium biurate crystals in the urine, considering the high concentration of ammonia in the blood.

Summary and outcome

The patient was diagnosed with an extrahepatic splenophrenic portosystemic shunt. Congenital portosystemic shunts are usually diagnosed in young dogs, but clinical signs may not occur until the dog is old if the shunt is small. The patient was treated medically; therapy included metronidazole, lactulose, a nonabsorbable sugar that traps ammonia, prednisolone, omeprazole, and mirtazapine, an appetite stimulant. The dog was euthanized by the rDVM a short time following diagnosis, and an autopsy was not performed.

Extrahepatic portosystemic shunts are anomalous vessels that join the portal and systemic venous circulation, thus bypassing the liver, at least to some extent. They result in hepatic encephalopathy due to increased blood ammonia concentrations, stunted growth, urate cystic calculi, and sometimes GI signs. They are more common in small-breed dogs, such as the Yorkshire terrier. Laboratory findings are dependent on the stage of liver disease and the degree of shunting of blood away from the liver. Microcytosis is a very common finding, and should trigger suspicion of a shunt if chronic blood loss is excluded. Decreases in blood urea nitrogen and albumin are common, due to a lack of synthesis by the liver, and glucose and cholesterol may be decreased. Serum liver enzyme activity may be increased. Urine specific

gravity is often decreased due to low urea concentration, and ammonium biurate crystals are commonly seen in the urine. Serum bile acid concentrations are increased due to the anomalous circulation of the portal vein. Blood ammonia is very commonly increased as well.

Acquired or inherited diseases of the proximal renal tubule are rare in domestic animals. Primary renal glucosuria and congenital and acquired Fanconi syndrome has been described. Fanconi syndrome is characterized by a failure to reabsorb glucose, amino acids, water, bicarbonate, phosphorus, calcium, and other electrolytes. Renal glucosuria in the face of normal or low serum glucose is usually the initial finding. Metabolic acidosis eventually develops and is often the cause of death. Blood gases or total CO_2 were not measured in this dog. The diagnosis is confirmed by the presence of increased amino acids in the urine. Fanconi syndrome is relatively common in Basenjis, and is inherited as autosomal recessive. Up to 10% of Basenjis are affected, with onset of disease usually at the age of 4–7 years. Idiopathic Fanconi syndrome has been described in border terriers, Norwegian elkhounds, whippets, Yorkshire terriers, Labrador retrievers, Shetland sheepdogs, and mixed-breed dogs. Age at diagnosis ranges from 10 weeks to 11 years, with most affected dogs developing clinical signs from about 2–4 years of age. Acquired Fanconi syndrome has been associated with hypovitaminosis D, hypoparathyroidism, and with drugs, such as chemotherapeutic agents and antibiotics including gentamycin and amoxicillin. Toxins found in contaminated dried meat treats have also been reported to induce proximal tubular disease and a Fanconi-like syndrome [1, 2].

There are numerous reports in the literature of dogs with liver disease that have acquired Fanconi syndrome [3]. Several of these were dogs shown to have copper-associated chronic hepatitis. In one series of 30 Labrador retrievers with copper-associated chronic hepatitis, approximately 30% of them had acquired Fanconi syndrome, and the authors suggested that increased ALT activity and glucosuria with normal serum glucose in a Labrador retriever is suggestive of copper-associated hepatopathy. Although increased amount of copper is present in the renal epithelial cells of these dogs, and has been postulated to be the cause of the proximal tubular defect, in some of these dogs the Fanconi syndrome resolved with therapy that did not involve copper chelation, suggesting that the renal defect is related to liver disease, and not copper toxicosis [4, 5]. Concurrent Fanconi syndrome and liver cirrhosis has also been reported in human patients [6]. In summary, this patient had a portosystemic shunt resulting in liver disease, and possible Fanconi syndrome. Also see Case 60 for similar laboratory findings in a puppy with portosystemic shunt and concurrent Fanconi syndrome.

Interpretive discussion

Hematology

This dog is anemic on both days. The anemia is more severe on Day 1 and is nonregenerative. Since the Day 1 blood sample was obtained 12 hours after the accident, it is likely that the anemia is due to acute blood loss. The concurrent hypoproteinemia (see discussion below) also supports blood loss as the cause of this anemia. Increased polychromasia and reticulocyte count are not evident in blood until 2–4 days following acute blood loss. While the anemia appears nonregenerative on the initial sample, by Day 6, the erythrocyte values have increased, and there is evidence of increased erythrocyte production (increased polychromasia and reticulocyte count). This dog is, therefore, responding appropriately to the blood loss.

Although normal on both days, the MCV increased between Day 1 and Day 6, probably due to increased erythrocyte production resulting in increased number of large, immature erythrocytes.

The dog has a mature neutrophilia and lymphopenia on Day 1. This is compatible with a corticosteroid-mediated leukogram, resulting from stress associated with pain or trauma.

Neutrophilia and a left shift on Day 6 are typical of an inflammatory leukogram. Tissue injury associated with the accident probably incited an inflammatory response. An infectious etiology cannot be excluded, however.

Biochemical profile

Mild hyperglycemia on Day 1 resulted from stress. The presence of a stress leukogram supports this explanation.

Slight hypocalcemia may be normal in this dog since young animals commonly have slightly lower serum Ca concentrations than adults. However, the serum Ca concentration returned to within the reference interval on Day 6,

suggesting that this is the more normal value for this dog. It is possible that the hypocalcemia on Day 1 resulted from loss of albumin and albumin-bound Ca during hemorrhage.

Hypoproteinemia and hypoglobulinemia on Day 1 probably resulted from loss of protein during hemorrhage. Although the serum albumin concentration is in the reference interval, this might actually be low for this animal. The serum albumin concentration increased by Day 6, implying that this is the more normal concentration for this dog. All protein concentrations returned to within the reference intervals by Day 6, indicating that compensatory mechanisms had replaced the protein lost through hemorrhage.

Both serum ALT and AST activities are markedly increased on Day 1 but decrease to nearly normal by Day 6. These increases suggest liver and/or muscle injury. High concentrations of ALT are present in the liver and lower concentrations are present in muscle. The marked increase in ALT in this case, therefore, probably resulted from liver injury, but muscle injury may have also contributed. Aspartate aminotransferase (AST) is present in high concentrations in both liver and muscle, and both tissues may be sources of AST in this case. Liver and muscle trauma may explain these increased enzyme activities on Day 1. Shock with subsequent hypoxia and tissue injury can also result in leakage and increased serum activities of both enzymes. Regardless of the underlying cause of their leakage, the decreasing activities of both enzymes by Day 6 imply the damage was acute, and it is no longer active.

Increased alkaline phosphatase (ALP) activities are likely normal for this dog. Young, growing animals commonly have slightly to moderately increased serum ALP activity since, due to active bone growth, increased amounts of ALP are released from osteoblasts.

There is a slight decrease in the total CO_2 on Day 1, suggesting metabolic acidosis. Hypovolemic shock leading to tissue hypoxia may have resulted in production of acid metabolites, and decreased renal blood flow may have interfered with renal acid-base regulation. The anion gap, while still within the reference interval, is higher on Day 1 as compared to Day 6, and this may have resulted from increased blood concentrations of anions such as lactate.

Urinalysis

In light of the relatively dilute urine (specific gravity = 1.019), the urine concentration of erythrocytes may be slightly increased. Mild hematuria may have resulted from trauma.

Summary

This dog had a dislocated hip and broken femur. Surgery was performed between Days 1 and 6. The dog's recovery was uneventful. This case demonstrates a normal response to acute blood loss. It also demonstrates the importance of serial measurement of serum enzyme activities in animals with increases of these activities. Steady or increasing activities of these enzymes indicates active and continuing damage to the tissue(s) of origin. Decreasing activities usually indicate that the injury has ceased and/or is resolving.

Case 64

Signalment: 5-year-old cocker spaniel

History: Presented for anorexia and dark orange urine and feces. Dog had ITP 2 years previously and has been given phenobarbital (100 mg bid) for epilepsy for several years.

Hematology		Reference interval

Interpretive discussion

Hematology

The dog is markedly anemic. Reticulocytes are not increased, indicating that the anemia is not regenerative. The presence of the imperfect spherocytes and agglutination is suggestive of immune-mediated hemolytic anemia, possibly very acute, or with destruction of precursors. An unexplained nonregenerative anemia, when platelets and neutrophils are normal and increased, respectively, triggered a bone marrow aspirate. The bone marrow aspirate findings further substantiated immune-mediated hemolytic anemia with destruction of polychromatophilic cells.

Neutrophilia, increased immature neutrophils, and monocytosis are indicative of inflammation.

If the animal has not received a previous transfusion, a positive Coombs test is suggestive of immune-mediated hemolytic anemia.

Bone marrow

In light of marked erythroid response in marrow, anemia is either very acute, and will respond, or precursors are being destroyed. Because imperfect spherocytes are present on blood film, the latter is more likely.

Biochemical profile

The serum glucose concentration is decreased. Differentials should include insulinoma and, in this patient, end-stage liver disease, since the animal is also hypoalbuminemic and hypocholesterolemic.

The BUN is increased, and although the creatinine is within the reference interval, one would expect the animal to be concentrating greater than 1.022 if the azotemia is prerenal. One should consider if the animal is bleeding into the GI tract, increasing the BUN, or since IMHA is suspected based on the hematology, if the animal has hemolysis with subsequent hemoglobinuric nephrosis. If the animal does have end-stage liver disease, one would expect the BUN to be decreased as well, so the increase in BUN is slightly confusing. The mild increase in serum phosphorus suggests decreased glomerular filtration rate.

The serum calcium is decreased, likely due to hypoalbuminemia. An ionized calcium could be measured to confirm this.

The serum total protein concentration is decreased due to hypoalbuminemia. Since the globulin is within the reference interval, liver failure would be the best differential, since the animal is not proteinuric. Another consideration would be that blood loss is causing the anemia and hypoproteinemia, but there is no clinical evidence of blood loss.

The serum bilirubin concentration is markedly increased and may be due to hemolysis, liver failure, or cholestasis or some combination of the three. The ALT is only slightly increased, indicating mild hepatocellular damage. The ALP activity is increased, as is GGT activity, indicating cholestasis. Alternatively, enzymes may be induced by phenobarbital.

Serum total CO_2 is decreased, suggesting metabolic acidosis. This may be secondary to lactic acidosis associated with marked anemia. Increased sodium and chloride suggest hypertonic dehydration or administration of hypertonic fluid. The hypokalemia in conjunction with metabolic acidosis (which should have caused an increased potassium) suggests whole body potassium depletion.

Urinalysis

The marked bilirubinuria reflects conjugated hyperbilirubinemia. Specific gravity is discussed above.

Summary

Immune-mediated hemolytic anemia, liver failure, and renal dysfunction. The dog died, and necropsy showed severe chronic micronodular cirrhosis and cholestasis, possibly related to phenobarbital. Bone marrow showed myeloid and erythroid hyperplasia. Examination of the kidneys revealed severe hemoglobinemic nephrosis with mild chronic interstitial nephritis.

Case 65

Signalment: 8-year-old male Samoyed
History: Diarrhea
Physical examination: Recumbent, arrested prior to treatment

Hematology		Reference interval

Ketones	0

No other abnormalities present.

Interpretive discussion

Hematology

There is moderate regenerative anemia. Considering the hypoproteinemia, hemorrhage is the most likely cause. The nucleated RBC are interpreted as part of the regenerative response. There is a marked leukocytosis characterized by prominent neutrophilia with toxic change and a left shift to myelocytes indicating inflammation. The mild thrombocytopenia may be caused by hemorrhage, and giant platelets indicate active thrombopoiesis.

Biochemical profile and urinalysis

There is marked hyperglycemia. This is associated with an expected glucosuria. The magnitude of hyperglycemia should prompt consideration of diabetes mellitus. The lack of urine ketones makes the diagnosis more difficult.

Moderate azotemia is indicated by increased concentrations of BUN and creatinine. The specific gravity indicates minimal concentrating ability in the face of azotemia. This suggests an element of primary renal disease. However, electrolyte depletion (see later) may be contributing to the decreased concentrating ability. The increased phosphorus is compatible with decreased glomerular filtration.

The hypoproteinemia along with regenerative anemia is compatible with blood loss.

There is a marked increase in ALT activity indicating hepatocellular injury. Diabetes is associated with fat mobilization to the liver; this may result in modest ALT activity increases. The magnitude of this ALT suggests more severe injury. There is also an element of cholestasis indicated by the marked increase in ALP and a minimal increase in bilirubin.

The hyponatremia is likely due to urinary sodium loss secondary to glucosuria (osmotic diuresis). Losses associated with diarrhea may have contributed. Additionally, cellular water may move from the intracellular compartment into the extracellular fluid compartment, diluting serum sodium (expect 1.6 mEq/L decrease in sodium for every 100 mg/dL increase in glucose). The hyperkalemia is probably due to a shift of potassium ions out of cells in exchange for hydrogen ions, which enter cells during metabolic acidosis. Another possibility is that the animal is becoming oliguric and retaining potassium.

Increased anion gap is due to the presence of "unmeasured" anions. In this dog, these likely include phosphates, as well as lactate, since the dog is markedly anemic. In addition, because this dog is diabetic, ketones may contribute to unmeasured anions. Since beta-hydroxybutyrate is not detected by routine urine dipstick methods, ketonuria may actually be present.

Summary

Further evaluation led to the findings of diabetes mellitus and hepatic lipidosis. The enlarged, fragile liver had led to a fractured liver. This latter injury likely contributed to the magnitude of the ALT increase.

Interpretive discussion

Hematology

The leukogram shows a lymphopenia with a high normal concentration of mature neutrophils; this is interpreted as a stress or steroid leukogram. There are acanthocyte-like or spiculated cells present. These are commonly observed in cats with liver disease or hepatic lipidosis.

Biochemical profile

The mildly decreased BUN may be insignificant or may be due to decreased hepatic urea production or decreased protein intake. The combination of hyperbilirubinemia and increased ALT and ALP activities is characteristic of hepatic lipidosis in cats. The combination of the hepatocellular injury (indicated by increased ALT) and cholestasis (indicated by increased ALP) lead to failure of bilirubin clearance and hyperbilirubinemia. This degree of increase in ALP activity is unusual in cats, other than in association with hepatic lipidosis. Lipidosis is thought to occur as a result of massive fat mobilization from adipocytes in association with anorexia of several days' duration or acute diabetes mellitus.

Summary

The biochemical findings are characteristic of hepatic lipidosis, which was confirmed by liver aspiration cytology.

Interpretive discussion

Hematology

The plasma protein determined by refractometer is significantly higher than the total protein determined on the biochemistry panel. This is due to the marked lipemia of the sample. Lipemia occurs when triglyceride concentrations are increased. The refractometer estimates plasma proteins by the bending of light in relation to the concentration of solutes in the sample. Hyperlipidemia will cause an artifactual increase in the plasma protein measurement. Although hypercholesterolemia does not cause visible lipemia, if markedly increased it can artifactually increase the refractometric plasma protein measurement.

Biochemical profile

There is a marked increase in triglycerides and cholesterol, compatible with hyperlipidemia that may develop in sick camelids. In this case, negative energy balance accompanying late term pregnancy likely precipitated this condition. The glucose in this case is still normal.

Increased activity of AST in combination with a normal creatine kinase is compatible with hepatocellular injury rather than muscle origin of the AST. Increased activity of SDH also suggests hepatocellular damage while GGT is an indicator of cholestasis. Increased AST, SDH, GGT, triglycerides and cholesterol are common findings in camelids with hepatic lipidosis. Neither ALP nor bilirubin are increased and have been shown to be less reliable indicators of hepatic lipidosis in camelids.

The alpaca is ketotic as evidenced by the increase in serum β-hydroxybutyrate and the presence of ketones in the urine. The low TCO_2 indicates a decrease in bicarbonate and a metabolic acidosis. A blood gas profile is needed to completely assess acid/base status.

Urinalysis

The hyposthenuria is of unknown significance at this time. Camelids with hepatic lipidosis are at risk for developing renal failure secondary to accumulation of lipid in the renal parenchyma. Although her BUN and creatinine are normal, her renal function should be carefully monitored. The alkaline urine pH is normal for herbivores. However, this is somewhat surprising in the face of metabolic acidosis and ketonuria.

Summary

Increased activities of AST, SDH, and GGT along with hypertriglyceridemia and hypercholesterolemia are common findings in camelids with hepatic lipidosis. Ketosis and metabolic acidosis also can develop in these patients. Although not measured in this case, nonesterified fatty acids (NEFA) are expected to be increased as a result of mobilization of fat. Hepatic lipidosis can be precipitated by severe negative energy balance associated with late term pregnancy, stress, or anorexia. Fat is mobilized to supply fatty acids for energy production. However, the supply of fatty acids exceeds the ability to utilize them in the tricarboxylic acid (TCA) cycle. Fatty acids in the liver are incorporated into triglycerides and released as very-low-density lipoproteins (VLDLs), resulting in the hypertriglyceridemia. However, hepatic production of triglycerides exceeds the ability to export them as VLDL so triglycerides accumulate in the cells. Fatty acids also will be shunted into ketogenesis, resulting in the observed increase in β-hydroxybutyrate and ketonuria.

Interpretive discussion

Hematology

PCV is decreased, indicating anemia. Reticulocytes are increased, indicating that the anemia is somewhat regenerative. MCV is decreased, particularly in light of increased reticulocytes, suggesting iron deficiency anemia secondary to chronic blood loss.

Inflammatory leukogram is present, as evidenced by the marked left shift and toxic change in neutrophils. In light of low normal number of segmented neutrophils, sepsis or endotoxemia may be present. Lymphopenia suggests a concurrent stress response.

The combination of thrombocytopenia, schistocytes, and prolonged PT and aPTT suggests disseminated intravascular coagulopathy (DIC). Alternatively, this degree of thrombocytopenia may be seen with immune-mediated destruction or ehrlichiosis.

Biochemical profile

Hypoglycemia may be due to sepsis (leukogram is suggestive of sepsis or endotoxemia), end-stage liver disease, insulinoma, or other type of neoplasia, such as a large hepatoma.

Hypoalbuminemia, in conjunction with low cholesterol, is indicative of GI disease (malabsorption, maldigestion, protein losing enteropathy) or end-stage liver disease. Another possible cause of low total protein is blood loss, since MCV indicates iron deficiency anemia. However, albumin is relatively lower than globulin.

Total bilirubin is increased. While the animal is anemic, and blood destruction is a possible cause, the MCV suggests blood loss. Therefore, the bilirubin is probably increased due to cholestasis or hepatocellular dysfunction. Increased alkaline phosphatase activity suggests cholestasis.

Cholesterol is decreased, likely due to end-stage liver disease (see hypoalbuminemia discussion).

Hypokalemia may be due to decreased intake. In face of acidosis, it indicates total body depletion of potassium.

Decreased total CO_2 indicates metabolic acidosis. The decrease is likely due to lactic acidosis in this patient, since the dog is not uremic and there is no evidence of diabetic ketoacidosis.

Abdominal fluid analysis

Transudate, likely due to liver disease and hypoalbuminemia.

Coagulation data

While prolonged PT and aPTT may be due to lack of synthesis of coagulation factors by the liver, another explanation is DIC, in light of the decreased platelets.

Summary

End-stage liver disease; cholestasis
DIC
Inflammation, possibly sepsis
Iron deficiency anemia

Dermatitis was determined to be necrolytic migratory erythema (superficial necrolytic dermatitis), which is associated with hyperglucagonemia, often seen with severe hepatic disease (hepatocutaneous syndrome).

Case 69

Signalment: 26-month-old female mixed-breed dog

History: Routine prespay CBC at 8 months of age revealed thrombocytopenia of 85,000/μL. Patient was 4Dx antibody and PCR negative for *Anaplasma platys*, *Ehrlichia canis*, and PCR negative for *Babesia canis* and *Babesia gibsoni*. Thrombocytopenia was persistent, ranging from 23-000 to 95,000/μL over the next several months. A tentative diagnosis of immune-mediated thrombocytopenia was made, and glucocorticoids were instituted (ranged from 0.5 to 1.0 mg/kg for approximately 18 months). Patient deteriorated rapidly 18 months following initial presentation. History at this time included lethargy and anorexia.

Physical examination: Marked muscle wasting, pendulous abdomen, palpable caudal liver

Interpretive discussion

CBC

Slightly decreased PCV, RBC and hemoglobin indicate a mild anemia. Leukocytosis and neutrophilia, in the absence of lymphopenia, may be indicative of inflammation. Because of the long history of glucocorticoid therapy, it is surprising that the patient does not have a lymphopenia.

Chemistry

BUN is slightly decreased. When considered with the hypoalbuminemia and increased bile acids, this is likely associated with decreased liver function. The creatinine is decreased, which is compatible with muscle wasting in this patient. A mild hypophosphatemia is present, and may be due to increased glomerular filtration as a result of glucocorticoid administration.

Hypoalbuminemia is significant, and in this case is most likely due to liver dysfunction, considering increased bile acid concentration. Other considerations would be lack of intake of protein and loss through the kidney. A normal globulin makes protein losing enteropathy unlikely. A urine analysis was not performed.

Cholesterol is increased, which is likely due to glucocorticoid administration in this patient. While cholestasis may contribute to increased cholesterol, the bilirubin concentration is within the reference interval.

Increased ALT activity is indicative of hepatocellular damage.

The marked increase in ALP activity is not likely due to cholestasis, since the bilirubin is normal. The most likely cause is glucocorticoid induction in this patient.

Increased bile acids are indicative of liver disease. Considering the history of glucocorticoid administration, the increased ALT and ALP, the decreased albumin and BUN, it is very likely that this patient has a steroid hepatopathy with liver dysfunction, secondary to iatrogenic Cushing syndrome. The normal coagulation profile suggests that liver failure has not yet occurred.

An ACTH stimulation test to confirm iatrogenic Cushing syndrome was not performed. Adrenal glands of patients with iatrogenic Cushing syndrome do not respond (increase serum cortisol) to ACTH because their adrenal glands are atrophied.

Summary and outcome

One week later the patient had a syncopal episode and was cyanotic. She was rushed to the hospital, had recovered by time of admission, and was hospitalized for observation. The following morning, she ate, went for a walk, returned to her

cage, and went into cardiac arrest. An autopsy revealed a pulmonary thromboembolism (Figures 1 and 2), pulmonary mineralization (Figure 3), steroid hepatopathy (Figure 4), and atrophied adrenal glands.

Thromboembolism has been reported in dogs and people with hyperadrenocorticism and iatrogenic Cushing disease due to a hypercoagulable state attributed to increased procoagulant factors and decreased fibrinolytic capacity. In healthy dogs treated with prednisone, a significant decrease in antithrombin was observed after 15 days of treatment.

Pulmonary mineralization has also been reported in dogs with hyperadrenocorticism and iatrogenic Cushing disease. Both pulmonary mineralization and pulmonary thromboemboli can result in hypoxemia, and pulmonary thromboemboli can result in death, as seen in this patient.

Prolonged glucocorticoid therapy can have significant side effects, including steroid hepatopathy, thromboembolism, and pulmonary mineralization, and should be avoided if possible. Some canine and human patients have chronic immune thrombocytopenia that is refractory to glucocorticoid therapy, and other treatment modalities should be tried, or conversely, if the platelet count does not drop below 30,000/µL one could opt to not treat, considering the serious side effects of glucocorticoids. While the cause of the chronic thrombocytopenia was not definitively diagnosed in this patient, immune thrombocytopenia is most likely.

Interpretive discussion

Hematology

A severe, normocytic, normochromic, nonregenerative (<60-000 reticulocytes) anemia is present. Considering the hypoproteinemia, a preregenerative phase following acute blood loss cannot be excluded and should be considered given the history of hemorrhagic diarrhea. A truly nonregenerative anemia could also reflect decreased marrow production and is supported by the pancytopenia in this case. On initial inspection, there appears to be a significant increase in nucleated erythrocytes as indicated by the 15nRBC/100 WBC, but this does not take into consideration the leukopenia. If the anemia is preregenerative, the presence of nRBCs could be considered appropriate, however, if this is a true nonregenerative anemia, the response would be inappropriate and differentials such as endotoxemia, heatstroke, marrow disease, and altered splenic function should be considered.

The mild neutropenia could reflect overwhelming tissue utilization (inflammation) but we would typically expect to see a left shift or toxic neutrophils. One should also consider decreased marrow production, and given the hemorrhagic diarrhea, parvovirus remains a possibility, albeit less likely given the age of the animal. Another cause of neutropenia in this animal could be increased margination of neutrophils from the circulating pool as seen with acute endotoxemia. The leukopenia is also characterized by a lymphopenia that is due to stress (corticosteroid induced).

Causes in this animal for the thrombocytopenia include decreased production (marrow disease), increased consumption (hemorrhage/DIC), and sequestration (occurs with endotoxemia). Thrombocytopenia is too severe for hemorrhage alone. The moderately increased MPV could reflect bone marrow stimulation and release of macroplatelets.

Coagulation

Increased PT and PTT clotting times suggest abnormalities in both the extrinsic and intrinsic pathways or common pathway. Differentials to consider include DIC or a factor deficiency secondary to hepatic dysfunction (see below).

Chemistry

Hypoglycemia may be due to liver dysfunction, but sepsis should also be considered, particularly given the animal's clinical signs and neutropenia.

An azotemia is present and characterized by an increase in both BUN and creatinine. Concurrent hyperphosphatemia and hypermagnesemia support decreased GFR and renal insufficiency. A USG would be required to confirm a renal vs. prerenal (dehydration) component, however, it is important to note that a dilute USG following fluid therapy (as is the case here) does not confirm renal insufficiency.

Panhypoproteinemia could reflect a protein losing enteropathy, hemorrhage or severe hepatopathy with decrease protein synthesis, all of which are highly possible and may be contributing to this case.

The hypocalcemia is likely a consequence of hypoalbuminemia given that 40–50% of serum calcium is protein bound but hypocalcemia can also be seen with sepsis or renal disease.

Marked increased in ALT activity is indicative of hepatocellular injury. This is supported by the concurrent increase in AST, which may, however, also be due to muscle injury as evidenced by the increased CK. A moderate increase in ALP with GGT being within normal limits is suggestive of steroid isoenzyme induction rather than cholestasis although hyperbilirubinemia may support the latter. Furthermore, hypoglycemia, hyperbilirubinemia, hypoalbuminemia and hypocholesterolemia could reflect hepatic insufficiency.

A selective chloride loss is indicative of "secretional" metabolic alkalosis and vomiting is generally the most likely cause of this abnormality. The anion gap is increased reflecting an increase in unmeasured anions such as uremic acids and lactate. Given the complex acid-base disturbances, the bicarbonate/TCO_2 is as predicted.

Summary and outcome

Laboratory findings suggest a severe hepatopathy, enteropathy, consumptive coagulopathy, and anemia that could be preregenerative, azotemia of undetermined source and mixed metabolic acid-base disturbances (hypochloremic metabolic alkalosis and high-AG metabolic acidosis).

The dog was euthanized based on poor clinical condition and prognosis. Necropsy and histopathology indicated severe hepatocellular necrosis, acute necrohemorrhagic enterocolitis, gastric hemorrhage/mucosal necrosis, and dirofilariasis (single adult worm). Enteric cultures for clostridium and salmonella were negative. The clinical and laboratory findings and lesions are very typical of sago palm (Cycad palm) toxicity. All parts of plant are considered toxic; cycasin is the hepato/entero-toxin [1]. Liver failure can be seen 2–3 days postingestion. Although not definitively confirmed, the plant was found in the neighbor's unfenced yard.

Interpretive discussion

Hematology

Mild leukocytosis characterized by a mild neutrophilia and marked left-shift is indicative of active inflammation and supported by the hyperfibrinogenemia.

Chemistry

The mild to moderate increase in AST activity could reflect hepatocellular injury or muscle damage. Given the concurrent increase in CK, these changes are most likely due to muscle injury secondary to recumbency.

The marked increased GLDH enzyme activity indicates hepatocellular injury.

Markedly increased GGT activity is specific for cholestasis, most likely intrahepatic in origin. This is also supported by the hyperbilirubinemia, which could reflect hepatic or posthepatic causes, but not prehepatic, given the absence of hemolysis.

Hyperproteinemia is characterized by a mild-to-moderate hyperglobulinemia that is most likely due to increased gamma globulins, suggesting antigenic stimulation. The biochemistry was performed on serum, so an increased fibrinogen would not have affected the protein measurement.

Decreased creatinine concentration is typically not clinically significant but could reflect decreased muscle mass.

Summary and outcome

This animal had photosensitization secondary to severe acute hepatic necrosis and cholestasis. The cause of hepatic injury was uncertain but in cattle is most often secondary to oral hepatotoxins. Decreased hepatic function in this case leads to increased phylloerythrin escaping liver metabolism and being deposited in the skin, which, after being exposed to UV radiation, forms free radicals, leading to local tissue damage.

Interpretive discussion

Hematology

The increase in hemoglobin concentration is discrepant with the other erythrocyte analytes (PCV, RBC) and probably due to artifact rather than a true or relative (dehydration) erythrocytosis. While not mentioned in the hematology profile, lipemia (see below) is most likely causing an erroneously high hemoglobin reading by the photometer in the hematology analyzer. This is also supported by difference between biochemical and refractometric measures of total protein, with lipemia falsely increasing the latter.

The presence of band neutrophils in combination with toxic change is indicative of inflammation with premature marrow release of immature forms. In the absence of a mature neutrophilia, the inflammation is likely to be acute or overwhelming. Endotoxemia is a possibility in this case and could be causing margination of mature neutrophils contributing to the low-normal value. With inflammation, an increase in fibrinogen is expected but not observed in this case, possibly due to the very acute nature of this process or decreased hepatic synthesis.

Chemistry and blood gas

In all mammals, a transient hyperglycemia can be induced by a corticosteroid or epinephrine response and is a possible cause in this case. Persistent hyperglycemia in equines can also be observed with pituitary pars intermedia dysfunction (**PPID**) which leads to insulin resistance from excess cortisol release.

A mild azotemia characterized by an increased creatinine and high normal urea is present and could be prerenal (dehydration) or renal. A urine specific gravity would be required to assess renal concentrating ability. It is also important to note that urea is a poor indicator of renal function

in horses (compared to small animals) given their ability to excrete urea through the gastrointestinal tract. The concurrent hyperphosphatemia indicates decreased GFR and does not elucidate the mechanism of azotemia.

Hypocalcemia is likely a due to decreased protein binding (secondary to hypoalbuminemia) given 40–50% of circulating calcium is protein bound; measuring ionized calcium is warranted. Other differentials to consider in a horse include gastrointestinal disease (decreased absorption vs. increased loss), renal losses, or excessive sweating.

A hypoproteinemia with a component of hypoalbuminemia could reflect a protein losing nephropathy (PLN) or enteropathy, although the latter tends to lead to panhypoproteinemia. A completely urinalysis and assessment of proteinuria could aid in ruling in/out a PLN. Also, worth considering is loss through third spacing such as effusions, as well as decreased hepatic synthesis. Albumin is a negative acute phase protein and can also be decreased with inflammation.

Anorexia is a common cause of hyperbilirubinemia in horses. However, the concurrent increase in ALP and GGT activity suggest cholestasis, such as might be seen with cholangiohepatitis. The concurrent increase in AST activity may suggest hepatocellular injury but could also be due to muscle injury with increased CK supporting this (AST has a longer half-life than CK).

There is a hyperlipidemia characterized by a marked increase in triglycerides. In horses, this typically occurs in states of negative energy balance, where poor nutrition leads to lipolysis and subsequent production of VLDL. Predisposing factors include being a miniature horse, anorexia, obesity and other conditions leading to insulin resistance (PPID, pregnancy). Excessive VLDL production can lead to storage of triglycerides in hepatocytes and result in hepatic lipidosis, a possibility in this case given the evidence of hepatobiliary disease.

Hypochloremia is present and the corrected chloride is calculated to be 94.8 mEq/l, indicating a mild selective chloride loss. Differentials to consider include gastrointestinal disease (diarrhea, gastric reflux) and excessive sweating.

With a selective chloride loss, one would expect a metabolic alkalosis. This, however, is not the case as the decreased bicarbonate and increased anion gap reveals a titrational metabolic acidosis with increased concentration of unmeasured anions. In this case, uremic acids and lactate are the most likely contributors. Blood gases confirm a metabolic acidosis with a compensatory respiratory alkalosis (low pCO_2). It is also likely that the chloride was slightly falsely decreased due to hyperlipidemia. Since an indirect ion-selective electrode measuring system was used. For every 885 mg/dL increase in total lipid concentration, there is a decrease of 1 mEq/L in chloride [1].

Summary and outcome

Laboratory abnormalities in combination with signalment and history are consistent with equine hyperlipemia syndrome. Hepatic lipidosis, inflammation and lactic acidosis are likely in this case.

Investigation revealed free peritoneal fluid that was septic and suppurative. The horse unfortunately died and presented to the necropsy service, where it was revealed to have hepatic lipidosis, renal tubular lipidosis, pulmonary hemorrhage, lymphoplasmacytic enteritis, a portion of necrotic cecum, and evidence of an early pregnancy. Cultures revealed salmonellosis.

Interpretive discussion

Hematology

Lymphopenia is indicative of increased endogenous (stress or hyperadrenocorticism) or exogenous corticosteroids. Increased immature neutrophil concentration is indicative of inflammation. Neutrophilia may be due to inflammation or stress. In summary, an inflammatory and stress (steroid) leukogram is present.

Biochemical profile

Hyperglycemia is of the magnitude that diabetes mellitus should be suspected. Hyperglycemia may also be secondary to hyperadrenocorticism; therefore, adrenocorticotropic hormone (ACTH) stimulation and low-dose dexamethasone suppression (LDDS) tests are indicated.

BUN is increased, but creatinine is within the reference interval. Urine specific gravity indicates kidneys are capable of concentrating, thus the azotemia is prerenal, perhaps clue to dehydration. However, albumin is within reference interval. The PCV is normal, suggesting that GI bleeding is not the cause of the increased BUN.

Total bilirubin is increased suggesting cholestasis, because anemia is not present. Alkaline phosphatase activity is increased, which is also suggestive of cholestasis. Another consideration is hyperadrenocorticism, with an increase in the corticosteroid-induced alkaline phosphatase isoenzyme. Increased cholesterol of this magnitude is probably due to lipidemia, although some component of the increase could also be due to cholestasis. ALT activity is increased, which is indicative of hepatocellular damage.

Sodium and chloride concentrations are decreased. Sodium may be lost through the kidney, although this animal is capable of concentrating. Although it is not mentioned in the history, abdominal pain may have been associated with vomiting, which would result in electrolyte loss. Hyperglycemia results in increased serum osmolality with a shift of intracellular fluid to extracellular fluid in an attempt to decrease extracellular fluid solute concentration. Sodium can be expected to decrease by 1.6 mEq/l for every 100 mg/dl increase in glucose.

Total CO_2 is decreased, indicating metabolic acidosis. The anion gap is increased, indicating increased unmeasured anions are present. In this case, unmeasured anions might be ketones, although they are not present in the urine. Urine ketone tests that use the nitroprusside reaction do not detect β-hydroxybutyric acid; therefore, the presence of this ketone cannot be ruled out. Other possibilities include lactic acidosis.

Serum lipase activity is increased. In this patient, this increase could partially be due to decreased GFR, as indicated by azotemia. However, the inflammatory leukogram, increased bilirubin, increased alkaline phosphatase activity, hyperglycemia, and lipemia are also suggestive of pancreatitis. This magnitude of lipase increase is highly supportive of pancreatitis. Prerenal azotemia due to hemoconcentration and poor renal perfusion is a common complication of pancreatitis. Likewise, so is hepatocellular injury and cholestasis.

Urinalysis

Urine specific gravity of 1.035 indicates the dog is capable of concentrating, thus the increase in BUN is prerenal (perhaps dehydration). Glucosuria and bilirubinuria are to the expected in light of the serum concentrations.

Endocrine data

ACTH stimulation test: Baseline cortisol is slightly above normal. Normal animals stimulate to around 10–16 μg/dl. Low-dose dexamethasone suppression test: Baseline cortisol is normal. Dog suppressed marginally at 8 hours. The endocrine data are not supportive of hyper-adrenocorticism.

Summary

This dog has primary hyperlipidemia, which has been shown to be familial in miniature schnauzers [1], and pancreatitis with secondary diabetes mellitus. Dogs with hyperlipidemia are predisposed to development of pancreatitis. While diabetes mellitus may be transitory, treatment is indicated. Some abnormalities (hyperglycemia, stress leukogram, increased alkaline phosphatase activity, lipemia, history, and physical appearance) were suggestive of hyperadrenocorticism. This possibility was ruled out by the ACTH stimulation and LDDS test. Imaging revealed evidence of swelling in the area of the pancreas.

Interpretive discussion

Hematology

The PCV is mildly decreased, no polychromasia was noted in the blood film, and the MCV is normal, indicating a mild nonregenerative anemia. Marked lipemia and hemolysis may have resulted in *in vitro* hemolysis, but this typically does not result in an important decrease in the PCV. There is a neutropenia with increased bands and marked numbers of toxic neutrophils. This suggests consumption as a result of severe inflammatory disease. Lymphopenia indicates a stress component. The thrombocytopenia is discussed with the coagulation data.

Biochemical profile

The serum glucose concentration is moderately increased. In this range, it is possible that this is a stress hyperglycemia

but is more likely due to some metabolic or endocrine abnormality.

The BUN and serum creatinine concentrations are normal. The serum phosphorus is normal, but there is a mild decrease in serum total calcium concentration. Given the degree of hypoalbuminemia, it is wise to attempt to correct the total calcium for the hypoproteinemia. In this case, the corrected value is 9.9 mg/dl (8.2 − 1.8 + 3.5), which is normal.

The serum cholesterol concentration is markedly increased. While this may be associated with cholestasis, given the degree of increase in cholesterol one should also consider other metabolic abnormalities including hepatic disease, disorders of lipoprotein metabolism, or endocrinopathies. The serum triglyceride concentration is markedly increased, and further supports a diagnosis of a metabolic and/or endocrinologic disorder. Cholestasis is indicated by the increased total bilirubin and ALP activity. The serum ALT, AST, and GGT activities are normal or near normal, reducing the likelihood of hepatocellular injury,

The serum amylase and lipase activities are significantly increased, and in the absence of azotemia suggest acute pancreatitis. This is a frequent complication of severe prolonged hyperlipidemia. The concurrent findings of hyperlipidemia and pancreatitis in a miniature schnauzer should alert one to the potential diagnosis of a primary dyslipidemia.

Coagulation data

The coagulation profile includes a normal PT, but prolonged aPTT. While it is more common for the PT to become prolonged first when there is impaired coagulation factor synthesis by the liver, incipient DIC (note the thrombocytopenia) or heparinization of the patient may result in changes in the aPTT alone.

Abdominal fluid analysis

Abdominal fluid chemical analysis similarly indicates accumulation of excess lipids in the peritoneal cavity. It is likely that the increased total protein by refractometry is spuriously elevated by this lipid. The cell concentration suggests a modified transudate.

Urinalysis

The urine specific gravity indicates that the kidneys are capable of concentrating, and the number of leukocytes and erythrocytes are not significant. However, there is 2+ proteinuria, some occult blood, and some hyaline and fine granular casts. Thus, there may be mild tubular and/or glomerular disease. In addition, there is significant glucosuria, which is explained by the hyperglycemia. It would be useful to evaluate the UPC in order to determine the magnitude of the proteinuria. Given the hypoalbuminemia and hypercholesterolemia, one should consider, the possibility of nephrotic syndrome; there may be a protein losing glomerulopathy without azotemia.

Summary

Miniature schnauzer hyperlipidemia and acute pancreatitis.

Case 75

Interpretive discussion

Hematology

Leukogram abnormalities include neutrophilia, a left shift, lymphopenia, and slightly toxic neutrophils. This is an inflammatory leukogram indicating a tissue demand for neutrophils. The lymphopenia suggests concurrent increase in corticosteroid concentrations due to stress. Toxic neutrophils indicate a rapid rate of neutrophil production.

Echinocyte formation can be an artifact, but in this case, it may have resulted from the marked hyperosmolality and electrolyte abnormalities. These may have caused movement of water from the cytoplasm of erythrocytes to the plasma with resulting shrinkage and crenation of erythrocytes.

Biochemical profile

The serum glucose concentration is markedly increased. The most likely cause of hyperglycemia of this magnitude is diabetes mellitus. Severe, acute excitement with release of catecholamines can cause marked hyperglycemia in cats, but serum glucose concentration is seldom greater than 400 mg/dl in such cats. This cat is azotemic, and decreased renal excretion of glucose, secondary to decreased glomerular filtration rate, may have augmented the magnitude of the hyperglycemia. Moreover, the cat does not have an excitement leukogram (lymphocytosis).

Both BUN and serum creatinine concentrations are increased. Since the urine specific gravity suggests adequate renal concentrating ability (i.e., the specific gravity is greater than 1.030), this appears to be a prerenal azotemia. However, the marked hyperproteinemia and hypernatremia suggest severe dehydration, and an even higher urine specific gravity would be expected in this situation. It is, therefore, possible that this cat has some loss of urine concentration ability. Alternatively, osmotic diuresis due to glucosuria may have contributed to the lower-than-expected urine specific gravity. The hyperphosphatemia is a result of a decreased glomerular filtration rate. Maintenance of normal serum phosphorus concentrations depends on phosphorus excretion through the kidney.

Hyperproteinemia (both plasma and serum protein) with concurrent hyperalbuminemia and hyperglobulinemia is typical of dehydration. Contraction of plasma water volume results in proportional increases in concentrations of both albumin and globulin. Although other abnormalities can cause hyperglobulinemia, dehydration is the only cause of hyperalbuminemia. Diuresis secondary to glucosuria is common in diabetes mellitus and can result in dehydration.

The serum cholesterol concentration is increased. In this case, this abnormality is probably secondary to diabetes mellitus and related abnormalities in lipid metabolism.

Serum activities of both ALT and AST are increased. The increased serum ALT activity is due to hepatocyte injury and subsequent leakage of this enzyme. This injury was probably caused by fatty change that developed secondary to the metabolic abnormalities of diabetes mellitus. The increased serum AST activity may also be due to leakage of AST from injured hepatocytes, but the higher activity of AST as compared to ALT suggests that there is also an extrahepatic source. This source may be muscle and may have resulted from muscle injury secondary to hypoperfusion, since the cat is very dehydrated.

Hypernatremia and hyperchloremia are probably due to severe dehydration. Glucosuria causes diuresis resulting in Na and Cl loss through the kidneys in nondehydrated or mildly dehydrated, diabetic animals. This can lead to hyponatremia and hypochloremia. When such animals become severely dehydrated, however, diuresis no longer occurs, and hypernatremia and hyperchloremia develop. These changes, in combination with hyperglycemia and azotemia, result in severe hyperosmolality.

Decreased serum total CO_2 concentration probably represents a primary metabolic acidosis. Serum total CO_2 concentration may also decrease as a compensatory reaction in animals with primary respiratory alkalosis, but in animals with diabetes mellitus, metabolic acidosis is more likely to be the primary alteration. Increased serum concentrations of ketones are a common cause of acidosis in diabetic animals, but the absence of urine ketones suggests that this cat is probably not ketotic. Urine ketone tests that use the nitroprusside reaction do not detect β-hydroxybutyric acid, therefore, the presence of this ketone cannot be ruled out. Increased serum lactate concentration may be contributing to the acidosis in this cat. The cat is markedly dehydrated and is, therefore, probably experiencing tissue hypoxia that may lead to increased lactate production.

The anion gap is increased. In most diabetic animals, increased ketoacid concentration in the blood is the major cause of this abnormality. In this cat, which is apparently not ketotic, increased blood lactate concentration is probably contributing to this gap.

The calculated osmolarity is increased and, in combination with other laboratory changes, suggests this cat has diabetic nonketotic hyperosmolar syndrome (see summary).

Urinalysis

This cat has a proteinuria with a mild pyuria. It is possible that the protein exuded into the urine as part of the inflammatory process; however, the degree of proteinuria appears to be excessive compared to the degree of pyuria. Other causes of proteinuria such as glomerular and tubular disease should be considered in this case. Although glomerular disease has been associated with diabetes mellitus in humans, this has not been documented in animals.

The strongly positive reaction on the chemical test for blood in combination with normal numbers of erythrocytes suggests that the positive reaction is due to either free hemoglobin or myoglobin. It is unlikely that this represents a hematuria with subsequent lysis of erythrocytes since such lysis is unlikely in urine with a high specific gravity. Absence of anemia suggests a significant hemolytic problem is not occurring in this cat. Myoglobinuria is a possible explanation, and severe muscle hypoxia secondary to hypovolemia may have occurred in this cat. However, the serum AST activity, while increased, does not suggest such massive muscle injury.

Glucosuria is a result of the serum glucose concentration exceeding the renal threshold.

Summary

The clinical diagnosis was diabetic nonketotic hyperosmolar syndrome. This syndrome is characterized by marked hyperglycemia (blood glucose concentration >600 mg/dL), hyperosmolarity (>350 mOsm/L), and absence of ketosis in a diabetic animal. Such animals commonly have prerenal or renal azotemia. The hyperosmolarity results in dehydration of neurons and subsequent neurologic signs. This syndrome is associated with a high fatality rate.

After a brief, unsuccessful attempt to decrease serum glucose concentrations with insulin therapy and to improve the cat's electrolyte and fluid balance by administration of fluids, the owner elected euthanasia. Necropsy revealed severs islet cell degeneration and amyloidosis and severe hepatocytic vacuolar degeneration. A few mineralized casts were present in renal tubules, but the kidneys were otherwise normal, and the azotemia was probably prerenal in this case. The cause of the inflammatory leukogram was not determined.

Interpretive discussion

Hematology

The packed cell volume, hemoglobin, and total RBC count are normal, but given the degree of hemoconcentration represented by the hyperproteinemia, it is possible that the PCV is actually lower. There is a slight increase in polychromasia and mild reticulocytosis. The anemia is rapidly progressive over a 1-week period of time. The presence of 2+ Heinz bodies indicates significant oxidative damage to the red blood cells, and is commonly observed in cats with diabetic ketoacidosis; however, the owner should be questioned as to whether the cat has received acetaminophen or other oxidant drugs or chemicals. Another potential cause of hemolytic anemia in this patient is hypophosphatemia. There is a stress leukogram, as indicated by the high normal neutrophil count and lymphopenia.

Biochemical profile

The serum glucose concentration is moderately increased. While a glucose concentration of this magnitude may be encountered due to extreme excitement (sympathetic activation) or stress (glucocorticoid release), diabetes mellitus is more likely. Evidence against excitement-induced hyperglycemia is the lack of an excitement leukogram (lymphocytosis). The BUN and serum creatinine concentrations are normal.

The serum phosphorus concentration is decreased, and given the degree of hyperglycemia, one should consider diabetic ketoacidosis-induced urinary phosphate loss. The serum total calcium concentration is normal, reducing the possibility of an endocrine abnormality causing the change in serum phosphorus. The serum total protein concentration is at the upper end of the reference interval, and serum albumin is increased, indicating hemoconcentration due to dehydration.

The serum cholesterol concentration is moderately increased. While this may be associated with cholestasis, as indicated by the increased total bilirubin, the ALP activity is normal. Given the degree of increase in cholesterol, one should consider metabolic abnormalities including hepatic disease, disorders of lipoprotein metabolism, or endocrinopathies. If not due to cholestasis, then the increase in bilirubin may be due to hemolysis. The serum ALT activity is increased modestly, which indicates hepatocellular damage. ALP is not induced by steroids in cats, thus, hyperadrenocorticism is a possibility. Serum lipase activity is only slightly increased, possibly reducing the probability for concurrent pancreatitis; however, increased lipase activity is not a reliable marker for feline pancreatitis.

Serum Na, K, and Cl concentration are decreased significantly. One should consider typical causes for electrolyte depletion, including pathologic losses from the gastrointestinal and urinary systems, as well as a shift to third space. The marked hyperglycemia should initiate consideration of diabetic ketoacidosis with subsequent urinary electrolyte loss. There is a marked decrease in serum total CO, suggesting metabolic acidosis. The increase in the anion gap is likely due to the presence of ketones, which are unmeasured anions.

Blood gas data

The blood gas panel indicates a metabolic acidosis (decreased pH and HCO_3) with respiratory compensation (decreased pCO_2). Ionized calcium is marginally decreased.

Urinalysis

The urinary specific gravity is normal. However, with marked increases in the concentration of solutes, such as glucose, not pertinent to urinary concentration capacity, one might question the accuracy of this measure, and consider determining urinary osmolality to address urinary concentration capacity specifically. The presence of 1+ protein and coarse granular casts is consistent with renal tubular disease. The absence of more significant proteinuria speaks against the possibility of glomerular protein loss, but a urinary protein:creatinine ratio should be determined to confirm this. In either case, urinary tract inflammation is not a likely cause of the observed changes, as there is only a small amount of occult blood and no pyuria. The presence of significant amounts of glucose and ketones supports a diagnosis of diabetic ketoacidosis. The mild bilirubinuria is a result of the increased serum bilirubin and subsequent renal excretion.

Summary

Diabetic ketoacidosis; Heinz body anemia

Case 77

Signalment: 8-year-old castrated male Labrador retriever

History: Two months of decreased activity, progressing to muscle fasciculations and mild intermittent seizures. Referring DVM prescribed phenobarbital and prednisone 5 days previously.

Physical examination: Obese, reluctant to move. Normal body temperature, heart rate, respiratory rate. Normal chest radiographs and abdominal ultrasound.

Interpretive discussion

Hematology

The only abnormalities are a mild mature neutrophilia and lymphopenia, consistent with a stress/steroid leukogram. This is not surprising given the history of prednisone administration.

Biochemical profile

Increased ALP and GGT activities are most likely due to steroid induction given the history of prednisone administration. There is no other evidence to support cholestasis or liver disease.

Hypoglycemia is pronounced. Appropriate sample handling procedures were followed, ruling-out artifactual hypoglycemia due to delayed removal of serum from the red cells, and episodic hypoglycemia fits the clinical signs. There is no evidence for sepsis (no inflammatory leukogram) or liver failure (BUN, cholesterol, albumin are normal).

Serum insulin concentration is increased at the same time this dog is hypoglycemic, which is an inappropriate response. Normally, feedback mechanisms result in low serum insulin concentrations when hypoglycemia exists. Uncontrolled insulin production from a neoplasm is most likely. The most common tumor associated with hypoglycemia in dogs is insulinoma, a neoplasm of pancreatic β-cells.

Summary

An exploratory laparotomy was performed and a small pancreatic mass was identified and removed. Small nodules were present in the liver, and regional lymph nodes were enlarged. Aspirates from an enlarged node were taken intraoperatively, and a metastatic endocrine tumor was diagnosed by cytology. Histopathology confirmed a β-cell carcinoma in the pancreas with metastases to liver and lymph node. It is important to measure serum insulin concentrations at the same time the dog is hypoglycemic, preferably when the blood glucose is <50 mg/dl. Under these conditions, a serum insulin concentration that is increased or in the upper half of the reference interval indicates a relative insulin excess, suggesting uncontrolled insulin production.

Case 78

Signalment: 6-day-old female Holstein

Interpretive discussion

Hematology

There is a monocytosis and a lymphopenia that represent the effects of stress. The plasma protein concentration is increased, most probably due to dehydration. Erythrocyte indices reflect hemoconcentration as well, as evidenced by the increased RBC count, hemoglobin concentration, and PCV. The MCV is decreased, which may be due to an underlying iron-deficiency anemia of the newborn that is obscured by hemoconcentration. The presence of several erythrocyte morphologic abnormalities supports this. Iron deficiency is frequently associated not only with a microcytic anemia but also with oxidative damage to the erythrocytes, resulting in membrane abnormalities and fragmentation changes.

Biochemical profile

There is a profound hypoglycemia, which in a neonatal calf with diarrhea is most probably related to decreased food intake, as well as the possibility of sepsis. Sepsis is unlikely, considering the normal neutrophil concentration.

The BUN and serum creatinine concentrations are increased, but the origin of this azotemia cannot be discerned from this data alone. Refer to the discussion in the urinalysis section below.

Serum calcium is mildly decreased, possibly due to decreased milk intake. The serum total protein and albumin concentrations are increased, further reflecting hemoconcentration due to dehydration. The serum CK and AST activities are modestly increased, which may be related to muscle damage subsequent to prolonged recumbency or hypoperfusion. The total bilirubin is increased. Together with the increased AST activity, this may indicate hepatocellular damage. Alternatively, there may be cholestasis due to dehydration or prehepatic icterus due to increased destruction of oxidatively-damaged iron-deficient erythrocytes.

The serum sodium and chloride concentrations are decreased, reflecting decreased intake and/or increased loss from the body. *Escherichia coli*-associated diarrhea in neonatal calves commonly results from increased sodium chloride loss

induced by the enterotoxin that promotes active secretion into the gut lumen. Increased water loss follows this osmotic gradient. Bicarbonate is also lost in the feces, and hypovolemia may lead to tissue hypoperfusion, lactic acidosis, and decreased bicarbonate concentration as well. Fecal potassium loss is typically increased, but concomitant metabolic acidosis results in exchange of intracellular potassium for extracellular protons and a redistributional hyperkalemia.

Blood gas data

There is a combined metabolic (decreased bicarbonate) and respiratory (increased pCO_2) acidosis. The metabolic acidosis results from bicarbonate loss in the diarrhea and from lactic acidosis due to tissue hypoperfusion. The increased anion gap reflects the accumulation of unmeasured anions such as lactate. The mild respiratory acidosis indicates pulmonary dysfunction. Early pneumonia or decreased pulmonary perfusion secondary to dehydration are possible explanations.

Urinalysis

The only significant abnormality is a urine specific gravity of 1.014. Six-day-old calves, unlike neonates of many other species, should have mature capacity to concentrate urine. Dehydration should stimulate antidiuretic hormone release from the hypothalamus, and increased water reclamation by the renal tubules. However, electrolyte loss in this type of hypotonic dehydration often leads to medullary solute depletion and a loss of the renal concentration gradient. Another alternative is that there is renal disease, due to renal hypoperfusion, sepsis, etc., resulting in both azotemia and loss of concentrating ability.

Summary

Secretory diarrhea and hypotonic dehydration in a neonatal calf.

Case 79

Signalment: 9-month-old bull
History: Anorexia, depression
Physical examination: Enlarged abdomen

pCO_2 (mmHg)	**80**	34–44

Interpretive discussion

Hematology

PCV is decreased, indicating anemia.

MCV is decreased, suggesting iron deficiency anemia secondary to chronic blood loss.

Neutrophilia, increased band neutrophils, and monocytosis are indicative of chronic inflammation.

Increased fibrinogen also suggests inflammation.

Keratocytes and schistocytes are commonly seen with iron deficiency anemia.

Biochemical profile

Glucose is markedly increased, perhaps a sympathoadrenal response that can be seen in severely ill cattle. Other possibilities include prior treatment with glucose-containing fluids, diabetes mellitus, or acute pancreatitis. Other lab data supports proximal duodenal obstruction, in which marked hyperglycemia is a consistent finding. This may be due to a combination of stress-induced hyperglycemia and poor peripheral perfusion, so that the glucose isn't used. Also, low K may result in decreased cell uptake of glucose.

BUN, creatinine, and phosphorus are increased. Urine specific gravity would help determine if renal or prerenal. Because of severe dehydration as indicated by increased albumin, at least a prerenal component is likely. Phosphorus may also be increased due to high GI obstruction, which is likely the diagnosis.

Calcium is slightly decreased. Phosphorus is excreted in the saliva of ruminants; with GI obstruction, elimination of phosphorus via the GI tract is decreased. Mild hypocalcemia has been reported with abomasal and forestomach disease.

Total protein and albumin are increased, indicating dehydration. Globulin is increased, which may be due to dehydration or antigenic stimulation.

Bilirubin is increased, which in this patient may be due to cholestasis or anorexia.

Serum creatine kinase activity is increased, probably indicative of myopathy. AST is mildly increased, either from myopathy or hepatocellular damage.

Marked hypochloremia is probably due to abomasal acid secretion into the lumen. Obstruction of abomasal outflow and distention exacerbates. Chloride is decreased more than would be expected with abomasal displacement or volvulus; this degree of hypochloremia is indicative of high GI obstruction. Potassium is likely decreased for the same reason.

Sodium is low and is perhaps being lost in urine. This may be due to hyperglycemia resulting in osmotic diuresis and thus increasing urinary losses of electrolytes.

Hyperosmolality may also be contributing to hyponatremia, as a result of cellular water moving into extracellular fluid compartment, diluting serum sodium (1.6 mEq/l decrease in Na for every 100 mg/dl increase in glucose)

Total CO_2 and HCO_3 are increased, indicating marked hypochloremic metabolic alkalosis. pH is in the high normal range as a result of compensatory respiratory acidosis (increased pCO_2). Remarkable hypochloremia and alkalosis indicated that there is obstruction of abomasal outflow, preventing re-exchange of chloride and bicarbonate.

Increased anion gap (36 mEq/L) also indicates increase in unmeasured anions. Most of the anions contributing to this are not truly "unmeasured," but are the increased phosphates and protein. Additionally, there may be increased lactate due to decreased tissue perfusion, or increased sulfates due to tissue breakdown.

Summary

This animal had a high GI obstruction (foreign body), thus explaining many of the abnormalities.

Azotemia was probably prerenal due to dehydration, although there are abnormalities in distal tubular transport that may be due to hypochloremia; osmotic diuresis may be also contributing to these abnormalities.

Inflammation is present, perhaps associated with the GI obstruction.

Iron deficiency anemia from chronic blood loss is present (perhaps abomasal ulcer, GI parasites).

Other tests that should be performed include urinalysis, especially specific gravity, and fecal occult blood.

Case 80

Signalment: 9-day-old female Holstein

History: Several days' duration of diarrhea, anorexia, extreme weakness

Physical examination: Hypothermic, 12% dehydrated

pCO_2 (mmHg)	**45.7**	34–44
HCO_3 (mEq/L)	**15.3**	23–31

Interpretive discussion

Hematology

There is a neutrophilia and monocytosis, indicating an inflammatory leukogram. The PCV is increased, reflecting hemoconcentration due to dehydration.

Biochemical profile

There is a profound hypoglycemia, which in a neonatal calf with diarrhea is most probably related to decreased food intake, as well as the possibility of sepsis. Considering the increased neutrophil concentration, sepsis is unlikely.

The BUN and serum creatinine concentrations are increased, but the origin of this azotemia cannot be discerned without a urinalysis. However, given the other evidence of hemoconcentration, prerenal azotemia is the most likely cause. Although higher serum phosphorus concentrations are common in young animals, this degree of hyperphosphatemia is more likely related to decreased glomerular filtration rate. There is a marked hypocalcemia, but this may be due solely to the hypoalbuminemia; i.e., the ionized calcium concentration may be normal, but the protein-bound fraction is decreased.

There is marked hypoproteinemia, despite the severe degree of dehydration. This is due both to hypoalbuminemia and hypoglobulinemia. The former may be due to liver disease, inanition, or intestinal loss associated with the diarrhea. The latter is very likely due to lack of passive transfer, which would have subsequently predisposed this neonate to infections, resulting in diarrhea and sepsis.

The increased serum CK and AST activities may be due to muscle damage, to prolonged recumbency, or hypoperfusion. The very slight increase in GGT activity may be due to absorption of a small amount of colostrum, which is high in GGT activity in ruminants.

The increased serum sodium and chloride indicate that this calf is hypertonically dehydrated. One typically expects hypotonic dehydration to develop in a neonatal calf with scours, owing to electrolyte loss in the secretory diarrhea. Thus, it is more likely that this is not a secretory diarrhea but rather another infectious cause of diarrhea, with or without septicemia. Water loss in excess of solute may be compounded by reduced water consumption, increased insensible losses due to fever, and/or exudation

(along with albumin) across a damaged intestinal mucosa. Although there may have been significant potassium loss in the diarrhea, redistributional hyperkalemia is commonly observed in cases like this owing to exchange of intracellular potassium for extracellular protons (H^+) in response to the metabolic acidosis. The respiratory acidosis suggests inadequate pulmonary perfusion.

Blood gas data

There is a combined metabolic (decreased bicarbonate) and respiratory (increased pCO_2) acidosis. The metabolic acidosis results from bicarbonate loss in the diarrhea and from lactic acidosis due to tissue hypoperfusion. The increased anion gap reflects the accumulation of unmeasured anions like lactate.

Summary

Nonsecretory diarrhea and hypertonic dehydration in a neonatal calf following failure of passive transfer.

Interpretive discussion

Hematology

Regenerative anemia is present as evidenced by reticulocytosis. This may be due to blood loss or blood destruction. Hypomagnesemia has been reported to cause hemolytic anemia in humans. The total protein is not useful to differentiate hemolysis from loss in this case, as it is likely decreased due to other causes. Blood loss could be though the GI tract.

An inflammatory leukogram is present as evidenced by neutrophilia and increased bands on 8/8.

A stress leukogram is present on 8/17 as evidenced by mature neutrophilia and lymphopenia. A monocytosis may be a component of a stress leukogram.

Plasma protein by refractometry is markedly decreased (see biochemical profile interpretation).

Biochemical profile

Numerous biochemical profiles were performed over several weeks. The common abnormalities are marked hypoproteinemia, hypoalbuminemia, hypoglobulinemia, and hypocalcemia, Hypocholesterolemia is present in three of the profiles, as well. All but the first biochemical profile also showed increased ALT, AST, ALP, and CK. Sodium and potassium are decreased in the last three profiles, and serum magnesium is markedly decreased. Serum creatinine is also decreased on the last two profiles. These abnormalities are discussed below.

Panhypoproteinemia

The most likely differential for a decrease of this magnitude in both serum albumin and globulin, particularly in a dog with a history of diarrhea, is protein losing enteropathy. Other possible causes would be blood loss or loss of protein into the abdominal cavity due to inflammation. The PCV is not low enough to explain this degree of hypoproteinemia.

Hypocalcemia

While some of the hypocalcemia can be explained by hypoalbuminemia, this cannot account for this degree of hypocalcemia. When corrected for hypoalbuminemia, the calcium is still low. (For example, in the profile on 8/17, $5.1 - 1.2 + 3.5 = 7.4$.) The decreased ionized calcium further substantiates that both ionized and bound calcium are decreased.

There is probably no differential for this degree of hypocalcemia other than the hypocalcemia that may occur in patients with protein losing enteropathy, since primary hypoparathyroidism should result in increased phosphorus concentration. While hypocalcemia with protein losing enteropathy is usually because of hypoalbuminemia, decreased ionized calcium may also occur in these patients as a result of decreased GI calcium absorption and also because of decreased vitamin D absorption. Hypomagnesemia may also result in hypocalcemia by leading to decreased synthesis or release of PTH or by leading to decreased responsiveness to PTH by skeletal and renal tissue. Moreover, hypomagnesemia can cause decreased activation of vitamin D by kidneys.

The hypomagnesemia is severe and in this case is likely due to loss through the GI tract. Decreased vitamin D may result in decreased magnesium absorption.

(Other possible causes of hypomagnesemia include loss through the kidney or shifts of magnesium from extracellular to intracellular, but there is no evidence for renal disease. Other disorders associated with hypomagnesemia include diuresis, diabetic ketoacidosis, pancreatitis, sepsis, and primary hyperparathyroidism, but again, there is no history or evidence of these.)

Hypocholesterolemia is usually due to either decreased intake through the GI tract, or decreased production as a result of liver failure. In this patient, it is likely due to increased intake, secondary to protein losing enteropathy.

Increased ALT and AST in later profiles are indicative of hepatocellular damage, although the AST may be increased due to muscle damage, as CK is increased. ALT may be induced by steroids, as well.

Increased GGT and ALP may be due to cholestasis or induced by corticosteroids. The serum alkaline phosphatase and GGT were not increased in the initial biochemical profile performed by the referring veterinarian. Additional history revealed that the dog had been receiving injectable glucocorticosteroids, which are likely responsible for the increase in these enzymes. The dog likely has a steroid hepatopathy at this time.

Hyponatremia and hypokalemia are also likely due to losses through the GI tract.

The increase in aPTT and PT are likely due to decreased vitamin K absorption, as it is also a fat-soluble vitamin.

The decreased antithrombin III is likely due to concurrent albumin losses.

Additional tests needed

Parathyroid hormone assay, vitamin D assay.

Summary

The most likely diagnosis in this dog is protein losing enteropathy with resulting severe hypocalcemia and hypomagnesemia, and likely secondary hypoparathyroidism.

Outcome

PTH was low normal and vitamin D was decreased. Small bowel biopsy showed mixed inflammation, dilated crypts, necrosis, bacterial overgrowth, and mild lymphangiectasia. Dog had positive occult blood in feces. It was treated by changing diet (Eukanuba low-residue dry), Prednisone (1.3 mg/kg bid), Tums, and enrofloxacin (Baytril), and coconut oil (10–20 mL per day added to food).

Case 82

Signalment: 10-year-old spayed female mixed-breed dog

History: Chronic weight loss, chronic voluminous diarrhea, ravenous appetite

Physical examination: Bright and alert, thin with a 1/5 body condition score, 5% dehydrated

Fecal float	Negative	

Interpretive discussion

The decrease in the plasma protein may be compatible with loss of protein or decreased protein production. On the biochemical profile, total protein, albumin and globulins are at the low end of the reference interval. Because the dog is dehydrated, it is possible that these values will decrease below the reference interval when the animal is rehydrated. Given the history of chronic diarrhea and the low body condition score, protein losing enteropathy or exocrine pancreatic insufficiency (EPI) are primary differential diagnoses.

The hypocholesterolemia can be the result of malabsorption, maldigestion, protein losing enteropathy, or liver failure. Given the normal liver enzymes and total bilirubin, there is no evidence of hepatocellular damage or cholestasis. However, liver enzymes do not measure liver function: fasting and postprandial bile acids were done to evaluate for hepatic insufficiency. Given the normal fasting and postprandial bile acids, decreased production of cholesterol secondary to hepatic insufficiency is unlikely.

The low normal total protein, albumin, and globulin in conjunction with hypocholesterolemia is compatible with protein losing enteropathy or EPI resulting in malabsorption and maldigestion, respectively. Both of these conditions are

associated with diarrhea and weight loss. Differentiating these two conditions requires additional testing. The normal serum folate in conjunction with decreased cobalamnie-B12 is compatible with distal small intestinal disease or EPI. The low TLI is diagnostic for EPI.

Summary

This dog was diagnosed with exocrine pancreatic insufficiency (EPI), and she responded to dietary supplementation with pancreatic enzymes and cobalamine injections. The syndrome of EPI results from inadequate production and release of pancreatic enzymes into the intestinal tract. Maldigestion and malabsorption of nutrients results in diarrhea that is often voluminous. Steatorrhea and hypocholesterolemia are consequences of maldigestion and malabsorption of fats. Unlike patients with protein losing enteropathy, many patients with EPI maintain their serum protein within the reference interval. Intrinsic factor is required for absorption of dietary cobalamine/vitamin B12. Because the pancreas is the source of intrinsic factor in the dog, cobalamine deficiency may develop as a result of malabsorption secondary to EPI and is reflected in the low serum cobalamine levels seen in this patient. Pancreatic ascinar atrophy is the most common cause of EPI in younger dogs and is seen most commonly in the German shepherd breed. When pancreatic ascinar atrophy occurs in an older dog such as this patient, other causes of EPI such as pancreatitis or neoplasia should be explored.

Interpretive discussion

CBC

The dog is anemic on Day 3, likely due to blood loss and rehydration. Considering that the dog was clinically dehydrated on presentation, the PCV on Day 1 is likely falsely increased.

An inflammatory leukogram is present, as indicated by the marked neutrophilia and presence of band neutrophils on Day 1. The monocytosis on Day 1 is also likely due to inflammation. A stress or corticosteroid leukogram is also present on Day 3, as indicated by the lymphopenia.

The platelets are slightly decreased on Day 3, possibly secondary to blood loss.

The plasma protein is markedly increased on Day 1, which should trigger measurement of albumin and globulin, and is compatible with marked dehydration.

Chemistry

A mild hyperglycemia is compatible with stress and increased cortisol.

Increased BUN and creatinine, indicating decreased glomerular filtration rate, resolved completely with fluids, indicating prerenal azotemia. The BUN is relatively more increased than the creatinine, suggesting prerenal azotemia. A urine analysis was not performed, but presumably the urine specific gravity would have indicated the ability to concentrate.

Hypercalcemia is mild and normalizes with fluid therapy. This may be due to dehydration (associated with a high-normal albumin) and decreased GFR; an ionized calcium would help determine if a true hypercalcemia is present.

The hyperphosphatemia is also due to decreased glomerular filtration, and corrects with fluid therapy. The calcium × phosphorus product is 114, suggesting the possibility of mineralization of the kidneys. However, the improvement of the azotemia following fluid therapy indicates that this has not occurred.

Marked hyperproteinemia is evident on Day 1. Albumin is at the high end of the reference interval, and hyperglobulinemia is present. This may be due to antigenic stimulation, but since it normalizes following fluid therapy, the hyperglobulinemia is likely due to dehydration. It is also possible that the protein decrease is due to blood loss.

Hyponatremia and hypokalemia are likely due to loss due to vomiting. Chloride is very low (corrected chloride is approximately 90), indicating a disproportionate loss of chloride. This is likely due to loss of gastric fluid in the vomitus consistent with a hypochloremic metabolic alkalosis.

Serum lactate is markedly increased, indicating severe lactic acidosis. The dog is alkalemic as indicated by the increased pH, and has a high blood bicarbonate, confirming metabolic alkalosis. This dog has a mixed acid-base status. In spite of the increased lactate, the dog has a metabolic alkalosis as a result of vomiting gastric fluid.

Summary

The presence of hypochloridemia and metabolic alkalosis in a vomiting dog suggests bowel obstruction and should trigger abdominal radiographs (Figure 1). The most common electrolyte and acid base abnormalities in dogs with gastrointestinal foreign bodies, regardless of the site or type of foreign body, are hypochloremia (51%), metabolic alkalosis (45%), hypokalemia (25%), and hyponatremia (20%). Hypochloremic, hypokalemic metabolic alkalosis is seen with both proximal and distal gastrointestinal foreign bodies.

Abdominal radiographs

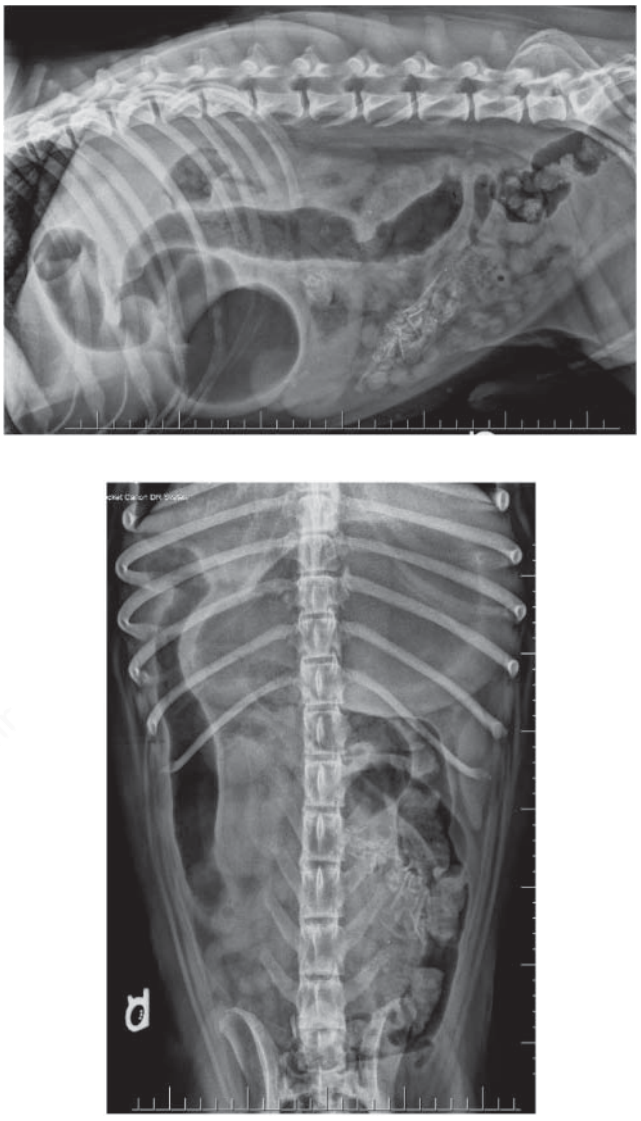

Figure 1 The stomach is distended with gas and fluid. There are two populations of small intestine with regard to diameter. The larger population includes the descending duodenum and some of the jejunum. The distended segments contain fluid and gas. In the lateral view there is also a region of distended small intestine in the caudal abdomen that contains bone shards accumulating against a rectangular object with a reticular gas pattern; this object is typical of a corncob. The images are diagnostic of a proximal small intestinal obstruction due to corncob ingestion.

Interpretive discussion

Hematology

Packed cell volume, hemoglobin, and red blood cell count are all increased. Considering the clinical evidence of dehydration and increased total protein, this is likely a relative erythrocytosis secondary to water loss as a result of vomiting. A leukocytosis is present due to neutrophilia and monocytosis. Considering the lymphopenia, the neutrophilia and monocytosis likely represent a stress leukogram. Plasma protein by refractometry is increased due to dehydration and there is a discrepancy of 1.1 g/dL between the refractometric estimate of total protein on the plasma and the biuret method on the clinical chemistry. While 0.2–0.4 g/dL discrepancy is expected, due to the presence of fibrinogen in the plasma, a discrepancy of approximately 0.7–0.9 g/dL remains in this patient, and can be explained by the increased serum urea and cholesterol, both of which contribute to the total solids measured by refractometry. Every 39 mg/dL in cholesterol accounts for an increase in the plasma protein refractometric reading by 0.14 g/dL [1]. Since the cholesterol in this patient is approximately 200 mg/dL over the upper limit of the reference range, cholesterol could be increasing the total protein estimate by approximately 0.5 g/dL. Moreover, azotemic patients may have refractometric total protein estimates of 0.5 g/dL or more over protein measured by the biuret assay, further explaining the marked discrepancy [2].

Chemistry

A mild hyperglycemia is compatible with stress and increased cortisol.

Increased BUN and creatinine, indicating decreased glomerular filtration rate, may be prerenal due to hydration, or renal. The urine specific gravity is 1.022, and while this might suggest renal impairment, the hyponatremia is likely interfering with concentrating ability due to medullary wash out (see below). The hyperphosphatemia is also due to decreased glomerular filtration.

Hyperproteinemia, hyperalbuminemia and hyperglobulinemia are present, likely due to dehydration, although an increase in immunoglobulins due to antigenic stimulation could be causing the hyperglobulinemia.

Bilirubin is very slightly increased, and since the dog is not anemic, this is either due to an intrahepatic cause, or cholestasis.

The cholesterol is markedly increased, and while cholesterol increases with cholestasis, this hypercholesterolemia is so marked that hypothyroidism and Cushing syndrome should be considered. Tests for endocrine function were not performed.

The ALP activity is increased, which in this case is also compatible with mild cholestasis, but could also be due to steroid induction.

Hyponatremia and hypokalemia are due to loss in vomitus. The hypokalemia may also be due to movement of potassium into cells, and hydrogen out of cells, in an attempt to correct the alkalosis. Chloride is very low, indicating a disproportionate loss of chloride when compared to sodium. This is likely due to loss of gastric fluid in the vomitus consistent with a hypochloremic metabolic alkalosis.

The bicarbonate is increased, indicating a metabolic alkalosis. Blood gas was not performed.

The anion gap is increased, indicating increased unmeasured anions. In this patient, the most likely cause of the increased anion gap is lactate, although acids due to azotemia may be contributing. Serum lactate was not performed.

Calculated osmolality is increased, in this case primarily due to increased urea.

Both amylase and lipase activity are increased, and while pancreatitis cannot be excluded, decreased glomerular filtration results in an increase in both serum amylase and lipase activity, because the enzymes are presumably eliminated through the kidney.

Urinalysis

The urine specific gravity is 1.022. Specific gravity should be at least greater than 1.035 in a dehydrated dog whose kidneys are concentrating maximally. However, the patient is hyponatremic, which is interfering with concentrating ability due to medullary washout. The urine is acidic, and in a dog with metabolic alkalosis this is indicative of paradoxical aciduria. The hypochloremia and hypovolemia stimulate aldosterone, which promotes sodium resorption by the kidney. Normally sodium is exchanged for potassium, but since potassium is depleted, it is exchanged for hydrogen, resulting in a paradoxic aciduria.

Summary and outcome

The presence of hypochloremia and metabolic alkalosis in a vomiting dog strongly suggests bowel obstruction, and should trigger abdominal radiographs. The most common electrolyte and acid base abnormalities in dogs with gastrointestinal foreign bodies, regardless of the site or type of foreign body, are hypochloremia (51%), metabolic alkalosis (45%), hypokalemia (25%), and hyponatremia (20%). Hypochloremic, hypokalemic metabolic alkalosis is seen with both proximal and distal gastrointestinal foreign bodies [3].

Unfortunately, abdominal radiographs were not performed in this patient, and an erroneous diagnosis of acute renal failure due to ethylene glycol toxicosis was made due to the presence of azotemia, relatively low urine specific gravity, and increased anion gap. The dog was euthanized, and at autopsy a peach pit (seed) was observed obstructing the intestine approximately 30 cm aboral to the pyloric sphincter. No histopathologic evidence of kidney disease or liver disease was seen, and no other gross lesions were observed. This case emphasizes the importance of suspecting an intestinal foreign body when hypochloremic metabolic alkalosis is observed.

Interpretive discussion

Hematology

A mild eosinophilia is usually associated with hypersensitivity reactions that may be secondary to allergic or parasitic disease, but mild eosinophilia can also be seen in this breed and in Rottweilers. In cases where there is a lack of a stress leukogram, Addison's disease should always be considered. A baseline cortisol or an ACTH stimulation test is recommended to rule in or out Addison's disease.

The plasma proteins are decreased, which may be due to decreased albumin (decreased production or loss) or decreased globulins. See chemistry section.

Chemistry

Glucose, phosphorus and renal parameters are within reference intervals.

Calcium is low normal and may be associated with the low albumin as approximately 40% of total calcium is albumin bound.

Total proteins and albumin are decreased with globulins within reference interval.

Decreases in albumin may be associated with decreased production by the liver or losses due to GIT or renal disease or third space shifting. Exudative skin disease is another less common possibility. Albumin may be decreased with severe or end stage liver disease, but this is not apparent on this sample. Liver enzymes are not necessarily increased in these cases as healthy functional hepatocytes are required to produce enzymes. The liver also produces BUN, glucose, and cholesterol. BUN and glucose are within reference intervals, making severe liver disease and decreased production less likely. Renal albumin loss can be excluded by the low urine protein:creatinine ratio.

GIT protein loss is evidenced by the increase in fecal α1-proteinase inhibitor (PI).

This is a protein that resists degradation by digestive and bacterial proteinases in feces and has nearly the same molecular mass as albumin and that is lost into the GI lumen at approximately the same rate as albumin and other plasma proteins. Both dogs and cats with gastrointestinal protein loss have an increased fecal α_1 PI concentration before protein loss is severe enough to notice hypoalbuminemia. α_1-PI of one individual sample of ≥15.0 μg/g feces is considered abnormal.

Liver enzymes are all within reference intervals, which suggests no overt liver abnormality. Normal serum bile acids would confirm normal hepatic function in most cases.

Cholesterol is decreased. Hypocholesterolemia can be associated with both liver failure and PLE, but elevations in α1-proteinase inhibitor can be used to differentiate these and should be normal in cases of liver disease.

The total CO_2 is mildly decreased suggesting a metabolic acidosis, which may be seen with diarrhea. This tends to be associated with increases in potassium. Anion gap is within reference interval in this case.

Other Tests

A decrease in vitamin B_{12} (cobalamin) with increased folate (because of bacterial overgrowth) in dogs suggests EPI, and TLI testing is indicated. Bacterial overgrowth increases serum folate concentrations because of bacterial synthesis of folate, and it decreases serum vitamin B_{12} concentrations because of bacterial binding of vitamin B_{12}.

Small intestinal bacterial overgrowth (SIBO) should always be considered with this combination of results. In this case the TLI is decreased, which is consistent with EPI (exocrine pancreatic insufficiency). Antibiotic responsive diarrhea (SIBO) is a relatively widespread secondary problem in dogs with EPI, and a common cause of cobalamin deficiency in dogs. Low B_{12} and high folate has a low sensitivity (5%) for detecting bacterial overgrowth but has high specificity (almost 100%).

Summary

This dog was diagnosed with exocrine pancreatic insufficiency (EPI) with concurrent antibiotic responsive diarrhea small intestinal bacterial overgrowth (SIBO). There was secondary gastrointestinal protein loss.

Interpretive discussion

Hematology

RBC parameters are at the lower end of the reference range and could reflect the early stages of an anemia of chronic disease.

Chemistry

A mild decrease in creatinine typically indicates low muscle mass and is often of minimal clinical significance. However, in this case it is most likely due to emaciation.

The hypoproteinemia characterized by hypoalbuminemia and the concurrent low cholesterol is probably due to gastrointestinal losses. Animals with protein losing enteropathies (PLEs) commonly have panhypoproteinemia, but if there is inflammation present this could increase the globulins, making interpretation difficult. Hypoalbuminemia and hypocholesterolemia can also be observed with hepatic insufficiency, albeit there is no overt evidence of hepatic disease in this case (ALT within normal limits). Bile acids are indicated to exclude the possibility of liver dysfunction.

The mild increase in ALP activity could be associated with gastrointestinal disease and is a relatively nonspecific finding. Furthermore, in dogs this could reflect induction of the corticosteroid isoenzyme associated with chronic stress.

Urinalysis

A USG of 1.036 demonstrates adequate renal concentration ability, as there is no azotemia or dehydration.

Other

Decreased B12 (cobalamin) and increased folate can be seen associated with small intestinal bacterial overgrowth (SIBO, antibiotic responsive diarrhea), and EPI.

Low B12 is also associated with villous atrophy and/or distal small intestinal disease.

Summary

Clinicopathological abnormalities in conjunction with the history and clinical signs are suggestive of a SIBO. A definitive diagnosis of SIBO is often difficult, but additional diagnostic tests may include Canine Microbiota Dysbiosis Index, or response to Tylosin. Specific culture of feces, and PCR may also be helpful.

Biopsy may be required in hypoproteinemic patients for a definitive etiological diagnosis but marked hypoalbuminemia in this patient could lead to dehiscence of an intestine biopsy.

A Trypsin-Like Immunoreactivity (TLI) assay would be required to rule out/in exocrine pancreatic insufficiency, a very possible differential diagnosis in this case.

Negative dipstick for glucose, proteins, ketones, blood.
Fecal examination for parasites negative.

Interpretive discussion

Hematology

Hypoproteinemia was the only observed abnormality on hematology and will be discussed in the chemistry section.

Chemistry

Mildly increased total calcium is significant with a lowered albumin as 40% of total calcium is protein bound. This is verified by the increased ionized calcium, which reflects a true hypercalcemia. The most common differential for a chronic hypercalcemia in a mature dog is hypercalcemia of malignancy.

Hypoproteinemia characterized by a hypoalbuminemia may suggest either decreased protein production, protein losing nephropathy (PLN) (e.g., amyloidosis and glomerulonephritis), or a protein losing enteropathy (PLE) (e.g., intestinal parasites, *Campylobacter*, *Salmonella*, *Giardia*, inflammatory bowel disease, neoplastic bowel disease, etc.). Third space shifting is another consideration. The simplest way to differentiate PLE/ third spacing from PLN is to do a dipstick examination on the urine looking for proteinuria, in this case a negative proteinuria makes PLN less likely. Additionally, cholesterol is usually increased with PLN. With a history of GI disease and chronic vomiting, PLE is the most likely differential and supported by the hypocholesterolemia, which is most likely due to GIT losses.

Mildly increased ALP, bilirubin and ALT can be seen in primary liver disease (e.g., cholangiohepatitis) and possibly gut disease. Differentials include hepatic neoplasia (lymphoma), chronic active hepatitis (Dobermans), bile duct obstruction (extrahepatic mass, choleliths), amyloidosis and idiopathic hepatic cirrhosis. Increased ALP activity may also be due to chronic stress and subsequent induction of the steroid isoenzyme.

The very mild hypochloremia may be insignificant, however, given the history of vomiting, this could be related to loss through stomach acid.

Urinalysis

Although the dipstick is negative for protein; with dilute urine (USG 1.019) one cannot rule this out completely and a protein: creatinine ratio may be indicated. A single low USG

is not necessarily significant (especially in a well-hydrated animal) but is worth repeating this to see if reproducible. The low specific gravity is likely associated with increased calcium causing inhibition of ADH.

Summary

Clinical signs in conjunction with laboratory abnormalities is strongly suggestive of a protein losing enteropathy. Protein losing enteropathy (PLE) can be associated with variety of disorders such as idiopathic inflammatory gastroenteropathies, small intestinal bacterial overgrowth (SIBO)/antibiotic responsive diarrhea, intestinal neoplasia, chronic intussusception, infectious enteritis, lymphangiectasia, etc.

On further workup the dog was found to have intestinal lymphoma. Retrospectively the mildly increased total and ionized calcium were clinically significant.

Case 88

Signalment: 8-year-old ovariohysterectomized female Labrador retriever that weighs 35 kg

History: Presented to referring veterinarian 2 weeks earlier for lameness in left shoulder, presumably due to osteoarthritis. She was treated with carprofen and tramadol. She became lethargic a few days after taking carprofen and was vocalizing in the night due to pain. Benadryl was prescribed to help her sleep. One day prior to presentation at referral clinic she vomited and had one episode of diarrhea, A few hours prior to presentation she began panting, continued vomiting, was ataxic and running into walls, and developed hematuria.

Physical examination: Obtunded on arrival at referral clinic. Pupils unresponsive to light, laterally recumbent, tachypneic, hypersalivating, and icteric mucous membranes. Approximately 5% dehydrated.

Hematology		Reference range

Lymphocytes ($10^3/\mu L$)	**0.3**	1.0–4.8
NRBC ($10^3/\mu L$)	**2.6**	
Platelets ($10^3/\mu L$)	**23**	200–500

Hemopathology: A hazy pink background consistent with free hemoglobin is present on the blood film, indicating hemolysis. A severe decrease in RBC density is present, consistent with severe anemia. Numerous spherocytes are present in every field, with occasional ghost erythrocytes. No red cell agglutination is observed. A few eccentrocytes are present. Mild polychromasia is observed. More band neutrophils than segmented neutrophils are present. Neutrophils have moderate toxic change with vacuolated basophilic cytoplasm and Dohle bodies. Lymphocytes are reactive with increased amount of basophilic cytoplasm. Blood film examination confirms thrombocytopenia, although a few small platelet clumps are seen. Numerous large platelets are present.

Description: Cells consist of 95% moderately degenerate neutrophils and 5% macrophages. Neutrophils occasionally contain one to two large rod-shaped bacteria (likely *Bacillus* or *Clostridium* sp.) within lysosomal vacuoles. Some macrophages contain hemosiderin and occasional rhomboid yellow crystals, consistent with hematoidin. No evidence of neoplasia is seen.

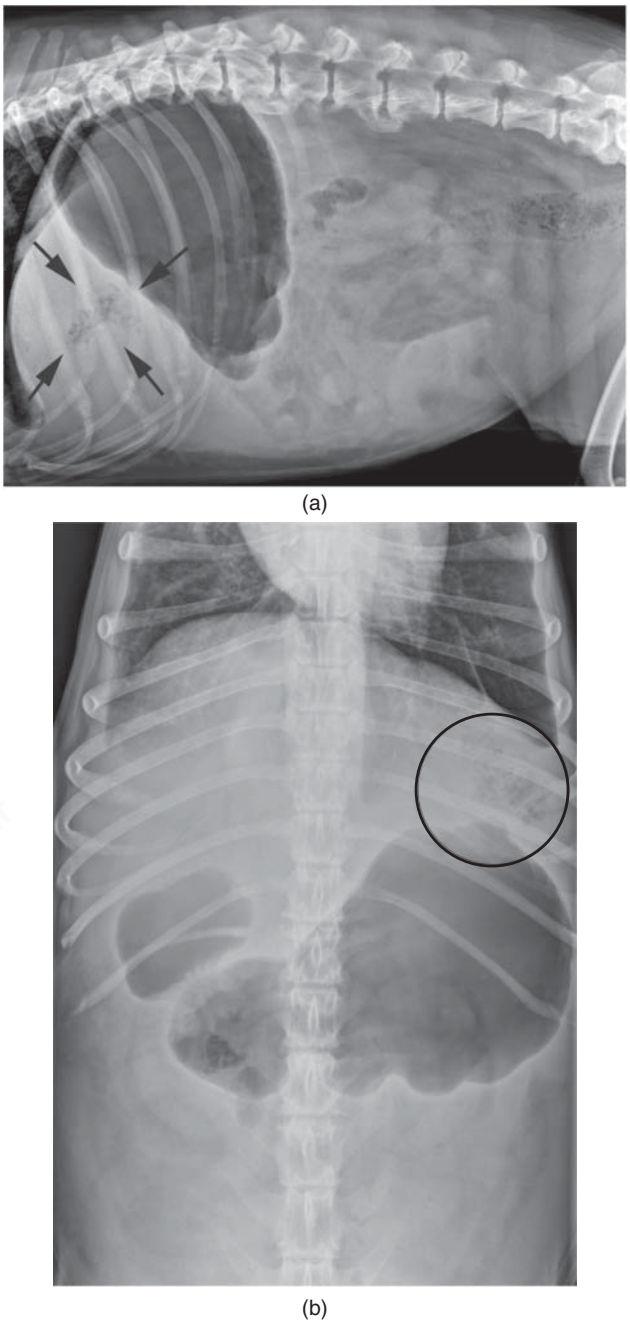

Figure 1 (a) Lateral radiograph of the abdomen. (b) Ventrodorsal radiograph of the cranial abdomen.

Interpretive discussion

Hematology

The PCV, RBC, and Hgb are all markedly decreased, with a normal MCV and MCHC, indicating a normocytic normochromic anemia. The reticulocyte concentration is slightly increased but is inadequate for this degree of anemia. It is possible that the anemia is too acute to have generated a bone marrow response yet (preregenerative anemia). Another possibility is that because the dog has severe inflammation, an anemia of inflammatory disease is superimposed on the original cause of anemia, resulting in a suppressed bone marrow response. The presence of spherocytes and ghost cells are diagnostic for immune-mediated hemolytic anemia (IMHA) with intravascular hemolysis. The presence of eccentrocytes suggests that oxidative damage may be playing a role in the hemolytic anemia. Increase in nucleated erythrocytes is compatible with a regenerative anemia and/or bone marrow damage, likely due to hypoxia or sepsis in this patient. The RDW is mildly increased as a result of increased variability in erythrocyte size.

The leukogram is markedly inflammatory as evidenced by the increase in band neutrophils. That immature neutrophils are more numerous than segmented neutrophils indicates an extreme tissue demand or overwhelming inflammation such as would be seen with bacterial peritonitis and/or sepsis (see abdominal fluid analysis). The toxic appearance of neutrophils is also indicative of inflammation since it results from rapid production and early release. A stress (cortisol) component is present as evidenced by lymphopenia. Reactive lymphocytes are likely a result of antigenic stimulation.

The patient is markedly thrombocytopenic. Large immature platelets indicate that the bone marrow is producing platelet Differentials for thrombocytopenia in a patient with IMHA are disseminated intravascular coagulopathy and immune-mediated thrombocytopenia. The thrombocytopenia in conjunction with prolonged aPTT and PT (see below) is very suggestive of disseminated intravascular coagulopathy (DIC).

Chemistry

Marked hypoglycemia on presentation is likely responsible for many of the clinical signs, including ataxia, blindness,

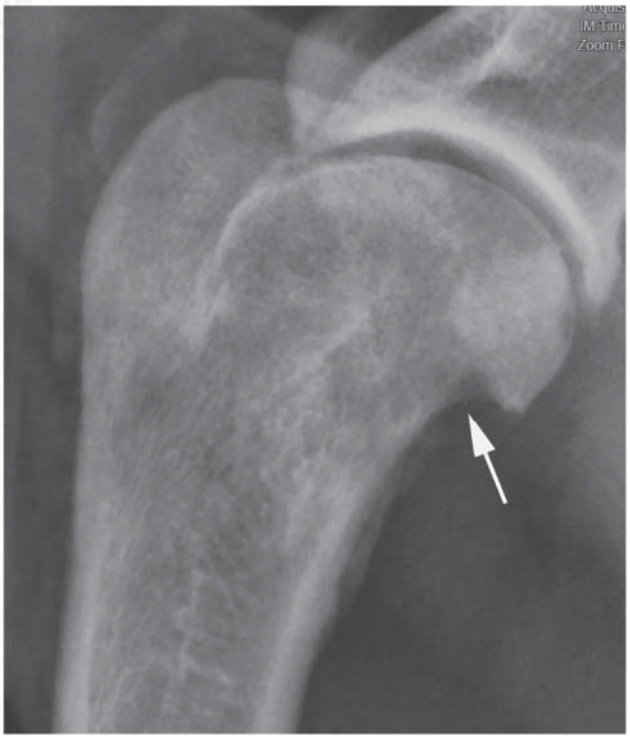

Figure 2 Lateral radiograph of the left shoulder.

and collapse, although increased blood ammonia concentrations could also account for these neurologic signs. Blood ammonia was not measured. Coma can occur at glucose concentrations at around 40–50 mg/dL, and neuronal death occurs at approximately 15 mg/dL. Differentials for severe hypoglycemia include insulinoma, administration of insulin, sepsis and liver failure. Insulin concentration was not measured in this patient. An insulinoma is less likely considering the history, as dogs with insulinomas usually have a longer history of intermittent weakness as a result of hypoglycemia. Sepsis is likely playing a role, considering the leukogram. Hypoglycemia secondary to sepsis is thought to be due to a combination of decreased caloric intake, hepatic dysfunction, and increased glucose consumption by bacteria, neutrophils, and peripheral tissues, the latter of which is attributable to inflammatory mediators. Liver necrosis in this patient (see summary) also likely contributed to the hypoglycemia, and although it does not typically result in this degree of hypoglycemia in dogs, hypoglycemia as severe as 10 and 37 mg/dL was reported in two human patients with liver failure [1].

The BUN and creatinine are increased, indicating decreased glomerular filtration rate. Urine specific gravity was not measured, thus it cannot be determined if the azotemia is prerenal due to dehydration or hypovolemia, or renal due to kidney dysfunction. Kidney dysfunction due to hemoglobinuria should be considered, since the patient has a hemolytic anemia.

The albumin is markedly decreased, and the globulin concentration is markedly increased. Part of the decrease in albumin could be due to inflammation, but hypoalbuminemia of this magnitude in the face of an increased globulin is likely due to either a lack of production by the liver or increased loss through the glomerulus. Since a urine analysis was not performed, it is not known if proteinuria is present.

Hyperglobulinemia of this magnitude should trigger protein electrophoresis to determine if the gammopathy is polyclonal or monoclonal. Based on other findings in this case, it was likely polyclonal and secondary to the bacterial infection and other causes of inflammation.

The serum bilirubin is markedly increased. Because the ALP activity is also increased, some of the increase is likely due to cholestasis. However, considering the increased ALT activity indicating marked hepatocellular damage, the increase in bilirubin could also be due to liver dysfunction. A third probability is increased erythrocyte destruction, since the dog has a hemolytic anemia.

CK is increased, indicating muscle damage.

Chloride is decreased below the reference interval, and sodium is at the lower end of the reference interval. In this case, sodium and chloride are likely being lost proportionally since the "corrected" chloride is in the reference interval (109.6 mEq/L). To correct the chloride to determine if chloride is being lost disproportionally to sodium, the following formula is used: *Corrected chloride = (normal sodium/measured sodium) ×measured chloride, where normal sodium is the midpoint of the reference range*.

The HCO_3 is decreased, evidence of a metabolic acidosis, likely due to increased lactate. The increased anion gap indicated an increase in unmeasured anions, and in this patient is also primarily due to the increase in lactate. Increase in lactate is probably due to hypovolemia and the hypoxia associated with immune-mediated hemolytic anemia [2].

The lipase activity is slightly increased, which might indicate pancreatitis. However, increases in lipase activity cannot be interpreted in animals that are azotemic, since the increase may be secondary to decreased glomerular filtration.

Venous blood gases

Venous pO_2 is below the reference interval, and although arterial pO_2 is needed to accurately determine hypoxia, this marked decrease in venous blood suggests that the patient is hypoxic.

HCO_3 and TCO_2 are decreased, indicating metabolic acidosis, even though the patient's pH is in the reference interval.

A high anion gap metabolic acidosis such as is seen in this patient is a result of bicarbonate being consumed in buffering the lactic acid, leaving the anion of lactic acid in its place. The HCO_3 is improved from the one on the biochemical profile. This could either be due to serum having been exposed to air, which could falsely decrease the profile $HC0_3$ (which is actually a measurement of TCO_2), or could be due to the

blood gas sample having been taken after fluid therapy was instituted, reflecting true patient improvement.

Coagulation panel

Both the aPTT and PT are prolonged; considering the thrombocytopenia, this is likely due to DIC. D-dimer concentration to confirm DIC was not performed due to hemolysis. Although hemolysis is considered to be a contraindication for performing the test, hemolysis itself does not actually significantly interfere. Because hemolyzed samples are often a result of traumatic venipuncture, with concurrent tissue contamination of the sample, it is generally recommended that hemolyzed samples not be used, but this is not true for intravascular hemolysis [3].

Liver failure in this patient could also contribute to decreased coagulation protein production, resulting in increased aPTT and PT. While the hypoalbuminemia and hypoglycemia may be due to liver failure, urea is increased and cholesterol is within the reference interval, which would argue against liver failure.

Radiographs

Lateral and ventrodorsal radiographs of the abdomen were made (Figure 1). There is a loss of contrast in the abdomen consistent with fluid and/or inflammation. There are multiple small gas pockets in the left ventral aspect of the liver (arrows). This is most consistent with a hepatic abscess though an emphysematous hepatic mass cannot be ruled out. Emphysematous cholecystitis would not be considered due to the left sided nature of this lesion. The gas in the stomach is most likely due to aerophagia.

Upon an ultrasound examination, there was no mass associated with the region of gas pocketing, raising concern for hepatic necrosis rather than an abscess. Also, an entire liver lobe in the right cranioventral liver, likely the right medial lobe, was hypoechoic and consistent with infarction. There was no blood flow in this lobe using Doppler interrogation.

A lateral radiograph of the right shoulder was also acquired (Figure 1). There is mottled lysis of the medullary cavity and a smooth periosteal reaction on the proximal humerus. There is an area of cortex effacement on the proximocaudal aspect of the metaphysis (arrow). There is also a small area of lysis in the caudal humeral head. The borders of the lesion are indistinct. This is an aggressive lesion and, in this location, a primary bone tumor should be considered. However, an attempt should also be made to tie this lesion in with all of the other findings in this patient rather than concluding two separate disease entities.

Abdominal fluid analysis

Septic suppurative inflammation, previous hemorrhage. The presence of a single type of bacterium is more consistent with a ruptured abscess than a ruptured GI tract. *Clostridium* organisms are sometimes seen in liver abscesses. The bacterial peritonitis is likely responsible for the neutropenia, since all available neutrophils are being recruited into the abdominal cavity.

Summary and outcome

The patient was intubated on presentation and remained so throughout the diagnostic procedures. She had a continuous infusion of lactated Ringer's solution and dextrose. She also received numerous dextrose boluses (0.5 mL/kg).

Because of the severity of the clinical signs and the likelihood of a neoplasm in the humerus, the patient was humanely euthanized.

On autopsy, primary findings include icterus, numerous petechia, numerous portal vein thrombi that are occluding blood supply to the liver, and melena, all likely due to DIC. Marked hepatic and adrenal gland necrosis is present, as is peritonitis. Approximately 150 ml of dark red fluid is present in the abdominal cavity.

The pancreas is neoplastic, and although poorly differentiated, appears to be a very aggressive exocrine pancreatic carcinoma with metastasis to the left humerus, left femur, liver, intestine, and adrenal glands.

The kidneys show moderate hemoglobinuric nephrosis. Approximately 50% of the tubules have no epithelium.

The bone marrow shows a mild increase in immature hematopoietic cells.

Cerebral edema is diffuse, likely secondary to severe hypoglycemia, and was probably responsible for the neurologic signs. Unlike most other body tissues, the brain requires a continuous supply of glucose. Diminished neuronal glucose concentration leads to inadequate ATP production within the neurons, leading to vascular permeability, vasospasm, vascular dilation, edema and neuronal death from anoxia. A lack of brain glucose also results in glutamate and aspartate accumulation, which is thought to play a role in sodium and water influx and edema formation, and may also be directly responsible for neuronal dysfunction and death during hypoglycemia.

In summary, the pancreatic tumor and metastasis were responsible for most of the laboratory abnormalities and clinical signs seen in this patient, including lameness, liver necrosis, and DIC. The liver necrosis, secondary to both metastasis and lack of blood supply, likely led to bacterial overgrowth in the liver, with resultant septic peritonitis. Hypoglycemia secondary to sepsis or liver necrosis was responsible for brain edema, which resulted in neurologic signs. Immune-mediated hemolytic anemia was also likely triggered by the neoplasm or its associated inflammation, and the hemolytic anemia was responsible for hemoglobinuric nephrosis.

Interpretive discussion

Hematology

The erythrogram is within reference intervals. Dehydration may mask anemia but these RBC parameters will most likely still be within range even taking this into account.

The leukogram shows a leukopenia, neutropenia, and toxic change with a significant left shift back to metamyelocytes, consistent with a significant (degenerative) left shift usually associated with severe inflammation. Neutropenia this low may predispose to sepsis if not already evident. Given the history of diarrhea, this leukogram is likely associated with GIT disease.

The leukogram is referred to by some as degenerative because there is a mature neutropenia that has immature neutrophils (band neutrophils and metamyelocytes) that exceed mature neutrophils. Prognostically this change is poor and suggests endotoxemia or overwhelming inflammation.

The lymphopenia is likely due to stress. Viral disease can also lower lymphocyte concentration.

Plasma protein is decreased. Serum proteins help to evaluate further – please see discussion under serum chemistry.

Plasma protein: fibrinogen ratio is 14.5. In horses a plasma protein fibrinogen ratio >15 is normal and can occur with dehydration, but <15 is suggestive of a true increase in fibrinogen concentration, which is consistent with inflammation.

Chemistry

Hypoglycemia can be due to decreased intake (history mentions anorexia) but can also be associated with sepsis, and given the leukogram, this remains a strong differential.

BUN and creatinine are both low normal and may be associated with decreased muscle mass or anorexia.

Apparent hypocalcemia is likely due to decreased albumin, as approximately 40% of total calcium is albumin bound. An ionized calcium is required to verify a low serum calcium. Decreased phosphorus can be due to decreased intake with anorexia.

Panhypoproteinemia may be due to a protein losing enteropathy (which is supported by the history), less likely a protein losing nephropathy (globulins are not normally decreased in these cases due to selective protein loss due

to size), but can also be associated with third space shifting if there is a focus of inflammation such as a peritonitis or abscess.

Increased bilirubin with other liver parameters within the reference interval in horses may be due to anorexia, or can be associated with functional cholestasis, secondary to inflammatory mediators and cytokines due to extrahepatic disease.

Mild increases in CK are not an uncommon finding and can be seen with a struggling animal, difficult bleed, prior injections, etc. and are generally not considered to be clinically significant at this activity.

Decreased sodium and chloride are likely due to GIT loss with the history of diarrhea.

Total CO_2 equates with bicarbonate and is decreased below the reference interval and is consistent with a mild metabolic acidosis most likely secondary to the diarrhea.

Potassium is low normal and in the light of an acidosis suggests that the potassium may even be lower as acidosis tends to be associated with increased potassium. There may be total body loss of potassium due to the diarrhea.

The anion gap is mildly increased, and a calculated estimation of the unmeasured anions present that are commonly found in cases of diarrhea such as lactic acid.

Differentials related to causes of panhypoproteinemia in horses of this age include intestinal parasites, cryptosporidium, coccidiosis, salmonellosis, *Rhodococcus*, *Lawsonia*, larval cyathostominosis (small strongyles), eosinophilic enteritis, small intestinal adenomatous polyposis (rare), to name a few. Given the leukogram a differential such as *Salmonella* with an endotoxemia would be the most likely consideration in this case.

Summary

A fecal culture revealed growth of *Salmonella*. The horse was diagnosed with salmonellosis, endotoxemia and severe protein losing enteropathy.

Unfortunately, response to treatment was poor and the hypoproteinemia progressed; the horse deteriorated and was euthanized on humane grounds.

Case 90

Signalment: 10-month-old stockhorse colt

History: This horse was kept in a small paddock with 15 other similarly aged horses. 10-day history of lethargy, inappetence, and weight loss. There is also moderate fecal staining of the perineum.

Now presenting with severe edema of the ventrum and all four limbs.

Figure 1 Photograph of the stomach. Note the parasitic botfly larvae (*Gasterophilus* spp.) attached to the gastric mucosa. There is marked edema of the submucosa.

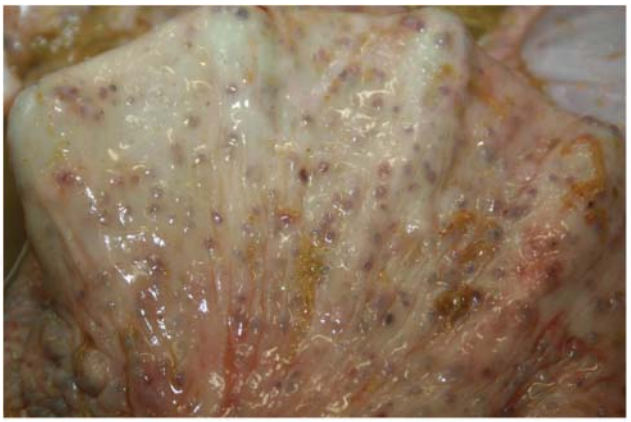

Figure 2 Photograph of the large colon. Notice the multiple red, nodular foci scattered throughout the mucosa.

Figure 3 Histological section of the right ventral colon. A small strongyle is encysted within the colonic mucosa (arrowhead). The submucosa is edematous and contains a large strongyle surrounded by a lake of neutrophils (arrow).

Interpretive discussion

Hematology

The decreased Hgb in the absence of anemia is likely an artifact.

A marked mature neutrophilia with a mild monocytosis suggests a significant inflammatory focus. Note also the fibrinogen is at top end of the reference interval.

Chemistry

Given that 40–50% of serum calcium is protein bound, the hypocalcemia is probably due to the hypoalbuminemia. An ionized calcium measurement may help further characterize this, and other causes to consider include gastrointestinal losses or excessive sweating (particularly in horses).

Hypophosphatemia is most likely due to decreased gastrointestinal absorption or increased losses (diarrhea). Note the animal has evidence of diarrhea.

A panhypoproteinemia comprised of marked hypoalbuminemia and moderate hypoglobulinemia is strongly suggestive of gastrointestinal losses (protein losing enteropathy). In the absence of anemia or a history of hemorrhage, hypoproteinemia due to blood loss is unlikely. Third spacing, and loss of protein through effusions is also possible in this case. Inflammation is also present, and this may be contributing to the hypoalbuminemia (albumin is a negative acute phase protein).

A decreased AST and GGT is not likely to be clinically significant. Mildly increased CK activity may be an indication of muscle injury.

The corrected chloride is calculated at 101 mmol/l, indicating a proportional loss of sodium and chloride. In this case, this is likely due to gastrointestinal losses from diarrhea and is compatible with the concurrent panhypoproteinemia. Other causes to consider include excessive salivating, drinking, or sweating, although the latter is less likely given that potassium is within reference interval.

Summary

At postmortem, this animal had severe submucosal edema of the gastrointestinal tract secondary to marked hypoalbuminemia (Figure 1). The botfly larvae present in Figure 1 were an incidental finding and are typically of no clinical significance but provide evidence to support poor deworming procedures as an aggravating factor in this case. There were also low numbers of large strongyles within the proliferative arteritis that was found within the wall of the cranial mesenteric artery.

The cause of hypoproteinemia was a protein losing enteropathy that developed as a result of severe intestinal infection with small strongyles (nodules in Figure 2), and to a lesser extent, large strongyles. The histological section (Figure 3) demonstrates both small and large strongyles within the colonic wall and the associated neutrophilic inflammation present in the form of "microabscesses." The focus of inflammation evidenced by the inflammatory leukogram is likely the large intestine.

Further investigation showed that these animals had been wormed three times with Ivermectin, but each dose was given within the first 3 months of life, and none of the animals had been wormed in the previous 6 months. This, combined with the high stocking density, explains the finding of high numbers of both small and especially large strongyles, which have a longer and more complex life cycle.

Interpretive discussion

Hematology

On initial presentation, there is a leukopenia characterized by a marked neutropenia and degenerative left shift consistent with overwhelming and likely, acute inflammation. Underlying endotoxemia may lead to margination of neutrophils and contribute to lower circulating numbers. Over the duration of a week, the neutropenia becomes less severe and the left-shift becomes mild, suggesting improvement of the inflammation. Fibrinogen remains within reference intervals on Day 1 and likely reflects the acute nature of the inflammation. On Day 8, fibrinogen was unable to determined due to the low (<2.5 g/dL) total protein reading, resulting in inability to calculate precipitated fibrinogen.

Observed echinocytes on Day 1 are possibly an artifactual change or may be a result of electrolyte depletion.

The mild thrombocytopenia observed on Day 8 is likely insignificant.

Chemistry

A mild hyperglycemia is observed on presentation and could reflect stress, endotoxemia or the potential use of some sedatives, namely Xylazine.

The persistent hypocalcemia in this horse most likely reflects gastrointestinal disease (increases losses or decreased absorption) and is supported by the hypomagnesemia that can also be observed with GI disease. Given that 40–50% of serum calcium is protein bound, the hypoalbuminemia is also contributing to the hypocalcemia. Hypocalcemia and hypomagnesemia are observed with blister beetle (Cantharidin) toxicosis and this should be considered if this animal is from an endemic region. Additionally, hypomagnesemia can result in hypocalcemia since magnesium is necessary for parathyroid hormone release.

Throughout serial measurements, the panhypoproteinemia becomes progressively worse and may reflect a protein losing enteropathy, decreased synthesis or third spacing (effusions). As albumin is a negative acute phase protein, inflammation may also be contributing to the hypoalbuminemia. Much less likely is a protein losing nephropathy given the concurrent loss of globulins. This may be assessed with a urine protein measurement.

Hyperbilirubinemia in a horse is most likely due to anorexia. Decreased feed intake and negative energy balance is also supported by hypertriglyceridemia, which occurs because of lipolysis and VLDL formation. Improvements to

both analytes are observed by Day 8 and could indicate return of appetite in this animal.

Decreased AST and GGT activity are likely clinically insignificant.

On Day 1, there is a proportional hyponatremia and hypochloremia, which could reflect losses through electrolyte-rich fluid such as diarrhea or sweat. By Day 3 calculation of corrected chloride (103.5 mEq/L) indicates a selective sodium loss that, given the panhypoproteinemia, is most likely due to a protein losing enteropathy or loss through diarrhea. Furthermore, there is likely loss of bicarbonate through the gastrointestinal tract leading to a secretional metabolic acidosis. A low anion gap is observed on Day 5 and is the result of hypoalbuminemia.

Summary

This patient tested negative for salmonella, *Clostridium*, *Lawsonia*, and *Neorickettsia risticii*. It was later discovered that a herd mate was diagnosed with coronavirus prior to this animal's presentation and fecal PCR confirmed infection in this patient. Equine Coronavirus has fecal-oral transmission route. Common clinical presentation of coronavirus in horses include lethargy, anorexia, fever and gastrointestinal signs.

Interpretive discussion

Hematology

A transient/relative erythrocytosis is present and supported by the hyperproteinemia. In horses, increased PCV can also be seen with splenic contraction. The hemoglobin is disproportionately increased, possibly due to lipemia (see triglyceride concentration). Increased MCHC is not physiologically possible and considered an analyzer artifact, perhaps due to hypo-osmolality in this animal, or due to a possibly false increased hemoglobin, since the MCHC is calculated by dividing the hematocrit into the hemoglobin.

Mild neutrophil toxicity is suggestive of inflammation and correlates with the hyperfibrinogenemia. However, it is important to note in dehydrated animals, fibrinogen can be relatively elevated (as with total protein). In such cases a total protein: fibrinogen ratio may shed light on the cause of hyperfibrinogenemia. For this case it is calculated to be 19.9 which is not definitive for inflammation (ratio <15) [1]. Despite this, the concurrent presence of reactive lymphocytes and hyperglobulinemia mean that inflammation cannot be excluded.

There is a mild lymphopenia that may reflect a stress (corticosteroid)-induced response.

Chemistry

A transient hyperglycemia could be an epinephrine or corticosteroid response, the latter supported by the lymphopenia. If this were a persistent hyperglycemia, disease states resulting in insulin resistance should be considered such as equine metabolic syndrome and pars pituitary intermedia dysfunction (PPID).

A moderate azotemia and concurrent hyperphosphatemia are suggestive of decreased glomerular filtration rate. This may be due to renal dysfunction, although a prerenal (dehydration) component is likely present. A urine specific gravity would be required to fully assess renal concentrating ability.

Hypocalcemia is moderate to marked and is unlikely to be linked to decreased protein binding as albumin is within reference range. In horses, gastrointestinal disease resulting in decreased absorption or increased loss of calcium is most common. Also possible in horses is excessive sweating leading to loss of calcium and some electrolytes such as potassium and chloride. Less likely is hypocalcemia associ-

ated with pregnancy, given the relatively early stage in this animal.

A hyperproteinemia characterized by a hyperglobulinemia is present. While a component of dehydration is likely present (given the history and clinical signs), inflammation should be considered as a differential for the hyperglobulinemia.

In the absence of increased hepatobiliary enzyme activity, the hyperbilirubinemia is most likely due to anorexia. Decreased feed intake and pregnancy can lead to a negative energy balance, which is evidenced in this case by the hypertriglyceridemia, is a result of lipolysis and VLDL production. Although a simple negative energy balance may be responsible for this abnormality, co-contributing factors such as insulin resistance should be considered, particularly given the hyperglycemia.

There is a marked hyponatremia with a slightly more severe hypochloremia.

The Corrected Cl = (normal Na/measured Na) × measured Cl = 136/112 × 73 = 89 mEq/l indicating a selective chloride loss. This is most likely due to loss of chloride rich fluid through diarrhea but may also be from gastric reflux or excessive sweating.

Hypokalemia in this animal is likely multifactorial and caused by a combination of gastrointestinal losses, anorexia, renal losses (aldosterone mediated) and excessive sweating. The potassium concentration may be increased by a concurrent metabolic acidosis, which leads to potassium retention in exchange for H+ secretion.

Decreased serum bicarbonate and concurrent increase in anion gap is suggestive of a titrational metabolic acidosis due to production of increased unmeasured anions. In this case uremic acids and lactate are most likely, with ketones being unlikely given horses do not readily form ketones in negative energy balances.

Summary and outcome

Clinicopathological abnormalities are supportive of a severe gastrointestinal disease leading to electrolyte losses and acid base imbalanced. This patient was subsequently humanely euthanized and sent for necropsy. Postmortem findings indicated extensive granulomatous enteritis, colitis and renal tubular nephrosis. A fecal PCR detected *Neorickettsia risticii*, the causative agent of Potomac horse fever, also known as equine ehrlichial colitis. *N. risticii* is a Gram-negative obligate intracellular bacterium that is thought to be transmitted by ingestion of snails, trematodes, and various types of flies, such as dragonflies and caddisflies [2]. The onset of diarrhea is often accompanied by mild abdominal discomfort. Some horses develop severe signs of sepsis and dehydration. Clinical signs can be indistinguishable from those of *Salmonella* and other infectious causes of enterocolitis.

Interpretive discussion

Hematology

Increased PCV, hemoglobin, and RBC indicate polycythemia. Since this cow is 10% dehydrated, this is relative (transient) polycythemia secondary to dehydration, supported by the increased albumin.

While the mature neutrophilia and lymphopenia is a typical corticosteroid-mediated (stress) leukogram, the presence of hyperfibrinogenemia suggests inflammation. Fibrinous inflammation occurs more commonly in ruminants than in other species. When this occurs, mature neutrophilia (and, possibly, lymphopenia if the animal is stressed) may be the only change in the leukogram. Hyperfibrinogenemia, however, will indicate that inflammation is occurring.

Hyperfibrinogenemia may be the result of inflammation but can also be caused by dehydration. In order to negate the effect of dehydration, a plasma protein: fibrinogen ratio should be calculated in animals with high fibrinogen concentrations.

Since both plasma protein and fibrinogen should increase proportionately in dehydrated animals, their ratio should stay the same regardless of the degree of dehydration. In this case, the plasma protein: fibrinogen ratio is plasma TP/Fibrinogen = 9.4/0.96 = 9.79.

Note that the fibrinogen concentration has been converted from mg/dl to g/dl for this calculation. In ruminants, a plasma TP:fibrinogen ratio of <10 : 1 indicates a true increase in fibrinogen and suggests inflammation. In this case, therefore, it appears that inflammation is occurring.

Biochemical profile

The mild hyperglycemia is probably a result of stress and is commonly observed in cases of volvulus.

Increased serum creatinine indicates decreased GFR, but urine specific gravity must be known to determine if this is a renal or prerenal azotemia. As the cow is dehydrated, there is certainly a prerenal component.

The marked hypocalcemia is typical of a lactating ruminant that experiences anorexia and/or a gastrointestinal abnormality. This cow was probably producing a large amount of milk, and this required a steady intake of Ca. The GI problem in this cow has decreased the intake and/or absorption of Ca and the result is hypocalcemia.

At around this degree of hypocalcemia (<6.4 mg/dL) one typically observes clinical signs of "downer syndrome."

Marked hyperphosphatemia in ruminants is usually associated with gut stasis. Approximately 90% of phosphorus excreted by ruminants is excreted through saliva and then passes through the GI tract out of the body. With GI stasis, there is less production of saliva, and P that enters the GI tract does not readily leave the body (and is probably reabsorbed if the GI tract is capable of this). As in other species, P is also excreted through the kidneys of ruminants; therefore, decreased GFR is also playing a role in the hyperphosphatemia.

There is mild hypermagnesemia that is due to the decreased GFR.

A hyperproteinemia is present and characterized by a hyperalbuminemia and globulin within reference range. The increased albumin is due to dehydration. As 40% of total calcium is albumin bound, this makes the calcium relatively lower than measured.

Cholestasis and liver disease inconsistently cause mild to moderate hyperbilirubinemia in ruminants. Mild increases in bilirubin concentrations can occur in anorexic cattle. Hemolysis is a common cause of hyperbilirubinemia in ruminants, but the data in this cow do not suggest a hemolytic process (no anemia). Hyperbilirubinemia in this cow is probably a result of anorexia, but a liver component cannot be discounted. The increase is mild and is not the primary concern.

Increased CK and AST in this cow are the result of muscle injury. Only a mild increase in SDH suggests liver injury, which could be due to localized hypoxia as a result of recumbency. As the SDH increase is so mild, the liver is not the major source of AST in this case. It is likely that this cow is spending more time in a recumbent position than normal due to its illness, and that this is leading to hypoxic muscle injury.

Hypokalemia is the result of alkalosis and redistribution of K into cells. In alkalosis, H ions leave cells in an effort to balance the concentration of H ions inside and outside cells. As H ions leave cells, K ions enter cells and hypokalemia can result.

Severe hypochloremia in ruminants is usually the result of sequestration of Cl in the abomasum. In this case the change in chloride is disproportionate to the change in sodium. This can occur with any type of GI stasis but is most severe with abomasal volvulus and with high duodenal obstruction or a left displaced abomasum (LDA).

Increased serum bicarbonate concentration (increased TCO_2) can also result from abomasal sequestration of Cl. Secretion of Cl into the abomasum is accompanied by secretion of H ions (HCL). This also results in production of HCO_3 that passes into the blood.

Blood gas analysis

The increased pH indicates an alkalosis. The bicarbonate is increased (an alkaline change) and the pCO_2 is increased (an acid change). Since the bicarbonate has changed in the same way that the pH has changed (alkaline), this is the primary change. The correct description of this blood gas profile is, therefore, primary metabolic alkalosis with partial respiratory compensation. The term "partial" is used since the compensatory change in pCO_2 has not resulted in return of the pH to normal. The metabolic alkalosis is a result of the sequestration of H ions in the abomasum.

Summary

This cow has a left displaced abomasum resulting in blockage of outflow and sequestration of HCl in the abomasum. The electrolyte and acid-base changes as described above resulted.

Additional tests to consider

Serum levels of ketones (beta–hydroxybutyric acid or BHB) should be measured in this case of a lactating pregnant cow that is not eating and going down.

Depending on the level of BHB, the ketosis may be either primary or secondary.

If the cow is in poor body condition little fat is available to mobilize and thus in thin animals the ketone body increase may not be significant.

Measurement of NEFAS (Non-esterified fatty acids) gives an earlier indication of low energy reserves/ketone production.

Interpretive discussion

Hematology

A mild nonregenerative, normocytic, normochromic anemia is the only abnormality in the CRC. "Target cells" are common and are not very diagnostically useful. They commonly present in animals with hypercholesterolemia.

Biochemical profile

The only abnormalities present are hypercholesterolemia and mild hyponatremia. Hypercholesterolemia is marked, and in conjunction with the history, physical examination, and mild anemia, is very suggestive of hypothyroidism. Mild hyponatremia has been reported in approximately 30% of dogs with hypothyroidism.

Endocrine data

Total T4 is within the reference interval. However, since many variables affect TT4, and this dog has clinical and laboratory findings that are suggestive of hypothyroidism a free T4 and endogenous TSH are indicated. The decreased FT4 and increased endogenous TSH are diagnostic for hypothyroidism.

Summary

Early primary hypothyroidism.

Case 95

Interpretive discussion

Hematology

The PCV and total RBC count are marginally decreased, with no abnormalities in red blood cell size, hemoglobin content, or morphology. One should consider recent blood loss (particularly GI hemorrhage) even though plasma protein concentration is normal. Alternatively, there may be a mild normochromic, normocytic anemia associated with renal failure. The leukocyte count is increased, with a mature neutrophilia and lymphopenia. This is a stress leukogram, and may support the possibility of hyperadrenocorticism as part of the disease process.

Biochemical profile

The serum glucose concentration is markedly increased. This is well beyond the level encountered due to excitement (sympathetic activation) or stress (glucocorticoid release), and should immediately suggest diabetes mellitus.

The BUN is disproportionately increased relative to the mild increase in serum creatinine concentration. The BUN: creatinine ratio is 50.6, which should suggest gastrointestinal hemorrhage, leading to an increase in hepatic urea

production. Nevertheless, some degree of azotemia (prerenal, renal, or postrenal) is probably also present (refer to discussion of urinalysis below). The serum phosphorus is moderately increased, and may be associated with the impaired glomerular filtration and the azotemia. Because the serum total calcium concentration is also decreased, one should consider dietary imbalance or renal disease as causes of secondary hyperparathyroidism. See discussion of ionized Ca below.

The serum total protein and albumin concentrations are normal. Unless there is a concomitant cause for hypoproteinemia, the absence of hyperproteinemia decreases the probability for hemoconcentration and prerenal azotemia due to dehydration.

The serum cholesterol is moderately increased. This may be related to cholestasis, as indicated by the moderate increase in serum to bilirubin concentration and serum ALP and GGT activities. However, the degree of increase in cholesterol is sufficient to warrant consideration of abnormalities in lipoprotein metabolism owing to hepatic disease or an endocrine abnormality. Likewise, the degree of increase in ALP and GGT activities suggests other means for their induction beyond cholestasis, such as hyperadrenocorticism. Marked increases in serum ALT and AST activities indicate hepatocellular damage, which may have contributed to the increases in ALP and GGT activities. The serum CK activity is essentially normal, and rules out the potential contribution of muscle damage to serum AST and ALT increases. Hepatic lipidosis associated with diabetes should be considered as a cause of hepatocellular injury and cholestasis.

A marginal increase in serum amylase and marked increase in serum lipase activities may indicate the presence of pancreatitis. However, concurrent azotemia may impair renal extraction of these enzymes from the serum, leading to increases in their activities.

Serum Na, K, and Cl concentrations are decreased. One should consider typical causes for electrolyte depletion, including pathologic losses from the gastrointestinal and urinary systems, as well as a shift to third space. The marked hyperglycemia should initiate consideration of diabetic ketoacidosis with subsequent urinary electrolyte loss. However, although the anion gap is increased, the serum total CO_2 is normal. It is possible that there are concurrent causes for metabolic acidosis (ketoacidosis) and metabolic alkalosis (vomiting and/or gastrointestinal stasis).

Urinalysis

The urinary specific gravity is in the isosthenuric range, despite azotemia and hyperphosphatemia. This may be the result of renal disease, or impaired concentrating ability due to electrolyte depletion and loss of the medullary concentration gradient. There is significant proteinuria, pyuria, hematuria, and bacteriuria, which most likely indicate a bacterial infection and inflammatory response in the urinary tract. In the absence of tubular casts or information regarding enzymuria or urinary fractional excretion of electrolytes, it is difficult to specify the anatomic location of this disorder. There is significant glucosuria corresponding to the marked hyperglycemia rioted earlier. The absence of ketones on the dipstick speaks against the possibility of prominent ketoacidosis (and ketonuria) noted above. However, this test does not detect one of the ketones, β-hydroxybutyric acid. One can anticipate that detectable ketosis would develop if untreated.

Coagulation data

The coagulation profile indicates a slightly prolonged aPTT and mildly increased FDP concentration. This may be the result of liver disease (although one may expect a change in PT prior to one in the aPTT), or incipient DIC (although platelet concentration is usually decreased with DIC). If liver disease was severe enough to impair coagulation factor synthesis, one would first expect to see hypoalbuminemia and/or hypocholesterolemia. It is not possible to draw conclusions with these borderline abnormalities.

Endocrine data

Low free T4, low total T4, and low endogenous TSH are diagnostic for secondary hypothyroidism. Secondary hypothyroidism as a result of decreased endogenous TSH is commonly associated with diabetes mellitus.

Summary

Diabetes mellitus and secondary hypothyroidism.

Interpretive discussion

Hematology

A mild anemia is present. Reticulocyte concentration was not determined, thus the degree of regeneration is unknown. Increased polychromasia is not mentioned, suggesting that the anemia is nonregenerative; however, the MCV is at the upper end of the reference interval, suggesting the presence of large immature erythrocytes. Considering the degree of dehydration, anemia is likely more severe than is apparent.

While the leukogram is normal, a patient that is ill and vomiting would be expected to have a stress leukogram. The absence of a stress leukogram should prompt consideration of hypoadrenocorticism.

Plasma protein is increased, probably as a result of dehydration.

Biochemical profile

Azotemia is evidenced by increased BUN, creatinine, and phosphorus concentrations. While azotemia may be prerenal, since the dog is dehydrated, one would expect the urine specific gravity to be greater than 1.030, if this were the case. However, the serum sodium concentration is decreased, and ability to concentrate is impaired by medullary washout of sodium. Refer to the discussion on sodium and potassium for further interpretation.

Hypercalcemia, in light of hyponatremia and hyperkalemia, is likely due to hypoadrenocorticism. The pathophysiology may be related to decreased glucocorticoids and subsequent increased GI calcium uptake, calcium retention by the kidney, as related to sodium loss, or increased albumin-bound calcium. Other causes of hypercalcemia, such as hypercalcemia of malignancy, primary hyperparathyroidism, and vitamin D toxicosis are much less likely in this patient.

Mild hyperproteinemia, due to hyperalbuminemia, is due to dehydration.

Hyponatremia and high normal potassium should cause suspicion of Addison's disease. While these electrolyte abnormalities are not marked, and result in a Na:K ratio of 24, they should prompt an ACTH stimulation test. Hyponatremia and hyperkalemia in this patient, on the other hand, could be a result of renal disease. Hypochloridemia is consistent with hyponatremia. Low total CO_2 is consistent with metabolic acidosis, and the anion gap is increased due to increased unmeasured anions, which in this dehydrated hypovolemic patient are probably lactic acids.

Mild increase in serum amylase and lipase activities are probably secondary to decreased glomerular filtration.

Endocrine data

The immeasurably low cortisol concentration with a "flat-line" response to ACTH confirms hypoadrenocorticism

Summary

Hypoadrenocorticism

Interpretive discussion

Hematology

The CBC reveals no significant abnormalities.

Biochemical profile

This dog is azotemic. Since urine concentration is not adequate (i.e., it is not >1.030), this may be a renal azotemia, but prerenal azotemia with inadequate renal concentrating ability may occur in hypoadrenocorticism. The hypotension and dehydration that accompany hypoadrenocorticism may result in azotemia, whereas hyponatremia and solute diuresis may result in medullary washout that, in turn, limits renal concentrating ability. The result is azotemia with a urine specific gravity indicating inadequate renal concentrating ability.

Hyponatremia and hyperkalemia, in combination with the abnormal response to ACTH stimulation, confirms the diagnosis of hypoadrenocorticism (see discussion of the ACTH stimulation test below). While a Na:K ratio <23 : 1 is suggestive of hypoadrenocorticism, hyponatremia and hyperkalemia are not specific for this disease. Oliguric or anuric renal failure are common causes of hyponatremia and hyperkalemia and should be considered when these abnormalities are observed, but the response to ACTH stimulation should he adequate to distinguish these diseases.

Hypochloremia is common in animals with hypoadrenocorticism. In renal tubules, Cl is reabsorbed with Na in both the proximal tubule and the loop of Henle. After hyponatremia develops, the concentration of Na in the ultrafiltrate is decreased, and this, in turn, decreases the amount of Na available for reabsorption in these portions of the nephron. The decreased Na absorption results in decreased Cl absorption and hypochloremia.

Decreased serum total CO_2 concentration suggests metabolic acidosis. Metabolic acidosis is common in hypoadrenocorticism and results from decreased tissue perfusion secondary to hypotension and from decreased renal tubular excretion of H+ secondary to mineralocorticoid deficiency.

Urinalysis

Except for the evidence of inadequate urine concentrating ability (see the discussion of azotemia above), the urinalysis is normal.

Endocrine data

The inadequate response to ACTH stimulation in combination with hyponatremia and hyperkalemia confirms hypoadrenocorticism. Dogs with hypoadrenocorticism commonly have decreased basal plasma cortisol concentrations that fail to increase or increase only slightly after ACTH stimulation. If these values do increase after ACTH stimulation, they are usually well below normal post-ACTH stimulation values, especially in dogs with primary hypoadrenocorticism.

Summary

Hyponatremia, hyperkalemia, and a Na:K ratio of 17 : 1 strongly suggest hypoadrenocorticism. An inadequate response to ACTH stimulation confirms this disease. The azotemia with evidence of inadequate urine concentrating ability, while typical of primary renal failure, is more likely due to a combination of prerenal azotemia and decreased renal concentrating ability resulting from the effects of mineralocorticoid deficiency. It is typical of ill animals to have a stress leukogram (Iymphopenia); absence of stress leukogram in this ill animal is compatible with hypoadrenocorticism.

Interpretive discussion

Hematology

There are no erythrocyte abnormalities. There is a lymphocytosis, which should prompt brief consideration of lymphoma (note the hypercalcemia), or that could be explained by a corticosteroid deficiency. Whenever an ill animal does not have a stress leukogram, one should consider the possibility of hypoadrenocorticism.

Biochemical profile

The BUN, serum creatinine, and phosphorus concentrations are moderately increased. These findings indicate decreased glomerular filtration rate. However, one cannot differentiate the nature of the azotemia (prerenal, renal, or postrenal) based on these findings alone. Refer to the discussion of urinalysis results for further interpretation.

VetBooks.ir

The serum total calcium concentration is moderately increased. The most common causes for this would be malignancy-associated hypercalcemia, hypoadrenocorticism, or renal failure. One might also consider primary hyperparathyroidism and vitamin D toxicosis.

The serum total protein, albumin, and globulin concentrations are normal. The absence of hemoconcentration decreases the probability for prerenal azotemia associated with dehydration.

There are no significant changes in indices of liver disease, with the exception of a mild increase in serum AST activity. This may be due to mild hepatocellular damage or muscle damage but is small enough that further consideration may not be necessary.

There are significant decrease in the serum concentrations of Na and Cl, as well as a significant increase in serum K concentration. The Na:K ratio is 17.5, which is strongly suggestive of hypoadrenocorticism. The presence of a metabolic acidosis (low total CO_2) is consistent with that possibility, and the anion gap may be increased owing to accumulation of unmeasured anions such as lactic acids or phosphates.

Blood gas data

The blood gas data indicate an uncompensated metabolic acidosis (decreased pH and HCO_3, normal pCO_2). The ionized calcium concentration is increased, further supporting a finding of hypercalcemia. One should consider the possibilities of either primary hypoadrenocorticism or renal disease resulting in a functional deficit in response to corticosteroids and calcium retention.

Urinalysis

The urinary specific gravity revels only marginal concentrating ability, which may result from either renal disease, or loss of the medullary concentration gradient due to electrolyte depletion. This is a common finding in hypoadrenocorticism that should prompt further diagnostics to rule out primary renal disease. The absence of nonregenerative anemia is evidence counter to chronic renal disease. The dipstick protein was negative, and the UPC is <1.0, supporting no significant urinary protein loss.

Endocrine data

The pre- and post-ACTH cortisol concentrations are both low, and there is an inadequate response. This confirms hypoadrenocorticism.

Summary

Hypoadrenocorticism with typical azotemia secondary to hypovolemia. While there is no biochemical evidence of hemoconcentration, hypovolemia is a consistent event in the pathogenesis of azotemia associated with hypoadrenocorticism.

Case 99

Interpretive discussion

Hematology

The PCV, hemoglobin, and total RBC count are within reference limits but plasma protein is increased indicating dehydration. If the animal is dehydrated, it is likely that it is mildly anemic. There are no abnormalities in leukogram. Ill animals usually have a stress leukogram.

Biochemical profile

The most significant abnormalities are Na, K, Na:K ratio, and Cl. There are three possible differential diagnoses. The most likely differentials are Addison's disease or chronic renal failure, possibly with a ruptured urinary bladder third. Chronic renal failure is not as probable considering that the creatinine is normal and the animal is capable of concentrating urine. The BUN:Ct ratio is 50, therefore one should suspect dehydration or GI bleeding. Dehydration is determined to be present by increases in both albumin and total serum and plasma protein and can be further confirmed by physical examination. Creatinine will increase in dehydration due to decreased excretion; however, the BUN increases earlier because there will be decreased excretion and increased reabsorption from tubules. The slow transit time of glomerular filtrate through the tubules due to dehydration allows for increased reabsorption of BUN, hence it increases more than creatinine. The urine specific gravity would be expected to be >1.035 if the dog is dehydrated and has normal renal function. The inability to concentrate beyond 1.020 is likely attributable to medullary washout due to the low sodium. Ruptured urinary bladder is unlikely since the dog is urinating and there is no history of trauma. To confirm Addison's disease, one should perform an ACTH stimulation test following the determination of baseline cortisol concentrations.

Further support for Addisonian is: hypercalcemia. Hypercalcemia is seen in one third of dogs with hypoadrenocorticism. However, hypercalcemia can also be seen in a small percentage of dogs with renal failure. It would not be expected in a dog with ruptured bladder. The presence of hypercalcemia in this dog helps prioritize Addison's before renal failure, ruptured urinary bladder, and other differentials. Hyperphosphatemia is attributed to decreased glomerular filtration rate due to dehydration in this case.

The serum glucose concentration is at the low end of the reference interval. Hypoglycemia is sometimes seen in patients with hypoadrenocorticism, likely due to a lack of glucocorticoids as well as mineralocorticoids.

The decreased bicarbonate (TCO_2) is indicative of a metabolic acidosis. Amylase is increased and this is attributed due to decreased glomerular filtration rate. Amylase and lipase are excreted through the urine and any cause of decreased GFR may result in one or both enzymes being increased.

Urine specific gravity of 1.022 in a dog with dehydration indicates inadequate concentrating ability, which could be due to renal disease or medullary washout of sodium. The latter is more likely as azotemia is considered to be prerenal and medullary washout fits with Addison's and chronic hyponatremia. The two most important solutes that produce a concentration gradient in the medullary interstitium are UN and sodium. The decreased sodium in the medullary interstitium means glomerular filtrate (forming urine) can only be partially concentrated.

Special testing

ACTH stimulation confirmed hypoadrenocorticism. The basal sample is less than 1 µg/dL, which strongly implicates Addison's especially given a Na:K ratio of 17. The postsample of 0.5 is not an increase over basal and is therefore flatline, which confirms hypoadrenocorticism in this dog.

Summary

Hypoadrenocorticism (Addison's disease), with prerenal azotemia and probable medullary washout.

The most likely lesion is lymphyocytic adrenalitis, which destroys all three cortical zones of both adrenal glands. Regeneration will not occur therefore recommend treatment with glucocorticoids and mineralocorticoids for life. Dog was treated successfully, gained weight, and lived for 7 years.

Interpretive discussion

Hematology

Mature neutrophilia, monocytosis, and lymphopenia are typically seen with increased endogenous or exogenous corticosteroids. Increased concentration of nucleated RBCs is seen with a variety of conditions; in this case they are likely secondary to hyperadrenocorticism.

Biochemical profile

Mild hyperglycemia is consistent with increased endogenous or exogenous corticosteroids. Glucocorticoids increase gluconeogenesis and decrease peripheral utilization of glucose by antagonizing the effects of insulin.

The BUN concentration is below the reference interval. While decreased BUN may be associated with liver failure or inadequate protein intake, diuresis will also result in increased urinary loss of urea nitrogen. In this case, diuresis is probably stimulated by glucocorticoids.

Hypercholesterolemia is associated with numerous conditions, including hypothyroidism, diabetes mellitus, hyperadrenocorticism, and cholestasis. In this patient, the increase is probably due to hyperadrenocorticism.

Alanine aminotransferase activity is mildly increased, indicating glucocorticoid-induced increase in ALT production or hepatocellular damage. Hepatocellular damage is an important feature of steroid hepatopathy, which may be occurring in this dog. Alkaline phosphatase activity is markedly increased. While cholestasis may result in an increase of this magnitude, bilirubin is not increased, suggesting that the

increase is likely due to corticosteroid induction of alkaline phosphatase. Activities of this magnitude are almost always related to steroid effect. Determination of steroid-induced alkaline phosphatase isoenzyme would be helpful.

Mild hypernatremia and hypokalemia are commonly seen in approximately 50% of dogs with hyperadrenocorticism.

Urinalysis

Urine specific gravity is low, and is likely due to hyperadrenocorticism. Glucocorticoids are thought to interfere with ADH receptors, resulting in isosthenuria or hyposthenuria, and polyuria and polydipsia.

Endocrine data

ACTH stimulation: The baseline cortisol concentration is well above normal and the post-stimulation cortisol concentration is within the reference interval. While most dogs with hyperadrenocorticism have normal basal cortisol concentrations, this increase is very suggestive of hyperadrenocorticism. While dogs with pituitary-dependent hyperplasia (PDH) have hyperplastic adrenals and dogs with functional adrenocortical tumors have the potential to respond to ACTH stimulation by increasing cortisol production and release, not all do so. Cortisol increases above the reference interval following ACTH stimulation in approximately 85% of dogs with pituitary-dependent disease, and in approximately 50% of dogs with adrenal tumors. In summary, while ACTH stimulation is a useful screening test for PDH and adrenal tumors, cortisol concentrations do not exceed the high end of the reference interval in many dogs. Thus, this dog may have pituitary-dependent disease or an adrenal tumor, based on the ACTH stimulation results.

Low- and high-dose dexamethasone suppression: Dexamethasone screening tests are diagnostically useful because in patients with pituitary-dependent disease, the abnormal pituitary is somewhat resistant to the negative feedback action of cortisol. Moreover, while dexamethasone may inhibit endogenous ACTH production in dogs with adrenal tumors, endogenous ACTH production is probably already maximally suppressed, and at any rate, these tumors usually autonomously secrete cortisol, independent of ACTH. In normal dogs, endogenous ACTH is suppressed by dexamethasone, resulting in a rapid decline in plasma cortisol concentrations, which remain suppressed for up to 48 hours. Thus, since this dog's cortisol concentration did not decrease, either pituitary-dependent disease resulting in adrenocortical hyperplasia, or adrenal neoplasia, is present.

Endogenous ACTH: Endogenous ACTH is below the reference interval in this dog, indicating that the dog has a functional adrenal tumor, rather than pituitary disease.

Summary

Hyperadrenocorticism due to functional adrenal tumor. On abdominal radiographs, a calcified mass cranial to the right kidney was observed. On ultrasound examination, a large right adrenal mass was seen. The left adrenal was not detectable. A CT scan of the brain was normal.

Interpretive discussion

Hematology

Mature neutrophilia, monocytosis, and lymphopenia are indicative of a corticosteroid (stress) leukogram.

Biochemical profile

Mild hyperglycemia is consistent with increased endogenous or exogenous corticosteroids.

Alkaline phosphatase activity is markedly increased. While cholestasis may result in an increase of this magnitude, bilirubin is not increased, suggesting that the increase is likely due to corticosteroid induction of alkaline phosphatase. Determination of steroid-induced alkaline phosphatase isoenzyme would be helpful.

Gamma glutamyltransferase activity is also markedly increased, and with the lack of increase in ALT and AST activities, as well as bilirubin concentration, corticosteroid induction is likely.

The combination of mild hyperglycemia and increased ALP and GGT activities, with no other evidence of cholestasis, should trigger further endocrine testing.

Urinalysis

Low urine specific gravity (often hyposthenuria) is commonly seen in patients with hyperadrenocorticism. Glucocorticoids are thought to interfere with ADH receptors, resulting in isosthenuria or hyposthenuria, and polyuria and polydipsia. Bacteriuria without significant pyuria may also occur with hyperadrenocorticism.

Endocrine data

ACTH stimulation: Patients with iatrogenic hyperadrenocorticism have a "flat-line" response to ACTH stimulation (much like a patient with hypoadrenocorticism) due to feedback to the pituitary and secondary adrenal atrophy. While some corticosteroid drugs cross-react on the cortisol assay, the post-ACTH response will not be higher than the pre-ACTH response.

Low-dose dexamethasone suppression: LDDS is not helpful in diagnosing iatrogenic hyperadrenocorticism. The pituitary is already responding to feedback from iatrogenic corticosteroids, and adrenal glands are atrophied.

Summary

Iatrogenic Cushing disease that resulted from Vetalog injections for flea allergy dermatitis. Fleas were eliminated, and the dog was slowly withdrawn from corticosteroids by treating on alternate days with decreasing doses over several months.

Interpretive discussion

Hematology

The PCV is mildly increased, with increased nucleated erythrocyte concentration. Possibilities for this combination might include hypoxia or other causes of increased erythropoietin concentration. Dogs with hyperadrenocorticism will sometimes have increased erythropoiesis. Additionally, corticosteroids may inhibit removal of NRBC by macrophages in spleen. Mature neutrophilia, monocytosis, and lymphopenia are indicative of a stress leukogram.

Biochemical profile

Mild hyperglycemia is consistent with a stress leukogram, and may be a result of increased endogenous or exogenous glucocorticoids.

Alkaline phosphatase is markedly increased, AST is mildly increased, and cholesterol is borderline high. No other abnormalities are present. Increased alkaline phosphatase activity and mild hypercholesterolemia may be secondary to cholestasis; however, serum bilirubin is not increased. Alkaline phosphatase activity may also increase secondary to steroid induction. This is most likely given the magnitude of increase. The slight increase in serum AST activity may be due to mild steroid hepatopathy or steroid induction.

Urinalysis

Urine specific gravity is quite low, and while it is not necessarily abnormal, it is consistent with decreased urinary concentrating ability in dogs with hyperadrenocorticism, related to decreased responsiveness to ADH. Bacteriuria without pyuria may be seen in dogs with hyperadrenocorticism.

Physical exam, history, stress leukogram, hyperglycemia, and increased serum alkaline phosphatase activity should trigger screening tests for hyperadrenocorticism.

Endocrine data

ACTH stimulation: Baseline cortisol is above normal and poststimulation is "borderline." Stimulation of above 20 is consistent with hyperadrenocorticism. Eighty-five percent of dogs with pituitary-dependent hyperplasia stimulate, as do approximately 50% of dogs with adrenal tumors. Thus, the ACTH stimulation is not diagnostic in this dog but is suspicious.

Low-dose dexamethasone suppression: Baseline cortisol is above normal. The dog suppressed at 3 hours, with escape from suppression at 8 hours. In normal dogs, endogenous ACTH is suppressed by dexamethasone, resulting in a rapid decline in plasma cortisol concentrations, which remain suppressed for up to 48 hours. Most dogs with adrenal tumors show no suppression at 3 or 8 hours. If a dog suppresses at 3 hours but does not remain suppressed at 8 hours, it is likely that the dog has PDH, rather than an adrenal tumor. This "escape" is thought to be due to rapid clearance of dexamethasone.

High-dose dexamethasone suppression: Baseline cortisol is above normal. The dog did not suppress to the range for normal dogs. Dogs with adrenal disease do not suppress, and most dogs with pituitary-dependent adrenal hyperplasia (PPH) do suppress. Very high-dose steroids will suppress ACTH production, and hence cortisol secretion, even with PPD. However, most dogs with pituitary macroadenomas do not suppress; an endogenous ACTH serum concentration is indicated.

Endogenous ACTH: Dogs with PDH have normal to increased endogenous ACTH, while dogs with adrenal tumors have decreased endogenous ACTH. Thus, this dog has pituitary-dependent disease.

Summary

A large pituitary macroadenoma was present in this dog. Note that multiple endocrine tests were required to make this diagnosis.

Interpretive discussion

Hematology

A few nucleated red blood cells are present in the absence of anemia. This may indicate a disruption in the endothelial barrier in centers of hematopoiesis, or is possibly a result of immunosuppression and lack of removal of nuclei by macrophages. Increased NRBCs can be seen with hemangiosarcoma, some leukemias, lead toxicity, hyperadrenocorticism (HAC) and DIC. The leukogram is characteristic of a stress or steroid response: mature neutrophilia, lymphopenia, eosinopenia, and monocytosis.

Biochemical profile

Marked increase in ALP with only mild increases in ALT and AST indicates possible cholestasis and/or hyperadrenocorticism. An ALP over 5000 IU/L without bilirubinemia and only mild increases in ALT and AST is most consistent with HAC. Further support for this diagnosis is history of alopecia and PU/PD coupled with dilute urine, cystitis and nucleated

red blood cells. Over 90% of Cushingoid dogs will have mild to marked ALP. If ALP is not increased it is very unlikely that a dog has HAC. Cholesterol is increased, which in this dog could be cholestasis, hypothyroidism, or HAC. Increases in ALT and AST are attributed to glycogen (steroid) hepatopathy induced by hyperadrenocorticism. Hyperglycemia is moderate, which is consistent with hyperadrenocorticism.

The urine analysis has abundant evidence for infectious cystitis; numerous leukocytes and bacteria are present. Collection method is not specified, therefore inflammation could be present anywhere in the urogenital tract. Proteinuria may be due to the inflammatory response and increased capillary permeability. Absence of casts and no azotemia support cystitis over pyelonephritis. Dilute urine is likely a result of a failure to concentrate due to glucocorticoid interference with ADH, subsequent polyuria, and responsive polydipsia. Cystitis is fairly common in dogs with hyperadrenocorticism.

At this point, laboratory evaluation of the endocrine system should be done. Initially, a low-dose dexamethasone suppression (LDDS) test should be performed. If LLDS indicates hyperadrenocorticism, one should then perform an endogenous ACTH to distinguish pituitary-dependent hyperadrenocorticism (PD HAC) from an adrenal tumor.

Endocrine testing

In this patient, the ACTH stimulation was done, and although the basal cortisol is normal, the post-stim sample is >22 μg/dL, which is excessive and supports hyperadrenocorticism. One must now differentiate pituitary-dependent disease from an adrenal tumor. The basal concentration of cortisol in the LDDS is just above reference interval but the 8-hour value is well above 1.4 μg/dL, therefore there was failure to suppress and Cushing's disease is ruled in when all of the other data fit, as in this dog. (False-positive rate for LDDS, however, is as high as 50%, therefore all of the other lab and historical and physical exam results need to fit with HAC.) Unfortunately, a 4-hour sample was not collected, which could have proven helpful to distinguish pituitary and adrenal-dependent HAC. If the 4-hour sample exhibited suppression (<1.4) with the present value for the 8-hour sample of no suppression, it would have indicated a rebound, which is consistent with pituitary-dependent Cushing's disease, the more common cause of HAC. The HDDS is confusing or at least not very helpful. The basal cortisol is normal, the 4-hour sample clearly failed to suppress and the 8-hour sample is above 1.4, but it is almost 50% less than the basal and the 4-hour samples. The interpretation is the HDDS failed to suppress, indicating AT or PD HAC (suppression would indicate the dog had PD HAC). Although the endocrine testing to this point indicates an adrenal tumor is possible, adrenal tumors only account for 10–20% of dogs with HAC. Furthermore, there seemed to be some suppression by the HDDS but even using a decrease of cortisol by 50% from basal it still did not clearly suppress. Another way to define suppression is if the 8-hour sample is less than 50% of basal even if it is still greater than 1.4 μg/dL. In this dog the 8-hour sample is 57% of basal, and the 8-hour sample is 47% of the 4-hour sample. Because distinction of AT and PD is needed for treatment and the HDDS was equivocal, abdominal ultrasonography (US) and an endogenous ACTH concentration were performed. Abdominal US did not identify an adrenal tumor and the endogenous ACTH clearly indicates this dog has PD HAC.

Summary

The e ACTH is markedly increased, and therefore the dog has a pituitary neoplasm secreting ACTH. The dog was given mitotane. The ACTH stim 2 weeks postdiagnosis indicates a flatline response. The dog was clinically normal, and the electrolytes were normal, and therefore this indicated degeneration to necrosis of zona fasciculata by the mitotane. When dosed correctly the cortex will eventually regenerate. Under the stimulation of the ACTH-secreting pituitary tumor the adrenal cortex will regenerate and is the reason repeated ACTH stims will be required during maintenance therapy. The results of the ACTH stim are the same pattern seen with hypoadrenocorticism, spontaneous disease, or from mitotane or steroid therapy.

Case 104

Signalment: 6-year-old male dog
History: Change in temperament from docile to irritable. Severe constipation for several days.
Physical examination: No abnormalities detected

Interpretive discussion

Hematology

In light of normal results for other erythrocyte measurements, the decreased MCHC is marginal and not important.

The mild mature neutrophilia, in the absence of lymphopenia, suggests normal variability or very mild inflammation. This dog's irritability may have predisposed it to epinephrine release when the venipuncture was performed, although excitement leukograms are quite rare in dogs.

Biochemical profile

Hypercalcemia and hypophosphatemia can occur with primary hyperparathyroidism and pseudohyperparathyroidism (hypercalcemia of malignancy). In this case, the increased intact parathormone (iPTH) and normal parathormone-related protein (PTH-rp) concentrations are most suggestive of primary hyperparathyroidism (see discussion of hormone assays below). Other causes of hypercalcemia include vitamin D toxicosis, excessive bone resorption, and renal failure (5–10% of these cases in dogs), but serum phosphorus concentration is typically normal to increased in these cases.

The slightly increased serum alkaline phosphatase activity is not significant. There is no evidence suggesting either cholestasis or increased corticosteroid levels. Since this dog

has an abnormality of calcium and phosphorus metabolism, it is possible that altered bone metabolism is occurring. Although the net effect in this animal is probably bone demineralization, increased osteoblastic activity, as part of effort to regenerate bone, may have resulted in this slight increase in activity.

Urinalysis

Low urine specific gravity may reflect this dog's hydration status and, therefore, may be normal in this patient. Hypercalcemia can, however, interfere with renal concentrating ability and can result in decreased urine specific gravity with subsequent polyuria and polydipsia. Nephrocalcinosis, other toxic effects of calcium on renal tubules, and interference with the action of antidiuretic hormone are possible mechanisms for decreased concentrating ability in hypercalcemic animals. The absence of polyuria and polydipsia in this dog suggests that calcium interference with renal concentrating ability is not a major factor.

Endocrine data

Increased intact parathormone (iPTH) concentration and undetectable PTH-related protein (PTH-rp) concentration indicate that this dog has primary hyperparathyroidism, rather than hypercalcemia of malignancy. The iPTH concentrations are increased due to overproduction of PTH by hyperplastic or neoplastic parathyroid glands. Parathormone-related protein is synthesized by malignant cells of neoplasms such as lymphoma and apocrine gland adenocarcinoma of the anal sac, but not by the parathyroid glands, and concentrations of PTH-rp are, therefore, not increased in animals with primary hyperparathyroidism.

Summary

The combination of hypercalcemia, hypophosphatemia, increased iPTH concentration, and undetectable PTH-rp concentration indicate primary hyperparathyroidism in this case. A mass in the neck region compatible in location with the parathyroid gland was found during a more thorough physical examination. Surgical removal and histopathologic examination revealed a parathyroid adenoma. This dog's clinical signs and serum calcium and phosphorus concentrations returned to normal after surgery. Irritability is unusual in hypercalcemic dogs; dullness is more common.

Urine s.g. voided	1.007

Interpretive discussion

Hematology

Unremarkable; absence of a stress leukogram may prove informative.

Biochemical profile

Mild hypercalcemia is the only abnormality. The increased total serum calcium explains the dilute hyposthenuria, as hypercalcemia affects the function of ADH on tubules. Serum phosphorus is normal, which is somewhat helpful to shorten the list of differentials for hypercalcemia. Recommend rechecking calcium, total and ionized, and if both are increased pursue possible causes of hypercalcemia. The calcium is likely to be increased again given the urine specific gravity. The two most likely differentials are hypercalcemia of malignancy and primary hyperparathyroidism because the serum phosphorus is normal and there are no other significant biochemical abnormalities. Unlikely differentials are hypoadrenocorticism, renal failure, vitamin D toxicity, and granulomatous diseases, all of which usually have increased serum phosphorus and produce other biochemical disturbances. The only two diseases that produce hypercalcemia and hypophosphatemia in dogs are hypercalcemia of malignancy and primary hyperparathyroidism.

Summary and follow-up

Both total serum calcium and ionized calcium were increased on a recheck. On physical examination, no evidence of lymphoma or perirectal apocrine gland adenocarcinoma was found. Serum was sent for PTH and PTH-rp.

Endocrine data		Reference interval
PTH (pmol/L)	**35.5**	3–17
PTH-rp (pmol/L)	0	0–0.9
iCa	**1.65**	1.25–1.45

These results confirm hypercalcemia and rule in primary hyperparathyroidism.

The neck region was explored and a small mass was found in the region of one thyroid lobe. During surgery a STAT methodology to measure PTH pre- and postremoval of any mass was employed and the results were:

Additional endocrine data		Reference interval
PTH Sample 1, pre, Turbo intact PTH (pg/mL)	**98**	11.2–72.8
PTH Sample 2, post, Turbo intact PTH (pg/mL)	**9.0**	

The decrease in PTH in the second sample, after the parathyroid mass was removed is dramatic (less than 50% of previous sample) indicating that the offending lesion was removed.

Comment

The serum concentration of PTH was increased in this dog when it was hypercalcemic, which makes the diagnosis of primary hyperparathyroidism (HPTH) quite simple. However, increased PTH is only present in about 25% of dogs and the remaining dogs (75%) with primary HPTH will have a concentration of PTH within reference interval. Moreover, 45% of dogs with primary hyperparathyroidism will have serum PTH concentrations in the low to middle range. Increased concentrations of PTH are the exception in dogs, but if PTH is detectable in an animal that is hypercalcemic and not azotemic, then this combination is inappropriately abnormal because PTH should be decreased or undetectable in response to nonparathyroid-induced hypercalcemia. If PTH is within the reference interval, it is inappropriately high in the face of hypercalcemia, and therefore diagnostic for primary HPTH. It indicates the parathyroid gland is secreting PTH at a time when secretion should be suppressed. It is critical to measure PTH-rp concurrently as many dogs with hypercalcemia of malignancy will have measurable PTH.

Ultrasonography of the neck region is just as accurate at identifying a parathyroid mass as is measuring serum PTH and if positive will localize the side of the neck to look for the adenoma during surgery. More than one mass is possible, especially in keeshonds.

Interpretive discussion

Hematology

There is a mild anemia. Although a reticulocyte count is not present, the indices are normocytic normochromic, which indicates it may be nonregenerative. The azotemia could explain this anemia if the azotemia is due to chronic renal disease. Anemia of inflammatory disease is another possible cause of the anemia in this dog. There is a stress leukogram as evidenced by the lymphopenia, eosinopenia, and monocytosis.

Biochemical profile

The dog has renal failure based on mild azotemia combined with isosthenuria. However, any time the serum calcium is increased the kidneys may not be able to concentrate urine adequately (interference with ADH) which in this case clouds the interpretation that primary renal disease is present. If this dog is dehydrated the azotemia may all or partially be due to prerenal and the dilute urine in the face of dehydration is caused by hypercalcemia. Hypercalcemia is severe, hyperphosphatemia is mild to moderate. The Ca × P product is 126, which indicates mineralization of soft tissues is occurring. Mineralization may have caused the renal failure or at least enhanced it. The diagnostic dilemma is to determine which came first, the renal failure or the hypercalcemia. It is often difficult to distinguish and there may be two diseases occurring, renal failure and a disease other than renal disease that caused hypercalcemia (e.g., a malignancy, vitamin D toxicity, etc.). In this dog it seems more likely the hypercalcemia came first or that there is a second disease causing hypercalcemia. This is based on mild hyperphosphatemia and marked hypercalcemia. Rules to help make this distinction are: the greater the serum P the more likely the primary disease is renal and the lower the serum P the more likely there is hypercalcemia of malignancy (HCM). The higher the serum calcium the more likely there is a malignancy and the lower

the calcium the more likely renal disease is causing hypercalcemia. The greater the azotemia the more likely it is primary renal and the lower the azotemia the more likely the renal problems are caused by the mineralization or it is pre renal. The easiest way to distinguish is to either find the malignancy or identify the type of renal failure (chronic, acute, glomerular, pyelonephritis, etc.). In this dog it seems clear the primary disease is one that is causing hypercalcemia because the azotemia is mild, the hypercalcemia is severe and hyperphosphatemia is mild. This distinction can be more difficult in other cases. A reasonable plan is to search for cancer and give the dog fluids to see if the azotemia can be reversed. Measuring ionized calcium may also be diagnostically helpful. If the ionized calcium is within the reference interval, then primary renal failure is more likely, but if ionized calcium is increased, it could still be either primary renal or a malignancy.

The urine is not concentrated, which could be primary renal or secondary to hypercalcemia. There is some blood likely due to cystocentesis, which may also be responsible for the 1+ protein. The rest of the analysis is unremarkable.

The hepatic leakage enzymes are increased (ALT and AST) and the enzymes associated with cholestasis are increased (ALP, GGT). There are many possible causes of cholestasis in this dog, one of which is an infiltrative disease in the liver such as lymphoma, another possibility is pancreatitis. The increases in lipase and amylase are mild and seem more likely due to decreased GFR (azotemia) and therefore decreased excretion than pancreatitis. If the dog had pancreatitis it may have hypocalcemia, tender abdomen and be overweight with an acute onset of problems, none of which this dog has. The dog has a metabolic acidosis probably caused by dehydration and/or renal disease.

A reasonable plan is to search for lymphoma (palpate lymph nodes, search for an anterior thoracic mass, abdominal organ evaluation, etc.) and do a rectal and perirectal exam to evaluate if a carcinoma of the anal sacs is present. If a malignant tumor is found there is no need to perform PTH and PTH rp assays.

Summary

A mass was found in the pelvic vault, and aspirational cytology indicated it was a tumor of the anal sacs. These are invariably malignant, but repeated excisions and/or chemotherapy can extend a dog's life for months or years. These owners declined treatments. Intravenous and subcutaneous fluid therapy decreased the azotemia, but it did not return to normal. An autopsy was not performed so it is not known if or what type of renal disease was present and whether mineralization played a role. The anemia was due to anemia of chronic disease (cancer) and/or concurrent renal disease. The most common substance secreted by tumors is PTH-rp, which stimulates phosphaturia and results in hypophosphatemia, absolute or as in this dog relative for the degree of azotemia. Primary hyperparathyroidism could cause the hypercalcemia and phosphaturia, but rarely is there concurrent azotemia with primary hyperparathyroidism.

Interpretive discussion

Hematology

Mature neutrophilia, lymphopenia, and monocytosis are typical of a stress leukogram.

Biochemical profile

The serum glucose concentration is in the range typical for glucocorticoid-induced hyperglycemia. Stress is the most likely cause in this case, particularly in light of the leukogram.

Decreased serum creatinine concentration is meaningless in most cases. This abnormality can result from diuresis, but, if this is the cause, the BUN concentration is usually also decreased. The absence of a history of polyuria and the normal BUN concentration make diuresis unlikely in this case.

Hypocalcemia and hyperphosphatemia can occur in renal failure, pancreatitis with prerenal azotemia, eating a diet containing excessive phosphorus, or hypoparathyroidism. Hypoparathyroidism is most likely in this case. Normal BUN concentration and decreased serum creatinine concentration indicate that renal function is normal. Clinical signs are not typical of pancreatitis, and there is no evidence of a prerenal azotemia. This dog may be receiving a diet with excessive phosphorus, but this is very unlikely if the dog is receiving a commercial diet. Hypoalbuminemia is another cause of hypocalcemia, but the absence of hypoalbuminemia indi-

VetBooks.ir

cates that this is not a consideration. Vitamin D deficiency may also result in hypocalcemia, but hypophosphatemia rather than hyperphosphatemia is typical of such a deficiency. Hypoparathyroidism can be confirmed by measuring the serum intact parathormone concentration (see below).

Slight hypochloremia, in the absence of abnormalities in Na, K, or total CO_2, is probably insignificant.

Urinalysis

The urinalysis is normal.

Endocrine data

The serum intact parathyroid hormone (iPTH) concentration is at the low end of the reference interval. The normal response of the parathyroid glands to hypocalcemia is production of PTH. Low normal iPTH concentration in a hypocalcemic animal strongly suggests inability of the parathyroid glands to respond to hypocalcemia and, therefore, hypoparathyroidism. Other possible causes of hypocalcemia (discussed above) should result in high normal to increased iPTH concentrations.

Summary

The combination of hypocalcemia with low normal iPTH concentration indicate hypoparathyroidism. Other diseases can result in hypocalcemia and hyperphosphatemia, but iPTH concentration in these diseases is typically high normal to increased.

Potassium (mEq/L)	**9.0**	**7.4**	3.7–5.8
Chloride (mEq/L)	**100**		108–120

Urine specific gravity: 1.022.

Interpretive discussion

Hematology

The dog is mildly anemic, which was masked by dehydration on Days 1 and 3. Considering the other laboratory findings, this is likely due to a lack of cortisol.

Neutrophilia in the absence of lymphopenia suggests inflammation. Although concurrent neutrophilia and lymphocytosis could be indicative of excitement, this is highly unlikely in a dog.

Eosinophilia may be due to hypersensitivity or parasites but with concurrent lymphocytosis, may be due to lack of cortisol.

Persistent lymphocytosis in this case is most likely due to a lack of cortisol considering hyponatremia and hyperkalemia, but other considerations would be recent vaccination considering the dog's age, tick-borne disease, especially ehrlichiosis, chronic lymphocytic leukemia, thymoma, and, less likely, excitement.

Monocytosis may be indicative of inflammation.

Chemistry

Increased BUN and creatinine, indicating decreased glomerular filtration rate, resolved almost completely with fluids, suggesting prerenal azotemia. The BUN is relatively more increased than the creatinine, suggesting prerenal azotemia due to dehydration or hypovolemia. A high-protein meal or blood loss into the intestine could also be contributing to an increase in BUN. The PCV is not decreased, suggesting no GI blood loss, although a decrease could be masked by dehydration.

While the urine specific gravity indicates an inability to concentrate (since the dog is azotemic), this is likely due to hyponatremia interfering with concentrating ability due to decreased medullary tonicity, rather than tubular disease, and/or hypercalcemia interfering with ADH receptors.

Hypercalcemia is moderate and decreases with fluid therapy. In this case, again considering Na and K, it is likely due to Addison disease. Approximately 30% of dogs with Addison disease are mildly hypercalcemic. Other considerations in this case would be vitamin D toxicosis (considering the hypercalcemia and hyperphosphatemia) and hypercalcemia of malignancy (considering the lymphocyte concentration). The hyperphosphatemia is also likely due to decreased glomerular filtration, although vitamin D toxicosis could be

considered. Additionally, both calcium and phosphorus can be mildly increased in growing puppies. Since the phosphorus improves with fluid therapy, it is likely due to decreased GFR. The calcium × phosphorus product is greater than 200, suggesting the possibility of mineralization of the kidneys. However, the improvement of the azotemia following fluid therapy suggests that this has not occurred.

Mild hypoproteinemia is evident on Day 3, although both albumin and globulin are in the reference interval. The lack of hyperalbuminemia in the presence of dehydration on Day 1 suggests that the dog may be hypoalbuminemic. Hypoalbuminemia has been reported in dogs with Addison disease, likely due to GI protein loss resulting from a lack of cortisol, which is necessary to maintain GI mucosal health.

The ALP activity increase is not likely due to cholestasis, since the bilirubin is normal. Other possibilities include steroid induction (not likely since this dog appears to have hypoadrenocorticism based on Na and K) or bone isoenzyme, since this dog is still growing at 17 weeks of age.

Hyponatremia and hyperkalemia with a Na:K ratio of approximately 15 is extremely suggestive of hypoadrenocorticism. Other possibilities would include Na wasting through the GI tract or kidney. The animal may be acidotic, which could also cause a potassium increase. Other possibilities of potassium increase would be anuria, but this patient is urinating.

The hypochloridemia is likely related to the hyponatremia.

Summary

Primary hypoadrenocorticism resulting in a lack of both mineralocorticoids and glucocorticoids due to destruction of the adrenal gland is the most likely differential considering the hyponatremia and hyperkalemia, lymphocytosis, eosinophilia, and hypercalcemia. Vomiting is seen in approximately 85% of dogs with hypoadrenocorticism. The lack of aldosterone results in the electrolyte abnormalities, and the lack of cortisol results in the lymphocytosis. Only approximately 20% of dogs with Addison disease present with lymphocytosis. More typically, patients with Addison disease present with a lack of a stress leukogram (lack of lymphopenia), which is unusual, especially if vomiting, and the lack of a stress leukogram should always trigger consideration of hypoadrenocorticism. Other possible differentials would include pseudo-Addison disease such as is seen with *Trichuris* (whipworms) parasitism or renal disease, possibly secondary to hypercalcemia and kidney mineralization. The electrolyte abnormalities do not suggest the latter.

Additional tests

The hyponatremia and hyperkalemia triggered an ACTH stimulation test, which confirmed that the patient had Addison disease.

		Reference interval
Baseline serum cortisol (µg/dL)	**<0.5**	1–4
Post-ACTH stimulation serum cortisol (µg/dL)	**<0.5**	10–20

Other tests that could be performed include fecal examination for *Trichuris*, flow or PARR for chronic lymphocytic leukemia, PTH-rp for the possibility of hypercalcemia of malignancy, or vitamin D concentrations to exclude the possibility of vitamin D toxicosis.

The laboratory findings in this patient are very typical of primary hypoadrenocorticism. Ninety five percent of dogs with primary hypoadrenocorticism are hyperkalemic, and 86% are hyponatremic. Approximately 90% have increased BUN, 65% have increased creatinine, 80% have increased phosphorus, and 70% are unable to concentrate maximally. Approximately 30% are hypoproteinemic.

Animals do not recover from adrenal gland destruction without life-long therapy, which consists of a mineralocorticoid and glucocorticoid. This patient was treated with prednisone 0.2 mg/kg daily and deoxycorticosterone pivalate (Percortin, Novartis) 2.2 mg/kg IM every 25 days.

Chloride (mEq/L)	**98**	108–120

Urine specific gravity: 1.020.

Interpretive discussion

Hematology

The hemoglobin is slightly increased, with the RBC concentration and PCV at the upper end of the reference interval; this is likely due to dehydration.

Mild lymphocytosis in this patient is most likely due to a lack of cortisol, considering the hyponatremia and hyperkalemia (see below). Lymphocytosis in a vomiting dog should always trigger the suspicion of Addison disease, as dogs with adequate cortisol typically have a stress response (lymphopenia) when vomiting.

Monocytosis is very mild and may be indicative of mild inflammation.

Chemistry

Increased BUN and creatinine, indicating decreased glomerular filtration rate, may be renal or prerenal. The BUN is relatively more increased than the creatinine, suggesting prerenal azotemia due to dehydration or hypovolemia.

The urine specific gravity of 1.020 indicates an inability to maximally concentrate, since the dog is azotemic and dehydrated. In a patient with azotemia due to dehydration that has normal kidney function, one would expect a urine specific gravity of at least >1.035. However, inability to concentrate is likely due to hyponatremia causing a lack of tonicity in the medullary interstitium, and hypercalcemia interfering with ADH receptors. On the other hand, the calcium × phosphorus product is 175.5, and it is very possible that soft-tissue mineralization resulting in kidney dysfunction could be occurring.

Hypercalcemia is moderate, and considering hyponatremia and hyperkalemia, it is likely due to Addison disease.

Other considerations in this case would be vitamin D toxicosis (considering the hypercalcemia and hyperphosphatemia) and hypercalcemia of malignancy. The mechanism of hypercalcemia in adrenal insufficiency is not completely understood but is thought to be due to increased calcium mobilization from bone, increased intestinal absorption, and increased calcium reabsorption in the proximal

VetBooks.ir

tubule due to decreased glomerular filtration rate [1]. Glucocorticoid replacement results in calciuresis, and calcium concentrations rapidly normalize.

The hyperphosphatemia is also likely due to decreased glomerular filtration, although vitamin D toxicosis could be considered. Additionally, both calcium and phosphorus can be mildly increased in growing puppies.

Hyponatremia and hyperkalemia with a Na:K ratio of 18 is extremely suggestive of hypoadrenocorticism. Other possibilities would include Na wasting through the GI tract or kidney. The animal may be acidotic, which could also cause hyperkalemia. Other possibilities of hyperkalemia would be anuria, but this patient is urinating.

The hypochloremia is likely related to loss from vomiting and may be related to the hyponatremia.

Urine Analysis

The urine specific gravity of 1.020 in an azotemic dehydrated dog indicates an inability to concentrate maximally. In this case, it is likely due to hyponatremia, but renal disease, possibly due to mineralization, cannot be excluded. Additionally, hypercalcemia interferes with concentrating ability. The ability of the kidney to concentrate urine depends on two processes: (i) generation of hypertonicity in the medullary interstitium and (ii) antidiuretic hormone-mediated water and urea transport in the collecting duct. Hypercalcemia interferes with both of these processes [2].

Summary and outcome

Primary hypoadrenocorticism resulting in a lack of both mineralocorticoids and glucocorticoids due to destruction of the adrenal gland is the most likely differential considering the hyponatremia and hyperkalemia, lymphocytosis, and hypercalcemia. The primary differential is renal disease possibly caused by mineralization of the kidneys, considering the azotemia and low urine specific gravity,

The lack of a stress leukogram in a vomiting dog should always trigger suspicion of Addison disease.

The hyponatremia and hyperkalemia triggered an ACTH stimulation test, which confirmed that the patient had hypoadrenocorticism.

		Reference interval
Baseline serum cortisol (µg/dL)	**0.9**	1–4
Post ACTH stimulation serum cortisol (µg/dL)	**1.3**	10–20

In addition, abdominal radiographs and a barium series were performed, and were normal.

The azotemia resolved with therapy, indicating that kidney function was normal.

Interpretive discussion

Hematology

A mild, nonregenerative, microcytic, hypochromic anemia is present typical of iron-deficiency. Also contributing to this may be the mild, normocytic, normochromic anemia commonly observed in dogs with hypothyroidism (see below). The mild thrombocytosis in the face of platelet clumping is a reactive process and is a common observation in cases of iron deficiency and other conditions such as chronic inflammation and neoplasia.

Chemistry and blood gas

A decrease in serum iron is present (iron-deficiency/hypoferremia) and in an older dog is most commonly due to external blood loss (e.g., chronic gastrointestinal bleeding) and warrants testing for occult blood in feces. Less likely causes for this abnormality include iron sequestration due to inflammation or decreased intake, which is very uncommon in small animals.

Vetbooks.ir

Total protein concentration between the refractometer and biochemical analyzer is discrepant due to falsely increased total protein estimation by refractometry, in this case due to interference by cholesterol. However, hyperproteinemia is present characterized by a hyperglobulinemia and could be reflective of dehydration, inflammation, antigenic stimulation or much less likely, neoplasia (multiple myeloma).

This degree of marked hypercholesterolemia and hypertriglyceridemia are strongly suggestive of hypothyroidism (see below). Other causes of hypercholesterolemia include nephrotic syndrome and cholestasis, but there is no evidence of nephrotic syndrome (proteinuria) or cholestasis (ALP and total bilirubin are within normal limits), and this breed is not predisposed to familial disorders of lipid metabolism, making other differentials less likely.

A very mild hyponatremia and concurrent hyperkalemia is present. In isolation these values are likely to be insignificant, but this animal has a calculated Na/K ratio of 27 which is on the margin for suspicion of hypoadrenocorticism. The sodium concentrations measured by the biochemical analyzer and the blood gas machine are discrepant, and this is explained by the marked hypertriglyceridemia and hypercholesterolemia, which can result in pseudohyponatremia when indirect measures of potentiometry are used (as is the case with the Beckman biochemistry analyzer) [1]. Decreased serum bicarbonate and low pH reflects metabolic acidosis and could be due to consumption or loss; as the anion gap is not increased the latter is more likely. Loss of bicarbonate typically occurs through the gastrointestinal tract or kidneys. In this case, renal losses are more likely and could be due to aldosterone insufficiency, which leads to decreased excretion of H+ in the kidneys (increased retention) and subsequent decrease in serum bicarbonate [2].

There is a mild increase in ionized calcium as measured in the venous blood gases, and typical differentials to consider for this include paraneoplastic syndromes, hyperparathyroidism, and renal disease. Based on biochemistry and endocrinology results, there is no evidence of these.

Urinalysis

Hyposthenuria (USG <1.008) indicates the kidneys' ability to dilute urine. A possible cause in this case may be medullary washout secondary to hypoaldosteronism (not Addison's in this case.) Less likely are central and nephrogenic diabetes insipidus and there is no history of polydipsia.

Endocrine

A marked decrease in serum T4 and T3 and concurrent increase in TSH is strongly supportive of primary hypothyroidism. Despite the suspicions of hypoadrenocorticism this dog's baseline cortisol was within normal limits.

Summary

A diagnosis of primary hypothyroidism was confirmed, and the neurological signs were thought to be a manifestation of this disease. Neurological disease associated with hypothyroidism is rare and while the link between the two is not confirmed, some authors believe decreased mitochondrial ATPase activity in these cases leads to axonal degeneration, whilst some believe accumulation of mucopolysaccharides in the endoneurium and perineurium impede function [3, 4]. Further, hypothyroidism and the subsequent hypertriglyceridemia and hypercholesterolemia predisposes individuals to the development of emboli and atherosclerosis, which may explain the embolic event in this case.

The electrolytes derangements, hyposthenuria, hypobicarbonemia, and small adrenal glands raised concern for Addison's but was ultimately ruled due to a normal baseline cortisol. However, a case of mineralocorticoid deficiency preceding glucocorticoid deficiency in hypoadrenocorticism has been reported [5]. Despite the anion gap being within normal limits, the metabolic acidosis in this case was most likely due to lactate production secondary to ischemia, and a serum lactate would have been warranted in this case.

Interpretive discussion

Hematology

The PCV, hemoglobin and RBC concentration indicate erythrocytosis, likely relative, due to dehydration.

The increase in band neutrophils and monocytosis are indicative of an inflammatory leukogram, and the lymphopenia is indicative of a stress or cortisol leukogram.

Platelets are markedly decreased, and no comment regarding platelet clumping on the blood film was made. Causes of thrombocytopenia should include canine ehrlichiosis, immune-mediated thrombocytopenia and disseminated intravascular coagulopathy (DIC). The aPTT and PT were within the reference interval, and fibrin degradation products (FDPs) were also normal, which would exclude DIC as a differential (see below).

The plasma protein estimate by refractometry is increased, and considering the hyperalbuminemia in the biochemical profile, this is likely due to dehydration. Lipemia could also falsely. Increase the refractometric reading, but the plasma

protein is only slightly higher than the serum protein analysis, and the difference can be accounted for by the presence of fibrinogen.

Chemistry

Hyperglycemia is of the magnitude that diabetes mellitus should be diagnosed. The increase in cortisol, as evidenced by the lymphopenia, could also be contributing slightly to the hyperglycemia. Fructosamine could be determined to further substantiate a diagnosis of diabetes mellitus but was not performed in this case.

Increased BUN and creatinine, indicating decreased glomerular filtration rate (GFR), is likely renal azotemia, considering the urine specific gravity. A prerenal component to the azotemia is also likely, considering that the dog is dehydrated. Phosphorus is slightly increased due to decreased GFR, and would probably be more increased if not for the polyuria.

Total protein and albumin are increased, likely due to dehydration.

Total bilirubin is increased, likely due to liver disease or cholestasis.

Cholesterol and triglyceride are both increased. Serum lipids are commonly increased in patients with diabetes, since fat is mobilized for energy. However, this patient has a long history of fasting lipemia, and considering the breed, this is likely familial hyperlipidemia that is commonly seen in miniature schnauzers. Triglycerides are increased in approximately 30% of miniature schnauzers, and the syndrome appears to worsen with age [1]. Cholesterol is increased in approximately 11% of miniature schnauzers, and is more likely to be increased in those that have marked hypertriglyceridemia. The disorder is thought to be familial, and may be due to decreased lipoprotein lipase activity, although the exact pathophysiology is still controversial.

The ALT activity is increased, indicating hepatocellular damage. Alkaline phosphatase and GGT activities are increased, suggesting cholestasis since the bilirubin is increased. Additionally, increased cortisol could be contributing to the increase in ALP and GGT activities. It is likely that the patient has hepatic lipidosis secondary to hyperlipidemia associated with diabetes mellitus and familial hyperlipidemia. Hepatic lipidosis could be responsible for both hepatocellular damage and cholestasis.

Chloride is slightly low and is likely being lost in the vomitus.

The total CO_2 is decreased, indicating metabolic acidosis.

By subtracting the sum of chloride and total CO_2 (major anions) from the sum of sodium and potassium (major cations) the anion gap in this patient is calculated to be 42.6 mEq/L (reference interval, 12–24). This increase in this patient is likely due to lactic acid or ketones, although the urine is negative for ketones. Urine test strips only measure for acetoacetate, and the major ketoacid in the blood is typically beta-hydroxybutyrate [2, 3]. Blood was not tested for ketones in this patient.

Amylase and lipase activity are both increased, and this increase is likely due to pancreatitis, although both amylase and lipase are commonly increased in patients that are azotemic, due to decreased clearance of the enzymes. Pancreatic lipase immunoreactivity is also increased, and this enzyme is not increased with azotemia [4], indicating that pancreatitis is quite likely. Although pancreatitis and hyperlipidemia are known to be associated with each other, and are speculated to be bi-directional (i.e., hyperlipidemia can cause pancreatitis, and pancreatitis can cause hyperlipidemia), recent studies have shown that only a small percentage of dogs develop hyperlipidemia secondary to pancreatitis, while a large percentage of dogs develop pancreatitis secondary to hyperlipidemia [5].

Urine Analysis

The urine specific gravity is only slightly above the isosthenuric range, and the glucose in the urine could be contributing to the urine specific gravity. In an azotemic, dehydrated dog with normal sodium concentration, this is very suggestive of renal azotemia. The urine contains glucose, as would be expected, since the serum glucose exceeds the renal threshold for glucose. The presence of protein in the urine is likely due to the inflammation secondary to the bacteriuria. The urine is negative for ketones, but the animal may be ketonemic since beta-hydroxybutyrate is not detected by the methodology used for urine (see above). The presence of bacteria and leukocytes in the urine is indicative of septic suppurative inflammation occurring somewhere in the urogenital tract. Considering the azotemia in this patient, pyelonephritis is likely. The erythrocytes may be present secondary to inflammation, or mild hematuria as a result of thrombocytopenia may be occurring.

Coagulation profile

The coagulation profile is normal, which excludes DIC as the cause of the thrombocytopenia.

Summary and outcome

Diagnoses in this patient include pancreatitis, diabetes mellitus, pyelonephritis, immune-mediated thrombocytopenia, and familial hyperlipidemia. It is likely that recurrent bouts of pancreatitis, likely caused by hyperlipidemia, resulted in diabetes mellitus. Diabetes mellitus probably predisposed to pyelonephritis, since glucosuria often results in cystitis that can ascend into the kidney. Therapy was instituted for the pyelonephritis and pancreatitis, the thrombocytopenia resolved, and the patient was treated with daily insulin and survived for 6 more years.

Interpretive discussion

Hematology

Interpretation of laboratory results is limited by the lack of well-established reference intervals for mules. The hemogram reveals a mild anemia that appears macrocytic (MCV) and hypochromic (MHCH) but these reference values are for an adult horse. Donkeys, and possibly mules, have a relative macrocytosis in comparison to horses. The subjective observation of anisocytosis is discrepant with the mild decrease in RDW, and erythrocyte morphology is possibly normal. Considering this, the anemia is suspected to be nonregenerative – possibly reflecting anemia of inflammation/chronic disease or an altered marrow microenvironment related to lymphoid neoplasia.

There is a marked leukocytosis comprised predominantly of small to medium sized lymphocytes. Assuming these lymphocytes have condensed chromatin and appear mature (rather than lymphoblastic), this is suggestive of late-stage lymphoma or chronic lymphocytic leukemia. Flow cytometry is recommended for immunophenotyping.

Chemistry and endocrinology

The mild decrease in creatinine likely reflects poor muscle mass.

The hyponatremia appears mild and unremarkable at first glance; however, chloride is observed moving in the opposite direction and in the upper end of the reference interval. The

corrected chloride is calculated to be 111 mEq/l, indicating hyperchloremia. This discrepancy is normally associated with hypobicarbonemia (hyperchloremic/strong ion metabolic acidosis); however, bicarbonate concentrations are in the middle of the reference interval in this case and the anion gap is negative. A subtle acid-base disturbance is present in this animal, and given the negative anion gap, likely reflects increased concentrations of unmeasured cations (see below).

Hyperproteinemia characterized by hyperglobulinemia could be polyclonal (inflammation) or monoclonal (associated with B-cell lymphoid neoplasia) and a serum protein electrophoresis is recommended.

A marked hypercalcemia is present and in the presence of increased PTH and lack of evidence of PTH-rp, this is most consistent with primary hyperparathyroidism. Primary hyperparathyroidism additionally promotes hypermagnesemia and PTH-induced hypophosphatemia. The marked hypercalcemia and increase in ionized calcium (Ca2+) may be responsible for the unexpected anion gap.

A mild increase in AST activity in the absence of elevated CK is suggestive of hepatocellular injury. It is, however, possible that see persistent AST following muscle injury in which CK has returned to reference interval.

Donkeys can have increased GGT activity relative to horses, so it is uncertain whether this animal has a true increase in enzyme activity. This is coupled by the low total bilirubin, which makes cholestasis unlikely. Elevated GGT can be seen with gastrointestinal diseases in horses such as gastroenteritis.

Urine chemistry

By performing urine chemistry one can calculate the fraction excretion of analytes by the kidneys. Unfortunately, as the analyzer yielded results of <1 mg/dl for phosphate in both the serum and urine, a fraction excretion for this analyte could not be attained.

Fractional excretion of Calcium = (Urine Ca 13.2/plasma Ca 25.4) × (Plasma creatinine 0.7/urine creatinine 17.6) × 100 = 2%. This value is relatively low given the marked hypercalcemia and reflect renal retention of Ca, likely due to hyperparathyroidism.

Fractional excretion of Sodium = 0.7%. This value is high considering the hyponatremia any may reflect renal losses as a contributor to this.

Summary

This patient had been diagnosed with primary hyperparathyroidism a year prior to this presentation. Flow cytometry of peripheral blood was interpreted as B cell lymphoproliferative disease. Serum protein electrophoresis was reported as polyclonal.

Patient was euthanized, and the following abnormalities were identified:

- B cell small cell lymphoma/Leukemia with specific tissues affected including marrow, lymph nodes, liver, stomach, and intestines
- Pituitary pars intermedia adenoma
- Spindle cell sarcoma on the serosal surface of the large colon
- Chronic mild lymphocytic interstitial nephritis
- Cortical cyst in the right kidney
- Splenic lymphoid hyperplasia

Although masses were found adjacent to the thyroid, and the thyroid gland appeared enlarged, no parathyroid tissue was found in the cut sections of the thyroid and the adjacent masses were lymph nodes with the neoplastic lymphocytes. It is therefore uncertain what the source of PTH was, and there is minimal evidence in the literature to suggest PTH secretion with neoplastic conditions (as opposed to those that produce PTH-rp).

Interpretive discussion

Hematology

The bird has a normal packed cell volume with moderate numbers of polychromatic erythrocytes, which is suggestive of some erythrocyte regeneration. The moderate leukocytosis with normal heterophil morphology could be indicative of a moderate inflammatory response that may not involve an infectious etiology. However, the associated lymphopenia may make a stress leukogram more likely.

Chemistry

In general, the blood glucose concentration in normal birds ranges from 200 to 500 mg/dl: therefore, the plasma glucose concentration in this avian patient demonstrates a marked increase. Hyperglycemia occurs with diabetes mellitus, catecholamine release, and glucocorticosteroid excess, such as occurs with stress or administration of corticosteroids. Excess glucocorticosteroid result in a mild to moderate increase in the blood glucose concentration (≤600 mg/dL) in birds. Exertion, excitement, and extreme temperatures stimulate the release of catecholamines, which also results in a mild to moderate increase in the blood glucose concentration. Glucose concentrations of greater than 700 mg/dl are suggestive of diabetes mellitus in most birds. The pathophysiology of diabetes mellitus in birds varies among different species and may result from increased glucagon secretion or hypoinsulinemia. Birds with diabetes mellitus have polyuria and urinary glucose concentrations exceeding 1 mg/dl.

The normal plasma cholesterol concentrations of most avian species range between 100 and 250 mg/dl. Because cholesterol is eliminated in the form of bile acids, increases in the plasma cholesterol concentration may be associated with extrahepatic biliary obstruction, hepatic fibrosis, and bile duct hyperplasia. Hypercholesterolemia also can be associated with conditions other than liver disease, such as hypothyroidism, high-fat diets, lipemia, and during egg production. Postprandial increases in cholesterol may occur as well.

In general, a blood uric acid concentration greater than 13 mg/dl is suggestive of impaired renal function from a variety of causes, including nephrotoxins, urinary obstruction, nephritis, nephrocalcinosis, and nephropathy associated with hypovitaminosis A. Uric acid is not a sensitive test for renal disease in birds, because a significant loss (approximately 75%) of renal function is required to increase the blood concentrations of this analyte. Uric acid is also not a specific test for renal disease, because increases can occur

after ingestion of a high-protein meal, during starvation, or with severe tissue necrosis. Blood uric acid can be used as an indicator of renal function in birds; however, it does not provide a diagnosis, nor do normal values guarantee an absence of renal disease. The blood urea nitrogen (BUN) concentration is slightly elevated. The normal blood urea nitrogen concentration of normal, noncarnivorous birds ranges between 0 and 5 mg/dl Urea is generally considered to have limited diagnostic value in the detection of renal disease in birds compared with that of uric acid. Unlike uric acid, which is generally excreted independently of hydration, BUN may be a sensitive test for prerenal azotemia in some avian species because it is eliminated by glomerular filtration, which depends on the hydration status of the bird. Therefore, the slightly increased BUN concentration may support a reduction of renal arterial perfusion in this bird. A urinalysis of the liquid component of this bird's droppings may have been useful in evaluation of the cause of the polyuria in this avian patient.

The normal plasma protein concentration in birds generally ranges from 2.5 to 4.5 g/dl with albumin representing 40–50% of the total plasma protein. The plasma albumin concentrations generally range from 0.8 to 2.0 g/dl in normal birds. Therefore, the total protein concentration in this bird may not be significantly decreased regardless of the published reference value. Avian albumin is difficult to measure accurately and results are likely often inaccurate as they may be below the sensitivity of the analyzer. Since albumin is subtracted from the total protein value to determine the globulin, globulin concentrations are also likely inaccurate. Both albumin and globulin are more accurately measured by protein electrophoresis.

The plasma creatine kinase (CK) activity is markedly increased, indicating skeletal muscle injury or exertion. The plasma aspartate aminotransferase (AST) activity is not significantly increased, which also supports skeletal muscle involvement. A much higher degree of AST activity would be expected with hepatocellular disease.

Summary

Because the bird's cachexia provided a grave prognosis, the owner elected for euthanasia rather than attempting treatment for diabetes mellitus. The body was submitted for necropsy. Significant necropsy findings included a moderate lymphoplasmacytic, heterophilic, multifocal, chronic-active cholangitis of the liver and moderate, multifocal, Islet cell vacuolar degeneration of the pancreas.

The vacuolar changes in the Islet cells within the pancreas are consistent with the metabolic disturbances resulting in marked increase in plasma glucose concentrations and the degenerative changes within the pancreas are suggestive of diabetes mellitus. Additionally, vascular degeneration within the liver and aorta was noted and appeared to be early atherosclerosis, which is relatively common in aged psittacines and can occur secondary to hypercholesterolemia and hyperlipidemia. This finding is often most prominent in the great vessels, although can occur in other arteries throughout the body. Diabetes mellitus and hypercholesterolemia predisposed this bird to atherosclerosis formation.

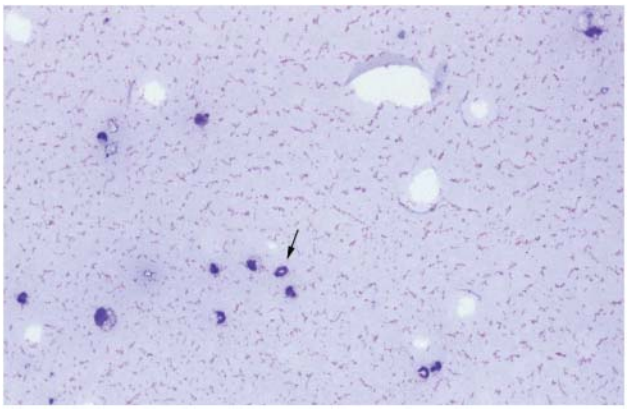

Figure 1 Direct film of abdominal fluid from cat. A few neutrophils (arrow) and macrophages are scattered throughout. Note the blue background and stippled appearance that are characteristic of a high-protein fluid. Protein has peeled off of the slide, leaving crescent-shaped structures and clear spaces.

Abdominal fluid analysis	
NCC (μL)	6000
Total protein (g/dL)	6.0

Cytology: A direct film of the fluid contains 60% segmented neutrophils that are nondegenerate, 30% lymphocytes, and 10% large mononuclear cells. No microorganisms are seen. The background is typical of a high-protein fluid (Figure 1).

Interpretive discussion

Hematology

The PCV is within the reference interval, but since the cat is dehydrated, he may actually have a mild anemia. The CBC should be repeated when the cat is rehydrated. An inflammatory leukogram is present as evidenced by the increased band neutrophils. The lymphopenia is due to a stress (cortisol mediated) response. The monocytosis may be due to either cortisol or inflammation.

Plasma protein estimate by refractometry is markedly increased, likely due to both dehydration and an increase in globulin (see below). The difference between the plasma protein and the serum protein is 0.2 g/dL, likely due to the presence of fibrinogen in plasma.

Biochemical profile

The BUN and creatinine are both increased. Considering that the urine specific gravity is 1.050, this is a prerenal azotemia, likely secondary to dehydration and hypovolemia. The hyperphosphatemia is also due to decreased glomerular filtration rate.

The albumin is increased, indicating dehydration. The globulin is also increased; a component of this increase is likely due to dehydration, but chronic antigenic stimulation is also likely a cause. A protein electrophoresis is indicated but was not performed.

Increase in ALT activity is indicative of hepatocellular damage.

Abdominal fluid analysis

The relatively low cell concentration and high-protein concentration are very suggestive of feline infectious peritonitis (FIP). The cell concentration of >3000 cells/μL puts the fluid in the exudate category. The differential count suggests mild mixed inflammation. The background protein seen in Figure 1 is very characteristic of FIP fluid.

Summary and outcome

A presumptive diagnosis of FIP was made in this cat, which was lost to follow-up.

Globulin concentration could be measured on the fluid; globulin concentration is consistently higher than albumin concentration in effusions caused by FIP.

FIP is a coronaviral disease that may affect cats of any age but is most common in cats that are 4–36 months of age. While some cats have a noneffusive form of FIP, the majority of cats have abdominal, or less commonly, pleural effusion. Most cats also have high serum globulin concentrations, usually a polyclonal gammopathy. The effusion has a very high-protein content that ranges from 3.5 to 9.8 g/dL and a relatively low cell concentration (<6000 cells/μL). The high-protein and globulin content in the effusion reflects that of the serum and results from leakage of proteins into the effusion due to serositis and vasculitis. The high-protein/Low cell concentration effusion is so characteristic of FIP that it suggests a presumptive diagnosis. Although the Rivalta test, a test to confirm the presence of protein in fluid, is commonly used to diagnose FIP effusions in Europe, it is rarely performed in the United States. Diseases other than FIP that produce positive Rivalta tests are lymphoma and bacterial peritonitis, which can usually be distinguished by cytologic evaluation of the fluid. Molecular tests can be used to help confirm a diagnosis of FIP, such as detection of viral RNA by serum or fluid reverse transcriptase polymerase chain reaction. The diagnostic gold standard is still histopathology for visualization of the classic lesions associated with FIP.

Radiographs

Radiographs were taken in June and September (Figures 1–2).

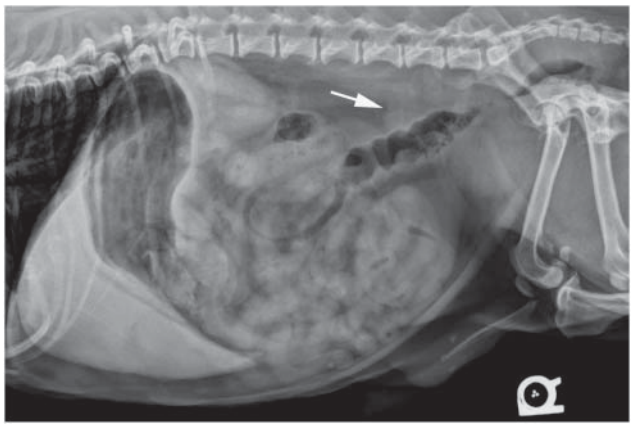

Figure 1 Abdominal radiograph made in June.

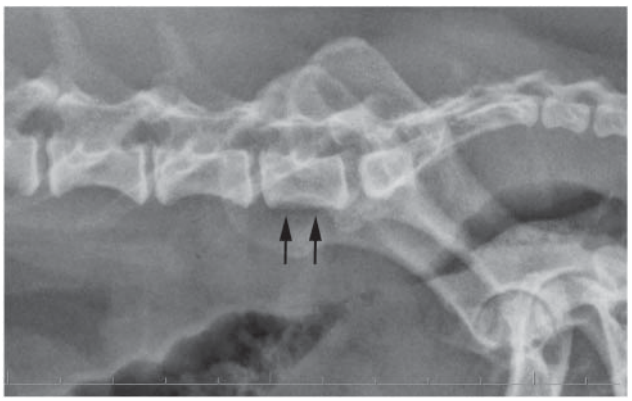

Figure 2 Close-up of the caudal aspect of the lumbar spine from June.

Figure 3 Abdominal radiograph made in September.

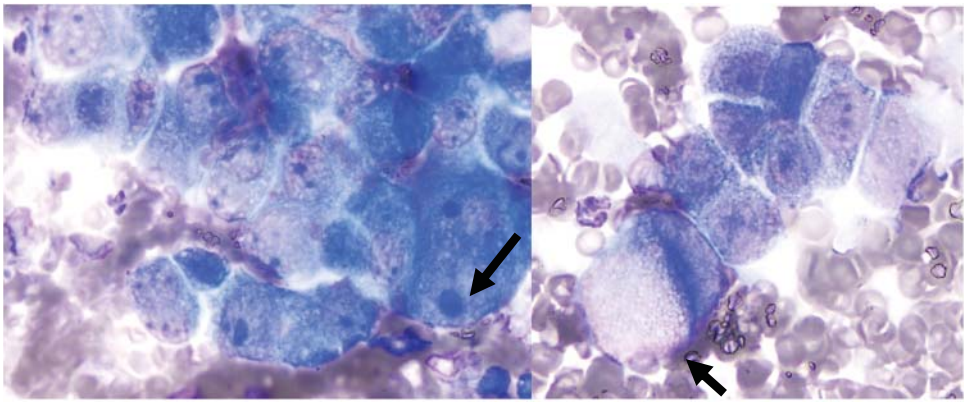

Figure 4 Traumatic catheterization of the bladder taken in June. Note the prominent nucleoli (arrows), anisocytosis, and anisokaryosis of the epithelial cells. The epithelial cell (arrow) in the image on the right contains eosinophilic amorphous material (glycosaminoglycans).

Cytology

A traumatic catheterization was performed due to the presence of clumps of epithelial cells in the urine sediment (Figure 2).

Interpretive discussion

Hematology

The patient became mildly anemic by September. The microcytosis suggests iron deficiency anemia secondary to chronic blood loss that may be associated with chronic hematuria or GI-tract blood loss due to a nonsteroidal anti-inflammatory drug (NSAID) he was given (see below). Serum iron was not measured. The increased MCHC in April is likely due to a falsely increased hemoglobin due to lipemia. A stress leukogram, characterized by a lymphopenia and mild neutrophilia, is present in June. The neutrophilia and increase in band neutrophils in September are indicative of an inflammatory leukogram.

The plasma protein by refractometry is slightly increased in June, and the increase may be false due to lipemia.

Chemistry

The increase in ALP activity is mild to moderate, and may be insignificant in an older dog. However, on imaging the liver was markedly enlarged, suggesting some type of hepatopathy with is likely resulting in the increased ALP activity. No further evaluation of the liver was made. The very mild albumin decrease could be due to inflammation or liver dysfunction, although there is no other laboratory evidence of liver dysfunction. Bile acids were not measured.

Urinalysis

Hematuria is evident, as reported in the history. The presence of leukocytes indicate inflammation somewhere in the urinary tract. Microorganisms were not seen, suggesting that the inflammation is not secondary to bacterial infection. One hyaline cast/lpf is likely not significant. The mild proteinuria is likely due to the presence of blood. The presence of clumps of epithelial cells in the urine triggered a traumatic catheterization (see cytology below).

Radiology

In the initial abdominal radiograph made in June, the prostate gland is enlarged and is displacing the urinary bladder cranially. There is a poorly defined mass effect just dorsal to the descending colon. In the closeup a very minimal smooth periosteal reaction is present on the ventral aspect of L7. Prostate gland enlargement is most commonly the result of benign hypertrophy but with the poorly defined mass effect in the territory of the sublumbar lymph nodes and the periosteal reaction on L7, neoplasia becomes the primary consideration. In the later abdominal radiograph, the mass effect is more obvious due to progressive enlargement of the sublumbar lymph nodes. The periosteal reaction on L7 is unchanged. The liver is also markedly enlarged. This could be due to vacuolar hepatopathy but other causes cannot be ruled out from survey radiographs.

Cytology

A traumatic catheterization was performed in June and was very cellular. Many clumps of epithelial cells were seen, and most of the cells exhibited criteria of malignancy, including large nucleoli, anisocytosis, and anisokaryosis. Some of the

epithelial cells had round accumulations of eosinophilic granular material in the cytoplasm that is characteristic of glycosaminoglycans within urothelial cells (Figure 2).

Summary and outcome

A diagnosis of urothelial or prostatic carcinoma was made on the basis of cytology and imaging. Urothelial carcinomas and prostatic carcinomas are difficult to differentiate on cytology, and many carcinomas of the prostate arise from urethral transitional epithelial cells. The patient was treated palliatively with antibiotics, piroxicam (an NSAID), and famotidine (a histamine 2 blocker because of NSAID administration) and he clinically improved. He was lost to follow up after September.

Urothelial carcinoma (also called transitional cell carcinoma [TCC]) is the most commonly diagnosed cancer of the urinary tract of dogs. Hematuria is common, as was seen in this dog; other clinical signs include stranguria and difficulty urinating. Clinical signs are similar to those seen with a urinary tract infection. Diagnosis may be made by cytologic analysis of urine sediment, traumatic catheterization, prostatic wash and/or fine needle aspiration, although percutaneous sampling of TCC should be avoided because of possible seeding of the abdominal wall with neoplastic cells [1, 2]. Cytology of bladder epithelium can be difficult, since hyperplastic epithelial cells can appear neoplastic [3]. A sensitive PCR assay (CADET™ *BRAF* test, Antech) has been developed and is commercially available. This test detects a somatic gene mutation in the *BRAF* gene resulting from a substitution of T to A at nucleotide 1784, which in turn causes an amino acid substitution from valine to glutamic acid at codon 595. This test detects approximately 85% of uroepithelial and prostatic tumors in dogs, and requires only a small amount of urine, since tumor cells commonly exfoliate into urine [4].

Case 116

Signalment: 6-year-old female mastiff mix breed

History: Presented for the investigation of a large mass on the 5th digit of the left thoracic limb.

On presentation, the animal had a 5 to 6 cm diameter mass emanating from the 5th digit. The mass was well-circumscribed, unencapsulated, ulcerated and highly vascular. A dorsopalmar radiograph of the manus was made (Figure 1), and fine needle aspirates of the mass were taken and submitted for cytologic examination (Figures 2–4).

Interpretive Discussion

Radiology

Figure 1. There is a large mass in the 5th digit of the manus with abaxial deviation of the entire 5th digit due to the mass. There is nearly total effacement of the ungual process of the distal phalanx and visible lysis in the ungual crest. The keratinized nail is absent. The lesion extends into the medial aspect of the distal interphalangeal joint and there is active bone proliferation on the middle phalanx of this digit. There is also a very small amount of bone proliferation on the distal-lateral aspect of the proximal phalanx. Given the large mass and the extent of lysis, the findings are most consistent with a large soft tissue tumor with secondary bone effacement and a small amount of associated periosteal proliferation.

There is also a small amount of periosteal proliferation in the distal-lateral aspect of MCIII and on the distal-medial aspect of MCIV. The border of this new bone on MCIV is slightly irregular. These changes could be due to chronic pulling of interconnecting soft tissue as a result of altered weight bearing. However, that these sites represent metastatic sites cannot be ruled out. The irregular soft tissue mineralization association with digits 2 and 3 is most likely due to superficial debris.

Gross and radiographic changes are consistent with an expansile mass of the 5th digit with extensive ulceration of the overlaying epidermis and severe lysis/remodeling of the underlying bone.

Cytology

The preparations are highly cellular, but poorly preserved, composed of lysed neutrophils, keratinocytes of varying maturity and a population of atypical epithelial cells. Figures 2 and 3 depict many keratinocytes with angular borders surrounded by dense aggregates of degenerate neutrophils. Figure 4 demonstrates atypical epithelial cells surrounded by poorly preserved neutrophils. Atypical cells are large, have flattened cytoplasmic borders, moderate amounts of basophilic cytoplasm and a round, centrally placed nucleus with up to two distinct nucleoli. Clear cytoplasmic vacuoles frequently surround the nucleus.

Figure 1 Gross image and radiograph of the left manus.

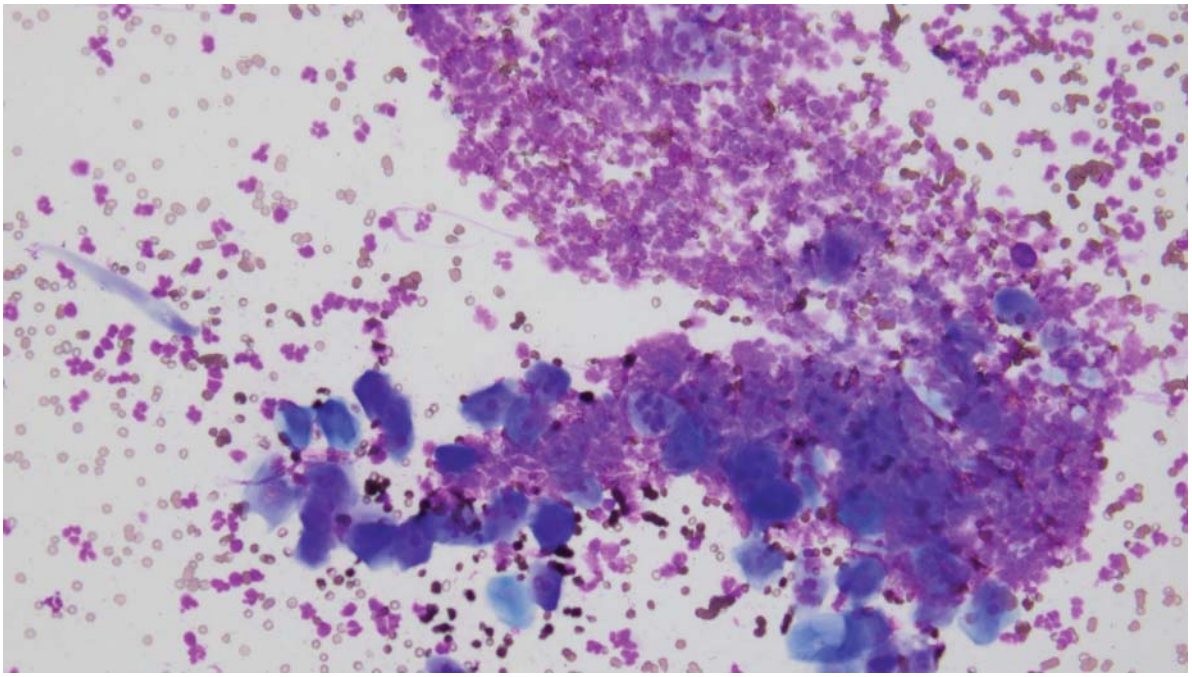

Figure 2 Fine needle aspirate of the digital mass. (Wright's stain, 10X objective) Image courtesy of Dr. Pedro Bittencourt

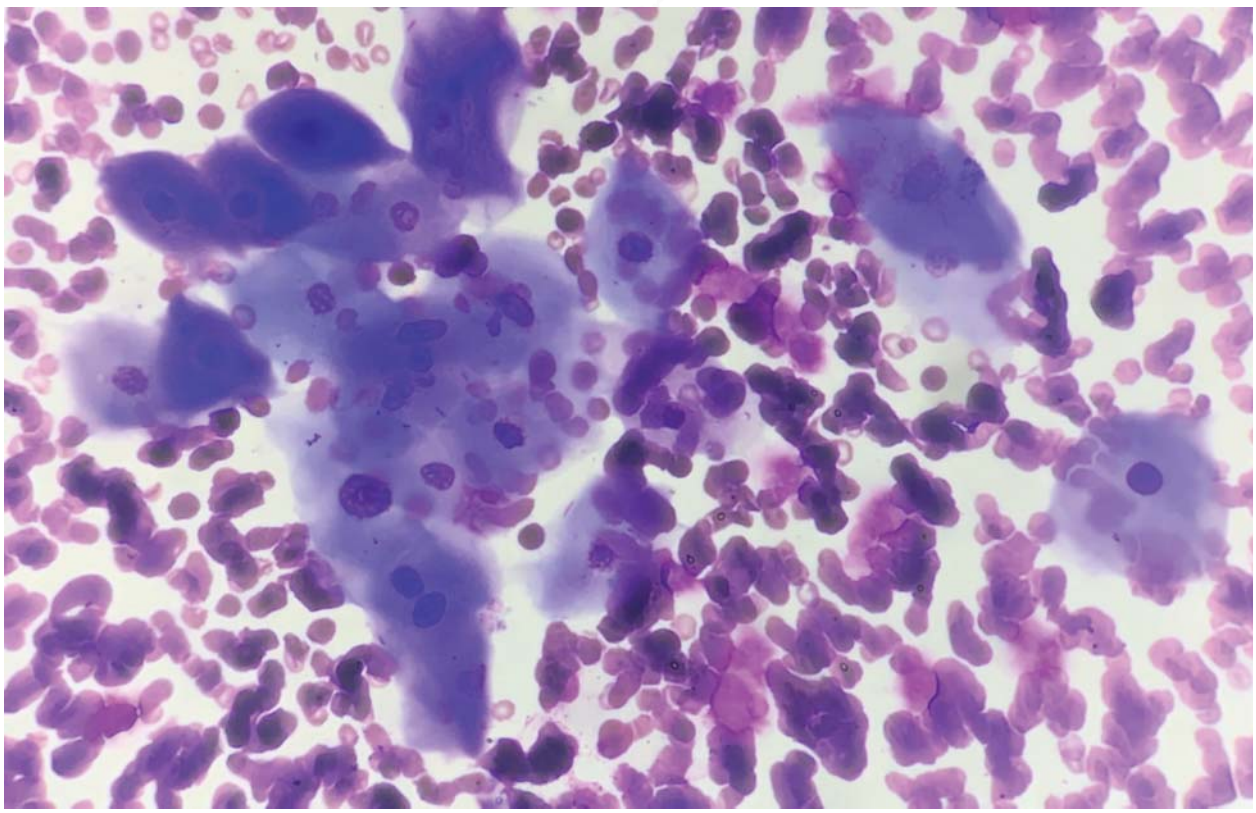

Figure 3 Fine needle aspirate of the digital mass. (Wright's stain, 40X objective) Image courtesy of Dr. Pedro Bittencourt

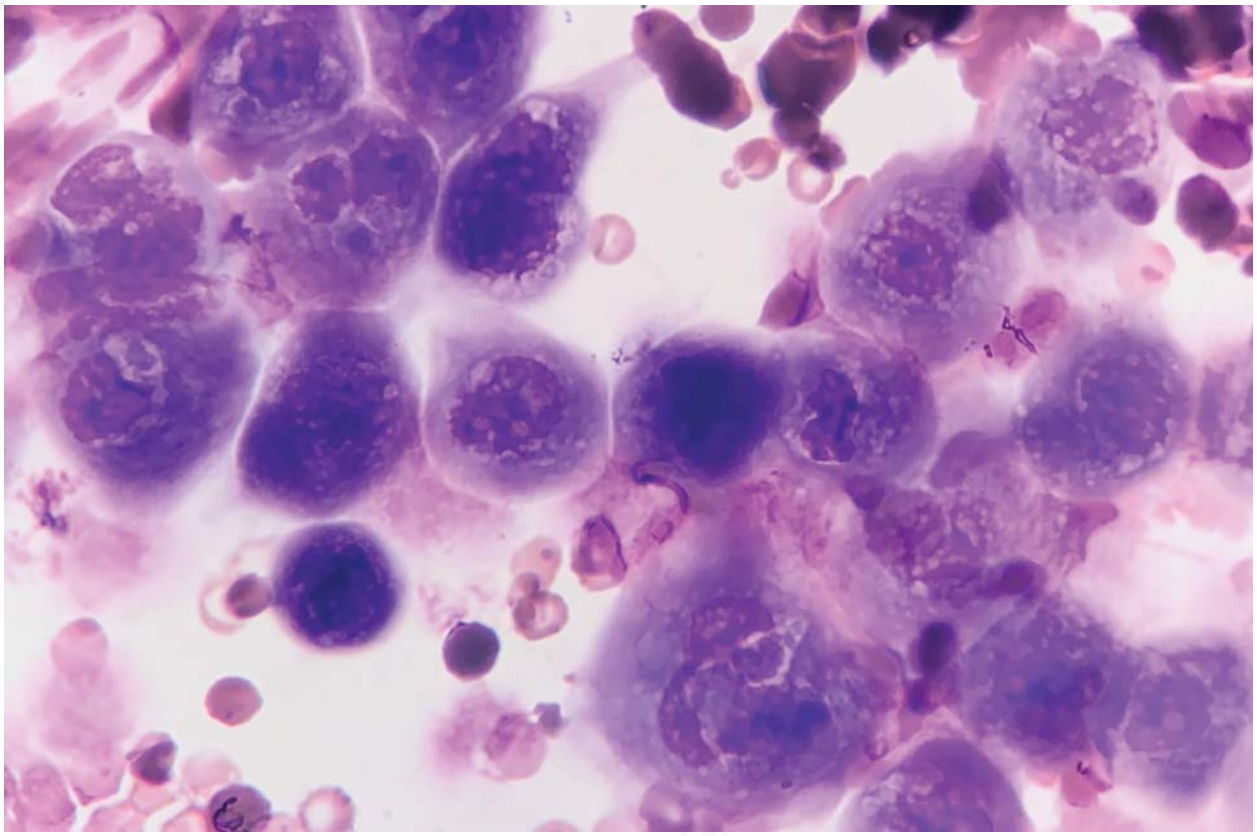

Figure 4 Fine needle aspirate of the digital mass. (Wright's stain 100X objective). Image courtesy of Dr. Pedro Bittencourt

Anisocytosis and anisokaryosis are moderate and multinucleate forms are present.

Interpretation of the atypical epithelial cells is difficult when concurrent inflammation is present as this could represent either a dysplastic or neoplastic change. The most likely diagnosis is a squamous cell carcinoma based on the criteria of malignancy present within the atypical epithelial cells and the perinuclear vacuoles, a common feature of SCC. Furthermore, suppurative inflammation is a common cytological feature of SCC and is likely a reaction to the keratin. Other conditions to consider include papilloma and much less likely, a non-neoplastic lesion such as an epithelial inclusion cyst. Ultimately, it was advised that this toe be amputated and submitted for histopathological analysis.

Histopathology

Extending from the surface epithelium and expanding the dermis, is an unencapsulated, infiltrative, moderately circumscribed neoplasm composed of inward papillary projections of epithelium supported by a thin fibrovascular stroma. Basal cells differentiate into hyperplastic, polygonal cells with distinct borders, abundant basophilic cytoplasm and a round to oval nucleus with stippled chromatin. Occasionally cells in the stratum spinosum have pale cytoplasm with eccentric nuclei (koilocytes). Neoplastic cells contain eosinophilic intranuclear inclusions (Figure 6, arrows) that measure up to 10 μm in diameter and commonly peripheralize the nucleus. The epidermis is multifocally ulcerated and contains varying combinations of neutrophils, cellular debris and mixed bacterial flora.

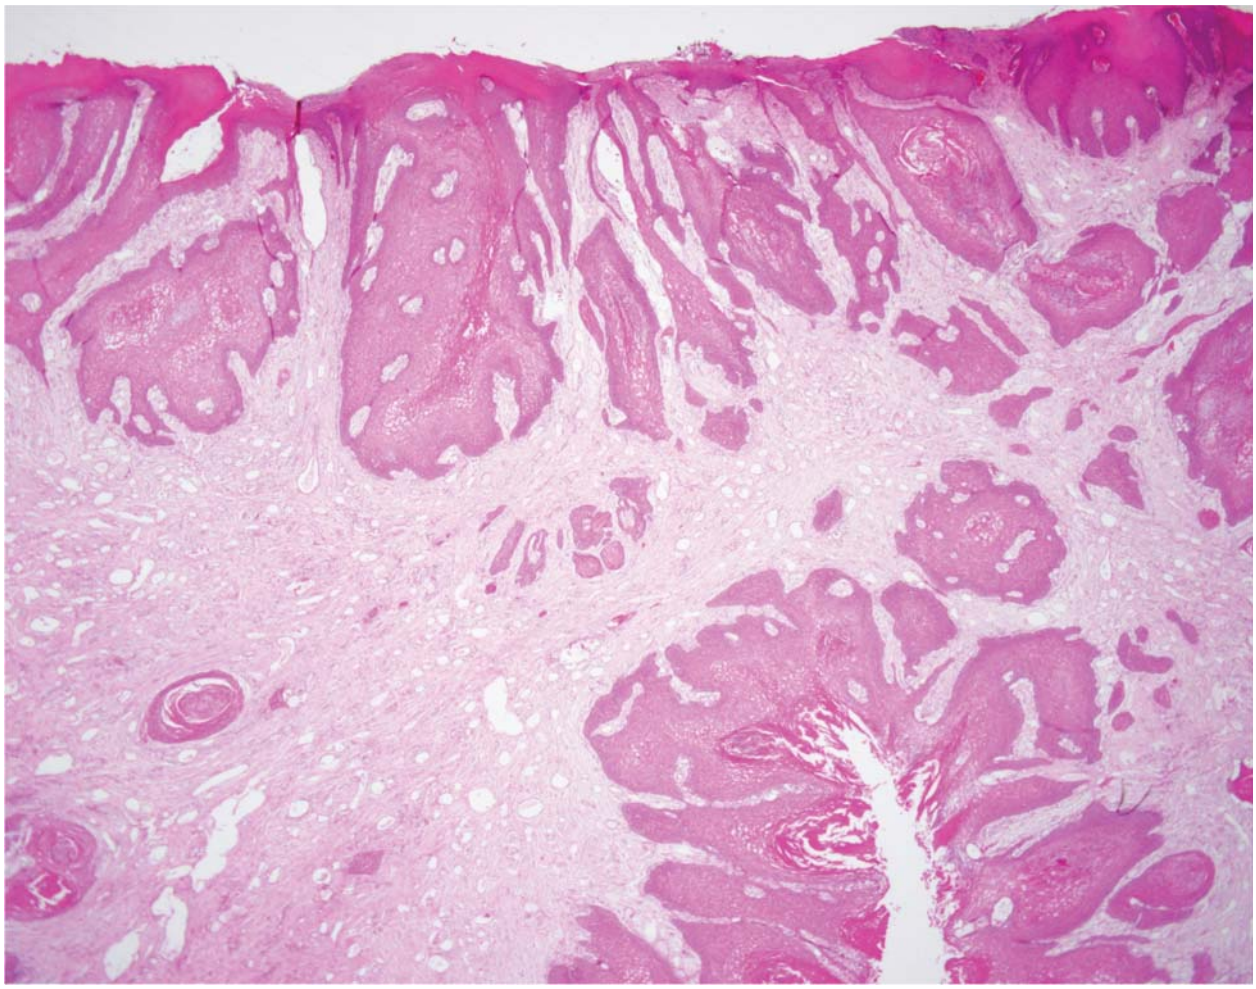

Figure 5 Histopathology of the digital mass. (H&E)

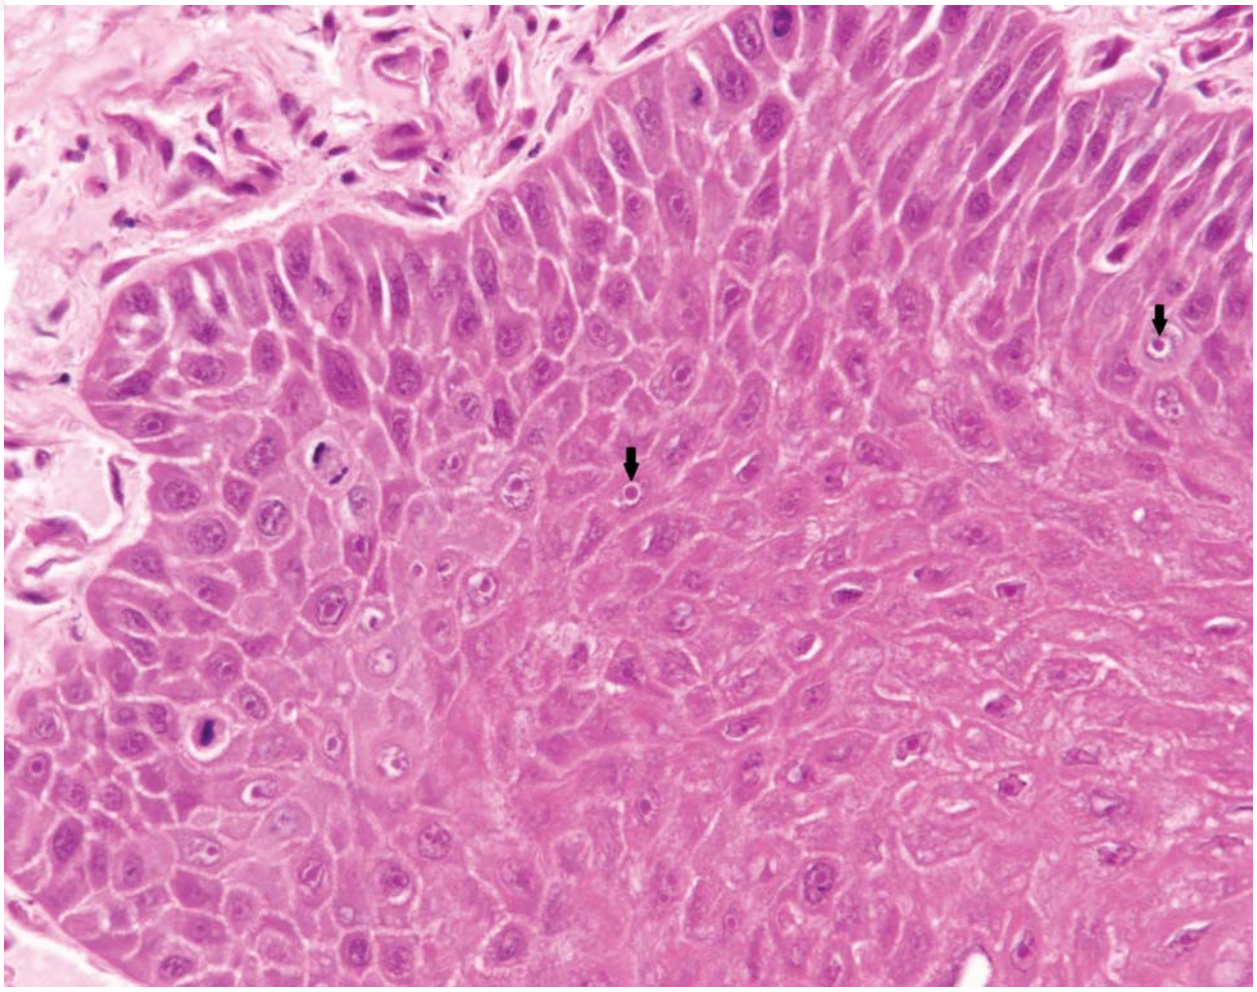

Figure 6 Histopathology of the digital mass. (H&E)

Summary and Outcome

Despite cytological findings, this neoplasm was ultimately diagnosed as an inverted canine viral papilloma. While most papillomas in dogs are exophytic (outwards growing), these neoplasms can occasionally grow inwards leading to inflammatory reactions secondary to exposure of the dermis to keratin. Subsequent inflammation and tissue reaction can lead to bone lysis and remodeling.

Case 117

Signalment: 24-year-old gelding horse
History: Chronic history of inappetence and pyrexia of unknown origin.

Hematology		Reference interval
Packed cell volume (%)	34	32–48
MCV (fL)	52	37–59
MCHC(g/dL)	31.6	31–39
Nucleated cells ($\times 10^3/\mu L$)	8.66	5.4–14.30
Segmented neutrophils ($\times 10^3/\mu L$)	**7.4**	3.0–6.0
Band neutrophils ($\times 10^3/\mu L$)	0	0–0.1
Lymphocytes ($\times 10^3/\mu L$)	**0.9**	1.5–5.0
Eosinophils ($\times 10^3/\mu L$)	0.3	0–1.5
Nucleated RBCs ($\times 10^3/\mu L$)	0.1	0
Platelets ($\times 10^3/\mu L$)	109	100–400
Plasma protein (g/dL)	7.7	6.0–8.5
Fibrinogen (g/dL)	**1.1**	0.1–0.4

Hemopathology: Rare reactive lymphocyte and moderately toxic neutrophils with Dohle bodies and cytoplasmic basophilia.
Imaging: Thoracic ultrasound revealed a bilaterally nodular appearance to the lung.
Cytology: A fine needle aspirate of one of the lung-nodules was submitted for evaluation.

Interpretive discussion

Hematology

While only mild, the neutrophilia in combination with toxic change and hyperfibrinogenemia is indicative of active inflammation. The lymphopenia is an indication of a concurrent stress (cortisol) response.

Cytology

The cytological preparation consists of a mixed inflammatory population. Activated macrophages and neutrophils predominate. Occasional bi-nucleated macrophages (Figure 1 arrowhead) are present as are low number of plasma cells (Figure 1 arrow). Figure 2 demonstrates normal ciliated columnar respiratory epithelium amidst macrophages and neutrophils. This submission was interpreted as pyogranulomatous inflammation.

Outcome

The horse was started on broad spectrum antibiotics and treated concurrently with nonsteroidal anti-inflammatories but failed to improve. Humane euthanasia was elected, and the animal was subsequently submitted to the necropsy service.

Gross and histopathology

Histologically, most of the pulmonary parenchyma is effaced by multifocal to coalescing nodules composed of proliferating

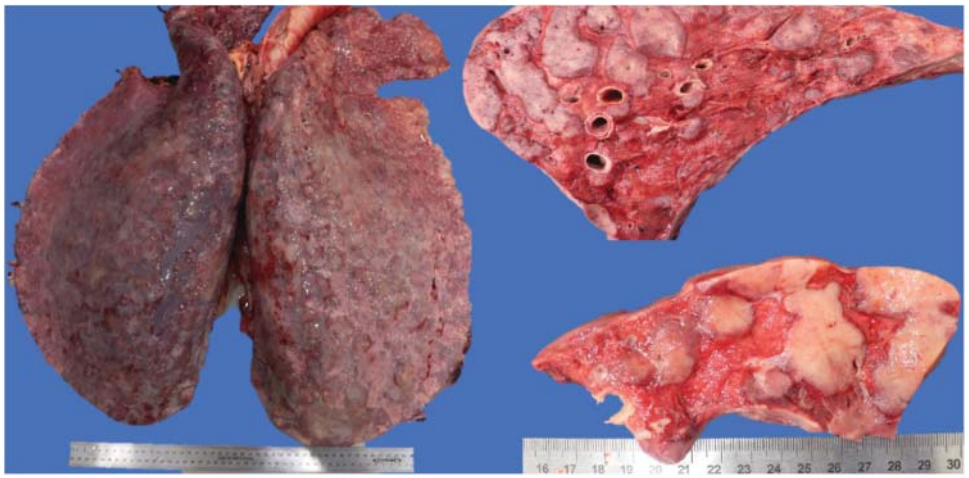

Figure 3 At the time of necropsy, the lungs were bilaterally enlarged and expanded by nodular, proliferative, and coalescing areas (from a few mm to more than 10 mm) that were hard in consistency and white to gray-tan. Tracheobronchial lymph nodes were mildly enlarged. Within the cortex of the left kidney was a white-gray multinodular area of similar appearance to the lung nodules.

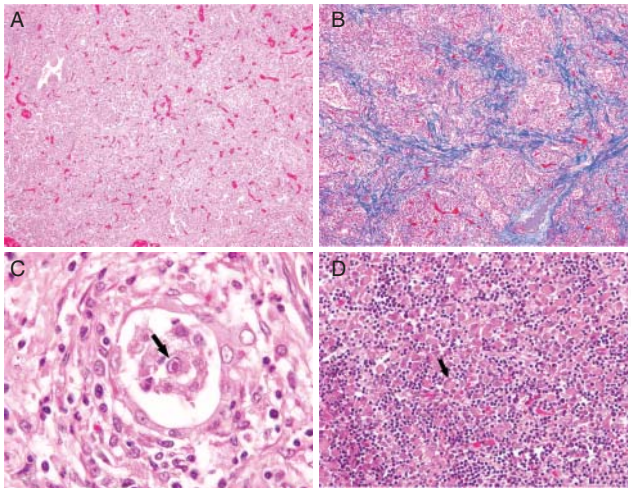

Figure 4 Histological sections of the lung (A–C) and tracheobronchial lymph node (D).

spindle cells (fibroblasts) (Figure 4A) embedded within a fibrillar eosinophilic (collagenous) stroma (stains blue on Masson's trichrome stain) (Figure 4B), and infiltrated by large numbers of lymphocytes and histiocytes, with fewer neutrophils. Occasionally, alveolar macrophages contained 3–4 μm diameter eosinophilic intranuclear inclusion bodies that peripheralized the chromatin (Cowdry Type A inclusions) (arrow in Figure 4C). The lymph node is expanded by an infiltrate of macrophages/histiocytes, some of which are multinucleated (arrow in Figure 4D).

Summary

Signalment, history, cytological and histological findings are consistent with a diagnosis of Equine multinodular fibrosis (EMPF). EMPF is a progressive fibrosing, interstitial lung condition associated with infection with Equine herpesvirus 5 (EHV-5). Grossly, this disease presents as multiple nodules of fibrosis within the lungs (Figure 3). Histologically, there is marked interstitial pulmonary fibrosis with airways containing neutrophils and macrophages. Occasionally in both cytological and histological specimens, macrophages may contain large eosinophilic intranuclear viral inclusion bodies.

overview of, 405–407
in reptiles, 620
sodium for correction of, 406
cholestasis
alkaline phosphatase (ALP) and, 430–433
gamma glutamyltransferase (GGT), 433–434
of liver, 733, 733f
overview of, 430, 512
cholesterol, 379
in birds, 611
in the blood, 505
in fish, 630
hypercholesterolemia, 511
hypocholesterolemia, 514
overview of, 440
renal function and, 360
structure of, 504f
chromogenic agars, for bacterial infections, 68
chronic basophilic leukemia, 193–194
chronic (from deficiency anemia) blood loss, 111–112
chronic gastritis, 482
chronic granulocytic (myelogenous) leukemia (CML), 192–193, 192f–193f
chronic granulomatous enteritis (Johne's disease), from bacterial infections, 79
chronic kidney disease (CKD), 381–382, 382t, 390
chronic lymphocyte leukemia (CLL), 196–197, 196f
chronic mycosis, from fungal infections, 81
chronic myeloproliferative neoplasms
about, 192
chronic basophilic leukemia, 193–194
chronic granulocytic (myelogenous) leukemia, 192–193, 192f–193f
eosinophilic leukemia, 193, 193f
essential thrombocythemia, 194
chronic progressive familial nephropathy (renal dysplasi), 391
chronic pyoderma, 494
chronic renal disease, anemia of, 109
chronic vomition, 482
chronic weight loss, 482
chylous effusions, 705t, 710, 711f
Circoviridae, 82
CKIT mutation, testing for in mast cell tumors, 164–165, 164f
classical swine fever, from viral infections, 82
classifications
of anemia
about, 100
bone marrow response, 101–103
erythrocyte size, 100–101, 102f–103f
hemoglobin concentration, 100–101, 102f–103f
pathophysiologic, 103
of body cavity effusions
about, 704t, 707
bile peritonitis, 705t, 709–710, 710f
carcinoma, 712–713, 714f–715f
chylous effusions, 705t, 710, 711f
exudates, 707–708, 708f
feline infectious peritonitis (FIP), 705t, 710, 710f
hemorrhagic effusions, 711–712, 712f, 714t
lymphoma, 712, 713f–714f
mast cell tumor, 712, 714f
mesothelioma and reactive mesothelial cells, 713–716, 715f–716f
neoplastic effusions, 712
sarcomas, 716
septic exudates, 708–709, 708f–709f
transudates, 707
uroperitoneum, 705t, 711, 711f

  for bone marrow aspirates, 36
Ehrlichia canis, 107, 758–759
Ehrlichia spp., 178–179
ehrlichiosis, 159
electrochemical techniques, 24
electrolytes
  abnormalities of, 457
  anion gap
    figure of, 410f
    overview of, 409, 409f
  in birds, 605–609
  calcium
    fractions of, 411f
    hypercalcemia, 411–413
    hypocalcemia, 413–414
    idiopathic hypercalcemia, 412
    overview of, 409–414
    pregnancy and, 413
  chloride
    hyperchloremia, 406–407, 407f
    hypobicarbonatemia, 406
    hypochloremia, 407, 407f
    iatrogenic hypochloremia, 407
    sodium for concentration correction of, 406
  laboratory abnormalities of, 479
  laboratory evaluation of reptiles, 620–621
  magnesium
    hypermagnesemia, 416
    hypomagnesemia, 413, 415–416
    overview of, 409–410, 415–416
  osmolality, 403
  phosphorus
    hyperphosphatemia, 413, 414–415
    hyperphosphatemia *versus* hypophosphatemia, 414–415
    hypophosphatemia, 415
    overview of, 409–410, 414–415
  potassium
    hyperkalemia, 407–408, 408f
    hypokalemia, 408–409, 408f
    overview of, 407–409
    pseudohyperkalemia, 408
  in rabbits, 596
  renal function and abnormalities of, 354–355
  sodium
    dehydration, 404
    hypernatremia, 403–404
    hyponatremia, 404–405
    renin-angiotensin-aldosterone system (RAAS), 403
    sodium potassium ratio, 406
electron microscopy, for diagnosing viral infections, 71–72, 71f, 82, 83
electrophoretogram, example of, 486f
elephants, viral infections in, 83
ellipticytes, 92, 93f
Embden-Meyerhof (EM) pathway, 132
encephalitis, from viral infections, 83
encephalomyelitis, from viral infections, 83
encephalomyocarditis, from viral infections, 83
endocrine disorders
  anemia associated with, 109
  clinical case presentations on, 778–779, 960–998
endocrine tumors, 658–659, 739
endocrinology, clinical
  adrenal gland
    background of, 531
    hyperadrenocorticism (HAC) (Cushing's syndrome), 530–531, 539–552
    hypoadrenocorticism (Addison's disease), 405, 530, 531–539
    pheochromocytoma, 552
    primary hyperaldosteronism (Conn's syndrome), 539
  diabetes insipidus, 555–558
  introduction to, 515–516
  laboratory evaluation
    of birds, 615–616
    of ferrets, 599–600
    of fish, 631
    of rabbits, 598
    of reptiles, 624
    of rodents, 595–596
  pituitary gland
    acromegaly (hypersomatotropism), 558–560
    disorders of, 552–555
    equine metabolic syndrome (EMS), 555
    pituitary dwarfism, 558–560
    pituitary pars intermedia dysfunction (PPID), 552–555
  thyroid
    hyperthyroidism, 514, 519–523
    hypothyroidism, 509–510, 516, 518, 519, 523–530
    overview of disorders, 516
  thyroid tests
    autoantibodies, 518
    fT4, 516–517, 520–521, 521–523, 525–526
    overview of, 517t
    rT3 reverse trilodothyronine, 517
    stimulation tests, 518–519
    T3 suppression, 521–523
    thyroid-stimulating hormone response test (TSH response), 522
    thyrotropin, thyroid-stimulating hormone (TSH), 517–518
    thyrotropin releasing hormone response test (TRH response), 522
    TRH response, 518–519
    TSH response, 518–519
    TT3 trilodothyronine, 517
    TT4, 516, 520–521, 525–526
endogenous ACTH (eACTH), for hyperadrenocorticism (HAC) (Cushing's syndrome), 546–548, 548t
endogenous immunoglobulins, 63
endothelium, 207
endotoxemia, 512
endpoint, as a factor influencing immunoassay design, 62
enteric disease
  from bacterial infections, 79, 80
  from bacterial pathogens, 78
enteritic disease, 482
Enterobacter, 76
Enterococcus, 76
enterocytes, 506
enterotoxemia, from bacterial pathogens, 78
environment, as a factor influencing immunoassay design, 62–63
enzootic bovine leukosis, 197
enzyme immunoassays (EIAs), 61
enzyme-linked immunosorbent assay (ELISA)
  for antibody detection, 72
  for diagnosing viral infections, 82
  for viral infections, 72
enzymes/enzymology
  half-life, 427
  hepatic leakage, 479
  overview of, 425–430
  sample handling of, 428
  tissues and, 427–428
  in urinalysis, 381, 381f
eosinophilia, 160
eosinophilic granuloma, 702, 702f
eosinophilic infiltrates, 481
eosinophilic leukemia, 193, 193f
eosinophils
  about, 141–142, 142f
  in amphibians, 336–337, 337t
  for birds, 274–277, 275t
  in body cavity effusions, 706–707, 706f–707f
  in bony fish, 321, 321f, 323f
  in fish, 323–326, 324t
  inflammation and, 637–638, 638f
  in lymph nodes, 756, 757f
  in reptiles, 304–308, 305t–306t
  screening tests for, 469
epidermal inclusion cyst (follicular cyst), 699–700, 701f
epinephrine release (excitement response), 156
epithelial cell tumors
  about, 181, 657
  apocrine gland adenocarcinoma (AGAC) of anal sacs, 688–690, 689f
  apocrine sweat gland tumors, 690
  basal cell neoplasm, 685, 686f
  mammary gland tumors, 690
  neoplasia and, 674
  perianal/circumanal gland tumors, 688, 688f
  sebaceous cell adenoma, 685–686, 686f
  sebaceous cell carcinoma, 686–687
  squamous cell carcinoma (SCC), 687–688, 687f
  thyroid tumors, 690–691
epithelial cells
  screening tests for, 468
  in urinalysis, 375–376
epitope, 58
epizootic hemorrhagic disease, from viral infections, 83
equilibrium dialysis (ED), 517
equine arteritis virus (EAV) infection, from viral infections, 82
equine infectious anemia (EIA), 107, 131
equine metabolic syndrome (EMS), 555

error, common factors that introduce, 52–53, 53f
Erysipelothrix rhusiopathiae, 75
erythrocyte histogram, 11–12, 11f
erythrocyte parasites, blood destruction and, 119–130
erythrocytes
about, 87–88, 88f, 88t
anemia and size of, 100–101, 102f–103f
arrangement on blood films
agglutination, 98, 98f
erythroid dysplasia and neoplasia, 99
Rouleaux formation, 97–98, 98f
in body cavity effusions, 707
color
hypochromasia, 88–89, 89f
polychomasia, 88, 89f
concentration of, 10–11
function of, 87
laboratory evaluation, 261–262, 262f, 262t, 297–300, 299t, 317–318, 317t, 332–333
morphology, 258–261, 259f–261f, 259t, 296–297, 296f–298f, 315–317, 316f–317f, 331–332, 332f–333f, 332t
normal erythrocyte physiology, 262–264, 263t
production of, 87
responses in disease, 264–266, 264f, 298f, 300–301, 300f–301f, 318–319, 332t, 333, 333f
shape
about, 90–91
acanthocytes, 91–92, 92f
eccentrocytes, 93, 94f
echinocytes, 92, 92f
ellipticytes, 92, 93f
leptocytes and codocytes, 93–94, 94f
schistocytes and keratocytes, 91, 91f
spherocytes, 92–93, 93f
stomatocytes, 94, 94f
size
about, 89
macrocytic erythcroctes, 90
microcytic erythrocytes, 89–90, 89f
structures in/on
basophilic stippling, 95, 95f
Heinz bodies, 94–95, 95f
Howell-Jolly bodies, 95f, 96
nucleated erythrocytes, 95, 95f
parasites, 96–97, 96f–97f
siderotic granules, 96, 96f
viral inclusions, 97, 98f
erythrocytosis
about, 135
absolute
primary, 136–137
secondary, 136
clinical findings, 137
diagnostic approach, 137–138, 137t
relative
caused by fluid shifts or dehydration, 135
caused by transient increase in red cell mass secondary to splenic contraction, 136
therapy, 138
erythroid
renal function and, 360
series of cells in bone marrow films, 170–171, 170f
erythroid dysplasia and neoplasia, 99
erythroleukemia (M6), 189–190, 191f
erythropietin, 87
erythropoiesis, 87, 287
erythropoietin receptor (EPOR), 135
Escherichia coli, 68, 79
essential thrombocythemia, 194
estrogen
stem cell injury from, 106
toxicity of for dogs, 159
estrogen toxicosis, 107, 179
ethylene glycol intoxication, 382–383
ethylene glycol toxicity, 575
ethylene-diaminetetraacetic acid (EDTA) salt, 30, 32, 227, 228, 229
European Committee on Antimicrobial Susceptibility Testing (EUCAST), 70
excitement response (epinephrine release), 156, 156f
exocrine pancreas, laboratory evaluation of birds, 614
exocrine pancreatic insufficiency (EPI)
decreased serum vitamin B_{12} (cobalamin) and, 474
defined, 458
laboratory abnormalities of, 480
overview of, 458–460
exotic pets
blood groups in, 221t, 222
crossmatching in, 228
donor selection for, 224
expected urine specific gravity, 389
external laboratory services, considerations for, 45
extramedullary hematopoiesis
of liver, 736, 736f–737f
of spleen, 742
extramedullary plasmacytoma, 494
extravascular hemolysis, 103
extrinsic pathways, 206
exudates, body cavity effusions and, 707–708, 708f
eye fluids, as a clinical sample, 68t
eye infections, from fungal infections, 81

false-negative results, with PCR tests, 73
false-positive results, with PCR tests, 73
familial primary erythocytosis, 136
Fanconi syndrome, 385, 415
fasting bile acid samples, 438
fatty acids, in the blood, 503
febrile illness
from bacterial infections, 79
from viral infections, 83
fecal antigen detection methods, as screening test, 477t
fecal assessment test, overview of, 462
fecal collection methods, 462–463
fecal cytology, as screening test, 467–469, 470
fecal elastase 1, as screening test, 473
fecal ELISA for bacterial enterotoxins, as screening test, 477t
fecal floatation, for diagnosing parasitic infections, 84
fecal occult blood, screening test for, 471–472
fecal PCR (bacterial or fungal culture), as screening test, 477t
fecal α_1-proteinase inhibitor concentration (α_1-PI), screening test for, 473
feces
as a clinical sample, 68t
as a clinical sample for detection of parasitic infections, 72–73
as a clinical sample for gastrointestinal infections, 76
feline calcivirus, from viral infections, 82
feline cytauxzoonosis (bobcat fever), 125–126, 126f
feline immunodeficiency virus (FIV), 83, 90, 759
feline infectious peritonitis (FIP), 705t, 710, 710f
feline infectious peritonitis virus (FIPV), 82
feline injection site sarcoma, 670t
feline leukemia virus (FeLV), 83, 90, 107–108
feline respiratory disease, from viral infections, 82
ferrets *(Mustela putotius)*
bone marrow disorders in, 175
drugs causing stem cell damage in, 106
endocrine disorder laboratory evaluation of, 599–600
features of, 248–250, 249f
glucose metabolism laboratory evaluation of, 599
hyperadrenocorticism (HAC) (Cushing's syndrome) in, 551–552
kidney laboratory evaluation of, 598–599
liver laboratory evaluation of, 599
lymphoma in, 772
muscle injury laboratory detection of, 599
plasma biochemical value in, 592t
protein laboratory evaluation of, 599
fetal serum, for diagnosing urogenital tract infections, 76
fibrin, 202
fibrindegradation products (FDPs), 202
fibrinogen, 202–204, 204f, 360
fibrinogen concentration, 488, 496–497

White sturgeon, 320
thrombocytes and hemostasis
about, 326
laboratory evaluation, 327
morphology, 317f, 322f–325f, 326–327, 327f–328f
responses in disease, 327
viral inclusions, 328–329
Flaviviridae, 82
flow cytometry
about, 165
cell surface antigens, 165
clinical applications of, 166, 167f
principles of, 166, 166f
fluid analysis, body cavity effusions, 703–704, 704f, 704t–705t
fluid and electrolyte and acid-base disturbances, clinical case presentations on, 778, 805–806, 826, 844–848, 855–858, 861–866, 872–878, 873–876, 889–890, 900–903, 921–924, 926–931, 936–939, 950–959, 963–970, 987–992
fluid shifts, relative erythrocytosis caused by, 135
fluid therapy
for treating anemia, 118
for treating erythrocytosis, 138
fluorescer, immunoassays and, 61
fluorometry, 21–23, 22f
foal pneumonia, from bacterial infections, 80
focal lesions, of the liver, 441
folate, 108, 473, 474–475
follicular lymphoma, 770
food poisoning, from bacterial pathogens, 77
foot and mouth disease virus (FMDV), from viral infections, 83
foot rot, from bacterial infections, 79
formed elements in urine, 391
forward light scatter, 166
fowl cholera, from bacterial infections, 80
fractional excretion of electrolytes, in urinalysis, 380
Francisella tularensis, 79, 761
free nuclei, in lymph nodes, 755f, 757–758
fructosamine, 454–455
fT4 test, for thyroid, 516–517, 520–521, 521–523, 525–526
full-thickness biopsy, for skin and soft-tissue infections, 75
fungal antigen detection, for fungal infections, 70
fungal culture, for diagnosing fungal infections, 81
fungal infections, 69–70
Fungal lymphadenitis, 763–765
fungi
as infectious agent, 642–647
screening tests for, 464t
Fusobacterium spp., 69t, 79

gall bladder, 741, 741f
Gallotia lizards, 305
gamma carboxylation, 207
gamma globulins, 58
gamma glutamyltransferase (GGT)
about, 381
in birds, 610
increased serum activities of, 426–427
overview of, 433–434
gammopathy
conditions associated with, 493–494
electrophoretogram example of, 492f–493f
gastric disease
from bacterial infections, 79
marker screening test for, 476
gastric ulceration, in horses, 471–472
gastritis, acute, 482
gastritis, chronic, 482
gastroenteritis
from bacterial infections, 80
from parasitic infections, 84
from viral infections, 82
gastrointestinal (GI) disease
acid-base abnormalities, 479
acute enteritis, 482
acute gastritis, 482
antibiotic responsive diarrhea (ARD)/enteropathy, 480
chronic diarrhea, 480–481
chronic gastritis, 482
chronic vomition, 482
chronic weight loss, 482
coagulation defects abnormalities, 479
colitis, 482–483
dehydration, 478–479
in dogs, 480
electrolyte abnormalities, 479
eosinophilic infiltrates, 481
examples of, 459t–460t
exocrine pancreatic insufficiency (EPI), 458–460
gastric ulceration in horses, 471–472
granulomatous enteropathies, 481
hemoconcentration, 478–479
hepatic leakage enzyme activity increase, 479
hypocholesterolemia abnormalities, 479
idiopathic pancreatic actnar atrophy, 460
infectious disease, 481
inflammatory bowel disease, 481
intestinal neoplasia, 483
introduction to, 458
juvenile pancreatic acinar atrophy, 460
laboratory abnormalizes of, 478–480
leukogram, 479
lymphangiectasia, 481–482
lymphoplasmacytic enteropathies, 481
malabsorption, 458–461
malabsorption syndrome abnormalities, 480
maldigestion, 458–460
pancreatic duct obstruction, 460
panhypoproteinemia abnormalities, 479
protein losing enteropathy (PLE), 460–461
screening tests for
absorption test, 476–477
in birds, 469–470
brush cytology, 470
canine microbiota dysbiosis index, 475–476
cytology of biopsy samples, 470
digestion/absorption, 472
fecal antigen detection methods, 477t
fecal assessment, 462
fecal collection methods, 462–463
fecal cytology, 467–469, 470
fecal elastase 1, 473
fecal ELISA for bacterial enterotoxins, 477t
fecal floatation and sedimentation, 463–467
fecal occult blood, 471–472
fecal PCR (bacterial or fungal culture), 477t

gastrointestinal (GI) disease (*continued*)
fecal α_1-proteinase inhibitor concentration (α_1-PI), 473
folate concentration, 473
in horses, 470
hydrogen breath test, 477t
intestinal biopsy, 477t
maldigestion, 478
markers for gastric disease, 476
methylmalonic acid (MMA), 475
oral D-xylose absorption test, 477
oral glucose absorption/tolerance test (OGTT), 477–478
oral lactose tolerance test, 478
ruminal fluid evaluation, 476
serum folate, 474–475
serum gastrin, 477t
serum pepsinogen, 477t
serum trypsin-like immunoreactivity (TLI), 472–473
serum vitamin B_{12} (cobalamin), 473, 475
starch digestion, 478
wet preparations, 463
serum amylase and lipase abnormalities, 479
from viral infections, 82
gastrointestinal infections, 75–76, 81
gastrointestinal parasitism, hypoalbuminemia and, 490
genotypic analysis, for bacterial infections, 68
gerbils, 238, 242, 246
Giemsa stains, 39, 67, 74
globulins
concentration measurement of, 485–488
hypoglobulinemia, 488–489, 489f, 490, 491–495
immunoglobulin concentration estimation, 486–488
overview of, 440, 484
glomerular disease, hypoalbuminemia and, 490
glomerular filtration rate (GFR), 389, 409
glomerular proteinuria, in urinalysis, 370–371
glossary, for urinary system, 389
glucagon, 450, 505t
glucocorticoid-deficient hypoadrenocorticism, 532
glucocorticoids, 118, 119, 450, 505t
glucose
clinical biochemistry procedures and, 33
in fish, 630
overview of, 440
in urinalysis, 372–373
glucose absorption, screening tests for, 476–477
glucose metabolism
curves of, 455f
hormones and, 449–450, 449t
laboratory evaluation
about, 453–456
of birds, 613–614
of ferrets, 599
of rabbits, 598
of reptiles, 623–624
of rodents, 594–595
monitoring of, 455–456
overview of, 449–453
glucose-6-phosphate dehydrogenase deficiency, 132–133
glutamate dehydrogenase (GLDH)
in birds, 609
hepatocyte injury and, 428, 430
glutaraldehyde coagulation test, 487–488, 496
glutathione S-transferase (GST), 128
glycated hemoglobin (GHb), 455

lymphoma in, 772
therileriosis in, 125
Goldfish, 319
Gomori tissue trichrome-Wheatley modification, 73
Gram staining, 67–68, 67f, 74, 76
granular casts, 378
granule contents, 205
granulocyte (myeloid) series, of cells in bone marrow films, 171–172, 171f
granulocytes, production of, 144–145, 145f
granulocytes of elasmobranchs (sharks and rays), 321, 322f–323f, 325f, 327f
granulomatous diseases, hypercalcemia and, 584
granulomatous enteropathies, 481
granulomatous inflammation, from bacterial infections, 79
granulopoiesis, 288–289
grass tetany, 415
gray-top or fluoride tube, 32
greasy pig disease, 75
green-top or heparin tube, 31
griseofulvin, stem cell injury from, 106
growth factors, neutrophils and, 146, 146f
guinea pigs *(Cavia porcellus)*, 244–246, 245f–246f

haemoplasmas of ruminants, 120–121, 121f
Haemoproteus, 281–282, 281f–282f
hamsters, 238, 242, 243, 246
hapten, 58
Hb
in amphibians, 332–333, 332t
for fish, 317–319, 317t
for reptiles, 297–300, 299t
HCO_2, technical considerations of, 418
HCO_3^-, evaluation of, 420
heart
for blood collection from fish, 315
for blood collection in amphibians, 330
heartwork antigen tests, 61
heavy metal poisoning, in birds, 265
hedgehogs
biochemical evaluation of, 600
plasma biochemical value in, 592t
Heinz bodies, 94–95, 95f
Heinz-body anemia, 93, 94f, 101, 126–127, 126f–127f
Helicobacter spp., 76, 79
hemagglutination inhibition (HI) assay
for antibody detection, 72
for diagnosing viral infections, 83
hemangioma, 696, 744, 744f
hemangiosarcoma, 91–92, 92f, 696, 744, 744f
hemarthrosis, synovial fluid and, 728–729, 729f
hematocrit, 12
hematologic malignancies
about, 161
case examples, 168–169, 168e–169e
clonality testing
clonal *versus* polyclonal lymphocyte expansion, 162
generation of antigen receptors in lymphocytes, 161–162, 162f
interpretation and uses of PARR assay, 163–164
lymphocytes with unique DNA sequences, 161
molecular biology of PARR assay, 162–163, 163f
detection of genetic alterations in cancer cells
principles, 164
testing for *CKIT* mutation in mast cell tumors, 164–165, 164f
flow cytometry
about, 165
cell surface antigens, 165
clinical applications of, 166, 167f
principles of, 166, 166f
high-throughput sequencing in diagnostics, 165
immunocytochemistry, 166–167, 166f–167f
hematologic response to inflammation, 153–156, 154f–155f, 155t
hematologic techniques
about, 3, 32–33
blood mixing, 3, 3f, 4f
determination of total leukocyte concentration, 6–7
items determined by cell (particle) counting and sizing
about, 9, 10, 11f
erythrocyte concentration, 10–11
erythrocyte histogram, 11–12, 11f
hematocrit, 12
mean cell volume, 11–12, 11f
platelet concentration, 12
red cell distribution width, 11–12, 11f
white blood cell and differential leukocyte concentration, 12
items determined by spectrophotometry or calculation
about, 9
hemoglobin concentration, 9
mean cell hemoglobin, 9
mean cell hemoglobin concentration, 9–10
laboratory tests for diagnosis of immune-mediated hemolytic anemia
Coombs or antiglobulin test, 15
saline fragility test, 15–16, 16f
microscopic differential count and assessment of 8f, 8e, morphology, 8–9

organization of complete blood count (hemogram), 14–15
packed cell volume, 3–5, 4f–6f
plasma proteins by refractometry, 5–6, 6f–7f
reticulocyte concentration, 12–14, 13f–15f
summary of blood analysis by automated/semiautomated instrumentation, 12, 13f
hematology
blood films, 32f, 34
clinical case presentations on, 777, 780–823
hematoma and seroma, 699, 700f
hematopoiesis
about, 311–313, 339
for amphibians, 339
band cells and mature granulocytes, 289
bone marrow, 285–286, 285f
erythropoiesis, 287
examination of bone marrow, 286–287
for fish, 329
granulopoiesis, 288–289
lymphocytes, 290
macrophages, 290
metamyelocytes, 288f, 289
monocytes, 290
myeloblasts, 288f, 289, 289f
myelocytes, 288f, 289, 289f
osteoblasts, 290
osteoclasts, 290, 290f
polychromatophilic erythrocytes and mature erythrocytes, 288
progranulocytes, 288f, 289
prorubricyte, 288, 288f, 289f
for reptiles, 311–313
rubriblasts, 287, 287f–288f
rubricyte, 287f–288f, 288
thrombocytes, 280f, 289–290
hematopoietic neoplasia, 514
hematuria, 363–365, 364t
hemoconcentration, laboratory abnormalities of, 478–479
hemoglobin (HgB)
for birds, 262–264, 263t
measurement of, 424
hemoglobin casts, 378
hemoglobin concentration, 9, 100–101, 102f–103f
hemoglobinopathies, 91
hemoglobinuria, 363–365, 364t
hemogram, 34
Hemogregarina, 327
hemogregarines, 309–310, 309f
hemolysis
as an interfering substance in samples, 53
hypophosphatemia-induced, 130
needle size and, 32
water intoxication-induced, 131
hemolytic anemia
in dogs, 93, 93f
from parasitic infections, 84
hemolytic crossmatch test, 231–232
Hemoproteus, 311
hemorrhage/diapedesis secondary to DJD/inflammation, synovial fluid and, 730
hemorrhagic disease, from viral infections, 82
hemorrhagic effusions, 711–712, 712f, 714t
hemorrhagic or hemodilute samples, synovial fluid and, 728
hemorrhagic septicemia, from bacterial infections, 80
hemosiderosis and siderotic nodules, of spleen, 742
hemostasis
about, 201, 326
blood parasites, 309
clinical approach to bleeding patients
about, 208
hemostatic defect *vs.* trauma-/disease-induced hemorrhage, 208
primary *vs.* secondary hemostatic defects, 208
signs associated with defects in primary hemostasis, 208–209
signs associated with defects of secondary hemostasis, 209
coagulation *vs.,* 206
common hemostatic diseases
about, 213
affecting primary hemostasis, 213–215
affecting secondary hemostasis, 216–219

sample collection and shipping, 66
transportation of biological samples, 66
for viral infections
about, 70
antibody detection, 72
direct fluorescent antibody testing, 71
electron microscopy, 71–72, 71f
ELISAs, 72
rapid point-of-care tests, 70–71
virus isolation, 72
virus neutralization, 72
infectious from immune-mediated arthropathies, general considerations in differentiating, 728
infectious lymphadenitis, lymph nodes and, 760–766, 761f, 763f–765f
infectious organisms, screening tests for, 469
infectious tracheobronchitis, from bacterial pathogens, 78
inflammation
adrenal gland (adrenalitis), 748
anemia of, 108–109
hyperfibrinogenemia and, 495
hyperlipidemia and, 512
inflammatory cell types
eosinophils, 637–638, 638f
lymphocytes, 636–637
macrophages, 635–636
mast cells, 637–638, 638f, 639f
neutrophils, 635
plasma cells, 636–637
of intestine, 749, 749f–750f
of kidney, 745–746
of liver, 733–734, 734f–735f
pyogranulomatous, 637f
septic, suppurative, 636f, 639f, 640f, 641f
of spleen (splenitis), 742
suppurative, 636f
types of, 636t
vaccine reaction example, 638f
inflammatory (suppurative) arthropathies, synovial fluid and, 722–723
inflammatory bowel disease, 481
influenza, from viral infections, 82
inherited abnormalities or morphology
about, 151
Birman cat neutrophil granulation anomaly, 151–152, 152f
Bovine leukocyte adhesion deficiency (BLAD), 152–153
Chédiak-Higashi syndrome, 152, 152f
of lymphocyte morphology, 153, 153f
mucopolysaccharidoses, 152, 152f
Pelger-Huët anomaly, 151, 151f
inherited defects, 217–219
in-house laboratory testing
advantages and disadvantages of, 43–44
considerations for, 44–45
injection-site sarcoma/vaccine-induced lesion, 694f, 696
injury, muscle
alanine aminotransferase (ALT), 499–500
aspartate aminotransferase (AST), 499
cardiac biomarkers, 500–501
creatine kinase (CK), 498–499, 498f
laboratory detection of, 498–501, 498f
lactate dehydrogenase (LDH), 500
myoglobinemia, 501
myoglobinuria, 501
instrumentation
as a consideration for external lab testing, 45
as a consideration for in-house lab testing, 44
insulin
lipids and, 505t
measurement of serum, 454
insulin resistance, hyperlipidemia and, 510–511
integrin beta-2 subunit (ITGB2) gene, 193
interfering substances, that cause errors in samples, 53
intermediate lymphocytes, in lymph nodes, 754, 755f
internal organ inflammation, from bacterial infections, 79
interpretation of liver aspirates, of liver, 732–733, 732f–733f
intestinal absorption, 458
intestinal biopsy, as screening test, 477t
intestinal neoplasia, 483
intestine
about, 748–749, 749f
carcinomas, 750–751, 750f
catcinoid, 751
inflammation, 749, 749f–750f
lymphoma, 749–750, 750f
mast cell neoplasia, 750
mesenchymal intestinal tumors, 751
neoplasia, 749
intracellular pigment, 677
intracellular signaling pathways, 205
intrachain disulfide bonds, 58–59, 59f
intrinsic pathways, 206
invasive infections, 70
ionized calcium, 562, 563–564, 578
iron, in birds, 611
iron hemoatoxylin stains, 73
iron-deficiency anemia, 91, 91f
irreversible stem cell injuries, bone marrow and, 179–180, 180f
islets of Langerhans (pancreas), 448–449, 449f
isolation, for diagnosing bacterial infections, 78
isosthenuria, 390
isotonic dehydration, 404

Janus kinase 2 (JAK2), 135
jaundiced foal agglutination test (colostrum crossmatch), 232–233
jugular venipuncture, 240, 255, 292–293
juvenile pancreatic acinar atrophy, 460

ketoacidosis, 513
ketones
in the blood, 507–508
diabetes mellitus laboratory abnormalities of, 456–457
measurement of, 508
in urinalysis, 373
ketosis, 513
kidneys
about, 745, 746f
inflammation, 745–746
laboratory evaluation
of birds, 602–603
of ferrets, 598–599
of fish, 626–627
of rabbits, 596
of reptiles, 619–620
of rodents, 590–592
laboratory tests for, 55t
renal neoplasia, 746
kinetics, neutrophils and, 146–147, 146f

affecting various body systems
about, 75
gastrointestinal infections, 75–76

nervous system infections, 76
respiratory tract infections, 76
skin and soft-tissue infections, 75
systemic infections, 76–77
urogenital tract infections, 76
for amphibians, 332–333, 338, 339t
anemia, 104
approach to, 53–55, 55t
for bacterial infections
aerobic culture, 68, 68f
anaerobic bacterial culture, 68–69, 69t
antimicrobial susceptibility testing, 69
culture and isolation, 68, 68t
direct microscopic examination, 67–68, 67f
limitation of routine culture, 69
of blood destruction, 119
common factors that introduce error, 52–53, 53f
direct examination of clinical specimens, 66–67, 66f–67f
erythrocytes, 261–262, 262f, 262t
for fish, 317–318, 317t, 323–324, 324t, 327
for fungal infections
about, 69–70
antifungal susceptibility tests, 70
fungal antigen detection, 70
molecular methods, 73–74, 73f
for parasitic infections, 72–73
pathogens/major infectious diseases, species of animals, and the recommended diagnostic tests, 77–84
predictive values, 49–51, 51f
quality control, 51–52, 52f
reference intervals, 46–49, 47f–49f, 48t
of renal function
about, 344–346, 345f
albumin, 360
azotemia, 348–353, 349f, 351t
blood gas, 359–360
cholesterol, 360
creatinine (Ct), 347–348, 347t
electrolyte abnormalities, 354–355
erythroid, 360
fibrinogen, 360
lipase and amylase in serum, 361
packed cell volume, 360
parathyroid hormone, 361
phosphorus and calcium, 355–359
potassium and magnesium, 359
protein abnormalities, 360
sodium and chloride, 359
symmetric dimethylarginine (SDMA), 353–354, 354t
urea nitrogen (UN), 346–347
vitamin D, 361
for reptiles, 297–300, 299t, 304, 308–309, 309f
role of biopsy and histopathology in, 74–75, 74f
role of postmortem investigation in, 74
sample collection and shipping, 66
sensitivity, 49–51, 51f
specificity, 49–51, 51f
transportation of biological samples, 66
of urinary system, 343–401
use of cytopathology, 55–57
for viral infections
about, 70
antibody detection, 72
direct fluorescent antibody testing, 71
electron microscopy, 71–72, 71f
ELISAs, 72
rapid point-of-care tests, 70–71
virus isolation, 72
virus neutralization, 72
lactate dehydrogenase (LD), 500, 609
lagenidium, as infectious agent, 649–650
Lainsonia, 310
lancet wounding, as blood collection method in birds, 256
large granular lymphocyte (LGL) lymphoma, 770
large immature lymphoid cells with apparent nucleoli, in lymph nodes, 754–755, 755f
lateral flow immunoassays (LFIAs), 62–63, 64
latex agglutination test, for diagnosing fungal infections, 81
lavender-top tube, 30–31
Lawsonia intracellularis infection, 74–75
LBL (precursor neoplasia), 769
leakage enzymes, 426, 426f
left shift concentration pattern, 148
Leishmania donovani, 178–179, 179f
Leishmania spp., 84, 310, 649, 649f, 762
Leishmaniasis
lymph nodes and, 759, 759f
from parasitic infections, 84
Lentz bodies, 97
leptocytes and codocytes, 93–94, 94f
Leptospira spp., 67, 67f, 69, 79
Leptospirosis, in sheep and cows, 131
lesions, from parasitic infections, 84
leucine, 380
leukemia concentration pattern, 148
leukocyte agglutination, 151, 151f
leukocytes/leukogram
abnormal concentration patterns
left shift, 148
leukemia, 148
lymphoproliferative disorders, 149, 149f
myeloproliferative disorders, 149, 149f
proliferative disorder, 148–149
suffixes, 148
about, 139, 148, 319, 320
acquired changes in morphology
leukocyte agglutination, 151, 151f
lymphocyte vacuolation, 151, 153f
neutrophil degeneration, 150–151, 150f
neutrophil hypersegmentation, 150, 150f
neutrophil toxic change, 149–150, 150f
for anemia, 116
basophilia, 160
basophils of bony fish, 321
Channel catfish, 319
common blood leukocytes
basophils, 142, 142f
eosinophils, 141–142, 142f
lymphocytes, 139–140, 140f–141f
monocytes, 140–141, 141f
neutrophils, 139, 140f
eosinophilia, 160
eosinophils of bony fish, 321, 321f, 323f
Goldfish, 319
granulocytes of elasmobranchs (sharks and rays), 321, 322f–323f, 325f, 327f
inherited abnormalities or morphology
about, 151
Birman cat neutrophil granulation anomaly, 151–152, 152f
Bovine leukocyte adhesion deficiency (BLAD), 152–153
Chédiak-Higashi syndrome, 152, 152f
of lymphocyte morphology, 153, 153f
mucopolysaccharidoses, 152, 152f
Pelger-Huët anomaly, 151, 151f
interpretation of
excitement response (epinephrine release), 156, 156f
hematologic response to inflammation, 153–156, 154f–155f, 155t
neutrophilia, 156–157, 157f
perspective, 153
stress response (corticosteroid release or administration), 156
interpretation of reptilian hemograms, 308
koi, 319
laboratory abnormalities of, 479
laboratory evaluation, 304, 323–324, 324t, 336–337, 337t
lymphocytes of fish (bony and cartilaginous), 321–322, 323f
lymphocytosis, 157–158, 157f–158f
lymphopenia, 160
monocytes of fish (bony and cartilaginous), 322–323, 324f
monocytosis, 160
morphology, 301–304, 302f–304f, 320–321, 320f, 333–336, 333f–336f
neutropenia
approach to, 159–160, 159f
caused by reversible stem cell injuries, 158–159
resulting from acute inflammatory consumption, 158
resulting from stem cell injuries, 158, 159f
neutrophils of bony fish, 320, 320f
rays, 320
Red pacu, 319
reference values, 142–143, 143t
responses in disease, 304–308, 305t–306t, 306f, 325–326, 325f, 337–338

chronic lymphocyte leukemia (CLL), 196–197, 196f
enzootic bovine leukosis, 197
plasma cell myeloma (multiple myeloma, disseminated plasma cell neoplasia), 197–200, 197f–199f
lymphoproliferative disorders concentration pattern, 149, 149f

MacConkey agar, for bacterial infections, 68
macrocytic anemia, 100, 101
macrocytic erythcroctes, 90
macrophages
about, 290
in bone marrow films, 176–177, 177f–178f
inflammation and, 635–636
in lymph nodes, 756, 756f
screening tests for, 469
macrothrombocytopenia, 210
magnesium
in fish, 629
hypermagnesemia, 416
hypomagnesemia, 413, 415–416
overview of, 409–410, 415–416
renal function and, 359
magnesium ammonium phosphate, 380
magnetic particles, in LFIAs, 64
magnitude of change, associated with disease, 54
malabsorption
in cats, 458–461
causes of, 461t
defined, 458
of dietary fats, 502
in dogs, 458–461
hypoalbuminemia and, 490
overview of, 458–461
protein losing, 514
in ruminants, 461–462
Malasezzia spp., 81, 647, 648f
maldigestion
in cats, 458–461
defined, 458
of dietary fats, 502
in dogs, 458–461
hypoalbuminemia and, 490
overview of, 458–460
protein losing, 514
in ruminants, 461–462
screening tests for, 478
malignant catarrhal fever, from viral infections, 82
malignant histiocytosis, 180–181
malignant neoplasia, 660–670, 666t
malignant plasma cell tumor, 659
mammals
blood collection and handling, 237–240
camelids, 251–252
deer, 252–253
ferrets *(Mustela putotius)*
endocrine disorder laboratory evaluation of, 599–600
features of, 248–250, 249f
glucose metabolism laboratory evaluation of, 599
kidney laboratory evaluation of, 598–599
liver laboratory evaluation of, 599
muscle injury laboratory detection of, 599
protein laboratory evaluation of, 599
general hematologic features of small, 240–242, 241t
hedgehogs
biochemical evaluation of, 600
features of, 250, 250f–251f
plasma biochemical value in, 592t
introduction to, 589
minipigs, 251
primates, 250–251
rabbits *(Oryctolagus cuniculus)*
amylase laboratory evaluation of, 598
calcium and phosphorus measurement in, 596
electrolytes and acid-base in, 596
features of, 246–248, 246f–248f
glucose metabolism laboratory evaluation of, 598
kidney laboratory evaluation of, 596
liver laboratory evaluation of, 596–597
muscle injury laboratory detection in, 598
protein laboratory evaluation of, 597–598
rodents
electrolytes and acid-base of, 592
endocrine disorder laboratory evaluation of, 595–596
glucose metabolism laboratory evaluation of, 594–595
guinea pigs *(Cavia porcellus)*, 244–246, 245f–246f
kidney laboratory evaluation of, 590–592
liver laboratory evaluation of, 592–594
mice *(Mus musculus)*, 241t, 242–244, 243f–244f
muscle injury evaluation of, 595
other rodents, 246
protein laboratory evaluation of, 594
rats *(Rattus norvegicus)*, 241t, 242–244, 243f–244f
sample collection and handling within, 589–590
sugar gliders
biochemical evaluation of, 600
plasma biochemical value in, 592t
mammary gland tumors, 690
Mannheimia hemolytica, 79
mantle cell lymphoma, 770
marginal zone lymphoma (MZL), 769–770
massively parallel sequencing. *See* next-generation sequencing (NGS)
mast cell neoplasia
of intestine, 750
of the liver, 741
mast cell tumors (MCT)
about, 677f–678f, 678–683
body cavity effusions and, 712, 714f
inflammatory cells for, 670t
testing for *CKIT* mutation in, 164–165, 164f
mast cells
about, 173
in body cavity effusions, 706–707, 706f–707f
inflammation and, 637–638, 638f, 639f
in lymph nodes, 756–757, 757f
mastitis
from bacterial infections, 79
from fungal infections, 81
maturation
neutrophils and, 145, 145f
orderliness of, in bone marrow films, 175–176, 177f
mature erythrocytes, 171
MCA, anemia and, 101
MDSs, 185
mean cell hemoglobin, 9
mean cell hemoglobin concentration, 9–10
mean cell volume, 11–12, 11f
mean corpuscular hemoglobin concentration (MCHC)
about, 95
in amphibians, 332–333, 332t
anemia and, 100–101
for birds, 262–264, 263t
for fish, 317–319, 317t
for reptiles, 297–300, 299t
mean corpuscular volume (MCV)
about, 89–90
in amphibians, 332–333, 332t
for birds, 262–264, 263t
for fish, 317–319, 317t
for reptiles, 297–300, 299t
measurement reproducibility, 54
meclofenamic acid, stem cell injury from, 106
medial metatarsal, venipuncture of, 255–256

medullary washout, 385, 390
megakaryoblastic leukemia (M7), 190–191, 192f
megakaryocyte series, of cells in bone marrow films, 172, 172f
megakaryocytes, in bone marrow films, 174
melanocytic tumors, 658
melanoma, 697–698, 698f
Melena, 104
meningoencephalitis, from bacterial infections, 79
mephalan, for treating multiple myeloma in dogs, 200
mesenchymal/spindle cell tumors
  about, 181, 657–658, 691–694, 693f–695f, 695t
  fibroma/fibrosarcoma, 696
  hemangioma/hemangiosarcoma, 696
  injection-site sarcoma/vaccine-induced lesion, 694f, 696
  of intestine, 751
  lipoma, 693f, 694–695
  liposarcoma, 693f, 695–696
  myxoma/myxosarcoma, 697
  neoplasia and, 674–675
  perivascular wall tumor/hemangiopericytoma/neurofibroma/peripheral nerve sheath tumors, 695f, 696–697
  rhabdomyoma/rhabdomyosarcoma, 697
  undifferentiated sarcoma, 697
mesenteric lymphadenitis, from bacterial infections, 80
mesothelioma and reactive mesothelial cells, 713–716, 715f–716f
metabolic acidosis
  expected magnitude of, 423t
  expected values within, 422t
  overview of, 419, 419t
metabolic alkalosis
  expected magnitude of, 423t
  expected values within, 422t
  overview of, 419–420, 419t
metabolic syndrome, hyperlipidemia and, 510–511
metamyelocytes, 171, 288f, 289
metarubricytes, 170
metastatic carcinoma, of the liver, 739
metastatic neoplasia
  of liver, 739–741, 739f–740f
  lymph nodes and, 772–773, 772f–773f
methemoglobin (Met-HGB), 424
methylene blue, as cause of Heinz body anemia, 129
methylmalonic acid (MMA), screening test for, 475
mice *(Mus musculus)*
  antibodies, 63
  features of, 241t, 242–244, 243f–244f
  membrane defects in, 131
microalbuminuria, 389
microbiome, 75
microcontainers, 32
microcytic anemia, 100, 101
microcytic erythrocytes, 89–90, 89f
microfilaria, 284, 311
microhematocrit method, 332–333
microorganisms
  blood destruction and, 130–131
  in bone marrow films, 177–178, 178f–179f
microproteinuria, 371–372
microscope, use of, 39–40
microscopic agglutination test, for diagnosing bacterial infections, 79
microscopic differential count, assessment of morphology and, 8–9, 8e, 8f
microscopic sediment examination, in urinalysis, 374–375
microscopy, pattern recognition in, 33–34
Microspirodians, 328
milk, as a clinical sample, 68t
milk fever, 576
milk tetany, 415–416
Milstein, César, 60
minimum inhibitory concentration (MIC), of antimicrobial agents, 69
minipigs, 251
molecular biology, of PARR assay, 162–163, 163f
molecular methods, infectious diseases and, 73–74, 73f
monoblasts, 172
monocional cryoglobulinemia, 493
monoclonal antibodies, 60
monocyte series, of cells in bone marrow films, 172, 172f
monocytes
  about, 140–141, 141f, 244, 290
  in amphibians, 336–337, 337t
  in birds, 274–277, 275t
  in fish, 322–323, 323–326, 324f, 324t
  in reptiles, 304–308, 305t–306t
monocytic leukemia (M5), 189, 190f–191f
monocytosis, 160
monogastric animals, bacterial infections in, 79
mononuclear cells, in body cavity effusions, 704–705, 705f–706f
morphology
  about, 308, 308f, 333–336, 333f–336f
  acquired changes in
    leukocyte agglutination, 151, 151f
    lymphocyte vacuolation, 151, 153f
    neutrophil degeneration, 150–151, 150f
    neutrophil hypersegmentation, 150, 150f
    neutrophil toxic change, 149–150, 150f
  for amphibians, 331–332, 332f–333f, 332t, 336f, 338
  assessment of, 8–9, 8e, 8f
  erythrocytes, 258–261, 259f–261f, 259t
  for fish, 315–317, 316f–317f, 320–321, 320f, 322f–325f, 326–327, 327f–328f
  for reptiles, 296–297, 296f–298f, 301–304, 302f–304f
Mott cells, 173
MRI, for hyperadrenocorticism (HAC) (Cushing's syndrome), 550
mucin quality, evaluating, 718
mucopolysaccharidoses, 152, 152f
mucous membranes, for diagnosing anemia, 104
Mullis, Kary, 73
multilocus sequence typing (MLST), 73–74
multiple myeloma, 494
multisystemic disease
  from parasitic infections, 84
  from viral infections, 82, 83
muscle catabolism, detection of, 499
muscle injury
  alanine aminotransferase (ALT), 499–500
  aspartate aminotransferase (AST), 499
  cardiac biomarkers, 500–501
  creatine kinase (CK), 498–499, 498f
  laboratory detection
    about, 498–501, 498f
    for birds, 614–615
    for ferrets, 599
    for rabbits, 598
    for reptiles, 624
    for rodents, 595
  lactate dehydrogenase (LDH), 500
  myoglobinemia, 501
  myoglobinuria, 501
Mycobacteria, 68, 761–762
Mycobacterium spp., 79
Mycoplasma haemocanis, 97, 97f, 120, 121f
Mycoplasma haemofelis, 96, 96f, 120, 120f
Mycoplasma haemolamae, 122, 122f
Mycoplasma spp., 69, 76, 79
Mycoplasma suis, 121–122, 121f
Mycoplasma wenyoni, 97, 97f
mycoplasmas, hemotropic, 119–120
myeloblastic leukemia with maturation (M2), 189, 189f
myeloblastic leukemia with maturation and atypical granulation of promyelocytes (M3), 189
myeloblasticleukemia (M1), 188, 189f
myeloblasts, 144, 171, 288f, 289, 289f
myelocytes, 144, 171, 288f, 289, 289f
myelodysplastic syndrome, 92, 184–185, 185f
myelofibrosis syndrome, 92
myeloid : erythroid ratio, in bone marrow films, 174–175, 175f
myeloid neoplasms, 184
myelolipoma, of spleen, 745
myelomonocytic leukemia (M4), 189, 190f
myelophthisic disease, 215
myelophthisis, 215
myeloproliferative and lymphoproliferative disorders
  about, 183–184, 183f–184f
  acute myeloid leukemias and myeloproliferative neoplasms, 186
  chronic myeloproliferative neoplasms
    about, 192
    chronic basophilic leukemia, 193–194
    chronic granulocytic (myelogenous) leukemia, 192–193, 192f–193f
    eosinophilic leukemia, 193, 193f
    essential thrombocythemia, 194
  classification of acute myeloid leukemias (AMLs)
    about, 186–187, 187f, 188t
    dendritic cell leukemia, 191
    erythroleukemia (M6), 189–190, 191f

megakaryoblastic leukemia (M7), 190–191, 192f
monocytic leukemia (M5), 189, 190f–191f
myeloblastic leukemia with maturation (M2), 189, 189f
myeloblastic leukemia with maturation and atypical granulation of promyelocytes (M3), 189
myeloblasticleukemia (M1), 188, 189f
myelomonocytic leukemia (M4), 189, 190f
undifferentiated leukemia (M0), 187
lymphoproliferative disorders
about, 194
acute lymphoblastic leukemia (ALL), 194–196, 194f–195f
chronic lymphocyte leukemia (CLL), 196–197, 196f
enzootic bovine leukosis, 197
plasma cell myeloma (multiple myeloma, disseminated plasma cell neoplasia), 197–200, 197f–199f
myelodysplastic syndrome, 184–185, 185f
myeloid neoplasms, 184
myeloproliferative disease, of the liver, 741
myeloproliferative disorders concentration pattern, 149, 149f
myeloproliferative neoplasms, acute myeloid leukemias and, 186
myocarditis, from viral infections, 83
myoglobin casts, 378
myoglobinemia, 501
myoglobinuria, 363–365, 364t, 501
myositis, from bacterial pathogens, 78
myxoma/myxosarcoma, 697

N-acetyl-glucosaminidase (NAG), 381
naphthalene, as cause of Heinz body anemia, 129
natriuretic peptides, 500–501
Natt-Herricks solution kit (Natt-Pete), 273–274
necrosis, of pancreas, 746
necrotic laryngitis, from bacterial infections, 79
needles
for bone marrow biopsy, 35–36
hemolysis and size of, 32
nematodes, screening tests for, 466t
neonatal isoerytholysis (NI), 119
neonates, nursing young and, 512–513
neoplasia
about, 652–655, 653f, 654t, 655f
adrenal gland, 748, 748f
benign *vs.* malignant, 660–670, 666t
confounders in interpretations, 670–673, 670t, 672f
hyperglycemia and, 453
hypoglycemia and, 451
initial examination, 655–660, 656f–665f
of intestine, 749
in lymph nodes, 766
overview of, 433
of pancreas, 746–747
pancreas and, 447
prognosis, 673–675, 674f
synovial fluid and, 730, 730f
neoplasms, 386
neoplastic cells
in body cavity effusions, 707
in lymph nodes, 757, 757f
neoplastic disorders, 180–182, 181f–182f
neoplastic effusions, 712
neoplastic lymphoid cell morphology, 767
neospora spp., as infectious agent, 648–649
nephrons, 389
Nephrotic syndrome, 385, 391, 512
nervous system infections, 76
neuroendocrine tumors (carcinids), 658–659, 675, 691, 692f, 739
neurologic disease, from viral infections, 82, 83
neutropenia
approach to, 159–160, 159f
caused by reversible stem cell injuries, 158–159
resulting from acute inflammatory consumption, 158
resulting from stem cell injuries, 158, 159f
neutrophil degeneration, 150–151, 150f
neutrophil hypersegmentation, 150, 150f
neutrophil toxic change, 149–150, 150f
neutrophilia, 156–157, 157f
neutrophils
about, 139, 140f, 144
in amphibians, 336–337, 337t
in body cavity effusions, 705–706, 705f, 706f
in bony fish, 320, 320f
in fish, 323–326, 324t
granulocyte production, 144–145, 145f
growth factors, 146, 146f
kinetics, 146–147, 146f
in lymph nodes, 755, 756f
maturation and orderly production, 145, 145f
overview of, 635
pools and trafficking, 145–146, 146f
regulation of production and blood concentration, 146, 146f
screening tests for, 468
trafficking, 155t
Newcastle disease, from viral infections, 83
next-generation sequencing (NGS), 74, 165
nicotinamide-adenine dinucleotide phosphate (NADPH), 127
nicotine adenine dinucleotide phosphate (NADPG), 132–133
nitrites, in urinalysis, 374
Nocardia spp., 76, 79
nodular hyperplasia, of liver, 736
noncompetitive immunoassays, 60–61
nonenveloped DNA virus, from viral infections, 82
noninflammatory/degenerative arthropathies, synovial fluid and, 722
non-neoplastic lesion, of spleen, 741
non-neoplastic skin and subcutaneous lesions
abscess, 699
eosinophilic granuloma, 702, 702f
epidermal inclusion cyst (follicular cyst), 699–700, 701f
hematoma and seroma, 699, 700f
salivary gland infarction, 701–702
sialocele/mucocoele, 700–701, 702f
sialodenosis, 701
nonregenerative anemia
about, 106
aplastic anemia (aplastic pancytopenia)
drugs, chemicals, toxins, and estrogen, 106–107, 107t
infectious agents, 107
pure red cell aplasia/nonregenerative immune mediated anemia, 107–108
red cell hypoplasia
about, 108
anemia associated with endocrine disease, 109
anemia associated with nutritional deficiencies, 109
anemia of chronic renal disease, 109
anemia of inflammation, 108–109
nonsecretory myelomas (NSM), 199
nonselective media, for bacterial infections, 68
nonthrombogenic surface, 201
normal lymph nodes, 758
normal resident cells, 656
nucleated erythrocytes, 95, 95f
null cells, 139
nutritional deficiencies, anemia associated with, 109

occipital venous sinus puncture, as blood collection method in birds, 256
oil immersion, for cytology and hematology, 39
oliguria, 389
one-stage prothrombin time ("OSPT" or "PT"), 212
Oomycosis lymphadenitis, 765
opportunistic infections, from bacterial infections/pathogens, 78, 80
oral cavity infections, 75–76
oral D-xylose absorption test, as screening test, 477
oral glucose absorption/tolerance test (OGTT), as screening test, 477–478
organ inflammation, from fungal infections, 81
organ neoplasia, diagnosis of specific, 56–57
Orthomyxoviridae, 82
osetoblasts, 173
osmolality, 403
osmole gap, 383
osmometry, 27
osmoregulation, in fish, 627
osmotic diarrheas, examples of, 461t
osteoblasts, 290, 431
osteoclasts, 173, 290, 290f
osteomyelitis, from bacterial pathogens, 77
osteosarcoma, in dogs, 92, 92f
otitis externa, from fungal infections, 81
oxalate, hypoalbuminemia and, 577–578
oxidative drugs, Heinz body formation and, 95
oxidative injury, 127
oxygenated hemoglobin (OXY-HGB), measurement of, 424
oxytetracycline, for treating anemia, 121–122

P. lutzii, 764–765
packed cell volume, 3–5, 4f–6f, 360
painting technique, 38, 39f

paired serum testing
for diagnosing urogenital tract infections, 76
for virus neutralization, 72
pancreas
about, 746, 747f
endocrine
amyloidosis, 452f
catecholamines, 449t, 450
diabetes mellitus laboratory abnormalities of, 456–457
fructosamine, 454–455
glucagon, 449t, 450
glucocorticoids, 449t, 450
glucose metabolism, 449–453, 453–456
glycated hemoglobin (GHb), 455
growth hormone, 449t, 450
hyperglycemia, 451–453, 452t
hyperinsulinism, 457
hypoglycemia, 450–451, 450t
islets of Langerhans, 448–449, 449f
overview of, 448–449
serum insulin in, 454
exocrine
azotemia, 448
cytologic evaluation of, 447
detection of injury of, 445–447
hypercalcemia and, 448
hypercholesterolemia and, 448
hyperglycemia and, 448
hypertriglyceridemia and, 448
hypocalcemia and, 448
injury abnormalities of, 447–449
lipase activities in, 447
overview of, 445
pancreatic lipase immunoreactivity (PLI) of, 446
peritoneal fluid amylase in, 447
serum amylase activity, 447
serum lipase activity of, 446–447
serum trypsin-like immunoreactivity, 446
necrosis and inflammation, 746
neoplasia, 746–747
overview of, 445
pancreatic duct obstruction, 460
pancreatic and gastrointestinal disease and glucose metabolism, clinical case presentations on, 778, 917–959
pancreatic duct obstruction, 460
pancreatic lipase immunoreactivity (PLI), 446
pancreatitis, 512, 575
panhypoproteinemia, laboratory abnormalities of, 479
papilloma, from viral infections, 83
papillomaviridae, 83
Pappenheimer bodies, 96
Paracoccidoides brasiliensis, 764–765
paradoxical aciduria, 391
Parainfluenza, from viral infections, 83
Paramyxoviridae, 83
parasites, 96–97, 96f–97f, 377
parasitic infections, 72–73
parathyroid adenoma (hyperplasia, carcinoma), 569–572
parathyroid glands
disorders of
hyopalbuminemia, 565
hypercalcemia, 562–563, 564, 570
hyperparathyroidism in, 563
hypoparathyroidism, 567–569
parathyroid adenoma (hyperplasia, carcinoma), 569–572
primary hyperparathyroidism (primary HPTH), 569–572
general introduction to, 561
laboratory evaluation of birds, 616
laboratory test background of
calcium-phosphorus product (Ca × P), 565
ionized calcium measurement, 563–564
parathyroid hormone, 566
protein adjusted calcium measurement, 564–565
PTH and PTH rp assays, 566–567
total serum calcium, 562–563
parathyroid hormone (PTH)
function of, 409–410
hypercalcemia and, 412
laboratory test background of, 566
measurement of, 561
renal function and, 361
PARR assay
interpretation and uses of, 163–164
molecular biology of, 162–163, 163f
parrots, clinical case presentations of, 823, 997–998

round cell neoplasms
about, 678
histiocytoma, 679f, 683
mast cell tumor (MCT), 677f–678f, 678–683
transmissible venereal tumor (TVT), 680f, 683–684
round cell tumors, 656–657, 673–674
rT3 reverse trilodothyronine test, 517
RT-PCR, for diagnosing viral infections, 82, 83
rubriblasts, 170, 287, 287f–288f
rubricytes, 170, 287f–288f, 288
ruminant abortion, from bacterial pathogens, 78
ruminants. *See also specific types*
AST activity in, 429
bacterial infections in, 79
cobalamin in, 475
haemoplasmas of, 120–121, 121f
hypothyroidism in, 530
malabsorption in, 461–462
maldigestion in, 461–462
neutrophil storage in, 145, 154
SBA activity within, 438
selenium deficiency in, 129
runimal fluid, screening tests for, 476
Russell bodies, 173

saline agglutination test, 98, 98f
saline fragility test, 15–16, 16f, 104
salivary gland infarction, 701–702
Salmonella spp., 68, 69, 76, 80
Salmonids, 319
sample pickup service, as a consideration for external lab testing, 45
samples
collecting and shipping for infectious disease diagnosis, 66
collection and handling of, for birds, 254–258, 255f–258f
considerations, as a factor influencing immunoassay performance, 63
handling errors for, 52–53
preparation of, for body cavity effusions, 703
sending to reference laboratories, 229
submitted and triage of samples of limited volume, 722
sarcomas
body cavity effusions and, 716
of the liver, 739
Saurocytozoon, 310
Sauroleishmania, 310
Schellackia, 310
schistocytes and keratocytes, 91, 91f, 111, 111f
screening tests
adrenal glands
ACTH stimulation, 536–539
basal cortisol, 536–538
for hyperadrenocorticism (HAC) (Cushing's syndrome), 543
for hypoadrenocorticism (Addison's disease), 536–538
creatine kinase (CK), 498–499, 498f
for diabetes insipidus, 557–558
endocrinology, low-dose dexamethasone suppression test (LDDST), 515–516
for gastrointestinal (GI) disease
absorption test, 476–477
in birds, 469–470
brush cytology, 470
canine microbiota dysbiosis index, 475–476
cytology of biopsy samples, 470
digestion/absorption, 472
examples of, 464t–466t
fecal antigen detection methods, 477t
fecal assessment, 462
fecal collection methods, 462–463
fecal cytology, 467–469, 470
fecal elastase 1, 473
fecal ELISA for bacterial enterotoxins, 477t
fecal floatation and sedimentation, 463–467
fecal occult blood, 471–472
fecal PCR (bacterial or fungal culture), 477t
fecal α_1-proteinase inhibitor concentration (α_1-PI), 473
folate concentration, 473
in horses, 470
hydrogen breath test, 477t
intestinal biopsy, 477t
maldigestion, 478
markers for gastric disease, 476
methylmalonic acid (MMA), 475
oral D-xylose absorption test, 477
oral glucose absorption/tolerance test (OGTT), 477–478
oral lactose tolerance test, 478
ruminal fluid evaluation, 476
serum folate, 474–475
serum gastrin, 477t
serum pepsinogen, 477t
serum trypsin-like immunoreactivity (TLI), 472–473
serum vitamin B_{12} (cobalamin), 473, 475
starch digestion, 478
wet preparations, 463
for hyperadrenocorticism (HAC) (Cushing's syndrome), 546–550
thyroid
autoantibodies, 518
fT4, 516–517, 520–521, 521–523, 525–526
hyperthyroidism, 520–521
hypothyroidism, 525–526
overview of, 517t
rT3 reverse trilodothyronine, 517
T3 suppression test, 521–523
thyroid-stimulating hormone response test (TSH response), 522
thyrotropin, thyroid-stimulating hormone (TSH), 517–518
thyrotropin releasing hormone response test (TRH response), 522
TRH response, 518–519
TSH response, 518–519
TT3 trilodothyronine, 517
TT4, 516, 520–521, 525–526
scruff-hold, 238
sebaceous cell adenoma, 685–686, 686f
sebaceous cell carcinoma, 686–687
secondary absolute erythrocytosis, 136
secondary hemostasis
about, 202, 203t, 206–208
cats with, 224
diseases affecting, 216–219
dogs with, 224
signs associated with defects of, 209
tests for, 211–212
secondary hemostatic defects, primary hemostatic defects *vs.,* 208
secondary hyperparathyroidism, 574–575
secondary pathologic hyperlipidemia, 509
secretory diarrheas, 461t
segmented granulocytes, 172
selective media, for bacterial infections, 68
selenium deficiency, as cause of Heinz body anemia, 129
sensitivity, laboratory data interpretation and disease diagnosis, 49–51, 51f
sepsis, hypoglycemia and, 451
septic, suppurative inflammation, 636f, 639f, 640f, 641f
septic exudates, body cavity effusions and, 708–709, 708f–709f
serology
for diagnosing bacterial infections, 77, 78, 79, 80
for diagnosing fungal infections, 81
for diagnosing parasitic infections, 84
for diagnosing viral infections, 82, 83
serum amylase activity, 447, 479
serum bile acid (SBA), 437–439
serum gastrin, as screening test, 477t
serum insulin, measurement of, 454
serum lipase activity, of the pancreas, 446–447
serum pepsinogen, as screening test, 477t
serum protein electrophoresis (SPE), 198–199, 485–486
serum proteins
abnormal concentrations of, 488–495
algorithm for, 489f, 491f
antibody-based detection kits, 488
fibrinogen concentration, 488
glutaraldehyde coagulation test, 487–488, 496
hyperviscosity, 493
measurement of, 485–488
monocional cryoglobulinemia, 493
plasma *versus,* 485
serum protein electrophoresis, 485–486
sodium sulfite precipitation test, 487, 495
total concentration of, 485
turbidity and coagulation assays for, 487–488
zinc sulfate turbidity test, 487, 495–496
serum trypsin-like immunoreactivity (TLI), 446, 472–473
serum virus neutralization, for diagnosing viral infections, 83

serum vitamin B_{12} (cobalamin)
overview of, 474
in ruminants, 475
screening test for, 473, 475
shape, of erythrocytes
about, 90–91
acanthocytes, 91–92, 92f
eccentrocytes, 93, 94f
echinocytes, 92, 92f
ellipticytes, 92, 93f
leptocytes and codocytes, 93–94, 94f
schistocytes and keratocytes, 91, 91f
spherocytes, 92–93, 93f
stomatocytes, 94, 94f
sharks, 320, 626
shearing technique, 39, 39f
sheep
alliums and, 128
anemia in, 119–120, 120f
bacterial infections in, 78, 130–131
blood groups in, 221t, 222
clinical case presentations of, 867–868
crossmatching in, 231–232
donor selection for, 223
drug and chemical toxins for, 129
erythrocytes in, 87–88, 88t
inherited defects in, 218t
leukogram reference values for, 143t
membrane defects in, 132
parasitic infections in, 84
pituitary diseases in, 560
therileriosis in, 125
viral infections in, 82
Shigella spp., 80
sialocele/mucocoele, 700–701, 702f
sialodenosis, 701
sickle cell anemia, 91
sickled cells, 252–253
side scatter, 166
siderotic granules, 96, 96f
silver stains, 74
simian polyomavirus (SV40), from viral infections, 83
size, of erythrocytes
about, 89
macrocytic erythcroctes, 90
microcytic erythrocytes, 89–90, 89f
skeletal muscle injury, detection of, 499
skin and subcutaneous masses
about, 676–678, 677f–682f
as a clinical sample, 68t
epithelial cell tumors
apocrine gland adenocarcinoma (AGAC) of anal sacs, 688–690, 689f
apocrine sweat gland tumors, 690
basal cell neoplasm, 685, 686f
mammary gland tumors, 690
perianal/circumanal gland tumors, 688, 688f
sebaceous cell adenoma, 685–686, 686f
sebaceous cell carcinoma, 686–687
squamous cell carcinoma (SCC), 687–688, 687f
thyroid tumors, 690–691
histiocytic sarcoma, 698–699
lymphoma, 682f, 684–685
melanoma, 697–698, 698f
mesenchymal/spindle cell tumors
about, 691–694, 693f–695f, 695t
fibroma/fibrosarcoma, 696
hemangioma/hemangiosarcoma, 696
injection-site sarcoma/vaccine-induced lesion, 694f, 696
lipoma, 693f, 694–695
liposarcoma, 693f, 695–696
myxoma/myxosarcoma, 697
perivascular wall tumor/hemangiopericytoma/neurofibroma/peripheral nerve sheath tumors, 695f, 696–697
rhabdomyoma/rhabdomyosarcoma, 697
undifferentiated sarcoma, 697
neuroendocrine tumors, 691, 692f
non-neoplastic skin and subcutaneous lesions
abscess, 699
eosinophilic granuloma, 702, 702f
epidermal inclusion cyst (follicular cyst), 699–700, 701f
hematoma and seroma, 699, 700f
salivary gland infarction, 701–702
sialocele/mucocoele, 700–701, 702f
sialodenosis, 701
plasma cell tumor, 681f, 684
round cell neoplasms
about, 678
histiocytoma, 679f, 683
mast cell tumor (MCT), 677f–678f, 678–683
transmissible venereal tumor (TVT), 680f, 683–684
skin infections
about, 75
from bacterial infections, 80
from bacterial pathogens, 78
from fungal infections, 80
skin inflammation from bacterial infections, 79
skunk spray, as cause of Heinz body anemia, 129
small intestinal bacterial overgrowth (SIBO), 474, 480
small intestine, 437f
small lymphocytes, in lymph nodes, 754, 755f
s-methyl L-cysteine sulfoxide, 128
smooth muscle injury, 499
snake envenomation, 92, 92f, 93
sodium
in birds, 606
for chloride concentration correction, 406
dehydration and, 404
hypernatremia, 403–404
hyponatremia, 404–405
laboratory evaluation of, 402–405
renin-angiotensin-aldosterone system (RAAS), 403
in reptiles, 620
sodium potassium ratio, 406
sodium chloride
in fish, 627–628
renal function and, 359
sodium citrate, 31
sodium fluoride, 32
sodium potassium ratio, 406
sodium sulfite precipitation test, 487, 495
soft-tissue infections, 75
soluble coagulation, 201
sorbitol dehydrogenase (SDH), 428, 429–430, 609
species-specific ability, as a consideration for external lab testing, 45
specific factor analysis, 212
specificity, laboratory data interpretation and disease diagnosis, 49–51, 51f
spectrophotometry
about, 370
items determined by
about, 9
hemoglobin concentration, 9
mean cell hemoglobin, 9
mean cell hemoglobin concentration, 9–10
spherocytes, 92–93, 93f
spiculated erythrocytes, 90
splatter techniques, 37–38, 38f
spleen
about, 741
extramedullary hematopoiesis, 742
in fish, 329
hemangioma and hemangiosarcoma, 744, 744f
hemosiderosis and siderotic nodules, 742
histiocytic sarcoma, 745
inflammation (splenitis), 742
lymphoma, 743–744, 744f
myelolipoma, 745
non-neoplastic lesion, 741
splenic hyperplasia, 741–742, 742f
splenic mast cell neoplasia, 745, 745f
splenic neoplasia, 743, 743f
splenic aspirates, 56
splenic hyperplasia, of spleen, 741–742, 742f
splenic mast cell neoplasia, of spleen, 745, 745f
splenic neoplasia, of spleen, 743, 743f
Sporothix schenckii, 81
sporothrix schenkii fungi, 643
sporotrichosis, 643f, 644f
spray droplet, 37–38, 38f
squamous cell carcinoma (SCC), 670t, 687–688, 687f
staging renal disease, 391
staining, 39, 39f
Staphylococcus hyicus, 75
Staphylococcus spp., 75, 80
starch digestion, screening test for, 478
starvation, hypoalbuminemia and, 490
statistical methods, to establish reference intervals, 47
stem cell injuries/disorders
of bone marrow
aplasia or hypoplasia, 180
dysmyelopoiesis, 180
irreversible stem cell injuries, 179–180, 180f
reversible stem cell injuries, 179
neutropenia caused by reversible, 158–159

stem cell injuries/disorders (*continued*)
neutropenia resulting from, 158, 159f
steroid hepatopathy, 443
steroid response, 156
stimulation tests, for thyroid, 518–519
stomatocytes, 94, 94f
strangles, from bacterial infections, 80
stranguria, 389
Streptococcus spp., 75, 80, 760
stress response (corticosteroid release or administration), 156
Striped bass, 319
struvite, 380
subcarapacial venous sinus, for blood collection from reptiles, 294–295
subendothelium, 201
suffixes concentration pattern, 148
sugar gliders
biochemical evaluation of, 600
plasma biochemical value in, 592t
sulfosalicylic acid turbidity test, 369–370
superficial lesions, as a clinical sample, 68t
suppurative inflammation, 636f
supravertebral sinus, for blood collection from reptiles, 293
Sure-Sep tube, 31–32
surface receptors, 205
swabs, as collection devices, 66
swine. *See* pigs
swine dysentery, from bacterial pathogens, 78
symmetric dimethylarginine (SDMA), renal function and, 353–354, 354t
synovial fluid
abnormal cytology
about, 722, 723t
contamination during collection, 729–730, 729f
general considerations in differentiating infectious from immune-mediated arthropathies, 728
hemarthrosis, 728–729, 729f
hemorrhage/diapedesis secondary to DJD/inflammation, 730
hemorrhagic or hemodilute samples, 728
immune-mediated conditions, 725–728, 726f, 726t
infectious conditions, 723–725, 724f–725f
inflammatory (suppurative) arthropathies, 722–723
neoplasia, 730, 730f
noninflammatory/degenerative arthropathies, 722
other causes of suppurative arthropathy, 728
about, 717
cytologic evaluation
about, 719
differential count, 721–722, 721f
estimation of cellularity, 719–720, 720f
estimation of viscosity/proteoglycan layer, 720–721, 720f–721f
preparation of cytologic slides, 719, 719f
parameters evaluated
mucin quality, 718
physical properties, 717–718
protein concentration, 719
total nucleated cell count (TNCC), 718–719
volume, 717
samples submitted and triage of samples of limited volume, 722
systemic diseases/infections
about, 70, 76–77
from bacterial infections, 79
from bacterial pathogens, 78
from fungal infections, 81
from viral infections, 82, 83

T lymphocytes, 139
T3 suppression test, for thyroid, 521–523
T-cell receptors, 161–162
tests
for evaluating hemostasis
activated clotting time (ACT), 211
activated partial thromboplastin time ("APTT" or "PTT"), 211–212
Buccal mucosal bleeding time (BMBT), 209
fibrinogen degradation products (FDPs), 213
of fibrinolysis, 213
hemostasis profiles (coagulation profiles), 213
one-stage prothrombin time ("OSPT" or "PT"), 212
platelet concentration (platelet "count"), 210
platelet function testing, 211
primary hemostasis, 209–212
secondary hemostasis, 211–212
specific factor analysis, 212
vWf assays, 210–211
inconsistency in results of, 55
normal *vs.* abnormal results, 55
tetracycline, for treating anemia, 122
TGEV direct immunofluorescence, for diagnosing viral infections, 82
Theiler, Arnold, 122
theileriosis, 124–125, 125f
therapy
for blood destruction, 118–119
for blood loss, 114
for erythrocytosis, 138
thiacetarsaminic, stem cell injury from, 106
thoracic encirclement method, 238
thrombocytes
about, 280f, 289–290, 326
blood parasites, 309
hemogregarines, 309–310, 309f
Hemoproteus, 311
laboratory evaluation, 308–309, 309f, 327, 338, 339t
Lainsonia, 310
Leishmania, 310
microfilaria, 311
morphology, 308, 308f, 317f, 322f–325f, 326–327, 327f–328f, 336f, 338
Pirohemocyton, 311, 311f
piroplasmids, 310–311
Plasmodium, 310
responses in disease, 327, 338
responses to disease, 309
Saurocytozoon, 310
Sauroleishmania, 310
Schellackia, 310
trypanosomes, 310
thrombocytopenia, 208–209, 210, 213–215
thromboembolic meningoencepahlitis, from bacterial infections, 79
thrombomudulin, 207
thrombopathia, 215
thrombopathy, 215
thrush, from fungal infections, 81
thyroid
disorders of
about, 516
hyperthyroidism, 514, 519–523
hypothyroidism, 509–510, 516, 518, 523–530
dog profile regarding, 525t–526t
hyperadrenocorticism (HAC) (Cushing's syndrome) and, 543
laboratory evaluation
of birds, 615–616
of fish, 631
tests for
autoantibodies, 518
fT4, 516–517, 521–523, 525–526
overview of, 517t
rT3 reverse trilodothyronine, 517
stimulation tests, 518–519
T3 suppression, 521–523
thyroid-stimulating hormone response test (TSH response), 522
thyrotropin, thyroid-stimulating hormone (TSH), 517–518
thyrotropin releasing hormone response test (TRH response), 522
TRH response, 518–519
TSH response, 518–519
TT3 trilodothyronine, 517
TT4, 516, 520–521, 525–526
thyroid hormones, lipids and, 505t
thyroid tumors, 690–691
thyroid-stimulating hormone response test (TSH response) test, for thyroid, 517–518, 522
thyrotropin releasing hormone response test (TRH response) test, for thyroid, 522
thyroxine, first quantitative in-clinic immunoassay for, 64
tick fever, from bacterial pathogens, 77
Tilapia, 320
timing, in urinalysis, 362
tissue aspirates
about, 34–35
as collection devices, 66
including bone marrow, 40–43
tissue contamination, 32
tissue factor, 206
tissue factor pathway inhibitor (TFPI), 207
tissue imprint, 36
tissues, enzymes and, 427–428
T-lymphoblastic lymphoma (TZL), 768–769

toenail clipping, as blood collection method in birds, 256
Togaviridae, 83
tonsillitis, 76
total leukocyte concentration, 6–7
total nucleated cell count (TNCC), in synovial fluid, 718–719
total protein concentration, 703
total serum calcium, 562–563
toxin screening, for diagnosing bacterial infections, 78
toxoplasma, as an infectious agent, 648–649, 648f
Toxoplasma gondii infection, 59, 84, 178–179, 179f, 762–763
tracheal washes, as a clinical sample, 68t
tracheobronchitis, from viral infections, 82
TRAF3 (tumor necrosis factor receptor associated factor 3), 184
transfusion reactions, 226–227, 227t
transitional cell carcinoma (TCC), 386–387, 391
translocational hyponatremia, 404–405
transmissible gastroenteritis virus (TGEV), from viral infections, 82
transmissible venereal tumor (TVT), 680f, 683–684
transudates, body cavity effusions and, 707
trauma-/disease-induced hemorrhage, hemostatic defect *vs.,* 208
TRH response test, 518–519
trichloroethylene, aplastic anemia from, 107
triglycerides
  in the blood, 503–504
  function of, 506–507, 506f
  hypotriglyceridemia, 514
trimethoprim-sulfadiazine, stem cell destruction from, 106
triple phosphate, 380
tripotassium (K3) salt, 30–31
troponins, cardiac, 500
Trueperella pyogenes, 80
Trypanoplasms, 328
Trypanosoma spp., 84, 284–285, 763
Trypanosomes, 310, 327–328
trypsin-like immunoreactivity (TLI) assay, 446
trypsinogen, 446
tryptocase soy agar, for bacterial infections, 68
TSH response test, 518–519
TT3 trilodothyronine test, 517
TT4 test, for thyroid, 516, 520–521, 525–526
tube agglutination crossmatch, 230–231, 230f–231f
tuberculosis, from bacterial infections, 79
tularemia, from bacterial infections, 79
tumor necrosis factor (TNF), 146
turbidity and coagulation assays, 487–488
turnaround time, as a consideration for external lab testing, 45
2, 3-diphosphoglycerate, 132
Tyler, Ron, 206
tyrosine, 380
Tyzzer's disease, 74–75
T-zone lymphoma (TZL), 166
ulcerative colitis, from bacterial infections, 80
ulcerative lymphangitis, from bacterial pathogens, 78
ulnar venous sinus, for blood collection from reptiles, 295
unassayed control samples, 51–52

  lipid, 377
  microscopic sediment examination, 374–375
  monitoring of renal patients, 361, 362t–364t
  nitrites, 374
  parasites, 377
  pH, 368–369
  physical examination of urine, 362–365
  postglomerular proteinuria, 371–372
  preglomerular proteinuria, 370
  protein, 369–370, 372t
  red blood cells, 375
  reference intervals, 380–381
  sources of technical error, 375
  summary, 362
  timing, 362
  urine concentration and urine specific gravity, 365–367, 365t
  urine specific gravity, 374
  urobilinogen, 374
  yeast and fungi, 377
urinary protein:Ct ratio (UPC), 391
urinary system
  about, 343–344, 344t
  definitions
    azotemia, 388
    creatinine (Ct), 388
    nephrons, 389
    postrenal azotemia, 388–389
    prerenal azotemia, 388
    renal azotemia, 388
    renal disease, 389
    renal failure, 389
    renal insufficiency, 389
    urea nitrogen (UN), 387
    uremia, 388
  disease conditions, 391
  diseases/syndromes
    chronic kidney disease, 381–382, 382t
    diethylene glycol, 383
    ethylene glycol intoxication, 382–383
    Fanconi syndrome, 385
    medullary washout, 385
    neoplasms, 386
    Nephrotic syndrome, 385
    osmole gap, 383
    progressive familial renal nephropathy/dysplasia, 385–386
    renal lymphoma, 386
    transitional cell carcinoma, 386–387
    uroabdomen, 384–385
  glossary, 389
  images for, 392f–401f
  laboratory evaluation of renal function
    about, 344–346, 345f
    albumin, 360
    azotemia, 348–353, 349f, 351t
    blood gas, 359–360
    cholesterol, 360
    creatinine (Ct), 347–348, 347t
    electrolyte abnormalities, 354–355
    erythroid, 360
    fibrinogen, 360
    lipase and amylase in serum, 361
    packed cell volume, 360
    parathyroid hormone, 361
    phosphorus and calcium, 355–359
    potassium and magnesium, 359
    protein abnormalities, 360
    sodium and chloride, 359
    symmetric dimethylarginine (SDMA), 353–354, 354t
    urea nitrogen (UN), 346–347
    vitamin D, 361
  methods for analyzing renal function, 391
  principles, 389–391
  terms, 391
  urinalysis
    about, 361
    bacteria, 376–377
    bilirubin, 374
    blood (occult blood, heme), 372
    casts, 378
    chemical examination of urine, 367–368
    collection, 362
    crystalluria, 378–380
    debris, 377
    early detection of disease, 361
    enzymes, 381, 381f
    epithelial cells, 375–376
    expected volume in healthy dogs/cats, 362
    fractional excretion of electrolytes, 380
    glomerular proteinuria, 370–371
    glucose, 372–373
    images for, 392f–401f

urinary system (*continued*)
ketones, 373
leukocytes, 374, 375
lipid, 377
microscopic sediment examination, 374–375
monitoring of renal patients, 361, 362t–364t
nitrites, 374
parasites, 377
pH, 368–369
physical examination of urine, 362–365
postglomerular proteinuria, 371–372
preglomerular proteinuria, 370
protein, 369–370, 372t
red blood cells, 375
reference intervals, 380–381
sources of technical error, 375
summary, 362
timing, 362
urine concentration and urine specific gravity, 365–367, 365t
urine specific gravity, 374
urobilinogen, 374
yeast and fungi, 377
urinary tract infections, from fungal infections, 81
urine bile acid:Ct ratio, 391
urine bile acids (UBA), 439
urine concentration and urine specific gravity, in urinalysis, 365–367, 365t
urine cortisol:creatinine ratio (UCCR), for hyperadrenocorticism (HAC) (Cushing's syndrome), 543–544
urine cortisol:Ct ratio (UCCR), 391
urine glucose, 453–454
urine specific gravity, in urinalysis, 374
uroabdomen, 384–385, 391
urobilinogen, in urinalysis, 374
urogenital tract infections, 76
uroperitoneum, 391, 705t, 711, 711f

vacuolar change, of liver, 734–736, 735f–736f
vacutainer tubes, 30
vacuum tubes, 32, 32f
Venezuelan equine encephalitis, from viral infections, 83
venipuncture sites, recommended for diagnostic screening procedures, 32
ventral abdominal vein, for blood collection in amphibians, 330
ventral caudal vein, for blood collection in amphibians, 330
ventral coccygeal vein, for blood collection from reptiles, 294
vesicular disease, from viral infections, 83
vesicular stomatitis virus (VSV0), from viral infections, 83
Veterinary Cytology (Sharkey), 731
veterinary medicine, laboratory technology for, 3–29
viral inclusions, 97, 98f, 328–329
viral infections
about, 70
antibody detection, 72
direct fluorescent antibody testing, 71
electron microscopy, 71–72, 71f
ELISAs, 72
rapid point-of-care tests, 70–71
virus isolation, 72
virus neutralization, 72
virus isolation
for diagnosing viral infections, 82, 83
for viral infections, 72
virus neutralization (VN)
for antibody detection, 72
for viral infections, 72
viruses, blood destruction and, 131
visceral leishmaniasis, 495
viscosity/proteoglycan layer, 720–721, 720f–721f
visna-maedi, from viral infections, 83
vitamin D
function of, 410
hypercalcemia and, 583–584
renal function and, 361
toxicity of, 412
vitamin K antagonism, 216–217, 216f
vitamin K epoxide reductase, 216
volume, of synovial fluid, 717
vomition, chronic, 482
von Willebrand disease (vWd), 215
von Willebrand factor (vWf), platelet adhesion and, 202, 204f
vWf assays, 210–211

"Walmart" cascade, 206
wash buffer, 62
washing, immunoassays and, 61
water
assessment of body water, 403
balance in reptiles, 620
balance of, 402
dehydration and, 404
hypernatremia, 403–404
osmolality and, 403
water intoxication-induced hemolysis in calves, 131
water reabsorption, 390
waxy casts, 378
wedge biopsy, 34, 75
weight loss, chronic, 482
West Nile virus (WNV), from viral infections, 82
Western blots, for antibody detection, 72
western equine encephalitis, from viral infections, 83
wet mounts, 73
wet preparation, as screening test, 463
white blood cells (WBC)
in amphibians, 336–337, 337t
for birds, 274–277, 275t
differential leukocyte concentration and, 12
for fish, 323–326, 324t
in reptiles, 304–308, 305t–306t
White sturgeon, 320
Wilted red maple leaves *(Acer rubrum),* 128
Witness test, 62
wound infections, from bacterial infections/pathogens, 77, 78, 79, 80
wounds, as a clinical sample, 68t
Wright stain, 39, 67, 94–95, 94f–95f
Wright-Giemsa-stained fecal smear, 468f, 470f

xanthine, 380
xylitol toxicity, hypercalcemia and, 584
xylose absorption, screening tests for, 476

yeast and fungi, in urinalysis, 377
yellow lamb disease, 130
Yersinia pestis, 760
Yersinia spp., 80

zebras, plant toxins and, 128
zinc
as cause of Heinz body anemia, 129
toxicity of for dogs, 93
zinc sulfate turbidity test, 487, 495–496
Zoetis VetScan test, 62
Zygomycets, 81
