Contents

Contributors *ix*
Preface *xv*

1 Clinical Pharmacology *1*
Leigh A. Lamont and Kurt A. Grimm

2 Analgesia *43*
Douglas P. Whiteside and Kurt K. Sladky

3 Effective Anesthetic Monitoring *91*
Sathya Chinnadurai

4 Emergencies and Complications *103*
Nigel Caulkett, Søren Boysen, and Jon M. Arnemo

5 Remote Drug Delivery *121*
Ramiro Isaza

6 Invertebrates *139*
Sarah J. Wahltinez, Craig A. Harms, and Gregory A. Lewbart

7 Cartilaginous Fishes: Elasmobranchs and Holocephalans *167*
Natalie D. Mylniczenko, Charlene Burns, and Tonya Clauss

8 Bony Fish (Lungfish, Sturgeon, and Teleosts) *225*
Natalie D. Mylniczenko, Charlene Burns, Whitney Greene, and Tonya Clauss

9 Amphibians *347*
Amy B. Alexander and Eric Baitchman

10 Tortoises, Turtles, and Terrapins (Chelonians) *359*
Alessio Vigani and Darryl Heard

11 Snakes and Lizards (Squamates) *387*
Catherine J.A. Williams, Tobias Wang, and Mads F. Bertelsen

12 Venomous Reptile Restraint and Handling *407*
Frederick B. Antonio

13 Crocodilians (Crocodiles, Alligators, Caiman, and Gharial) *423*
Darryl Heard

14 **Crocodilian Capture and Restraint** *437*
Kent A. Vliet and Gen Anderson

15 **Cagebirds (Parrots and Perching Birds)** *451*
Michelle G. Hawkins and Peter J. Pascoe

16 **Pigeons and Doves (Columbiformes)** *513*
Darryl Heard

17 **Chickens, Quail, Turkeys, Pheasants, Peafowl, and Other Galliformes** *521*
Darryl Heard

18 **Raptors** *533*
Michelle Willette, Patrick Redig, Dana Franzen-Klein, and Julia Ponder

19 **Ratites** *553*
Jessica Siegal-Willott

20 **Penguins** *569*
Kate Bodley and Todd L. Schmitt

21 **Ducks, Geese, and Swans (Waterfowl)** *583*
Daniel Mulcahy and Darryl Heard

22 **Birds: Miscellaneous** *607*
Darryl Heard

23 **Mice, Rats, Guinea Pigs, Gerbils, Hamsters, Chinchillas, and Other Rodents** *615*
Darryl Heard

24 **Chiropterans (Bats)** *631*
Darryl Heard

25 **Rabbits, Hares, and Pikas** *643*
Marta Romano

26 **Marsupials** *671*
Peter Holz

27 **Echidnas and Platypus** *683*
Peter Holz

28 **African Pygmy Hedgehog and Other Insectivores** *687*
Darryl Heard

29 **Xenarthrans** *691*
Gianmarco Rojas Moreno

30 **Aardvarks** *707*
Felicia Knightly

31 **Lemurs** *713*
Catherine Williams and Randall E. Junge

32 Monkeys and Gibbons *723*
Rolf-Arne Ølberg and Melissa Sinclair

33 Apes *737*
Jennifer D'Agostino

34 Canids *755*
R. Scott Larsen and Anneke Moresco

35 Bears *775*
Nigel Caulkett and Jon M. Arnemo

36 Procyonids and Mustelids *785*
Noha Abou-Madhi

37 Viverrids and Herpestids *801*
Anneke Moresco and James G. Johnson III

38 Hyenas *813*
Nina Hahn, John M. Parker, Gregory Timmel, Mary L. Weldele, Wm. Kirk Suedmeyer, and Nigel Caulkett

39 Felids *821*
Andrew Cushing

40 Pinnipeds (Seals and Sea Lions) *833*
James E. Bailey and Shawn Johnson

41 Walrus *857*
Michael T. Walsh, James E. Bailey, and David B. Brunson

42 Sirenians (Manatees and Dugongs) *871*
Elizabeth C. Nolan, Michael T. Walsh, and James E. Bailey

43 Cetaceans *887*
James E. Bailey and Chris Dold

44 Elephants *925*
Jeffery R. Zuba and Khursheed R. Mama

45 Nondomestic Equids *965*
Chris Walzer

46 Tapirs *977*
Budhan Pukazhenthi, Rebecca Richard, Paulo Rogerio Mangini, and Dawn Zimmerman

47 Rhinoceroses *991*
Robin W. Radcliffe and Peter vdB. Morkel

48 Suids *1027*
Luis R. Padilla and Jeff C. Ko

49 Hippopotamidae *1043*
Michele A. Miller, David V. Cooper, and Peter E. Buss

50 Camelids *1055*
Khursheed R. Mama and Chris Walzer

51 Giraffidae *1069*
Scott B. Citino and Mitchell Bush

52 Deer *1081*
Nigel Caulkett and Jon M. Arnemo

53 Gazelles *1091*
Kristen A. Phair and Matthew Kinney

54 Antelopes *1113*
Elizabeth E. Hammond and Holly J. Haefele

55 Wild Sheep and Goats *1147*
Nigel Caulkett and Chris Walzer

56 Cattle and Buffalo *1155*
Julia E. Napier

57 Bison *1167*
Nigel Caulkett

Index *1173*

Preface

Welcome to the third edition of *Zoo Animal and Wildlife Immobilization and Anesthesia*. This edition was developed at a time of great clinical and research advances in the anesthesia of wildlife. The goal of this work was to develop a textbook that promotes best practices in anesthesiology and supports the efficient acquisition and sharing of knowledge. We realize there is some redundancy, but we have tried to reduce repetition wherever possible. Clinical problems are often managed differently, and we understand that clinical experience may influence the decision-making process in anesthesia. We hope that this textbook will also continue to help practitioners prepare for board certification.

We have many new contributors in the third edition, and this has offered a fresh point of view on many subjects.

We want to express our sincere appreciation to all of our contributors who have allowed us to deliver an outstanding new edition.

Gary West, Darryl Heard, and Nigel Caulkett

1

Clinical Pharmacology

Leigh A. Lamont and Kurt A. Grimm

Introduction

Pharmacology is the study of drugs and their interactions with organisms (Page & Maddison 2002). Pharmacology incorporates aspects of statistics, biochemistry, biology, pathology, and medicine. Failure to interpret the description of drugs' pharmacological properties in the context of the clinical picture (i.e., clinical pharmacology) can result in unintended outcomes.

The pharmacological data available for most drugs are mean values derived from a relatively small number of individuals (usually healthy individuals). While this approach provides a starting point for clinical use of drugs, individual responses can vary greatly due to disease states, body condition, environment, genetics, coadministered drugs, and many other factors. When the toxic dose is close to the therapeutic dose (as is often the case with drugs used for immobilization and anesthesia), careful titration of dose and patient monitoring are required. However, the nature of working with wildlife and captive nondomestic species often precludes baseline health assessment, individualization of dosing, and intensive patient monitoring. This is one factor associated with increased risk of adverse outcomes when capturing or anesthetizing nondomestic species. It should also be appreciated that advances in drug safety will likely result in only limited improvement of the safety of anesthesia and immobilization. Management of other risk factors through airway management, reduction of stress, and improvements in supportive care will also be beneficial.

Pharmacokinetics

Pharmacokinetics can be generally defined as what an organism does to a drug. Absorption, distribution, biotransformation, and elimination are processes which determine the concentration of drug at the site of action (i.e., biophase). Pharmacokinetic parameters are estimates of these processes in the group of animals studied. These estimates can be used to predict or understand the way a drug interacts with an organism. It is important to understand that pharmacokinetic parameters can vary between individual animals and can be influenced by many different drug- and organism-related factors. Additionally, pharmacokinetic parameters are derived using mathematical models selected by the investigator. There is usually no correlation between model components and anatomical structures.

Pharmacodynamics

Pharmacodynamics can be generally defined as what a drug does to an organism. Pharmacodynamics includes intended drug effects as well as adverse drug actions. Drugs such as opioids, alpha-2 adrenergic agonists, and antimuscarinics act by binding to relatively well-characterized receptor complexes located on cellular membranes and produce well-characterized effects. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin production by binding to cyclooxygenase enzyme isoforms. Relating plasma drug concentrations to observed NSAID actions can be complex in comparison to other drugs (e.g., opioids) due to the different nature of the action. Preexisting prostaglandins, as well as the slower process of inhibiting an enzyme system, confound the relationship between drug concentration and effect. The molecular and neurophysiologic actions of inhalant anesthetics, in contrast, have not been completely characterized even though the drugs have been used clinically for many years and their pharmacodynamic effects have been well described (Steffey et al. 2015).

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

Pharmacodynamic effects are predictable for most clinically used drugs. However, individual animal responses can vary considerably. Additionally, the nature of capture of free-ranging and captive wildlife often makes accurate dosing and drug delivery difficult or impossible. Therefore, close monitoring of patient response and preparation for supportive care are paramount to safe immobilization and anesthesia.

Inhalant Anesthetics

Inhalant anesthetics are commonly used in companion animal veterinary practice. Their use under field conditions is limited due to the requirement for specialized delivery devices and a supply of delivery gas (e.g., oxygen). However, inhalant anesthetics are used commonly in controlled settings such as zoological parks and research laboratories because of the ease of titration of anesthetic depth and rapidity of recovery. Inhalant anesthetics should be delivered by a well-maintained anesthetic machine and properly trained individuals. While inhalant anesthetics are relatively safe, their low therapeutic index mandates frequent and careful monitoring of anesthetic depth.

Physics of Gases and Vapors

An understanding of the processes which influence the uptake and delivery of inhalant anesthetics allows the anesthetist to predict and respond to individual circumstances.

Brief Review of Molecular Theory

Molecules in a liquid state have more vibrational energy than when in a solid state, and each molecule can move through the liquid. If heat is added to a liquid, each molecule gains more kinetic energy and eventually some overcome the forces exerted by their neighbors and escape into the space above the liquid. This state is that of a gas or a vapor. A gas is a phase of matter that expands indefinitely to fill a containment vessel. A vapor is the gaseous state of a material below its boiling point.

A vapor is in equilibrium with the liquid beneath it. Because both gaseous and liquid molecules have kinetic energy, they are in constant motion. The molecules in the vapor phase are striking the liquid–gas interface and returning to the liquid, while liquid molecules are leaving the interface to become vapor. The relationship between these two phases depends mainly on the physicochemical properties of the molecules and the temperature of the system.

Vapor Pressure

Molecules in a gaseous state possess kinetic energy and collide with the walls of the containment vessel. These collisions produce a force on the walls. This force is spread over a surface area and therefore is a pressure (pressure = force/area). This pressure is called the vapor pressure. Since kinetic energy increases directly with temperature, vapor pressure must always be given with reference to the temperature it was measured at (e.g., vapor pressure of water is 47 mmHg at 37°C).

When many gases are present in a mixture, such as with atmospheric air or during delivery of inhalant anesthetics, each gas has a vapor pressure that is independent of the other gases (Dalton's law of partial pressures). It is convention to refer to vapor pressure as partial pressure under these conditions. Partial pressure of an anesthetic agent is analogous to the concept of "free drug" and is important for determining the effect of the anesthetic (e.g., the level of central nervous system (CNS) depression correlates directly with the partial pressure of isoflurane within the brain) (see Table 1.1) (Steffey et al. 2015).

Vapor Concentration

Vapor (i.e., partial) pressure is important for the observed pharmacological effect of inhalant anesthetics. However, almost all anesthesiologists refer to the amount of anesthetic delivered in units of volumes % (said as volumes-percent), or just percent, which is a concentration. The fundamental difference between anesthetic partial pressure and anesthetic concentration is that partial pressure relates to the absolute number of molecules and their kinetic energy whereas concentration refers to the number of molecules of anesthetic relative to the total number of molecules present.

Table 1.1 Anesthetic agent vapor pressures at 20 and 24°C.

Anesthetic Agent	Vapor Pressure @ 20°C in mmHg	Vapor Pressure @ 24°C in mmHg
Methoxyflurane	23	28
Sevoflurane	160	183
Enflurane	172	207
Isoflurane	240	286
Halothane	243	288
Nitrous oxide	Gas	Gas

Critical Temperature

The critical temperature is the temperature above which a substance cannot be liquefied no matter how much pressure is applied. The critical temperature of nitrous oxide is 36.5°C. Consequently, nitrous oxide can be (and is) a liquid below this temperature, but is a gas at greater temperatures. Placing a nitrous oxide tank near a heat source will result in volatilization of liquid nitrous oxide, resulting in a high tank pressure and danger of explosion or tank venting.

The critical temperature of oxygen is −119°C, therefore at room temperature oxygen cannot be liquefied. All compressed cylinders of medical oxygen contain only gas. There are liquid oxygen tanks, but the internal tank temperature is below −119°C.

Henry's Law

Henry's law states the solubility of a gas in a liquid is proportional to the pressure of the gas over the solution. It describes the solubility of an anesthetic in body fluids or other liquids. From it you can derive the formula $c = k \cdot P$, where c is the molar concentration (mol/L) of the dissolved gas and P is the pressure (in atmospheres) of the gas over the solution. For a given gas k is the Henry's law constant and is dependent on temperature.

Partition Coefficient

A partition coefficient is the ratio of the concentration of a substance in one medium relative to another at equilibrium. It is related to the solubility of an agent. At equilibrium the partial pressure is the same throughout the body, including the alveolar gas, but the concentration of total drug may be very different due to partitioning into tissues or body fluids (Table 1.2) (Steffey et al. 2015). Partition coefficients are not absolute constants for an anesthetic agent. Tissue composition may change as a function of age, sex, body condition, etc. and these changes may influence partitioning.

Table 1.2 Selected partition coefficients of commonly used anesthetic agents.

Anesthetic	Blood:Gas Partition Coefficient	Brain:Blood Partition Coefficient
Nitrous oxide	0.47	1.1
Desflurane	0.42	1.3
Enflurane	2.00	1.4
Sevoflurane	0.68	1.7
Methoxyflurane	15.0	2.0
Isoflurane	1.46	2.7
Halothane	2.54	2.9

Mechanism of Action of Inhaled Anesthetics

The simplest definition of general anesthesia is a reversible drug-induced loss of consciousness (Franks 2006). All clinically used injectable and inhaled general anesthetics reversibly induce unconsciousness at low concentrations and induce an increasing lack of responsiveness at higher concentrations (Franks 2006). Though there are a number of other desirable clinical end-points including amnesia, analgesia, immobility and muscle relaxation (Brown et al. 2010), commonly used anesthetics vary in their ability to produce these effects. Consequently, any explanation of anesthetic mechanism of action must focus on unconsciousness as the critical end-point.

Despite their longstanding and widespread use, and well-characterized pharmacodynamic effects, the specific molecular and neurophysiologic mechanisms of action of general anesthetics are only now beginning to be elucidated thanks to research accumulated over the past 120 years.

The first widely accepted theory of general anesthesia was published by Meyer and Overton in 1901. They observed that most anesthetics were lipophilic and highly hydrophobic and noted a correlation between an anesthetic's potency and the agent's oil–gas partition coefficient (Meyer 1901; Overton 1901). The so-called Meyer–Overton correlation formed the basis for numerous lipid bilayer hypotheses of anesthetic action that dominated the literature until the 1970s.

Franks and Leib were among the first to question the unitary hypothesis that the lipid bilayer was the sole site of anesthetic action (Franks & Leib 1978). They subsequently published their seminal work demonstrating that the Meyer–Overton correlation was preserved for inhibition of firefly luciferase, a soluble lipid-free model protein (Franks & Lieb 1984), which gave rise to the protein receptor hypothesis of general anesthesia. While many potential protein targets have been studied, strong evidence for direct involvement in anesthetic-induced loss of consciousness currently exists for only three: gamma-aminobutyric acid subtype A ($GABA_A$) receptors, two-pore-domain potassium (2PK) channels, and N-methyl-D-aspartate (NMDA) receptors (Uhrig et al. 2014; Chau 2010; Franks 2008).

The $GABA_A$ family of receptors is responsible for most of the fast neuronal inhibition in the mammalian CNS and enhanced GABA-activated chloride currents cause hyperpolarization of neuronal membranes and reduce neuronal activity. Almost all general anesthetics have been found to potentiate GABA-induced chloride currents but are only

capable of directly activating $GABA_A$ receptors at much higher, clinically irrelevant concentrations. Several different mutations in the alpha subunits of the $GABA_A$ receptor have been shown to eliminate or reduce the effects of volatile anesthetics (Mihic et al. 1997; Krasowski & Harrison 2000; Jenkins et al. 2001, 2002; Nishikawa & Harrison 2003; Forman & Miller 2016), whereas those in the beta subunits can reduce the effects of both intravenous and volatile anesthetic agents (Krasowski & Harrison 2000). Experiments demonstrating a correlation between stereoselectivities seen in genetically modified animals in vivo and those found with extrasynaptic $GABA_A$ receptors in vitro provide convincing evidence that these receptors play an important role in volatile anesthetic-induced loss of consciousness (Franks 2008).

The 2PK channels are thought to provide "background" modulation of neuronal excitability. Five members of this channel family (TREK1, TREK2, TASK1, TASK3, and TRESK) can be directly activated by volatile anesthetics (Patel et al. 1999) but anesthetic sensitivity among these channels is not uniform. Anesthetic activation of 2PK channels generally inhibits neuronal activity by either hyperpolarizing the membrane and/or increasing membrane conductance, thus reducing the effects of excitatory currents (Franks 2008). However, these channels are also found presynaptically and their activation here may be inhibitory (if at an excitatory synapse) or excitatory (if at an inhibitory synapse). A growing body of evidence suggests these channels mediate at least some of the effects of volatile anesthetics (Franks 2008).

NMDA receptors mediate the slow components of synaptic transmission in the CNS and may be important targets for certain anesthetics. Both gaseous (i.e., xenon and nitrous oxide) and volatile (i.e., isoflurane, sevoflurane, halothane, and desflurane) inhaled anesthetics inhibit NMDA receptors to some extent but considerable variability exists among agents. Although it is likely that NMDA receptor antagonism plays a role in the actions of xenon and nitrous oxide and, to a lesser extent, the volatile agents, additional targets are required to account for their ability to cause loss of consciousness (Franks 2008).

Determining the cascade of events that follow binding of an anesthetic agent to its molecular target(s) leading to loss of consciousness has proven difficult. Remarkable advances in neuroscience and neuroimaging techniques (e.g., positron emission tomography, functional magnetic resonance imaging [fMRI], magnetoencephalography, and electroencephalography) over the past two decades are beginning to unravel the neural correlates of consciousness which will help answer this longstanding question.

Convergent evidence from multiple studies involving multiple species, multiple neuroimaging modalities, multiple analytic techniques, and diverse drug classes suggests that anesthetic-induced unconsciousness is characterized by a functional fragmentation (also referred to variably as a disconnection or uncoupling) of cortical and thalamocortical networks (Hudetz & Mashour 2016; Li et al. 2017; Mashour & Hudetz 2017). One specific cortical region, known as the lateral frontoparietal network, has received considerable attention over the last decade. Both fMRI and electroencephalographic studies of diverse classes of anesthetics, including volatile inhaled agents, consistently show a functional breakdown in frontoparietal connectivity and surrogates of frontoparietal information transfer (Hudetz & Mashour 2016; Mashour & Hudetz 2017). As our understanding of consciousness continues to evolve, traditional references to the "depth of anesthetic hypnosis" may require revision to reflect the fact that general anesthetics may variably suppress certain higher-order components of consciousness while retaining others (Sleigh et al. 2018).

Inhalant Anesthetic Pharmacokinetics

Anesthetic Uptake and Distribution

A series of partial pressure gradients, beginning at the vaporizer, continuing in the anesthetic breathing circuit, the airways, alveoli, blood, and ending in the tissues will drive the movement of an anesthetic gas. The movement of that gas will continue until equal partial pressures are present throughout the system. Since the lung is the point of entry and exit to the body, the alveolar partial pressure governs the partial pressure of the anesthetic in all body tissues. Therefore, it is most important to understand how to influence the alveolar partial pressure. Increasing alveolar minute ventilation, flow rates at the level of the vaporizer, and inspired anesthetic concentration can speed the delivery of anesthetic and increase the rate of rise of alveolar anesthetic partial pressure. Solubility, cardiac output, and the alveolar-to-venous anesthetic gradient are factors that determine the uptake of the anesthetic from the alveoli into the blood. Solubility describes the affinity of the gas for a medium such as blood or adipose tissue and is reported as a partition coefficient. The blood/gas partition coefficient describes how the gas will partition itself between the two phases (blood and alveolar gas) after equilibrium has been reached. Isoflurane, for example, has a blood/gas partition coefficient of approximately 1.46 (Steffey et al. 2015). This means that if the gas partial pressures are in equilibrium, the concentration in blood will be 1.46 times greater than the concentration in the alveoli. A higher blood/gas partition coefficient means a greater uptake of the gas into the blood, therefore a slower rate of rise of alveolar and blood partial pressure. Since the blood partial pressure rise is slower, it takes longer for the brain partial pressure of the gas to increase, resulting in a longer induction time.

Increased cardiac output exposes the alveoli to more blood per unit time. The greater volume of blood removes more inhalant anesthetic from the alveoli, therefore lowering the alveolar partial pressure. The agent might be distributed faster within the body, but the partial pressure in the arterial blood is lower. It will take longer for the gas to reach equilibrium between the alveoli and the brain, therefore a high cardiac output usually prolongs induction time. The alveolar to venous partial pressure difference reflects the tissue uptake of the inhaled anesthetic. A large difference is caused by increased uptake of the gas by the tissues during the induction phase.

Transfer of the gas from the arterial blood into tissues such as the brain will depend on perfusion and the relative solubility of the gas in the different tissues. The brain/blood coefficient describes how the gas will partition itself between the two phases after equilibrium has been reached. Isoflurane has a brain/blood coefficient of 2.7, therefore when the system is at equilibrium the concentration in the brain will be 2.7 times greater than the concentration in the blood (Steffey et al. 2015). All contemporary inhalation anesthetics have high adipose/blood partition coefficients. This means that most of the gas will accumulate in adipose tissue as times goes by. The partial pressure of the gas in adipose tissue will rise very slowly since this tissue has a high capacity (as indicated by the high adipose/blood partition coefficient). Inhalation anesthetics stored in obese patients may delay awakening at the end of long periods of anesthesia. Fortunately, adipose tissue has a relatively low blood flow and doesn't accumulate significant amounts of anesthetic during the short periods of anesthesia commonly encountered in veterinary medicine.

Elimination of Inhaled Anesthetics

The rate of induction and recovery from anesthesia with inhalant anesthetics differs between agents due to differences in tissue solubility, but general statements can be made. During induction all tissue partial pressures are zero. During recovery, different tissues in the body have different partial pressures of anesthetic, which are governed by the tissue anesthetic content and not the alveolar partial pressure. Recovery is not as controllable as induction of anesthesia. During recovery from anesthesia, elimination occurs due to exhalation and biotransformation.

The enzymes responsible for inhalant anesthetic metabolism are mainly located in liver and kidneys. Anesthetic elimination via metabolism is approximately 50% for methoxyflurane, 10–20% for halothane, 5–8% for sevoflurane, 2.5% for enflurane, about 0.2% for isoflurane, 0.001% for desflurane, and nearly zero for nitrous oxide (Steffey et al. 2015). The amount of anesthetic eliminated from the body during anesthesia due to metabolism is small compared with the amount exhaled. However, anesthetic metabolism accounts for a larger proportion of the anesthetic clearance after anesthetic delivery ceases. The low, but prolonged, blood partial pressure of the anesthetic found after terminating delivery is no longer overwhelming the enzyme systems (enzymes become saturated above ~1 MAC [minimum alveolar concentration]) so metabolism accounts for a larger proportion of clearance than it did during exposure to high partial pressures.

Elimination of the anesthetic via the lungs can be complex. The first point to consider is what effect an increase in alveolar minute ventilation will have on recovery. During recovery, increasing minute ventilation will decrease alveolar anesthetic partial pressure and increase the gradient for diffusion from the blood to the alveoli. This increases elimination, especially for most anesthetic agents with high blood/gas partition coefficients.

Another situation to consider is what effect a change in cardiac output will have on the rate of decrease of partial pressure of the inhalant anesthetic. During induction, high cardiac output will increase the rate at which anesthetic is removed from the lung, slowing the rate of rise of anesthetic partial pressure and slowing induction. When cardiac output is reduced (e.g., cardiogenic shock) there is a slower removal of anesthetic and subsequently a faster rate of rise of alveolar partial pressure and induction occurs. During recovery a high cardiac output will increase the rate at which anesthetic is returned to the lung for excretion. Since the partial pressure of anesthetic in the blood is determined by the tissues, the higher blood flow will shorten recovery. During low cardiac output situations there will be a slower recovery due to the decreased rate at which tissue anesthetic partial pressure decreases.

The last major influence on the rate of induction and recovery is the solubility of the anesthetic agent. Agents with high blood/gas solubility will be partitioned into the blood to a greater extent than agents with low blood/gas solubility. The blood acts as a depot for agent maintaining anesthetic partial pressure. Agents with low blood/gas solubility do not partition into the blood to the extent of highly soluble agents, thus the decrease in partial pressure is faster and recovery time is reduced. Highly soluble agents have high blood concentrations and it will take longer for the partial pressure to decrease if all other factors are equal. In summary, elimination of a volatile anesthetic depends on the ventilation, cardiac output, and solubility of the gas in blood and tissue.

Control of the Partial Pressure of Delivered Anesthetic

Inhalant anesthetics can be classified as either gaseous (nitrous oxide and xenon) or volatile (isoflurane, sevoflurane, halothane, methoxyflurane, and desflurane). Gaseous

anesthetics are usually delivered to the anesthesia machine under pressure and their rate of delivery to the breathing circuit is controlled by a flow meter. Volatile anesthetics are liquids at room temperature and pressure, and are usually delivered by a specialized apparatus that controls the volatilization of the liquid and proportioning of the vapor in the fresh gas delivered to the patient. A vaporizer can be as simple as piece of cotton soaked with agent held near the nose (not recommended) or can be as complex as the desflurane vaporizer, which is an electrically powered device with a heated vaporizing chamber.

The Breathing System

With most modern anesthetic machines the outflow gas from the vaporizer will be delivered to the patient through a set of tubes and machinery collectively called a breathing system. There are many styles of breathing systems, each with a multitude of uses. It is important that the anesthetist understands how the type of breathing circuit used will impact the rate at which the anesthetic concentration can be changed and the relationship between the vaporizer setting and inspired concentration.

Waste Anesthetic Gases

The health effects of chronic exposure to waste anesthetic gases are not completely known. The frequency of inhalant anesthetic use and the lack of significant associations between exposure and most types of chronic toxicities (e.g., cancer, infertility, birth defects, etc.) would suggest there is only a very low risk (if any) associated with chronic exposure. However, certain individuals are highly susceptible to potentially life-threatening reactions, even with trace level exposure (e.g., malignant hyperthermia). In light of this, and with the admission that we do not completely understand all the risks associated with chronic exposure, it is generally agreed that the exposure of personnel be kept as low as reasonably acceptable (ALARA). In the United States, the Occupational Safety and Health Administration requires veterinary hospitals to maintain a system to prevent waste gases from building up in the area of use and can enforce exposure limits that are consistent with guidance from the National Institute of Occupational Safety and Health (NIOSH). Currently, no NIOSH–recommended exposure limits exist for the three most currently used anesthetics (isoflurane, desflurane, and sevoflurane) and at present NIOSH has no published permissible exposure limits regulating these specific agents (American Veterinary Medical Association 2020).

Minimum Alveolar Concentration

Although loss of consciousness is arguably the most critical end-point of general anesthesia (see section on the inhaled anesthetic mechanism of action), it remains challenging to measure in a clinical setting. Immobility in the face of a noxious stimulus is also an important end-point and has formed the basis of the standard unit of inhaled anesthetic potency – minimum alveolar concentration (MAC) – since the 1960s (Merkel & Eger 1963). While our understanding of how inhaled anesthetics produce immobility continues to evolve (Eger et al. 2008), MAC remains the standard measurement of dose in clinical anesthesia. It is defined as the minimum alveolar concentration at 1 atmosphere required to prevent gross purposeful movement in 50% of the subjects tested, following a 60-second application of a supramaximal stimulus (Steffey et al. 2015). One MAC is by definition the EC_{50} (i.e., the effective concentration in 50% of patients) for that agent. Animals awaken from anesthesia at approximately 0.5 MAC, surgical anesthesia occurs at approximately 1.3 MAC, and severe autonomic nervous system depression occurs around 2 MAC.

Birds and many reptiles do not have true alveoli so the concept of MAC has been modified or redefined to be the minimum anesthetic concentration. It is not identical to MAC from other species, but closely approximates it in many ways.

Physiological and Pharmacological Factors That Alter MAC

Minimum alveolar concentration is age-dependent, being lowest in newborns, reaching a peak in infants, and then decreasing progressively with increasing age (Lerman et al. 1983, 1994; Taylor & Lerman 1991). Increases in MAC can also occur from hyperthermia and hypernatremia, and decreases in MAC can result from hypothermia, hyponatremia, pregnancy, hypotension, and drugs such as lithium, lidocaine, opioids, and alpha-2 adrenergic agonists.

General Pharmacological Actions of Inhalant Anesthetics

Inhalant anesthetic agents have more similarities than differences with respect to their effects on vital organ systems. The differences are primarily related to the speed and magnitude with which the changes occur. There are a few classic differences that have been included in the following synopsis.

Central Nervous System

All inhalant general anesthetics alter consciousness, memory, and pain perception by acting on the CNS. Most inhalant anesthetics cause a mild to moderate decrease in the cerebral metabolic requirement for oxygen ($CMRO_2$) and they usually have minimal effects on cerebral blood flow autoregulation at low MAC multiples (Mielck et al.

1998, 1999). Patients with intracranial hypertension should not be anesthetized with nitrous oxide because it may cause an increase in $CMRO_2$ (Roald et al. 1991; Algotsson et al. 1992; Hoffman et al. 1995). Halothane is also a poor choice because of its significant effects on cerebral blood flow autoregulation (Steffey et al. 2015). Isoflurane, sevoflurane, and desflurane are the inhalants of choice.

Cardiovascular System

Most inhalant anesthetic agents cause direct myocardial depression. Halothane is the most depressant on contractility, but it generally has the fewest effects on vascular resistance (Steffey et al. 2015). Isoflurane, enflurane, sevoflurane, and desflurane cause some degree of vasodilatation, which tends to improve forward blood flow and maintain tissue perfusion. The reduction in afterload also tends to offset some of the direct myocardial depressant effects and may result in a net improvement in cardiac output. Nitrous oxide is a sympathomimetic and can improve contractility, blood pressure, and heart rate at light levels of anesthesia. Rapid changes in anesthetic concentration (especially with desflurane) may result in a sympathetic response and temporarily increase cardiac work.

Respiratory System

All anesthetics tend to depress the chemoreceptor response to carbon dioxide, leading to an accumulation of carbon dioxide and a respiratory acidosis unless ventilation is assisted or controlled. The ether derivatives tend to be the most depressant, but all agents may cause significant depression. Most inhalant agents may interfere with hypoxic pulmonary vasoconstriction and may worsen ventilation-perfusion matching in the lung. This is most dramatic in larger animals, where significant pulmonary shunting is often observed.

Genital-Renal Systems

Most anesthetics cause a decrease in renal perfusion and an increase in antidiuretic hormone (ADH) secretion. Inhalant anesthetics may be the safest anesthetic techniques in anuric renal failure since pulmonary excretion is not dependent on renal function.

Inhalant anesthetics may cause an increase in postpartum uterine bleeding. This is a bigger consideration in primate anesthesia due to placentation characteristics. Isoflurane, sevoflurane, desflurane, and nitrous oxide have been advocated for use during Caesarian section because of the rapid onset and termination of effect, and the transient effects on the delivered fetuses. Methoxyflurane and halothane are less desirable due to their greater solubility and slower elimination.

Clinically Useful Inhalant Anesthetics

Nitrous Oxide

Nitrous oxide is commonly used in combination with a primary inhalant or injectable anesthetic drug. The reason it is not useful in veterinary anesthesia as a solo anesthetic is because of its low potency. Nitrous oxide's MAC value has been estimated to be near 100% for humans and closer to 200% for veterinary patients. It is obvious that 200% nitrous oxide cannot be delivered; in fact no more than 79% nitrous oxide can be safely delivered without creating a hypoxic gas mixture. In practice it is common to use a 50% nitrous oxide mixture with the balance of the mix being oxygen. If 50% nitrous oxide is delivered to an animal it is only providing approximately 0.25 MAC of anesthesia. A potent volatile anesthetic, injectable agent, or other sedative/analgesic drug must supply the remaining 0.75 MAC. Because of this limited anesthetic effect, nitrous oxide use for anesthetic maintenance is not widespread in veterinary medicine. Nitrous oxide is used by some anesthetists during induction of anesthesia for the *second gas effect*. Since nitrous oxide is present in the inspired gas mixture in a relatively high concentration and it rapidly diffuses into the body from the alveoli, the rate of rise of partial pressure of a second coadministered inhalant anesthetic is increased and the induction time can be shortened.

Nitrous oxide has a low blood/gas partition coefficient and has a rapid onset and recovery. The gas can diffuse out of the blood so rapidly that if nitrous oxide delivery is suddenly halted and supplemental oxygen is not administered, a situation known as *diffusion hypoxia* may result. Diffusion hypoxia happens when the mass movement of nitrous oxide down its partial pressure gradient results in high alveolar nitrous oxide partial pressure at the expense of oxygen and nitrogen partial pressures. Since breathing room air will result in an alveolar oxygen partial pressure of approximately 100 mmHg under ideal circumstances, any displacement of oxygen by nitrous oxide will result in alveolar hypoxia. Diffusion hypoxia can be minimized or prevented by continuing the administration of oxygen enriched gas for 5–10 minutes following the discontinuation of nitrous oxide. This helps because during normal breathing, 100% oxygen should result in an alveolar oxygen partial pressure close to 500 mmHg. The partial pressure of oxygen can drop a lot further before hypoxia develops.

Nitrous oxide is contraindicated in animals with pneumothorax, gastric dilatation/rumen tympany, gas embolism, and other conditions that are exacerbated by accumulation of gas inside a closed space. This effect is caused by diffusion of nitrous oxide out of the blood into the preexisting gas space in an attempt to establish equilibrium. Nitrous oxide is also contraindicated in animals with

gas diffusion impairment such as interstitial pneumonia. These animals typically have low arterial oxygen partial pressure when breathing oxygen-rich mixtures. The dilution of oxygen by nitrous oxide will lower the inspired oxygen partial pressure and may worsen hypoxemia.

Halothane

Halothane was a major advancement in inhalant anesthesia in its day. It was introduced in the late 1950s and was potent, nonirritating, and nonflammable. Chemically it is classified as a halogenated hydrocarbon and it is not chemically related to the ethers. Halothane was used widely in human anesthesia until it became apparent there were potentially fatal adverse effects associated with its use. Human patients developed a syndrome known as *halothane hepatitis* (Daghfous et al. 2003; Neuberger 1998). This rare, but life-threatening, complication is still somewhat of a mystery, although an immunological etiology is implicated. The disease appears as a fulminant hepatitis, similar to that seen with viral hepatitis, which develops after a short period of apparent recovery. A second, more common, form of hepatitis is less severe and is characterized by a reversible elevation in liver enzymes. The etiology of this second form is thought to be anesthetic-related hepatic hypoxia and does not appear to be immune related. Diagnosis of the correct form is important since repeated exposure to halothane, or any of the volatile agents producing trifluoroacetic acid, is more likely to trigger the immunologically mediated form and result in high morbidity and mortality. Both forms are not commonly documented in veterinary patients; however, transient elevation of liver enzymes may occur postoperatively in some patients. A thorough diagnostic workup is required due to the nonspecific and multifactorial etiology of elevated liver enzymes.

A second complication associated with halothane anesthesia is the development of arrhythmias. Halogenated hydrocarbon anesthetics, especially halothane, can sensitize the myocardium to the arrythmogenic effects of epinephrine. Halothane is generally contraindicated in patients that are predisposed to ventricular arrhythmias (e.g., hypoxia, trauma, or myocardial disease) (Steffey et al. 2015). Arrhythmias that develop during halothane anesthesia may resolve when the anesthetic agent is switched to isoflurane or sevoflurane. Other causes of perianesthetic arrhythmias should also be ruled out.

Halothane undergoes extensive hepatic metabolism (~20%) and is not chemically stable (Steffey et al. 2015). Commercially available halothane contains thymol, a preservative, which does not volatilize to the same degree as halothane. This results in a sticky residue inside the vaporizer that should be cleaned out during periodic maintenance. Veterinary use of halothane is declining due to the increasing popularity of isoflurane and sevoflurane, and its limited availability worldwide.

Isoflurane

Isoflurane is arguably the most widely used veterinary inhalant anesthetic in the world today. It is stable, potent, and undergoes little metabolism. Isoflurane can be irritating to airway tissues at high-inspired concentrations and its use for induction in people has been limited because of patient complaints and complications. However, in veterinary medicine isoflurane mask induction is still common. Isoflurane is a potent agent (MAC ~1.3% in dogs) and has a high saturated vapor pressure (~240 mmHg at room temperature) (Steffey et al. 2015). These characteristics, coupled with the fact that it is possible to cause rapid partial pressure changes in the brain, would suggest that only precision vaporizers located outside the circuit should be used to deliver the agent. However, several reports of the use of modified vaporizer inside circuit (VIC) vaporizers suggest that this type of anesthetic system can be used to safely administer the agent (Bednarski et al. 1993; Laredo et al. 1998).

Isoflurane metabolism is minimal (less than 1%) and fluoride-induced nephrotoxicity is uncommon. Isoflurane and many of the ether-derivative volatile agents are excellent vasodilators and can cause or worsen hypotension.

Desflurane

Desfluane use in veterinary medicine is limited to academic institutions and a very limited number of private practices. The main disadvantage to desflurane use is the cost associated with the agent and the cost associated with a specialized vaporizer that is required to deliver the drug. Desflurane is extremely insoluable and is capable of producing extremely rapid inductions and recoveries (Barter et al. 2004; Clarke 1999). Its main market is for human outpatient anesthesia, where rapid recovery is a large cost savings. It is highly fluorinated, has a very low potency (MAC ~9%), and has a high saturated vapor pressure (~670 mmHg at room temperature) (Steffey et al. 2015). Desflurane boils at 23°C and must be handled using specialized apparatus for vaporizer filling. The vaporizer is specific for desflurane and is electrically heated to boil the desflurane so that a reliable vapor pressure will be produced. Then sophisticated differential pressure transducers and electronic circuits calculate an injection ratio for delivery of the desired anesthetic concentration. Desflurane is very stable and undergoes almost no metabolism.

Sevoflurane

Sevoflurane is the newest volatile inhalant anesthetic approved for veterinary use. Sevoflurane has a low blood/gas partition coefficient (~0.7) which is greater than desflurane and nitrous oxide, but about half of that of isoflurane. Extensive pulmonary elimination of sevoflurane minimizes the amount available for metabolism. Up to 3–8% of the sevoflurane dose is metabolized and appears in the urine as inorganic fluoride (Steffey et al. 2015). This fluoride exposure does not appear to be clinically significant, although serum levels of fluoride can approach those previously reported to be nephrotoxic for methoxyflurane. Factors other than peak serum fluoride concentrations appear important for predicting the incidence of nephrotoxicity (Driessen et al. 2002).

Sevoflurane represents a deviation from the methyl ethyl ether structural theme present in other contemporary volatile anesthetics. Sevoflurane is chemically related to methyl-isopropyl ethers. The structure is significant because an important metabolite of most methyl-ethyl ether volatile anesthetic agents (trifluoroacetic acid) is a suspected trigger of halothane hepatitis. Sevoflurane cannot be metabolized to form this compound. This is not a major consideration in veterinary medicine but is important in human anesthesia. Sevoflurane is also pleasant and nonirritating when used for mask induction and many pediatric anesthesiologists suggest this agent is the drug of choice for pediatric induction via mask. Sevoflurane is less potent than isoflurane (MAC ~2.3% for dogs and horses). When used for induction of anesthesia it is common to use 7–9% sevoflurane.

An early subject of controversy surrounding sevoflurane anesthesia was the production of compound A. Compound A is a degradation product produced when sevoflurane reacts with the carbon dioxide absorbent. Early toxicology studies performed in rats suggested that proximal tubular renal damage could result from clinically relevant exposure to compound A. This led to the suggestion that sevoflurane should not be used in closed-circuit anesthesia or with fresh gas flow rates lower than 2 L per minute. However, since that time little clinical evidence of renal damage in humans and dogs has emerged, even with very low fresh gas flows. Some have suggested that rats have a 10–100 times higher level of the enzyme beta-lyase that is believed to convert the intermediate compounds of Compound A metabolism to a nephrotoxic molecule (Kharasch et al. 2005; Sheffels et al. 2004). Humans and dogs do not appear to have the same level of enzyme conversion and are therefore less susceptible to Compound A toxicity. Safety studies in most other rodents and exotic animals are not published and caution should be used when administering sevoflurane via a breathing system using a carbon dioxide absorbant until further safety data are available (Table 1.3).

Table 1.3 Structure and characteristics of inhalation anesthetics.

Agent	Year Introduced	Structure	Type
Halothane	1956	CF_3–CHClBr	Alkane
Isoflurane	1981	CF_3CHCl–O–CHF_2	Ether
Enflurane	1972	$CHClF$–CF_2–O–CHF_2	Ether
Methoxyflurane	1960	$CHCl_2$–CF_2–O–CH_3	Ether
Desflurane	1992	CF_3CHF–O–CHF_2	Ether

Injectable Anesthetics

Injectable anesthetics are an important family of compounds used for immobilization and anesthesia of wildlife. The dissociative anesthetics in particular are commonly combined with other adjunctive drugs such as alpha-2 adrenergic agonists and opioids to improve the reliability and speed of onset of action.

Barbiturates

Barbiturates can be classified in several ways. One is by chemical structure. Oxybarbiturates are historically important, but not commonly used today due to their slower onset of action, long recovery characteristics, and relatively small margin of safety. Pentobarbital is the prototypical oxybarbiturate. It has been combined with several adjunctive drugs for anesthesia. The thio (i.e., sulfur-substituted) analog of pentobarbital, thiopental, was commonly used in veterinary medicine for intravenous induction of anesthesia for many years but is no longer widley available.

Barbiturates cause anesthesia through global depression of CNS activity. This is accomplished through interference with nervous system impulse conduction. Like many other anesthetics, other excitable tissues can be affected, resulting in commonly encountered side effects, including depression of cardiorespiratory function. Barbiturates decrease cerebral blood flow (CBF) and the $CMRO_2$. $CMRO_2$ decreases progressively until electroencephalographic activity becomes isoelectric (Branson 2007).

Propofol

Propofol (2,6-di-isopropylphenol) is commonly used for sedation, induction, and maintenance of anesthesia in humans and domestic species. Propofol is supplied as a milky white liquid for intravenous injection. It is insoluble in aqueous solution therefore it is usually formulated as an emulsion of 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide. Some formulations of propofol (e.g., Diprivan®, Propoflo™) do not contain preservative and will support bacterial and fungal growth should the drug become contaminated. This has led to the label recommendation of discarding unused drug at the end of the procedure or within 6 hours of opening a vial. Other formulations have additives such as benzyl alcohol (e.g., PropoFlo28®) to improve stability or reduce the potential of contamination with storage. Species-sensitivities to these additives should be investigated before their use (Davidson 2001).

Propofol is classified as an ultrashort-acting injectable anesthetic agent. Duration of effect is typically 5–10 minutes in dogs and 5–20 minutes in cats. Its rapid recovery characteristics are maintained in most species following prolonged infusions. Recovery times may be prolonged in the cat (and other species that have reduced capacity for glucuronidation of drugs) following repeated doses or continuous rate infusions.

Propofol has been used in dogs, cats, horses, pigs, goats, sheep, and even birds. Wild turkeys, mallard ducks, pigeons, and chickens have been anesthetized with propofol, but there is significant cardiorespiratory depression in ducks and chickens, indicating birds may need ventilatory support during anesthesia (Machin & Caulkett 1998). Apnea and respiratory depression are the best known side effects of propofol administration. The incidence of apnea may be reduced by administering the drug over 60–90 seconds (Muir & Gadawski 1998). It would be prudent to be prepared to intubate and support ventilation if apnea occurs. Pain is reported on propofol injection by some people. Muscle fasciculations and spontaneous twitching can occur in some animals.

Dissociative Anesthetics

Ketamine

Most veterinary formulations of ketamine are a racemic mixture consisting of two optical enantiomers. However, in many countries (*S*)-ketamine is available as a human or veterinary product. The *S* enantiomer is less cardiodepressant and has a four-fold greater affinity for the phencyclidine site in the NMDA receptor. Serotonin transport is inhibited two-fold by the *R* form. Some of ketamine's effects are not stereoselective. Norepinephrine release is equivalent from the *S* and *R* forms (Kohrs & Durieux 1998).

Ketamine can be administered intramuscularly to anesthetize animals which are not easily given drugs intravenously. Intramuscular administration will produce a longer duration of anesthesia than intravenous administration, but the recovery is usually longer and can be accompanied by more dysphoria. Recovery from ketamine appears to be due to redistribution and metabolism similar to the thiobarbiturates. Hepatic biotransformation to norketamine (metabolite I) and dehydronorketamine (metabolite II) is the major route of metabolism in most species studied. It was thought ketamine was excreted unchanged in the urine of cats, but this originated from one paper published in 1978 by Gaskell et al. and since that time it has been shown by Waterman that biotransformation is an important route of elimination in domestic cats (Waterman 1983). Norketamine is about one-third to one-fifth as potent as the parent compound but may contribute to the prolonged analgesic effects of ketamine (Kohrs & Durieux 1998).

Ketamine produces a form of anesthesia that is different from other hypnotic drugs. In general terms, ketamine induces anesthesia and amnesia by functional disruption (dissociation) of the CNS through marked CNS stimulation resulting in catalepsy, immobility, amnesia, and marked analgesia. Electroencephalographic analysis indicates that depression of the thalamoneocortical system occurs in conjunction with activation of the limbic system. Awakening from ketamine anesthesia in people is frequently characterized by disagreeable dreams and hallucinations. Sometimes these unpleasant occurrences may recur days or weeks later. Almost half of adults over the age of 30 exhibit delirium or excitement, or experience visual disturbances. The occurrence of adverse psychological experiences is much lower in children. The incidence of adverse psychological experiences in animals is unknown, but a significant number of animals transiently vocalize and have motor disturbances during recovery.

Ketamine's neuropharmacology is complex. The compound interacts with NMDA and non-NMDA glutamate receptors, nicotinic, muscarinic cholinergic, monoaminergic, and opioid receptors. In addition there are interactions with voltage-dependent ion channels such as Na^+ and L-type Ca^{2+} channels. It is believed that the NMDA receptor antagonism accounts for most of the analgesic, amnestic, psychomimetic, and neuroprotective effects of the compound, but the exact mechanism of its anesthetic action is not known. NMDA receptor activation is believed to play a role in the "memory" of the CNS, which is involved in the "wind-up," hyperalgesia, and allodynia seen in certain pain syndromes (Kohrs & Durieux 1998).

Ketamine can increase the $CMRO_2$ due to increased metabolic activity associated with increased activity in certain

areas of the brain. Intracranial pressure (ICP) also increases, possibly because of two mechanisms: (1) ketamine can increase mean arterial blood pressure so CBF can increase and ICP can passively increase in patients with altered autoregulation, and (2) ketamine can depress respiration, increasing the arterial partial pressure of carbon dioxide $PaCO_2$. The brain responds to elevations in $PaCO_2$ by increasing CBF, which will increase ICP. Ventilation may reduce the increase in CBF. Current clinical dogma dictates avoiding ketamine in patients with suspected head trauma.

Ketamine causes a characteristic breathing pattern termed *apneustic breathing*, characterized by prolonged inspiratory duration and relatively short expiratory time. When ketamine is administered by itself, it typically causes minimal respiratory depression that is short-lived. Hypoxic and hypercapnic respiratory regulation appears to remain intact, but ketamine is seldom given alone. It is often combined with benzodiazepines, acepromazine, opioids, or alpha-2 adrenergic agonists. The combined effect of these drugs is usually decreased minute ventilation, increased $PaCO_2$, and mild respiratory acidosis.

Ketamine, when given to animals with functioning sympathetic nervous systems, generally increases heart rate and arterial blood pressure. Cardiac output will usually stay the same or slightly increase. Ketamine is seldom given alone to healthy animals. The use of adjunctive drugs, such as benzodiazepines, acepromazine, or alpha-2 adrenergic agonists, tends to blunt the sympathomimetic effect of ketamine and will tend to decrease cardiac function and decrease arterial blood pressure.

Tiletamine/Zolazepam

Tiletamine/zolazepam combinations are available in a fixed ratio. Telazol® is a non-narcotic, nonbarbiturate, injectable anesthetic agent. Chemically, Telazol® is a combination of equal parts by weight of tiletamine hydrochloride (2-[ethylamino]-2-[2-thienyl]-cyclohexanone hydrochloride), an arylaminocycloalkanone dissociative anesthetic, and zolazepam hydrochloride (4-[o-fluorophenyl]-6,8-dihydro-1,3,8-trimethylpyazolo[3,4-e][1,4]diazepin-7[1H]-1-hydrochloride), a benzodiazepine having minor tranquilizing properties. The product is supplied sterile in vials, each containing a total of 500 mg of active drug as free base equivalents and 288.5 mg of mannitol. The addition of 5 mL of diluent produces a solution containing the equivalent of 50 mg of tiletamine base, 50 mg of zolazepam base and 57.7 mg of mannitol per milliliter. The resulting solution has a pH of 2–3.5. Zoletil® is available in many countries outside North America and is commonly marketed as a mixture containing 25 mg/mL each of zolazepam and tiletamine (Zoletil 50®) or 50 mg/mL each (Zoletil 100®).

Duration of effect is dependent on the route of administration and amount of drug given. When used intravenously it lasts approximately 15–20 minutes. When given intramuscularly it may last 30–45 minutes. It is commonly used in place of ketamine and its duration is typically longer.

Tiletamine induces dissociative anesthesia similar to ketamine. It has the potential to cause seizure activity, but when combined with zolazepam the incidence of seizures is greatly reduced. Its effects on CBF and ICP are similar to those of ketamine. Nephrotoxicity in New Zealand white rabbits has been reported following Telazol® administration (Doerning et al. 1992). Anecdotally, tigers do not appear to recover well after tiletamine/zolazepam therefore its use is generally contraindicated. Tiletamine/zolazepam can be combined with other drugs to improve its analgesic and recovery characteristics.

Miscellaneous Anesthetics

Etomidate

Etomidate has been used extensively as a hypnotic agent for the induction of anesthesia in humans, but less commonly in other species. Etomidate is a rapidly acting, ultrashort acting imidazole derivative. The duration of effect following intravenous bolus administration is typically 5–10 minutes. Etomidate causes dose-dependent CNS depression leading to sedation, hypnosis, and finally an isoelectric electroencephalogram.

Etomidate, in contrast to almost all other induction agents, does not seem to cause significant depression of cardiac contractility and has minimal effects on heart rate, cardiac output, and arterial blood pressure. Elimination of etomidate occurs by ester-hydrolysis in plasma and in the liver at approximately equal rates. Metabolism of etomidate in the liver is a capacity-limited Michaelis–Menten process. Hepatic hydrolysis results in the corresponding inactive carboxylic acid. Etomidate will temporarily reduce steroidogenesis (Boidin 1985; Moon 1997). Steroid synthesis usually increases with the stress of anesthesia so the net effect may be little or no change (Dodam et al. 1990). It is not a clinical contraindication except for animals with hypoadrenocorticism (Addison's disease). Intravenous administration of etomidate may induce excitement, myoclonus, pain on injection, vomiting, and apnea during induction of anesthesia. Some animals may have purposeless myoclonic muscle movements during recovery from anesthesia. The frequency and severity of the side effects can be attenuated or eliminated by the administration of adjunctive drugs such as diazepam, acepromazine, or opioids prior to etomidate administration. A constant rate infusion of etomidate may result in hemolysis (Van de Wiele et al. 1995; Moon 1994). This is thought to be due to

the propylene glycol carrier and the very high osmolality of available products (Doenicke et al. 1997).

Alfaxalone

Alfaxan®

Alfaxalone is a synthetic neurosteroid anesthetic with a relatively wide margin of safety and little cardiovascular or respiratory depression. Due to its poor water solubility, earlier formulations (Saffan®) were a mixture of alfaxalone and alfadolone combined with cremophor EL® as a solubilizing agent. Adverse effects, including histamine release and anaphylactic reactions associated with Cremophor, led to the withdrawal of that product from the market. A novel formulation of alfaxalone, Alfaxan-CD®, was released in Australia in 2001, in the United Kindgom in 2007, in Europe in 2008, in Canada in 2011, and in the United States in 2012. It is a 1% aqueous solution with a pH of 6.5–7.0 containing a non-cremophor vehicle (2-hydroxypropyl-β-cyclodextrin) which does not cause histamine release. The drug is approved for induction and maintenance of general anesthesia in dogs and cats via intravenous administration and has also been approved for intramuscular administration in some countries. Until recently, Alfaxan® was exclusively supplied as a 10-mL vial without added antimicrobial preservatives. This resulted in a shelf-life of only 6 hours and a label recommendation to discard unused drug within this timeframe (Berry 2015). A newer multidose formulation containing the preservatives ethanol, chlorocresol, and benzethonium chloride has recently been approved and appears to have the same efficacy and safety as the preservative-free formulation but offers the advantage of a 28-day shelf-life.

Like other injectable anesthetics, alfaxalone produces its clinical effects via potentiation of GABA at $GABA_A$ receptors in the CNS, resulting in modulation of chloride transport and neuronal hyperpolarization (Berry 2015). After intravenous administration, it produces rapid onset of action and satisfactory muscle relaxation but has no significant analgesic effects. In dogs and cats, it undergoes rapid hepatic metabolism, has a relatively short half-life, and does not accumulate after repeated dosing (Ambros et al. 2008; Ferre et al. 2006; Whittem et al. 2008).

Depending on the species and country-specific labelling, alfaxalone can be used for intramuscular sedation or premedication, for intravenous induction of anesthesia prior to transfer to an inhaled agent, or for intravenous maintenance of anesthesia via intermittent boluses for short procedures or via continuous rate infusion (CRI) for longer procedures. Other off-label routes of administration have been reported, including subcutaneous injection in various domestic and exotic species, intraperitoneal injection in laboratory animals, and immersion/irrigation in fish and amphibians.

Premedication or coadministration with a sedative and/or analgesic is recommended to reduce the dose of alfaxalone required, provide analgesia, and smooth recovery, which can otherwise be rough. Paddling, vocalization, rigidity, myoclonus, and trembling have been reported in dogs and cats recovering from alfaxalone that did not receive other drugs concurrently (Berry 2015). Also, with intramuscular administration, the relatively large volume of alfaxalone required can be a limiting factor and coadministration of more potent sedative and/or analgesic agents may help overcome this.

Alfaxalone produces dose-dependent respiratory depression and apnea is common after rapid intravenous injection of clinically relevant doses (Muir et al. 2008, 2009). Slow injection over 60 seconds is recommended and the anesthetist should be prepared to intubate, provide supplemental oxygen, and support ventilation when administering alfaxalone. Cardiac output and arterial blood pressure remain generally stable after administration of clinically appropriate doses in healthy patients, although caution should be exercised when administering alfaxalone to patients with limited cardiac reserve capacity or hemodynamic instability.

In addition to dogs and cats, off-label alfaxalone use has been reported in many other domestic species and exotic pets, including horses, sheep, swine, rabbits, ferrets, rodents (excluding mice, rats, guinea pigs, chinchillas), birds (excluding budgerigars and finches), reptiles (excluding lizards, turtles, tortoises, and snakes), and amphibians (excluding frogs, toads, and axolotls). It has also been used in a diverse range of captive zoo species (excluding civet cats, macaques, sea lions, crocodiles, pythons, flamingos, parrots, blue crabs, carp, and tarantulas); as well as in free-ranging wildlife (excluding deer, bighorn sheep, seals, koalas, wallabies, and river turtles).

Opioids

All drugs classified as opioids are chemically related to a group of compounds which have been purified from the juice of a particular species of poppy, *Papaverum somniferum*. The unrefined extract from the poppy is called opium and contains approximately 20 naturally occurring pharmacologically active compounds, including morphine and codeine. In addition, numerous semisynthetic and synthetic analogs of these natural compounds have been developed for clinical use. The word "opioid" is typically used to encompass all chemical derivatives of the compounds purified from opium and will be the term used to describe this class of analgesics throughout this section.

The opioids are a versatile group of drugs with extensive applications related to the management of pain in companion animal veterinary medicine. In the past, their use in wild and exotic species has been largely limited to the ultra-potent agents utilized in remote capture techniques. However, with the rapid evolution of zoo animal medicine and surgery, the opioids are being used increasingly as analgesics for the management of surgical pain in a wide variety of species. Although there are few pharmacokinetic or pharmacodynamic studies involving opioids in wild and exotic animals, a general discussion of opioid pharmacology is relevant and may facilitate extrapolation from companion animal species.

Opioid Receptors

It is well known that exogenously administered opioids such as morphine or heroin exert their effects by interacting with specific opioid receptors and mimicking naturally occurring molecules known as endogenous opioid peptides. It is now accepted that there are three well-defined types of opioid receptors, most commonly known by their Greek letter designations as μ (mu), δ (delta), and κ (kappa) (Harrison et al. 1998; Kieffer 1999; Janecka et al. 2004; Inturrisi 2002). This classic system of nomenclature has been under reconsideration for a number of years and during this time several alternative naming systems have been proposed, leading to considerable confusion. In addition, a fourth type of opioid receptor, the nociceptin receptor (also known as the orphanin FQ receptor), has been characterized (Moran et al. 2000; Smith et al. 2001). According to the most recent recommendations of the International Union of Basic and Clinical Pharmacology Committee on Receptor Nomenclature and Drug Classification (NC-IUPHAR), variations based on the Greek letters remain acceptable. Thus, mu, μ, or MOP (for "mu opioid peptide"); delta, δ or DOP (for "delta opioid peptide"); kappa, κ or KOP (for "kappa opioid peptide"); and NOP (for "nociceptin opioid peptide") are considered interchangeable abbreviations. Distinct cDNA sequences have been cloned for all four opioid receptor types, and each type appears to have a unique distribution in the brain, spinal cord, and periphery (Smith & Lee 2003).

The diversity of opioid receptors is further extended by the existence of several subtypes of μ, δ, and κ receptors. Based on pharmacologic studies, there are thought to be at least three μ receptor subtypes, μ_1, μ_2, and μ_3; two δ receptor subtypes, δ_1, and δ_2; and perhaps as many as four κ receptor subtypes, κ_{1a}, κ_{1b}, κ_2, and κ_3 (Smith & Lee 2003) The discovery of opioid receptor subtypes generated great enthusiasm among researchers and introduced the possibility of developing subtype-specific therapeutic agents with favorable side-effect profiles. At this point, however, the functional significance of these receptor subtypes remains unclear and distinct cDNA sequences corresponding to these subtypes have not yet been identified (Smith & Lee 2003).

In general, it appears that the μ receptor mediates most of the clinically relevant analgesic effects, as well as most of the adverse side effects associated with opioid administration (Kieffer 1999). Drugs acting at the δ receptor tend to be poor analgesics but may modify μ receptor-mediated antinociception under certain circumstances and mediate opioid receptor "cross-talk". The κ receptor mediates analgesia in several specific locations in the CNS and the periphery, but distinguishing μ- and κ-mediated analgesic effects has proven to be difficult (Kieffer 1999; Smith & Lee 2003). In contrast to the classic opioid receptors, the nociceptin receptor does not mediate typical opioid analgesia, but instead produces anti-opioid (pro-nociceptive) effects (Janecka et al. 2004; Moran et al. 2000; Smith et al. 2001). Due to the considerable structural homology between the three classically described opioid receptors, it is likely that there are significant interactions between these receptors in different tissues, and the loosely defined physiologic roles ascribed to each receptor type still require further clarification.

Endogenous Opioid Receptor Ligands

The opioid receptors discussed above are part of an extensive opioid system that includes a large number of endogenous opioid peptide ligands. Endogenous opioid peptides are small molecules that are naturally produced in the CNS and in various glands throughout the body, such as the pituitary and the adrenal (Janecka et al. 2004). Three classical families of endogenous opioid peptides have been identified: the enkephalins, the dynorphins, and β-endorphin. Each of these is derived from a distinct precursor polypeptide, pro-enkephalin, pro-dynorphin, and pro-opiomelanocortin, respectively (Janecka et al. 2004). These classical endogenous opioid peptides are expressed throughout the CNS and their presence has more recently been confirmed in peripheral tissues as well (Janecka et al. 2004). There are considerable structural similarities between these three groups of peptides, and each family demonstrates variable affinities for μ, δ, and κ receptors. None of them bind exclusively to a single opioid receptor and none of them have any significant affinity for the nociceptin receptor. The physiologic roles of these peptides are not completely understood at this time. They appear to function as neurotransmitters, neuromodulators and, in some cases, as neurohormones. They mediate some forms

of stress-induced analgesia and play a role in analgesia induced by electrical stimulation of discrete regions in the brain, such as the periaqueductal gray of the mesencephalon (Inturrisi 2002).

Nociceptin (also known as orphanin FQ) is the endogenous ligand for the more recently discovered nociception receptor. Nociceptin is derived from pro-nociceptin, and its amino acid sequence is closely related to that of the classical endogenous opioid peptides discussed above (Janecka et al. 2004; Moran et al. 2000). Despite this homology, nociception binding is specific for the nociception receptor and the peptide does not appear to interact with μ, δ, or κ receptors. Furthermore, the physiologic effects of nociceptin are in direct contrast to the actions of the classical endogenous opioid peptides, with nociception producing a distinctly pro-nociceptive effect (Janecka et al. 2004; Moran et al. 2000; Smith 2001). The functional significance of nociception and its receptor remains to be elucidated, but additional insight into this novel opioid peptide may have substantial implications in future therapeutic drug development.

In addition to the enkephalins, dynorphins, β-endorphin, and nociception, there are now two other discovered endogenous opioid peptides called endomorphin-1 and endomorphin-2 (Zadina et al. 1990). These peptides are putative products of an, as yet, unidentified precursor and have been proposed to be the highly selective endogenous ligands for the μ receptor (Janecka et al. 2004; Zadina et al. 1990). The endomorphins are small tetrapeptides that are structurally unrelated to the classical endogenous opioid peptides (Zadina et al. 1990). Their identification has heralded a new era in research of the μ opioid system which may contribute to our understanding of the neurobiology of opioids, and provide new avenues for therapeutic interventions.

Another endogenous opioid receptor agonist, dermorphin, was discovered in the early 1980s in the skin of a South American frog species belonging to the genus Phyllomedusa. Dermorphins are full μ receptor agonists with approximately 30–40 times the potency of morphine. Shortly after the discovery of amphibian dermorphin, another endogenous opioid, deltorphin, was isolated and shown to act as an agonist at δ receptors. These natural opioid peptides appear to be unique to amphibians and, although their functional role is not entirely clear, it has been speculated that they may be involved in protection from predators and/or hibernation (Mosely & Mosely 2015). While the discovery of the dermorphins generated initial interest as potential clinical analgesic agents, little work has been done in recent years. Dermorphin has been used illegally in horse racing as a performance-enhancing drug (Robinson et al. 2015).

Opioid Receptor Signaling and Mechanisms of Analgesia

Binding of an opioid agonist to a neuronal opioid receptor, regardless of whether the agonist is endogenous or exogenous, typically leads to several events that serve to inhibit the activation of the neuron. Opioid receptors are part of a large superfamily of membrane-bound receptors that are coupled to G-proteins (Smith & Lee 2003). As such, they are structurally and functionally related to receptors for many neurotransmitters and other neuropeptides which act to modulate the activity of nerve cells. Opioid receptor binding, via activation of various types of G-proteins, may lead to inhibition of adenylyl cyclase (cAMP) activity, activation of receptor-operated K^+ currents, and suppression of voltage-gated Ca^{2+} currents (Inturrisi 2002).

At the pre-synaptic level, decreased Ca^{2+} influx will result in reduced release of transmitter substances, such as substance P, from primary afferent fibers in the spinal cord dorsal horn, thereby inhibiting synaptic transmission of nociceptive input (Inturrisi 2002). Post-synaptically, enhanced K^+ efflux will result in neuronal hyperpolarization of spinal cord projection neurons and inhibition of ascending nociceptive pathways. A third potential mode of opioid action involves upregulation of supraspinal descending antinociceptive pathways in the periaqueductal gray. It is now known that this system is subject to tonic inhibition mediated by GABAergic neurons, and opioid receptor activation has been shown to suppress this inhibitory influence and augment descending antinociceptive transmission (Inturrisi 2002; Christie et al. 2000). The proposed cellular basis for this involves μ receptors present on pre-synaptic GABAergic nerve terminals which activate voltage-dependent K^+ currents and thereby inhibit GABA release into the synaptic cleft (Christie et al. 2000). It is important to note that while our collective understanding of opioid receptor-mediated signaling has increased dramatically in recent years, the relationship of such subcellular events to clinical analgesia at the level of the organism requires further clarification.

Opioid Receptor Distribution and Therapeutic Implications

While cellular and molecular studies of opioid receptors and ligands are invaluable in understanding their function, it is critical to place them in their anatomical and physiologic context to fully appreciate the opioid system and its relevance to pain management. It has long been a principle tenet of opioid analgesia that these agents are centrally acting, and this understanding has shaped the way we use opioid analgesics clinically. It has been well

established that the analgesic effects of opioids arise from their ability to directly inhibit the ascending transmission of nociceptive information from the spinal cord dorsal horn, and to activate pain control circuits that descend from the midbrain via the rostral ventromedial medulla to the spinal cord. Within the CNS, evidence of μ, δ, and κ opioid receptor mRNA and/or opioid peptide binding has been demonstrated in supraspinal sites, including the mesencephalic periaqueductal gray, the mesencephalic reticular formation, various nuclei of the rostral ventromedial medulla, forebrain regions including the nucleus accumbens, as well as spinally within the dorsal horn (Gutstein & Akil 2001; Yaksh et al. 1998). The interactions between groups of opioid receptors at various spinal and supraspinal locations, as well as interactions between different receptor types within a given location, are complex and incompletely understood at this time.

Systemic administration of opioid analgesics via intravenous, intramuscular, or subcutaneous injection will result in a relatively rapid onset of action via interaction with these CNS receptors. Oral, transdermal, rectal, or buccal mucosal administration of opioids will result in variable systemic absorption, depending on the characteristics of the particular agent, with analgesic effects being mediated largely by the same receptors within the CNS. In addition, neuraxial administration, into either the subarachnoid or epidural space, is a particularly efficacious route of administration. Small doses of opioids introduced via these routes readily penetrate the spinal cord and interact with spinal and/or supraspinal opioid receptors to produce profound and potentially long-lasting analgesia, the characteristics of which will depend on the particular drug utilized.

Despite the fact that opioids have long been considered the prototype of centrally acting analgesics, a body of evidence has emerged over the past decade which clearly indicates that opioids can produce potent and clinically measurable analgesia by activation of opioid receptors in the peripheral nervous system (Stein et al. 2001). Opioid receptors of all three major types have been identified on the processes of sensory neurons, and they respond to peripherally applied opioids and locally released endogenous opioid peptides when upregulated during inflammatory pain states (Stein 1993; Stein et al. 1993, 2001, 2003; Fields et al. 1980). Furthermore, sympathetic neurons and immune cells have also been shown to express opioid receptors, but their functional role remains unclear (Stein et al. 2003). While the binding characteristics of peripheral and central opioid receptors are similar, the molecular mass of peripheral and central μ opioid receptors appears to be different, suggesting that selective ligands for these peripheral receptors could be developed which would produce opioid analgesia without the potential to induce centrally mediated adverse side effects (Stein 1995, Stein & Yassouridis 1997; Stein et al. 1996, 2001, 2003).

Adverse Effects of Clinically Used Opioids

While opioids are used clinically primarily for their pain-relieving properties, they also produce a host of other effects on a variety of body systems. This is not surprising in light of the wide distribution of endogenous opioid peptides and their receptors in supraspinal, spinal, and peripheral locations. Since information regarding opioid side effects in most wild and exotic animals is lacking, reference is made to common domestic species where appropriate.

Central Nervous System

Level of Arousal

There are considerable species differences in the CNS response to opioid analgesics that cannot be attributed to pharmacokinetic variations alone. CNS depression (i.e., sedation) is typically seen in the dog, monkey, and human, while CNS stimulation (i.e., excitement and/or spontaneous locomotor activity) may be elicited in the cat, horse, goat, sheep, pig, and cow following systemic administration of various opioids, most notably morphine (Branson et al. 2001). The reasons for these different responses are not entirely clear at this time, but are presumably related to differing concentrations and distributions of μ, δ and κ receptors in various regions of the brain in these species (Hellyer et al. 2003). Details regarding the CNS responses of specific wild and exotic species to opioids are not yet known. Regardless of the species, however, there are numerous factors which may play a role, including the temperament or condition of the animal, the presence or absence of pain in the animal, the dose, route and timing of drug administration, and the specific opioid administered.

Thermoregulatory Center

The hypothalamic thermoregulatory system is also affected by opioid administration. Hypothermia tends to be the most common response, particularly when opioids are used during the perioperative period in the presence of other CNS depressant drugs (Gutstein & Akil 2001; Branson et al. 2001). Under some clinical circumstances, however, hyperthermia is observed in cats, horses, swine, and ruminants following opioid administration (Niedfeldt & Robertson 2006; Posner et al. 2007, 2010). Part of this increase in body temperature may be attributed to an increase in muscle activity associated with CNS excitation in these species, but a specific central hypothalamic mechanism has also been implicated, although it remains poorly understood (Branson et al. 2001).

Emetic Center

Nausea and vomiting associated with opioid administration are a result of direct stimulation of the chemoreceptor trigger zone for emesis located in the area postrema of the medulla (Gutstein & Akil 2001; Stoelting 1999). As with the other centrally mediated side effects, species plays a role in determining an individual's tendency to vomit after an opioid is administered. Horses, rabbits, ruminants, and swine do not vomit with opioid administration. Cats may vomit, but usually at doses that are greater than those which stimulate vomiting in dogs. Dogs will commonly vomit following opioid administration, especially with morphine.

Cough Center

Opioids have variable efficacy in depressing the cough reflex, at least in part, by a direct effect on a cough center located in the medulla (Gutstein & Akil 2001). Certain opioids are more effective antitussives than others, including drugs like codeine, hydrocodone, and butorphanol.

Pupillary Diameter

As a general rule, opioids tend to produce mydriasis in those species that exhibit CNS excitation, and miosis in those that become sedated following opioid administration (Branson et al. 2001; Stephan et al. 2003; Lee & Wang 1975; Wallenstein & Wang 1979). Miosis is due to an excitatory action of opioids on neuronal firing in the oculomotor nucleus (Stoelting 1999; Lee & Wang 1975; Wallenstein & Wang 1979). In the cat, and presumably in other species that exhibit mydriasis, this increase in activity in the oculomotor nuclear complex still occurs but the miotic effect is masked by increased release of catecholamines, which results in mydriasis (Wallenstein & Wang 1979).

Respiratory System

Opioids produce dose-dependent depression of ventilation, primarily mediated by μ_2 receptors leading to a direct depressant effect on brainstem respiratory centers (Gutstein & Akil 2001; Stoelting 1999). This effect is characterized by decreased responsiveness of these centers to carbon dioxide and is reflected in an increased resting $PaCO_2$ and displacement of the carbon dioxide response curve to the right. This effect is compounded by the coadministration of sedative and/or anesthetic agents, meaning that significant respiratory depression and hypercapnia are much more likely to occur in anesthetized patients who receive opioids versus those who are conscious. It should be noted that, in general, humans tend to be more sensitive to the respiratory depressant effects of opioids when compared to most veterinary species. However, respiratory support and/or specific opioid antagonists should be immediately available anytime very high doses, or very potent opioids are used.

Cardiovascular System

Most opioids have minimal effects on cardiac output, cardiac rhythm, and arterial blood pressure when clinically relevant analgesic doses are administered. Bradycardia may occur as a result of opioid-induced medullary vagal stimulation and will respond readily to anticholinergic treatment if warranted. Particular opioids (morphine and merperidine) can cause release of histamine, especially after rapid intravenous administration, which may lead to vasodilation and hypotension (Branson et al. 2001; Smith et al. 2001). Due to their relatively benign effects on cardiovascular function, opioids commonly form the basis of anesthetic protocols for human patients or animals with preexisting cardiovascular disease.

Gastrointestinal System

The gastrointestinal effects of the opioids are mediated by μ and δ receptors located in the myenteric plexus of the gastrointestinal tract (Gutstein & Akil 2001; Branson et al. 2001). Opioid administration may stimulate defecation in certain species. Following this initial response, spasm of gastrointestinal smooth muscle predisposes to ileus and constipation. Horses and ruminants in particular may be predisposed to gastrointestinal complications associated with opioid administration such as colic and ruminal tympany, respectively. Chronic opioid use may predispose to gastrointestinal stasis in other species.

In human patients, opioids (most notably fentanyl and morphine) have been shown to increase bile duct pressure through constriction of the sphincter of Oddi (Radnay et al. 1984). The incidence of this side effect in humans is, however, quite low (Jones et al. 1981). The incidence of increased bile duct pressure secondary to opioid administration in various animal species, and its potential clinical significance, is unknown at this time.

Genitourinary System

Opioids, particularly when administered neuraxially, may cause urinary retention through dose-dependent suppression of detrusor contractility and decreased sensation of urge (Kuipers et al. 2004; el Bindary & Abu el-Nasr 2001). Urine volume may also be affected by opioids and the mechanism of this effect appears to be multifactorial. μ agonists tend to produce oliguria in the clinical setting and this is in part a result of increased antidiuretic hormone release leading to altered renal tubular function (Stoelting 1999; Mercadante & Arcuri 2004). Elevations in circulating plasma atrial natriuretic peptide may also play a role in morphine-induced antidiuresis (Mercadante & Arcuri 2004). Conversely, κ agonists tend to produce a diuretic effect, possibly through inhibition of antidiuretic hormone secretion (Stoelting 1999; Mercadante & Arcuri 2004).

Other peripheral mechanisms involving stimulation of renal alpha-2 adrenergic receptors may also contribute to this κ agonist effect (Mercadante & Arcuri 2004).

Opioid-Induced Hyperalgesia

There is a growing body of evidence from both human and rodent studies supporting the existence of a condition called opioid-induced hyperalgesia (Lee et al. 2011; Gomez et al. 2009; Yu et al. 2016; Colvin et al. 2019). This phenomenon is characterized by a paradoxical increase in pain associated with opioid administration and can contribute to poorly controlled pain and dose escalation. In humans, it has been observed with acute and chronic exposure, high and low doses, and with different types of opioids and routes of administration. The mechanisms underlying opioid-induced hyperalgesia are not well understood but both μ opioid receptors on transient receptor potential vanilloid-1 (TRPV1)-expressing dorsal root ganglion neurons and NMDA receptors in the spinal cord dorsal horn appear to be involved (Deng et al. 2019). At this time, animal studies involving opioid-induced hyperalgesia are largely confined to experimental pain models in rodents, however, awareness in veterinary medicine is increasing and publications involving dogs and cats are beginning to emerge (Ruíz-López et al. 2020; Borland & Garcia 2019; White et al. 2017).

Opioid Agonists

Almost all clinically useful opioids exert their analgesic and immobilizing effects by acting as agonists at μ receptors. While there are a few opioids which act as κ agonists, these drugs also tend to have antagonist or partial agonist effects at μ and/or δ receptors and are thus not classified as *pure* agonists. Pure or full opioid agonists are capable of eliciting maximal activation of the receptor when they bind it and the subsequent downstream processes result in a maximal analgesic effect (Fig. 1.1). Clinically, the full μ agonists are superior analgesics and they are the drugs of choice for pain of moderate to severe intensity in many veterinary species. The following section contains brief descriptions of full μ agonists currently used in veterinary medicine. Specific details regarding μ agonist clinical pharmacology in various wild and exotic species are lacking.

Morphine (Morphine Sulfate)

Morphine is the prototypical opioid analgesic and acts as a full agonist not only at μ receptors, but also at δ and κ receptors (Gutstein & Akil 2001). Despite the development of numerous synthetic opioids, many of which are more potent than morphine and may have other characteristics that make them desirable alternatives to morphine in certain

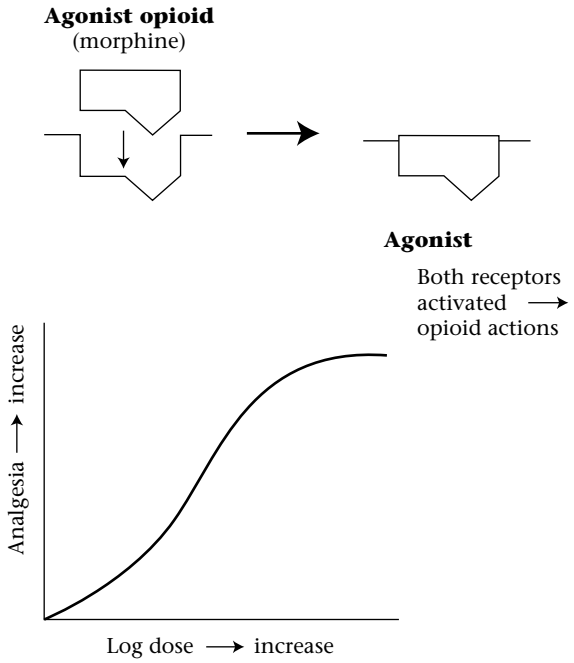

Figure 1.1 Effects of opioid agonists.

circumstances, it is worth noting that no other drug has been shown to be more efficacious than morphine at relieving pain in humans. Compared to the synthetic opioid agonists, morphine is relatively hydrophilic in nature and crosses the blood–brain barrier more slowly than fentanyl or oxymorphone, thereby delaying the peak effect somewhat even after intravenous administration (Gutstein & Akil 2001; Stoelting 1999). Clinically, this lag is not likely to be significant under most circumstances, with the onset of analgesia occurring reasonably promptly after a single dose of morphine and typically lasting 3–4 hours (Barnhart et al. 2000; Taylor et al. 2001). Morphine's poor lipid solubility means that it can produce long-lasting analgesia when administered into the epidural or subarachnoid space, with effects persisting for 12–24 hours. The first-pass effect is significant after oral administration and the bioavailability of oral morphine preparations is at best only in the range of 0–25%.

In most species, the primary metabolic pathway for morphine involves conjugation with glucuronic acid leading to the formation of two major metabolites, morphine-6-glucuronide and morphine-3-glucuronide (Gutstein & Akil 2001; Faura et al. 1998). Despite the low levels of glucuronyl transferase in the cat, the pharmacokinetics of morphine in this species seem to be broadly comparable to the dog and human, though clearance rates may be marginally slower (Barnhart et al. 2000; Taylor et al. 2001; Faura et al. 1998). This suggests that morphine must undergo a different type of conjugation reaction in this species. Morphine-6-glucuronide

has pharmacological activities that are indistinguishable from those of morphine in animal models and in human beings, while morphine-3-glucuronide appears to have little affinity for opioid receptors, but may contribute to the excitatory effects of morphine in some situations (Gutstein & Akil 2001; Smith 2000). With chronic morphine administration, it is likely that the active metabolite, morphine-6-glucuronide, contributes significantly to clinical analgesia.

Very little morphine is excreted unchanged in the urine. The major metabolites, morphine-3-glucuronide and, to a lesser extent, morphine-6-glucuronide, are eliminated almost entirely via glomerular filtration. In human patients, renal failure may lead to accumulation of morphine-6-glucuronide and persistent clinical effects, while liver dysfunction seems to have minimal impact on morphine clearance (Gutstein & Akil 2001; Stoelting 1999).

The side effects associated with morphine administration are typical of most opioid agonists and have been discussed previously in this chapter. In particular, the increased incidence of vomiting after morphine administration as well as its potential to cause histamine release after intravenous administration distinguish morphine from other full opioid agonists.

Hydromorphone

Hydromorphone is a synthetic opioid that acts as a full agonist at μ receptors and is used in both human and veterinary medicine. Clinically, hydromorphone and oxymorphone have similar efficacy, potency, duration of analgesic action, and side-effect profiles, but hydromorphone remains significantly less expensive. Like oxymorphone, hydromorphone is not associated with histamine release so bolus intravenous administration is considered safe (Smith et al. 2001).

Meperidine

Meperidine is a synthetic opioid that exerts its analgesic effects through agonism at μ receptors. Interestingly, it also appears able to bind other types of receptors, which may contribute to some of its clinical effects other than analgesia. Meperidine is capable of blocking sodium channels and inhibiting activity in dorsal horn neurons in a manner analogous to local anesthetics (Wagner et al. 1999; Wolff et al. 2004). It has also recently been shown that meperidine exerts agonist activity at alpha-2 receptors, specifically the alpha-2B subtype, suggesting that it may possess some alpha-2 agonist-like properties (Takada et al. 1999, 2002).

Meperidine has a considerably shorter duration of analgesic action compared to morphine, oxymorphone or hydromorphone, typically not extending beyond 1 hour (Branson et al. 2001). Metabolic pathways vary among different species but, in general, most of the drug is demethylated to normeperidine in the liver and then undergoes further hydrolysis and ultimately renal excretion (Branson et al. 2001; Taylor et al. 2001; Yeh et al. 1981). Normeperidine is an active metabolite and possesses approximately one half of the analgesic efficacy of meperidine (Gutstein & Akil 2001; Branson et al. 2001). Normeperidine has produced toxic neurologic side effects in human patients receiving meperidine for prolonged periods of time, especially in the presence of impaired renal function (Stoelting 1999; Stone et al. 1993).

Unlike most of the other opioids in clinical use, meperidine has been shown to produce significant negative inotropic effects when administered alone to conscious dogs (Priano & Vatner 1981). In addition, due to its modest atropine-like effects, meperidine tends to increase heart rate rather than predispose to bradycardia as is often seen with other opioids (Branson et al. 2001; Stoelting 1999). The clinical significance of these cardiovascular effects in the peri-anesthetic period has never been clearly ascertained. Like morphine, meperidine also causes histamine release when administered intravenously (Branson et al. 2001).

A rare but life-threatening drug interaction has been reported in human patients receiving meperidine that may have relevance in veterinary medicine. The combination of meperidine (and perhaps other opioids) with a monoamine oxidase inhibitor may lead to "serotonin syndrome" which is characterized by a constellation of symptoms including confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, and diarrhea (Sporer 1995; Bowdle 1998; Heinonen & Myllyla 1998; Tissot 2003). A monoamine oxidase inhibitor, selegiline (Deprenyl®), has been used in dogs to treat pituitary-dependent hyperadrenocorticism or to modify behaviour in patients with canine cognitive dysfunction. Though there have not, to date, been any reports of adverse meperidine-selegiline interactions in dogs, the veterinarian must be aware of the potential for complications if analgesia is required in patients receiving monoamine oxidase inhibitors. A recent study has evaluated the effects of other opioids (oxymorphone and butorphanol) in selegiline-treated dogs and did not identify any specific adverse drug interactions in these animals (Dodam et al. 2004).

Fentanyl

Fentanyl is a highly lipid-soluble, short-acting synthetic μ opioid agonist. A single dose of fentanyl administered intravenously has a more rapid onset and a shorter duration of action than morphine. Peak analgesic effects occur in about 5 minutes and last approximately 30 minutes (Gutstein & Akil 2001; Stoelting 1999). Rapid redistribution of the drug to inactive tissue sites, such as fat and skeletal

muscle, leads to a decrease in plasma concentration and is responsible for the prompt termination of clinical effects. In most veterinary species the elimination half-time after a single bolus or a brief infusion is in the range of 2–3 hours (Carroll et al. 1999; Lee et al. 2000; Maxwell et al. 2003). Administration of very large doses or prolonged infusions may result in saturation of inactive tissues with termination of clinical effects becoming dependent on hepatic metabolism and renal excretion (Gutstein & Akil 2001; Stoelting 1999). Thus, the context-sensitive half-time of fentanyl increases significantly with the duration of the infusion, and clinical effects may persist for an extended period following termination of a long-term intravenous infusion.

Side effects associated with fentanyl administration are similar to those of the other full μ agonist opioids. In general, cardiovascular stability is excellent with fentanyl and intravenous administration is not associated with histamine release (Gutstein & Akil 2001; Stoelting 1999). Bradycardia may be significant with bolus doses but readily responds to anticholinergics if treatment is warranted (Gutstein & Akil 2001; Branson et al. 2001). In human patients muscle rigidity, especially of the chest wall, has been noted after administration of fentanyl or one of its congeners. The potential significance of this adverse effect in animal patients is not clear at this time, and the risk is considered minimal if large rapid bolus administrations are avoided.

Clinically, fentanyl is used most frequently in dogs and cats but it is also a potentially useful analgesic in other species, including the horse, cow, sheep, goat, and pig. Historically, fentanyl was available in combination with the butyrophenone tranquilizer droperidol in a product called Innovar-Vet, which was typically administered in the preanesthetic period to provide sedation and analgesia. This product is no longer available and systemic administration of fentanyl today is usually via the intravenous route.

The development of novel less-invasive routes of opioid administration for use in human patients led to the marketing of transdermal fentanyl patches (Duragesic®). The patches are designed to release a constant amount of fentanyl per hour which is then absorbed across the skin and taken up systemically. Fentanyl patches are designed for human skin and body temperature; however, their use has been evaluated in a number of domestic veterinary species (Carroll et al. 1999; Maxwell et al. 2003; Gilberto et al. 2003; Franks et al. 2000; Wilkinson et al. 2001; Egger et al. 1998, 2003; Gellasch et al. 2002; Robinson et al. 1999). Substantial variations in plasma drug concentrations have been documented and significant lag times after patch placement are common prior to onset of analgesia (Carroll et al. 1999; Lee et al. 2000; Egger et al. 1998, 2003). Furthermore, changes in body temperature have been shown to significantly affect fentanyl absorption in anesthetized cats, and it is likely that other factors associated with skin preparation and patch placement have the potential to substantially alter plasma fentanyl levels and analgesic efficacy (Pettifer & Hosgood 2003). Fentanyl patch safety and efficacy in most species is unknown at this time.

Alfentanil, Sufentanil, and Remifentanil

Alfentanil, sufentanil, and remifentanil are all structural analogues of fentanyl that were developed for use in humans in an effort to create analgesics with a more rapid onset of action and predictable termination of opioid effects. All three are similar with regard to onset and all have context-sensitive half-times that are shorter than that of fentanyl after prolonged infusions (Stoelting 1999) Remifentanil is unique among opioids because it is metabolized by nonspecific plasma esterases to inactive metabolites (Chism & Rickert 1996; Hoke et al. 1997). Thus, hepatic or renal dysfunction will have little impact on drug clearance and this, in combination with the robust nature of the esterase metabolic system, contributes to the predictability associated with infusion of remifentanil (Gutstein & Akil 2001; Stoelting 1999).

All three of these drugs are used during general anesthesia for procedures requiring intense analgesia and/or blunting of the sympathetic nervous system response to noxious stimulation. These agents, specifically remifentanil, are the opioids most frequently associated with opioid-induced hyperalgesia in humans (Santonocito et al. 2018). As yet, they have limited applications for postoperative or chronic pain management. Like fentanyl, they can be administered at relatively low infusion rates as adjuncts to general anesthetic protocols based on volatile inhalant or other injectable agents, or they can be administered at higher rates as the primary agent for total intravenous anesthesia. The minimum alveolar anesthetic concentration-sparing properties of these agents have been demonstrated in both the dog and cat (Hoke et al. 1997; Michelsen et al. 1996; Mendes & Selmi 2004; Ilkiw et al. 1997; Pascoe et al. 1997). In the horse, systemic infusions of alfentanil did not have significant effects on minimum alveolar concentrations of inhalant anesthetics and when administered to conscious horses were associated with increases in locomotor activity (Pascoe et al. 1991, 1993; Pascoe & Taylor 2003). There is little evidence to suggest that any of the fentanyl analogues offer advantages over morphine when administered into the epidural space for analgesia (Natalini & Robinson 2000).

Methadone

Methadone is a synthetic μ opioid agonist with pharmacologic properties qualitatively similar to those of morphine, but possessing additional affinity for NMDA receptors (Gorman et al. 1997; Ripamonti & Dickerson 2001). Methadone's unique clinical characteristics include excellent absorption following oral administration, no known active metabolites, high potency, and an extended duration of action (Gutstein & Akil 2001; Branson et al. 2001; Ripamonti & Dickerson 2001). In human patients, the drug has been used primarily in the treatment of opioid abstinence syndromes but it is being used increasingly for the management of chronic pain. In contrast to humans, methadone has low bioavailability in most veterinary species and consequently has limited efficacy when administered orally. A racemic injectable formulation of methadone hydrochloride (Comfortan®) is approved for use in dogs and cats for analgesia and premedication prior to general anesthesia in Europe and the United Kingdom. Numerous publications involving intramuscular, intravenous, and subcutaneous methadone in these and other domestic species have emerged in recent years as the drug gains popularity in clinical veterinary practice (Bini et al. 2018; Bitti et al. 2017; Hunt et al. 2013; Slingsby et al. 2015; Shah et al. 2018; Trimble et al. 2018; Warne et al. 2013; Gozalo-Marcilla et al. 2019).

Codeine

Codeine is the result of substitution of a methyl group onto morphine which acts to limit first-pass hepatic metabolism and accounts for codeine's high oral bioavailability (Gutstein & Akil 2001; Stoelting 1999). Codeine is well known for its excellent antitussive properties and is often combined in an oral formulation with a nonopioid analgesic, such as acetaminophen (Tylenol 3®), for the management of mild to moderate pain in human patients.

Oxycodone and Hydrocodone

Oxycodone and hydrocodone are opioids that are typically administered orally for the treatment of pain in human patients. Though oxycodone is available as a single drug continuous-release formulation (Oxycontin®), these drugs are most often prepared in combination with nonopioid analgesics such as aspirin and acetaminophen (Percocet®, Percodan®, Lorcet®, Vicodan®, etc.). In light of the epidemic of opioid addiction in humans and the potential for drug diversion, veterinarians are advised to prescribe alternative analgesics and avoid off-label use of opioids such as oxycodone and hydrocodone due to their extremely high abuse potential.

Etorphine and Carfentanil (M-99® and Wildnil®, Respectively)

These two opioids are discussed together because they are both used exclusively for the restraint and capture of wild animals, rather than as analgesic agents. They are extremely potent opioids and the immediate availability of a suitable antagonist is mandatory before these drugs are to be used, not only to reverse drug effects in animal patients, but also as a safety precaution in the event of accidental human injection. Though etorphine and carfentanil are most often injected intramuscularly (usually using a remote drug delivery technique) recent studies suggest that carfentanil is useful when administered orally in a variety of species, including the brown bear, the Brazilian tapir, and the chimpanzee (Mortenson & Bechert 2001; Pollock & Ramsay 2003; Kearns et al. 2000; Mama et al. 2000). A number of different drugs have been used in combination with etorphine or carfentanil to enhance muscle relaxation, including acepromazine, xylazine, and medetomidine (Caulkett et al. 2000; Miller et al. 2003; Ramdohr et al. 2001; Roffe et al. 2001).

Thiafentanil

Thiafentanil is an opioid agonist that has been utilized to facilitate the capture of many species of mammals, mainly ungulates, as well as large birds. It is pharmacologically classified as a synthetic opioid that has a relatively short duration of action. The shorter duration of action in combination with its reversibility with the opioid antagonist naltrexone make it an attractive agent when long periods of narcotization are not desirable.

Opioid Agonist-Antagonists and Partial Agonists

This group includes drugs that have varying opioid receptor binding profiles, but which have one thing in common: they all occupy μ opioid receptors, but do not initiate a maximal clinical response. Drugs such as butorphanol and nalbuphine are classified as agonist-antagonists. They are competitive μ receptor antagonists, but exert their analgesic actions by acting as agonists at κ receptors (Fig. 1.2). Buprenorphine, on the other hand, is classified as a partial agonist and binds μ receptors but produces only a limited clinical effect (Fig. 1.3). These mixed agonist-antagonist drugs were developed for the human market in an attempt to create analgesics with less respiratory depression and addictive potential. Due to their opioid receptor binding affinities, the side effects associated with these drugs demonstrate a so-called "ceiling effect" whereby increasing doses do not produce additional adverse responses. Unfortunately, the benefits of this ceiling effect on ventilatory depression come at the expense of limited analgesic efficacy and only a modest ability to decrease anesthetic requirements.

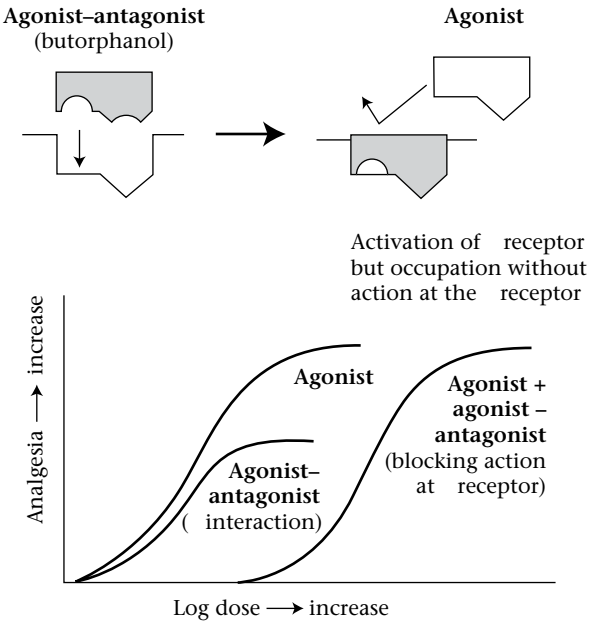

Figure 1.2 Activation of κ receptor, but occupation without action at the μ receptor.

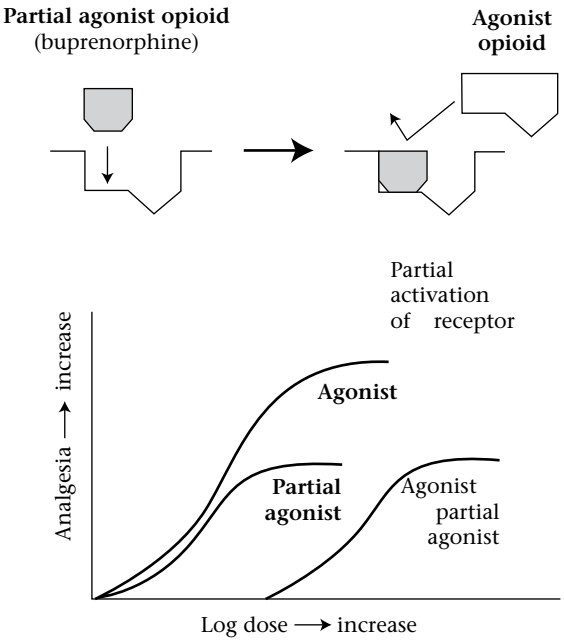

Figure 1.3 Partial activation of μ receptor.

The coadministration of opioids with differing receptor binding profiles is currently an active area of research that deserves further attention. The interactions in this setting are complex and it appears that opioid coadministration has the potential to produce additive, synergistic, or antagonistic analgesic effects depending on the particular species, dosage, drugs, and pain model being evaluated. The following section contains brief descriptions of opioid agonist-antagonists and partial agonists that are currently used in veterinary medicine.

Butorphanol

Butorphanol is a synthetic agonist-antagonist opioid and has been used extensively in a wide variety of veterinary species. The drug was originally labelled as an antitussive agent in dogs and, even now, is approved as an analgesic in the cat and horse only (Branson et al. 2001). Butorphanol exerts its relevant clinical effects through its interactions at κ receptors and acts as an antagonist at μ receptors. The duration of butorphanol's analgesic effects remains somewhat debatable and likely varies with species, type and intensity of pain, dosage, and route of administration (Sawyer et al. 1991; Robertson et al. 2003a; Sellon et al. 2001). In general, its effects are shorter-lived than those of morphine and are probably in the range of one to three hours. Butorphanol does not induce histamine release when administered intravenously and has minimal effects on cardiopulmonary function. There is conflicting evidence regarding the effects of butorphanol on inhalant anesthetic requirements in the dog, cat, and horse. Earlier studies failed to demonstrate a significant sparing effect on minimum alveolar concentration when butorphanol was coadministered with halothane in dogs and ponies (Quandt et al. 1994; Doherty et al. 1997; Matthews & Lindsay 1990). More recently, isoflurane MAC reductions have been documented after administration of clinically relevant doses of butorphanol in both dogs and cats (Ilkiw et al. 2002; Ko et al. 2000). The reasons for these discrepancies are probably related to differences in study techniques and, in the dog and cat specifically, it seems that butorphanol is capable of inducing at least modest reductions in inhalant anesthetic requirements.

Traditionally, it was thought that the simultaneous or sequential administration of butorphanol with a pure μ opioid agonist such as morphine or hydromorphone would be counterproductive from an analgesic standpoint because butorphanol's ability to antagonize μ receptors could inhibit or even reverse the effects of the agonist drug. Certainly, it has been clearly demonstrated that excessive sedation associated with a pure μ agonist can be partially reversed by the administration of low doses of butorphanol, and it was presumed that butorphanol would similarly reverse the μ-mediated analgesic effects as well. It would now appear that the potential interactions between butorphanol and full μ-opioid agonists are more complex than originally believed. One study demonstrated that coadministration of butorphanol and oxymorphone to cats subjected to a visceral noxious stimulus resulted in enhanced analgesic effects (Briggs et al. 1998). A more recent feline study, however, evaluated the combination of butorphanol

and hydromorphone in a thermal threshold pain model and failed to demonstrate enhanced analgesia and suggested that butorphanol did, in fact, inhibit hydromorphone's analgesic effects (Lascelles & Robertson 2004). These contradictory findings illustrate that we still have much to learn about coadministration of opioid agents with differing receptor binding profiles and the clinical effects produced by such coadministration likely depend on many factors, including species, type of pain, dose, and the specific drugs involved.

Nalbuphine and Pentazocine

Nalbuphine and pentazocine are classified as agonist-antagonist opioids and are clinically similar to butorphanol. They induce mild analgesia accompanied by minimal sedation, respiratory depression, or adverse cardiovascular effects. Like butorphanol, nalbuphine is occasionally used to partially reverse the effects of a full μ agonist opioid while maintaining some residual analgesia.

Buprenorphine

Buprenorphine is a semisynthetic, highly lipophilic opioid derived from thebaine. Unlike other opioids in this category, buprenorphine is considered to be a partial agonist at μ opioid receptors. The drug binds avidly to and dissociates slowly from μ receptors, but is not capable of eliciting a maximal clinical response. Due to its receptor binding characteristics, buprenorphine has a delayed onset of action and takes at least 60 minutes to attain peak effect after intramuscular administration. It also has a relatively long duration of action with clinical analgesic effects persisting for 6–12 hours in most species. Also, its high affinity for the μ receptor means that it may be difficult to antagonize its effects with a drug such as naloxone. Buprenorphine has most often been administered intravenously or intramuscularly, however, due to the long lag time before clinical effects are achieved after intramuscular administration, the intravenous route is preferred. Comparable plasma drug levels and analgesic efficacy with oral transmucosal administration versus intravenous administration has been demonstrated in cats (Robertson et al. 2003). Compounded versions of buprenorphine are widely available and include higher concentrations for convienent dosing to larger animals and sustained release formulations for increased duration of action. Reports describing use of the compounded sustained-release buprenorphine formulation by ZooPharm are available in a wide range of zoo and wildlife species. If sustained release preparations are used, there should be a plan for supportive care should significant adverse effects occur since complete reversal of buprenorphine with conventional antagonists is often unsuccessful. In addition, a commercially available highly concentrated formulation (1.8 mg/mL) called Simbadol® has been approved for perioperative analgesia in domestic cats with a label dose of 0.24 mg/kg administered subcutaneously every 24 hours for up to 3 days. Extralable intravenous and intramuscular administration has been used at lower doses and dosing intervals comparable to tradidional buprenorphine doses. The duration of action of Simbadol is not due to any specific formulation characterists. Rather it is a function of administration into adipose tissue which results in a gradual release into the circulation. A recent report describes the pharmacokinetics of highly concentrated buprenorphine/Simbadol® in Rhesus macaques (Mackiewicz et al. 2019).

Opioid Antagonists

These drugs have high affinities for the opioid receptors and are able to displace opioid agonists from μ and κ receptors. After this displacement, the pure antagonists bind to and occupy opioid receptors, but do not activate them (Fig. 1.4). Under ordinary circumstances, in patients that have not received exogenous agonist opioids, the opioid antagonists have few clinical effects when administered at clinically relevant dosages (Gutstein & Akil 2001). It is important to recognize that these drugs will rapidly reverse all opioid-induced clinical effects, including analgesia.

Naloxone

This pure opioid antagonist is capable of reversing all opioid agonist effects, producing increased alertness, responsiveness, coordination, and, potentially, increased perception of pain. Naloxone's duration of action is shorter than many

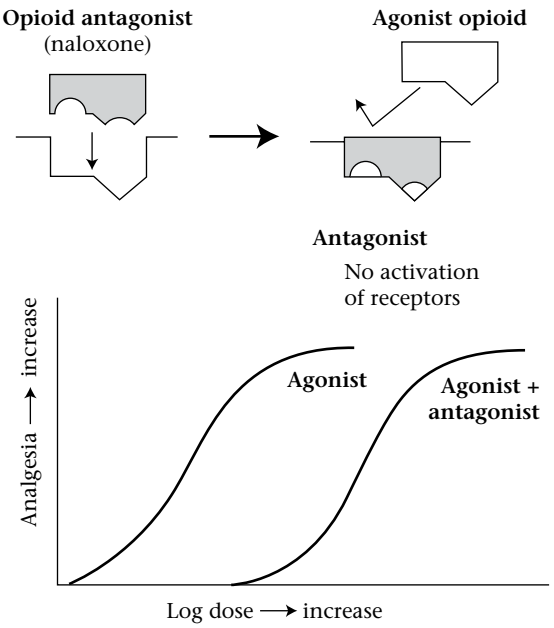

Figure 1.4 No activation of receptors.

of the opioid agonists with recommended intravenous doses lasting between 30 and 60 minutes. Consequently, animals need to be closely monitored for renarcotization after a dose of naloxone. Occasionally, excitement or anxiety may be seen after naloxone reversal of an opioid agonist. Premature ventricular contractions have also been documented after reversal, but are not a common occurrence and seem to be more likely if there are high levels of circulating catecholamines. This drug is sometimes administered sublingually to neonatal patients exhibiting respiratory depression that have been delivered by Caesarean section after maternal administration of an opioid agonist.

Nalmefene and Naltrexone

Both of these drugs are pure opioid antagonists with clinical effects that last approximately twice as long as naloxone (Veng-Pedersen et al. 1995). Though little is published about the use of these drugs in veterinary patients, they may be advantageous in preventing renarcotization when used to antagonize the effects of a long-acting opioid.

Nonsteroidal Anti-inflammatories

The nonsteroidal anti-inflammatory analgesics (NSAIDs) relieve mild to moderately severe pain and have been used extensively in a wide variety of domestic animals for many years. While pharmacokinetic and pharmacodynamic studies involving NSAIDs in wild and exotic animals are lacking, their use in such species continues to increase. This class of drugs dates back thousands of years, with the salicylates being among the oldest and still most commonly used analgesics (Vane & Botting 2003). Salicylate is a naturally occurring substance found in willow bark and was used for centuries to manage pain associated with rheumatism prior to production of the synthetic compound. In 1878, Felix Hoffman working at the Bayer company in Germany made the acetylated form of salicylic acid which has come to be known as aspirin (Vane & Botting 2003). While aspirin (acetylsalicylic acid [ASA]) has been found to be effective in the management of acute and chronic mild discomfort, the newer injectable NSAIDs appear to have comparable efficacy to the pure μ agonist opioids in controlling moderate to severe soft tissue and orthopedic pain. The NSAIDs appear to confer synergism when used in combination with opioids and may demonstrate an opioid-sparing effect should lower dosages of opioid be required. Their extended duration of action, in addition to their analgesic efficacy, make the NSAIDs ideal for treating acute and chronic pain in veterinary species. Careful patient and drug selection is critical, however, due to their potential for harmful side effects.

Cyclooxygenases and Prostaglandin Synthesis

In 1971, Vane discovered the mechanism by which aspirin exerts its anti-inflammatory, analgesic, and antipyretic actions. He proved that aspirin and other NSAIDs inhibited the activity of a cyclooxygenase (COX) enzyme which produced prostaglandins (PGs) involved in the pathogenesis of inflammation, swelling, pain, and fever (Vane 1971). Twenty years later, the discovery of a second COX enzyme was made and more recently COX-3 (Botting 2000, 2003; Chandrasekharan et al. 2002). Cyclooxygenase (previously termed prostaglandin synthase) oxidizes arachidonic acid (previously termed eicosatetraenoic acid) to various eicosanoids (including PGs and other related compounds) (Fig. 1.5) (Livingston 2000). Oxidation of arachidonic acid by 5-lipoxygenase (5-LOX), the most biologically important of the mammalian oxygenases, results in the series of eicosanoids termed leukotrienes (Fig. 1.5). The release of arachidonic acid from membrane phospholipid is catalyzed by the enzyme phospholipase A_2 and is the rate-limiting step in PG and leukotriene synthesis. Prostaglandin G_2 is the initial prostanoid formed, followed by prostaglandin H_2 which serves as a substrate for prostaglandin E-synthetase, prostaglandin D-isomerase, prostaglandin F-reductase, prostacyclin synthetase, and thromboxane synthetase for conversion to a variety of other prostenoids ubiquitous throughout cells and tissues in the body (Livingston 2000). These include the PGs PGE_2, PGD_2, PGF_2, and PGI_2 (prostacyclin), and the thromboxanes TXA_2 and TXB_2, all with diverse functions (Vane & Botting 1995). The PGs are not stored but are synthesized at a constant rate. They have short half-lives of 4–6 minutes at 37°C, and act locally at the site of production.

The PGs produced by both COX-1 and COX-2 are ubiquitous throughout the body and serve to facilitate many normal physiologic functions during both health and illness. Consequently, the clinical use of NSAIDs has the potential to disrupt these functions with the possibility of significant organ dysfunction. Thus, in addition to their role as analgesics, the effects of NSAIDs on the constitutive functions of the PGs must always be considered. There are several key points to note: (i) COX-1 generates PGs that are responsible for "mucosal defence" (i.e., secretion of bicarbonate and mucus, mucosal blood vessel attenuation of constriction, and mucosal epithelial regeneration), as well as thromboxane A_2, which is necessary for platelet function; (ii) COX-2 produces PGs which function in the prevention and promotion of healing of mucosal erosions, exert anti-inflammatory effects by inhibiting leukocyte adherence, aand play a role in renal protection and maturation; and (iii) COX-3 produces PGs which exert a protective function by initiating fever (Vane & Botting 1995; Botting 2003).

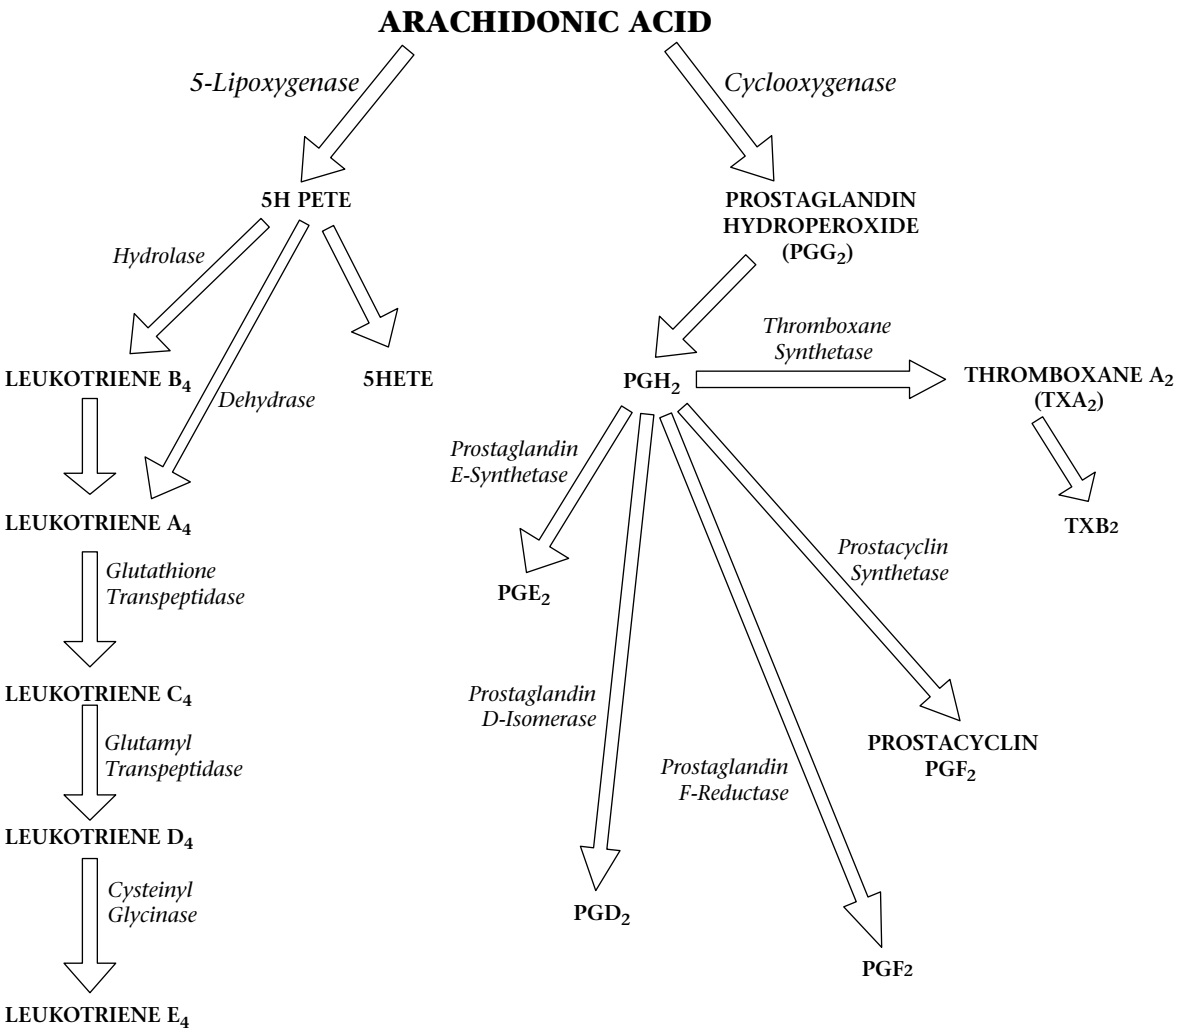

Figure 1.5 Eicosanoid synthesis.

Thus, depending on the NSAID selected, primary plug formation of platelets, modulation of vascular tone in the kidney and gastric mucosa, cytoprotective functions within the gastric mucosa, smooth muscle contraction, and regulation of body temperature will all be affected (Vane & Botting 1995). However, in this regard not all NSAIDs are created equal. As noted above, the COX-1, COX-2 and COX-3 enzymes make variable contributions to these functions, and individual NSAIDs inhibit each of these enzymes differently. Some NSAIDs inhibit both COX-1 and COX-2 (i.e., aspirin, phenylbutazone, ketoprofen/Anafen®, ketorolac/Toradol®, flunixin meglumine/Banamine®), while other NSAIDs preferentially inhibit COX-2 with only weak inhibition of COX-1 (i.e., meloxicam/Metacam®, carprofen/Rimadyl®, etodolac/Etogesic®, vedaprofen/Quadrisol-5®, tolfenamic acid/Tolfedine®). Yet others inhibit COX-2 exclusively (i.e., deracoxib/Deramax®, firacoxib/Previcox®, Robenacoxib/Onsior®, mavicoxib/Trocoxcil®), while still another drug, acetaminophen, only weakly inhibits both COX-1 and COX-2, but is able to inhibit COX-3 activity preferentially (Botting 2000).

Several in vitro studies investigating NSAID selective inhibition of the COX-1 and COX-2 isoenzymes have been published, but these are very difficult to interpret due to inconsistencies in the assays used (Kay-Mugford et al. 2000). Clinically, this information is confusing as it does not consider the pharmacokinetics of particular drugs and their concentrations in various tissues (Bertolini et al. 2001). Most NSAIDs that inhibit COX have been shown to result in diversion of arachidonate to the 5-LOX pathway. 5-LOX is principally found in polymorphonuclear cells, mast cells, monocytes, basophils, and B lymphocytes that are recruited during inflammatory and immune reactions (Bertolini et al. 2001). This enzyme catalyzes the initial step in leukotriene biosynthesis, which subsequently produces various eicosanoids, with LTB_4 being the most notable potent mediator of inflammation. The excessive production of leukotrienes has been implicated in the

creation of NSAID-induced ulcers (Hudson et al. 1993; Rainsford 1992). As always, however, the biological system is not clear-cut. While the LOX pathway is pro-inflammatory, there is also an anti-inflammatory pathway, which is discussed in more detail later (Serhan & Chiang 2004).

The contribution of the leukotrienes to the inflammatory process would seem to suggest that inhibition of both the COX and 5-LOX pathways by a therapeutic agent would result in an enhanced safety profile and may confer even greater analgesic efficacy due to broader anti-inflammatory and antinociceptive effects (Kirchner et al. 1997a). Data available show that dual-acting compounds are effective in arthritic models, where they also retain antithrombotic activity, produce little or no gastrointestinal damage, and do not adversely affect the asthmatic state (Bertolini et al. 2001).

A dual COX/5-LOX inhibitor called tepoxalin/Zubrin® underwent clinical trials and was approved for veterinary use in dogs (Kirchner et al. 1997b; Argentieri et al. 1994). Tepoxalin demonstrated gastrointestinal anti-inflammatory activity in mice, which supported the theory that 5-LOX inhibition may play a vital role in the prevention of NSAID-induced gastric inflammation (Kirchner et al. 1997b). Despite its approval in the United States, the manufacturer has voluntarily withdrawn the product from the market and it is no longer available.

Prostaglandin Receptor Antagonism

Instead of limiting prostaglandin production through COX inhibition, a novel and more targeted therapeutic approach involves a class of drugs known as piprants, which are prostaglandin receptor antagonists (PRAs). Prostaglandin E_2 has been identified as a key mediator of the classic signs of inflammation including swelling, erythema, and pain through PGE_2-mediated sensitization of peripheral neurons, as well as vasodilation and increased vascular permeability (Ricciotti & FitzGerald 2011). While PGE_2 exerts its effects via four different G protein-coupled receptors (EP1, EP2, EP3, and EP4), the EP4 receptor has been shown to play a dominant role in inflammation and pain, and may mediate central sensitization in chronic pain states. A specific EP4 receptor antagonist, grapiprant/Galliprant®, has been demonstrated to provide relief from arthritic pain in canine clinical patients and appears to act without affecting the synthesis and widespread activity of PGE_2 and other prostanoids (Kirkby Shaw et al. 2015).

Analgesic and Anti-inflammatory Effects of NSAIDs

There is overwhelming evidence indicating that decreased PG synthesis due to COX inhibition and/or antagonism of PG activity at the EP4 receptor mediates NSAID-induced analgesic and anti-inflammatory effects. Traditionally, NSAIDS have been considered peripheral-acting drugs that penetrate inflamed tissues, decrease PG-induced vasodilation and extravasation of protein exudates, and attenuate nociceptor sensitization. These local effects make them excellent analgesic choices for injuries with associated inflammation, as well as conditions such as synovitis, arthritis, cystitis, dermatitis, etc. (Chopra et al. 2000).

In addition to their peripheral effects, central analgesic effects have also been documented in several animal models of pain where NSAIDs have been shown to disrupt prostaglandin-mediated effects at both spinal and supraspinal levels (Chopra et al. 2000; Malmberg & Yaksh 1992; McCormack 1994; Yaksh et al. 1998). This central effect may account for the overall well-being and improved appetite that is often observed in patients receiving parenterally administered NSAIDs for relief of acute pain.

The relationship between COX inhibition and clinical relief of pain and inflammation in the intact animal is complex. Nociceptive pathways may involve either the COX-1 or COX-2 gene, and these genes are expressed in different locations and under different circumstances.

NSAIDs and Fever

Just as the relationship between pain and the various activities of the COX system is complex, so too is the association between fever and the COX isoenzymes. The mechanisms leading to the generation of fever vary depending on the inciting factor, which may be peripheral (i.e., endotoxin) or central (i.e., endogenous pyrogens, such as IL-1). Interspecies variation is also substantial and the definitive role of the COXs in pyresis remains to be clearly elucidated. Evidence suggests that COX-2 plays a role in endotoxin pyrexia while, based on the antipyretic effects of acetaminophen and aspirin, COX-1 and COX-3 appear to function in endogenous pyrexia (Botting 2000, 2003; Chandrasekharan et al. 2002).

Other Pharmacologic Considerations for NSAID Use

Because of their high protein binding NSAIDs can displace other drugs from their plasma protein binding sites and potentially increase their plasma concentration. This is rarely a concern unless administered to animals with organ dysfunction or in those receiving other highly protein-bound medications with a narrow therapeutic index. Interference with the metabolism and excretion of certain coadministered drugs may occur, therefore verifying the safety of combination therapy is always mandatory.

Some NSAIDs may induce the syndrome of inappropriate secretion of ADH. Renal water reabsorption depends

on the action of ADH mediated by cyclic adenosine monophosphate (cAMP). As PGs exert a controlled negative feedback action on cAMP production, inhibition of PG synthesis results in above normal levels of cAMP with potential for enhanced ADH activity. In addition, the administration of a COX-2 selective NSAID may enhance sodium and water reabsorption. Clinically, both mechanisms may result in high specific gravity urine with dilutional hyponatremia. Urine volume may be decreased through this mechanism but without renal injury (Petersson et al. 1987; Dunn & Buckley 1986).

Contraindications for NSAIDs

Nonsteroidal anti-inflammatory analgesics should not be administered to animals with acute renal insufficiency, hepatic insufficiency, dehydration, hypotension, conditions associated with low effective circulating volume (i.e., congestive heart failure, ascites), coagulopathies (i.e., factor deficiencies, thrombocytopenia, von Willebrand's disease), or evidence of gastric ulceration (i.e., vomiting with or without the presence of "coffee ground material", melena). Administration of NSAIDs following gastrointestinal surgery must be determined by the health of this organ at the time of surgery. As the COX-2 isoenzyme is important for healing, intuitively NSAIDs would be contraindicated where a compromised bowel is noted. Concurrent use of other NSAIDs (i.e., aspirin) or corticosteroids is not recommended. The COX-1 preferential NSAIDs are contraindicated in animals with spinal injury (including herniated intervertebral disc) due to the potential for hemorrhage and neurologic deterioration, and due to excessive bleeding at the surgical site should surgical treatment be pursued. The NSAIDs should never be administered to animals in shock, trauma cases at the time of presentation, or animals with evidence of hemorrhage (i.e., epistaxis, hemangiosarcoma, head trauma). Animals with severe or poorly controlled asthma, or other types of moderate to severe pulmonary disease, may deteriorate with NSAID administration. Aspirin has been documented to exacerbate asthma in human patients, but COX-2-specific NSAIDs did not result in worsening of clinical signs (West & Fernandez 2003). It is not known whether animals may be affected in this way. Although administration of NSAIDs in head trauma, pulmonary diseases, or thrombocytopenia is generally contraindicated, COX-2 preferential NSAIDs (i.e., meloxicam, etodolac, carprofen, tolfenamic acid, and deracoxib) may prove to be safe with further study. Due to inhibition of PG activity, the NSAIDs may be detrimental to reproductive function. Indomethacin may block PG activity in pregnant women, resulting in cessation of labour, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation (DuBois et al. 1998). These effects may occur in animals, therefore NSAIDs should not be administered during pregnancy. As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo (DuBois et al. 1998), NSAIDs should also be avoided in breeding females during this stage of the reproductive cycle. As previously mentioned, the COX-2 isoenzyme is required for maturation of the embryological kidney so administration to lactating mothers should be avoided.

NSAIDs Used in Veterinary Medicine

There are few data regarding clinical pharmacology of NSAIDs in exotic species, thus care must be taken when extrapolating from common domestic species.

Meloxicam

Meloxicam is a COX-2 preferential NSAID approved for use in dogs in Australasia, Europe, and North America. The parenteral formulation is approved for cats in the United States and Australasia. Its use in cats in Canada is under investigation, with completed studies indicating safety and efficacy. Its use in horses is also under investigation, with pharmacokinetic studies indicating that the half-life is shorter and clearance greater than in the dog, suggesting that dosing more than once a day may be necessary (Sinclair et al. 2003).

Studies indicate no renal or hepatic abnormalities with acute administration and minimal to no antithromboxane activity, suggesting hemostasis in normal animals may not be a problem (Mathews et al. 1999; Poulsen & Justus 1999). Few adverse reactions have been documented and most involve the gastrointestinal tract. A recent study showed no difference in gastric erosions over saline placebo when meloxicam was administered at 0.1 mg/kg for 3 days post electrical stimulation (i.e., surgical simulation) under anesthesia. However, corticosteroids plus meloxicam in this study resulted in significant gastric erosions (Boston et al. 2003). A case report of combination aspirin and meloxicam in a dog resulted in duodenal perforation (Reed 2002). This case illustrates the importance of COX-2 in intestinal protection when aspirin is coadministered, and reinforces that different NSAIDs should not be administered concurrently. Analgesia is excellent when meloxicam is combined with an opioid.

In recent years, meloxicam has become the most widely used NSAID in exotic and zoo animals, including reptiles, birds, and numerous mammalian species. Drug use remains off-label, with doses largely extrapolated from domestic animal pharmacokinetic and pharmacodynamic studies. Species-specific studies are beginning to appear in

the literature and should be consulted wherever possible prior to prescribing meloxicam or any NSAID.

Carprofen

Although classified as a NSAID, carprofen administration to beagle dogs did not inhibit PGE_2, 12-hydroxyeicosatetrenoic acid, or thromboxane B_2 synthesis in an experimental study utilizing subcutaneous tissue cage fluids (McKellar et al. 1994b). It was concluded that the principle mode of action of carprofen must be by mechanisms other than cyclooxygenase or 12-lipoxygenase inhibition. However, more recent studies indicate that it is a COX-2 preferential NSAID (Kay-Mugford et al. 2000; Ricketts et al. 1998). Carprofen is approved for perioperative and chronic pain management in dogs in Australasia, Europe, and North America. Carprofen is approved for single dose, perioperative use in cats in Europe, and is licensed for use in horses in the United Kingdom. In sheep, carprofen (0.7 mg/kg IV) resulted in plasma concentrations of 1.5 μg/mL, similar to those required to confer analgesia in horses, for up to 48 hours (Welsh et al. 1992). However, analgesia was not assessed in this sheep study (Welsh et al. 1992). Antithromboxane activity is minimal, suggesting that induced coagulopathy may not be a problem in animals with intact hemostatic mechanisms (Poulsen & Justus 1999; McKellar et al. 1990).

Ketoprofen

Ketoprofen is approved for postoperative and chronic pain in both dogs and cats in Europe and Canada. Ketoprofen is also approved for use in horses and ruminants. As ketoprofen is an inhibitor of both COX-1 and COX-2, adverse effects are a potential problem requiring careful patient selection. Although several studies using ketoprofen preoperatively indicate its effectiveness in controlling postoperative pain, a general consensus among veterinarians has restricted its use primarily to the postoperative period to reduce the potential for hemorrhage (Mathews et al. 1999; Lobetti & Joubert 2000; Pibarot et al. 1997). Ketoprofen should not be administered to patients with risk factors for hemorrhage. It is often administered to animals immediately after orthopedic procedures (i.e., fracture repair, cruciate repair, onychectomy).

Deracoxib

Deracoxib is a COX-2 specific inhibitor. It is approved in the United States and Canada for control of postoperative pain and inflammation associated with orthopedic surgery in dogs. The incidence of vomiting and diarrhea were similar in dogs receiving deracoxib compared to dogs receiving placebo in a perioperative field trial, and overall the drug was well tolerated and effective (Novartis Animal Health USA 2004). It was also shown to be effective in attenuating lameness in dogs with urate crystal-induced synovitis after prophylactic and therapeutic administration (McCann et al. 2004; Millis et al. 2002). This group of NSAIDs appeared to be gastroprotective in human patients when compared to the less COX-2 specific NSAIDs, when used for 8 days to 3 months (Silverstein et al. 2000). However, more recent studies in humans indicate these NSAIDs cannot guarantee gastroprotection with chronic use. Furthermore, in a canine study comparing the gastrointestinal safety profile of licofelone (a dual inhibitor) to rofecoxib (another specific COX-2 inhibitor), rofecoxib was found to induce significant gastric and gastroduodenal lesions (Moreau et al. 2005).

Diclofenac

Diclofenac is available worldwide as several different human and veterinary formulations. It is a useful anti-inflamatory and analgesic drug, and has been studied for antimicrobial activity (Dutta eta l. 2007). Diclofenac has been observed to cause severe hepatic and nephrotoxicity in many species of birds and its use, or accidental ingestion from carcasses, should be avoided (Jayakumar et al. 2010; Jain et al. 2009; Naidoo et al. 2009; Hussain et al. 2008; Taggart et al. 2007; Oaks et al. 2004).

Firocoxib

Firocoxib is available as an oral paste and injectable for horses and as an oral formulation for dogs. The efficacy and adverse events appear similar to other coxib-class NSAIDs (US Food and Drug Administration 2011). There are few reports of firocoxib use in birds, reptiles, or exotic mammals in the literature.

Robenacoxib

Robenacoxib is available as an oral and injectable formulation for treatment of pain and inflammation in both dogs and cats. Specific label indications and doses vary by country. The efficacy and adverse events appear similar to other coxib-class NSAIDs.

Mavicoxib

Mavicoxib is a long-acting NSAID approved outside the United States for use in dogs. The dosing interval is usually 2 weeks between doses 1 and 2, then 4 weeks between subsequent doses. The elimination half-life in healthy dogs is approximately 2 weeks (range 7.9–38.8 days) (Cox et al. 2010). Significant individual and breed-associated differences have been observed but effects on drug safety and effectiveness have yet to be determined (Cox et al. 2011).

Tolfenamic Acid

Tolfenamic acid is approved for use in cats and dogs in Europe and Canada for controlling acute postoperative and chronic pain. The dosing schedule is 3 days on and 4 days off, which must be strictly adhered to. Reported adverse effects are diarrhea and occasional vomiting. Tolfenamic acid has significant anti-inflammatory and antithromboxane activity, therefore post-traumatic and surgical hemostasis may be compromised during active bleeding after administration of this NSAID (McKellar et al. 1994b).

Flunixin Meglumine

Flunixin meglumine is a COX-1 and COX-2 inhibitor that is approved for use in dogs in Europe but not North America. It is also approved for use in ruminants and horses, and is commonly used for equine colic pain.

Phenylbutazone

Phenylbutazone is approved for use in horses, cattle, and dogs in North America. Since safer NSAIDs are approved for dogs, phenylbutazone is not recommended for this species. In horses, there is high risk of gastric ulceration and nephrotoxicity, where signs of toxicity may progress from inappetence and depression to colic, gastrointestinal ulceration, and weight loss (MacAllister et al. 1993; Collins & Tyler 1984; Snow et al. 1981). Phenylbutazone has a prolonged elimination half-live in cattle, ranging from 30 to 82 hours (DeBacker et al. 1980; Arifah & Lees 2002).

Aspirin

Aspirin is primarily a COX-1 inhibitor. It has been most commonly used as an analgesic for osteoarthritic pain in dogs. It is also available in proprietary combinations with various opioids (aspirin plus codeine or aspirin plus oxycodone) to achieve a synergistic effect for the treatment of moderate pain. It is also used as an antipyretic and anticoagulant in dogs and cats. Aspirin has also been recommended in cattle (Gingerich et al. 1975).

Grapiprant

Grapiprant is a non-COX-inhibiting NSAID that acts as an EP4 PG receptor antagonist downstream of traditional NSAIDs in the arachidonic acid cascade. It is approved for treatment of pain and inflammation associated with osteoarthritis in dogs and is supplied in 20-, 60-, and 100-mg flavored tablets. In a clinical trial submitted as part of the regulatory approval process in the United States, grapiprant was found to be effective compared to placebo, although there was no positive control. In the same study, grapiprant was generally well tolerated by dogs, with intermittent diarrhea, vomiting, and anorexia the most commonly reported adverse effects (Rausch-Derra e al. 2016). More studies are needed to demonstrate grapiprant's analgesic efficacy in osteoarthritis and other types of pain and inflammation in dogs and to compare its safety to other approved COX-2 inhibiting NSAIDs.

NSAIDs Not Approved for Use in Veterinary Medicine (Off-label Use)

Ketorolac

Ketorolac is a COX-1 and COX-2 inhibitor that is included for the benefit of those working in the research setting associated with human hospitals where the availability of ketorolac is more likely than other NSAIDs. Adverse gastrointestinal effects are common.

Acetaminophen

Acetaminophen is a COX-3 inhibitor with minimal COX-1 and COX-2 effects. It should not be administered to feline species due to deficient glucuronidation of acetaminophen in these species (Court & Greenblatt 1997). Reptiles are known to be particularly sensitive to the toxic effects of acetaminophen and this has been exploited to combat the invasive brown treesnake on the island of Guam by lacing dead mice with 80 mg of acetaminophen and baiting snake habitats. A recent study has confirmed that the standard 80-mg dose used operationally to kill brown treesnakes produced acute methemoglobinemia, with severe hypoxia and respiratory failure cited as the probable cause of death (Mathies & Mauldin 2020). Based on these findings, acetaminophen should not be administered to any reptile at any dose.

Dipyrone

Dipyrone is a COX-3 inhibitor and is approved for use in cats and dogs in Europe and Canada. Dipyrone should be given intravenously to avoid the irritation experienced when given intramuscularly. The analgesia produced is not usually adequate for moderate to severe postoperative pain, and dipyrone is reserved for use as an antipyretic in cases where other NSAIDs are contraindicated. Dipyrone induces blood dyscrasias in humans, but this has not been reported in animals.

Alpha-2 Adrenergic Receptor Agonists and Antagonists

Introduction

The use of alpha-2 adrenergic agonists in veterinary medicine began following the synthesis of xyalazine in 1962. Early reports of the sedative and anesthetic sparing qualities of xylazine predated the elucidation of its mechanism

of action in 1981. Alpha-2 adrenoreceptors have been identified in the CNS, cardiovascular, respiratory, renal, endocrine, gastrointestinal, and hemotologic systems, resulting in widespread drug effects (Aantaa et al. 1995). Most FDA-CVM approved alpha-2 agonists carry label indications as sedatives and analgesics.

Alpha-2 adrenoceptors are linked to Gi-protein second messengers (Aantaa et al. 1995). These are similar to those used by many opioid receptor subtypes and in fact opioid and alpha-2 agonists usually have additive or synergistic effects (Maze & Tranquilli 1991). Alpha-2 adrenoreceptors are classically described as being located presynaptically at noradrenergic neurons, exerting an inhibitory feed-back role on the release of subsequent norepinephrine (Maze & Tranquilli 1991). This results in decreased sympathetic nervous system efferent activity and is probably related to the decreased vigilance, decreased anesthetic requirements, and decreased heart rate and blood pressure observed following administration of these drugs to most species. Alpha-2 adrenoreceptors are also found in the vascular smooth muscle (a non-presynaptic site) and when activated result in vasoconstriction. This results in increased vascular resistance and will result in increased baroreceptor-mediated vagal tone. The result is slowing of heart rate and decreasing cardiac output, but blood pressure remains within physiologic normal values. Confusion often exists about the clinical effect of alpha-2 agonist administration (e.g., hypertension [post-synaptic[vs. hypotension [pre-synaptic[) expected in a patient. The net clinical result will vary with route of administration, dose, species, and the duration of time following the administration.

Alpha-2 agonist doses vary at least 10-fold across species. Pigs tend to have the highest requirements, followed by cats, dogs, horses, and finally ruminants. Breed and sex differences also exist within cattle that should be appreciated.

Alpha-2 Adrenergic Agonist Effects

Central Nervous System

Alpha-2 adrenergic agonists exert many of their inhibitory effects on CNS function through inhibiting norepinephrine release from sympathetic neurons (Maze & Tranquilli 1991). Inhibition of intraneuronal transmission is also responsible for muscle relaxation observed following alpha-2 adrenergic agonist administration. Analgesia is mediated by spinal and supraspinal alpha-2 adrenergic receptors. Agonist binding modulates afferent activity at a spinal level and increases the diffuse noxious inhibitory control system activity. The net result is sedation, reduced anesthetic requirements, reduced stress responses, and analgesia. It should be noted that alpha-2 agonists, like all sedatives and tranquilizers, are not anesthetics. Although animals can appear in a sleep-like state, they may become aroused by noxious stimulation and may become defensive. Additionally, on rare occasions, paradoxical behavior (aggression rather than sedation) may be noted. Accidental intracarotid injection of alpha-2 adrenergic agonists will induce seizure-like activity and must be avoided.

Emetic Center

Alpha-2 agonists are predictable emetics in cats and dogs, especially at high doses. This is due to activation of the chemoreceptor trigger zone of the area postrema (Hikasa et al. 1992). Dopaminergic blocking agents do not prevent alpha-2 induced emesis.

Thermoregulation

Alpha-2 agonists will often cause changes in thermoregulation. The effect is usually a decrease; however, increases can be seen when animals are placed in warm environments. This is especially a concern when alpha-2 agonists are used for capture of cattle or other hoof-stock. If possible, body temperature should be monitored for 12–24 hours following sedation or administration of an alpha-2 adrenergic antagonist should be considered. In smaller animals, hypothermia is more common and may be due to decreased metabolic activity accompanying sedation as well as decreased thermoregulatory control. It is usually not a life-threatening problem if managed appropriately.

Eyes

Alpha-2 agonists generally cause mild miosis to little change in pupil diameter and a mild decrease in intraocular pressure (IOP) (Verbruggen et al. 2000). This class of drugs is relatively contraindicated, with increases in IOP or corneal lacerations because of the probability of inducing vomiting (which causes further increases in IOP) in those species that can vomit.

Respiratory System

Most alpha-2 adrenergic receptor agonists can cause decreased responsiveness to CO_2, especially in higher doses. This effect is compounded by the coadministration of opioids or anesthetic agents and is of concern during anesthesia. In some species alpha-2 agonists do not normally depress respiration to the point of creating hypoxia and cyanosis. In fact, arterial blood gas values for PaO_2 are usually normal. The bluish color of the mucous membranes that may be noticed on occasion is usually due to slowed venous blood flow accompanying vasoconstriction. As the capillary transit time increase, oxygen extraction increases and notable hemoglobin desaturation will appear as a blue(ish) color. Oxygen therapy will often resolve this

condition. However, in sheep and possibly some other species, xylazine administration has been shown to result in central hypoxemia related to pulmonary changes (Celly et al. 1997, 1999).

Cardiovascular System

Intravenous administration of alpha-2 adrenergic agonists typically results in rapid and pronounced vasoconstriction (Pypendop & Verstegen 1998). If heart rate and cardiac output do not decrease (as can be seen with atropine administration), blood pressure would increase impressively (Alibhai et al. 1996; Short 1991). However, normal baroreceptor reflexes attempt to maintain blood pressure within physiologic limits by increasing vagal tone and slowing heart rate. Heart rate may decrease by 50–75% in some individuals. The cardiac rhythm is often a slow sinus rhythm characterized by two or three sequential beats followed by a long sinus pause. Occasionally, second degree atrioventricular blockade will be seen. Both rhythms are often responsive to antimuscarinic administration (block the vagal reflex) and high heart rates (and blood pressures) will result. Intramuscular or oral administration tends to decrease the incidence of profound bradycardia.

After the initial direct vasoconstriction occurs, vasodilation and reduction in blood pressure may be seen. This is more prominent in primate species. The alpha-2 adrenergic receptor agonists decrease sympathetic nervous system efferent activity, which results in decreased vasomotor tone and heart rate. Alpha-2 adrenergic agonists have historically been used in humans as antihypertensive agents because they reduce vasomotor tone and block the reflex increase in heart rate that can accompany alpha-1 antagonists.

Most of the contraindications to alpha-2 adrenergic receptor agonist administration are related to their cardiovascular side effects. As a general rule, this class of drugs should not be administered to animals that do not have normal healthy cardiovascular systems and/or are exercise intolerant. There are some exceptions, but a thorough understanding of the underlying disease is required and appropriate monitoring is necessary.

Urinary Tract

Alpha-2 adrenergic receptor agonists increase urine output by increasing production of dilute urine (Saleh et al. 2005; Grimm et al. 2001). This is primarily related to inhibition of ADH release and/or synthesis as well as changes in renal hemodynamics (Saleh et al. 2005).

Gastrointestinal Tract

Animals may have complications associated with decreased propulsive activity, including colic and bloat, although this is unusual in most species (Thompson et al. 1991). Longer-acting drugs are more likely to result in a problem. Patients should be observed following alpha-2 adrenergic receptor agonist administration for signs of abdominal distension.

Endocrine

A classic neroendocrine response is hyperglycemia following alpha-2 agonist administration (Abdel el Motal & Sharp 1985; Osman & Nicholson 1991). This is due to a decrease in insulin release. It is usually transient and not clinically significant, although alpha-2 agonists should not be used to sedate animals for glucose curves.

Since alpha-2 agonists reduce sympathetic activity and inhibit the stress response, neuroendocrine markers of the stress response should be affected. Cortisol levels are usually decreased following alpha-2 agonist administration and may not be reliable as indicators of stress or pain (Brearley et al. 1990; Sanhouri et al. 1992).

Specific Drugs

Several alpha-2 adrenergic receptor agonists are approved for veterinary use. Generally, their pharmacologic actions will be similar, but the duration of action and species compatibility will vary. All alpha-2 agonists are potent and potentially dangerous following accidental human ingestion or injection. Care should be taken when handling syringes loaded with these drugs and medical help should be sought immediately if exposure occurs.

Xylazine

Xylazine is the prototypical veterinary alpha-2 adrenergic receptor agonist. Another alpha-2 agonist, clonidine, has been used in humans as an antihypertensive agent and is often used as the prototypical drug in research applications. Xylazine has been administered to many different species, both domestic and exotic. It is readily available and relatively inexpensive.

Xylazine has a shorter duration of action than many of the other drugs. Typical doses will result in muscle relaxation and sedation of horses for 45–60 minutes. This can be advantageous when performing field anesthesia/sedation when a rapid recovery is desired. Xylazine is often combined with opioids such as butorphanol to enhance sedative and analgesic qualities.

Detomidine

Detomidine is a longer-acting alpha-2 agonist approved for use in horses as a sedative. It is commonly administered when profound, long-lasting sedation is needed. When used in high doses as a preanesthetic, low respiratory rates may accompany induction. Detomidine is not used in small

animals but there are a number of reports evaluating its use in combination with other agents in large exotic species, including rhinoceros and zebras.

Medetomidine

Medetomidine is formulated as a racemic mixture that was originally approved as a sedative/analgesic in dogs. Though it is no longer widely available except as formulations prepared for wildlife capture and restraint, it has been extensively evaluated in all domestic species and many exotic and zoological species. It is extremely selective for the alpha-2 receptor and binds it avidly. Atipamezole was developed as the specific antagonist for medetomidine for this reason.

Romifidine

Romifidine is an alpha-2 adrenergic receptor agonist that is approved for use in horses. It has been evaluated in other species and appears to be relatively safe but offers few advantages over other approved products. Some equine clinicians believe is it is a good sedative without causing excessive ataxia.

Dexmedetomidine

Dexmedetomidine contains only the pure dextrorotatory enantiomer of racemic medetomidine, which appears to be responsible for all of the clinically relevant properties of the drug. Due to the absence of the inactive levorotatory enantiomer, dexmedetomidine is twice as potent as medetomidine. It is currently marketed as a solution with half the strength of medetomidine, meaning that equivalent doses of dexmedetomidine and medetomidine have the same volume. The sedative, analgesic, and anesthetic-sparing effects of both drugs appear to be similar when administered at equivalent doses in dogs and cats (Ansah et al. 1998; Granholm et al. 2006, 2007; Kuusela et al. 2000). Hemodynamic side effects and reversal characteristics with administration of the specific antagonist atipamezole also appear similar. Dexmedetomidine has been evaluated in combination with a variety of other injectable agents, including benzodiazepines, dissociatives, opioids, and alfaxalone, in many zoo, exotic, and wildlife species.

Alpha-2 Adrenergic Receptor Antagonists

One big advantage alpha-2 adrenoreceptor agonists have over other sedative/tranquilizers such as acepromazine is reversibility. It is possible to administer an antagonist and within minutes animals will regain function and be able to be released. Antagonist administration will usually result in opposite hemodynamic effects (e.g., acute vasodilation and tachycardia) and they should not be administered in a cavalier fashion. Many of the difficulties (including some deaths) occur with reversal. Also, alpha-2 agonist mediated analgesia is reversed, necessitating administration of other analgesic classes to painful animals. Some species (e.g., domestic horses) are not routinely reversed because of the potential for uncontrollable activity and possible self-trauma.

Yohimbine

Yohimbine is a plant-derived compound that has been used by humans for centuries because of its performance enhancing properties. It is relatively effective for reversing xylazine in horses, dogs, and cats, but is less effective in ruminants. Additionally, yohimbine has some stimulant actions that may result in excitation on recovery. Yohimbine has not been effective at reversing newer agents, such as medetomidine.

Tolazoline

Tolazoline was originally used as a therapy for human infants suffering from pulmonary hypertension. It is a relatively nonselective alpha-receptor blocker and is useful for reducing pulmonary vascular resistance. It is also effective at antagonizing xylazine sedation. It is most commonly used for equine and ruminant species. It appears more effective in ruminant species than yohimbine.

Atipamezole

Atipamezole is the marketed antagonist for medetomidine and dexmedetomidine. It is effective at reversing all available alpha-2 adrenoreceptor agonists and its use is limited only by cost. It is relatively selective for alpha-2 adrenergic receptors and usually does not cause excessive stimulation, although excitation may occur. Atipamezole is approved for use in dogs, but it is used in other species commonly. Under most circumstances, it is best given by the intramuscular route except in emergency situations.

Phenothiazines and Butyrophenones

Introduction

The phenothiazines and butyrophenones produce an array of behavioral, autonomic, and endocrine effects and have been used clinically in numerous domestic and wild species. Their tranquilizing effects are mediated by antagonism of dopamine receptors (primarily the D2 subtype) located in the cerebral cortex, basal ganglia, and limbic system. In addition, other antidopamine effects are noted in the hypothalamus (increased prolactin secretion and impaired thermoregulation), brainstem (impaired vasomotor reflexes), and chemoreceptor trigger zone of the

medulla (antiemesis). Both drug classes also have varying antagonistic effects at adrenergic (alpha-1 and alpha-2), serotonergic (5-hydroxytryptamine receptors), muscarinic (M1), and histaminergic (H1) receptor systems. It is important to note that they do not possess any inherent analgesic properties and their effects are not reversible.

Acepromazine

Acepromazine is the most widely used phenothiazine tranquilizer in veterinary medicine. In dogs and cats it is commonly combined with an opioid to produce a state historically referred to as "neuroleptanalgesia". Such combinations are suitable to provide chemical restraint for short, noninvasive procedures or as preanesthetic medication prior to induction of general anesthesia. Acepromazine administration in the preanesthetic period will cause dose-dependent reductions in both injectable and inhalant anesthetic requirements in these species. In horses and cattle, the drug is used primarily for its anti-anxiety effects. In susceptible pigs, acepromazine has been shown to prevent or reduce the onset of halothane-induced malignant hyperthermia. In certain wild and exotic species, the combination of acepromazine and the potent opioid etorphine (Large Animal Immobilon) has been used for immobilization and anesthesia.

The cardiovascular effects of acepromazine include decreases in mean arterial blood pressure in the range of 20–30% accompanied by dose-dependent reductions in stroke volume and cardiac output. Isoflurane, due to its potent vasodilatory effects, appears to potentiate acepromazine-induced hypotension. At clinically relevant doses, heart rate may not change appreciably or may increase slightly. At very high doses, bradycardia and sinoatrial block may occur. Acepromazine has also been shown to reduce the arrhythmogenic effects of epinephrine and halothane.

In general, effects on pulmonary function (i.e., oxygenation and ventilation) tend to be minimal in conscious animals, although respiratory rate may decrease somewhat. Acepromazine has been shown to dose-dependently decrease hematocrit by as much as 20–50% in dogs and horses due to splenic sequestration. This effect occurs within 30 minutes and appears to persist for at least 2 hours. The drug also decreases platelet aggregation but the clinical hemostatic significance of this appears minimal.

Regarding the gastrointestinal system, acepromazine has been shown to have antiemetic effects when administered 15 minutes prior to morphine, hydromorphone, or oxymorphone. Lower esophageal sphincter tone is reduced, which may lead to an increased risk of gastric reflux, though this has not been proven. Decreased gastrointestinal motility and delayed gastric emptying have been demonstrated in horses.

Renal blood flow and glomerular filtration rate appear to be well-maintained in dogs receiving acepromazine and isoflurane. In cats under halothane anesthesia, urethral pressure has been shown to decrease by 20% with acepromazine administration. There are anecdotal reports of penile prolapse/priapism in stallions. The magnitude and duration of the protrusion appear to be dose-dependent and this side effect appears to be mediated by alpha-adrenergic antagonism. Also, because of its antihistaminergic effects, acepromazine is not suitable for allergic skin-testing.

Azaperone

Azaperone is classified as a butyrophenone and its only approved indication is for control of aggression associated with mixing or re-grouping of swine. It is also used as a preanesthetic agent in pigs and has clinical properties and side effects similar to acepromazine. In various wild and exotic species azaperone is used in combination with potent opioids such as etorphine or carfentanil to produce immobilization or anesthesia.

Analgesia

Douglas P. Whiteside and Kurt K. Sladky

"Pain is inevitable, suffering is optional." Buddhist proverb

Introduction

Over the past decade, pain management has emerged as an important discipline in veterinary medicine, with significant growth of scientific knowledge in neuroanatomy and neurophysiology across the vertebrate taxa. Pain is often now referred to as the fifth vital sign. Optimal management of pain, and the development of future analgesic strategies, requires a lucid understanding of the pathophysiology of pain across taxa, and of the basic pharmacology of the analgesic drugs used to treat it. While pain can be a protective mechanism against acute injury, it also can be a chronic, nonrelenting, and crippling sensory experience that leads to severe stress, with profound changes in normal behaviour and in neuroendocrine, metabolic, and immune responses (Kehlet 1997; Kehlet & Wilmore 2002; Lemke & Creighton 2010; Sneddon et al. 2014; Sneddon 2019).

Many myths have been associated with pain management in zoological, aquatic, and free-living wildlife species and this has led to poor analgesia use in the past. New understandings and techniques have allowed us to develop improved strategies for analgesia and to promote education in their use. Adequate pain relief is not only humane but improves recovery. Understanding that pain is a continuum across species allows for more effective treatment.

Clinicians working with wildlife under human care or in a free-living setting face a number of unknown variables compared to their companion animal counterparts due to the tremendous diversity of species they are presented with, marked differences in physiology across the vertebrate taxa, lack of diagnostic techniques and pain scoring systems to adequately evaluate pain, and the paucity of pharmacokinetic (PK) or clinical studies for free-living and captive wildlife species. However, the physiological, behavioural, and ethical consequences of inadequate pain management behoove us as responsible clinicians to make every effort possible to prevent or control pain in the animals under our care (Hess 2010; Sneddon et al. 2014; Chinnadurai et al. 2016; Balko & Chinnadurai 2017; Mather 2019).

Numerous barriers exist to appropriately managing pain in wildlife species, including lack of familiarity with current therapeutic modalities and techniques, concerns regarding drug-induced adverse effects or toxicity, inadequate species-specific PK and clinical efficacy data, economic considerations, poor assessment of pain, and personal views on pain perception. However, studies of behaviour demonstrate that animals not only experience pain but remember the experience and try to avoid it in the future. No longer should the question be asked "Does the animal experience pain?", but rather "What kind of pain can the animal experience?" Species variability in the expression of pain can occur due to a failure to recognize species-specific pain behaviours, difference in pain sensitivity, and the conscious response of a species. Pain does not always lend itself to objective measures, so the art of medicine should not be overlooked in favour of the science (Nolen 2001; Paul-Murphy et al. 2004b; Hawkins 2006; Chinnadurai et al. 2016; Balko & Chinnadurai 2017; Sneddon 2019).

This chapter is an overview of analgesia across vertebrates and invertebrates, and readers are encouraged to refer to other chapters for references on pharmacology and for more species-specific information.

Physiology of Pain

Pain is a complex sensation that requires integration of nociceptive and other sensory input at the cortical level, while nociception is the neural response to a noxious

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

stimulus. The International Association for the Study of Pain (1979) defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. The inability to communicate pain, and the lack of understanding of whether the vast number of species that are worked with actually experience the emotional experience of pain, does not negate the fact that all potential or actual tissue damages in animals should be considered painful. In addition, it must be recognized that neonates are capable of experiencing pain; in mammals the pain pathways necessary for pain perception are well developed in late gestation, and in humans the spinal cord sensory nerve cells are more excitable in infants with an amplified, prolonged response and larger receptive field to pain. As a result, painful experiences in early life may produce long-term alterations in sensory processing and pain sensitivity (Anand & Hickey 1987; Fitzgerald & McIntosh 1989; Walker 2008; Babos et al. 2013; Anwar 2016).

Our understanding of pain is still based primarily on mammalian studies, although the recognition of pain and its treatment is receiving much more attention now in non-mammalian species. An understanding of the pathophysiology of pain is important to enable more effective management and target future research. Pain can be classified anatomically as somatic or visceral pain, or temporally as acute or chronic. While a significant amount of research has been carried out with acute pain, there is still a paucity of information regarding chronic pain. Pain also is commonly categorized as physiologic or clinical (inflammatory or neuropathic in origin). Physiological pain is protective in nature, well localized, proportionate to the peripheral stimulus, and subsides once the inflammatory process resolves. Clinical pain occurs with significant tissue trauma and inflammation, and is pathological or debilitating in nature. It is diffuse, disproportionate to the peripheral stimulus, and can continue beyond the resolution of the inflammatory process. Clinical pain can take on a disease character in pathological states such as inflammation, neuropathy, cancer, viral infections, chemotherapy, and diabetes. This state is manifest as an increased sensitivity to painful stimuli (hyperalgesia) or withdrawal behavioural responses to innocuous stimuli (tactile allodynia). Furthermore, individuals with chronic pain often show maladaptive, disease-induced, therapy-resistant deviations from normal tactile sensation, such as paraethesias and dysesthesias (Truini & Cruccu 2006; Kuner 2010; Lemke & Creighton 2010; Babos et al. 2013; Anwar 2016).

Ascending Nociceptive Pathways

Most tissues are rich in afferent nociceptors, the free nerve ending receptors that are responsible for the detection of thermal, mechanical, or chemical noxious stimuli. The majority of these receptors are nonselective cation channels that are gated by temperature (e.g., transient receptor potential channels), chemical ligands (e.g., acid sensing ion channels), or mechanical shearing forces. Activation of these channels increases inward conduction of sodium and calcium ions, which ultimately depolarizes the membrane and generates a burst of action potentials. Tissue trauma leads to the release of inflammatory mediators from damaged cells (H^+, K^+, prostaglandins), plasma (bradykinin), platelets (serotonin), mast cells (histamine), and macrophages (cytokines). Some of these inflammatory mediators activate nociceptors directly (bradykinin), whereas others sensitize nociceptors (prostaglandins). Release of neuropeptides such as substance P leads to vasodilation and edema, resulting in further activation and sensitization of nociceptors. Ultimately, tissue trauma and inflammation produce a "sensitizing soup" of chemical mediators that convert high-threshold nociceptors to low-threshold nociceptors. This is known as peripheral sensitization (Muir & Woolf 2001; Lemke & Creighton 2010; Babos et al. 2013; Anwar 2016; Sneddon 2019).

Somatic tissues have a higher density of nociceptive nerve fibers and smaller receptive fields, whereas visceral tissues have a lower density of nociceptive nerve fibers and larger receptive fields. These anatomical differences may account for some of the qualitative differences between somatic (discrete) and visceral (diffuse) pain. The stimuli are converted to an electrical signal (transduction), which is then transferred via myelinated A β and Aδ fibers (sharp or pricking pain, rapid transmission) or unmyelinated C fibers (dull burning pain, slow transmission) to the spinal cord dorsal horn cells (nerve conduction) where they synapse with second-order neurons. Visceral pain, in contrast to somatic pain, lacks the fast and slow components (Julius & Basbaum 2001; Woolf & Ma 2007; Yaksh 2009; Babos et al. 2013; Anwar 2016; Sneddon 2019). Polymodal C fibers can adapt to a variety of physiologic changes with responses to hypoxia, hypercapnea, hyperthermia, hypothermia, hypoglycemia, hyperosmolarity, hypoosmolarity, and lactic acidosis (Riddell & Craig 2003; Sneddon 2019).

Second-order projection neurons in the spinal cord are responsible for transmission of signals (projection) to the thalamus, hypothalamus, medulla, pons, and midbrain. Spinal inhibitory and excitatory interneurons are responsible for gating and modulating nociceptive input from the periphery. The spinothalamic tract is the major ascending nociceptive pathway. Additionally, propriospinal neurons that project across several dermatomes are present in the dorsal horn and are responsible for segmental reflexes associated with nociception. Glutamate is the primary excitatory neurotransmitter in the dorsal horn of the spinal

cord. Nociceptive as well as non-nociceptive fibers co-release glutamate and neuropeptides such as substance P and neurokinin A. Activation of a specific type of glutamate receptor, the N-methyl-D-aspartate (NMDA) receptor, plays a key role in the development of central sensitization, known as "wind up" (Woolf & Chong 1993; Muir & Woolf 2001; Lemke & Creighton 2010; Babos et al. 2013; Anwar 2016).

Third-order supraspinal neurons integrate the input from spinal neurons, thalamus, hypothalamus, medulla, pons, and midbrain and project to the somatosensory and insular (interoceptive) cortex where the pain is perceived (perception) and there are linkages with the autonomic nervous system. Projection from neurons in the lateral thalamus to neurons in the insular and secondary somatosensory cortex appears to be responsible for the sensory-discriminative aspects of pain. Projection from neurons in the medial thalamus to neurons in the anterior cingulate cortex appears to be responsible for the motivational-affective (emotional) aspects of pain. Projection from neurons in the motor thalamus to neurons in the primary somatosensory cortex appears to be responsible for sensory and motor integration. Once received by the conscious brain, the brain interprets and gives cognition to nociceptive signals, giving rise to a state of pain-induced distress (Kuner 2010; Lemke & Creighton 2010; Babos et al. 2013; Anwar 2016).

Antinociceptive Descending Pathways

Modulation or inhibition of nociceptive input at the spinal and supraspinal levels is the basis for descending antinociceptive pathways. This modulation leads to hyposensibility or a lack of pain in spite of inputs coming in from the periphery. The antinociceptive pathways begin at the supraspinal level (thalamus, hypothalamus, midbrain, medulla, and pons) with indirect input from the insular cortex and the anterior cingulate cortex. Release of norepinephrine, endogenous opioids (endorphins, enkephalins, dynorphins), and gamma-aminobutyric acid (GABA) inhibits synaptic transmission between primary afferent neurons and projection neurons by inhibiting neurotransmitter release and hyperpolarizing the postsynaptic membrane, which effectively shuts down the key synapse in the dorsal horn. This has evolutionary value because these mechanisms can enable the organism to ignore pain in critical situations, such as flight or fight, and may contribute to analgesia produced by a variety of nonpharmacological pain control approaches, such as transcutaneous electrical nerve stimulation and acupuncture (Muir & Woolf 2001; Kuner 2010; Lemke & Creighton 2010; Babos et al. 2013; Sneddon et al. 2014; Anwar 2016).

Principles of Pain Management

Effective analgesic therapy blunts the neuroendocrine response, reduces major complications, produces discernible changes in posture and behavior, and improves outcome (Carli & Schricker 2009; Wu & Liu 2009; Mosley 2011; Sneddon et al. 2014). The World Health Organization outlines a three-step analgesic ladder for the control of cancer pain in people, which has been well received and adapted by the veterinary community for managing pain (World Health Organization 2018). Nonopioids, generally nonsteroidal anti-inflammatory drugs (NSAIDs), are used for mild pain. If the pain persists, or is of moderate intensity, it is treated with the combination of a nonopioid and a 'weak' opioid. More severe pain dictates that a "strong" opioid replace the 'weak" opioid, often at higher doses or titrated to the degree of pain. At any of these levels, adjunctive analgesia (e.g., local anesthetics, alpha-2 agonists, NMDA antagonists, tricyclic antidepressants, anticonvulsants, corticosteroids, bisphosphonates, nutraceuticals), can be used to augment analgesia, taking into consideration the potential interactions and side effects (Babos et al. 2013).

Pain management should not just revolve around drugs, and whenever possible a more holistic, multimodal approach should be taken. Environmental conditions should be optimized for the species. Weight loss and adjunctive therapies such as chondroprotectants, physical therapy and rehabilitation, acupuncture and laser therapy, dietary manipulations, and even surgery also play an important role in the multimodal approach to pain (Truini & Cruccu 2006; Whiteside et al. 2006; Koski 2011; Rychel et al. 2011; Dadone & Harrison 2017). Atraumatic surgical technique is always the most effective method to prevent peripheral and central sensitization and the development of postoperative pain (Lemke & Creighton 2010).

There are five major classes of analgesic drugs, and each class blocks or modulates nociceptive input at one or more sites of action (Fig. 2.1). Alpha-2 agonists and opioids alter the central perception of pain. Activation of supraspinal and spinal alpha-2 receptors and opioid receptors also inhibits synaptic transmission in the dorsal horn of the spinal cord. Peripheral and central neural blockade with local anesthetics inhibits the development of central sensitization, as does administration of dissociative anesthetics such as ketamine which block NMDA receptors on projection neurons. Cyclooxygenase (COX) inhibitors such as NSAIDs reduce the synthesis of prostaglandins, which reduces inflammation and limits the development of both peripheral and central sensitization (Lamont & Grimm 2014; Lemke & Creighton 2010; Babos et al. 2013).

Trauma and inflammation sensitize the peripheral nervous system, and the subsequent barrage of nociceptive input

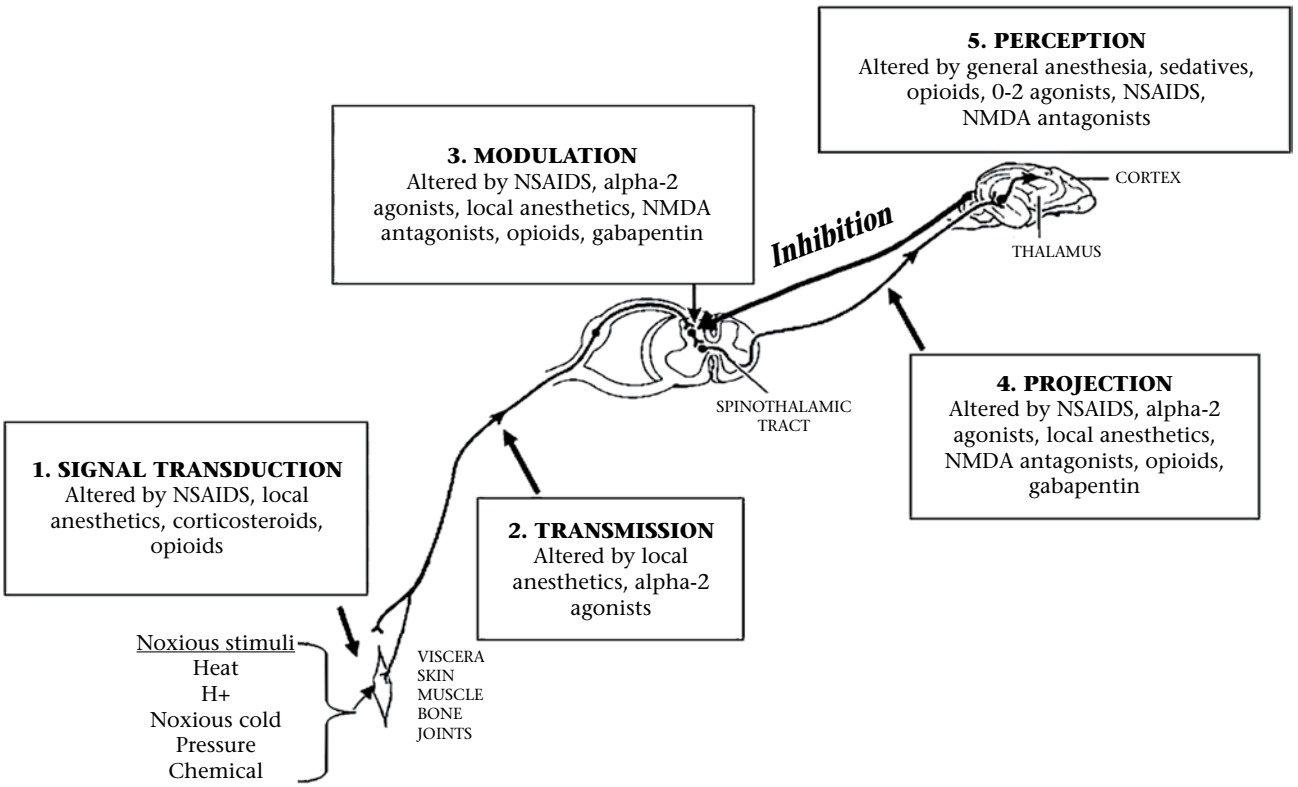

Figure 2.1 The pain pathway. Alpha-2 agonists, NMDA, N-methly-D-aspartate; NSIADs, nonsteroidal anti-inflammatory drugs.

produces sensitization of neurons in the dorsal horn of the spinal cord. Peripheral and central sensitization of nociceptive pathways plays a central role in the development of pathological pain (Woolf & Chang 1993; Babos et al. 2013). Blockade or attenuation of ascending nociceptive pathways or activation of descending antinociceptive pathways by different classes of analgesic drugs usually provides better analgesia with fewer side effects than unimodal therapy with a single class of analgesic drugs. Because peripheral and central neural blockade with local anesthetics are the only analgesic techniques that can produce complete blockade of peripheral nociceptive input, these techniques are the most effective way to attenuate sensitization of the central nervous system and the development of pathological pain (Lemke & Dawson 2000; Carli & Schricker 2009; Siddall & Cousins 1998; Lemke & Creighton 2010; Babos et al. 2013).

Behavioural responses are one of the first observable signs that an animal is reacting to a stimulus. Whenever possible, species-specific pain scores should be developed that incorporate established normal behaviours and alterations associated with pain (Hampshire & Robertson 2015; Dunbar et al. 2016; Klune et al. 2019; MacRae et al. 2018; McLennan et al. 2019). However, using a consistent generic scale (e.g., 1–10 scale) can also be of great value to evaluate pain and response to therapy (Paul-Murphy & Hawkins 2012).

Pain and its Management in Vertebrate Species

Historically, it was a commonly held belief that mammals had a higher neurological capacity to experience pain compared to nonmammalian species, and that this capacity was directly related to the phylogenetic hierarchy. However, biochemical, anatomical, and physiological studies convincingly show the transmission, mediation, and central processing and modulation of painful stimuli in the lower vertebrates is analogous to that of mammals (Chandroo et al. 2004; Sneddon et al. 2014; Sneddon 2019). Neuroanatomy is largely conserved among vertebrate animals within the peripheral nervous system and central nervous system (Brenner et al. 1994; Chandroo et al. 2004; Butler & Hodos 2005; Sneddon et al. 2014; Sneddon 2019). While mammals, birds, and reptiles have more highly developed specialized sensory cortical regions of thickened grey matter covering the telencephalon known as the neopallium or neocortex, the relative lack of pallial development in amphibians and fish, unfortunately, has formed the basis for biases that the latter do not experience pain but rather only nociception (Striedter 1997). However, fundamental features have been conserved throughout pallial evolution. The less-evolved pallium still can execute similar

physiological functions in fish and amphibians as in higher vertebrates because the neural basis for consciousness involves widespread integration of differentiated neurons in the pallial and subpallial regions of the brain (Echteler & Saidel 1981; Northcutt 1981; Davis & Kassel 1983; Saidel et al. 2001; Wullimann & Rink 2002; Chandroo et al. 2004; Sneddon et al. 2014). Summaries of commonly used analgesics in nonmammalian vertebrates and in mammals are provided in Tables 2.1 and 2.2, respectively.

Fish

Fish nociceptors are physiologically identical to higher vertebrates, responding to mechanical pressure, heat, and noxious chemical stimuli (Sneddon 2004, 2009; Ashley et al. 2007). Of the three major classes of fish, Osteichthyes (bony fishes) have both types of polymodal fibers (Aδ and C fibers), with Aδ fibers being the predominant type (Sneddon et al. 2003a; Chandroo et al. 2004; Ashley et al. 2007; Webber 2011). In Chondrichthyes (elasmobranchs), only Aδ fibers have been identified (Coggeshall et al. 1978; Chandroo et al. 2004) while the Agnatha (hagfishes and lamprey) primarily have C-type fibers (Matthews & Wickelgren 1978).

Fish also show similar organization of their major spinal pathways (spinothalamic tract and trigeminal tract) as in other tetrapods and exhibit analogous biochemical mediation of nociception (Ronan & Northcutt 1990; Sneddon 2011, 2019; Webber 2011). In teleosts, several peptides may transmit and modulate nociceptive signals (e.g., substance P), and the behavioural and autonomic nervous system responses to noxious stimuli are specifically indicative of detection (Ostlund & Von Euler 1956; Weld & Maler 1992; Ide & Hoffmann 2002; Chandroo et al. 2004). Electrical activity during noxious stimulation has been recorded in the forebrain and midbrain of rainbow trout, goldfish, and Atlantic salmon (Dunlop & Laming 2005; Nordgreen et al. 2007), and this electrical activity differed according to stimulus type (e.g., simple touch vs. noxious, potentially painful stimuli). In addition, rainbow trout and carp exposed to noxious stimuli experienced global gene expression changes to their brains, particularly the forebrains, which mirrors the importance of the forebrain in mammalian pain processing (Reilly et al. 2008; Sneddon 2009).

Opioid receptors and endogenous substances (e.g., enkephalin-like) are present in the brain and spinal cord of those fish species studied, and frequently demonstrated a similar distribution pattern to that of higher vertebrates (Buatti & Pasternak 1981; Rosenblum & Callard 1988; Li et al. 1996; Porteros et al. 1999; Alvarez et al. 2006; Sneddon 2009, 2019). Administration of morphine can blunt physiological and behavioural changes associated with noxious stimuli in fish species (Ehrensing et al. 1982; Sneddon 2003, 2019; Nordgreen et al. 2009). COX enzymes have also been identified in a zebrafish (Grosser et al. 2002; Teraoka et al. 2009).

Recognition of Pain in Fish

Current behavioral studies of pain in fish are restricted to a few species (zebrafish, rainbow trout, common carp, koi, and silver catfish) and include three experimental models and one surgical model of pain. Experimental models include subcutaneous (SC) injection of noxious substances such as acetic acid and bee venom, thermonociception, and, more recently, electrical nociception. One study evaluated a surgical model of pain in koi, in which an ethogram was developed for measuring pain-related behaviours (Baker et al. 2013). As fish are one of the most diverse vertebrate groups, there is a definite need for future research to include a wider range of species, different pain measures, and different models of pain. However, these studies have provided further proof that fish have the capacity to detect, conceptualize, and subsequently respond to nociceptive stimuli. There is growing scientific evidence to support the case for fish perceiving and experiencing some of the negative affective aspects of pain. It is clear that a painful stimulus does result in adverse changes in behaviour and physiology which may impair the welfare and well-being of fish (Sneddon 2003; Chandroo et al. 2004; Reilly et al. 2008; Sneddon et al. 2003b; Roques et al. 2010; Correia et al. 2011; Sneddon 2011, 2019; Webber 2011).

The paucity of comprehensive clinical baseline data for the majority of fish species complicates the identification of pain and or distress in fish. Depending on the environment, it may be difficult to observe behavioural changes, especially with secretive species. Most behavioral changes in fish after noxious stimulation occur in the period immediately after the treatment for up to 6 hours, often peaking between 1 and 1.5 hours. Goldfish and trout demonstrate learned avoidance behaviour after exposure to a noxious stimulus (Overmier & Hollis 1990; Ehrenshing et al. 1992; Sneddon et al. 2003b). Clinical signs ascribed to pain in fish are anomalous behaviors such as rubbing the affected area, rocking from side to side with the pectoral fins, decreased activity or swimming behaviour, increased gill ventilation (opercular) rates, decreased feeding behaviour, colour changes, changed postural positions in the water column, increased cortisol levels, and exocytosis of mucous from gill cells. In rainbow trout, the administration of morphine significantly reduced all of the behavioral and physiological changes described above, further demonstrating that they were specifically due to pain (Sneddon et al. 2003b; Chandroo et al. 2004; Reilly et al. 2008; Ashley et al. 2009; Sneddon 2011; Webber 2011).

Table 2.1 Commonly used analgesics in nonmammalian vertebrates.

Analgesic	Avian	Reptiles	Amphibians	Fish
Opioids				
Buprenorphine	0.1 mg/kg IM q6h (American kestrel) (Cuelmans et al. 2014; Gustavsen et al. 2014) 0.25–0.5 mg/kg IM q2–5h (pigeon) (Gaggermeier et al. 2003) 1.8 mg/kg IM q24–48h sustained release formulation (American kestrel, red tailed hawk) (Mazor-Tomas et al. 2014; Gleeson et al. 2018; Sanchez-Migallon Guzman et al. 2017a, 2018a) No evidence of analgesic efficacy in studied psittacines or chickens (Paul-Murphy et al. 2004a; Sanchez-Migallon Guzman et al. 2018)	No evidence of analgesic efficacy	46–100 mg/kg SC, ICe q24h (Stevens 2004; Koeller 2009)	0.1 µg/mL (zebrafish larvae) (Steenbergen et al. 2018) No evidence of analgesic efficacy; prolonged bradypnea and bradycardia (trout) (Mettam et al. 2011; Grans et al. 2014)
Butorphanol	1.0–5.0 mg/kg IM Frequent dosing needed due to short half-life (Paul-Murphy et al. 1999; Hawkins 2006; Klaphake et al. 2006; Sladky et al. 2006; Hawkins & Paul-Murphy 2011; Sanchez-Migallon Guzman et al. 2011; Singh et al. 2018)	1.5–8.0 mg/kg SC, IM UID-BID (Greenacre 2008) Questionable efficacy in some studied species Respiratory depression and profound sedation at >10 mg/kg	25–33 mg/kg SC q8–12 h (Stevens et al. 2011) 0.5 mg/L continuous bath q24h (Koeller 2009)	0.25–0.5 mg/kg IM q24h (Harms et al. 2005; Davis et al. 2006) No clear efficacy after gonadectomy (koi) (Baker et al. 2010) Equivocal data using MS-222 MAC (goldfish) (Ward et al. 2012) No efficacy in studied elasmobranch (dogfish)
Fentanyl	0.02 mg/kg IV (raptors) (Pavez et al. 2011) Fentanyl patch (7.3–11.3 µg/kg/h) (chicken) (Delaski et al. 2016) 5 mg/kg transdermal (helmeted guineafowl) (Waugh et al. 2016)	12 µg/h patch q72h (skinks) (Gamble 2009) 12 µg/h patch (snakes) PK (Kharbush et al. 2017) 0.05 mg/kg SC (slider turtles) (Kaminishi et al. 2019)	0.8 mg/kg SC q24h (Stevens 2004, 2011) 0.5 mg/kg SC (bullfrog) (Van Bonn 2009)	6 µM bath (larval zebrafish) (Curtright et al. 2015)
Hydromorphone	0.1–0.6 mg/kg IM q3–6h (American kestrel) (Sanchez-Migallon Guzman et al. 2013b, 2014) No evidence of analgesic efficacy in studied psittacines (Houck et al. 2018)	0.1–1.0 mg/kg SC, IM q24h (Mans et al. 2011) 0.5–1.0 mg/kg SC q24h (RES, BD) (Hawkins et al. 2019) Watch for sedation and respiratory depression >0.5 mg/kg	No data available	0.25–0.5 mg/kg IM
Morphine	Not recommended	Saurians, Chelonians: 1–5 mg/kg SC, IM, IT q24h (Mauk et al. 1981; Hawkins 2006; Mans et al. 2011) Crocodilians: 0.3 mg/kg q24h (Kanui & Hole 1992) 0.5 mg/kg + lidocaine (4 mg/kg) IT (bearded dragons) (Fink et al. 2022)	114 mg/kg SC q12h (Stevens 2004, 2011) 40–100 mg/kg SC (leopard frogs) (Stevens 2011) 10 mg/kg ICe (Xenopus and leopard frogs) (Coble et al. 2011; Moorea & Jessop 2003)	5–40 mg/kg IM, IP q24–48h (Nordgreen et al. 2009; Newby et al. 2009; Baker et al. 2012) 3–6 mg/kg IM (zebrafish) (Correia 2011) 48 mg/L bath (zebrafish) (Lopez-Luna et al. 2017a,b) Decreased MS-222 MAC (goldfish) (Ward et al. 2014)

Nalbuphine	12.5 mg/kg IM Frequent dosing needed due to short half-life (Sanchez-Migallon Guzman et al. 2011b)	No data available	No data available	No data available
Remifentanil	No data available	No data available	2.8 mg/kg SQ (Mohan & Stevens 2006)	No data available
Tramadol	5 mg/kg IV, 5–30 mg/kg PO (Souza et al. 2009, 2010; Black et al. 2010; Geelan et al. 2013; Kilburn et al. 2014; Bailey et al. 2019; Raisi et al. 2019)	5.0–25 mg/kg PO q48–72h (Greenacre 2008; Baker et al. 2011; Norton et al. 2015)	25 mg/kg PO q24–48h	0.26–2.6 mg/kg IM (Chervova & Lapshin 2000)
NSAIDS				
Aspirin				2.5 mg/L bath (larval zebrafish) (Lopez-Luna et al. 2017a,b)
Carprofen	2.0–4.0 mg/kg SC, IM q12h (Paul-Murphy et al. 2009; Oakes & Meteyer 2012)	2.0–4.0 mg/kg IM q24h (Greenacre 2008)	2.0–4.0 mg/kg IM q24h	2–3 mg/kg IM (Mettam et al. 2010)
Flunixin	3.0–5.5 mg/kg IM Watch for renal lesions and muscle necrosis (Machin et al. 2001; Baert & De Backer 2003)	0.1–2.0 mg/kg SQ, IM q24–48h (Mosely 2011)	25 mg/kg SC q24h (Terril-Robb et al. 1996; Coble et al. 2011)	2–8 mg/L bath (zebrafish) (Deakin et al. 2019) 2.2 mg/kg IM (Nile tilapia) PK (Martin 2021)
Ketoprofen	2.0–5.0 mg/kg IM, PO q8–12h (Graham et al. 2005; Machin et al. 2001; Oaks & Meteyer 2012)	2.0 mg/kg SC, IM >q31h (Greenacre 2008; Tuttle et al. 2006) 2.0 mg/kg IM/IV (PK, loggerhead sea turtles) (Thompson et al. 2018; Harms et al. 2021)	No data available	No evidence of analgesic efficacy
Meloxicam	1–2 mg/kg SC, IM q12–24h 0.5–2 mg/kg PO q12–24h (Baert & De Backer 2003; Wilson et al. 2005; Lacasse et al. 2013; Molter et al. 2013; Lindemann et al. 2016; Zordan et al. 2016; Boonstra et al. 2017; Dhondt et al. 2017; Montesinos et al. 2017; Morrison et al. 2018; Miller et al. 2019; Sartini et al. 2019) Sustained release formulation: 3 mg/kg (Guzman et al. 2017; Sim & Cox 2018)	0.1–0.5 mg/kg SC, IM, PO q24–48h (Greenacre 2008; Divers et al. 2010; Lai et al. 2015) 1.0 mg/kg SC q24h and 2.0 mg/kd SC q48h (PK, sea turtles) (Norton et al. 2021a,b)	0.2–0.3 mg/kg SC, IM q24h (Coble et al. 2011; Minter et al. 2011)	0.2–0.3 mg/kg SC, IM q24–48h
Piroxicam	0.5–0.8 mg/kg PO q12h (Paul-Murphy 2010)	No data available	No data available	No data available

Analgesia in Fish

Although empirical usage of analgesics in fish has become more widespread in a captive setting, its use in a field setting has been minimal where invasive surgeries such as implantation of intracoelomic electronic transmitters occurs (Harms & Lewbart 2011). The lack of approved analgesics for fish further complicates treatment. There are relatively few studies of analgesic use in fish, and varying results highlight the challenge of extrapolating findings between species.

Sladky et al (2001) demonstrated that red pacu (*Piaractus brachypomus)* anesthetized with eugenol, the active ingredient in clove oil and an effective studied anesthetic in numerous fish species, did not blunt the responses to a noxious stimulus compared to tricaine methanesulfonate (MS-222). In zebrafish injected with acetic acid in the face, low concentrations of eugenol had no effect on pain-associated behavior (Baldisserotto et al. 2018). No other published studies have demonstrated an analgesic effect of eugenol in fish. This is particularly concerning with the worldwide use of isoeugenol for fish anesthesia, including invasive surgical procedures, which likely provides no analgesic properties. Alpha-2 agonists, such as medetomidine, induce sedation in those fish species studied but analgesic activity has not been demonstrated (Neiffer & Stamper 2009). Local anesthetics such as lidocaine and benzocaine have been used for immersion anesthesia and for local effects anecdotally, but have not been well studied in a research setting. Mettam et al. (2011) demonstrated that local infiltration of lidocaine (6.25–16 mg/kg) was the most effective analgesic compared with buprenorphine and carprofen in trout being injected with noxious acetic acid. Using a caudal fin forceps pinch to induce a painful stimulus in adult zebrafish, a combination of lidocaine (100 μg/mL) + propofol (1.25 μg/mL) administered as a bath solution was as effective as MS-222 for reducing a movement response to the pinch (Martins et al. 2018). In larval zebrafish, lidocaine (5 mg/L) administered as a bath decreased behavioral changes induced by acetic acid added to the water of the fish (Lopez-Luna et al. 2017a).

Parenteral morphine, a μ receptor agonist, has been demonstrated to be effective in ameliorating the adverse physiological or behavioural reactions to noxious stimuli in goldfish, winter flounder (*Pseudopleuronectes americanus*), and trout, and to pain from gonadectomy in koi (*Cyprinus carpio*) (Sneddon 2003; Newby et al. 2007, 2009; Baker et al. 2013). Morphine also reduced the minimum inhibitory concentration (MAC) of MS-222 in goldfish that was deemed necessary to attenuate a response to an intramuscular (IM) needle insertion in goldfish, therefore suggesting morphine may have analgesic properties (Ward et al. 2012). In adult zebrafish, morphine administered 30 minutes prior to acetic acid injections into the lips attenuated the decreased activity observed in control fish receiving saline; naloxone eliminated this response (Correia et al. 2011). Morphine (48 mg/L) administered as a bath decreased behavioral changes after exposure to acetic acid and hot water baths in larval zebrafish, but had no effect on the fish when exposed to a cold-water bath (Lopez-Luna et al. 2017a,b). This suggests that the type of experimental model plays a role in how and when fish species will respond to specific noxious stimuli. Conversely, morphine was found to be ineffective at studied doses (40 and 50 mg/kg) in goldfish in thermonociception experiments (Nordgreen et al. 2009), supporting the idea that the type of noxious stimulus may be important in determining the efficacy of an analgesic in fish. Morphine has also been shown to have potential deleterious consequences in fish species. In winter flounder, morphine administration was associated with a marked bradycardia and reduction in cardiac output initially, followed by a significant increase in heart rate for 48 hours compared to controls (Newby et al. 2007). The elimination half-life of morphine in studied fish species is several fold longer that in mammals, ranging from 12.5 to 37 hours, and may be associated with water temperature (Nordgreen et al. 2009). Morphine elimination after IM administration appears to be species-specific, as rainbow trout eliminated morphine faster than winter flounder (Newby et al. 2007). However, morphine administered via the water had extremely slow uptake in goldfish (Newby et al. 2009).

Butorphanol (0.4 mg/kg IM), a κ-opioid receptor agonist, but not ketoprofen (NSAID) was effective at reducing postsurgical pain-related behavioural changes in koi, although ketoprofen reduced postsurgical muscle damage (Harms et al. 2005). At higher doses butorphanol (10 mg/kg) provided antinociceptive activity in koi undergoing gonadectomy but was associated with respiratory depression and abnormal buoyancy (Baker et al. 2013). However even at higher doses, neither drug was effective in an elasmobranch, the chain dogfish (*Scyliorhinus rotifer*), for reducing minimum anesthetic concentrations (Davis et al. 2006). In a (MAC) study using goldfish as subjects, a low dose of butorphanol decreased the MAC of MS-222, but a higher dose increased the MAC of MS-222, making interpretation of analgesic properties unclear (Ward et al. 2012).

Other opioid or opioid-like drugs, buprenorphine (partial μ agonist), and tramadol (μ-opioid properties), also have been studied in fish. IM buprenorphine did not provide evidence of analgesia in rainbow trout subjected to SC acetic acid injections (Mettam et al. 2011). However, in zebrafish larvae, bath-administered buprenorphine prevented stimulus-induced responses to noxious stimuli (e.g., electrical, thermal, and SC acetic acid administration), and

these responses were eliminated when bath naloxone was administered prior to the buprenorphine (Steebergen 2018; Curtright et al. 2015). Buprenorphine administered intramuscularly to rainbow trout caused significant and prolonged bradycardia and bradypnea that lasted 4–5 days post-administration (Grans et al. 2014). Tramadol administered intramuscularly in common carp induced a prolonged (greater than 2 hours) dose-dependent analgesic response to a noxious electrical stimulus, while still maintaining normal swimming and other behaviours (Chervova & Lapshin 2000). However, in a study using zebrafish, tramadol (25 μg/fish IM) caused hyperactivity and tachypnea, and at 50 μg/fish caused 100% mortality (Zhao et al. 2016). These conflicting data may be due to species or dose-response differences.

Fentanyl, a synthetic μ-opioid agonist that is approximately 80–100 times the potency of morphine, attenuated nocifensive behavioral reactions to formalin added to water (6 μM bath) in larval zebrafish, but also caused respiratory depression (Zaig et al. 2021). The μ-opioid antagonist naloxone reversed these behaviors, and so these data corroborate the morphine data that μ-opioid receptor agonists are a logical choice when considering opioid analgesic drugs in fish.

There are very few data in the literature with respect to nonsteroidal analgesic efficacy or anti-inflammatory activity in fish species, primarily because efficacy is difficult to measure. Aspirin (2.5 mg/L) prevented the hypoactivity associated with exposure to 0.1% or higher acetic acid in zebrafish (Lopes-Luna et al. 2017). Ketoprofen was demonstrated to reduce the MAC of MS-222 in goldfish (Ward et al. 2012). Carprofen administered to rainbow trout appeared to normalize behavior (increase activity and decrease respiratory rate) after acetic acid was administered subcutaneously, but decreased activity was observed at a high dose (Mettam et al. 2011). Meloxicam has not been systematically studied as an analgesic in fish species but is eliminated more rapidly in Nile tilapia compared to mammals when administered both intramuscularly and intravenously (Fredholm et al. 2016). Nevertheless, in clinical practice, meloxicam is administered empirically at doses of 0.2–0.3 mg/kg as an analgesic and anti-inflammatory drug. Flunixin meglumine (2.2 mg/kg IM) administered to Nile tilapia achieved relatively high plasma concentrations by 12 hours post drug administration and remained detectable for 96 hours, although concentrations were below clinically relevant plasma concentrations (compared to mammals) by 24 hours post administration (Martin 2021). These data compare favorably to an efficacy study in which the avoidance behavior of female zebrafish subjected to a fin clip was unchanged after exposure to bath flunixin meglumine at multiple concentrations (2, 4, and 8 mg/L) (Deakin et al. 2019). More recently, using a different NSAID, robenacoxib (2 mg/kg IM) was shown to be antinociceptive in rainbow trout after acetic acid lip injections, and the clinically relevant plasma concentrations (compared to mammals) lasted up to 3 days after a single IM dose (Raulic et al. 2021). More NSAID efficacy and PK studies are needed across a variety of fish species, since NSAID use is a staple of clinical veterinary medicine.

A few other classes of drugs have been evaluated as analgesics in zebrafish using a thermal nociceptive model in which fish are exposed to either cold or hot water, with and without the drug, and their behavior measured. Both clonidine (an alpha-2 adrenergic agonist) and amitriptyline (a tricyclic antidepressant and used for neuropathic pain) diminished the behavioral response to thermal noxious stimuli, but gabapentin did not (Curtright et al. 2015). Using an different alpha-2 adrenergic agonist in goldfish, medetomidine (0.025 mg/kg IM), had a minimal effect on decreasing the MAC of MS-222, suggesting a possible, yet negligible, analgesic effect (Ward et al. 2012).

Amphibians

Amphibian nociceptive afferents are analogous to the primary afferents of other vertebrates, including mammals, with both lightly and heavily myelinated (Aβ and Aδ, respectively) and unmyelinated (C) afferent fibers found in mixed-fiber peripheral sensory nerves (Stevens 2004, 2011). The majority of all impulses induced by noxious stimuli such as pinching, pin pricks, and heat are conducted by slowly conducting C fibers, while epidermal application of dilute acetic acid evoked Aδ and C fibers to a relatively equal extent (Maruhashi et al. 1952; Hamamoto & Simone 2003). Sensory afferents terminate in the dorsal horn of the spinal cord and, similar to mammals, pain-signaling neurotransmitters such as substance P, glutamate, and calcitonin have been identified (Inagaki et al. 1981; Lorez & Kemali 1981). Amphibian studies have demonstrated responsiveness to alpha-2 agonists and to local anesthetics. In addition, met-enkepahalin and four types of opioid receptor (μ, κ, δ, and ORL-1) are abundant in the amphibian spinal cord and brain but exhibit less selective binding compared with mammals (Newman et al. 2002; Stevens 2004; Walthers et al. 2005; Bradford et al. 2005). There have only been a few studies that evaluated opioid receptor density in amphibians, with μ receptors being more abundant than κ receptors in leopard frogs (*Lithobates pipiens*), but the reverse was found in marine toads (*Bufo marinus*) (Brooks et al. 1994; Newman et al. 2002). Further research is required to elucidate opioid receptor densities in other amphibian species.

Although the spinal ascending nociceptive pathways in amphibians are not clearly defined, a single study in frogs

identified that electrical stimulation of the sciatic nerve traveled through the spinal ascending pathways and produced evoked potentials in the thalamus and primordial hippocampus (Vesselkin et al. 1971; Munoz et al. 1997). Thalamocortical projections in anurans are more diffuse and less organized than in mammals, but terminate in the nonolfactory telencephalon as with other vertebrates. Similar to fish, there is minimal cerebral or limbic cortical pallial development, but it is likely that other neural pathways have developed for the perception of pain (Stevens 2004, 2011).

Recognition of Pain in Amphibians

The acetic acid test has been used for decades to assess amphibian nociception, with application of varying diluted concentrations to the hind limb and monitoring for a wipe response by the fore limb (Pezalla 1983; Coble et al. 2011; Stevens 2011). The primary problem associated with the acetic acid test is that it causes inflammation, in addition to being a noxious nociceptive chemical, which is a confounding factor in attempts to discriminate only nociception. Based on this test, dermal exposure to other noxious stimuli is likely to elicit a similar response. More recently the Hargreaves test has been validated to evaluate thermonociception, where heat is applied to the inner thigh of the frog in a specialized apparatus and the frog is monitored for withdrawal movement of the hind limb (Coble et al. 2011). Recently, this model was applied to African clawed frogs (*Xenopus laevis*) after surgical laparotomy, but the author concluded that the frog subjects, with or without MS-222 anesthesia, did not consistently respond to the thermal noxious stimulus (Vachon 2014). In a different study, the thermal noxious stimulus withdrawal model was used in comparison with the acetic acid wipe test in *Xenopus laevis*, and the authors found the acetic acid test caused significant skin lesions, while the thermal latency test was useful for testing analgesic and anti-inflammatory drugs (Coble et al. 2011). One of the current author's laboratories (K.K.S.) recently determined that White's tree frogs and leopard frogs consistently respond to a thermal noxious stimulus applied to the hind limb, but there was wide variability in the temporal latency for the responses (Sladky 2019).

Physiologic changes have been used to quantify stress and pain in amphibians (Moorea & Jessop 2003). In a comparative anesthesia/analgesia study using Oriental fire-bellied toads (*Bombina orientalis*), heart and respiratory rates were depressed in toads immersed in alfaxalone-butorphanol, but the same toads immersed in alfaxalone-morphine had normal heart rates and depressed respiratory rates (Adami et al. 2016). In Indian bullfrogs (*Rana tigrina*), the number of eye blinks and the gular respiration rate were used to measure pain associated with intracoelomic administration of concentrated saline (Pathak et al. 2014). Changes in these two behaviors were quantified following administration of NSAIDS to determine analgesic efficacy. Piroxicam, diclofenac sodium, and ketoprofen decreased the number of eye blinks, but there were no statistically significant differences compared with saline controls.

Several behavioural parameters have been clinically associated with pain in amphibians, including decreased activity and feeding behaviour, colour changes, increased reclusive behaviours, and postural changes. Painful amphibians also may spend more time in atypical locations (Duncan 2012). Koeller (2009) demonstrated that Eastern red-spotted newts (*Notophthalmus viridescens*) undergoing bilateral forelimb amputation did not eat for 72 hours post surgery without analgesics, while feeding resumed within 24 hours in those newts receiving intracoelomic buprenorphine or immersion bath butorphanol. In addition, the newts that received no analgesics did not move in response to tapping on the aquarium glass until 72 hours post surgery, while those receiving an analgesic moved at the first postsurgical test point at 24 hours. Finally, abnormal postures in nontreated newts were observed for 72 hours post surgery, while eight out of 10 newts treated with buprenorphine or butorphanol had resumed normal postures within 4 hours and 10 out of 10 by 24 hours post surgery.

Analgesia in Amphibians

Numerous analgesics have been studied in a research setting in amphibians for brief noxious stimuli, but very little data exist for analgesic use in a clinical setting for pain. The most effective studied analgesics to date in amphibians are the opioids followed by the alpha-2 agonists, particularly dexmedetomidine. Although the μ agonist opioids demonstrate more effectiveness compared with κ agonists, owing to the decreased selective binding of the opioid receptors, both appear suitable for use in amphibians. Amphibians require higher doses of opioids compared with mammals, but the analgesic effect of the opioid also lasts longer (Benyhe et al. 1990; Stevens 2004, 2011; Koeller 2009). In Oriental fire-bellied toads, an antinociceptive response was elicited to a noxious mechanical stimulus when toads were sedated with alfaxalone and morphine in an immersion bath (Adami et al. 2016). Using multiple experimental models, including the acetic acid wipe test, the thermal noxious withdrawal stimulus test, and a mechanical noxious stimulus test (von Frey filaments model of nociception), morphine, at very high doses, was antinociceptive in Northern leopard frogs (*Rana pipiens*) across all nociceptive models (Willenbring & Stevens 1996). An analog of oxymorphone, oxymorphazone, a μ-opioid agonist, was demonstrated to be a relatively weak analgesic drug, even

at 200 mg/kg, when subcutaneously administered to edible frogs (*Rana esculenta*, now *Pelophylax esculentus*) and subjected to the acetic acid wipe test, but had an approximately 48-hour duration of effect (Benyhe et al. 1990). In Northern leopard frogs, fentanyl and remifentanil were determined to be antinociceptive in frogs after either SC or intraspinal administration using the acetic acid wipe test (Stevens 2004). Using fentanyl in a clinical situation, Van Bonn (2009) administered a presurgical dose (0.5 mg/kg) into the dorsal lymph sac of an American bullfrog during an extra-articular surgical stifle stabilization, and the frog recovered normally and returned to normal behavior immediately post surgery. Using intracoelomic buprenorphine, Eastern red-spotted newts (*Notophthalmus viridescens*) subjected to limb amputation surgery displayed more normal postoperative behavior (e.g., feeding, body posture, and response to observer) compared to saline controls (Koeller 2009). However, in axolotls, buprenorphine administered either intracoelomically or as an immersion bath did not provide analgesia after animals were subjected to the acetic acid test or a von Frey mechanical noxious stimulus (Llaniguez et al. 2020).

In a single study, the antinociceptive effects of tramadol were studied in White's tree frogs and Northern leopard frogs using a thermal noxious stimulus, but there were no significant differences in hindlimb withdrawal latencies after administration to either species at any of three tramadol doses (15, 25, and 40 mg/kg per os [PO]) (Hausmann et al. 2021). From a clinical perspective, one current author (D.W.) has used tramadol orally in aged marine toads with arthropathies (25 mg/kg PO every 48 hours) with positive clinical results. Further evaluation of tramadol use in amphibians is needed.

Other parenteral anesthetics have been studied in amphibians. Intraspinal dexmedetomidine, an alpha-2 receptor agonist, administered to Northern grass frogs (*Rana pipiens*) caused a dose-dependent increase in pain thresholds using the acetic acid wipe test (Stevens & Brenner 1996). In a similar study using the acetic acid wipe test in Northern grass frogs (*Rana pipiens*), systemic administration of dexmedetomidine was analgesic compared to other alpha-adrenergic agonists (Brenner et al. 1994). Similarly, a thermal noxious withdrawal stimulus test and a mechanical noxious stimulus test applied to Northern leopard frogs (*Lithobates pipiens*) showed that dexmedetomidine was antinociceptive after exposure to the acetic acid and thermal noxious stimuli, but not after exposure to the von Frey filaments (Willenbring & Stevens 1996).

Of the few studied NSAIDs in amphibians, flunixin meglumine (25 mg/kg SC) has been the most effective for decreasing responsiveness to cutaneous noxious stimulation (Terril-Robb et al. 1996; Coble et al. 2011). In African clawed frogs, flunixin meglumine (25 mg/kg) administered in the dorsal lymph sac may have contributed to analgesia-related behavior using the acetic acid test, but exposure to 50 mg/kg caused death in five of 12 frogs (Smith et al. 2018). Minter et al. (2011) demonstrated that the systemic administration of meloxicam at a dosage of 0.1 mg/kg once daily decreases the circulating serum prostaglandin E2 levels in North American bullfrogs (*Rana catesbeiana)* measured 24 hours after the induction of the inflammatory cascade through surgical muscle biopsies. Meloxicam (0.2 mg/kg SC) in African clawed frogs (*Xenopus laevis*) demonstrated a very mild analgesic effect against cutaneous noxious stimuli (Coble et al. 2011). It is quite probable that for analgesic effects, the dose needs to be increased, especially when compared to the flunixin dose, which is approximately 20–25-fold higher than in mammals. One current author (D.W.) has observed anti-inflammatory effects of meloxicam when administered parenterally (0.2–0.3 mg/kg) in frogs with cutaneous ulcers. Further research is needed to assess the clinical efficacy, PKs, and toxicity of NSAID use in amphibians.

Local anesthetics should be used judiciously in amphibians due to potential systemic toxicity associated with dermal absorption, but they can be very effective when local analgesia is required (e.g., microchip implantation, distal digital amputation). Topical applications of lidocaine, benzocaine, or a prilocaine-lidocaine (EMLA®) have all been used anecdotally for their local effects (Fig. 2.2). However, in one study that evaluated benzocaine and prilocaine-lidocaine as potential topical agents to induce anesthesia in leopard frogs, the latter was associated with 41.7% mortality at a dose greater than 5 mg/kg (Guenette & Lair 2006). There is recent evidence in amphibians that lidocaine will

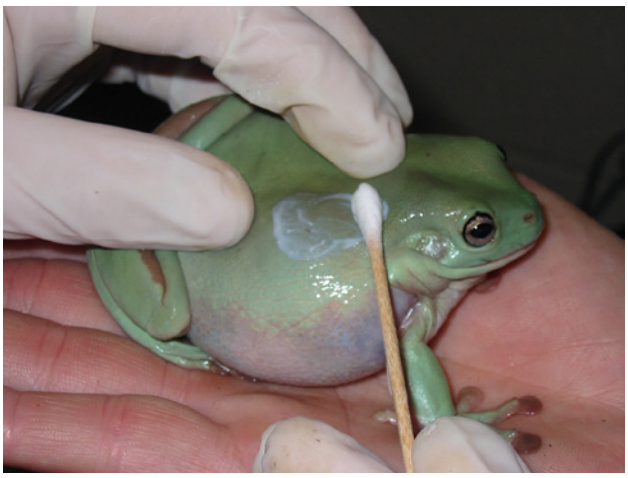

Figure 2.2 Topical application of a local anesthetic cream (lidocaine/prilocaine) in a White's tree frog (*Litoria caerulea*) prior to microchipping.

have systemic effects at very high doses (Williams et al. 2017). In bullfrogs (*Lithobates catesbeianus*), lidocaine (50 mg/kg), administered subcutaneously, caused a significant decrease in respiratory rate, a progressive loss of righting and palpebral reflexes, and contralateral toe pinch withdrawal. However, these systemic effects were not associated with local analgesia and frogs reacted to a forceps pinch at the site of the lidocaine injection at the time of maximal systemic effects (Williams et al. 2017).

Reptiles

Similar to mammals and birds, reptiles possess the appropriate neuroanatomical components for nociception with well-developed antinociceptive mechanisms. Aδ nociceptors have been isolated in the oral mucosa and facial skin of snakes, which are similar to those in primates, and the arrangement of the spinal cord in reptiles is similar to that in mammals. Spinal projections between the brainstem and the superficial layers of the dorsal horn have been identified in Tokay gecko lizards (*Gekko gecko*) and are analogous to those in mammals that promote spinal inhibition. In addition, neurotransmitters responsible for nociceptive modulation in other vertebrates have been identified in reptiles, and nociception can be modulated with analgesics used in other taxa. Opioid receptors are present throughout the central nervous system, although the efficacy of opioid agonists may vary between species. Cyclooxygenase enzymes can be inhibited by the use of NSAIDs in reptiles (Ng et al. 1986; Reiner 1987; ten Donkelaar & de Boer-van 1987; Kanui et al. 1990; Kanui & Hole 1992; Liang & Terashima 1993; Schaefffer & Waters 1996; Seebacher & Franklin 2003; Sladky et al. 2007, 2008, 2009; Mosley 2011; Sladky & Mans 2012).

Recognition of Pain in Reptiles

An objective understanding of the normal behavior of a particular species, and the ability to differentiate the presence of abnormal behavior indicative of discomfort, are critical to the understanding of pain and analgesia. Methods for assessing and measuring pain in reptiles have been described previously (Sladky & Mans 2014). Ideally, a combination of appropriate behavioral and physiologic parameters might best be employed to measure pain and analgesia in reptiles. Clinical experience and research demonstrate that reptiles display a number of behaviours that are consistent with pain in mammalian species, including decreased activity levels and appetite, immobility, guarding of painful limbs or regions, changes to ambulation patterns, exaggerated withdrawal, escape or avoidance responses, attempts to bite, closed eyes, colour changes, abnormal posture, and elevated heart and respiratory rates (Kanui & Hole 1992; Stoskopf 1994; Eatwell 2010; Mosley 2011; Duncan 2012; Sladky & Mans 2014). Tortoises can accurately locate a tactile stimulus applied to the shell and respond by rubbing at the stimulated area with a foot (Stein & Grossman 1980; Rosenberg 1986). However, it is important to realize that some reptiles may suppress some pain-related behaviours when an observer is present (Fleming & Roberston 2006). The development of a species- and context-specific ethogram for each species being evaluated would provide the best method for distinguishing normal versus abnormal (e.g., painful) behaviours, and should be the standard for any clinical study.

Analgesia in Reptiles

In general, the opioids have been the most studied analgesic drugs in reptile species. Morphine sulfate, a μ-opioid agonist, has been shown to be an effective analgesic in reptiles (Sladky & Mans 2014). In the anole lizard (*Anolis carolinensis*), intraperitoneally administered morphine at 5 mg/kg slowed the tail-flick response to a noxious stimulus (Mauk et al. 1981). Green iguanas (*Iguana iguana*) demonstrated significantly reduced tail movement after an electrical stimulation when IM morphine (1 mg/kg) was administered (Hawkins 2006), while crocodiles developed significant latencies in response to painful stimuli with maximal effect at 0.3 mg/kg (Kanui & Hole 1992). Morphine also has clear analgesic effects in red-eared sliders (*Trachemys scripta*) and bearded dragons (*Pogona vitticeps*), but profound long-lasting respiratory depression was observed in the turtles at higher doses. When morphine was administered intrathecally (0.1–0.2 mg/kg) to red-eared slider turtles, it resulted in thermal antinociception of the hind limbs for up to 48 hours (Mans et al. 2011). Morphine at studied doses was not found to be effective in corn snakes (*Elaphe guttata*) (Sladky et al. 2008). Morphine and pethidine, a synthetic, short-acting μ-opioid agonist, provided analgesia in Speke's hinged tortoises (*Kinixys spekii*) exposed to formalin administered into a limb, which was reversible after naloxone administration (Wambugu et al. 2010). The duration of action may vary considerable between species, and the onset of action of morphine may be delayed for 2–8 hours after administration (Sladky et al. 2007, 2008). Related to morphine, hydromorphone is a semisynthetic, μ-opioid receptor agonist, which was demonstrated to be provide analgesia in red-eared sliders using the thermal hindlimb withdrawal nociception model at 0.5 mg/kg SC for up to 24 hours (Mans et al. 2012). Hydromorphone plasma concentrations were considered analgesic for 12–24 hours after bearded dragons and red-eared slider turtles were administered either 0.5 or 1.0 mg/kg (Hawkins et al. 2019). Respiratory depression is a side effect at higher doses.

Fentanyl is a synthetic, μ-opioid receptor agonist, with 75–100 times the potency of morphine, which can be administered either transcutaneously as an impregnated patch, subcutaneously, intramuscularly or intravenously. In reptiles, two separate studies have evaluated the PKs of fentanyl in two reptile species. In ball pythons, fentanyl plasma concentrations reached 1 ng/mL within 4 hours of application of a transdermal fentanyl patch (12.5 μg/h) (Kharbush et al. 2017) and were detectable by 4–6 hours, and for more than 72 hours, in the plasma of prehensile-tailed skinks (fentanyl dose was applied at 10% exposure of a total surface area of a 25 μg/h patch for 72 hours) (Gamble 2009). It remains unclear whether there is any biological significance to these plasma fentanyl concentrations. A recently completed study in one current author's (K.K.S.) laboratory evaluated the efficacy of transdermal fentanyl patch (12.5 μg/h) administration in ball pythons and found no analgesic efficacy, even after repeating the study. At the same time it was confirmed that fentanyl was readily absorbed through the skin of the snakes and remained at very high plasma levels during patch application. Fentanyl patch application decreased respiration in the same snakes, indicating that fentanyl is biologically active in the snakes, even though analgesic efficacy cannot be determined using current laboratory methods (Kharbush et al. 2017). Further evaluation of fentanyl analgesic efficacy using a surgical model in several snake species is underway.

Although butorphanol has been used frequently as an analgesic with variable clinical results, few studies support its analgesic properties in reptiles. In red-eared slider turtles and bearded dragons it did not yield significant antinociceptive effects (Sladky et al. 2007, 2008). However, in snakes at higher doses (20 mg/kg) it did result in thermal antinociception, but the authors suggested using caution (Sladky et al. 2008). Olesen et al. (2008) demonstrated that butorphanol (5 mg/kg IM) did not have analgesic properties in ball pythons (*Python regius)* and had no effect on physiologic parameters compared to salin. In green iguanas, butorphanol (1 mg/kg) did not have an isoflurane sparing effect on minimum alveolar concentrations (Mosley et al. 2003), but analgesia was observed at doses between 1.5 and 8.0 mg/kg in electrostimulation experiments (Greenacre et al. 2006).

Buprenorphine is an effective analgesic in many mammalian species and is used extensively due to its longer duration of action compared to other opioids. However, there is no published evidence that buprenorphine has analgesic activity in studied reptiles (red-eared slider turtles or green iguanas), but does cause profound respiratory depression red-eared slider turtles (Greenacre et al. 2006; Sladky & Mans 2012).

Tramadol has become a widely used analgesic alternative to other opioids in veterinary medicine because it can be administered orally and has a relatively long duration of action. Tramadol and its major active metabolite, O-desmethyl-tramadol (M1), produce analgesia in mammals by activating μ-opioid receptors, but also by inhibiting central serotonin and norepinephrine reuptake. In bearded dragons, a significant analgesic effect was observed in electrostimulation experiments at 11 mg/kg (Greenacre et al. 2008). Long-lasting analgesia (up to 96 hours) was observed after oral and SC tramadol administration (10–25 mg/kg) in red-eared sliders, but a significant decrease in ventilation rates was observed and at the highest dose sedation with flaccid neck and limbs was observed (Baker et al. 2011). Doses of 5 mg/kg did not suppress ventilation and provided analgesia for at least 24 hours (Baker et al. 2011). Recently, tramadol PKs and efficacy were evaluated in yellow-bellied slider turtles (*Trachemys scripta scripta*) after a single IM dose (10 mg/kg) administered in either the hind limb or fore limb (Giorgi et al. 2015a). Using a thermal hindlimb withdrawal latency test, antinociceptive efficacy appeared to last approximately 48 hours regardless of whether the tramadol was administered in the fore limb or hind limb, and tramadol and O-desmethyl-tramadol remained above a high target plasma concentration for approximately 48 hours. In loggerhead turtles (*Caretta caretta*), plasma concentrations of tramadol and O-desmethyl-tramadol remained above the target concentration for analgesia for approximately 48 hours at a dose of 5 mg/kg PO and for 72 hours when tramadol was administered at 10 mg/kg PO Subjectively, appetite, swimming, and general activity level did not change after drug administration (Norton et al. 2015). Tapendatol, similar mechanistically to tramadol, was administered to red-eared and yellow-bellied slider turtles and plasma concentrations were detectable for approximately 24 hours and the duration of antinociceptive efficacy was approximately 10 hours in both turtle species (Giorgi et al. 2014, 2015b). The shorter duration of antinociceptive efficacy, compared to tramadol, may have been due to the lack of an active metabolite.

NSAIDs are the most widely used analgesic in reptiles, with very few clinical studies to evaluate their PKs or clinical efficacy (Read 2004; Greenacre et al. 2008; Olesen et al. 2008; Mosley 2011). Determining the efficacy of NSAIDs in reptiles is very difficult, which is why most studies of reptiles and NSAIDS are PK studies. As such, it is difficult to recommend effective and safe dosing intervals as plasma concentrations of NSAIDS do not always directly correspond with clinical efficacy (Mosley 2011). Meloxicam has been used most frequently by clinicians, with no reports of toxicity in reptiles. Daily IM administration of meloxicam (0.2 mg/kg) or carprofen (2 mg/kg) for 10 days

in green iguanas did not yield any significant alterations to hematological or serum biochemical parameters (Trnková et al. 2007), and high daily oral doses of meloxicam (1 or 5 mg/kg) for 12 days did not induce any histological changes to renal, hepatic, or gastric tissues (Divers et al. 2010). In green iguanas dosed orally or intravenously at 0.2 mg/kg, plasma concentrations associated with analgesia in other species were maintained for 24 hours (Divers et al. 2010). In loggerhead turtles, meloxicam (0.1 mg/kg) administered both intramuscularly and intravenously did not reach plasma concentrations consistent with analgesia in humans, horses, or dogs, and the half-life was short (Lai et al. 2015). In red-eared slider turtles, IM administration of meloxicam (0.5 mg/kg) provided for the most consistent clinical PK behaviour with a terminal half-life of 7.57 hours, while oral bioavailability was only 37% (Rojo-Solís et al. 2009). In a PK study in which meloxicam (0.2 mg/kg IM and IV) was administered to red-eared slider turtles, the IM dose provided a therapeutic (i.e., anti-inflammatory) concentration range equivalent to mammals for approximately 48 hours (Di Salvo et al. 2015). In a different study evaluating the PKs of meloxicam (0.2 mg/kg PO, ICe and IM) in red-eared slider turtles, only the ICe and IM routes, but not the PO route, provided mean blood concentrations of meloxicam that were above those considered effective to induce anti-inflammatory effects in mammals for approximately 8 hours (IM) or 12 hours (ICe) (Uney et al. 2016). Meloxicam has PK patterns that differ species of sea turtles. For example, administration of meloxicam (1 mg/kg SC) in Kemp's ridley (*Lepidochelys kempii*) and green sea turtles (*Chelonia mydas*) resulted in plasma concentrations greater than those considered effective in mammals for 12 and 120 hours, respectively, while the administration of meloxicam (2 mg/kg SC) to loggerhead sea turtles resulted in plasma concentrations greater than those considered effective in mammals for only 4 hours (Norton et al. 2021b). The same authors used a follow-up, multidose PK study to demonstrate that meloxicam (1 mg/kg SC) should be administered to Kemp's ridley sea turtles every 12 hours and in green sea turtles every 48 hours (Norton et al. 2021a). Olesen et al. (2008) found no discernable effects on mitigating changes in physiological parameters in ball pythons undergoing surgery when comparing preoperative meloxicam (0.2 mg/kg IM) to saline. However, meloxicam (0.4 mg/kg IM) was effective in significantly decreasing tail movement responses in bearded dragons to electrostimulation, as was carprofen (2 and 4 mg/kg IM) and ketoprofen (2 mg/kg IM), compared with saline (Greenacre et al. 2008). Ketoprofen bioavailability when administered intramuscularly in green iguanas was 78%, with a longer terminal half-life compared with dogs (Tuttle et al. 2006). The longer half-life of studied NSAIDs necessitates judicious use in compromised reptiles. In loggerhead sea turtles, a ketoprofen dose (2 mg/kg IM or IV q24h) is likely appropriate based on therapeutic plasma concentrations equivalent to mammals (Thompson et al. 2018). Regarding safety, ketoprofen (2 mg/kg IM) administered q24h for up to 5 days in loggerhead sea turtles appeared to be safe with respect to several hematologic parameters (Harms et al. 2021). Recently, the safety of ketoprofen was evaluated in bearded dragons and it was found that there were no significant biochemical or pathologic changes other than muscle necrosis at the administration site (Vigneault et al. 2022). Using a different NSAID, the PKs of a single dose of ketorolac (0.25 mg/kg IM) was evaluated in loggerhead sea turtles, and therapeutic plasma concentrations equivalent to mammals were never achieved, so its use in this species couls not be recommended (Gregory et al. 2021). However, the same dose of ketorolac (0.25 mg/kg IM) administered to eastern box turtles (*Terrapene carolina carolina*) provided plasma concentrations above a therapeutic target level for 24-hour analgesia in mammals (Cerreta et al. 2019).

Local anesthetics are commonly used for surgical procedures in reptiles and can be an effective local analgesic (Bennet 1998; Hawkins 2006). Care must be taken to avoid accidental overdose, especially in small patients. Doses should not exceed 10 mg/kg for lidocaine, 5 mg/kg for bupivacaine, or 25 mg/kg for mepivacaine (Wellehan et al. 2006; Eatwell 2010; Mosley 2011). For smaller patients, less concentrated commercially available solutions (e.g., 1% lidocaine or 0.25% bupivacaine) should be used to minimize the decreased efficacy of local anesthetics when they are diluted (Kanai & Hoka 2006; Kanai et al. 2007). Some clinicians, including one author (D.W.), prefer to combine these two local anesthetics in a 1:1 ratio to enhance effects and duration, and minimize the potential for toxicity (Eatwell 2010). Clinical evaluation of local anesthetic use in reptiles is rare in the veterinary literature. A technique for a mandibular nerve blockade using 2% mepivacaine was described in crocodilians (Wellehan et al. 2006) and more recently intrathecal administration of lidocaine (4 mg/kg) or bupivacaine (1 mg/kg) in red-eared sliders resulted in motor block of the hind limbs for approximately 1 and 2 hours, respectively (Mans et al. 2011). Lidocaine (4 mg/kg, <1 hour duration), bupivacaine (1 mg/kg, 1–2 hours duration) or preservative-free morphine sulfate (0.1–0.2 mg/kg, up to 48 hours duration) can be administered intrathecally between the coccygeal vertebrae of turtles and bearded dragons (Mans et al. 2011; Ferreira et al. 2021). In a clinical setting, bupivacaine (0.1 mL for each 10 cm of carapace) was administered intrathecally to facilitate surgical excision of fibropapillomas from the posterior flippers of a green sea turtle (Futema et al. 2020).

Similarly, lidocaine (1 mL/20–25 kg) was administered intrathecally in hybrid Galapagos tortoises (*Chelonoidis niger*) prior to phallectomy surgery (Rivera et al. 2011). Lidocaine can be combined with morphine for intrathecal administration in bearded dragons, providing analgesia to the caudal half of the body for 12–24 hours (Fink et al. 2022). In desert tortoises (*Gopherus agassizii*) undergoing orchiectomy, lidocaine (2 mg/kg) + morphine (0.1 mg/kg) intrathecal was effective in providing analgesia in the caudal half of the body (Proenca et al. 2014a,b). For topical ocular administration to block corneal sensitivity, the local anesthetic, proparacaine hydrochloride (0.5%), was used clinically in reptiles during eye examinations, especially to measure intraocular pressure (Gornik et al. 2015). Similar proparacaine results were determined in bearded dragons and Yacare caiman (*Caiman yacare*) (Ruiz et al. 2015; Schuster et al. 2015). Further research into local anesthetic use in reptiles is needed.

There are few published data demonstrating analgesic efficacy associated with administration of other anesthetic drugs, such as ketamine, dexmedetomidine, medetomidine, midazolam, or propofol in reptiles. While alpha-2 adrenergic drugs are commonly used, in combination with ketamine or midazolam, for sedation in reptiles, few data exist with respect to the analgesic effects of these drugs. A recently completed study in one current author's (K.K.S.) laboratory demonstrated that dexmedetomidine (0.1 mg/kg) produced antinociception for up to 24 hours in ball pythons (*Python regius*) (Bunke et al. 2018). In tegu lizards (*Salvator merianae*) exposed to a toe pinch, dexmedetomidine (0.2 mg/kg IM) provided antinociception without sedation, while midazolam (1.0 mg/kg IM) provided no antinociception, but caused sedation (Bisetto et al. 2018). While there is interest in the fact that low-dose ketamine provides analgesia in mammals, there are no current data in reptiles to support this.

Complementary therapies such as acupuncture (Fig. 2.3) and cold laser therapy appear to be valuable based on clinical impressions and deserve further study (Koski 2011; Dadone & Harrison 2017; Sladky & Mans 2014).

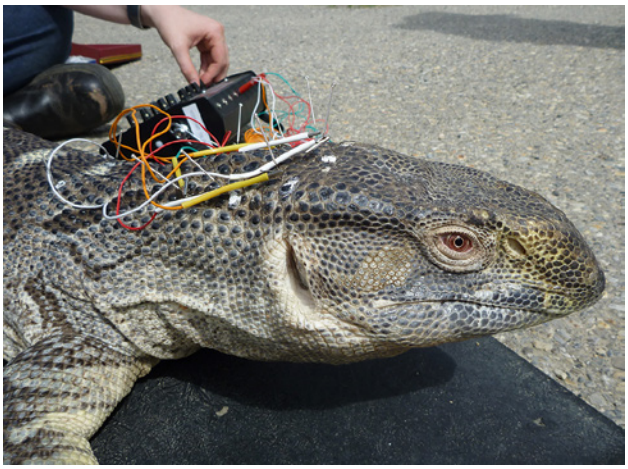

Figure 2.3 Electroacupuncture in a black throated monitor (*Varanus albigularis ionidesi*) for cranial cervical trauma that had resulted in tetraparesis. The monitor had not improved with pharmaceuticals and aqua-therapy, but significant clinical improvement was noted within three acupuncture treatments.

Birds

The neurological components necessary to respond appropriately to painful stimuli in avian species are analogous to those in mammals, with well-developed antinociceptive mechanisms to diminish pain, modulation of pain pathways, and behavioural responses to painful stimuli with pharmacological agents (Gentle 1992; Machin & Livingston 2002; Hawkins 2006; Douglas et al. 2018). Three types of nociceptors have been identified in birds: thermal and mechanical nociceptors, and high threshold nociceptors that are polymodal in nature and respond to mechanical, thermal, and chemical stimulation (Necker & Reiner 1980; Gottschaldt et al. 1982; Gentle 1992; McKeegan 2004; Douglas et al. 2018). Opioid receptors are detectable as early as 10 days in embryonic chicks (Hendrickson & Lin 1980), and the μ, δ, and κ opioid receptors in birds are similarly distributed in the forebrain and midbrain as in mammals, with κ receptors predominating in forebrain of pigeons and songbirds, while μ receptors were most prevalent in chickens. However there have been only a few studied species, with variability existing in receptor density, distribution, and structure, even between strains of the same species (Mansour et al. 1988; Reiner et al. 1989; Csillag et al. 1990; Duhamelle et al. 2018; Douglas et al. 2018). Beta-endorphin has been noted in a wide variety of birds and maintains its structure between different species, indicating that it is important in the resppnse to noxious stimuli or stress (Scanes & Pierzchala-Koziec 2018).

Cyclooxygenase enzymes (COX-1 and COX-2) are widely distributed in birds and can be modulated with NSAIDs (Lu et al. 1995; Mathonnet et al. 2001; Douglas et al. 2018).

Recognition of Pain in Bird Species

In general, similar to many wild species, birds tend not to show overt signs of pain as obvious distress behaviors may attract unwanted attention; rather they will demonstrate more subtle or cryptic behavioural signs of their discomfort. As there are no universal indicators of pain in birds, the assessment of pain must take into account the species-specific normal behaviour and individual behaviour, strain, gender, age, concurrent disease states, type of pain, and the environment. In addition, it is important that behavioural

observations occur at appropriate times for each species, such as observing nocturnal species at night (Hughes 1990; Sufka et al. 1992; Hawkins & Paul-Murphy 2011; Mazor-Thomas et al. 2014; Mikoni et al. 2022).

Birds that are acclimated to handling may mask physiological changes often associated with pain, such as elevations in body temperature, respiratory rate, or stress hormones. However, birds that are comfortable with their environment also may more readily demonstrate painful behaviours such as limb guarding, withdrawal responses, or squinting of the eyes (Heatley et al. 2000; Hawkins 2006; Sneddon et al. 2014). In chickens, elevations in blood pressure were consistently associated with painful procedures, but the measurement of blood pressures is not always feasible (Gentle & Hunter 1991). A study in red-tailed hawks with orthopedic injuries (Mazor-Thomas et al. 2014) demonstrated significant reductions in head movement frequency, beak clacks, and overall movement. Subtle changes to mobility, due to diseases such as pododermatitis and osteoarthritis, can be objectively detected through pressure-sensitive walkways (Sheldon et al. 2019). Immobility is a shared finding across numerous avian species, and in social species isolative behaviour can often be observed (Gentle & Hill 1987; Gentle 1992; Graham 1998; Paul-Murphy & Hawkins 2012; Mikoni et al. 2022). Many bird species that are being handled will respond to acute painful procedures with vocalizations, excessive movement, and escape reactions, but with progression of the painful stimulus will revert to immobility. Normally passive birds may act aggressively when painful. With prolonged pain, decreased appetite and activity are often observed, especially behaviours such as preening or dust bathing, although in some individuals, particularly with psittacines and mynahs, overgrooming and feather destructive behaviour may ensue (Gentle & Hunter 1991; Hawkins & Paul-Murphy 2011; Mikoni et al. 2022).

Analgesia in Birds

Based on pharmacodynamic (PD) studies, clinical reports, and experience, butorphanol is the recommended opioid for use in most avian species at a doses of 1–5 mg/kg intramuscularly every 3–24 hours, as it has poor oral availability (Paul-Murphy et al. 1999; Hawkins 2006; Klaphake et al. 2006; Sladky et al. 2006; Sanchez-Migallon Guzman et al. 2008, 2011; Hawkins & Paul-Murphy 2011). In some species, particularly *Buteo* sp. raptors and corvids, butorphanol can be associated with profound sedation at the higher doses. In PK studies the half-life is only 0.5–2 hours so frequent dosing may be necessary depending on clinical need (Riggs et al. 2008; Sanchez-Migallon et al. 2011a; Paul-Murphy & Hawkins 2012; Singh et al. 2018). A study in common peafowl (*Pavo cristatus*) that utilized subcutaneously implanted osmotic pumps for 7 days maintained serum levels at or above reported antinociceptive concentrations until pump removal with no evidence of sedation (Clancy et al. 2015). Administration of butorphanol tartrate in a long-acting polymer gel formulation (12.5 mg/kg) to Hispaniolan Amazon parrots increases the potential for analgesia for 4–8 hours (Laniesse et al. 2017). An experimental liposome-encapsulated butorphanol also holds promise for the future as it provides analgesic effects for 3–5 days after a single SC injection of 15 mg/kg (Sladky et al. 2006; Paul-Murphy et al. 2009a,b) but commercial development has been slow.

Another κ agonist and partial μ antagonist that may have future clinical use is nalbuphine hydrochloride. In Hispaniolan Amazon parrots (*Amazona ventralis*) it increased pedal thermal withdrawal thresholds for up to 3 hours after single IM administration of 12.5 mg/kg (Sanchez-Migallon Guzman et al. 2011). However, a PK study in the same species (Keller et al. 2011) revealed a short terminal half-life of 30 minutes. Similar to butorphanol, a slow-release formulation has been studied and would be clinically ideal, but is not yet commercially available (Sanches-Migallon Guzman et al. 2013a,c).

The partial μ agonist opioid buprenorphine is being more commonly used and studied with mixed results. In American kestrels (*Falco sparverius*), a dosage of 0.1 mg/kg increased thermal thresholds for at least 6 hours compared with saline controls, with high bioavailability after IM injection (Ceulemans et al. 2014; Gustavsen et al. 2014). At dosages of 0.25 and 0.5 mg/kg in pigeons, it was associated with a positive analgesic response for 2 and 5 hours, respectively (Gaggermeier et al. 2003). In red-tailed hawks (*Buteo jamaicensis)*, buprenorphine ameliorated pain-suppressed behaviours associated with orthopedic injuries, while administration of concentrated buprenorphine (0.3 and 1.8 mg/kg SC) sustained plasma levels >1 ng/mL for 24 and 48 hours, respectively (Mazor-Tomas et al. 2014; Gleeson et al. 2018). A sustained-release buprenorphine formulation at 1.8 mg/kg IM increased thermal thresholds for 24 hours with mild sedation noted (Sanchez-Migallon Guzman et al. 2018a). However, buprenorphine administered intra-articularly in domestic fowl, intramuscularly at 0.1 mg/kg in African grey parrots (*Psittacus erithacus*), or intramuscularly in cockatiels (*Nymphicus hollandicus*) at 1.8 mg/kg failed to demonstrate an analgesic effect (Gentle et al. 1999; Paul-Murphy et al. 1999, 2004a; Sanchez-Migallon Guzman et al. 2018b). Further studies in other avian species are needed.

Other opioids such as fentanyl and hydromorphone have demonstrated mixed results in clinical studies. Fentanyl at 0.02 mg/kg intramuscularly in white cockatoos (*Cacatua alba*) was not effective, but increasing the dose to 0.2 mg/kg

yielded a positive analgesic response but was associated with undesirable hyperactivity (Hoppes et al. 2003). Transdermal fentanyl application at 5 mg/kg in helmeted guineafowl (*Numida meleagris*) sustained plasma concentrations above those associated with analgesia in dogs for at least 7 days (Waugh et al. 2016). In domestic chickens, a 25 μg/h transdermal fentanyl patch (7.23–11.36 μg/kg/h) maintained levels considered analgesic in humans and several mammalian species for the entire 72-hour period that they were applied for (Delaski et al. 2016). Under constant rate infusion studies in red-tailed hawks, fentanyl significantly lowered the minimum anesthetic concentration of isoflurane by 31–55%, supporting its clinical application as an intra-operative analgesic (Pavez et al. 2011).

In American kestrels, IM hydromorphone has a short half-life (1.26 hours) with dosages of 0.1, 0.3, and 0.6 mg/kg IM resulting in antinociception for 3–6 hours with mild sedation noted at the highest dose (Sanchez-Migallon Guzman et al. 2013b, 2014). In contrast, the same dosages of hydromorphone administered to cockatiels failed to provide an analgesic effect but did cause sedation (Houck et al. 2018). Similar to buprenorphine, μ-agonist opioids may not be efficacious in psittacine species, and further study is required in other species.

The PKs of tramadol have been studied in bald eagles (*Haliaetus leucocephalus*), African penguins (*Spheniscus demerus*), red-tailed hawks, peafowl, and Hispaniolan Amazon parrots with oral doses between 5 and 11 mg/kg achieving serum levels equated with analgesia in humans (Souza et al.2009, 2010, 2011; Black et al. 2010; Kilburn et al. 2014). Tramadol (30 mg/kg PO) was as effective as meloxicam (1 mg/kg PO) for providing analgesia for experimentally induced temporary arthritis in ducks (*Cairina moshata domestica*) (Bailey et al. 2019). Preliminary efficacy studies using noxious thermal stimuli in Hispaniolan Amazon parrots reveal that an IV dosage of 5 mg/kg increases the nociceptive threshold for at least 4 hours, while an oral dose of 30 mg/kg provides analgesia for up to 6 hours, indicating that higher doses may be needed for clinical effect (Souza et al. 2010; Geelen et al. 2013). Tramadol administration to common buzzards (*Buteo buteo*) as part of ketamine-based anesthetic protocols provided for analgesia post procedure for up to 3 hours (Raisi et al. 2019). As with other analgesics, significant interspecific PK and PD variability likely exists and deserves further exploration.

The most frequently used NSAIDS in avian species are meloxicam, carprofen, and ketoprofen, with selective use of celocoxib and piroxicam. Meloxicam is the most commonly used NSAID in zoological medicine and has shown a wide margin of safety in a large and diverse number of species (Cuthbert et al. 2007; Naidoo et al. 2008; Hawkins & Paul-Murphy 2011; Whiteside 2014; Dijkstra et al. 2015; Summa et al. 2017; Miller et al. 2019). Significant interspecific variation exists in birds, with elimination half-life in studied species when administered parenterally ranging from as short as 30 minutes in ostrich (*Struthio camelus*), less than an hour in cockatiels, great-horned owls (*Bubo virginianus*), and red-tailed hawks, to approximately 2 hours in American flamingos (*Phoenicopterus ruber*, Caribbean flamingos (*Phoenicopterus ruber ruber*), and lesser flamingos (*Phoeniconaias minor*), over 3 hours in chickens, 4 hours in ring-necked parakeets (*Psittacula krameri*), 5 hours in Bilgorasjka geese (*Anser anser domesticus*) and zebra finches (*Taeniopygia guttata*), 16 hours in Hispaniolan Amazon parrots, 32 hours in African penguins, and as long as 35 hours in African grey parrots (Baert & De Backer 2003; Wilson et al. 2005; Lacasse et al. 2013; Molter et al. 2013; Lindemann et al. 2016; Zordan et al. 2016; Boonstra et al. 2017; Dhondt et al. 2017; Montesinos et al. 2017; Morrison et al. 2018; Miller et al. 2019; Sartini et al. 2020). In Hispaniolan Amazon parrots, IM dosages of 1 mg/kg every 12 hours were needed for effective analgesia for experimentally induced arthritis, but very few long-term studies have been carried out to assess for adverse side effects in birds (Cole et al. 2009). Injectable sustained-release meloxicam formulations yielded highy variable PK results in Hispaniolan Amazon parrots and did not extend the half-lives compared to regular formulations in American flamingos (Sanchez-Migallon Guzman et al. 2017a; Sim & Cox 2018). Until further studies are completed, meloxicam should be used cautiously.

Oral administration of meloxicam yields variable bioavailability, with studied half-lives ranging from less than 1 hour in cockatiels, great-horned owls and red-tailed hawks, 2 hours in Caribbean flamingos, 3 hours in chickens, 4 hours in American flamingos, 5 hours in geese, 6 hours in lesser flamingos, 16 hours in ring-necked parakeets and Hispaniolan Amazon parrots, 29 hours in African penguins, and up to 33 hours in African grey parrots (Wilson et al. 2005; Molter et al. 2013; Lindemann et al. 2016; Zordan et al. 2016; Boonstra et al. 2017; Montesinos et al. 2017; Souza et al. 2017; Morrison et al. 2018; Sartini et al. 2020). Based on the authors' clinical experience a dose range of 1–2 mg/kg SC or IM has proven efficacious in many species, and generally favourable clinical results were noted with chronic oral usage at 0.5–1.0 mg/kg up to twice daily with no complications. As with the other NSAIDS, further studies are needed to evaluate the PK and PD behaviour of meloxicam in various avian taxa, as well as evaluation for adverse effects with chronic administration.

Carprofen has yielded variable results in studied species, with either a very high dose (30 mg/kg) needed to provide

analgesia for experimentally induced arthritis in chickens (McGeown et al. 1999; Hocking et al. 2005) or a very short duration of action noted when a lower dose (3 mg/kg) was administered to Hispaniolan Amazon parrots (Paul-Murphy et al. 2009b). Concerns about its safety have been documented in Cape vultures (Fourie et al. 2015) and high oral doses in feed-induced nephrotoxic and hepatotoxic changes in chickens (Dabhi et al. 2015). Ketoprofen administered orally or parenterally (2 mg/kg) to Japanese quail (*Coturnix japonica*) had a very short half-life of less than 35 minutes despite the route of administration (Graham et al. 2005), while in mallard ducks (*Anas platyrhynchos*), an IM dose of 5 mg/kg was associated with decreased levels of the inflammatory mediator thromboxane for up to 12 hours after administration (Machin et al. 2001), and provided analgesia against a noxious stimulus while under isoflurane anesthesia (Machin & Livingston 2002). However in spectacled (*Somateria fischeri*) and king (*Somateria spectabilis*) eider ducks administration of ketoprofen at 2 and 5 mg/kg IM was associated with severe renal tubular necrosis, visceral gout, acute rhabdomyolysis, and death in 40% and 83% of treated males, respectively, although gender-linked behaviours may have increased the susceptibility of these birds to the side effects of ketoprofen (Mulcahy et al. 2003). In addition, ketoprofen has proven toxic to *Gyps* vulture species at doses above 1.4 mg/kg (Naidoo et al. 2010).

The use of the "coxib" class of NSAIDS (e.g., celecoxib) has been anectodally reported (Dhondt et al. 2017). A potentially promising new "coxib" for birds is mavacoxib. Studies in cockatiels (Dhondt et al. 2017) and Caribbean flamingos (Huckins et al. 2020) demonstrated a long elimination half-life (135 and 75 hours, respectively) after a single oral dose. Clinical efficacy studies remain to be completed. Piroxicam has not been scientifically studied in avian species, but has been used successfully for the chronic treatment of arthritis in cranes (Paul-Murphy & Hawkins 2012). While other NSAIDS, such as flunixin meglumine, have been used historically, they have a very short elimination half-life (<1 hour) in budgerigars (*Melopsittacus undulatus*) and Patagonian conures (*Cyanoliseus patagonus*), and have also been associated with a higher degree of undesirable side effects such renal toxicity and gastrointestinal ulceration (Pereira & Werther 2007; Musser et al. 2013). The most severe example of NSAID-induced renal toxicity is the diclofenac-linked severe decline of Asian *Gyps* vulture species (Green et al. 2004; Oaks et al. 2004; Meteyer et al. 2005; Hussain et al. 2008; Naidoo & Swan 2008).

Unlike other NSAIDS that rely on COX enzyme inhibition, the prostaglandin E_2 (PGE_2) receptor agonist grapiprant binds to the EP4 receptor and blocks the sensitization of sensory neurons and stimulation of inflammation mediated by the PGE2 receptor. Studies in red-tailed hawks administered a 30 mg/kg oral dose indicate excellent bioavailability with no adverse clinical effects noted, although when administered with food, it resulted in mildly lower plasma concentrations and delayed absorption. Further studies are needed to evaluate the PKs, efficacy, and safety in avian species, but it may hold promise (Rodriguez et al. 2021, 2022).

Local anesthetics have been used successfully in a clinical setting, although there are very few scientific studies evaluating efficacy, time to effect, or duration of activity (Lee & Lennox 2016). Historically it was believed that birds may be more sensitive to the effects of local anesthetics owing to more rapid absorption and delayed clearance compared with mammals, thus lower doses were often indicated to avoid signs of toxicity such as drowsiness, recumbency, seizures, cardiovascular effects, and death (Hocking et al. 1997; Hawkins & Paul-Murphy 2011). However in chickens, the toxic dose of intravenous (IV) lidocaine is approximately 30 mg/kg, which is greater in than mammals (Imani et al. 2013), and for IV bupivacaine the effective dose (ED_{50}) to induce cardiovascular effects is 1.96 mg/kg (DiGeronimo et al. 2017). Further studies in different species are required. Regional local anesthetic infiltration is generally effective for joints and soft tissue. In chickens, spinal subarachnoid injection of lidocaine (2 mg/kg) at the synasacrococcygeal space for regional pericloacal anesthesia induced a duration of analgesia of 21 minutes (Kazemi-Darabadi et al. 2019). Sciatic-femoral nerve blocks with lidocaine (1 mg/kg per nerve) in peregrine falcons (*Falco peregrinus*) for pododermatitis surgery provided an analgesic effect for up to 2.5 hours (d'Ovidio et al. 2015). Brachial plexus blockade with lidocaine in Hispaniolan Amazon parrots or high-dose lidocaine with epinephrine or bupivacaine in chickens and mallard ducks failed to prevent nerve transmission (Figueiredo et al. 2008; Brenner et al. 2010; da Cunha et al. 2013). However, a brachial plexus block using ropivacaine (2 mg/kg) was successful in a striped owl (*Asio clamator*) undergoing wing amputation (do Nascimento et al. 2019).

Gabapentin has been used anecdotally, at significantly higher dosages than in mammals, as an adjunctive treatment for suspected neuropathic pain in a few species or for abatement of self-mutilation (Doneley 2007; Siperstein 2007; Shaver et al. 2009). In great-horned owls, oral gabapentin (11 mg/kg) sustained plasma levels associated with therapeutic levels (2 μg/mL) for 8.8 hours, while in Caribbean flamingos a dosage of 25 mg/kg PO maintained plasma concentrations above 2 μg/mL for approximately 12 hours (Yaw et al. 2015; Browning et al. 2018). Based on the authors' experience with gabapentin use in various

species, its efficacy is difficult to determine and highly variable, and further studies are indicated.

Polysulfated glycoaminoglycans (PSGAGs) have been used very cautiously in avian species due to fatal coagulopathies following IM administration of 0.5–100 mg/kg (Anderson et al. 2013). However, Wonn et al. (2022) studied the hypocoagulability of a commonly used veterinary PSGAG product (Adequan 100 mg/mL) and recommend 1 mg/kg subcutaneously once weekly for four doses, followed by once every other week for two doses, then monthly for chronic maintenance.

Other drugs, such as NMDA antagonists, have not been evaluated, while complementary therapies such as acupuncture, physiotherapy, and the use of nutraceuticals have been anecdotally effective and are in need of further study (Crouch 2009; Koski 2011; Rychel et al. 2011; Whiteside 2014).

Mammals

Despite advances in pain management, compared with the lower vertebrate species, there is still a paucity of scientific studies evaluating species-specific pain responses and analgesia in wild mammals. However, studies in laboratory and companion zoological species have increased significantly over the past decade.

Recognition of Pain in Mammals

In general, many of the recognized clinical signs associated with pain in domestic mammals may be seen in wild species, although they are often more subtly expressed, especially in prey species, which may not display behavioural alterations to a painful event. Often remote evaluation is needed to truly evaluate the degree of pain, and advances in wireless monitoring technology can be useful (Oliver et al. 2017; Klune et al. 2019). It is important for clinicians to understand the normal behavior of species in order to evaluate for such changes in behavior that may be related to pain (Hawkins 2002; Flecknell 2008; Whiteside 2014; Dunbar et al. 2016)

Objective assessment of pain can be done through evaluation of physiological and biochemical (e.g., alterations in corticosteroid levels) indices and behaviour. The former indices are often difficult to assess in the conscious animal, although noninvasive biochemical methodologies (e.g., fecal glucocorticoid metabolite monitoring) have become more common (Goldschlager et al. 2013). Nonspecific clinical signs such as tachypnea, trembling, bruxism, salivation, muscle spasms, sweating in species capable of doing so, and dilated pupils can be associated with pain in mammals, while it is often difficult or impossible to evaluate for more specific changes such as tachycardia or pyrexia in the conscious animal. Changes in facial expressions such as wrinkling the brow, frowning, or grimacing are not usually recognized in most species (Williams 2002; Sneddon et al. 2014). However, a small number of studies have validated the use of facial expressions (changes in the shape of the mouth, cheeks, ears, nose, and eyes) to assess for pain in mammals (McLennan et al. 2019). These "grimace scales" have been developed and validated for mice, rats, rabbits, horses, ferrets, and neonatal harbour seals (Leach et al. 2012; Dalla Costa et al. 2014; Hampshire & Robertson 2015; Leung et al. 2016; Reijgwart et al. 2017; MacRae et al. 2018; Klune et al. 2019). Other subjective measures should be evaluated, such as changes in demeanour, altered social interactions, variations in feeding or foraging patterns, changes in posture, mobility, or activity level, alterations of sleep–awake patterns, self-directed behaviours such as looking, biting, kicking, chewing, or rubbing of painful areas, changes in vocalization, and altered response to touch (Bufalari et al. 2007; Walker et al. 2010; Sneddon et al. 2014). Any of these measures may be altered with pharmacologic agents. In some social species, pain responses may elicit assistance or directed aggression from conspecifics within the social group (Sanford et al. 1996).

Analgesia in Mammals

Much of the analgesic drug selection and doses used in mammals are extrapolated from domestic and laboratory species, although much-needed studies of analgesics in wildlife continue to expand.

Opioids are frequently used for analgesia in a zoological setting, but less frequently with free-living wildlife owing to concerns for the potential for sedation. PK and PD studies are limited outside of a laboratory animal setting, but include the PKs of butorphanol in elephants (Tana et al. 2010), PKs and PDs in llamas (Carroll et al. 2001), PKs in ferrets (Katzenbach et al. 2018), the PKs and PDs of morphine in llamas (Uhrig et al. 2007), the PKs of fentanyl patches in llamas (Grubb et al. 2005) and cynomologus macaques (Carlson et al. 2016), the PKs of buprenorphine in macaques (Nunamaker et al. 2013; Mackiewicz et al. 2019), ferrets (Katzenbach et al. 2018), and northern elephant seals (Molter et al. 2015), the PKs of hydromorphone in ferrets (Katzenbach et al. 2018), and the PKs of tramadol hydrochloride in alpacas (Edmondson et al. 2012), macaques (Kelly et al. 2015), and California sea lions (Boonstra et al. 2015). These studies continue to highlight the need for species-specific studies as extrapolation from taxonomically similar species is not always appropriate and the biovailability of parenteral versus oral administration can vary tremendously.

Even though the duration of activity of butorphanol is relatively short compared with other opioids, it is still

frequently used as an analgesic (e.g., maned wolf [McNulty et al. 2000], microchiropterans [Wellehan et al. 2001], African lions [Kolata 2002], Egyptian fruit bats [Lafortune et al. 2004; Tuval et al. 2018], Asian and African elephants [Abou-Madi et al. 2004; Kottwitz et al. 2016], white-tailed deer [MacLean et al. 2006], African hedgehog [Done et al. 2007], otariid and phocid seals [Haulena 2014; Lynch & Bodley 2014], parma wallabies [Okeson et al. 2009], polar bears [Velguth et al. 2009], prehensile tailed porcupine [Guthrie & DeMaar 2011], rhinoceros [Kottwitz et al. 2016], giraffe [Boothe et al. 2016], hippopotamus [Boothe et al. 2016]. Opioid formulations of longer durations such as buprenorphine (e.g., lions [Kolata 2002], polar bears [Velguth et al. 2009], hyena [Hahn et al. 2014], pinnipeds [Moore et al. 2010; Molter et al. 2015], guinea pigs [Smith et al. 2016; Zanetti et al. 2017], chinchillas [Fox & Mans 2018]}, hydromorphone (e.g., squirrel monkey [Wellehan et al. 2004], binturong [Spriggs et al. 2007], chinchillas [Evenson & Mans 2018]) , transdermal fentanyl or fentanyl patches (llama [Grubb et al. 2005], binturong [Spriggs et al. 2007], macaques [Carlson et al. 2016; Salyards et al. 2017]), or epidural morphine are used frequently for analgesia by clinicians in a zoological setting, and are more commonly reported in the literature. Sustained-release formulations of buprenorphine are now available and may offer significant advantage in providing analgesia while minimizing handling (Nunamaker et al. 2013; Molter et al. 2015; Cary et al. 2017; Zanetti et al. 2017; Mackiewicz et al. 2019). Opioid use may result in significant weight loss in some species (Oliver et al. 2017) and care must be taken when utilizing fentanyl patches as ingestion can lead to serious morbidity or mortality (Deschamps et al. 2012).

Based on clinical experience, tramadol also is an effective analgesic in many species (Souza & Cox 2011), with examples of its reported use including large felids (McCain et al. 2008, 2009), Western lowland gorilla (Rush et al. 2010), binturong (Spriggs et al. 2007) pinnipeds (Moore et al. 2010) Atlantic bottlenose dolphin (Schmitt & Sur 2012), elephants, giraffe, rhinioceros, and hippopotamus (Boothe et al. 2016; Kottwitz et al. 2016). A PK study in koalas concluded that SC administration of tramadol at 4 mg/kg was predicted to have analgesic activity based on plasma concentrations (Kimble et al. 2021).

Meloxicam is the most widely administered NSAID in zoological species, with increasing applications in free-ranging wildlife. Its PKs have been studied in nondomestic species such as mini-pigs, baboons, and rodents (Busch et al. 1998), rabbits (Carpenter et al. 2009; Fredholm et al. 2013; Delk et al. 2014), dromedary camels (Wasfi et al. 2012), llamas (Kreuder et al. 2012), koalas (Kimble et al. 2013), macaques (Bauer et al. 2014), ferrets (Chinnadurai et al. 2014), bottlenose dolphins (Simeone et al. 2014), prairie dogs (Cary et al. 2017; Wright et al. 2017), and Malayan flying foxes (Goodnight & Cox 2018). Sex difference in PK behaviour can exist (Chinnadurai et al. 2014). It has been used parenterally or orally in most mammalian families by the authors with no observed or reported side effects. Oral bioavailability may be significantly reduced compared to parenteral administration (Kimble et al. 2013). Based on the reported literature and the authors' experience, oral dosages required for complexed stomached species are higher than those for simple monogastric species. (Whiteside & Black 2004; Whiteside et al. 2006; Pye et al. 2008, 2010; Okeson et al. 2009; Twomey et al. 2010; Dadone et al. 2011; Whiteside 2014).

Carprofen and ketoprofen also are frequently used NSAIDs for captive and free-living mammals. The PKs of carprofen have been established in white rhinoceros (Leiberich et al. 2018). In general, carprofen has been found to be efficacious (Dutton et al. 2002; Mylniczenko et al. 2005; Velguth et al. 2009; Boothe et al. 2016; Kottwitz et al. 2016; Fernando et al. 2016). However, even in taxonomically similar species, there may be profound differences in efficacy. As Walker et al. (2011) reported, it was not effective in controlling postsurgical pain in Stellar sea lions when administered at dosages suggested by Dold et al. (2004) based on PK and PD studies in California sea lions. The PKs of ketoprofen have been studied in camels (Alkatheeri et al. 1999) and elephants (Hunter et al. 2003), and its anecdotal use has been reported in a wide variety of species (e.g., golden lion tamarin [Bronson et al. 2005], exotic ruminants [Howard & Richardson 2005], sun bear [Mylniczenko et al. 2005], pinnipeds [Fauquier et al. 2008; Rush et al. 2012; Dennison et al. 2007], koalas [Pye et al. 2008], bongo [Gyimesi et al. 2008, 2011], agoutis [Zimmerman et al. 2009], giraffes and hippopotamus [Boothe et al. 2016], elephants and rhinoceros Kottwitz et al. 2016]).

NSAIDS such as phenylbutazone and flunixin meglumine are still utilized for analgesia, particularly with larger mammalian species (e.g., rhinoceros [Wack et al. 2010; Harrison et al. 2011; Kottwitz et al. 2016], giraffe [James et al. 2000; Boothe et al. 2016; Gardner & Rourke 2021], elephants [Kottwitz et al. 2016], hippopotamus [Boothe et al. 2016], exotic ruminants [Howard & Richardson 2005; Gyimesi et al. 2011], deer [Mansfield et al. 2006], elk [Larsen et al. 2000], Stellar sea lions [Walker et al. 2009], bison [Minter et al. 2011]). The PKs of phenylbutazone have been carried out in Asian and African elephants (Bechert et al. 2008) and dromedary camel (Kadir et al. 2003), with the PKs of flunixin also studied in African and Asian elephants (Bechert et al. 2021), dromedary camel (Oukessou 1994), and white rhinoceros (East et al. 2019).

The PKs of ibuprofen have been studied in Asian and African elephants (Bechert & Christensen 2007), and its use has been reported in primates (Wellehan et al. 2004; Bronson et al. 2005; Robbins et al. 2009), rhinoceros (Bertelsen et al. 2004; Kottwitz et al. 2016), elephants (Kottwitz et al. 2016), giraffe, and hippopotamus (Boothe et al. 2016). Its use in carnivore species is not recommended based on side effects noted in domestic canids and felids. Increasingly the 'coxib' NSAIDs (e.g., deracoxib, robenacoxib, firocoxib) are being used (Boothe et al. 2016; Kottwitz et al. 2016). Other sporadically used NSAIDs include tepoxalin, etodolac, tolfenamic acid, and naproxen, which are occasionally reported in the literature (Hahn et al. 2014; Williams & Junge 2014; Stringer et al. 2012). Care should be exercised if using these, as the PK or PD behaviour, and the potential negative side effects, are not known.

Corticosteroids are infrequently used for pain management in exotic species owing to the potential negative side effects, but medium- to long-acting steroids such as triamcinolone acetate and medroxyprednisolone acetate have been used successfully for joint infusions in mammals with arthritis refractory to other therapies.

Local anesthetics are frequently used with zoological species, and their use continues to expand in a free-range setting. Doses are extrapolated from domestic mammals. They are effective when used topically, epidurally, intra-articularly, intrapleurally, or intra-abdominally for specific nerve blocks (such as dental blocks for tooth extractions or endodontic procedures (Fig. 2.4) or regional nerve blocks), nonspecific infiltration such as ring blocks or line blocks, or for IV regional blocks (Mylniczenko et al. 2005; Mansfield et al. 2006; Beasley & Rhodes 2007; Borkowski et al. 2009; Morges et al. 2009; Pye et al. 2010; Schroeder et al. 2010; Clarke & DeVoe 2011; Dadone et al. 2011; Schäffer et al. 2017). The combination of lidocaine and bupivacaine is often advantageous due to a faster onset of action and prolonged effect (Anagnostou et al. 2015; Vicente & Bergström 2018). Care must be taken, particularly with smaller species, to avoid approaching toxic dosages (Heard 2014a; Gyimesi & Burns 2009; Flecknell 2018; D'Ovidio & Adami 2019).

In a clinical setting, the use of alpha-2 agonists, such as medetomidine, or NMDA antagonists, such as ketamine or amantadine, for analgesia independent from anesthesia is rarely described in the literature for exotic species. In a giant panda, amantadine in combination with carprofen provided effective analgesia (Fernando et al. 2016). Amantadine also was anecdotally used as part of multimodal analgesia in a Southern white rhinoceros (Gardner & Rourke 2021). Anecdotal evidence suggests that ketamine at 1/10th of the anesthetic dose for a species can be efficacious for analgesia, or as a constant rate infusion at 0.01–0.02 mg/kg/min, which limits its use in a field setting (Cracknell 2007). The addition of magnesium (Mg^{+2}) with ketamine enhances its analgesic effect (Liu et al. 2001).

Figure 2.4 Rostral mandibular (middle mental) nerve block with bupivicaine in an Amur tiger (*Panthera tigris altaica*) for an endodontic procedure. This dental block would be useful for premolar extraction for aging studies as well.

Gabapentin use, particularly as part of multimodal therapy for chronic neuropathic pain or chronic disease states such as osteoarthritis or cancer pain, is apparently effective and warrants further study (Adkesson 2006; Bronson et al. 2008; Vonsy et al. 2009; Boothe et al. 2016; Kottwitz et al. 2016; Huckins et al. 2018; Gardner & Rourke 2021). Other adjunctive therapies, such as oral glucosamine sulfate, chondroitin, omega-3 fatty acid supplementation, or injectable polysulfated glycoaminoglycans, are frequently utilized in a zoological setting for chronic arthritides and are anecdotally effective (Stringfield & Wynne 1999; Whiteside et al. 2006; Pye et al. 2008), but there are no supporting scientific studies that clearly demonstrate a benefit with oral products, and there are legitimate questions of oral bioavailability, especially in herbivores. Recent analyses of multiple studies in dogs and humans indicate there is conflicting evidence as to the benefit to glucosamine, chondroitin, green lipped mussels, or methylsulfonylmethane supplementation (Neil et al. 2005; Aragon et al. 2007; Teets et al. 2010; Vandeweerd et al. 2012). Further research associated with their use in zoological species is indicated. Maropitant, a neurokinin-1 antagonist, also is being studied and used anecdotally as a potential analgesia, especially

for abdominal pain (e.g., abdominal surgeries), often in combination with other analgesics (Corrêa et al. 2019; Karna et al. 2019). However, a recent meta-analysis (Kinobe & Miyake 2020) concluded that although maropitant definitively reduced the minimum alveolar concentrations for isoflurane and sevoflurane, there was not strong enough evidence that it has significant analgesic or anti-inflammatory effects at recommended manufacturer doses. Other modalities, such as acupuncture or cold laser therapy, also have produced favourable analgesic responses for osteoarthritis or neuropathic pain, and deserve further study (Maenaka et al. 2006; Cassu et al. 2008; Teets et al. 2010; Koski 2011; Rychel et al. 2011; Dadone & Harrison 2017).

Pain in Invertebrates

There is growing scientific evidence suggesting that invertebrate species, especially the more advanced species found in the phyla Arthropoda and Mollusca, have the ability to experience pain, rather than just respond to nociceptive stimuli. This is based on the presence of suitable receptors and the central nervous system, responsiveness to analgesics and anesthetics, physiological changes, avoidance learning, protective motor reactions, and cognitive abilities and sentience (Barr et al. 2008; Crook & Walters 2011; Elwood 2011, 2019; Sneddon et al. 2014; Rotllant et al. 2023). Many of the advanced invertebrate species have brains that, relative to their body weight, are larger than those in many vertebrates species. In addition these invertebrate species have complex brain structures for sensory analysis, memory, learning, and decision making, which are analogous to the functions of the cerebral cortex in vertebrate species (Smith 1991; Sandeman et al. 1992; Elwood et al. 2009; Sneddon et al. 2014; Sneddon 2015; Burrell 2017).

Behavioural evidence for the likely experience of pain has been demonstrated in several invertebrate species through avoidance learning research and protective motor reflexes. Algae octopus (*Abdopus aculeatus*) demonstrate increased sensitivity and targeted wound tending behaviour after injury (Alupay et al. 2014). Estuarine crabs (*Chasmagnathus granulatus*) associated an electrical shock with a particular location for a minimum of 3 hours after the event, and even 24 hours later in multiple trials (Denti et al. 1988; Fernandez-Duque et al. 1992). Long-term behavioural changes were observed in hermit crabs (*Pagurus bernhardus*) within their shell after they were shocked on the ventrum compared with crabs that were not shocked, which included sustained grooming of the ventral shock location (Elwood & Appel 2009; Elwood 2011). Acetic acid or sodium hydroxide applied to the antenna or eye of glass prawns resulted in an immediate tail-flick response followed by increased grooming or rubbing of the affected area. Topical application of the local anesthetic benzocaine markedly decreased these responses but did not interfere with swimming, indicating that analgesia and not anesthesia was achieved (Barr et al. 2008). Finally, some arthropods such as spiders or crabs will automize limbs when injected with noxious substances known to be painful in vertebrates, such as the bee or wasp venom or acetic acid, or when exposed to a hot plate or electric shock (Eisner & Camazine 1983; Fiorito 1986; Elwood 2011).

Further research is needed to fully characterize the pain experience and the PKs and PDs of analgesic drugs in invertebrate species. However, until such research is available, clinicians should consider the administration of analgesics to patients that are being subjected to a procedure that is deemed painful in vertebrates. This includes general anesthesia with a volatile anesthetic such as isoflurane or sevoflurane, and administration of peri-procedural analgesics such as local anesthetics (diluted lidocaine, bupivacaine, and benzocaine) (Mosley & Lewbart 2014; Cooper 2011; Lewbart & Mosley 2012; Andrews et al. 2013; Rottlant et al. 2023).

Effective Anesthetic Monitoring

Sathya Chinnadurai

Physiologic monitoring is critical to help an anesthetist achieve and maintain an appropriate plane of anesthesia, anticipate and detect when changes in delivery of anesthetic drugs are required, and promptly identify preoperative, intraoperative, and postoperative complications. Without detailed monitoring, accurate record keeping, and careful assessment and reassessment of the patient, it is nearly impossible to provide effective, safe anesthesia to an animal (Chinnadurai et al. 2016). With the constant discovery of new drugs and the development of anesthetic induction protocols, it is easy to focus on finding the mythical "safe" protocol instead of developing a safe anesthetist. Regardless of the induction protocol used, an anesthetist must be ready and able to assess the patient and make adjustments to anesthetic maintenance based on that assessment. This includes increasing and decreasing anesthetic depth, maintaining normothermia, ventilatory support, and maintenance of normotension.

This chapter serves as a refresher on the effective use of common anesthetic monitors, including the challenges of using those monitors in nondomestic species. In addition, we will discuss a systematic approach to the diagnosis and treatment of common anesthetic problems. The most basic anesthetic monitoring consists of measuring heart rate, respiratory rate, and body temperature. Monitoring of blood oxygenation, ventilation (carbon dioxide excretion), and blood pressure requires additional monitors. Pulse oximeters, capnographs, electrocardiograms (ECGs), and oscillometeric blood pressure monitors are the commonly used standard anesthetic monitors in veterinary anesthesia but require some accommodation for use in nondomestic species, especially in a field setting (Chinnadurai et al. 2016). It is important to remember that even though these devices are widely used in wildlife medicine, very few have been objectively evaluated in nondomestic species (Watson et al. 2019).

This chapter discusses monitoring individual body systems, with a focus on respiratory and cardiovascular monitoring. Detail of the individual monitors themselves is given and some of the nuances in using those monitors in nondomestic species are discussed. Finally, the treatment of common anesthetic complications is covered.

Anesthetic Monitor Review

Prior to any anesthetic procedure, a plan for appropriate monitoring should be developed. This plan should be based on the anesthetic risk to the animal based on the species of interest, the anesthetic drugs used, the proposed procedures, the environment, and the anticipated complications. The remote setting of field anesthesia often dictates the limitations of equipment and personnel that are available for patient monitoring during the anesthetic event. While the most basic forms of anesthetic monitoring consist of measurements of heart rate, pulse quality, respiratory rate, and body temperature and can be carried out by the anesthetist with the use of their eyes, ears, a stethoscope, and a rectal thermometer, more advanced monitoring equipment is now available for field use. Ideally, monitoring of the cardiovascular and respiratory systems should be continuous, with intermittent recordings of the parameters every 5–10 minutes on a designated anesthetic record. In addition to these continuously monitored parameters, the anesthetic depth and temperature should be monitored intermittently.

While it is critical to interpret monitoring devices simultaneously and in relation to one another, it is helpful to categorize monitors based on function and body system, specifically, those used for respiratory, cardiovascular, thermal, and, less commonly, depth of anesthesia monitoring. Each of the anesthetic monitoring parameters simply evaluates a relationship of metabolic supply and demand.

The most simplistic and yet most critical aspect of respiratory physiology is knowing that the respiratory system is always serving metabolic demand by performing two primary tasks: (i) absorbing oxygen and (ii) eliminating carbon dioxide (ventilation). To complete these tasks, the cardiovascular system must ensure the delivery of oxygen and the removal of carbon dioxide from distant parts of the body through blood flow (perfusion). Assigning numerical values to the interplay of oxygenation, ventilation, and perfusion is the sole function of an anesthetic monitor.

Anesthetic monitoring devices are categorized as either direct (invasive) or indirect (noninvasive) indicators of respiratory and cardiovascular function (Dorsch & Dorsch 2008). Direct monitoring devices are often considered the most accurate and applicable across taxa. Noninvasive monitors carry many benefits for the anesthetist and the patient, but can be hampered by inaccuracy and species-specific nuances. For this reason, indirect devices need to be validated in the species of interest (Brown et al. 2007; Mosley 2015).

Respiratory Monitoring Devices

The primary means of assessing oxygenation and ventilation are visual assessment of respiratory depth and frequency, indirect monitoring with pulse oximetry and capnography, and direct monitoring with blood gas analysis (Dorsch & Dorsch 2008). While visual assessment is crucial in each anesthetized case, without objective quantification of oxygenation and ventilation complete assessment of the respiratory system is impossible. States of hypoxia and hypercapnia can both affect respiratory rate and rhythm, necessitating deeper evaluation.

The Pulse Oximeter

The pulse oximeter is a commonly used, noninvasive device that uses photoplethysmography to determine arterial hemoglobin saturation. It uses light-emitting diodes (LEDs) and photosensors to detect pulsatile blood flow and determine a ratio of oxygenated to deoxygenated hemoglobin based on differential light absorption. Its primary purpose is to provide real-time assessment of changes in oxygenation. As values are generated with each beat of the heart and subsequent pulse wave, changes can be detected almost instantaneously. The limitations come from the fact that a pulse oximeter can only provide information about the oxygen saturation of hemoglobin in pulsatile arterial blood (SaO_2) (Dorsch & Dorsch 2008). Oxygen is carried bound to hemoglobin (Hb) in red blood cells and dissolved in the blood (measured as the partial pressure of dissolved oxygen in arterial blood, PaO_2). Total arterial oxygen content (CaO_2) is determined by the following equation: $CaO_2 = (1.34 \times Hb \times SaO_2) + (0.0031 \times PaO_2)$. Because hemoglobin carries the majority of oxygen, total content can be heavily influenced by both hemoglobin saturation and hemoglobin content.

Because the pulse oximeter is a simple and easily available, near-instantaneous monitor, it is very widely used and is capable of providing real-time indications of changes in oxygenation and heart rate. This timely feedback allows an anesthetist to intervene quickly to control hypoxemia.

The pulse oximeter probe typically consists of two light emitters and one or more light sensors. Each of the two LEDs projects a different wavelength of light through the tissue bed it is contacting. The two different wavelengths correspond to the wavelengths of light absorbed by oxygenated and deoxygenated hemoglobin. Opposite the LED, a photosensor measures the light that is transmitted (i.e., not absorbed) through the tissue and the machine calculates the ratio of oxygenated to deoxygenated hemoglobin (Dorsch & Dorsch 2008).

Accurate performance depends on multiple factors, including good tissue perfusion, good pulse quality, light-permeable epidermis, and hemoglobin and oxyhemoglobin, which absorb light at preset wavelengths. Pulse quality can be affected by hypotension and low cardiac output, and regionally affected by vasoconstriction and vasodilation. Species differences in hemoglobin structure could affect the accuracy of the reading. In cases of anemia, a patient may have excellent hemoglobin saturation, but an overall deficiency in hemoglobin will still result in poor oxygen delivery. Other sources of error include patient movement, bright ambient light, and the fact that most devices are not calibrated to read accurately below 80%.

Capnography

Capnography is arguably the most useful anesthetic monitoring technique and often the most underused (Fig. 3.1). Effective capnography can identify conditions that might lead to hypoxia before a patient is hypoxic and is one of the most reliable ways of detecting cardiac arrest and airway obstruction. The capnograph can also be used for confirming endotracheal tube placement in challenging intubations, detecting disconnections and leaks, and problems with sodalime and one-way valves. The capnograph typically uses infrared spectrometry to determine the partial pressure of CO_2 in expired gas (Bednarski et al. 2011; Mosley 2015). This generates three pieces of information (i) the end-tidal CO_2 ($ETCO_2$) partial pressure, (ii) the capnograph waveform, and (iii) the respiratory rate. The accuracy of capnography has been evaluated in very few nonmammalian species (Desmarchelier et al. 2007).

Figure 3.1 Monitoring a dolphin with mainstream capnography at the blowhole. The animal is lightly sedated and manually restrained, and ventilation is monitored continuously. Electrocardiography leads are placed on either side of the thorax behind the pectoral flippers for two-lead electrocardiography. Photo credit: Chicago Zoological Society.

For CO_2 to be detected on a capnograph, three critical physiologic processes must be happening: (i) cellular metabolism has to produce CO_2, (ii) circulation has to bring CO_2 from the periphery to the lungs, and (iii) the lungs have to be ventilating for the CO_2 to be exhaled and detected by the monitor. Abnormalities in $ETCO_2$ can occur due to derangements in any of those three processes. In a healthy "normal" animal, $ETCO_2$ provides a close approximation of the arterial partial pressure of CO_2 ($PaCO_2$), the indicator of ventilatory function and respiratory pH balance. Typically, $ETCO_2$ underestimates $PaCO_2$ by 2–5 mmHg. Hypoventilation can cause increases in $ETCO_2$ and $PaCO_2$. Hyperventilation can cause decreases in both. There are also numerous scenarios when the discrepancy between expired and arterial CO_2 may grow (Morkel et al. 2010). These include any state of poor perfusion, which decreases cardiac output and pulmonary perfusion. With less blood delivered to the lungs, there is less CO_2 exhaled, but there is no change in CO_2 production.

Many practitioners use their capnograph simply for one value, the $ETCO_2$. That single number can be used as an effective indicator of ventilatory function, but the capnograph waveform provides many more valuable pieces of information about equipment and animal function. It can track changes in not only ventilation, but cardiac output and metabolic rate.

Blood Gas Monitoring

Blood glucose, systemic lactate, and blood gases can be easily assessed with point-of-care portable analyzers (Burgdorf-Moisuk et al. 2012; Posner et al. 2005). These measurements, in conjunction with other monitoring techniques, allow an overall assessment of the animal, including cardiopulmonary stability, tissue perfusion, and likelihood of intraprocedural or postcapture complications.

Deleterious changes in blood pH, oxygenation, and ventilation can be rapidly diagnosed and treated. Point-of-care blood gas analyzers are ideally suited for use in field and zoological settings. The most commonly used analyzers are battery operated and require only a small volume of blood (0.2–0.5 mL). This allows them to be used in remote settings and with small patients. Additionally, results are generated in 2–3 minutes, which can satisfy the needs of many impatient zoo clinicians (Fahlman et al. 2010). Most analyzers can provide immediate information about blood oxygenation, ventilation, blood pH, glucose, and electrolytes. Immediate information also allows rapid adjustment of anesthetic management.

Maintenance of normal blood pH (approximately 7.4 for most mammals) is crucial for homeostatic function. As such, respiratory and metabolic processes have evolved with multiple redundancies to preserve physiologic pH. Most ectothermic species, and some mammals and birds (especially diving animals) have adaptations which allow for a much wider range of acceptable blood pH. While this provides an additional safety buffer for these animals, it does complicate interpretation of blood gases and determining what is normal and what requires correction. Hypoxemia, hypoventilation, and poor perfusion are some of the most significant anesthetic complications experienced in the anesthesia of captive and free-ranging wildlife. With routine use of blood gas analyzers many of these complications can be detected early and potentially corrected. While pulse oximetery and capnography provide useful, noninvasive, second-to-second assessments of ventilation and oxygenation, both methodologies can have some drawbacks that compromise their accuracy. Direct blood gas analysis can identify abnormalities in species for which noninvasive methodology is not validated. A capnograph can provide a noninvasive assessment of expired CO_2, which should be similar to arterial CO_2. Without blood gas analysis, it is possible that an increase in physiologic dead space could compromise the accuracy of the capnograph. In species capable of pulmonary shunting, such as reptiles, the expired CO_2 may not represent the arterial CO_2 at all.

Sample Collection

Blood should be collected anaerobically into a heparinized syringe. Excessive heparin can affect parameters, including hematocrit and ionized calcium. Samples should be analyzed as quickly as possible and care should be taken to not

introduce air bubbles into the sample. In reality, small air bubbles may not affect the accuracy of the sample significantly, but can cause the analyzer to malfunction. Excessive room air contamination can cause a decrease in the measured CO_2 and an increase or decrease in PaO_2 depending on the percentage of inspired oxygen.

- Arterial collection sites:
  - auricular artery: elephants, rhinoceros, most ruminants
  - facial, transverse facial artery: equids, some ruminants
  - radial artery: apes
  - dorsal pedal artery: large carnivores
  - femoral artery: small carnivores, small primates
  - superficial ulnar artery: birds
- Venous collection sites: jugular, auricular or lingual veins

Jugular and auricular sites provide the easiest sampling and jugular sampling also provides the closest approximation of a true mixed venous sample. Lingual samples provide a close approximation of arterial gas tensions.

Arterial versus Venous Comparison

Arterial samples are crucial for assessing pulmonary performance, especially oxygenation. A venous blood gas can provide pH, CO_2, and a crude estimate of body oxygen demand. The oxygen content of venous blood varies greatly depending on the sampling site and level of metabolism and should not be used to approximate arterial oxygen content. A central mixed venous sample can provide very useful information about oxygen consumption and anaerobic metabolism, but requires an arterial sample for comparison.

A blood gas report contains multiple values, some of which are directly measured and some of which are calculated from the measured parameters based on algorithms validated for human use. Measured parameters include pH, partial pressure of CO_2 ($PaCO_2$), partial pressure of oxygen (PaO_2), hematocrit, and lactate. Most analyzers also measure certain electrolytes, including Na, Cl, K, and ionized Ca. From these measurements, the machine will calculate hemoglobin, bicarbonate (HCO_3), base excess, and oxygen saturation (SO_2). The formulae for calculated parameters are given in Appendix 3.1. Oxygen saturation is calculated assuming a "normal" adult human hemoglobin oxygen dissociation curve. Some machines will correct for changes in electrolyte concentrations based on changes in blood pH.

All blood gas analyzers measure dissolved gases at a standard temperature (usually, 37°C). When the patient's body temperature differs significantly from 37°C it may be useful to "correct" the sample data to the body temperature (Dorsch & Dorsch 2008). Temperature correction of blood gases is fairly controversial, even in human medicine. In short, the concern is that in a hypothermic patient, reported values (measured at 37°C) may not represent the true values in the patient. At the same time, corrected values are not applicable to any known reference ranges. Human reference ranges are designed to be used with a blood temperature of 37°C. For near-normothermic mammals, temperature correction does not make a significant difference and the difference is not usually a reason to change the course of treatment. For ectotherms and severely hypothermic mammals, temperature correction may be more valuable (Hanley et al. 2010). Most analyzers use a built-in algorithm for temperature correction. There are multiple published references detailing correction formulae for ectotherms (Keller et al. 2012).

Basic interpretation should be a straightforward, step-by-step process.

Six-step interpretation:

1) What is the pH? Normal pH for most mammals is 7.35–7.45. Is the patient's pH low (acidemia) or high (alkelemia)?
2) What is the PaO_2 (arterial sample)? Normal arterial PaO_2 is 100 mmHg, while breathing room air. Is the patient hypoxemic? Is the patient's oxygen tension appropriate for the fraction of oxygen that it is breathing?
3) What is the $PaCO_2$? Normal $PaCO_2$ is 35–45 mmHg. $PaCO_2$ represents the respiratory component of the acid-base derangement. Changes in $PaCO_2$ result in respiratory acidosis and alkalosis.
4) What is the metabolic component (HCO_3 and base excess)? Are the changes appropriate for the changes in $PaCO_2$ or is there a metabolic acidosis or alkalosis?
5) What is the level of compensation? Derangements of either respiratory or metabolic acid-base balance often result in compensatory change from the other system, i.e. metabolic acidosis often results in a compensatory respiratory alkalosis (hyperventilation).
6) Are there abnormalities in electrolytes or lactate?

1) pH: pH only gives us the direction and extent of the derangement, but does not tell us the source of the problem. It does help narrow down the differentials for the primary problem and the list of actions that need to be carried out to correct the problem. Carnivores tend to have slightly more acidic pH, while herbivores and omnivores with high carbohydrate diets tend to have more alkaline blood pH.
2) PaO_2: Normal PaO_2 (arterial partial pressure of oxygen) is 100 mmHg when breathing room air and 400–500 mmHg when breathing 100% oxygen. Hypoxemia is defined as $PaO_2 < 60$ mmHg. Calculating an alveolar-to-arterial oxygen gradient (A-a gradient)

provides useful information about the cause of the hypoxemia. In addition, calculating a PaO_2/FiO_2 (partial pressure to fraction of inspired oxygen) ratio provides a very easy means of assessing pulmonary function. The A-a gradient is most accurate when the patient is breathing room air (21% oxygen) while the PaO_2/FiO_2 ratio can be done with any FiO_2.

A measured hypoxemia is typically the result of one of five problems (Paterson et al., 2009):

1) Hypoventilation: The patient is not breathing frequently or deeply enough. In cases of hypoventilation, the PaO_2 is low but there is a normal A-a gradient.
2) Low FiO_2: The inspired percentage of oxygen is too low. This is rare as most anesthetized animals are breathing an enriched oxygen mixture. The animal is hypoxemic with a normal PaO_2/FiO_2 (partial pressure of arterial oxygen/fraction inspired oxygen) ratio.
3) Ventilation/perfusion mismatching: This is quite common and is likely the main source of hypoxemia in anesthetized large animals. It is often associated with atelectasis and can be exacerbated by poor cardiac output and poor pulmonary perfusion (Morkel et al. 2010).
4) Diffusion impairment: Rare, will not discussed.
5) Anatomic right-to-left shunt: Rare, rare will not be discussed.

3) $PaCO_2$: Carbon dioxide tension quantifies the balance between cellular metabolism and alveolar ventilation. Hypercapnea typically results from a decrease in ventilation, but can be a result of increased metabolism (exertion). Hypocapnea could be from hyperventilation or decreased metabolic activity. $PaCO_2$ can also be compared to $ETCO_2$ to determine if there is an increase in physiologic dead space. $ETCO_2$ should slightly underestimate arterial CO_2 by 5 mmHg. An increase in this difference indicates that there are areas of lung that are ventilated, but not perfused. This occurs with pulmonary thromboembolism and decreased pulmonary perfusion secondary to decreased cardiac output.
4) Bicarbonate and base excess: Both of these calculated parameters provide information about metabolic alkalosis or acidosis. These are indirect measures as both are derived from the measured CO_2 on the blood gas (formulas given above). A typical reference range for HCO_3 is 19–24 mEq/L. To account for the effect of CO_2 on HCO_3 calculation, base excess (BE) can be used. BE determines the amount of bicarbonate that needs to be added to blood to bring the pH back to 7.4, when $PaCO_2$ is set at 40. Essentially, BE factors in the effect of body buffer systems and factors out the effect of CO_2 on bicarbonate to determine the metabolic contribution to the acid-base balance. The reference interval for bicarbonate is −4 to 4 mEq/L. While not a perfect system, the BE provides a rapid way of determining the metabolic disturbance. If the BE is high, there is a metabolic alkalosis and if it is low there is a metabolic acidosis, regardless of the respiratory disturbance.
5) Compensation: Before evaluating compensation, look back at the pH. If the pH is low, the primary process is an acidosis and the compensatory process (if present) is an alkalosis. Compensation rarely brings the patient back to a normal pH and never overcompensates. A primary chronic respiratory acidosis (hypoventilation) will lead to a compensatory metabolic alkalosis, but pH will not return to normal and will not become alkalotic. Methods of compensation include chemical buffers (few seconds), respiratory (few minutes), and metabolic compensation (few days).
6) Lactate and electrolytes: Blood lactate is a by-product and indicator of anaerobic metabolism (Harms et al. 2003). Increases in blood lactate typically accompany decreases in tissue perfusion. This could include ischemic muscle from a positional or exertional myopathy in which metabolic oxygen demand has outstripped the available oxygen delivery. Focal ischemia (strangulated intestine, compromised blood flow to a limb after trauma) can also increase lactate production, and in some cases the hyperlactatemia will only be seen after perfusion is reestablished. Electrolyte interpretation is similar to routine chemistry interpretation.

Effect of Capture on Blood Gases

Typically changes seen during capture include hypoxemia, hypercapnea, lactic acidosis, and hyperkalemia from acidosis and myocyte rupture. Strenuous capture can result in metabolic acidosis from increased production of lactate. Hypoxemia can exacerbate lactate production and hypercapnea from increased metabolic production of CO_2 during exertion can lead to worsening of acidosis (Fahlman et al. 2011; Hanley et al. 2005; Mans et al. 2012). Similar changes in blood oxygenation, CO_2, and lactate production can result from body positioning during anesthesia. For example, moving a rhinoceros from lateral to sternal recumbency may improve its ventilation and oxygenation while compromising muscle perfusion and increasing lactate build-up (Morkel et al. 2010).

Ectotherm Blood Gases

There are a number of published reports on the use of blood gases for evaluating reptiles, fish, and invertebrates (Hanley et al. 2010; Lewbart et al. 2014; Sheldon et al. 2019).

Important aspects to keep under consideration include the role of temperature compensation and the wide range of acceptable blood pH in most ectotherms (Keller et al. 2012). Most of the referenced studies use a taxon-specific formula for correcting pH and dissolved gases for body temperature. In many cases, body temperature is assumed to be the ambient temperature. In some instances, clinically significant abnormalities were not noted unless temperature correction was performed. While the correction formulas may be valid, it is important to remember that corrected values should not be compared to standard reference ranges. Species- and temperature-specific ranges should be established.

Cardiovascular Monitoring

Cardiovascular monitoring consists of assessing the heart rate and rhythm with auscultation, palpation, and electrocardiography and quantifying perfusion with direct and indirect measurement of blood pressure.

Electrocardiography

Electrocardiography is applicable to a wide ranges of species and not only provides information about heart rate and rhythm, but can be used to diagnose conduction abnormalities associated with electrolyte abnormalities and myocardial ischemia (Bartlett et al. 2009; Harms et al. 2013; Hassanpour et al. 2013). Accurate diagnosis of the rhythm is imperative for guiding treatment. Some anesthetic agents, especially the alpha-2 agonists, can induce bradyarrythmias and atrioventricular nodal blocks, which may be difficult to discern by auscultation alone. Ventricular arrhythmias may be associated with hypoxia, myocardial damage, and excessive catecholamine release seen with ultrapotent opioid administration. Diagnosis of the rhythm is imperative for guiding treatment. For routine anesthetic monitoring, a three-lead ECG is typically employed, utilizing the principles of Einthoven's triangle. The three leads are positive, negative, and ground (neutral) leads; animal body confirmation may affect the necessary lead placements to create an appropriate vector across the heart (Dorsch & Dorsch 2008; Schumacher et al. 2003). In typical small quadrupedal species, the most common recording is a lead II ECG with the negative electrode at the right forelimb and the positive electrode at the left hindlimb (Fig. 3.2). In larger animals, a base–apex placement is used, with the positive electrode on the left thorax caudal to the heart, the negative electrode on the skin over the right jugular furrow, and the ground electrode attached to the skin far from the heart (Gandolf et al. 2010; Pourjafar et al. 2011). These basic techniques for ECG recording have been modified and normal values have been described for cetaceans, elephants, reptiles, and a wide variety of birds (Bartlett et al. 2009; Harms et al. 2013; Hassanpour et al. 2013).

Blood Pressure Measurement

In many cases, blood pressure itself is not a primary concern and is an easily measured surrogate for cardiac output and perfusion (Mosley 2015). Blood pressure is product of two values: cardiac output and systemic vascular resistance (SVR). Cardiac output itself is determined by two values, heart rate (HR) and stroke volume (SV). Based on these relationships, derangements of blood pressure typically result

Figure 3.2 Surgical monitoring of a smokey jungle frog (*Leptodactylus pentodactylus*). Two-lead electrocardiography is used to monitor heart rate and rhythm, and a pulse oximeter has been placed on the left hind foot for approximation of hemoglobin oxygen saturation. The animal is endotracheally intubated and monitored with capnography. Photo credit: Chicago Zoological Society.

from a change in HR, SV or SVR or some combination of these three parameters. Unfortunately, cardiac output and SVR are not easily measured in clinical patients and thus blood pressure is the most convenient and reliable surrogate.

There are two means of collecting blood pressure: direct or indirect methods. Direct, or invasive, measurement of blood pressure requires inserting a catheter in a suitable artery and measuring arterial pressures with a transducer. This remains the gold standard, although it can be technically challenging (Brown et al. 2007; Watson et al. 2019).

Indirect, or noninvasive, blood pressure measurement is typically performed with an oscillometric monitor. The device inflates an air-filled cuff to occlude blood flow in an artery. It then decreases pressure in the cuff in a stepwise fashion to detect changes in the frequency of oscillation produced by pulses in blood vessels. If the time between successive pulses is sufficiently long, the device may provide an inaccurate reading (Dorsch & Dorsch 2008). This source of error is commonly seen when oscillometric devices are used on animals with low heart rates, such as reptiles or equids (Chinnadurai et al. 2009). Other sources for failure of the oscillometric device include movement by the patient and poor signal quality. Hypotensive patients with poor peripheral perfusion often generate errors in blood pressure measurement. Unfortunately, these are often the patients that need accurate readings the most.

Due to the high potential for inaccuracy with commercial oscillometric units in veterinary medicine, the American College of Veterinary Internal Medicine released a consensus statement outlining guidelines for blood pressure measurement in dogs and cats. Those guidelines state that "ideally blood pressure should be measured with devices that have been validated in the species of interest and under the circumstances in which the patient is being tested" (Brown et al. 2007). Given the wide range of animals that are housed and treated in zoological collections, this bar is rarely ever met, but should be a goal for ideal patient care.

Various oscillometric methods and devices have been evaluated for use in nondomestic species, including megavertebrates, nondomestic felids, Hispaniolan Amazon parrots, lizards, and snakes, with varying results (Acierno et al. 2008; Bertelsen et al. 2017; Chinnadurai et al. 2009, 2010; Sadler et al. 2013). Many have reported that indirect methods cannot be substituted for direct blood pressure measurements. These findings are important because often oscillometric blood pressure is used across taxa in veterinary medicine without questioning the validity. Doppler ultrasound devices can be used for detection of heartbeat or peripheral pulsations and, in some species, approximation of blood pressure when used with a sphygnomanometer.

There are intrinsic limitations when devices designed and validated for humans or domestic mammals are applied to nonmammalian species. Two studies in avian species showed poor correlation between direct systolic arterial blood pressure measurements and indirect measurements using either Doppler or oscillometric devices (Acierno et al. 2008; Zehnder et al. 2009). In fact, studies in multiple parrot species raised doubts that indirect measurements of blood pressure by Doppler are even repeatable in the same animal at the same time point due to disagreement between cuff placements on the same limb from the same bird (Acierno et al. 2008). The overall precision of Doppler blood pressure measurements was poor. Based on these findings, even using Doppler blood pressure measurements to monitor trends in an individual bird is dubious clinical practice.

Similar findings have also been reported in boid snakes and green iguanas. In iguanas, an oscillometric device failed to provide reading for most attempts and had poor correlation when compared to directly measured pressures (Chinnadurai et al. 2010). When used on the tail of anesthetized boid snakes, the same device had a much lower failure rate and consistently overestimated systolic blood pressure, while underestimating diastolic and mean pressures (Fig. 3.3) (Chinnadurai et al. 2009).

The most accurate technique for blood pressure assessment involves placement of an arterial catheter and measurement through an arterial blood pressure (Saugel et al. 2014). Invasive blood pressure monitoring with an intraarterial catheter requires continuous connection of the animal to a monitoring device, limiting movement. These devices can be technically challenging to place and operate, and carry the risk of thrombosis and hemorrhage. Placement sites for arterial catheters are the same as those listed for arterial sampling of blood gases.

Body-temperature Monitoring

Peri-anesthetic hypothermia is one of the most common complications in veterinary anesthesia (Ko & Krimins 2014). Anesthetic drugs often cause blunting of normal physiologic thermoregulation and shivering, inhalants, and some injectables cause direct vasodilation, increasing heat loss from the skin. During field captures, especially with high ambient temperatures, hyperthermia can easily occur (Chinnadurai et al. 2016). Even short-duration derangements in body temperature can alert metabolic oxygen demand, affect recovery time, and increase the risk of wound infection as well as contribute to arrhythmias and coagulation defects (Pottie et al. 2007; Torossian 2008), making temperature monitoring and thermal support essential, especially in field settings.

During an anesthetic episode, body heat may be lost by four mechanisms: radiation, convection, conduction, and

Figure 3.3 Doppler ultrasound placement over the heart on an anesthetized snake for monitoring heart rate. Photo credit: Chicago Zoological Society.

evaporation. Radiation is loss of heat through infrared emission to the environment surrounding the patient. This does not include heat lost through direct contact with a cold surface. Radiation accounts for 60–70% of heat loss in anesthetized humans. Convection is loss of heat to air currents around the body. Most hospital situations involve conditioned air moved through ventilation systems with a high turnover rate. This results in a continuous loss of heat to the air. Conduction consists of direct loss of heat to surfaces in contact with a patient. This includes the operating table, as well as intravenous fluids, ultrasound gel, and water on the patient. Evaporation is the loss of warm, humid air from the respiratory tract, skin, or an open surgical wound (Ko & Krimins 2014; van Zeeland et al. 2012). Alcohol application can accelerate evaporative cooling from the skin.

Inexpensive thermometers designed for home use by people often have a narrow working range of temperatures and may fail to give a reading in hypothermic and hyperthemic patients or ectothermic patients. Thermistor probes associated with anesthetic multiparameter monitors maintain a much larger working range and can be used as esophageal or rectal probes. To assess core body temperature, it is important to position the tip of an esophageal thermistor probe close to the heart (Dorsch & Dorsch 2008; Machon 1999). In some species, cloacal or distal rectal temperatures may underestimate core temperature.

Systematic Assessment and Treatment of Anesthetic Complications

Veterinary students are taught to use subjective and objective data to identify a problem, generate a list of differentials, and systematically rule in or rule out those differentials until coming to a diagnosis that dictates treatment. Unfortunately, when it comes to anesthetic management, skilled veterinarians often fail to take the same linear and logical approach of identifying changes in vital parameters as data to be used in the diagnosis of a problem and its treatment.

The first step in diagnosing an anesthetic problem is determining if you have an equipment problem or a patient problem. We do this by instinct sometimes, but too often, we write off a real problem as an equipment problem. The easiest way to distinguish patient problems from equipment problems is to employ redundant monitors. If the patient is bradycardic on the ECG, check the pulse oximeter or auscultate with a stethoscope. Sometimes the interpretation of the redundant monitor is less straightforward. If the patient's blood pressure drops suddenly, check the heart rate. A normal animal should compensate for a sudden drop in blood pressure with a compensatory increase in heart rate. Very rarely does an acute change in heart rate, respiratory rate, blood pressure, oxygen saturation, or expired CO_2 occur without deviation in another parameter. Years of clinical practice often result in some instinctual responses to anesthetic problems. The patient is tachycardic, therefore it must be light, and the anesthetist should turn up the inhalant anesthetic. This approach is piecemeal and often ends up in misdiagnosis and mistreatment. We will look here at some of the most common anesthetic complications that we deal with every day, but we will look at them with a problem-based approach. With each problem "symptom" we will list three or four differentials.

Hypotension

Most causes of hypotension involve a change in HR, SV, or SVR, as mentioned above. Changes in the different parameters are interrelated. Aside from being important for basic physiology, remembering these three components gives you a set list of differentials for why your patient is hypotensive. Decreased heart rate can be caused by drugs, such as opioids or alpha-2 agonists, or simply high vagal tone in the patient. Decreased systemic vascular resistance is often

drug-induced vasodilation from inhalant anesthesia, acepromazine, or azaperone. It can also be inappropriate vasodilation, which occurs with sepsis. Decreased strove volume occurs with decreased preload or venous return. This can accompany true hypovolemia with dehydration or blood loss, mechanical obstruction to venous return from an abdominal mass, or as a side effect of positive pressure ventilation.

Steps in treating hypotension:

1) Assess and adjust anesthetic depth. Inhalant anesthetics affect vascular tone and contractility, and are potent hypotensive agents. Too often, a vaporizer is set at a given percentage and forgotten for the remainder of the procedure. Use only as much as you need.
2) Address preload. Hypovolemia can be temporarily addressed with intravenous fluids such as crystalloids and colloids. Animals with high volume abdominal contents, like a rumen, fetus, or abdominal mass, may have decreased return of venous blood through the caudal vena cava to the heart, especially in dorsal recumbency, and may benefit from being rolled into lateral recumbency. Additionally, positive pressure ventilation also decreases venous return and may need to be adjusted in the face of hypotension.
3) Improve vascular tone. Adjusting depth may increase sympathetic stimulation and promote vasoconstriction. Drugs such as ephedrine, phenylephrine stimulate alpha-1 receptors and cause vasoconstriction.
4) Increase cardiac output:
   - If the animal is bradycardic, consider atropine or glycopyrrolate.
   - Increase the contractile force of the heart by using pressors such as dopamine or dobutamine.

Treating Tachycardia and Bradycardia

Changes in heart rate are integrally tied to changes in blood pressure. In many situations, the absolute heart rate is not nearly as important as the role heart rate plays in cardiac output and perfusion. It is crucial to interpret heart rate in relation to blood pressure and cardiac output. It is rarely necessary to treat bradycardia in a normotensive, nonarrhythmic patient. For abnormalities in heart rate, treating the primary problem is the primary concern.

Reasons for tachycardia:

1) compensation for low blood pressure (baroreceptor response)
2) compensation for hypoxemia (chemoreceptor response)
3) sympathetic stimulation from noxious stimuli (i.e. patient is too light)

Reasons for bradycardia:

1) response to high blood pressure (baroreceptor response)
2) direct vagal stimulation from anesthetic drugs (opioids, alpha-2 agonists)
3) excessive anesthetic depth.

Hypoxemia

In terrestrial mammals, hypoxemia is defined as an arterial partial pressure of oxygen less than 60 mmHg or an SpO_2 of less than 90%. Reasons for hypoxia are defined in the blood gas section above.

Tachypnea

We often assume that if a patient's respiratory rate increases, that it is light. In truth, there are likely four reasons why a patient is tachypneic under anesthesia:

1) they are hypercapneic
2) they are hypoxemic
3) they are at a light plane of anesthesia and responding to noxious stimulus
4) they are hyperthermic and trying to lose heat

When noticing any change in respiratory rate and character it is critical to evaluate the four possibilities above: the $ETCO_2$, the SpO_2, body temperature, and depth of anesthesia.

Effective anesthetic monitoring requires a basic understanding of the function of the monitor and the function of the body systems being monitored. Understanding that interaction will allow a safe anesthetist to make timely and accurate assessments and interventions to preserve organ function and the life of the patient (Fig. 3.4).

Appendix

Formulae used by blood gas analyzers to calculate parameters:

1) HCO_3: $\log HCO_3 = pH + \log(PaCO_2 - 7.608)$
2) Base excess = $HCO_3 - 24.8 + 16.2(pH\ 7.4)$
3) Anion gap: $([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$
4) A-a gradient = $PaO_2 - PaO_2 = (FiO_2 \times (P_{bar} - PH_2O) - PaCO_2/0.8) - PaO_2$

   If performed at standard atmospheric pressure (760 mmHg) and room air (21% oxygen) the formula is simplified to $150 - 1.2(PaCO_2) - PaO_2$. The normal A-a gradient is 10–15 mmHg.
5) Physiologic dead space: $Vd/Vt = (PaCO_2 - EtCO_2)/PaCO_2$. The normal dead space is 0.3–0.5.

Emergencies and Complications

Nigel Caulkett, Søren Boysen, and Jon M. Arnemo

Emergency Preparedness

A key element of any successful anesthetic procedure is to anticipate and prepare for potential complications. This is particularly important in zoo and wildlife situations because anesthesia may take place in remote environments with limited availability of equipment and drugs for supportive care. Careful consideration of potential complications prior to the anesthetic procedure will help improve outcomes when emergencies occur. This section provides a summary of considerations prior to an anesthetic or capture event. More complete guidelines can be found in Chinnadurai et al. (2016) and Arnemo et al. (2014).

Environmental Considerations

Prior to any capture event careful consideration should be given to the environment in which the event will take place. With zoo animals it is sometimes possible to plan the event in a relatively controlled environment, but with free-ranging wildlife that is rarely the case. Consideration should be given to ambient temperature because this can increase the risk of thermoregulatory complications. The type of terrain should be considered, particularly the presence of waterbodies or cliffs. Forested terrain can mean challenges in tracking animals and telemetry darts may need to be considered. Access to the capture site is a consideration. If only foot access is available there will be a limit on how much equipment can be carried and careful consideration must be given to the type and amount of equipment carried.

Pre-immobilization Plan and Briefing

Prior to any immobilization a plan should be formulated based on the environmental conditions and the necessity to perform the procedure, i.e. is the procedure elective or emergent. The plan should include a human safety briefing and include how the team will respond to a human or animal emergency. Personnel should be familiar with the contents of the emergency pack and should be aware of their individual roles in an emergency.

Emergency Pack

An emergency pack should be carried during any immobilization procedure. At minimum it should contain the following:

- Equipment to provide airway support.
- Equipment to provide ventilation (if possible).
- Equipment to provide supplemental inspired oxygen.
- Intravenous catheters and tape.
- Intravenous fluids and administration sets.
- Emergency drugs, at minimum epinephrine, atropine, dexamethasone, and lidocaine without epinephrine.
- Equipment and supplies to treat trauma (wounds).
- Long-acting antibiotics and a nonsteroidal anti-inflammatory drug.
- A rumen tube to treat bloat.
- A means of providing euthanasia.

Immobilization, Sedation, and Anesthesia

The reliability of a capture technique is a major consideration during the capture process. The choice of technique can vary between captive and free-ranging animals, and depending on the ability to safely physically restrain the animal if arousal occurs. The process of zoo animal and wildlife capture and handling has improved dramatically over the years. Early techniques relied on the use of muscle relaxants alone. These drugs would paralyze the animal but not render them unconscious. The techniques were not humane or safe for the animals and sudden recoveries

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.
© 2025 John Wiley & Sons, Inc. Published 2025 by John Wiley & Sons, Inc.

could place capture crews at risk. These techniques were simply a form of chemical immobilization. Potent opioids will induce a state of immobilization where the animal may still be responsive to external stimulation and may still have the potential to injure handlers if care is not taken around limbs, horns, or antlers. These drugs are often combined with a tranquilizer or sedative to induce a state of neuroleptanalgesia (Kreeger et al. 2009). Sedation is a component of anesthesia but differs from anesthesia in that stimulation may rouse the patient from their soporific state. Sedative techniques may be used to capture and restrain wildlife, particularly wild ungulates. The use of alpha-2 agonists alone can be unreliable. Combining alpha-2 agonists with tranquilizers and/or opioids will induce a synergistic effect and a deeper plane of sedation. The butorphanol-azaperone-medetomidine (BAM) combination is a good example of this synergism. Studies in American elk, using the bispectral index (BIS) to determine the plane of anesthesia, demonstrated that elk receiving BAM developed a deeper state of anesthesia than elk receiving carfentanil-xylazine. The BIS values reported with BAM were consistent with deep sedation (Kreeger et al. 2009). Caution should always be exercised to avoid arousal of animals restrained with deep sedation. Noise should be kept to a minimum, animals should be repositioned or moved in a cautious manner, and appropriate analgesia should be used to prevent painful stimulation. Sedation is appropriate in many capture situations, but anesthesia should be considered for larger or more dangerous species. Anesthesia differs from sedation in that the patient loses consciousness and cannot be roused until the drugs are metabolized. The most commonly used anesthetic drugs for wildlife capture and handling are the dissociative anesthetics, ketamine and tiletamine. Alfaxalone is a more recent addition to capture protocols. These drugs are typically used in addition to a sedation protocol. Dissociative anesthetics produce dose-dependent effects ranging from sedation to anesthesia. It is important to choose an appropriate intramuscular dose if anesthesia is desired. In some situations, intravenous (IV) titration and maintenance is advisable to achieve a desired plane of anesthesia, particularly if surgical interventions are to be performed. Dissociatives should be combined with a tranquilizer or sedative to reduce the risk of muscle rigidity or convulsive activity.

Inadequate Drug Dosing

Anesthesia and immobilization of zoo and wild animals is a particularly challenging field of veterinary anesthesiology. There are many factors that contribute to these challenges but a major one is the delivery of an appropriate drug dose to achieve reliable sedation or anesthesia. The use of remote drug-delivery techniques can pose a particular challenge. Injection site, needle length, and complete or partial failure of drug delivery from the dart can result in either failure to deliver the complete dose or delayed absorption into the circulation (Bergvall et al. 2015). The clinical impact is that the induction period may be very prolonged, the animal may completely fail to become recumbent, or it may be aroused when approached. Pharmacodynamics also play an important role. It is common for free-ranging or very excited animals to require a greater dose of capture drugs compared to calm or captive animals (Kreeger et al. 2023). This phenomenon can be particularly apparent when protocols based on alpha-2 agonists are utilized because competition for noradrenergic receptors increases in the face of elevated endogenous catecholamines. As sedation, with these drugs, occurs from reduction of sympathetic outflow in the central nervous system these animals may take longer to sedate or may fail to sedate adequately. The drug doses outlined in this textbook will serve as a good starting point for immobilization or anesthesia of a given species. It is important to note if the recommended dose was determined in captive or wild animals and the delivery technique used. There has been a great deal of good science performed to develop these capture techniques, but they will fail on occasion. The art of anesthesia comes into play when a decision must be made on how to best re-dose the animal. In some situations, a full dose of the drugs may be required, particularly if dart failure is suspected, if the animal is showing no signs of drug effect, or if human or animal safety is at risk. If the animal is showing some signs of drug effect a decision may be made to deliver a partial dose of the drugs. It can be challenging to determine what dose to deliver and the experience of the capture team plays an important role. It is always best to learn from experienced people who have mastered the art of these techniques to make the best judgement call on additional dosing in these situations.

Airway Support

Airway support can be challenging during an immobilization event as the induction period may be prolonged and with many species it is important to ensure that the animal is safely anesthetized prior to approach. The airway may be lost in this time period, with severe consequences. During the induction period it is important to observe the animal for chest excursions and to listen for upper airway noise. As soon as it is safe to approach the animal, the airway should be checked for patency and the head and neck placed in a

position to maximize ventilation. A complete discussion of airway support can be found in Cracknell (2014).

Unsupported Airway

Wild animals are frequently maintained with an unsupported airway during capture procedures. Unfortunately, this will place the animal at risk of hypoventilation, hypoxemia, and aspiration. Ideally the airway should always be supported, but logistically this may be a challenge under field conditions. If the animal is maintained with an unsupported airway, it should always be closely monitored to ensure that adequate chest excursions are present and that oxygenation is appropriate. Equipment should always be available to provide airway support in the event of loss of airway or apnea.

Infraglottic Airways

Endotracheal intubation via either the nasotracheal or orotracheal approach is the ideal method to provide airway support. A variety of endotracheal tube styles are available. The choice of a particular endotracheal tube depends on the species and the procedure being performed. Various methods are also available to facilitate endotracheal tube placement, including manual manipulation, laryngoscopy, and fiberoptic-guided placement. The equipment required and the technique is very species dependent. Please refer to individual species chapters in this textbook for recommendations on each species.

Supraglottic Airways

Supraglottic airways include nasopharyngeal airways and laryngeal mask airways (LMAs). Commercial veterinary LMAs are currently available for cats and rabbits (Croatz 2010). Human LMAs have been adapted for a variety of species (Cracknell 2014). The use of these devices has recently been described in calves (Armstrong et al. 2018) and free-ranging bighorn sheep (Hee et al. 2020). One major advantage of LMAs is the fact that they can readily be placed with a blind technique. This is a potential advantage in emergent situations, particularly for individuals who are not proficient at laryngoscopy (Fig. 4.1).

Confirmation of Airway Placement

It is always important to confirm correct airway placement immediately following intubation. The most rapid method to confirm placement is with capnography (Fig. 4.2). Placement of a capnograph and visualization of a normal capnograph waveform should be used whenever equipment is available. Alternate techniques can include palpation of the trachea and esophagus to determine if inadvertent esophageal intubation has been performed. Chest auscultation for bilateral lung sounds during ventilation will also assist in confirmation that placement is endotracheal rather than endobronchial.

Figure 4.1 Placing a laryngeal mask airway in a Bighorn sheep lamb.

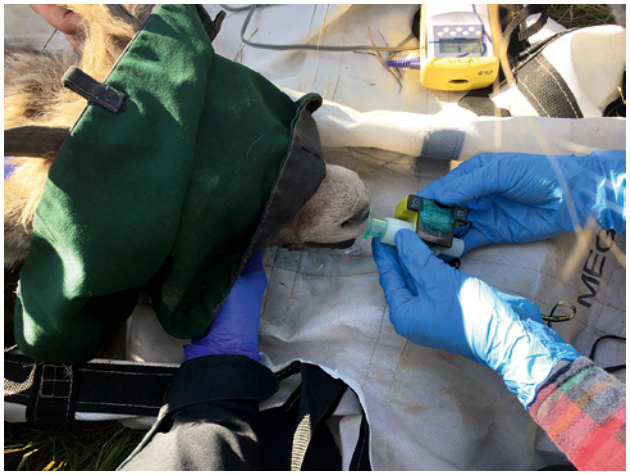

Figure 4.2 Capnography can be used to determine correct placement of endotracheal tubes or supraglottic airways.

Hypoventilation

Hypoventilation during zoo animal and wildlife anesthesia is typically the result of drug-induced respiratory depression. Potent opioids, alpha-2 agonists, dissociative anesthetics, GABAergic induction agents, and volatile anesthetics can all contribute to hypoventilation. Hypoxemia may be a consequence of hypoventilation,

particularly if the animal is breathing ambient air. Hypoxemia is exacerbated by ventilation-perfusion mismatching induced by drugs, positional changes, or recumbency. Given the frequency and potential adverse consequences of these complications, availability of equipment for ventilation and oxygenation is advocated as a best practice guideline during wildlife anesthesia (Chinnadurai et al. 2016). Hypoventilation can be challenging to treat under field conditions. Pharmacological interventions may include partial antagonism of potent opioids (Moresco et al. 2001; Buss et al. 2018) or the use of respiratory stimulating drugs (Haw et al. 2016). These methods may be useful in specific situations and deserve more study. Currently the definitive treatment for hypoventilation is the use of intermittent positive pressure ventilation (IPPV). In zoo situations ventilation can typically be performed with a small or large animal ventilator attached to an anesthetic machine. In field situations a bag valve mask (BVM) may be an option in animals up to 100 kg. A demand valve can be used in animals >100 kg. Both of these techniques will require placement of an airway prior to use.

Bag Valve Mask

The BVM or ambu bag is a self-inflating bag with a valve that directs inspiratory and expiratory flow to provide ventilator support. The bag can be used with a mask in humans, but in veterinary patients it is typically attached to an endotracheal tube. Flow is typically adjusted to obtain adequate chest excursions and rate is adjusted by the operator. Ideally a BVM with a pressure relief valve should be used to help avoid barotrauma. Adult and pediatric bags are available and can be readily adapted to many veterinary patients. The BVM can be used with ambient air or enriched oxygen if a tank and regulator are available.

Demand Valves

In field situations, IPPV of large animals can be accomplished with a demand valve. The demand valve has been used to successfully ventilate horses for many years, particularly in the postoperative period (Waterman et al. 1982). The use of demand valves has also been described in extremely large mammals. Horne et al. (2001) described a technique whereby two demand valves combined with a Y connector can be used to ventilate African elephants. Demand valves offer an advantage over large animal ventilators for field use as they are compact and easy to transport. They must be manually cycled, however, which ties up personnel, and high flows of oxygen are required to run them, but oxygen supply can be a challenge in the field.

Hypoxemia

Hypoxemia is a very common complication associated with immobilization and anesthesia. It is often defined as partial pressure of arterial oxygen (PaO_2) <60 mmHg or hemoglobin saturation <85%, but a number of factors, particularly the species or altitude, can influence normal values. Several factors contribute to the development of hypoxemia during wildlife capture and handling. Hypoventilation, induced by potent opioids, can result in hypoxemia (Buss et al. 2018; Haw et al. 2016; Paterson et al. 2009; Moresco et al. 2001). Many other drugs, including ketamine, alfaxalone, and propofol, can contribute to hypoventilation. The alpha-2 agonists will exacerbate ventilation:perfusion (V/Q) mismatching and contribute to hypoxemia (Kästner 2006; Lakhdhir et al. 2020; Read 2003). Other factors that can contribute to hypoxemia include positional changes (Cattet et al. 1999), ruminal tympany, and compromised airways. Severe hypoxemia may induce arrhythmias (Caulkett et al. 1994, 2000) and potentially acute death. The impact of mild to moderate hypoxemia in wildlife is not well described. Hypoxemia will result in prolongation of recovery time following reversal (Paterson et al. 2009; Risling et al. 2011). The impact on the animal post recovery has not been determined. It is considered good anesthetic practice to prevent or treat hypoxemia. In controlled settings an anesthetic machine with an appropriate circuit is the simplest way to provide supplemental oxygen to an anesthetized patient. Treatment of hypoxemia in the field is typically achieved via the provision of intranasal or intratracheal oxygen. A complete discussion of hypoxemia can be found in Fahlman (2014).

Intranasal and Intratracheal Oxygen Administration

Intranasal administration of oxygen can be used to increase the fraction of inspired oxygen (FIO_2), which will help offset the decrease in PaO_2 observed during immobilization. In this technique a cannula is placed into the nostril and advanced to the level of the medial canthus of the eye. The cannula is connected via an oxygen line to an oxygen tank with a regulator or to an oxygen concentrator. Variations of delivery include the use of a cannula in each nostril or the use of human nasal prongs. The oxygen flow rate is adjusted with a flow meter. In general, higher flow rates will typically increase FIO_2, resulting in a greater PaO_2. In field situations flow is adjusted to the lowest flow required to maintain greater than 95% hemoglobin saturation to preserve the oxygen supply in the tank. Flows required to offset hypoxemia in different species are variable and the

Figure 4.3 Delivery of supplemental inspired oxygen to an anesthetized moose.

literature should be reviewed for guidance on flows to initiate therapy. Higher flows are typically required in larger species. A flow rate of 10 L/min has been used in American elk, which typically weigh 300–400 kg (Read et al. 2001). In female reindeer, typically weighing 50–100 kg, a flow of 1–2 L/min will effectively treat hypoxemia (Evans et al. 2013). Flow rates of oxygen as low as 1 L/min effectively treated hypoxemia in female white-tailed deer weighing 55–65 kg (Fahlman et al. 2014). If the patient is intubated a cannula can be placed into the endotracheal tube and oxygen delivered by the transtracheal route. Lower flow rates are required than via the intranasal route and greater FIO_2 values can be achieved.

Oxygen Delivery Equipment

In clinical situations oxygen can be delivered to deeply sedated patients via an anesthetic machine, with an appropriate circuit and a face mask or endotracheal tube. In field situations a D or E oxygen cylinder coupled with a regulator and flow meter can be used to deliver supplemental inspired oxygen (Fig. 4.3). It may be challenging to restock cylinders in remote areas and portable oxygen concentrators can be valuable in these conditions as they are battery operated and can be recharged overnight. The use of portable oxygen concentrators has been described in wildlife (Fahlman 2014; Fahlman et al. 2012).

Cardiovascular Complications and Emergencies

Bradycardia

In defining bradycardia it is important to know normal values for the species and the impact of the anesthetic technique being used. Vagally mediated bradyarrhythmias are very common in animals anesthetized with alpha-2 based protocols. These bradyarrhythmias are often not treated. Profound bradyarrhythmias may result from a variety of causes, including vagal stimulation, profound hypoxemia, hyperkalemia, and cardiac disease. In general, the underlying cause should be identified, and if the situation is life-threatening atropine should be administered at a dose of 0.02–0.04 mg/kg (Lerche 2015). Glycopyrrolate can also be used to treat vagal arrhythmias but due to its slow onset it is less useful than atropine in emergent situations. Hyperkalemia has been reported in a number of exotic felids anesthetized with protocols containing alpha-2 agonists. This complication can be severe and may result in cardiac arrest. It is good practice to monitor cardiac rhythm and electrocardiograph (ECG) morphology when anesthetizing wild felids (Romano et al. 2018).

Tachycardia

Tachycardia is often an indication of underlying complications under anesthesia and can be associated with pain, awareness, hypotension, hypoxemia, or hypercarbia. These conditions often induce a stress response. It is important to rule out these complications when attempting to determine the root cause of the tachycardia. Primary tachyarrhythmias can originate anywhere in the heart. An ECG is required to characterize the arrhythmia prior to treatment. Treatment of ventricular tachycardia is typically initiated with a class 1B antiarrhythmic drug such as lidocaine (1–2 mg/kg). Initial treatment of supraventricular tachyarrhythmias is typically achieved with a beta-blocking drug. Esmolol is often the drug of choice during anesthesia as it can be readily titrated in an acute setting. Esmolol is typically administered to dogs and cats at a loading dose of 2 μg/kg followed by a constant rate infusion (CRI) of 50 μg/kg/min (Murrell 2015).

Hypotension

Hypotension is a relatively common complication during anesthesia, particularly when volatile agents such as isoflurane or sevoflurane are used for maintenance of anesthesia. Hypotension is typically defined as a systolic arterial pressure <90 mmHg or a mean arterial pressure <60 mmHg. This definition is based on humans and may vary amongst other species. When treating hypotension it is important to identify the underlying cause. Pre-existing or ongoing fluid deficits or hemorrhage should be treated with volume replacement. Depending on the situation, isotonic replacement fluids, hypertonic fluids, colloids, or whole blood may be indicated. In field situations it can be challenging to carry large volumes of crystalloid fluids and

low volume resuscitation fluids such as hydroxyethyl starch can be a useful addition to resuscitation with isotonic crystalloids. Hypotension induced by isoflurane or sevoflurane may be treated by reducing the inspired concentration of volatile agent. Additional drugs such as alfaxalone, opioids, lidocaine, or alpha-2 agonist CRIs can be considered to maintain an appropriate plane of anesthesia when the volatile agent is reduced. Alpha-2 agonist CRIs have an additional benefit as they will increase peripheral vascular resistance and counter vasodilation. Pharmacological treatment of hypotension can include the use of dobutamine, dopamine, ephedrine, and norepinephrine. Most of these drugs must be administered as CRIs. Ephedrine is potentially useful in field situations because it can be administered at a bolus dose of 0.06 mg/kg (equine dose). The onset is approximately 5 minutes and effects will last approximately 30 minutes. Boluses can be repeated if needed to prolong drug effects (Trim & Shepherd 2015).

Hypertension

Acute hypertension during the capture and handling of wildlife is often drug related. Protocols based on alpha-2 agonists or potent opioids are often associated with hypertension. Normal blood pressure is difficult to define in zoo and wildlife species, therefore it can be difficult to define hypertension. Systolic pressure >160 mmHg is often used in domestic mammals. Hypertension may also result from a stress response due to light anesthesia, hypoxemia, or hypercarbia. It is important to identify the root cause of hypertension in order to treat it appropriately.

Shock

Shock during wildlife capture and handling can result from many different causes. The underlying cause should be identified, if possible, to determine appropriate treatment. During wildlife capture and handling hypovolemic shock resulting from trauma and capture shock syndrome are probably the most common forms of shock encountered. Shock can be very difficult to treat under field conditions, particularly in large animals. Generally, therapy should be directed at maintaining oxygen delivery to the tissues. Supplemental inspired oxygen should be considered to maximize arterial oxygen content and appropriate fluid replacement is vital in most forms of shock. Availability of blood products and large volumes of fluid is a challenge in zoo and wildlife anesthesia but an isotonic replacement fluid such as lactated Ringer's solution should always be available. If large animals are anesthetized hypertonic saline may be considered and/or a colloidal solution. Vasoconstrictive and/or inotropic drugs should also be considered. Given the challenges in treating shock under field conditions, every step should be taken to prevent trauma or capture myopathy during the capture process.

Hyperthemia

Hyperthermia can be challenging to define as normothermia may vary considerably between species and over seasons. Recent approaches have proposed that hyperthermia should be defined as an increase of >2°C from normal body temperature for a certain species in a certain season. Hyperthermia is a very common complication during wildlife capture and handling. It is important to monitor body temperature throughout an immobilization procedure, particularly if an animal has undergone a chase prior to induction. It is important to note that rectal temperature measurement may underestimate core temperature by as much as 1°C (Ozeki et al. 2015). Factors that increase the risk of hyperthermia during capture include prolonged pursuit and interference of thermoregulation from capture drugs. Alpha-2 agonists promote heat conservation via peripheral vasoconstriction. Symptoms of hyperthermia include rapid breathing, weak, rapid, or irregular heartbeat, and finally convulsions and death. In many mammalian species a body temperature greater than 41°C results in an emergent situation that requires immediate intervention. Treatment in the field may include immersion in cool water, movement into a shaded area, packing the inguinal or axillary areas with snow or ice, or fanning the animal. Cold water enemas combined with cold IV fluid administration have been shown to reduce the core temperature of hyperthermic bears (Ozeki et al. 2015). If cold water enemas are used, rectal temperature measurement is no longer reliable and another route of temperature measurement, such as esophageal or tympanic, should be considered. Antagonism of alpha-2 agonists can also help to normalize body temperature (Ozeki et al. 2015). It is always best to prevent hyperthermia as it can be difficult to treat. Try to avoid capture procedures during the warm hours of the day, minimize pursuit times, and avoid prolonged physical restraint.

Hypothermia

Hypothermia is typically encountered in very young animals, animals that have small body masses, and animals in poor body condition. It is difficult to define a temperature where hypothermia becomes a concern because there is a wide variation in normal body temperature among species. It is probably simplest to define hypothermia as a body temperature >2°C lower than normal. Marsupials can have

particularly low normal body temperatures. In many mammalian species hypothermia is defined as a core temperature less than 34°C. Hypothermia may lead to arrhythmias, prolonged recovery, or acidosis. Causative factors can include low ambient temperature, wind chill, precipitation, or drugs that impair thermoregulation. If body temperature is declining and trending towards hypothermia it is best to proactively treat it. Treatment may include drying wet animals, covering the animal, or providing external heat sources. In controlled settings convective warming can be particularly effective. It is always best to try to prevent hypothermia from occurring. Insulate the animal from the ground to prevent conductive heat losses and cover the animal to prevent losses from radiation or convective cooling.

Vomiting and Regurgitation

Vomiting and regurgitation are emergencies in an immobilized animal. If inhalation of stomach contents occurs, aspiration pneumonia can result, requiring prolonged intensive care that usually is not possible for wild animals. Animals should be positioned so that the nose is sloping downwards from the back of the head to decrease the risk of inhaling regurgitated materials. If vomiting occurs in smaller moveable animals, the animal should be placed in sternal recumbency with the head pointed downwards. A long-acting broad-spectrum antibiotic should be considered for animals showing signs of aspiration such as witnessed aspiration events, rumen contents in the nostrils, or harsh lung sounds.

Bloat

Bloat during wildlife capture is usually caused by lateral recumbency or by ruminal atony following administration of alpha-2 agonists. Ruminants should be positioned in sternal recumbency to reduce the risk of ruminal tympany. Tympany results from the inability to relieve gases from the rumen or stomach through eructation. Supportive treatment consists of placing the immobilized animal in sternal recumbency with the neck extended and the head forward, permitting saliva to drain. Move the animal from side to side over the brisket and elevate the front quarters of smaller animals. If positioning does not relieve the bloat, insert a lubricated and properly sized tube via the esophagus into the rumen to relieve pressure. Generally, in animals immobilized with alpha-2 agonists, bloat will resolve following the administration of an alpha-2 antagonist. In the face of severe bloat, procedures should be completed and the immobilization should be reversed. The last resort is trocharization of the rumen using a large-bore (2.5 mm), long (60–80 mm) needle.

Trauma

During the process of immobilization and capture, physical injuries, such as contusions, lacerations, abrasions, punctures, and fractures, may be inflicted on the animal accidentally or as a result of mishandling. Minor lacerations may be flushed, cleaned, and protected with an insect repellant. An appropriate long-acting antibiotic may be given to help prevent infection. Closure may be considered for large lacerations, and they should be flushed copiously, cleaned, and debrided. These lacerations are often contaminated and if they are closed appropriate drainage must be considered in the closure. Fractures and other serious conditions are difficult to treat effectively and will often require that the animal be euthanized for humane reasons.

Physical trauma may be prevented by taking notice of any hazard in the environment that may cause injury to the animal during capture and by careful handling. If traps, snares, nets, or other forms of manual capture or restraint are used, they should be appropriate for the species and set by well-trained individuals.

Pneumothorax

An uncommon cause of hypoxemia is pneumothorax. Dart penetration of the thoracic cavity can result in open or closed pneumothorax. It may be possible to treat pneumothorax with thoracocentesis. Equipment should be carried to perform thoracocentesis in the field. See Sigrist (2008) for instructions on thoracocentesis.

Myopathy

Most free-ranging wild animals exert themselves only infrequently to escape danger. They are not conditioned for running hard over long distances. Chasing wild animals by helicopter or motor vehicle for capture causes a tremendous amount of stress, resulting in intensive muscular activity. The effects of sympathetic exhaustion from sustained stress, combined with intense muscular exertion, are causative factors of various life-threatening syndromes known as *capture myopathy*. Capture myopathy is difficult to treat and prevention is of utmost importance. Capture myopathy may be prevented by reducing capture stress, fear, and exertion (by limiting chasing time), minimizing visual and auditory stimulation, careful handling and restraint of the captured animal, and providing a stress-free recovery environment. For a complete discussion of capture myopathy refer to Paterson (2014) and Breed et al. (2019).

Cardiopulmonary Resuscitation

Evidence-based cardiopulmonary resuscitation (CPR) guidelines do not exist for wildlife; recommendations are based on human medicine, small animal RECOVER guidelines, experimental animal models, and expert opinion.

Several concepts are universally accepted regardless of species: preparedness and prevention, basic life support (BLS), advanced life support (ALS), monitoring, and post-cardiac arrest care. This chapter focuses on the first four concepts.

In an ideal setting CPR success is <6% in veterinary patients (Hofmeister et al. 2009), with numbers likely much lower in wildlife, particularly in the field. This emphasizes the need to be prepared. All members should be familiar with a designated crash cart or mobile CPR kit containing the necessary supplies, drugs, equipment, and documents, which should be routinely checked on a per-use basis to ensure it is properly stocked, that all equipment functions properly, and that nothing has expired.

It should take <10–15 seconds to confirm cardiopulmonary arrest (CPA) through auscultation of the heart, palpation for pulses, and observation for breathing, which is immediately followed by BLS if an arrest is suspected. There is no evidence that initiating compressions when an animal is not in arrest causes significant harm (Fletcher et al. 2012; Fletcher & Boller 2015).

Presence of Apnea

If there is any doubt act as if the patient is not breathing and intervene. Apnea in an unresponsive patient with an inability to locate a pulse within 10 seconds should trigger CPR (Fletcher et al. 2012). Agonal breaths preceding an arrest are sometimes confused for respirations; CPR should proceed in the presence of agonal breaths.

Absence of a heartbeat and/or pulses (femoral artery) should prompt initiation of BLS. Prolonged efforts to locate a pulse should be avoided if the patient is apneic and unresponsive; proceed with BLS.

BLS should be initiated if the patients is apneic, a pulse is not identified within 10 seconds, and there is loss of consciousness with fixed, dilated (unresponsive) pupils.

Pulmonary Arrest without Cardiac Arrest

When respiratory arrest occurs without cardiac arrest (absence of respiratory effort with a palpable pulse) intubate and give two to four large breaths. If apnea persists after several seconds, start positive pressure ventilation (PPV). If the patient progresses to CPA, begin chest compressions immediately.

Arrests during Anesthesia

Consider discontinuation of volatile anesthesia or administration of a specific antagonist in anaesthetized wildlife if it is safe to do so; this will depend on the species and the environment.

Basic Life Support

BLS is the attempt to sustain life by artificially maintaining blood flow through performing chest compressions and artificially maintaining oxygenation of the blood and removal of carbon dioxide through PPV.

The Alphabet of an Arrest: A, B, C or C, A, B

After confirming CPA, the ABC of CPR is essential. Recent evidence suggests the algorithm of CAB (circulation, airway, breathing) is preferred over ABC (airway, breathing, circulation) as blood flow is the highest priority and chest compressions provide ventilation even prior to intubation and PPV (Fletcher & Boller 2015).

Circulation

Under ideal conditions only 30–45% of normal cardiac output is achieved during BLS, emphasizing the importance of proper CPR (Plunkett & McMichael 2008; Andreka & Fenneaux 2006).

Although chest compressions and internal cardiac message are both applicable in emergency critical care, because of the unlikelihood of performing open chest CPR in wildlife field conditions, only chest compressions will be discussed in this chapter.

Chest Compressions

Although chest compressions only generate a small amount of blood flow, if started early and performed properly they can provide critical blood flow to the brain and myocardium, which may be sufficient to achieve the return of spontaneous circulation (ROSC).

Start compressions immediately on identification of CPA; interruptions of compressions must be minimal and only for essential interventions (i.e., endotracheal intubation, defibrillation, or catheter placement). Even short interruptions to compressions negatively impact outcome in humans and continuous effective compressions must be maintained throughout the resuscitation attempt (Deakin et al. 2010; Neumar et al. 2010).

When an essential intervention is deemed necessary, interruption in compressions should not exceed 5–10 seconds (Deakin et al. 2010; Neumar et al. 2010).

Technique for Chest Compressions: General Delivery of chest compressions will vary according to the wildlife species in which it is performed (Table 4.1).

If at least two people are present, the goal should be to provide respirations and chest compressions. If only one person is present, chest compressions take precedence (Deakin et al. 2010; Neumar et al. 2010). Intubate and start PPV when help arrives.

If only one person is present and the patient is already intubated, give 30 chest compressions and two ventilations (Deakin et al. 2010; Neumar et al. 2010).

Providing good-quality chest compressions is exhausting; chest compressors should be alternated every 2 minutes (Malzer et al. 1996; Orliaguet et al. 1995). Interruption of compressions to alternate compressors should take <5 seconds.

A CPR leader should monitor the quality of CPR and alternate CPR providers or technique if quality is poor.

Maximizing Blood Flow during Chest Compressions The chest should be compressed by approximately one-third of the thoracic width at its widest point (Plunkett & McMichael 2008).

Frequency of compressions should follow guidelines for the species and weight (see Table 4.1). Exceeding recommended rates is not beneficial and can decrease filling time during the chest recoil phase. Compressions below the recommended rate are associated with poorer outcomes.

Chest compression to relaxation time should be approximately 1:1, making sure full chest recoil is attained between each compression relaxation cycle (Plunkett & McMichael 2008).

In general, there are two theories to explain blood flow during chest compressions: the cardiac pump theory and thoracic pump theory. With the cardiac pump theory, direct compression of the heart between the two sides of the rib cage results in forward blood flow. This mechanism is most likely prominent in animals less than 15 kg or during internal cardiac massage (Plunkett & McMichael 2008).

With the thoracic pump theory changes in intrathoracic pressure during compressions and relaxation of the chest (not direct cardiac compression) result in blood flow. This mechanism likely accounts for the majority of blood flow in animals greater than 15 kg (Plunkett & McMichael 2008).

Airway

Maintain the airway, provide oxygen support as soon as possible, and ventilate the lungs with the most appropriate equipment immediately available (see breathing).

Confirm the airway is not obstructed and intubate as quickly as possible; if possible, avoid stopping compressions for >5–10 seconds to intubate.

If the animal is intubated, make sure the tube is patent (not obstructed with mucous or kinked) and in the right location (not esophageal). Ensure the cuff is inflated to allow PPV. High-volume, low-pressure cuffs are preferred over low-volume, high-pressure cuffs due to the risk of pressure necrosis of the tracheal mucosa (Plunkett & McMichael 2008).

If intubation is not possible (e.g., masses or laryngeal collapse), a tracheostomy tube may be required. Minimize interruption of chest compressions to perform a tracheostomy. Tracheostomy closure is usually through second intention healing, although primary closure may be preferred in the field setting, particularly if animals may enter bodies of water.

Breathing (Ventilation)

The optimal tidal volume, respiratory rate, and inspired oxygen content to use during CPR are unknown and may vary between individuals, breeds, and species. Slow delivery of breaths, with an inspiratory time of 1 second and enough volume (10 mL/kg) to produce a normal chest rise is recommended (Plunkett & McMichael 2008). Hyperventilation can be harmful because it increases intrathoracic pressures, decreases venous return, and subsequently decreases cardiac output and cerebral perfusion pressures (Aufderheide & Lurie 2004). Therefore, a balance between hypoventilation (too few breaths or incomplete expansion of the lungs) and hyperventilation must be achieved.

Avoid overinflation of the lungs (if a pressure gauge is available, do not exceed 20 cmH_20 pressure), but make sure the chest visibly rises with each breath (Plunkett & McMichael 2008).

PPV can be delivered by connecting the patient to an anesthetic machine and using the rebreathing bag (rare in field settings), ambu bag, or demand valve depending on the size of the animal and environment encountered.

Time permitting, confirm proper connection and function of anesthetic machines (tubing free of obstruction, oxygen on and flowing, proper connection to the endotracheal tube, etc.). Begin PPV using the reservoir bag and pop-off valve. The pop-off valve can be closed or partially closed during compression of the reservoir bag to allow filling of the lungs; do not to exceed 20 cmH_2O of pressure during compression of the reservoir bag.

An ambu bag is inexpensive and can be used with room air until connected to an oxygen source. Although not common, pressure gauges can be used with ambu bags. Use of a reservoir bag with the ambu bag (available on some ambu bags) increases the inspired oxygen content during PPV (the reservoir bag fills with oxygen, which the ambu bag draws from, decreasing the chance of mixing oxygenated air with room air).

Oxygen content should initially be set at 100% if it is available (Plunkett & McMichael 2008). Following ROSC and spontaneous respirations, the inspired oxygen content

Table 4.1 CPCR techniques for avian and mammalian patients

Species	Position	Compression Site	Technique	Rate/Minute	Ventilation	Notes
Avian patients (small)	Dorsal	Sternum	One or two fingers	Up to 200	20–30 bpm	Intubation is challenging in very small birds, consider chest compressions only with oxygen supplementation provided by mask or flow by
Avian patients (large)	Dorsal	Sternum	Palm of the hand on the keel bone	100–120	10 bpm	Very large birds such as larger ratites may require a similar technique to 100–250 kg mammals
Mammals ≤1 kg	Right lateral	Caudal to the forelimb	Two fingers	150–200	20–30 bpm	If intubation is not possible, mask ventilation may be attempted
Mammals 1–10 kg	Right lateral	Fifth to sixth intercostal space over the heart (cardiac pump)	Palm of the hand on the sternum with the fifth to sixth intercostal space between the finger and thumb	100–120	10–15 bpm depending on weight	Direct compression of the heart when the fingers and thumb are squeezed together Fingers and thumb of the opposite hand can be placed over the first hand if more vigorous compressions are required Avoid using only the fingertips to compress the chest as this may result in poorer efficacy and decreased blood flow
Mammals 10–100 kg	Right lateral	Widest point of the chest (thoracic pump)	Keep shoulders, elbows, and hands in a straight line so the weight of the upper body is transferred into the compressions via the arms	100–120	10 bpm	Consider approach for patients >250 kg if technique fails and animal is >70 kg
Mammals 100–250 kg	Right lateral	Widest part of the chest (thoracic pump)	Use one foot, with the knee and hip in a line over the foot	100	8–10	There is no published literature on any technique to perform cardiopulmonary cerebral resuscitation in patients between 100 and 250 kg in body weight If this technique fails, consider technique for patients >250 kg
Mammals >250 kg	Right lateral	Widest part of the chest (thoracic pump)	Use one knee to "fall" on the patient at the widest point of the chest just caudal to the left elbow	80	8–10	Technique is physically demanding for the operator and it may be best used intermittently for short periods

For all species: Compress the chest by approximately 30% in a 1:1 compression to relaxation rate, allowing full chest recoil between each compression. Switch out chest compressors every 2 minutes or less if fatigue sets in earlier. Minimize interruption in compressions to less than 5–10 seconds at any time.
bpm, breaths per minute.

is titrated to a level that provides adequate partial pressure of arterial oxygen or hemoglobin saturation ($PaO_2 \geq$ 70 mmHg and $SaO_2 \geq 93\%$) while minimizing the risks of oxygen toxicity.

Advanced Life Support: D, E, F

ALS interventions are unlikely to lead to ROSC without effective BLS, and thus should be instituted without interruption of BLS.

Drugs

There are generally five routes of drug administration; central venous catheter (jugular vein), peripheral venous catheter (i.e., cephalic or saphenous), intraosseous (IO) catheter, intratracheal (IT), and intracardiac (only recommended during open chest CPR). Do not discontinue compressions during the administration of drugs via any route!

Central line administration is the most rapid and preferred CPR route (Emerman et al. 1988). However, unless already in place, a peripheral catheter is recommended over a central line due to increased ease of placement and decreased risk of complications. With difficult IV access a venous cutdown (<60 seconds) or automated IO catheters (<10 seconds) can be placed. IO catheters show equal efficacy to peripheral lines and may be equivalent to central lines when placed in proximity to the heart (e.g., proximal humerus) (Neumar et al. 2010). In general, if a drug can be given IV it can be given IO at the same dose.

Drugs delivered IV or IO should be followed by a bolus of fluids (10–20 mL/kg) to "push" administered drugs more rapidly towards the heart (Emerman et al. 1990).

The IT route is less frequently used in human CPR due to unpredictable plasma concentrations (Neumar et al. 2010). However, it is still frequently used in veterinary patients due to its low cost and ease of use. The optimal IT dose for most drugs is unknown but should be two to three times the IV dose. Evidence suggests the IT epinephrine dose may need to be three to 10 times the IV dose (Hörnchen et al. 1987). With the exception of bicarbonate, all drugs given IV can be given IT. To ensure the drug reaches the small airways administer the drugs via a long 5–8 Fr red rubber feeding tube passed through the endotracheal tube. A small bolus of air equal to the volume of the feeding tube is administered after the drug to ensure the drug reaches the lungs and does not remain within the feeding tube. Ventilate the patient with two or three rapid breaths to help distribute the drug within the lungs.

Intracardiac administration is no longer recommended due to the risk of lacerating coronary vessels, injury leading to arrhythmias, and accidental intracardiac muscle injection.

A drug dose chart is given in Table 4.2.

Epinephrine

Epinephrine remains the gold standard CPA drug because of its alpha sympathomimetic effects (Deakin et al. 2010).

The dosage and frequency vary from 0.01 to 0.1 mg/kg of 1:1000 ratio repeated at 3–5-minute intervals (Neumar

Table 4.2 Cardiopulmonary cerebral resuscitation drug doses

Drug	Dose	2.5 kg	5 kg	10 kg	15 kg	20 kg	25 kg	30 kg	40 kg	50 kg
Epinephrine 1:1000 1 mg/mL	0.01 mg/kg (0.1 mg/kg)	0.025 0.25	0.05 0.5	0.1 1	0.15 1.5	0.2 2	0.25 2.5	0.3 3	0.4 4	0.5 5
Atropine 0.5 mg/mL	0.05 mg/kg	0.25	0.5	1	1.5	2	2.5	3	4	5
Lidocaine 20 mg/mL	2 mg/kg	0.25	0.5	1	1.5	2	2.5	3	4	5
Bicarbonate 1 meq/mL	1 meq/kg	2.5	5	10	15	20	25	30	40	50
External defibrillation	4–6 J/kg	10	20	40	60	80	100	120	160	200
Internal defibrillation	0.5–1 J/kg	2	3	5	8	10	15	15	20	25
Vasopressin 20 U/mL	0.8 U/kg	0.1	0.2	0.4	0.6	0.8	1	1.2	1.6	2

Drugs are in mL per kg, administration IV, double or triple the dose if given endotrachealy.

et al. 2010), making every other compression cycle an ideal time for administration. The low dose (0.01 mg/kg IV or IO) is associated with a higher rate of survival to discharge, while the high dose (0.1 mg/kg IV or IO) is associated with a higher rate of ROSC (Rozanski et al. 2012). Until further studies show otherwise, the standard of care is to administer epinephrine at 0.01 mg/kg. If 0.01 mg/kg fails to provide ROSC after one or two boluses, a 0.1 mg/kg dose or use of vasopressin can be considered.

Vasopressin

The only promising alternative to epinephrine is vasopressin. Vasopressin is a vasoconstrictor and antidiuretic that can be used in lieu of or in conjunction with epinephrine. Increased responsiveness in acidic environments and a lack of inotropic and chronotropic effects that can add to myocardial ischemia when ROSC is achieved may be an advantage of vasopressin over epinephrine. The current trend is to administer vasopressin in place of the first or second dose of epinephrine (Neumar et al. 2010; Fletcher & Boller 2015; Rozanski et al. 2012). The suggested dose in companion animals is 0.8 U/kg IV or IO.

Atropine

Atropine is a parasympatholytic agent. It inhibits the effects of acetylcholine and increases heart rate. Its primary indication is when increased vagal tone is the suspected cause of CPA. It is no longer routinely used for treatment of pulseless electrical activity (PEA)/asystole in people (Neumar et al. 2010), however, given there is no evidence to suggest it has detrimental effects during bradycardic or asystolic CPA, it may still play a role in the veterinary profession (see sections on PEA and asystole below).

Bicarbonate

Routine administration of sodium bicarbonate during CPA or after ROSC is not recommended in humans. It may be beneficial in cases where the arrest was caused by hyperkalemia (i.e., urethral obstruction, uroabdomen, or addisonian crisis etc.) or pre-existing metabolic acidosis was present. If given, blood gases should be followed serially to determine response to therapy and the possible need for repeat doses. It is important that ventilation be maintained if bicarbonate is administered to prevent paradoxical central nervous system acidosis.

Lidocaine and Amiodarone

There is no evidence that antiarrhythmics given during cardiac arrest increase survival. They may be considered in ventricular fibrillation or pulseless ventricular tachycardia when defibrillation is not available. Amiodarone is recommended over lidocaine in the human literature (Neumar et al. 2010).

Calcium Gluconate and Glucose

Both have been used during cardiopulmonary cerebral resuscitation (CPCR), but they should only be given when indicated (i.e., pre-existing conditions).

Electrocardiogram

There are three common fatal arrhythmias reported in association with CPA. One may proceed to another.

Ventricular Asystole

Ventricular asystole is characterized by an absence of all electrical ventricular activity: the ECG tracing is a flat line (Fig. 4.4a).

Atropine is no longer recommended for asystole in humans due to a lack of demonstrable benefit. However, given asystole in veterinary patients may be the result of increased vagal tone, until proven otherwise, atropine in conjunction with epinephrine may still be beneficial.

Pulseless Electrical Activity

This is the most common arresting arrhythmia reported in veterinary patients. PE) is characterized by a visible ECG tracing (electrical activity present) in the absence of myocardial contractility (Fig. 4.4b). Treatment is difficult and often unsuccessful. Epinephrine is recommended in cases of PEA. Although atropine is no longer recommended in humans, CPA in veterinary patients often results from increased vagal tone, therefore atropine may still play a role in conjunction with epinephrine, particularly if the cause of CPA was not witnessed, in veterinary patients.

Ventricular Fibrillation

This is the most common arresting rhythm in people, often secondary to myocardial infarctions. It is characterized by a completely disorganized and anarchic rhythm, which results in complete absence of coordinated or effective ventricular contractions. It may be coarse or fine (Fig. 4.4c–e). Electrical defibrillation is the recommended treatment for this arrhythmia, which transiently depolarizes all cardiac cells simultaneously (complete cardiac standstill), with the hope they will restart in a synchronized pattern (Deakin et al. 2010; Neumar et al. 2010).

Given defibrillators are not common in most wildlife field settings, a precordial thump (strong quick thump on the chest wall over the heart) can be attempted. The idea is to traumatically depolarize the heart or stun it.

Fluids

Resuscitation with fluids is only recommended in cases of confirmed hypovolemia to avoid volume overload and pulmonary edema (Deakin et al. 2010). IV administration is

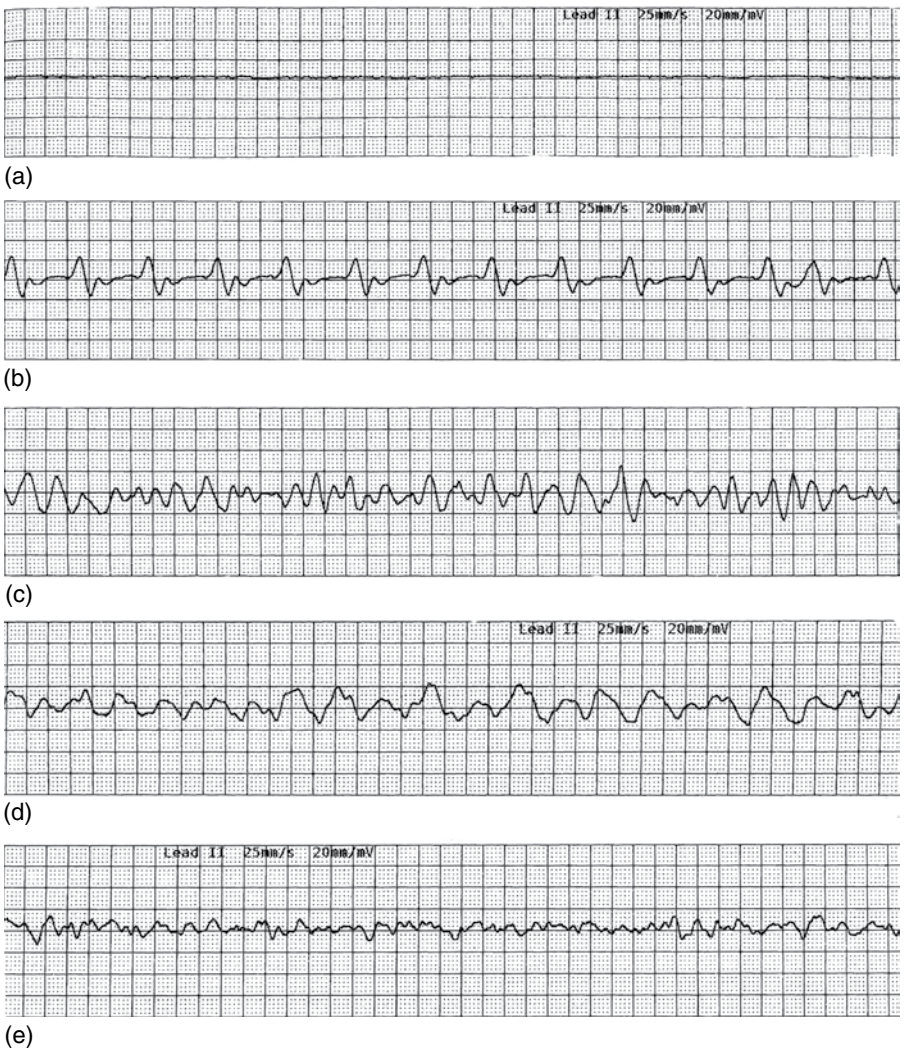

Figure 4.4 (a) Electrocardiograph tracing of ventricular asystole. Note the absence of any electrical activity. (b) An example of pulseless electrical activity. Note that the ECG tracing can vary from near-normal to very bizarre depending on the electrical activity present. The key thing to note is that there is synchronous electrical activity from the heart in the absence of a detectable pulse. (c–e) ECG tracing of coarse ventricular fibrillation progressing to fine ventricular fibrillation.

the preferred route. Alternatively, the IO route can be used. Any fluid boluses given to "chase" CPR drugs should be included in fluid volume calculations.

Monitoring Efficacy of CPCR

Femoral pulse palpation is an easy technique to monitor the efficacy of CPR. If compression efforts fail to produce a palpable pulse, then a change in compression technique should be considered. Palpation of a pulse when chest compressions are stopped is a fairly reliable indicator of ROSC (Neumar et al. 2010). Do not discontinue chest compression for more than 10 seconds to assess ROSC.

Measurement of end-tidal CO_2 is one of the most consistent and reliable measures of CPR and detection of ROSC. Unlike ECG analysis, it does not require an interruption in chest compressions to monitor (Neumar et al. 2010). Although specific parameters have not been established, an end-tidal CO_2 of >18 mmHg likely represents efficacious CPR (Grmec & Klemen 2001; Kolar et al. 2008; Pokorna et al. 2009). With ROSC the end-tidal CO_2 will rapidly rise and likely exceed 30 mmHg (Fig. 4.5) (Sehra et al. 2003; Ahrens et al. 2001).

End-tidal CO_2 may also be used to confirm endotracheal tube placement in some animal species, particularly those that are difficult to intubate.

Discontinuing CPCR

The risk of permanent severe neurologic injury is significant after 15–20 minutes of decreased cerebral blood flow, therefore it is reasonable to discontinue CPR if ROSC is not re-established within this timeframe (Plunkett & McMichael 2008). However, the prognosis will vary depending on the underlying cause, the conditions under which CPCR is performed, and ultimately the quality of life of the patient.

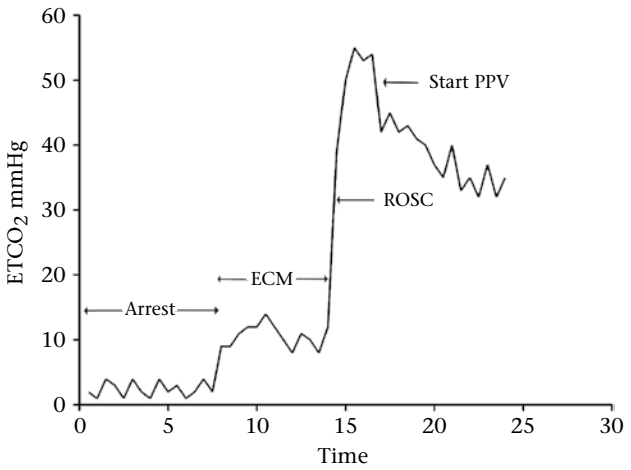

Figure 4.5 End-tidal carbon dioxide ($ETCO_2$) measurement and its association with cardiac arrest, effective external cardiac message (ECM), return of spontaneous circulation (ROSC), and initiation of positive pressure ventilation (PPV).

Prognosis and Return of Spontaneous Circulation?

Outcome depends on the underlying cause, the training of personnel, species, duration of the arrest, and the equipment available. The prognosis is generally poor, with very few patients achieving normal neurologic function (although this varies with the underlying cause). Studies in small animals demonstrate that 30% of patients will have ROSC, re-arrest occurs in 35–70% of ROSC patients, 5–10% will be discharged from the hospital, and 1% will have a return to normal function. Discharge from respiratory arrest alone varies from 25% to 60% in small animals.

CPA caused by anesthesia, drug overdose, increased vagal tone, or electrolyte imbalances tends to have a better prognosis than patients with serious underlying critical illnesses such as sepsis, systemic inflammatory response syndrome, or neoplasia. Early intervention is critical and patients with significant underlying illness should be monitored closely to allow earlier intervention. In addition, well-trained staff (frequent practice of CPR) with properly equipped facilities oxygen, suction, etc. will further increase success rates. Finally, the prognosis changes by species: small animal veterinary patients have a better prognosis compared to large animal patients.

If ROSC is achieved close intensive monitoring is needed to prevent a second CPA and most patients require vasopressors. Mechanical ventilation may also be necessary for a period of time following ROSC to decrease the chance of a second arrest.

Euthanasia

Equipment or drugs for humane euthanasia should always be carried during animal captures. The method of euthanasia depends on the situation and species. In many countries, the veterinarian is legally responsible for the death of animals, including endangered species, that eat a euthanized carcass. If firearms or bolt guns are used (recommended if the meat will be salvaged), personnel must be trained in the use of the firearms and the appropriate bullet/bolt placement. In anesthetized animals, potassium chloride may be considered as an option for euthanasia as there is less risk of death to animals that may consume the carcass when compared to pentobarbital. Animals that die or are euthanized during a capture procedure should be removed from the site and transported for necropsy. These animals should not be left in the field due to the risk of intoxication of scavengers. A more complete discussion of euthanasia in zoo animals and wildlife can be found in American Veterinary Medical Association (2020), Canadian Council on Animal Care (2003), and Woodbury (2014).

Remote Drug Delivery

Ramiro Isaza

Introduction

Prior to the development of effective anesthetics and remote delivery systems, veterinary procedures on nondomestic species were either impossible to accomplish or associated with unacceptably high mortality rates. This chapter examines the methods of anesthetic drug delivery with an emphasis on the commercial equipment available to the zoological medicine practitioner in North America.

Direct Delivery for Cooperative Animals

Animal Training for Direct Drug Administration

The technique a clinician selects to administer anesthetic drugs to an animal depends largely on whether the animal is cooperative during the preinduction period. Too often the clinician assumes that most nondomestic species are either uncooperative or too dangerous for traditional routes of drug administration such as hand injection. However, through proper training, many nondomestic species can be behaviorally restrained and will allow the veterinarian to perform a routine physical examination or administer medications on a regular basis. Animals trained for voluntary behavioral restraint are usually well socialized and become tolerant of human manipulation. For these animals, intramuscular and even intravenous injections can be administered as would be typical for domestic species in a traditional veterinary practice. For example, a chimpanzee can be trained to place its arm through the cage bars to receive intramuscular injections rather than be subjected to darting. More extreme examples are well-trained elephants or whales that permit direct manipulation despite their overwhelming size.

For some nondomestic species, combinations of mechanical restraints and behavioral training are viable options. With proper techniques and safety precautions, manual restraint of smaller nondomestic species for direct drug administration is often possible. Various mechanical restraint devices typically associated with domestic hoofstock, such as horse stanchions or cattle chutes, can be adapted for the treatment of nondomestic species (Haigh 1999). An example would include teaching a giraffe or rhinoceros to walk through and stand in a chute for daily physical examinations and routine treatments (Fig. 5.1). Once mechanically restrained, the animal can be induced with injectable agents or forced to breathe inhalant anesthetics.

It must be restated that for any of these methods of direct drug administration to succeed, prior training of the nondomestic animal is critical. Attempting to restrain an animal in an unfamiliar environment for direct drug administration is often stressful, dangerous, and ultimately unsuccessful for both the animal and the staff. Consultation with professional trainers and a clearly defined set of target behaviors needed for drug administration should be the first step, and the trainer's relationship and trust with the animal should not be underestimated. Often an animal will refuse medication offered by a stranger yet will subsequently accept the same medication if presented by the trainer. Ultimately, effective training prior to the anesthetic procedure can reduce the stress associated with anesthesia and increases the likelihood of compliance.

Nevertheless, the veterinarian must be aware of the limitations of a priori training. Quiet, well-trained animals may become dangerous if placed in unfamiliar environments such as hospitals, separated from their conspecifics, or given unexpected painful stimuli such as injections. Some of these issues, however, also can be minimized with advanced planning. For example, having the anesthetic procedures begin in the animal's regular enclosure with its usual handler will often facilitate induction, but equipment should be brought to the enclosure well in advance of the procedure to minimize disruption.

Manual Drug Delivery Routes for Cooperative Animals

Oral

Oral anesthetics are occasionally useful in zoological medicine. Some induction agents can be simply sprayed into the oral cavity or placed inside a food item that is then offered to the animal. Oral administration of various anesthetics has been accomplished using various juices, maple syrup, peanut butter, marshmallow cream, and honey (Thurmon et al. 1996). Oral carfentanil was administered to chimpanzees, tapirs, and bears transmucosally by mixing the injectable formulation of the drug into food (Kearns et al. 2000; Pollock & Ramsay 2003; Mortenson & Bechert 2001). The transmucosal formulation of fentanyl was evaluated for use as part of a preanesthetic protocol in great apes (Hunter et al. 2004).

Wild animals can be baited with medicated food that is placed in traps or spread out on the ground. One example is the use of oral alpha-chloralose to capture birds (Hayes et al. 2003; Loibl et al 1988). In situations where animals aggressively open their mouths when provoked, injectable anesthetics can even be sprayed into the mouth or the nose for mucosal absorption (Grove & Ramsay 2000). In practice, all these methods of oral administration are difficult to apply consistently as they require some measure of voluntary cooperation. Also, because the drug needs to be absorbed through the oral or nasal mucosa, it must remain in contact with the mucosa and not swallowed. Generally, such inductions are prolonged and frequently unpredictable, but may occasionally work as preinduction sedation.

Hand-held Injection

Hand injection is the most direct method of administering induction agents to an animal, requiring either exceptionally cooperative behavior or good restraint for proper placement. For an effective intramuscular injection, even a restrained animal must be approached quietly and given the injection quickly.

Administering a hand injection generally involves the following steps:

1) A sterile plastic disposable syringe with a Luer-lock hub is selected to avoid needle detachment.
2) A sterile large 18–14-gauge needle is chosen to prevent breaking the needle during injection and allow fast deposition of the drug.
3) The needle is firmly attached to the syringe hub and the attachment double-checked prior to injection.
4) The syringe is filled with an appropriate dose of the drug.
5) The loaded syringe is grasped with the thumb over the plunger.
6) The injection site is selected.
7) Using a quick flick of the wrist, the plunger is rapidly pressed down as the needle begins to penetrate the skin.

Slower placement of the drug, with aspiration prior to injection, rarely succeeds in unrestrained nondomestic species. The hand injection method of drug administration is considered dangerous for the person injecting the anesthetic. Trauma from bite wounds, kicks, and crushing injuries are common. Of equal concern is the possibility for self-injection after the animal's sudden movements or exposure to aerosol sprays from a broken syringe. Hand administration of potent narcotics such as carfentanil is therefore not recommended.

Pole Syringes

A pole syringe is essentially a hand injection with the added safety of a long pole. Pole syringes were primarily developed for use in chute, cage, or trap-restrained animals and they enable the operator to avoid some of the potential trauma associated with direct hand injections. This added safety is, however, at the expense of control of the injection process. Poorly restrained animals invariably react to the needle by moving away or attacking prior to full injection. As with hand injection, this technique requires a quick delivery through a large-gauge needle (14–18 gauge). The needle is inserted in a large muscle, and then the pole is held in position until the drug is deposited.

Three types of pole syringes are available. The manual pressure pole syringe has a typical syringe body with an extended plunger to provide extra length. Once inserted into the animal, the plunger is pushed against the resistance of the animal's body. In the second type, an extension pole is attached to the body of the syringe with a second internal extension of the syringe plunger that is manually depressed to deposit the drug. The final type incorporates a mechanism with a spring or pressurized gas-loaded plunger that is triggered when the needle presses on the skin. Although considered safer than hand injection, animals may still react to the needle and injure themselves by moving or misdirecting the pole syringe.

Remote Delivery Systems for Uncooperative Animals

Unfortunately, in zoological medicine, many anesthetic procedures must be performed on uncooperative animals for various reasons. Animals that are not acclimated to human contact generally become agitated and aggressive when approached. This is typically the case in free-living species or in captive animals where routine direct human contact is discouraged. Second, some species, such as large carnivores or hoofstock, pose significant inherent risks to the veterinarians and keepers that preclude the possibility of using behavioral or physical restraint. Finally, even in cooperative or human-habituated animals, trained behavior can significantly change due to illness or pain so that the training no longer helps facilitate direct anesthetic drug delivery methods (Fig. 5.2).

When injectable anesthetic agents are used in unrestrained nondomestic species, a remote delivery system consisting of a dart and projector is often the most practical option. Darts can be projected via a blowpipe, compressed air projector, or gunpowder cartridge rifle (Bush 1992). All darts have four basic components: a drug storage compartment, a method of injecting the drug, a needle to penetrate the skin, and a stabilizer on the tail for accurate flight. Commercially available darts differ in their methods of drug expulsion, materials used in their construction, drug payload volumes, and dart attachments such as the needle or tail. In this chapter, the method of drug delivery will be used to distinguish the darting systems.

Figure 5.2 Use of a blowpipe for short-range injection of a white rhinoceros that would react if hand injected.

Several homemade dart and projector systems have been described in the literature (Haigh & Hopf 1976; Warren et al. 1979; Barnard & Dobbs 1980; Lochmiller & Grant 1983). Here, descriptions and discussions of equipment will be limited to those drug delivery systems that are currently commercially available. The choice of delivery system is subject to the clinician's preferences, needs, or experience, but almost any commercial system can be effective when used by experienced operators. The similarity between available equipment systems allows some interchange of components that can be configured to meet the clinician's specific preferences. However, this interchangeability can also be somewhat misleading and may lead to dart failure caused by subtle differences in the darting systems. Generally, it is recommended that one manufacturer's system be purchased along with the relevant product lines to ensure that they are effective and reliable when used as designed.

Historical Development of Remote Delivery Systems

Remote delivery of drugs was first used globally by indigenous hunters with poison-tipped projectiles (Nielsen 1999; Bush 1992). For example, plant extracts containing curare were used by pre-Columbian South American Indians to produce effective neuromuscular blockage and muscle paralysis in animals and are still used by some aboriginal groups that continue to hunt. When these poison-tipped darts are projected with long blowpipes they can be delivered by experienced hunters with extraordinary precision and to lethal effect. The precise dosage, relevant to delivery and margins of safety, was not an important consideration since the purpose of darting was to kill the animal.

In the first half of the twentieth century, zoological collections relied on manual restraint as the primary means of administering veterinary care. These restraints were dangerous for both the humans and the animals, often resulting in stress, injury, and occasional animal mortalities. In the mid-1950s the first remote delivery device was described in the literature (Hall et al. 1953). It consisted of a modified metal drill bit with a gallamine and glucose paste packed into the groves. The bit was attached to a dart and delivered with a Crossman air gun. Once the animal was paralyzed

and the procedure completed, the gallamine was reversed. Although effective, the paste was absorbed slowly, leading to development of a "flying syringe" to deliver liquid injections (Crockford et al. 1958). This aluminum dart used an acid-base reaction to inject the drug. After extensive modifications and improvements, this dart became the prototype for many of the modern darts in use today (Bush 1992). Around the same time, Colin Murdoch, a veterinarian and inventor from New Zealand, also developed a series of darts and projectors that became known as Paxarms. Subsequently, plastic two-chambered gas darts were introduced to zoological medicine and developed into several commercial darting systems (Bush 1992). Several authors have reviewed the development of darting equipment over the past 40 years (Bush 1992; Nielsen 1999; Fowler 1995; Harthoorn 1976; Fritsch 1982). A listing of some currently available darts and delivery systems can be found in Table 5.1:

Table 5.1 Description of currently available darts by manufacturer.

Manufacturer and Dart Description	Dart Type	Payload Volume (mL)	Dart Diameter (mm)	Needle Sizes (mm)	Tailpieces	Recommended Projector
Dan-inject blow dart syringe	Two-chambered	1.5, 3	11.8	1.1 × 25 or 1.2 × 38	Orange cloth	12-mm Dan-inject 1.25- or 1.8-m (2 piece) blowpipe
Telinject blow dart syringe	Two-chambered	1, 2, 3	10.8	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Orange cloth or plastic tailpiece	11-mm Telinject 1- or 2-m blowpipe or 16-mm, 2.2-m high-performance blowpipe with plastic tailpiece
Telinject blow dart syringe	Two-chambered	5	14.0	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Red with yellow cloth or plastic tailpiece	14-mm Telinject 1.5-m blowpipe or 16-mm, 2.2-m high-performance blowpipe with plastic tailpiece
Dist-Inject "Softy" blow dart syringe	Two-chambered	3.8	10.8	1.2 × 25 or 1.6 × 38	Red cloth or PVC tailpiece	11-mm mini-Ject 0.9-m blowpipe or 16-mm Dist-Inject 1.5 cm with PVC tailpiece
Maxi-Ject veterinary syringe dart	Two-chambered	1, 2	9.7	1.9 × 25 or 1.2 × 38	Yellow cloth	10 mm Maxi-Ject 2-piece, 1-m blowpipe
Maxi-Ject veterinary syringe dart	Two-chambered	1, 2, 3	10.7	1.9 × 25 or 1.2 × 38	Orange cloth	11-mm Maxi-Ject 2-piece, 1-m blowpipe
Maxi-Ject veterinary syringe dart	Two-chambered	5	13.7	1.2 × 38	Red with yellow cloth	14-mm Maxi-Ject 2-piece, 1-m blowpipe
TeleDart veterinary syringe blow dart	Two-chambered	1, 2, 3	10.7	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Pink cloth with yellow base	11-mm B11 or 16-mm B16 TeleDart blowpipes with plastic tailpiece
TeleDart veterinary syringe blow dart	Two-chambered	5	13	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Pink cloth with red base	14-mm B14 or 16-mm B16 TeleDart blowpipes with plastic tailpiece
Telinject "Vario" molded polyamide nylon syringe	Two-chambered	1, 3	10.8	1.5 × 20 to 2.0 × 100 (2 gauges and 10 lengths)	Red cloth	11-mm Telinject Vario pistol or Vario 1V and 3V rifles
Telinject "Vario" molded polyamide nylon syringe	Two-chambered	5, 10, 15, 20	12.2	1.5 × 20 to 2.0 × 60 (2 gauges and 10 lengths)	Red with yellow cloth	13-mm Telinject Vario pistol or Vario 1V and 3V rifles
Dan-inject "S" series molded nylon syringe	Two-chambered	1.5, 3	10.7	1.5 × 20 or 2.2 × 100 (3 gauges and 9 lengths)	Red cloth	11-mm Dan-inject model PI pistol or JM/IM injection rifles

Table 5.1 (Continued)

Manufacturer and Dart Description	Dart Type	Payload Volume (mL)	Dart Diameter (mm)	Needle Sizes (mm)	Tailpieces	Recommended Projector
Dan-inject "S" series molded nylon syringe	Two-chambered	5, 10	12.5	1.5 × 20 or 2.2 × 100 (3 gauges and 9 lengths)	Red with white cloth	13-mm Dan-inject model PI pistol or JM/IM injection rifles
Dist-Inject "Mini-Ject 2000" molded nylon syringe	Two-chambered	1, 2, 3, 5	10.8	1.1 × 25 or 1.2 × 35	Red cloth	11-mm model 45 delta pistol, model 35N pistol, or model 50N, model 70, model 72 rifles
Dist-Inject "easy" butane charged molded nylon syringe	Two-chambered	3, 5	10.6	1.1 × 25 or 1.2 × 35	Orange and yellow fins	11-mm model 45 delta pneumatic 0.35-m blowpipes
TeleDart "TD" veterinary syringe molded plastic dart	Two-chambered	1, 2, 3, 5	10.8	1.5 × 20 to 2.0 × 60 (2 gauges and 8 lengths)	Pink cloth with orange base	11-mm model RD206 pistol, RD406 pistol, or model RD706 TeleDart injection gun
TeleDart "TD" veterinary syringe molded plastic dart	Two-chambered	1, 2, 3, 5, 10, 15, 20	12.6 or 15.5	1.5 × 20 to 2.0 × 60 (2 gauges and 8 lengths)	Pink cloth with orange base	16-mm model RD206 pistol, RD406 pistol, or model RD706 TeleDart injection gun
Palmer Cap-Chur "Aero" clear plastic dart	Two-chambered	1, 2, 3, 4, 5	12.5	2.5 × 19 to 2.5 × 38 (11 lengths)	Tetra plastic tail	12.7 Palmer Cap-Chur short, mid, and long-range CO_2 projectors
Pneu-Dart "P" polycarbonate dart with "Slo-inject"	Explosive	0.5, 1, 1.5, 2	12.5	2.1 × 9.5 to 2.0 × 50.8 (7 lengths) Open or tri-port	Yellow plastic	12.7-mm Blo-Jector blowpipe
Pneu-Dart "P" and "U" polycarbonate or aluminum darts with "Slo-inject"	Explosive	0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9, 10	12.5	2.1 × 9.5 to 2.0 × 50.8 (7 lengths) Open or tri-port	Yellow plastic	12.7-mm G2 X-Caliber rifle, X-2 pistol, model 178BS air rifle, or Model 190B pistol
Pneu-Dart "C" polycarbonate or aluminum darts with "Slo-inject"	Explosive	0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 10	12.5	2.1 × 6 to 2.0 × 50.8 (7 lengths) Open or tri-port	Orange plastic	12.7-mm model 193, 194, 196 and 2000 Pneu-Dart cartridge fired rifles
Clear Dart "Petite" clear plastic dart	Explosive	0.5, 1, 1.5, 2	12.4	2.1 × 9.5 to 2.0 × 50.8 (7 lengths) Open or side port	Pink plastic	Any 2.7–13-mm barrel
Clear Dart "Original" clear plastic dart	Explosive	3, 5, 7.5, 10	12.4	2.1 × 9.5 to 2.0 × 50 (7 lengths) Open or side port	Pink plastic	Any 2.7–13-mm barrel
Palmer Cap-Chur aluminum dart	Explosive	0.5, 1, 2, 3, 4, 5, 7, 10, 15, 20	12.5	2.5 × 13 to 2.5 × 76 (11 lengths)	Yarn or plastic "Tetra"	12.7-mm #1300 Mid-range pistol, #1200 long range CO_2 rifle
Dist-Inject aluminum dart	Explosive	1, 2, 3, 4, 5, 7, 10, 15	12.5	2.5 × 19 to 2.5 × 78	Yarn, plastic finned, and feathered	13-mm model 30N pistol, model 60N rifle
Dist-Inject disposable molded nylon "Speedy" dart	Explosive	3	12.5	2.5 × 20 to 2.5 × 30 barbed	Yellow plastic finned	13-mm model 30N pistol, model 60N rifle

Dart Types

Two-chambered Compressed (Pressurized) Gas Darts

These darts are lightweight and usually made of plastic or occasionally aluminum. They are made of a variety of injection-molded plastic materials. The exact composition of the plastic and manufacturing process is often proprietary information. The dart body is divided into dual chambers by a movable, rubber syringe plunger in the center, with the anterior chamber holding the anesthetic drug and the posterior chamber for compressed gas (Fig. 5.3).

The anterior drug chamber is bounded by the central plunger and by a syringe hub that accepts a needle at the front of the dart. The posterior gas chamber is enclosed by the central plunger in front and by a second, smaller movable rubber plunger at the back. The posterior plunger acts as a one-way valve that allows gas to be inserted through the posterior hub, but then occludes the posterior hub to prevent gas escape. The caudal part of the dart body has a syringe hub that accepts a tailpiece. The dart needles for this system are hollow with a sharp, sealed tip and an opening cut into the side a few millimeters away from the tip from which the medication is expelled. A small silicone sleeve is placed over this opening before the needle is attached to the anterior hub of the dart (Fig. 5.4).

The drug is instilled into the anterior chamber of the dart, then the needle with the silicone sleeve is securely attached to the hub. These darts are then charged by placing the compressed gas into the back chamber. The pressurized gas may be room air introduced manually with an adapter attached to a second air-filled syringe or compressed butane liquid inserted into the posterior chamber of the dart (Fig. 5.5).

Leakage of drug too early in the darting process is prevented by the silicone sleeve occluding the needle vent but as the needle enters the animal's skin, the sleeve remains on the skin surface, exposing the needle vent. The pressurized gas then pushes the central plunger forward and forces the drug out of the anterior chamber and through the needle. If the darts and needles are cleaned and maintained between usages, they are usually reusable at least a few times. For cleaning, the plastic darts can be gas sterilized and the needles can be autoclaved or gas sterilized.

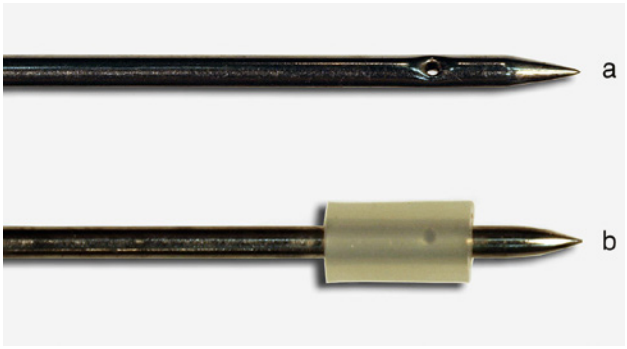

Figure 5.4 Photograph of two side-ported needles. (a) Needle with its side port exposed. (b) Similar needle with a silicone sleeve occluding the port.

Because this dart type is relatively lightweight with a slow deposition of drug over several seconds, the injection is relatively nontraumatic to the animal. The dart's sharp needles make them ideal for penetration of most skin types. With proper selection of needle lengths and dart sizes, these darts can be used safely on a large variety of species. They are generally used for short ranges, and because their trajectories are easily affected by wind gusts, they are preferably used during calm weather conditions. Their primary disadvantages are that they can be destroyed by hitting unintended solid objects and their complexity makes them prone to dart failures.

Loading a two-chambered plastic dart involves the following steps:

1) An appropriate-sized clean or sterilized dart is removed from the package.
2) The dart is inspected for cracks and abnormal shape.
3) The dart is tested by placing air pressure in both compartments to make sure that the plungers move easily and that the dart does not leak. A metal connector is required to attach regular 6 or 12 cc syringes to the hub of the dart to inject air into the posterior chamber.

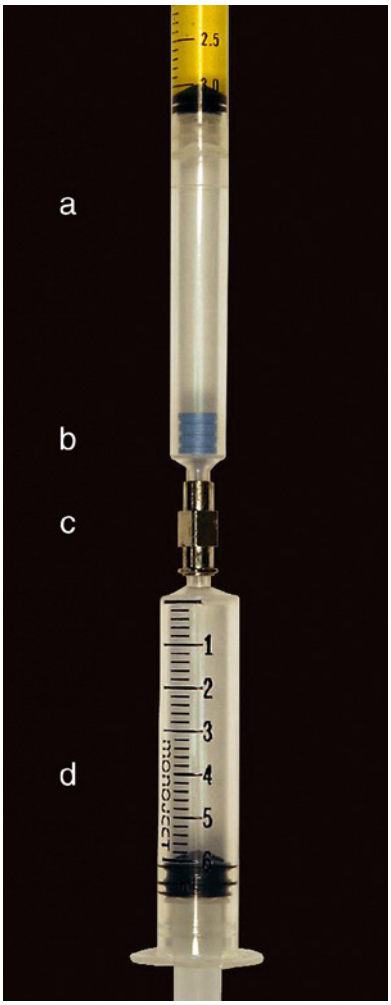

Figure 5.5 Photograph of a two-chambered compressed gas dart being filled. (a) Posterior chamber of the dart. (b) Posterior plunger acting as a one-way valve to allow introduction of compressed gas, but preventing its escape. (c) Coupler that is needed to allow air to pass from the syringe to the dart. (d) Standard syringe used to force air into the dart.

4) Next an appropriately sized, sterile needle is selected. The needle must be inspected for patency and for the presence of a sharp tip. It must be free of burrs or bends from previous impacts.
5) A silicone sleeve is placed over the needle tip and slid down over the needle vent. Many dart manufactures have proprietary colored sleeves to fit their different needle diameters. Some people chose to place sterile ointment on the needle surface to provide lubrication. The sleeve is moved up and down the needle several times to be sure it moves easily before it is placed over the vent opening in the needle.
6) The needle with the silicone sleeve in place is placed onto a clean, empty syringe. To confirm that the sleeve has completely occluded the needle vent, an attempt should be made to force air through the needle.
7) Prior to loading the dart with drugs, the posterior plunger (one-way valve) should be displaced with a venting pin to make sure the posterior chamber is not pressurized.
8) The central plunger is then positioned to provide the correct volume for the drug in the anterior chamber.
9) The needle of a second syringe containing the drug is inserted through the anterior hub and the anterior chamber is slowly filled with the drug to avoid creating bubbles by too rapid filling.
10) The occluded needle with the preplaced silicone sleeve is attached to the dart. This attachment must be secure, with the needle firmly seated on the anterior dart hub. A hemostat or pliers is sometimes used to tighten it in place, being careful not to damage the dart with these tools.
11) A transparent safety cover, such as a syringe casing, is placed over the end of the needle.
12) The dart is held in a vertical position with the needle pointing upwards.
13) The dart is charged with either air or butane placed into the posterior chamber. The air or gas is forced in through the posterior hub, around the one-way valve, and into the posterior chamber of the dart. When properly charged, the rubber plunger at the back of the dart will be firmly pressed against the caudal portion of the posterior chamber.
14) An appropriate tailpiece for the dart is selected. The tailpiece should be inspected to ensure that it is clean, dry, and symmetrical.
15) The tailpiece is firmly attached to the posterior hub of the dart, making the dart ready for use.

Two-chambered Blow Darts

Several types of two-chambered darts use pressurized gas to push the drug into the animal (Fig. 5.6).

The first is the blow dart, which is constructed of very lightweight, clear medical-grade plastic similar to the material used in disposable plastic syringes. The blow dart body usually has a Luer-lock syringe tip hub on the anterior drug compartment. The blow dart needle is exceptionally sharp, constructed from a modified hypodermic needle with a tip that is soldered closed and an opening cut into the side (Fig. 5.7).

The blow dart's lightness and sharper needles make it ideal for use with blowpipes. These darts are most accurate when used indoors. Blow darts should never be used in carbon dioxide (CO_2) or gunpowder cartridge-propelled projectors as their light construction causes erratic flight at high velocities and because they often shatter on impact.

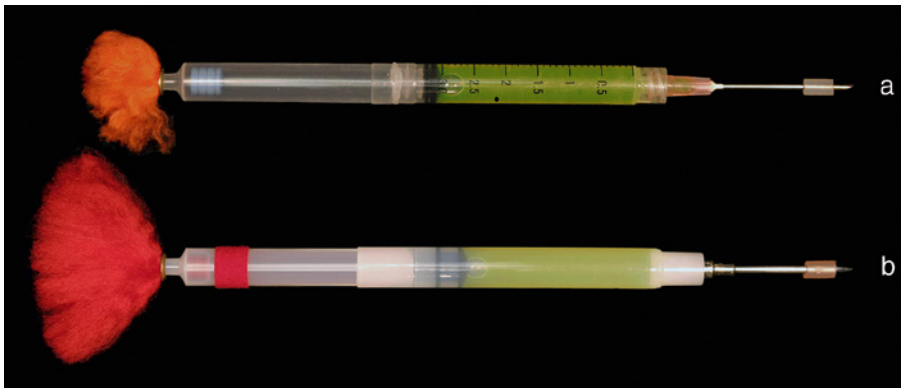

Figure 5.6 Photograph showing the difference between two types of two-chambered compressed gas darts. (a) Blow dart. (b) Injection-molded plastic dart.

Figure 5.7 Photograph of two needle types used in different types of two-chambered compressed gas darts. (a) Hypodermic needle with a sharp tip occluded with solder and used in blow darts. (b) Thicker, blunter, machined needle used in injection-molded plastic darts.

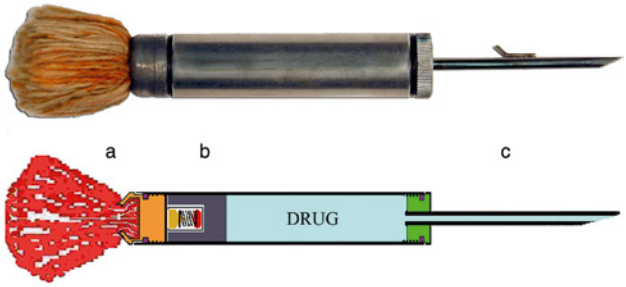

Figure 5.8 Photograph and illustration of a gunpowder explosive powered dart. (a) Yarn tailpiece that is threaded into the back of the dart body. (b) Movable central syringe plunger which contains the explosive charge. (c) Forward ported needle with a wire barb is threaded into the front of the dart body.

Injection-molded Two-chambered Plastic Darts

These darts are heavier than blow darts and are constructed of a variety of synthetic plastic materials. The construction of the dart body is more robust and often reinforced. The anterior hub has a thick collar to better seat the needle and to provide additional strength to the needle attachment. The needles are machined from a thicker metal that resists bending and breaking better than the modified hypodermic blow dart needles.

Injection-molded plastic darts are designed for use in CO_2 or compressed air-powered projectors. Improved ballistic properties enable them to fly true at higher velocities. They are also made to withstand greater impact forces. This gives them a much greater range and allows them to be used outdoors in moderately windy conditions. The blunter needles have no difficulty penetrating most animal skin when powered by these projectors, but are ineffective when projected with a blowpipe. When used correctly and at appropriate distances, these injection-molded plastic darts are safe for the animal and cause only minor trauma (Cattet et al. 2006). A variety of needle sizes are available. Needles can be fitted with barbs to reduce bouncing out of the animal. Impact absorbers can also be placed at the base of the needles to prevent them from penetrating beyond the intended depth and decrease dart trauma (Wiesner 1998). The potential problems associated with these darts are that they can cause significant trauma when used with gas-powered projectors at inappropriately close ranges. Such trauma includes soft tissue damage resulting from the dart embedding too deeply and even long bone fractures.

Gunpowder Explosive Darts

Explosive powered darts use a black gunpowder explosive cap to generate the force needed to discharge the drug. A movable plastic plunger is placed into the center of the dart body to separate the drug from the explosive cap and trigger mechanism (Fig. 5.8).

The anterior chamber holds the drug. The posterior chamber holds a metal explosive unit that contains an explosive cap, a weighted firing pin, and a spring that keeps the firing pin away from the cap prior to dart impact (Fig. 5.9).

The explosive unit is set behind the caudal aspect of the central plunger, and the back of the dart is sealed with a tailpiece. The needles are hollow, forward, or side ported, and do not need to be capped. They come in a large variety of lengths and are usually barbed.

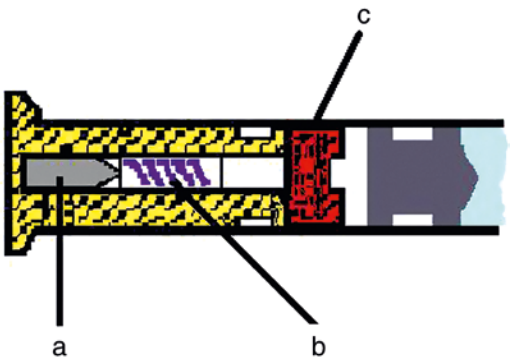

Figure 5.9 Illustration of the tail section and trigger mechanism of a Pneu-Dart gunpowder explosive-powered dart. (a) Movable weight. (b) Spring that holds the weight back. (c) Explosive cap.

Gunpowder charged darts are loaded by placing the drug through the needle lumen and into the anterior chamber. When the dart hits the skin of the animal, the needle penetrates and the body of the dart is stopped by the skin surface. The forward momentum of the dart is carried to the metal firing capsule, where the small spring is overpowered and the firing pin impacts the cap, resulting in an explosion. Expanding gas within the posterior chamber then rapidly forces the plunger cranially, thus pushing the drug out through the needle. Drug injection occurs within approximately 0.001 seconds and can cause considerable tissue trauma (Kreeger et al. 2002; Cattet et al. 2006). Additionally, the explosive rate of the injection causes a rocket effect that propels the dart out of the animal. For the explosive unit to work, the dart must strike the animal with enough force at a perpendicular angle to the target. This necessary force can result in significant dart trauma, particularly in small or delicate species.

Modular Gunpowder Explosive Powered Darts

The Palmer Cap-Chur syringe is an example of a modular gunpowder-explosive powered dart because the operator can build a highly specific dart configuration by choosing different available components. The body of each dart is an aluminum 12.6-mm diameter (.50 caliber) tube with internally threaded ends. The aluminum syringe barrel comes in various lengths that can hold 0.5–20 mL of drug. The Palmer Cap-Chur gunpowder charges come in three different power strengths, each appropriate for a different dart volume. The charges are color-coded: yellow for 0.5–3 mL, orange for 4–10 mL, and red for 15–20 mL. Dart failure can occur with improper charge selection. The metal explosive charge fits with its closed, rounded, cranial end into a pocket in the caudal aspect of the central plunger (Fig. 5.10).

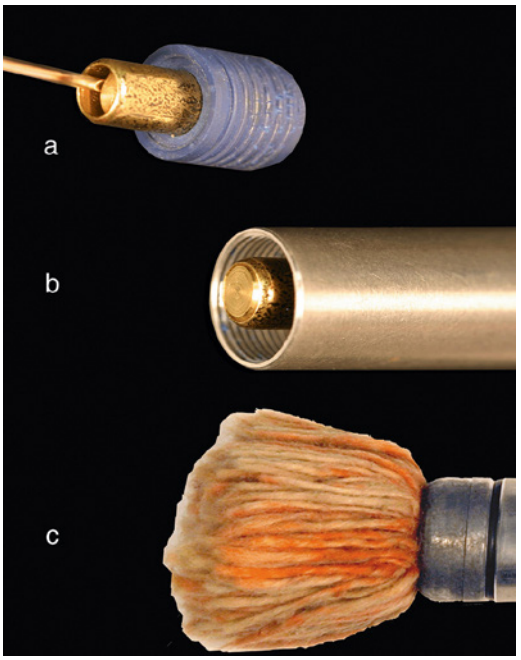

Figure 5.10 Photograph demonstrating the steps in assembling the tail section and trigger mechanism of a Palmer Cap-Chur gunpowder explosive powered dart. (a) The charge has been placed into the caudal pocket of the central plunger. The needle is pressing against the weight and spring to demonstrate the proper orientation of the explosive charge. (b) The plunger and explosive charge have been inserted into the posterior part of the dart body. (c) The yarn tailpiece has been threaded into place.

The explosive unit must be oriented correctly with the open end facing caudally for the dart to discharge. The back of the dart is sealed with a tailpiece that screws into the internally threaded dart body. The needle is threaded into the anterior end of the dart. The needles are hollow and do not need to be capped. Forward-ported and side-ported needles are available in a variety of lengths and with several barb styles (Fig. 5.11).

These modular systems are the oldest commercially available darts and have many years of proven reliability. The many possible dart configurations that can be created depending on choice of needle length, needle style, and payload volume (i.e., tube length) make this the most versatile darting system available. From one set of dart components, darts can be configured with short needles for carnivores or very large needles and barrels for elephants and rhinoceroses. The dart components, except the explosive units, are reusable if cleaned and maintained properly. Keeping the dart components sterile is challenging, but using unsterilized equipment may lead to dart-induced infections (Bush & Gray 1972). The biggest weakness of the system is that the heavy darts and the explosive discharge of drug can lead to significant tissue damage.

Figure 5.11 Photograph of the three needle types used in gunpowder explosive powered darts. (a) Pneu-Dart needle with a green gel cone collar barb. (b) Palmer Cap-Chur needle with a small metal collar. (c) Palmer Cap-Chur needle with a wire barb.

Loading a Palmer Cap-Chur dart involves the following steps:

1) The appropriately sized and sterilized dart components are removed from their packages.
2) The dart parts are inspected for cracks and abnormal shape. The needle, body, and tail are preliminarily assembled to ensure proper threading and then passed through the syringe barrel of the projector to ensure that the dart passes freely.
3) A sterile, central, rubber plunger is selected and then lubricated. It is placed inside the body of the dart, and the plunger is moved back and forth within the length of the dart body to ensure that it moves easily.
4) The plunger is positioned in the caudal part of the dart body.
5) An appropriate strength metal explosive unit is fitted into the pocket in the caudal aspect of the rubber plunger. It is crucial to make sure that the explosive unit is oriented correctly, with the movable plate exposed caudally.
6) A tailpiece is selected and threaded into the caudal part of the dart body.
7) An appropriately sized sterile needle with an acceptable barb style is selected. It must be inspected for patency and to make sure that it does not have a burr at the tip or is bent from a previous impact.
8) The needle is then threaded onto the cranial part of the dart body.
9) The dart is loaded by passing the needle of a syringe containing the drug through the dart needle lumen and depositing the drug into the anterior chamber of the dart. The syringe needle should be longer than the dart needle and the drug introduced slowly to avoid drug back flow from that dart needle.
10) Sterile water is used to completely fill the remaining volume in the anterior chamber of the dart.

Prefabricated Gunpowder Explosive-powered Darts

Pneu-Darts and Clear Darts are examples of prefabricated rather than modular gunpowder explosive-powered darts. The explosive mechanisms are similar, except that they come already positioned in the dart by the manufacturers. The darts, which come as complete units that cannot be taken apart, are made of a combination of aluminum or polycarbonate plastic bodies, a hollow needle, and a plastic tailpiece. The function and limitations of this type of darts are similar to those of modular systems.

The simplicity of the prepurchased dart makes them appealing products. The operator selects the dart volume, needle length, and barb configuration that will be needed for the anesthetic event. Most needles come with a green gelatin collar or barb to prevent the dart from being ejected from the skin when the dart discharges. Loading the dart is a simple matter of placing the drug through the dart needle and into the anterior chamber.

Pneu-Darts come in three types. The first is the "P" dart line, with a yellow tailpiece, designed for blowpipes or CO_2 powered projectors. The second is the "U" dart with yellow tailpieces fitted with an orange plastic spacer that retains the dart in the rifle barrel. The final dart line is the "C" dart, with orange tailpieces that are designed for the 22 blank-powered cartridge projectors. They differ only in the diameter of the tailpieces: larger in the "C" dart to help engage the rifled barrel and in the tensile strength of the spring in the explosive unit, which is weaker in the "P" and "U" darts. The Pneu-Dart line offers several available dart configurations that include clear polycarbonate plastic or aluminum bodies and are available with tri-ported needles.

Loading a Pneu-Dart or similar dart involves the following steps:

1) Select a dart with the appropriate drug payload size and needle length from the package.
2) Note the tailpiece color and package label to make sure that the dart type selected matches the intended projector. A yellow tailpiece indicates the "P" and "U" dart lines designed for blowpipes or CO_2 powered projectors. An orange tailpiece indicates the "C" dart line designed for the 22 blank-powered cartridge projectors.
3) Inspect the dart for cracks and other manufacturing abnormalities.
4) Inspect the dart for dirt or moisture damage that may compromise sterility or dart function.
5) Load the dart by passing the needle of a syringe containing the drug through the dart needle lumen and depositing the drug into the anterior chamber of the

dart. The syringe needle should be longer than the dart needle and the drug introduced slowly to avoid drug back flow from the dart needle.

6) Use sterile water to completely fill the remaining volume in the anterior chamber of the dart.

Miscellaneous Dart Types

Modified Two-chambered Compressed Gas Dart

Palmer Cap-Chur produces a modified clear plastic two-chambered compressed gas dart that uses the projector's CO_2 to automatically pressurize the dart. The dart has a unique one-way valve system in the tailpiece that allows entry of pressurized CO_2 from the projector into the posterior chamber of the dart. The dart has an open needle that is occluded with a plastic tip. The function and loading of this dart are like that of two-chambered gas darts, without the need for prior pressurization.

Chemical-powered Darts

Chemical darts use an effervescent acid/base reaction to produce gas and thus inject the anesthetic (Fig. 5.12).

The design has a two-chamber configuration with the chemicals placed in the posterior chamber. Prior to discharge the chemicals are kept apart. On impact, a variety of mechanisms have been devised to allow the chemicals to mix and produce gas (Bush 1992). Because the drug compartment is not under pressure, open-ended needles can be used. These darts are easy to load and are reliable in most field situations. The injection speed is slower than that of compressed gas or explosive charged darts, but this slow discharge is usually acceptable and in fact beneficial in that it causes minimal injection trauma and limited blow-back from the dart. No chemical darts are commercially available in the United States, but they are used and available in Africa and Europe (Nielsen 1999).

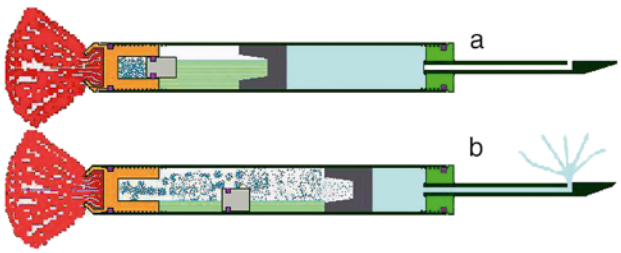

Figure 5.12 Illustration of a chemical reaction-powered dart. (a) Representation of the loaded dart prior to impact. The chemical reagents are kept separated by a weight occluding the chemical chambers. (b) Representation of the dart after impacting the target and during discharge of the drug. The weight is now dislodged and the chemicals have mixed and produced a gas that pushes the central plunger forward.

Spring-powered Darts

Spring-powered darts are also not currently commercially available in the United States. The design is like that of the two-chambered dart, except that the posterior chamber is replaced with a spring to provide the injection force. The spring is attached anteriorly to the central plunger and posteriorly to the back of the dart body. Trigger mechanisms usually involve silicone-capped needles that function similarly to those in two-chambered darts. The dart body is constructed of plastic or aluminum depending on the projector that will be used. The major problem with these darts is that the process of loading the dart is both difficult and dangerous due to inadvertent spraying of the drug during the loading process.

Solid Drug Darts

Solid drug projectiles are constructed in a manner similar to the original gallamine paste projectiles used in the 1950s. Several attempts have been made to develop a solid, lightweight, absorbable bullet (Bush 1992). Current versions are made of various materials, such as hydroxypropylcellulose, that dissolve and absorb into the muscle of the animal (Jessup 1993; van de Wijdeven 2002). An example is the Ballistivet system, which was developed for vaccination of domestic livestock, but can be applied to anesthesia of both captive and wild nondomestic species. As in the original descriptions of solid drug injection systems, the limitations of payload size and slow absorption are persistent obstacles in their use for primary induction of anesthesia.

Remote Delivery Projectors

Compressed Gas Projectors

Blowpipes

Blowpipes are by far the most versatile, inexpensive, silent, lightweight projectors available. In short ranges, an experienced darter can have exceptional accuracy. The light darts combined with their slow velocity produce minimal impact and tissue trauma. The operator can adjust the dart speed instantly and therefore deliver the dart as gently as needed.

Blowpipes consist of a long lightweight tube with a mouthpiece on one end. A blow dart is placed in the end of the pipe and compressed gas is provided by the operator blowing with a rapid, strong breath through the tube. The longer the pipe, the greater the accuracy of the dart. Commercial blowpipes are available from several manufacturers in various pipe lengths, diameters, and shapes of mouthpieces. Selection is based on personal preference for the mouthpiece and the diameter of the dart type selected.

Using a blowpipe requires practice. The pipe is held horizontally and grasped in the hand opposite to the dominant eye. The operator should look at the tip of the pipe and aim

it at the target. Compressed air is provided following a deep inhalation then a rapid exhalation in a manner somewhat approximating a combination of coughing and blowing through the pipe. Because of the slow dart velocity, the dart will tend to fly in an exaggerated downward arc instead of a straight line. Effective blowpipe range is about 0.5–10 m. Because darts may occasionally leak and the mouth must be placed on the mouthpiece, darts containing dangerous drugs such as concentrated narcotics should not be projected using a blowpipe.

Gauged Blowgun Projectors

A modification to the blowpipe is to add an external source of compressed gas, thereby eliminating the need for the operator to exhale through the pipe (Fig. 5.13).

Gauged blowgun projectors are designed to shoot heavier injection molded two-chambered plastic darts or type "P" or "U" Pneu-Darts. These projectors utilize a source of compressed gas, a combination pressure gauge and valve system to control the gas pressure, and a trigger mechanism. Gas power can be provided either by air via a foot pump or by compressed CO_2 from a pressurized cylinder. Pressure gauges and release valves allow the pressure to be increased or decreased as needed during darting. A detachable, long barrel is then mounted on either a pistol handle or a rifle stock. The projectors can be equipped with a telescopic sight. Different diameter barrels can be interchanged to accommodate either 10.8- or 12.5-mm darts. Pistols are used for short range or indoors where space is limited, but are less accurate than rifles, which are used outdoors over longer distances. Careful selection of the dart type is important, as lightweight plastic blow darts will often not fly correctly in these CO_2-powered projectors.

Gauged blowgun projectors are quiet, reasonably accurate, and provide a simple means of darting exotics for distances between 5 and 30 m. Many veterinarians in zoological collections use this system exclusively.

Air and CO_2 Rifles and Pistols

Pistols and rifles are compressed gas projectors with their barrel permanently mounted onto a triggered compressed gas power source (Fig. 5.14).

The compressed gas power source can be provided by CO_2 cylinders or using an attached air pump similar to a pellet gun. These projectors generally lack accurate pressure gauges and valve systems with the ability to change the gas pressure. Instead, they typically have two or three presets that can be dialed in for selecting power levels. These systems are usually designed for 12.5-mm metal darts such as Palmer Cap-Chur and type "P" or "U" Pneu-darts. Due to their short barrels, the pistols are notoriously inaccurate at long range. In contrast, rifles can be very accurate at moderate distances. Both systems, when used at short range, can cause significant trauma due to the lack of accurate pressure control.

Gunpowder Cartridge-powered Rifles

These rifles have permanently mounted barrels on a rifle stock. They are powered by .22 caliber blanks that come in several charge strengths with different amounts of gunpowder. Charge strengths are color-coded. In the Palmer Cap-Chur system, brown is the weakest cartridge, followed by green, yellow, and red as the strongest (Fig. 5.15).

Lacking pressure gauges, preset lower power levels can often be manually selected. Although these rifles are too powerful for short-range or indoor use, they have the longest effective range of any projector and can be used in

Figure 5.13 Photograph of two Dan-Inject blowgun type projectors. (a) Model CO_2 PI pistol with an 11-mm barrel. The pistol is powered with a compressed CO_2 cartridge. (b) JM Special rifle with 11-mm barrel. It is also powered by a compressed CO_2 cartridge.

Figure 5.14 Photographs of three compressed gas-powered 12.7-mm (.50 caliber) projectors. (a) Palmer Cap-Chur Model #1300 mid-range pistol powered with two compressed CO_2 cartridges. (b) Pneu-Dart Model 178B air pump rifle. (c) Palmer Cap-Chur Model #1200 long-range rifle powered with two compressed CO_2 cartridges.

Figure 5.15 Photographs of two cartridge-powered 12.7-mm (.50 caliber) projectors. These powerful guns are used only outdoors for long-range targets. (a) Palmer Cap-Chur Model #1000 extra long-range rifle. (b) Pneu-Dart Model 196 rifle.

windy conditions. With a 12.7-mm (.50 caliber) bore, these rifles are designed for 12.5-mm metal darts such as Palmer Cap-Chur or type "C" Pneu-Darts.

Miscellaneous Projector Types

Crossbows and Bows

Although uncommon, commercially available darts can be mounted on arrow shafts and delivered with either crossbow or conventional bows. In Africa, several Ju/'Hoan bushmen were given arrows with Pneu Darts attached at the tips. Using these arrows and their archery hunting techniques, they were successfully able to immobilize free-ranging lions and leopards (Stander et al. 1996). Archery-based projectors are accurate, but if not properly controlled the velocity of the heavy arrows will cause trauma to the animals.

Injection Collars

Remote injection collars can be placed on an animal prior to release and used to inject the animal later (Jessup 1993). Commercially available products have been used in white-tailed deer and wolves. The injection is triggered by remote control. Combined with telemetry and a safety collar release if the batteries that power them run low, they can be a valuable tool for use in wildlife. Application of these collars in zoological collections has been limited, but may be practical in situations that require multiple immobilizations in animals that are difficult to dart.

Darting Accessories

Many manufacturers provide practice darts and targets for their equipment. These practice darts are cheaper than operational darts and are consistently weighted to help improve accuracy. Through practice the operator will develop proficiency with the equipment and reliable accuracy. During practice it is important to develop a feeling for the proper impact velocity required to prevent excessive trauma.

Laser range finders, scopes, and binoculars are useful in outdoor darting procedures. Calibrating the projector for selected distances is the best method of consistently producing accurate and atraumatic shots. Once the calibration is completed during practice sessions, using the range finder significantly improves range estimates and allows the operator to make confident and accurate projector settings. The binoculars are useful for selecting the target and then confirming that the dart has hit the animal.

Cleaning and Reusing Darts

Many of the remote drug delivery systems, such as pole syringes, two-chambered compressed gas darts, and modular gunpowder explosive powered darts, are designed to be reusable. However, for proper function these darts must be cleaned, maintained, and stored correctly. Specific procedures and maintenance recommendations should be obtained from the dart manufacturer based on the preferences of the individual practitioner.

General dart cleaning and storage procedures:

1) Every effort should be made to locate and retrieve the dart after the procedure.
2) The retrieved dart should be placed in a labeled and secure container during transport prior to dismantling and cleaning.
3) Using gloves and proper eye protection, the dart should be inspected for residual drug or unreleased internal pressure.
4) While submerged under water the dart is carefully disassembled. The water provides protection from drug aerosolization and also dilutes any residual drug from the dart. Alternatively, disassembly can be performed under flowing tap water or in a safety cabinet.
5) After disassembly, each component of the dart is individually cleaned with warm soapy water and then inspected. The dart bodies are inspected for bending or cracks. Needles are inspected for patency, bending, or damaged retention barbs. Needle tips are inspected for sharpness and tip burs. Damaged parts should be discarded or repaired.
6) The dart parts should then be soaked in a disinfectant solution, carefully rinsed, and individually dried.
7) The dart components should be lubricated according to the manufacturer's recommendations.
8) The darts components are then sorted and packaged in sealable containers or surgical instrument wrappers.
9) Finally, the dart components can be sterilized according to manufacturer's recommendations.

Drug Delivery Problems

Dart Failure

Although darts and their projectors have become indispensable tools in zoological medicine, dart failures are common. The most important factor causing a dart to miss the target is operator error from inexperience with the darting system. Each darting system has individual characteristics that must be learned by the operator. Accuracy and consistency are only developed with persistent practice.

Unfortunately, all darting systems are prone to high failure rates, and even when the darts hit their intended target, many fail to discharge. More complex darting systems are more likely to fail. Careful preparation and testing of the darts are essential steps prior to each darting. Each darting system has critical or failure-prone components that must be carefully checked by the operator. Maintaining the equipment in portable organized kits helps ensure that the proper components are available and facilitates the darting procedures (Fig. 5.16).

Examples of common problems are explosive charges that fail to fire, blocked dart needles, and central plungers that stick. Ambient temperatures can affect dart function and the performance of compressed gas darts. In very cold temperatures darts may fracture on impact, drugs can freeze or become thick, and compressed gas exerts less pressure, causing incomplete discharges.

Drug Failure

The selection of anesthetic drugs is beyond the scope of this chapter, but inappropriate choices can definitely result in immobilization failures. Improper deposition of the darted drugs can also produce unexpected results. Darts that deposit drugs into vascular structures or medullary cavities of bones can have rapid onset similar to intravenous administration. Conversely, deposition into skin, subcutaneous space, tendons, fat deposits, or other poorly vascularized tissues can result in unacceptably slow absorption. Some clinicians recommend the usage of hyluronidase to improve absorption of drugs injected with darts (Kock 1992).

Drug interactions when mixed into a syringe must be considered, but have been poorly studied. Environmental conditions such as freezing or heating may also alter drug potency. Long-term storage of drugs in preloaded darts is questionable because the drug's potency and purity may change with time (Kreeger 2002).

Aerodynamics of Darts

Darts have poor ballistic properties compared to bullets or arrows. Their variable shapes and shifting liquids often cause their flight to be very erratic. Bent darts or needles damaged by previous impacts can radically alter a flight trajectory. Aside from the shape, the velocity of the dart as it exits the projector is another important variable in

Figure 5.16 Photograph of a darting kit with essential components separated into compartments. Note that a radio is included to provide emergency communications.

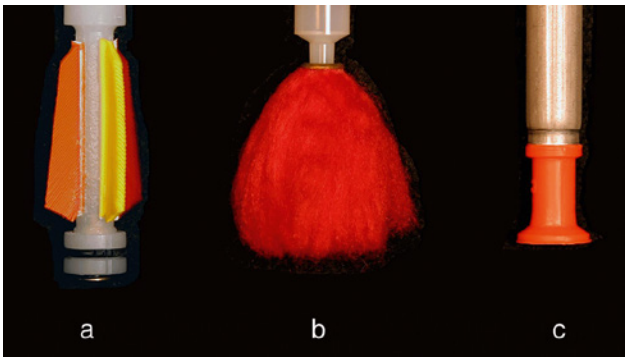

Figure 5.17 Photograph of three types of dart tails. (a) Four fin tail from a Dist-Inject mini-ject easy dart. (b) Cloth tail from a Dan-inject S series plastic dart. (c) Plastic tail from a Pneu-Dart type C dart.

determining the dart's trajectory. Fast muzzle velocities produce flat flight trajectories similar to those of a bullet. Although accurate, these faster velocities are associated with severe impact trauma and dart malfunctions. Furthermore, all darts, even when properly loaded and balanced, will destabilize at very high velocities. As a result, all darting systems are forced to use relatively slow muzzle velocities. At these slower velocities, the dart's trajectory becomes a downward arc which increases with darting distance. This arc must be anticipated, and an experienced darter will compensate appropriately.

The tailpiece is designed to provide the dart with aerodynamic stability (Fig. 5.17).

Available tails range from finned tails like archery arrows to wool and cloth tail stabilizers. Finned tails are considered very reliable, whereas wool and cloth tail stabilizers can cause problems if they are asymmetrical. Rifling of the projector barrel is a method of increasing flight stability by forcing the projectile to spin on its horizontal axis. Although available in some projectors, few darts can engage the rifled barrel surface and therefore do not actually spin well in flight (Fig. 5.18). Additionally, some dart tails, such as cloth and finned configurations, actually resist the horizontal spin that the rifled barrel is intended to provide.

Environmental conditions can also have significant effects on dart trajectories. Objects such as trees or large plants may deflect the dart. Winds and wind gusts can cause darts to fly in unexpected directions. Helicopter down drafts can affect darts as well. Due to their light weight, plastic darts are more prone to this problem.

Animal Injury

Severe tissue injury, including hemorrhage, necrosis, and bone fractures, can occur whenever darts are used. Any projectile with a needle can cause injury when it hits an animal in an unintended location. Sudden movements

Figure 5.18 Photograph through the barrel of a rifle barrel showing the spiral riffling intended to cause a dart to spin on its horizontal axis during flight.

from the targeted animal can lead to inadvertent injury to either the target or other animals in the group. Common examples include dart injuries to the eye, thorax, abdomen, and testicles. It is ultimately the operator's responsibility to only take shots that are likely to hit the expected target in an anatomically appropriate location.

In choosing the site selection on the animal, the operator must evaluate whether enough muscle mass is present to allow for injection of the drug and safe impact of the drug. In most animals the muscles of the upper hind legs are the safest selection. Occasionally the base of the neck or the triceps can be targeted. In addition, the choice of needle should limit tissue trauma while effectively providing adequate penetration for injection of the drug into the muscle. Needle length is selected based on the thickness of the animal's skin and the expected depth of the muscle mass. Inappropriately long needles have the potential to fracture bones on impact. Choice of needle diameter requires consideration of the potential for the needle to break on impact. Broken dart needles retained in muscle tissue have been reported when too thin a needle diameter was chosen (Cohn 1998).

Trauma to an animal from a dart is directly related to the kinetic energy (KE) of the dart (Karlsson & Stahling 2000; Kreeger et al. 2002). This energy can be estimated by knowing the mass and speed of the dart at impact in the following relationship: $KE = \frac{1}{2}(\text{mass}) \times (\text{velocity})^2$. Since velocity is squared it therefore has the greatest influence on the injuries caused on impact and means that heavy darts are not always more harmful for the animal than lighter ones (Kreeger et al. 2002). Although all darts require enough kinetic energy for the needle to enter the

skin and trigger discharge, excessive amounts of energy are associated with trauma and dart failure. In extreme situations the whole dart can become imbedded into the muscle or fracture a bone.

Darts can also injure tissues by overly forceful injection of drug (Cattet et al. 2006). This is particularly true of large-bore, open-ended needles that are discharged with explosive force. Both severe tissue injury and tissue necrosis have been documented with these types of darts (Wiesner 1998; Cattet et al. 2006).

Needle trauma caused by movement of the needle after discharge can similarly be significant. Often the first reaction of a darted animal is to jump, run, or remove the dart. Barbs and collars on dart needles are designed to keep the darts lodged in the animal, but if retained in live tissue for long periods or forcefully removed, they can lead to injury.

Infection of the dart site is generally rare, but can be another cause of serious complications to routine darting procedures. Unavoidably, needle penetration of the dart occurs through unclipped, unprepared, and often grossly contaminated skin. Some darts have been shown to directly introduce hair and other foreign material deep into the dart injection site (Cattet et al. 2006). Unsterile darts and contaminated drugs can further inoculate the injection site with bacteria. Once introduced into the dart wound, bacteria may grow rapidly in the traumatized tissues associated with the dart site, resulting in significant and deep wounds that develop into gross clinical infections. Inspection of the dart site and local wound care during the anesthetic procedure is always recommended. Many practitioners also recommend the use of prophylactic antibiotics, although the effectiveness of a single antibiotic injection is questionable and has not been prospectively evaluated. To minimize dart site infection, most darting needles can be sterilized prior to use. Aseptic techniques can be used during dart preparation, such as wearing sterile gloves while assembling the dart and loading it (Bush & Gray 1972).

Human Safety Concerns during Darting Procedures

Dart projectors should be considered firearms and treated with the same rules of basic gun safety to prevent accidental discharges. The ballistic properties of any dart can lead to serious injuries to people. Because darts are subject to radical changes in trajectory when they are deflected by wind, obstacles, and bouncing off animals, the operator must evaluate the position of all personnel around and particularly behind the target before the pulling trigger.

Most of the dart systems described previously are designed to automatically discharge drugs, making an accidental drug exposure likely when they hit a human. On rare occasions, darts may expel the drug prior to full needle penetration or after bouncing out of the animal's skin. In these cases, the drug can be aerosolized or sprayed onto the surface of the animal, resulting in accidental human drug exposure. Emergency plans for managing accidental human drug exposure must be in place prior to any immobilization procedures. Such plans should include access to effective emergency communication equipment such as a cellular telephone or two-way radios, knowledge of CPR, and basic first-aid procedures.

The most important safety considerations are proper planning and familiarization with the drug delivery method selected. Advanced planning for each procedure is also essential so that each person involved is cognizant of their roles and safety considerations. Prior practice and familiarization with the equipment make the operator more confident and effective in delivery of the anesthetics. Ultimately, the responsibility for the safety of an anesthetic delivery is on the anesthetists and the operator of the equipment.

Conclusions

The methods of drug delivery to nondomestic species are essential to the practice of zoo animal and wildlife anesthesia. However, these methods are often complicated and must be learned and practiced before application. Each remote delivery system has both advantages and significant limitations. Practitioners interested in obtaining equipment should familiarize themselves with all the available systems. Commercial websites often provide detailed information on specific product lines. Classes and conference lectures or wetlabs can provide valuable comparative product information and the opportunity to use several products. Additional information is also available in other books that describe the use of this equipment for specific applications (Kreeger et al. 2023; Kock & Burroughs 2012).

Invertebrates

Sarah J. Wahltinez, Craig A. Harms, and Gregory A. Lewbart

Introduction

What sort of topic is invertebrate anesthesia and analgesia? A better first question might be "What exactly are invertebrates?" The invertebrates are a collection of animals, comprising more than 95% of the earth's species, unified by the lack of a single anatomical trait: the vertebral column. Ruppert et al. (2004) stated invertebrates are a group of unrelated taxa that share no universal "positive" traits.

There are currently approximately 40 recognized phyla of invertebrates (not including the protozoans). Many of these phyla are not well known to veterinary medicine, but for no better reason than they may contain few species, microscopic representatives, or have no obvious economic value. Each phylum and its members are important to the diversity and survival of the planet, even if the group is only studied by a small number of scientists. Relatively little is known about the veterinary care, and more specifically acceptable anesthesia and analgesia choices, for many of these taxa. Writing a comprehensive book chapter for all invertebrate groups would be inefficient. Consequently, we have elected to include information on the metazoan taxa encountered by veterinarians and researchers. This chapter reviews the most common anesthetic techniques for these taxa, with a focus on those species most frequently under human care as well as a review of acceptable euthanasia methods.

Invertebrates are subjects of in situ and ex situ research, are kept as pets, and are common display animals in public aquaria. Many invertebrate species (e.g., flatworms, nematodes, cephalopod and gastropod mollusks, horseshoe crabs, and various species of insects (e.g., fruit flies)) have been used in research laboratories for decades. Their related contributions have greatly increased our understanding of heavy metal and pesticide toxicity, color perception and vision, embryology, and an extensive list of diseases, including cancer, diabetes, inherited genetic disorders, multiple sclerosis, and Parkinson's disease. In zoos and public aquaria, invertebrates are attractive display animals and common inhabitants in interactive exhibits such as touch pools, butterfly houses, and invertebrate zoos. Interaction with invertebrates at touch pools in public aquaria has been shown to impart positive attitudes and changes in the knowledge of visitors (Ogle 2016).

The influence and elevated awareness of animal welfare and shifting public opinion have resulted in increased consideration for the welfare of invertebrate animals. In research, the attempts and efforts to reduce, refine, and replace the use of vertebrate species have impacted invertebrate animal models. The general perception that invertebrates are more acceptable than vertebrates in research settings is primarily due to the belief that invertebrates do not experience pain. Selecting invertebrates for research makes the process of Institutional Animal Care and Use Committee oversight very easy since there are no regulations or restrictions in the United States on invertebrate use. Despite growing concerns from different organizations and institutions, the Animal Welfare Act and Public Health Service Policy do not protect invertebrates. Some organizations, including many zoos and aquariums, require a protocol for invertebrates used in research. The United States Department of Agriculture (USDA) has an Information Resource on the Care and Use of Invertebrates (AWIC Resource Series No.8 2000) document that has numerous references for invertebrates used in research. In zoos and aquaria, standards for the care of invertebrates are increasing. The Association of Zoos and Aquariums (AZA) has published care manuals for giant Pacific octopus, Japanese spider crab, and jellyfish. The USDA has standards for nonindigenous arthropods (USDA APHIS 2002), but these guidelines are geared towards preventing the release of potentially invasive species. *The UFAW Handbook on the Care and Management of Laboratory Animals* has in its eighth edition a section on cephalopods with references

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

(Hubrecht & Kirkwood 2010). Several reviews, references, and recommendations have been published on behaviors and husbandry of different invertebrate species (Anderson & Wood 2001; Fiorito et al. 2015; Smith & Berkson 2005; Wood & Anderson 2004).

The discussion about pain recognition and welfare in invertebrates is slowly moving and many changes have been initiated from the United Kingdom and other European countries (Berry et al. 2015; Cooke et al. 2019; Diggles 2019; Elwood 2019). The increased veterinary interest in invertebrate medicine will result in more research and scientific findings, leading to appropriate care for invertebrate species in clinical and laboratory settings. It is possible that selected invertebrates will soon be included in US animal welfare regulations, leading to regulatory oversight for invertebrate species in research. Cephalopod mollusks are protected in the European Union under EU Directive 2010/63/EU and in the United Kingdom, Canada, and Australia. Decapod crustaceans and cephalopod mollusks are protected in in Switzerland, Norway, and New Zealand (Smith et al. 2013). Sentience in some cephalopod mollusks and decapod crustaceans was recently reviewed with implications for animal welfare regulations (Birch et al. 2021). The criteria evaluated included (1) associative learning beyond habituation and sensitization, (2) flexible self-protective behaviors in response to injury and threat, (3) behavior demonstrating the animal values local anesthetics or analgesics when injured, (4) motivational trade-offs demonstrating balancing of threat versus opportunity for reward, (5) responses affected by potential local anesthetics or analgesics, (6) connections between nociceptors and integrative brain regions, (7) possession of integrative brain regions, and (8) possession of nociceptors. Based on these criteria, Birch et al. (2021) concluded there is very strong evidence of sentience in octopods and strong evidence for true crabs (infraorder Brachyura).

Animal welfare considerations aside, effective anesthesia can facilitate successful completion of procedures more efficiently, and often with less biological disruption than physical restraint alone, leading to better results.

Anesthesia Overview

Hypothermia, despite its prominence in the literature, is not considered anesthesia and does not provide analgesia or muscle relaxation. Hypothermia is thought to be painful and should not be used as an anesthetic, especially for surgery or other potentially painful procedures. Distress and mortalities have been reported from hypothermia in squid (Bower et al. 1999). Cardiovascular and respiratory system compromise during hypothermia, as well as consequences of rewarming, may be the leading causes of adverse outcomes.

There is a lack of evidence-based information on anesthetic monitoring of invertebrates. Respiratory and cardiovascular systems knowledge for the species should dictate anesthetic monitoring. Ruppert et al. (2004) contains relevant information on life history and physiology that can be helpful in determining anesthetic depth and monitoring invertebrates under anesthesia.

Aquatic Invertebrates

Aquatic invertebrates are commonly anesthetized by immersion in a solution containing an anesthetic, which can be considered analogous to inhalant anesthetics for vertebrates. The anesthetic water should match the water quality of the animal's environmental water as closely as possible (e.g., hardness, osmolality, pH, salinity, and temperature). Immersion anesthetic agents may be delivered as a static bath treatment for short-term procedures or via a recirculating system for longer duration procedures. Induction, maintenance, and recovery water should be well aerated.

With the exception of crustaceans, magnesium salts ($MgCl_2{\cdot}6H_2O$ and $MgSO_4{\cdot}7H_2O$) are commonly used as immersion agents for sedation, anesthesia, and euthanasia of many aquatic invertebrates. Hexahydrate magnesium chloride and heptahydrate magnesium sulfate (Epsom salts) are the compounds typically meant when $MgCl_2$ and $MgSO_4$ are referred to in invertebrate anesthesia literature. For our purposes $MgCl_2$ and $MgSO_4$ will refer to $MgCl_2{\cdot}6H_2O$ and $MgSO_4{\cdot}7H_2O$, respectively. At a 7.5% concentration (75 g/L) in distilled water, $MgCl_2{\cdot}6H_2O$ is nearly isosmotic with seawater. Thus, 7.5% stock solution can be added incrementally to seawater without altering osmotic pressure, whereas adding $MgCl_2{\cdot}6H_2O$ directly to seawater can markedly increase osmolarity, an important consideration for anesthetizing aquatic invertebrates.

Opinions differ about the ability of $MgCl_2$ to produce adequate sedation and analgesia via blocking nerve transmission and neurotransmitter release, or if it acts solely as a neuromuscular blocking agent (Clark et al. 1996). Unique aspects of invertebrate anatomy and physiology as well as routes of administration, when compared to vertebrates, seem to play a role in the observed effects; however, the issue remains unresolved for all taxa (Clark et al. 1996). Magnesium ions act centrally in suppressing neural activity in cephalopods (Messenger et al. 1985) and cephalopods have been found to lose both afferent and efferent nerve transmission, indicating true anesthesia (Butler-Struben et al. 2018). Further research is needed to evaluate the

Figure 6.1 Purple sea urchin (*Arbacia punctulata*) being observed during an anesthesia trial with MS-222. The idea of invertebrate anesthesia is a new concept for many people and was an engaging subject for this group of schoolchildren. Image by GA Lewbart.

effects of $MgCl_2$ on nerve transmission across invertebrate taxa to determine if it is a true anesthetic.

Ethanol is another frequently used immersion agent for aquatic invertebrates. Its depressive effects on the central nervous system have been well described and include inhibition of neuronal calcium and sodium channels in mollusks (Deitrich et al. 1989). Concentrations of ethanol used for anesthesia (up to 10%) are far lower than those used as a tissue preservative (70% and greater). The latter high concentrations are unsuitable for use for anesthesia or for a first- or single-step euthanasia.

Tricaine methanesulfonate (MS-222), an immersion anesthetic agent commonly used for fish, is often assumed to be a logical choice to try on aquatic invertebrates simply because of their common environment. In practice, with the exception of some echinoderms (Fig. 6.1), jellyfish (Fig. 6.2), and anemones, MS-222 is less effective for aquatic invertebrates (Butler-Struben et al. 2018; Gorges et al. 2022) or requires substantially higher concentrations (Applegate et al. 2016).

Other agents used for aquatic invertebrate anesthesia include benzocaine, eugenol/clove oil, ketamine, lidocaine, menthol, pentobarbital, 2-phenoxyethanol, propylene phenoxytol, tiletamine-zolazepam, urethane, and xylazine. Details are included with specific taxa below.

Figure 6.2 This moon jelly (*Aurelia aurita*) has been euthanized with an overdose of magnesium chloride (142 g/L for 15 minutes) and is being weighed prior to fixation in Davidson's fixative. Image by GA Lewbart.

Terrestrial Invertebrates

Terrestrial invertebrates can be anesthetized or immobilized with various gaseous and volatile agents, including chloroform, carbon dioxide, desflurane, isoflurane, and sevoflurane. These are administered in exposure chambers either commercially designed for invertebrates, adapted from small mammal chambers, or custom-made. Anesthetics may be administered via precision vaporizer into the chamber or by adding liquid anesthetic to a fibrous matrix (e.g., cotton ball, filter paper, rayon pad) within the chamber, ensuring no direct contact with the invertebrate to be anesthetized. This latter method is simpler, but less controlled, and can result in high anesthetic concentrations with greater risk for anesthetic complications. See the arachnid section for details on anesthetic chambers for terrestrial invertebrates.

Anesthesia by Taxa

Coelenterates

Anatomy, Physiology, and Natural History

Coelenterates (cnidarians) have a radially symmetric body with a single gastric opening surrounded by tentacles and derive their name from their cnidocytes, or stinging cells. The two basic body forms are called polyps and medusae, which may occur at different life stages in the same individual. Polyps are tube-shaped and attached to substrate while medusae are bell-shaped and free swimming. There are over 11,000 species of coelenterates, including anemones, corals, and jellies. Their nervous system is composed of a pair of nerve nets comprising interconnected neurons. Medusae also possess nerve rings and ganglia found along the edges of the bell (Ruppert et al. 2004).

Many coelenterates, especially those in tropical waters, have endosymbiotic tissue dinoflagellates most commonly from the genus Symbiodinium. These intracellular algae, known as zooxanthellae, allow coelenterates to thrive in oligotrophic waters by sharing products from photosynthesis in exchange for a protected environment and nutrients from the host coelenterate (Ruppert et al. 2004).

Anesthetic Agents Used and Techniques

Most reports of coelenterate anesthesia are based on relaxation or narcotization in preparation for terminal fixation to prevent contraction of polyps, therefore there is limited information about the recovery and lasting impacts of these narcotization solutions on the animals. Further research is needed to determine optimal anesthetic protocols for survival procedures in this phylum. Doses for coelenterate anesthesia are reported in Table 6.1.

Jellyfishes

Anatomy, Physiology, and Natural History

The iconic adult jellyfish is the medusa, however, there is a jellyfish developmental polyp stage (Ruppert et al. 2004).

Physical Restraint

During handling, jellyfish can be easily damaged by nets or hands, and should be submerged in water at all times. Jellyfish can be captured using bowls or plastic bags in a swirling motion to draw water into the vessel. After handling, jellyfish should be carefully inspected to ensure there is no air trapped under the bell, which can be detrimental to their health. Trapped air can be removed by gently turning jellyfish upside down and tapping the bell from below (AZA Aquatic Invertebrate TAG 2021). Some jellyfish are venomous and stings can be harmful to humans. Precautions, including wearing protective gloves, should be taken to prevent human envenomation.

Anesthetic Agents Used and Techniques

Jellyfish have been anesthetized using a menthol solution (Fuentes et al. 2011) and MS-222. Moon jellyfish immersed in MS-222 at 0.3 and 0.6 g/L had reduced response to stimuli and decreased movement with no mortality observed (Gorges et al. 2022). Medusae have also been relaxed with $MgSO_4$ iso-osmotic to seawater (Colley & Trench 1985), isotonic $MgCl_2$ (Kikinger 1992) and menthol (Park 1998), however, these animals were fixed and dehydrated for histology. To evaluate anesthetic depth, a rocking stimulus test, probe stimulus test, and bell contraction quality and body tone have been used (Gorges et al. 2022).

Sea Anemones

Anatomy, Physiology, and Natural History

Sea anemones exist as large solitary polyps and lack a medusa stage (Ruppert et al. 2004).

Physical Restraint

Sea anemone often retract their tentacles in response to disturbances, which prevents visual examination, procedures, and interpretation of histology if animals are fixed without relaxation.

Anesthetic Agents Used and Techniques

Sea anemones have been anesthetized by immersion in seawater with menthol crystals titrated until the animals were nonresponsive. This method did not appear to impact their regenerative abilities, but, other health parameters were not examined (Bossert et al. 2013). Juvenile and adult anemones have also been relaxed in $MgCl_2$ (71.4 g/L) diluted 1:6 with 1/3-strength artificial seawater for 10–15 minutes (Amiel et al. 2015). Another reported anesthetic dose is 7 g $MgCl_2$ dissolved in 100 mL of 1/3-strength artificial seawater (Stefanik et al. 2013).

Prior to fixation, anemones can be relaxed using immersion in solutions of menthol crystals (50 g of crystals in 100 mL of water), $MgCl_2$ (19 or 35–75 g/L), or $MgSO_4$ (35–75 g/L), tricaine methanesulfonate (MS-222, 200–500 mg/L) (England 1987; Haussermann 2004; Moore 1989; Morrall et al. 2000; Sebens & Paine 1978; Spano & Flores 2013). The immersion time required may depend on animal size. Menthol or a combination of menthol and $MgSO_4$ may be more effective in larger anemones (England 1987). $MgCl_2$ (60 g/L) has also been administered directly into the gastrovascular cavity immediately before immersion in fixative (Spano & Flores 2013). Since these

animals did not recover, anesthetic doses may need to be adjusted for recovery procedures.

Corals

Anatomy, Physiology, and Natural History

There are two main types of corals: stony corals (Scleractinia), which create a calcium carbonate exoskeleton (e.g., staghorn and elkhorn corals), and soft corals (Octocorallia), which lack a stony skeleton (e.g., sea fans and sea pens). Corals are very diverse and may be solitary or colonial (Ruppert et al. 2004).

Physical Restraint

Scleractinian corals often retract their polyps in response to handling, which precludes visual examination or sampling of their soft tissue.

Anesthetic Agents Used and Techniques

Menthol crystals have been used to anesthetize corals with a quick recovery (Agostini et al. 2008). Corals have been relaxed in calcium-free seawater prior to fixation (Chen et al. 2008). Due to potential physiological derangements this calcium-free method is not recommended for anesthesia. Prior to dissection for electron microscopy, corals have been relaxed using $MgSO_4$ (Kawaguti 1964). To relax soft corals, a $MgSO_4$ solution (110 g/L) has been added to seawater containing the animals in 5-mL increments every 15–20 minutes prior to fixation (Janes 2008).

Mollusks

Anatomy, Physiology, and Natural History

The mollusks are a diverse and large phylum that occupy freshwater, marine, and terrestrial environments. There are approximately 100,000 described species with high environmental and economic value. They are an important source of food, animals for pets, display, research, jewelry, artwork, and the lucrative shell-collecting hobby. Details of molluscan anatomy, physiology, and natural history can be found in a number of references, including Ruppert et al. (2004), Lewbart (2022), and any general invertebrate zoology text. Presented here are three major classes of mollusks (gastropods, cephalopods, and bivalves), with the most economically important groups discussed regarding anesthesia and analgesia. Doses for mollusk anesthesia are reported in Table 6.2.

Gastropods

Anatomy, Physiology, and Natural History

The gastropods are a large and easily recognized group that includes the abalone, nudibranchs, sea hares, slugs, and snails, among others. Most are aquatic and have a well-developed head and sensory organs, an external shell, muscular foot, and gills within a respiratory chamber. Many aquatic gastropods have an operculum that can seal the shell aperture and prevent access to the gills and other soft body parts. This behavior can impede anesthetic induction via immersion.

Physical Restraint

Gastropods are generally easy to restrain manually or with a protective container. While most gastropods are harmless to humans, members of the tropical genus Conus can inflict serious injury with small venomous "harpoons," which are modified radular teeth.

Abalones are commercially farmed and frequently require physical examination, sizing, pearl seeding, and removal from tanks for maintenance and harvesting (White et al. 1996). Research in abalones involves furthering knowledge of their ecology, genetics, and reproduction. Removing abalones is often only possible with mechanical assistance due to their ability to tightly adhere to the substrate. Forced removal may result in injury or mortality. A muscle-relaxing agent may be necessary to avoid stress and mechanical injury related to dislodging.

Anesthetic Agents Used and Techniques

Snails can be anesthetized using immersion in 5% ethanol (Flores et al. 1983) or menthol, or with inhalant agents like isoflurane (Girdlestone et al. 1989). Snail anesthesia is defined as when the body and tentacle withdrawal response to gentle stimulation is absent. A positive tentacle withdrawal reflex suggests an insufficient depth for surgery or invasive procedures (Girdlestone et al. 1989). A 10% Listerine® solution (ethanol 21.9%, menthol 0.042%) in normal *Lymnaea*, saline is commonly used to anesthetize snails (Woodall et al. 2003). Sodium pentobarbital at 400 mg/L in water has been reported to produce anesthesia with a slow onset (8 hours), good effect, and low mortality rate (Martins-Sousa et al. 2001). A combination of MS-222 and sodium pentobarbital has been described as a useful method of relaxing and anesthetizing various species of snails (Joosse & Lever 1959; Mutani 1982) with an onset time of approximately 60 minutes and long duration.

Isoflurane anesthesia for terrestrial snails requires an anesthetic chamber with fresh gas inflow and waste gas scavenging (Girdlestone et al. 1989). For pond snails, the minimum alveolar (or, more correctly, anesthetic) concentration is reported as 1.09% (Girdlestone et al. 1989). Induction is relatively fast (<10 minutes), but excitation is common. The main disadvantage of inhalant methods is the need to take the animal out of the chamber for a procedure, resulting in fluctuation of anesthetic depth and increased pollution of the working area. Furthermore, the depth of anesthesia may not be suitable for surgery.

Table 6.2 Anesthetic drugs and dosing for mollusks.

Mollusca					
Class	**Agent**	**Dose**	**Method of Administration**	**Species**	**Source**

		120 mg/L and 3 g/L	Immersion	*Biomphalaria* spp., *Helisoma* spp.	Mutani (1982)
Cephalopoda	Ethanol	1.5–3%	Immersion	*Sepia officinalis*	Harms et al. (2006)
		2%	Immersion	*Octopus vulgaris*	Andrews & Tansey (1981)
	Magnesium chloride ($MgCl_2 \cdot 6H_2O$)	6.8 g/L	Immersion	*Sepia officinalis*	Gore et al. (2005)
		37.5 g/L	Immersion	*Sepia officinalis*, *Loligo forbesi*, *Alloteuthis subulata*, *Octopus vulgaris*, *Eleodine cirrhosa*	Messenger et al. (1985)
Bivalvia	Chloral hydrate	4 g/L	Immersion	*Ostrea edulis*	Heasman et al. (1995)
	Magnesium chloride ($MgCl_2 \cdot 6H_2O$)	35 g/L	Immersion	*Ostrea edulis*	Culloty & Mulcahy (1992)
		30–50 g/L	Immersion	*Pecten fumatus*	Heasman et al. (1995)
	Propylene phenoxytol	1–3 mL/L	Immersion	*Pinctada maxima*	Mills et al. (1997)
		2–3 mL/L	Immersion	*Pinctada albina*, *Pinctada margaritifera*	Norton et al. (1996)

* Not all animals were recovered, dose may need to be adjusted for anesthesia.
MAC, minimum anesthetic concentration.

Ketamine and propofol do not induce anesthesia and may have an excitatory effect (Woodall & McCrohan 2000), while ketamine in combination with xylazine may be toxic (Martins-Sousa et al. 2001).

Aplysia spp. sea snails are commonly anesthetized with intramuscular or intracoelomic injection of $MgCl_2$ (Junge & Ortiz 1978; Kanz et al. 1979). Induction is fast (2–5 minutes), smooth, and results in good muscle relaxation. Immersion in 50 g/L $MgCl_2$ resulted in an initial increase in activity followed by progressive sedation (loss of attachment to substrate and righting reflex) and anesthesia (immobile and nonresponsive) over the course of 35 minutes, with rapid recovery (less than 1.5 minutes) following rinsing in and return to anesthetic-free water (Anderson et al. 2010). Halothane via immersion and MS-222 via immersion and intracoelomic administration appear to be ineffective anesthetic agents in *Aplysia* spp. (Clark et al. 1996).

Protocols used in abalones for removal and research include benzocaine (100 mg/L), ethanol (3%), 2-phenoxyethanol (1 mL/L), $MgSO_4$ (40–220 g/L), and sodium pentobarbital (1 mL/L) (Aquilina & Roberts 2000; Edwards et al. 2000; White et al. 1996). Magnesium sulfate can be administered in water (4–22 g/100 mL) with the concentration depending on size of the abalone; higher doses are needed for larger animals (White et al. 1996). Induction time is fast (5–8 minutes) and recovery is usually uneventful (3–35 minutes, depending on dose and anesthesia time). Phenoxyethanol is administered at 0.5–3.0 mL/L with rapid induction (1–3 minutes) and recovery (5–20 minutes) (White et al. 1996). Nembutal (sodium pentobarbital, 1 mL/L) produces good muscle relaxation with an induction time of 15 minutes and complete recovery (Aquilina & Roberts 2000). This compound has the distinct drawback of being a controlled drug with the challenges surrounding this class of compounds. Clove oil (0.5–1.5 mL/L) and propylene phenoxytol (2.5 mL/L) are not recommended because both agents can cause high mortality (Aquilina & Roberts 2000; Edwards et al. 2000) and MS-222 (1 g/L) and benzocaine (0.1 g/L) are ineffective as muscle relaxants (Aquilina & Roberts 2000). Both MS-222 and propylene phenoxytol cause significant excitation at induction, resulting in copious mucus production and loss of pigment (Aquilina & Roberts 2000).

Recovery from any immersion anesthesia requires thorough washing of the abalone and exposure to flowing anesthesia-free seawater delivered at the optimal temperature (18°C) until muscle strength returns.

Cephalopods

Anatomy, Physiology, and Natural History

This group of predatory and specialized mollusks includes such familiar forms as the chambered nautilus, cuttlefish, octopuses, and squids. Cephalopods are exclusively marine and most have the ability for fast locomotion. They have advanced nervous systems, excellent vision and tactile senses, closed circulatory systems, and high metabolic rates. Most have an internal skeleton or shell. The exceptions to this are the octopuses with no shell and the chambered nautilus with an external shell. Cephalopods have been extensively studied in many fields and the scientific literature is filled with their contributions.

Physical Restraint

Cephalopods, when stressed, which is common under human care, often expel ink as a defense mechanism. They are generally difficult to handle, other than for a quick move or relocation, without sedation. Cloth gloves prevent cephalopod suckers from gaining purchase on hands and wrists, and allow a greater degree of control for brief manual restraint. Buckets, plastic nets, or other smooth objects may be used to capture or restrain cephalopods. It should be kept in mind that these species are "specialized escape artists" (Wood & Anderson 2004). Artificial turf lining the upper reaches of aquatic enclosures discourages climbing by octopuses.

Anesthetic Agents Used and Techniques

The two most commonly used anesthetic agents in cephalopods are ethanol and $MgCl_2$, with the latter being the preferred option. It is employed by preparing an isotonic solution of 7.5% (75 g/L) $MgCl_2$ in distilled water mixed with an equal volume of seawater (Messenger et al. 1985). Induction time is between 1.5 and 13 minutes, with a short period of hyperventilation, then a gradual increase in arm flaccidity and righting reflexes; it is typically considered to be very smooth (Messenger et al. 1985). Respiration decreases and may even cease if the anesthetic concentration is not reduced. The gills should be at least intermittently, and ideally constantly, perfused with seawater containing the anesthetic of choice. Time of recovery from $MgCl_2$ is fairly quick (1–10 minutes), but dependent on the length and type of procedure (can be up to 20 minutes after longer procedures).

Cuttlefish have been successfully anesthetized with 1.5–3% ethanol (15–30 mL/L) diluted in seawater (Harms et al. 2006). Inductions are rapid (1 minutes), especially at higher concentrations, and dilution to a lower concentration (10–15 mL/L) to decrease the risk of overdosing should be considered. Occasional transient excitement has been noticed with lower concentrations of ethanol (Harms et al. 2006). If the procedure cannot be performed with the animal submerged, anesthesia is maintained with a recirculating anesthesia system (Lewbart & Harms 1999). The anesthetic concentration of the water should be adjusted by dilution over time to the anesthetic depth desired.

For cuttlefish, a 7.5% (75 g/L) $MgCl_2$ stock solution is prepared with distilled water (Gore et al. 2005). The stock solution is mixed with a known amount of seawater to prepare an anesthetic concentration suitable for induction. A final concentration of 6.8 g/L (100 mL of the stock solution mixed with 1 L of seawater) has been reported to have an induction time of 6–12 minutes without negative side effects (Gore et al. 2005). For most cuttlefish, a total water volume of 6–8 L is commonly needed. Induction is usually smooth and without a period of excitation. Decreases in concentration via dilution may be required to adjust the depth of anesthesia.

Octopuses are anesthetized in a similar manner as above. Two commonly employed anesthetic agents are ethanol and $MgCl_2$. Ethanol (2% v/v in seawater) can produce excitement during the short induction time (increased respiratory rate, attempts to climb out of the solution, and ink ejection; Andrews & Tansey 1981). Induction time has been reported to be 4 minutes and full recovery at 2.5 minutes after removal of the anesthetic solution (Andrews & Tansey 1981). Ethanol (2%) is not effective in cold-water species (below 15°C) (Gleadall 2013).

The use of urethane has been reported (Andrews & Tansey 1981; Messenger et al. 1985; Gleadall 1991) and was routinely used in the 1970s and 1980s, but despite good anesthetic effect, the traumatic effect on the animals from excitation during induction could be severe, and there are human exposure concerns. Chloroform, chloral hydrate, and CO_2 are unsuitable anesthetic agents in cephalopods as they can lead to high mortality (Garcia-Franco 1992; Gleadall 1991).

For recovery or resuscitation, the cephalopod is placed in a container with anesthesia-free, aerated, and/or circulated seawater and anesthesia-free water should be directed over the gills for a washout effect. If spontaneous respiration is not present, gentle and slow mantle massage of the mantle/body can be used to provide a combination of circulatory and respiratory support until normal respiration returns. The tentacles remain extended and flaccid in the first phase of the recovery and will retract in response to light stimulus (e.g., pinching) with progressive awakening (Harms et al. 2006).

Cephalopods can be monitored with visualization of respiratory rate and pattern. Normal awake values for 100–800 g *Octopus vulgaris* are 26–30 breaths per minutes (Andrews & Tansey 1981). The cardiovascular system is assessed by placing a Doppler probe on the dorsal area (above the aorta) or behind the gills (above either branchial heart) to monitor blood flow and heart rate. In transparent species (especially with $MgCl_2$), the organs inside the mantle cavity can be observed. Depth of anesthesia is difficult to assess in cephalopods. Anesthetic level seems adequate when no response to tactile and surgical stimuli is present (e.g., withdrawal of appendages or movement, contraction of the skin around the eye in response to pressure on the globe, withdrawal of the animal in response to a pinch of the skin over the eye (Andrews & Tansey 1981)). Other indicators of anesthetic depth are loss of normal posture, flaccidity of the arms, and an inability to regain normal posture (Andrews & Tansey 1981). Respiration is usually spontaneous; a depression or cessation is a sign of a concerningly deep level of anesthesia.

Bivalves

Anatomy, Physiology, and Natural History

This vast and economically important group of highly adapted aquatic mollusks includes the clams, mussels, oysters, and scallops. They lack a well-developed head, are generally nonvisual (the scallops are an exception), feed by filtration utilizing the gills for food transport, and use a muscular and sometimes quite large foot for locomotion. Research on these species focuses on their importance as a human food source and as environmental indicators.

Physical Restraint

Bivalves are generally easy to handle and restrain safely. Nearly all will tightly close their calcareous valves when handled or disturbed and may require sedation or physical manipulation (prying) to open the valves, which are held fast by strong adductor muscles. This behavioral response can greatly impede anesthetic induction, particularly if the anesthetic is irritating to any degree.

Anesthetic Agents Used and Techniques

Propylene phenoxetol (1%) can be used to anesthetize oysters in a dose range from 1 to 3 mL/L. Higher doses induce a rapid and relatively deep level of anesthesia (Mills et al. 1997) and may need diluting throughout the procedure to decrease recovery time (Norton et al. 1996). Generally, concentrations of 1–2 mL/L are safe and effective. The oyster should be placed hinge down in the solution and leaning against the wall of an aerated container to facilitate monitoring. Induction time is reported between 6 and 15 minutes. Adequate anesthesia is reached when the oyster gapes wide enough to part the gill curtain and shows no responsiveness to handling (Mills et al. 1997) or soft tissue contraction to a stimulus (Norton et al. 1996). Reducing handling stress before placing oysters into the anesthesia container will improve the anesthetic effects and facilitate valve opening. Recovery time is short (less than 30 minutes), although it depends on the length of procedure, concentration of anesthetic, and temperature (Norton et al. 1996).

Magnesium chloride seems to have variable effects on oysters. Some describe little effect of $MgCl_2$ in pearl oysters (Mills et al. 1997; Norton et al. 1996), mainly due to long induction times (1–2 hours). Culloty and Mulcahy (1992)

reported good anesthetic effects, but long induction and recovery times (90 minutes) at 3.5%. The effect of $MgCl_2$ seems to be dependent on species and concentration. Chloral hydrate and MS-222 are not effective in oysters due to slow induction and recovery, and are associated with complications, including death. Some of these undesirable effects may be related to the low pH of unbuffered MS-222 (Norton et al. 1996).

In scallops, anesthesia may be required for muscle relaxation and valve opening. In general, the depth of anesthesia/relaxation is adequate when handling and stimulating the mantle tissue fails to produce valve closure. Recovery is often defined as the regained ability for valve closure in response to a stimulus (Heasman et al. 1995).

Magnesium chloride is the drug of choice in scallops due to its rapid and consistent induction and recovery. The agent is dissolved in a small volume of seawater and then added to the aerated induction container to reach a concentration of 30–50 g/L. Induction times at these concentrations are quick and in the range of 2–6 minutes. Recovery time in scallops anesthetized with $MgCl_2$ seems to be consistently short (10 minutes) regardless of concentration used or temperature (Heasman et al. 1995).

Chloral hydrate has variable effects on scallops, with significant changes in induction and recovery at different concentrations and temperatures (Heasman et al. 1995). A concentration of 4 g/L produces anesthesia in 10–25 minutes at a temperature of 24°C. Lower temperatures significantly slow induction time. Higher concentrations shorten the induction time but can result in increased mortality. Recovery time at 4 g/L is between 20 and 30 minutes, but varies widely depending on temperature and concentration. Aerated recovery water and continuously flushing with anesthetic-free seawater facilitate recovery.

Other drugs have been examined for scallop anesthesia with little success. Benzocaine causes initial hyperactivity, ethanol does not have any effect, MS-222 causes hyperactivity and hyperextension, metomidate results in shell-closure, and $MgSO_4$ leads to high mortality (Heasman et al. 1995). Giant clams (*Tridacna* sp.) have been anesthetized with propylene phenoxetol (Mills et al. 1997).

Annelids

Anatomy, Physiology, and Natural History

The annelids are a large and diverse group of segmented vermiform animals that that are divided into three classes: Polychaeta, Clitellata (earthworms and leeches), and Sipuncula (peanut worms), formerly its own phylum. Some taxonomists include the sipunculids with the polychaetes. A former class of annelids, the Branchiobdellida, which are only found as crayfish ectoparasites, is now an order in the subclass Hirudinea. All are characterized by coelomic cavity, circulatory, excretory, and nervous system segmentation. This segmentation probably evolved as a means of burrowing via peristaltic contractions (Ruppert et al. 2004). A cuticle covers the animal, and setae occur in nearly all annelids. A linear gut tube lies between the anterior mouth and posterior anus (Ruppert et al. 2004). Anesthetic agents and dosing are reported in Table 6.3.

Table 6.3 Anesthetic drugs and dosing for annelids.

Annelida					
Class	**Agent**	**Dose**	**Method of Administration**	**Species**	**Source**
Polychaeta	Dentol®	8%*	Immersion	Nereidid worms from the Persian Gulf	Bonyadi-Naeini et al. (2016)
	Magnesium chloride ($MgCl_2 \cdot 6H_2O$)	75 g/L	Immersion	*Parapionosyllis manca*	Lewbart & Riser (1996)
		80 g/L*	Immersion	*Eurythoe complanata*	Müller et al. (2003)
Oligochaeta	Alcohol (presumably ethanol)	5%	Immersion	*Lumbricus terrestris*	Cooper & Roch (1986)
	Ethanol	5%	Immersion	*Lumbricus terrestris*, *Eisenia foetida*	Cooper (1968); Marks & Cooper (1977)
		5%	Immersion	*Lumbricus terrestris*	Salgado et al. (2014)
Hirudinea	Benzocaine	400 mg/L	Immersion	*Hirudo medicinalis*	Cooper et al. (1986)
	Mephenesin	Saturated	Immersion	*Hirudo medicinalis*, *Glossiphonia complanata*	Tettamanti et al. (2003)
	Soda water (50%)	500 mL/L	Immersion	*Hirudo medicinalis*	Cooper et al. (1986)

* Not all animals were recovered, dose may need to be adjusted for anesthesia.

Polychaetes

Anesthetic Agents Used and Techniques

Like many marine invertebrates, polychaetes can be sedated with $MgCl_2$ via immersion. While it is likely that some species are more sensitive than others, a concentration of between 7.5% and 8.0% seems to work well for relaxation (Lewbart & Riser 1996; Müller et al. 2003). A 2016 study by Bonyadi-Naeini et al. determined that a product called Dentol® (Khoraman Laboratory, Iran), which contains 10% carvacrol, was very safe and effective for the relaxation of nereid polychaetes. Animals were placed in an 8% Dentol® solution in seawater and were relaxed in less than 1 minute. Carvacrol is an aromatic oil found in many different plants (Bonyadi-Naeini et al. 2016). Dentol® may be hard to find outside of Iran.

Oligochaetes

Anesthetic Agents Used and Techniques

Cooper and Roch (1986) anesthetized the earthworm (*Lumbricus terrestris*) with a 5% alcohol (presumably ethanol) solution for a period of 1 hour prior to tissue grafting experiments. In earlier experiments, Cooper (1968) used 5% ethanol in Rushton's Ringers solution until the worms (*L. terrestris* and *Eiesnia foetida*) were immobilized. Marks and Cooper (1977) used 5% ethanol at 23°C for *L. terrestris* and *E. foetida*, and Salgado et al. (2014) reported success using 5% ethanol for anesthetizing *L. terrestris*.

Hirudineans

Anesthetic Agents Used and Techniques

The literature on leech anesthesia is minimal. One study found that immersion of *Hirudinaria medicinalis* in 400 mg/L benzocaine adequately immobilized the animals with a recovery time of approximately 3 hours (Cooper et al. 1986). The same study found that 50% soda water (active ingredient CO_2), at a concentration of 500 mL/L, was effective following a 2-minute excitatory period. This protocol resulted in a variable recovery period of up to 4.5 hours. One article describes the use of saturated mephenesin (3-o-toloxy-1,2-propanediol) to anesthetize leeches for grafting research (Tettamanti et al. 2003).

Arachnida

Doses and drugs for anesthesia of arachnids are reported in Table 6.4.

Spiders and Scorpions

Anatomy, Physiology, and Natural History

There are over 70,000 species of arachnids, with the majority identified as spiders or mites. Most arachnids are terrestrial carnivores. Arachnids respire through invaginations of the exoskeleton into their hemocoel, either through book lungs or tracheae. Scorpions respire using four pairs of book lungs while spiders perform gas exchange through lungs and/or tracheae. Like most arthropods, spiders and scorpions have a well-developed, open circulatory system of hemolymph pumped into sinuses by a muscular tubular heart in the anterior abdomen (Ruppert et al. 2004).

Physical Restraint

Manual restraint is commonly used to handle and transport spiders, but it is advisable to wear latex or nitrile gloves, as some tarantula species are capable of shedding urticating hairs that can be quite irritating, especially to allergic individuals. Direct handling of scorpions should be kept to a minimum for the safety of both the handler and

Table 6.4 Anesthetic drugs and dosing for arachnids.

	2-phenoxyethanol	2 mL/L	Immersion		

the animal. Clear plastic containers, and in some cases utensils like long forceps or tongs, can be used to move an animal from one place to another (Frye 2022). The primary drawbacks to manual restraint of scorpions or spiders are stress and injury to the animal and envenomation of the handler. Caution should be taken not to drop the animal or have it leap or fall to the ground.

Anesthetic Agents Used and Techniques

Inhalant anesthetic agents are most commonly and successfully used to anesthetize spiders and scorpions. All agents (desflurane, isoflurane, sevoflurane) can be used depending on cost and availability; isoflurane and sevoflurane are most commonly used for scorpions and spiders (Cooper 2001; Melidone & Mayer 2005; Pizzi & Kennedy 2022; Sheldon et al. 2019; Zachariah et al. 2009, 2014).

Several different induction chambers have been described (Cooper 2001; Melidone & Mayer 2005; Pizzi and Kennedy 2022) and used successfully for delivering inhalant anesthesia to spiders and in some cases scorpions. Ideally these chambers are commercially available invertebrate-specific with appropriate fresh gas inflow and scavenging outflow. Regular small mammal induction chambers or simple self-made clear plastic containers also work.

In containers without the use of an inflow and outflow system, a cotton swab soaked with a small amount of inhalant agent is placed into the box. The animal should be placed in a separate smaller container with ventilation pores. The smaller container holding the animal is placed into the larger box, allowing the inhalant to diffuse while ensuring that no direct animal contact with the inhalant-soaked cotton swab will occur. This method is not ideal because of the higher anesthetic agent exposure risk personnel, less control of the anesthetic amount, and higher risk of overdose (e.g., up to 32% isoflurane in air).

An induction chamber using anesthetic gas given via a vaporizer is preferred. The animal is placed in the chamber and the chamber is filled with the anesthetic gas (3–5% for isoflurane, 4–6% for sevoflurane). To decrease the filling time in larger chambers, the oxygen flow rate can be high at the beginning (1–3 L/min) and decreased to a minimum if there are no leaks in the system (300–1000 mL/min). Oxygen flow lower than 200 mL/min decreases vaporizer accuracy and may decrease the amount of anesthetic agent in the chamber due to the uptake by the animal. The amount of carbon dioxide accumulation in the chamber may increase using low fresh gas flows. An appropriate scavenging system is necessary to decrease pollution and staff exposure to anesthetic gases. With increasing anesthetic depth, the vaporizer can be adjusted by decreasing the anesthetic concentration over time.

The advantages of the chamber technique are convenience of use, low cost, and safety to the patient. The disadvantage is that the animal can only be temporarily sedated or anesthetized. For most procedures the animal is removed from the chamber, limiting the time for any procedure before the animal recovers. Repeated inductions also increase the exposure of the clinician and staff to the anesthetic gases. A chamber has been developed (Melidone & Mayer 2005) that allows the clinician to perform surgery or other manipulations on the animal without removing the animal from the chamber.

Another technique is to induce the spider in an anesthetic chamber and then place its abdomen (with the associated book lungs/tracheae) into a smaller chamber "sealed" with a latex glove. This technique has merit when a procedure must be performed on the cephalothorax or limbs (Dombrowski 2006).

Carbon dioxide, nitrogen, and hypothermia have also been used to immobilize spiders (Madsen & Vollrath 2000; Pizzi & Kennedy 2022). No reports about the amount of nitrogen used or the quality of nitrogen anesthesia could be located. Carbon dioxide gas is administered in a chamber, often producing 98% saturation. Dilution with air or oxygen is difficult, resulting in an increased risk for mortalities (Pizzi & Kennedy 2022). The side effects of CO_2 anesthesia are well recognized in vertebrates (e.g., respiratory acidosis, behavioral signs of distress), which, if also observed in invertebrates, may indicate that other anesthetic options are preferable.

Observe the spider or the scorpion for righting reflexes and other movements to assess depth of anesthesia. It may take 10–15 minutes and several attempts until full immobilization has occurred. During the procedure, leg movement in response to stimuli is a sign of insufficient depth of anesthesia. An increase in heart rate and respiratory rate may occur but is often unrecognized. Deep anesthesia can be difficult to evaluate; slow respiratory rate and heart rates are often the only way to assess a patient for excessive depth of anesthesia.

Respiratory rate is observed at the cranial lateral side of the animal. A Doppler or ultrasound machine can be used to monitor heart rate. The spider heart lies under the dorsal surface of the body. The Doppler's pinpoint-crystal head is placed over the heart area with an appropriate amount of gel. Normal heart rates are considered to be 30–70 beats per minute in large spiders and up to 200 beats per minute in smaller species.

After turning off anesthetic delivery, recovery from anesthesia is usually gradual and can take between 3 and 20 minutes depending on ambient temperature and the depth of anesthesia during the procedure. When fully awake the animal should be returned to its enclosure and

maintained at its preferred ambient temperature. Feeding after anesthesia should be delayed for 48 hours (Pizzi & Kennedy 2022).

Horseshoe Crabs

Anatomy, Physiology, and Natural History

The American horseshoe crab (*Limulus polyphemus*) is the most common of four global species and is frequently used as a laboratory animal model to study its sensory structures, the nervous system, and embryology. Horseshoe crabs have a well-developed semiclosed circulatory system composed of a tubular heart, arterial system, and sinuses. Ventilation is achieved through gill movements that pump water around the gills as well as pumping hemolymph through the gills. Horseshoe crab hemolymph contains hemocyanin, a respiratory pigment, which gives their hemolymph its characteristic blue color (Ruppert et al. 2004). The horseshoe crab's most common use and value to humans comes from *Limulus amebocyte* lysate, an extract of amoebocyte cells from the hemolymph, which is a critical component in assessing the safety of medical equipment and pharmaceuticals by detecting the presence of endotoxin (Smith & Berkson 2005; Smith 2022).

Physical Restraint

Horseshoe crabs are easily handled and restrained, although strong locomotion and righting reflexes can make examinations challenging (Smith & Berkson 2005). Holders are cautioned not to pinch their fingers between the lateral edge of the opisthosoma and the genal angle of the prosoma (Smith 2022).

Anesthetic Agents Used and Techniques

The dorsal, tubular heart of the horseshoe crab is located over the entire length of the prosoma (Spotswood & Smith 2007). The hemolymph collection site has been well described (Smith & Berkson 2005; Smith 2022) and is easy to perform. Hemolymph pH and blood gases may be measured for monitoring anesthesia (Archibald et al. 2019). Electrocardiogram (ECG) patches placed on the cephalothorax can detect heart rate. Normal awake heart rates in horseshoe crabs are reportedly 30 beats per minute at a temperature of 23°C and may vary by temperature (Redmond et al. 1982). Ultrasonography may be used to measure heart rate, as well as cardiac contractility and respiratory rate through the carapace without having to invert the animal to view the book gill excursions (Archibald et al. 2019). Resting heart rate, cardiac fractional shortening, and respiratory rate at 22.8–28°C were ~22–50 per minute, ~32–50%, and ~35–53 per minute, respectively (Archibald et al. 2019). Immersion in MS-222 at 1 g/L buffered with sodium carbonate (not bicarbonate), and 2-phenoxyethanol at 2 mL/L provided effective anesthesia with clinically useful induction and recovery times (Archibald et al. 2019). Effective buffering of MS-222 at this concentration required sodium carbonate rather than sodium bicarbonate to avoid simultaneously markedly increasing the salinity of the anesthesia water. Both MS-222 and 2-phenoxyethanol reduced cardiac contractility and respiratory rate with minimal effect on heart rate. Subjectively, 2-phenoxyethanol provided smoother anesthesia.

Crustaceans

Anatomy, Physiology, and Natural History

Crustaceans are a large group of diverse arthropods that includes an estimated 67,000 species (50,000 are marine), including barnacles, crabs, crayfish and lobsters, prawns, shrimps, and water fleas (Applehans et al. 2012). Crustaceans belong to the clade Mandibulata, which also includes insects and myriapods (centipedes and millipedes). Crustacea are aquatic mandibulate arthropods with two pairs of antennae, stalked compound eyes, biramous jointed appendages, one or more pairs of segmental excretory organs, a carapace, gills, and a free-swimming nauplius larvae. The second pair of antennae and mandibles provide the sharpest distinction from other arthropods. Martin and Davis (2001) treat the taxon Crustacea as a subphylum. Recent and compelling work has led most taxonomists to accept that insects (Hexapoda) are actually crustaceans and should be included in a combined crustacean-hexapod clade (Ahyong 2020). Several names have been proposed for this new taxon, including Crustaceomorpha, Pancrustacea, and Tetraconata (Ahyong 2020). This revision addresses the conundrum of why insects never colonized the marine environment and why crustacean success on land and in freshwater is limited. The combined group has exploited all three biomes (Ahyong 2020). In this chapter we will conform with the conventional separation of crustaceans and insects.

Physical Restraint

Some species can be manually restrained with gloved hands or with the help of utensils such as tongs or nets. Because some larger crustaceans can cause serious injury to handlers, care should be taken when manipulating or restraining these animals (e.g., some crabs and lobsters).

Anesthetic Agents Used and Techniques

Various anesthetic agents can be used on crustaceans. Doses are reported in Table 6.5. Immersion in clove oil or

Table 6.5 Anesthetic drugs and dosing for crustaceans.

Crustacea					
Order	**Agent**	**Dose**	**Method of Administration**	**Species**	**Source**

		70 mg/kg	Intravascular injection	*Carcinus maenas*	Oswald (1977)

* Sedation at lower doses, anesthesia at higher doses.

isobutyl alcohol, and injections of alfaxalone, ketamine, lidocaine, tiletamine-zolazepam, and xylazine have been reported (Brown et al. 1996; Ferraro & Pressacco 1996; Foley et al. 1966; Gardner 1997; Minter et al. 2017; Oswald 1977; Quesada et al. 2011). An intravascular injection can be performed in large crabs through the coxal arthropodial membrane of a cheliped (Oswald 1977; Gardner 1997) using a small needle (25 gauge). Anesthetic immersions commonly used in other aquatic invertebrate taxa, such as MS-222, 2-phenoxyethanol and magnesium salts ($MgCl_2$ and $MgSO_4$), are generally not effective in decapod crustaceans (Coyle et al. 2005; Foley et al. 1966; Fregin & Bickmeyer 2016; Gardner 1997; Oswald 1977). Immersion in isobutyl alcohol (1.5–7.0 mL/L) results in sedation at low doses and anesthesia at high doses. The induction time and duration of effect are dose dependent (Foley et al. 1966).

Lidocaine (0.4–1 mg/g) can be injected intramuscularly into the tail and anesthesia lasts for about 5–30 minutes in crayfish, depending on the dose administered, with an average induction time of 1.5 minutes (Brown et al. 1996). Intravascular lidocaine (0.2 mg/g) lasted approximately 3 minutes in blue crabs (*Callinectes sapidus*) (Quesada et al. 2011).

Ketamine has been used in crayfish (40–90 mg/kg [μg/g]) (Brown et al. 1996), the Australian giant crab (*Pseudocarcinus gigas*) (0.025–0.1 mg/kg intravenous [IV]) (Gardner 1997), and blue crabs (Quesada et al. 2011) with variable success. Ketamine given intramuscularly to crayfish provides consistent anesthesia (induction time 1 minute) for over 10 minutes (40 μg/g) to 2 hours (>90 μg/g) without excitatory side effects during induction or recovery (Brown et al. 1996). When ketamine alone was given to the giant crab (*P. gigas*) intravascularly, a short

period of excitement occurred, but the induction time was short (15–45 seconds). The duration of anesthesia was dose dependent and lasted between 8 and 40 minutes (Gardner 1997). Intravascular injections of ketamine (20 mg/kg) in blue crabs resulted in a smooth and fast induction (<60 seconds) but the duration of anesthesia was only 3–12 minutes. The majority of crabs were categorized as having light anesthesia. Intracardiac injections of ketamine (20 mg/kg) resulted in death in four out of five crabs (Quesada et al. 2011).

Xylazine has shown good anesthetic effects in adult giant crabs when used at doses between 16 and 22 mg/kg IV (Gardner 1997) or in common shore crabs (*Carcinus maenas*) at 70 mg/kg IV (Oswald 1977). Induction seems to be smooth and fairly fast (3–5 minutes); dose dependent immobilization lasts 25–45 minutes. Side effects, including bradycardia, dysrhythmias, and extrasystoles, have been reported with high doses (70 mg/kg) (Oswald 1977). A similar short induction (30–60 seconds) was seen in blue crabs administered xylazine (20 mg/kg) IV, with a duration lasting 5–30 minutes (Quesada et al. 2011). Higher doses of xylazine (70 mg/kg) resulted in the death of blood-spotted crabs (*Portunus sanguinolentus*) (Premarathna et al. 2016). Care should be taken when using high-end doses of xylazine.

Ketamine and xylazine combined (20 mg/kg each) IV resulted in a quick induction (30–40 seconds) and lasted 5–10 minutes in blue crabs. Tiletamine-zolazepam (30 mg/kg) IV also had a quick induction (20–60 seconds) and lasted 5–7 minutes (Quesada et al. 2011). Intravascular injections of alfaxalone provide sedation (15 mg/kg) and anesthesia (100 mg/kg). Induction is rapid (<1 minute) but prolonged recoveries have been observed with higher doses (Minter et al. 2013). Intravascular injections of etomidate (16 mg/kg) were ineffective and propofol (20 mg/kg) is not recommended as it can result in limb autotomy in blue crabs. Pentobarbital (20 mg/kg) IV produced inadequate sedation in five out of six blue crabs (Quesada et al. 2011).

Procaine (25 mg/kg IV) has been used in crabs and provides good anesthesia with a very short induction time (20–30 seconds). This included a 10-second excitatory period that led to tonic contraction before paralysis. Duration was very long (2–3 hours) with slow recoveries (Oswald 1977) and may be reserved for long-term experimental procedures.

For smaller crabs, in which an intramuscular or IV injection is impractical, clove oil can be used as a bath treatment and has shown a 16-minute onset of anesthesia at a dose of >0.125 mL/L and a long recovery phase (2.5 hours). Once the animal is anesthetized, a reduction of concentration is necessary because 0.125 mL/L clove oil over a long period of time is also used for euthanasia (Gardner 1997). Freshwater prawns (*Macrobrachium rosenbergiii*) were anesthetized with immersion in eugenol and experienced a lower oxygen consumption rate at doses higher than 0.2 mL/L. Induction and recovery times were similar with immersion in eugenol and a mixture of eugenol and menthol (Saydmohammed & Pal 2009). Immersion in AQUI-S (isoeugenol; 100 mg/L) has been reported for anesthesia of the freshwater prawn (*M. rosenbergii*) (Coyle et al. 2005). Southern rock lobsters (*Jasus edwardsii*) immersed in AQUI-S (40-200 mg/L) exhibited sedation at the lower end of the dose range and anesthesia at the higher end (Robertson et al. 2018).

Crustacean heart rates can be measured by applying ECG pads with ample gel on the carapace above the heart or by Doppler flow probe (Fig. 6.3). The normal heart rate for lobsters is between 5 and 20 beats per minute with a circadian influence (higher at night) (Aguzzi et al. 2004) and 30–70 beats per minute for the shore crab (Styrishave et al. 2003), depending on pH and temperature. Anesthetic depth is evaluated in crustaceans by the relaxation of the body, the ability to withdraw extremities, and very slow withdrawal of their antennae.

Figure 6.3 This American lobster (*Homarus americanus*) has been anesthetized with eugenol immersion and is being euthanized with injectable intracardiac potassium chloride. A Doppler is being used to monitor heart rate. Within seconds of the potassium chloride administration the heart stopped beating. Image by GA Lewbart.

Analgesics and their effects are understudied in crustaceans. Morphine has been shown to decrease the response of crabs (100 mg/kg) and shrimp (91 mg/kg) to noxious stimuli; this effect is reversible with naloxone administration (Lozada et al. 1988; Maldonado & Miralto 1982; Tomsic & Maldonado 1990). However, this decreased response appears to be due primarily to sedation rather than analgesia (Barr & Elwood 2011). Ketorolac administered intracardiac was fatal to blue crabs (*C. sapidus*); consistent concentrations were observed when administered to crabs intramuscularly (0.25–0.75 mg/kg); however, in light of observed mortalities in blue crabs, use in crustaceans may be contraindicated pending studies in other species (Souza et al. 2020).

Insects

Anatomy, Physiology, and Natural History

The insects are a diverse group with nearly a million described species that some taxonomists term the Hexapoda. Insects are arthropods with three major body segments (head, thorax, and abdomen) and three pairs of legs. Most have well-developed mouthparts, keen eyesight, sensory antennae, and wings. They have an open hemolymph circulatory system and gases are exchanged through spiracles that open into a system of tracheae. Insects have been employed as research animals for many decades. *Drosophila* may be the best-known representative for genetic research studies, but other species are important contributors of information on pathogen–vector interaction in various diseases, metamorphosis and anatomy/physiology (facet eye, senses), ecology and agriculture, pharmaceutical control etc.

Figure 6.4 This fully awake Australian thorny devil stick bug (*Eurycantha calcarata*) is being given fluids as part of a hemolymph transfusion study. Insects and other terrestrial invertebrates can frequently be examined and weighed without the need for anesthesia. In cases where anesthesia is required, a number of inhalant agents have been successfully used. Image by GA Lewbart.

Physical Restraint

In most cases insects can be handled and restrained manually without risk to the animal or handler (Fig. 6.4). In some cases, gloves are recommended as a protective measure and various utensils can be employed to immobilize or restrain insects (Cooper 2022).

Anesthetic Agents Used and Techniques

Recent works have investigated the effects of isoflurane (Troup et al. 2019), sevoflurane (Chen et al. 2019), and isoflurane and sevoflurane on *Drosophila* (MacMillan et al. 2017). This latter paper found that both gas inhalants were superior to hypothermia and carbon dioxide with regards to side effects, such as reproductive compromise and juvenile mortality. No deleterious side effects were noted with sevoflurane anesthesia (MacMillan et al. 2017). Chen et al. (2019) found no mortality associated with sevoflurane but the gas did lead to an exacerbation of eye phenotype in the offspring.

Carbon dioxide remains popular for immobilizing insects in entomological research, although multiple side effects and high mortality are recognized (Nicolas & Sillans 1989; Valles & Koehler 1994; MacMillan et al. 2017). A more progressive approach is the use of volatile anesthetic agents such as isoflurane or sevoflurane. This requires a chamber apparatus to allow for appropriate delivery and scavenging of the inhalant agent (Walcourt & Ide 1998) (see the section on arachnids for further details on anesthetic chambers). Exposure to chloroform or desflurane in custom-made small glass tube induction chambers immobilized *Drosophila* larvae for survival confocal imaging (Cevik et al. 2019). Chloroform resulted in more rapid induction but slower recovery than desflurane, with less depression of heart rate and auditory response. Doses for the anesthesia of insects are reported in Table 6.6.

Hypothermia has been reported for immobilization of insects, but its use is discouraged for surgical and otherwise stressful or painful procedures (Cooper 2005; MacMillan et al. 2017).

Table 6.6 Anesthetic drugs and dosing for insects.

Insecta					
Order	**Agent**	**Dose**	**Method of Administration**	**Species**	**Source**
Diptera	Chloroform	30 seconds × 2	Inhalant	*Drosophila melanogaster*	Cevik et al. (2019)
	Desflurane	10 minutes × 2			Cevik et al. (2019)
	Isoflurane	ED_{50} = 0.3%*			Troup et al. (2019)
		4.6%			MacMillan et al. (2017)
	Sevoflurane	2.1%, 3%			Chen et al. (2019)
		6.7%			MacMillan et al. (2017)

* The effective dose (ED_{50}) is the concentration where half of the animals tested were immobile for longer than 10 seconds.

Nematodes

Anatomy, Physiology, and Natural History

Nematodes are one of the largest groups of invertebrates, with approximately 500,000 known species (Bodri 2022). Numerous species have been extensively used in research for plant–parasite effects, diseases, and genetics.

Caenorhabditis elegans is the most researched nematode as it is commonly used as an animal model. Its size, small and consistent number of somatic cells, and easily accessible nervous system make it an ideal research animal. *C. elegans* studies have led to scientific information about meiosis, nicotine dependence, volatile anesthetics, and genetics.

Anesthetic Agents Used and Techniques

Due to its popularity, most anesthetic agents reported for nematodes are based on *C. elegans* and anesthetic effects on the animal are well described (Bodri 2022). *C. elegans* has been anesthetized with CO_2 (Bodri 2022), 4.5% ethanol (Morgan & Sedensky 1995), propylene phenoxetol (Nelson & Riddle 1984), and numerous inhalants (chloroform, flurothyl, fluorxene, halothane, and isoflurane) (Crowder et al. 1996; Morgan & Cascorbi 1985; Morgan et al. 1990). Much higher concentrations of inhalant anesthetics are required for *C. elegans* compared to vertebrates (Zalucki and van Swinderen 2016). Crowder et al. (1996) recommend 6.5% isoflurane. The effective dose (ED_{50}, the concentration where half of the animals tested were immobile for longer than 10 seconds) values for the nine inhalant agents were established in Morgan's studies and the anesthetic chamber for these species has been described (Morgan & Cascorbi 1985; Bodri 2022). This included isoflurane with a concentration range of 5.6–7.18%, consistent with the findings of Crowder et al. (1996). Doses for the anesthesia of nematodes are reported in Table 6.7.

Echinoderms

Anatomy, Physiology, and Natural History

Echinoderms have deuterostome development, pentaradial symmetry as adults, and a calcium carbonate endoskeleton. There are approximately 7000 species divided into five classes, including sea stars and sea daisies (Asteroidea), brittle and basket stars (Ophiuroidea), sea cucumbers (Holothuroidea), sea urchins, sea biscuits, sand dollars (Echinoidea), and feather stars and sea lilies (Crinoidea) (Ruppert et al. 2004). The echinoderm nervous system is composed of a circumoral nerve ring with extending radial nerves. While the circumoral nerve ring is centrally located, it does not appear to have a coordinating function and is not a true central nervous system (Cobb 1995).

Physical Restraint

Most species of the echinoderm phylum can be handled safely and effectively without anesthesia or sedation. They are slow moving and quite hardy (one exception being the brittle stars). Certain species of sea urchins can inflict a painful "sting" with movable, sharp spines. Nets, tongs, and gloves can aid in the safe handling for physical restraint. Anesthesia should be used for invasive and potentially painful procedures.

Anesthetic Agents Used and Techniques

If echinoderms need to be anesthetized/immobilized, immersion in $MgCl_2$ or MS-222 is commonly used (Harms 2022). Doses for the anesthesia of echinoderms are reported in Table 6.8.

Brittle and Basket Stars

Anatomy, Physiology, and Natural History

Brittle stars have thin arms while basket stars have branched arms (Ruppert et al. 2004).

Table 6.7 Anesthetic drugs and dosing for nematodes.

Nematoda					
Order	**Agent**	**Dose**	**Method of Administration**	**Species**	**Source**
Rhabditida	Chloroform	ED_{50} = 0.52%*	Inhalant	Caenorhabditis elegans	Morgan & Cascorbi (1985)
		ED_{50} = 1.47%*	Inhalant		Morgan et al. (1990)
	Ethanol	4.5%	Immersion		Morgan & Sedensky (1995)
	Flurothyl	ED_{50} = 8.1%*	Inhalant		Morgan & Cascorbi (1985)
		ED_{50} = 14.3%*	Inhalant		Morgan et al. (1990)
	Fluorxene	ED_{50} = 10.9%*	Inhalant		Morgan & Cascorbi (1985)
		ED_{50} = 10.8%*	Inhalant		Morgan et al. (1990)
	Halothane	ED_{50} = 0.85%*	Inhalant		Morgan & Cascorbi (1985)
		ED_{50} = 3.18%*	Inhalant		Morgan et al. (1990)
		ED_{50} = 3.6%*	Inhalant		Crowder et al. (1996)
	Isoflurane	ED_{50} = 4.9%*	Inhalant		Morgan & Cascorbi (1985)
		ED_{50} = 6.5%*	Inhalant		Crowder et al. (1996)
		ED_{50} = 7.18%*	Inhalant		Morgan et al. (1990)
	Propylene phenoxetol	0.5 µL/mL for L1 larvae, 1.5 µL/mL for L2 larvae, 2.0 µL/mL for L3 larvae, 4.0 µL/mL for dauer larvae, 2.5 µL/mL for L4 larvae, and 3.0 µL/mL for adults	Agar Pad		Nelson & Riddle (1984)

* The effective dose (ED_{50}) is the concentration where half of the animals tested were immobile for longer than 10 seconds.

	2-phenoxyethanol	30 g/L	Immersion	*Strongylocentrotus droebachiensis*	Hagen (2003)
	Potassium chloride (KCl)	2.5–50 g/L	Immersion	*Strongylocentrotus droebachiensis*	Hagen (2003)

* Not all animals were recovered, dose may need to be adjusted for anesthesia.
† Sedation at low dose, anesthesia at high dose.

Physical Restraint

As brittle and basket stars are fragile, they must be handled gently to prevent autotomy. Sedation or anesthesia, when possible, is recommended to prevent injury to the animal.

Anesthetic Agents Used and Techniques

MS-222 (1 g/L), $MgCl_2$ (1:1 ratio of iso-osmotic $MgCl_2$ to seawater), menthol (half saturation), and 2-phenoxyethanol (5%) have been shown to reduce or prevent arm autotomy in brittle stars (Dobson 1985). Details pertaining to anesthetic plane are not reported but the brittle stars reportedly recovered. A 2.5–5% solution of menthol in seawater has been reported for anesthesia of *Amphipholis squamata* (Costello & Henley 1971). Prior to fixation or preservation, brittle stars have been anesthetized by immersion in propylene phenoxetol (1 g/L) (Wilkie 1992).

Feather Stars and Sea Lilies

Anatomy, Physiology, and Natural History

Feather stars and sea lilies are the most ancient of the echinoderms. They are typically sessile or semisessile. Feather stars are free-swimming while sea lilies are attached to the substrate with a stalk. They are suspension feeders, collecting food using their branched arms (Ruppert et al. 2004).

Anesthetic Agents Used and Techniques

There are few reports of anesthetizing feather stars and sea lilies. They reportedly do not respond to magnesium salts. MS-222 (1 g/L) (Hendler 2004) and propylene phenoxetol titrated to effect (Nichols 1960) may be more effective. Bubbling nitrogen gas in seawater for 10–15 minutes has been reported to successfully immobilize feather stars, with the animals recovering successfully (Zmarzly 1984).

Sea Cucumbers

Anatomy, Physiology, and Natural History

Sea cucumbers are elongated and cylindrical, with a soft and leathery body wall characterized by a thick dermis. Their mouth and anus are found at opposite ends (Ruppert et al. 2004).

Anesthetic Agents Used and Techniques

Some sea cucumbers may respond less well to magnesium salts and better to propylene phenoxetol (Hendler et al. 1995). When exposed to seawater saturated with propylene phenoxetol, sea cucumbers exhibited increased activity for the first 30 minutes, began to relax after 1 hour and were fully relaxed after 2 hours. These animals recovered in running seawater. Sea cucumbers left in the propylene phenoxetol for 13 hours did not survive (Hill & Reinschmidt 1976). Another reported dose for propylene phenoxetol is 2 g/L (Van den Spiegel & Jangoux 1987), however, these sea cucumbers were dissected in a terminal procedure. Menthol crystals have also been used to anesthetize sea cucumbers (Costelloe & Keegan 1984).

Sea Stars

Anatomy, Physiology, and Natural History

Most sea star species have five arms, or rays, which extend from their central disc, but some species can have more than 40 (Ruppert et al. 2004).

Anesthetic Agents Used and Techniques

A common sea star anesthetic is $MgCl_2$. A 75 g/L $MgCl_2$ solution (75 g $MgCl_2$ in 1 L of dechlorinated freshwater) is isotonic to natural seawater (Wahltinez et al. 2021). Immersion in either an 80 g/L $MgCl_2$ solution (Anderson 1965) or a 1:1 mixture of 7.5% stock solution with seawater has been reported (McCurley & Kier 1995). Higher concentrations, however, may be needed for induction but may be hyperosmotic. Adjustments over time during maintenance of anesthesia may be accomplished by gradually diluting the anesthetic solution by administering more seawater. A wide range of MS-222 doses (Fig. 6.5) has been reported and used in a concentrated form (1–10 g/L in seawater) (O'Neill 1989, 1994). Other reported anesthetic agents are menthol (10 g/L) (Pinn et al. 2014; Saha et al. 2006) and propylene phenoxetol (1 g/L in seawater) (Santos et al. 2005). Sea star induction can be assessed by evaluating the loss of righting reaction and response to tactile stimulation of the ambulacral groove.

Sea Urchins

Anatomy, Physiology, and Natural History

Sea urchins have spherical bodies with long spines, except in the flattened "irregular" urchins like sea biscuits and sand dollars, which bury themselves in the substrate. (Ruppert et al. 2004).

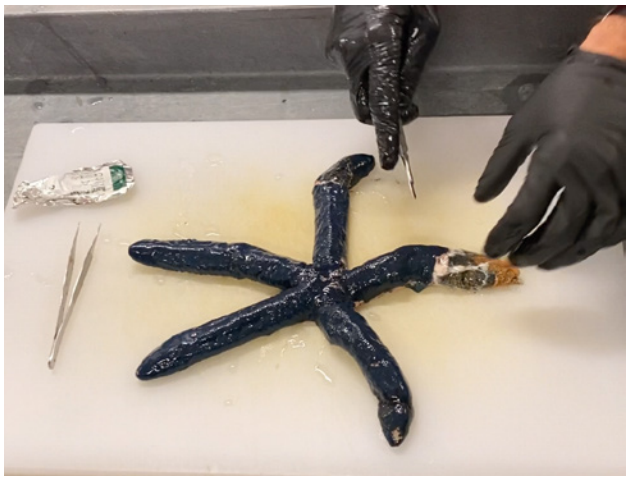

Figure 6.5 This sea star (*Linckia* spp.) has been sedated with immersion in MS-222 prior to partial amputation of a necrotic arm. Image by GA Lewbart.

Anesthetic Agents Used and Techniques

Anesthesia in sea urchins is primarily geared towards preventing spawning, preserving the commercial value of the gonad. $MgCl_2$ doses may vary by species and urchin age. A low dose of $MgCl_2$ (1.0 g/L) prevented spawning and decreased mortality in adult purple urchins (*Paracentrotus lividus*) while higher doses of 8.1–20.3 g/L were associated with increased mortality (Arafa et al. 2007). No mortality was observed in juvenile green sea urchins (*Strongylocentrotus droebachiensis*) immersed in 100 g/L $MgCl_2$ (Hagen 2003). MS-222 buffered with sodium bicarbonate was an effective sedative (0.4 g/L) and anesthetic (0.8 g/L) for sea urchins (Applegate et al. 2016). Criteria for evaluating anesthetic effects included drooping spines, loss of adhesion to a vertical surface, decreased response to tactile stimuli, and loss of righting response (Applegate et al. 2016). Other anesthetics reported for use in sea urchins are KCl (2.5-50 g/L) and 2-phenoxyethanol (30 g/L). Benzocaine (20 g/L) has been deemed unsuitable (Hagen 2003).

Pain and Analgesia

The concept that invertebrates have the capacity to feel pain is a current topic of debate. The crux of the debate may lie in the differentiation between nociception and pain. Nociception describes the neurophysiologic components leading to the sensation of pain but excludes the central perception of nociceptive input that ultimately leads to pain sensation. Pain is defined as "an unpleasant sensory and emotional experience associated with, or resembling that

associated with, actual or potential tissue damage". In humans, pain is modulated by the cerebral cortex (Xie et al. 2009). Although invertebrates do not possess a central nervous system with a well-described cortex or similar structure, a nociceptive response is present (Tobin 2004), nociceptor cells are present (Nicholls & Baylor 1968), and opioid systems have a functional role in invertebrate nociception (Kavaliers et al. 1983; Kavaliers 1988; Fiorito 1986; Saksida et al. 1993; Smith 1991; Thomas et al. 1997). No definitive answer exists, however, as to whether invertebrates perceive pain and would suffer emotional distress from it. The animals' response to chemical, electrical, and mechanical stimuli is seen by withdrawal and escape behaviors. This response is decreased or slowed when an analgesic is used (Kavaliers & Hirst 1983). It is not yet clear if this decreased response is due to a sedative effect or an analgesic effect. With the increase in pain research and animal welfare recognition, our knowledge on this complex topic will expand and these questions may be answered.

Until more information is available regarding pain perception by invertebrates, an anesthetic should be given to any animal that is subjected to a painful procedure, and the amount of stress and pain induced should be reduced through appropriate anesthetic choices.

The use of analgesic agents in invertebrate species has its own limitations since very few reports document the administration and dosing of analgesic agents, especially very small species. More importantly, there are few to no studies evaluating the effects and impact of different analgesics on the patient, receptors, anesthesia, and recovery.

More research is required in this area, but in the meantime, if possible, and if not harmful (e.g., ketorolac in blue crabs), drugs with analgesic properties should be used to anesthetize invertebrates when invasive procedures are performed. Hypothermia and CO_2 do not possess analgesic properties and may even show hyperalgesic characteristics. An inhalant agent is preferred over the latter methods. Although inhalant agents do not possess true analgesic properties, they do render mammalian patients insensible to painful stimuli when administered at sufficient doses. If a procedure is expected to be associated with significant postoperative pain, the administration of an analgesic is advisable. Knowledge concerning analgesic receptors in invertebrates, and if or how commonly used analgesics of vertebrates would apply, is sparse. Sodium channels are conserved across taxa, which makes local anesthetics (e.g., lidocaine) a promising option for invertebrate analgesia. Lidocaine injections have been shown to block afferent signal to the central nervous system and prevent behavioral responses to noxious stimuli in cephalopods, indicating analgesic properties (Butler-Struben et al. 2018; Crook 2021). Morphine does not appear to have analgesic properties in decapods (Barr & Elwood 2011).

Euthanasia

A section on invertebrates was included in the *AVMA Guidelines for the Euthanasia of Animals* for the first time in the 2013 edition, and was revised and expanded in the 2020 edition (Leary et al. 2020). Further guidance can be found in other sources (Cooper 2022; Murray 2022; Reilly 2001; Poole 1999).

Due to challenges in confirming death in many invertebrates, a two-step euthanasia protocol is recommended where the first step renders the animal nonresponsive and the second step ensures death. Acceptable first-step methods for aquatic invertebrates include immersion in clove oil, ethanol, eugenol, and magnesium salts. Acceptable first-step methods for terrestrial invertebrates include inhalant gas anesthetics delivered via an induction chamber and injection of pentobarbital-containing euthanasia solution into the circulating hemolymph. Acceptable second-step methods include immersion in fixatives such as 70% alcohol, 10% formalin, Davidson's solution, and physical methods such as boiling, freezing, and pithing. Methods that do not cause rapid death or cause stress and trauma prior to loss of response are not euthanasia. Unacceptable methods as a solo or first step for euthanasia of invertebrates include removal of aquatic animals from water or immersion of terrestrial animals in water to die by hypoxia, leaving animals in a container without aeration to die by anoxia, freezing, or immersion in a caustic chemical such as tissue fixative (Leary et al. 2020).

Despite the ongoing debate on the capacity of invertebrates to perceive pain, it is widely accepted that different species of invertebrates show various types of stress responses and react to noxious stimuli. Even if the perception of pain is not yet understood, it is our responsibility to treat every living creature with respect, assure the well-being of these animals, and decrease any stress in the best way possible (Murray 2022).

The most commonly used methods for euthanasia are terminal anesthesia followed by physical destruction of the nervous system. Physical destruction of the nervous system/primary ganglia may be added to the chemical method because death is often difficult to verify (Hackendahl & Mashima 2002). The nervous system varies in the different invertebrate species and decapitation alone may not always be a suitable method (Hackendahl & Mashima 2002). Other destructive methods may have to be implemented when doubts about the confirmation of death from an anesthetic overdose are present. More information about ideal species-specific methods of euthanasia is needed.

Specific euthanasia methods and techniques used can be adjusted for sample analyses and research goals. Horseshoe crabs can be euthanized with an injection of

1–2 mL of pentobarbital-containing euthanasia solution directly into the cardiac sinus (Smith & Berkson 2005). Sea stars have been euthanized by immersion in $MgCl_2$ (75 g/L) until they are nonresponsive followed by a physical method of quick dissection. This method allows for the isolation of high-quality RNA (Wahltinez et al. 2021). Jellyfish euthanized in an immersion of $MgCl_2$ (142 g/L) were suitable for NMR spectroscopy-based metabolomics analysis. The recommendations for cephalopods are an overdose of ethanol or $MgCl_2$ followed by brain destruction (Murray 2022; Reilly 2001; Scimeca et al. 2022). Recommended euthanasia methods for crustaceans are an overdose of ethanol or clove oil followed by destruction of ganglia (Reilly 2001). Eugenol immersion at 500 mg/L followed by intracardiac ivermectin at 5 mg/kg or KCl at 10 mmol/kg were effective methods of euthanasia in blue crabs (*C. sapidus*) (Mones et al. 2022). Injection of KCl at 13 mmol/kg at the base of the second walking leg to flood the hemolymph sinus containing the ventral nerve cord has been recommended for euthanasia of American lobsters (*Homarus americanus*) (Battison et al. 2000). Despite presumed rapid effects on the central nervous system, this method may be better applied as the second step of a two-step protocol. This method has also been applied to terrestrial arthropods, and termed "targeted hyperkalosis" to describe terminal depolarization of the thoracic ganglia leading to death (Bennie et al. 2012). Pizzi describes the immersion in 70% ethanol after general anesthesia as an acceptable euthanasia method in spiders (Pizzi 2010, 2022).

Cartilaginous Fishes: Elasmobranchs and Holocephalans

Natalie D. Mylniczenko, Charlene Burns, and Tonya Clauss

Introduction

The class Chondrichthyes comprises nearly 1200 extant species worldwide (Compagno 1999) belonging to two subclasses, Elasmobranchii and Holocephalii. They are probably the most successful of all fishes based on historical endurance in the fossil records (Grogan & Lund 2004). Elasmobranchs (sharks and batoids) represent 96% of the cartilaginous fishes while the Holocephalans (chimeras and elephant fish) represent only 4% (Compagno 1999) and, as such, elasmobranchs are the primary focus in this chapter. With so many different species and such a variety of anatomical and physiological characteristics among them, immobilization and anesthesia can be challenging. Additionally, much of the information relied on for anesthesia in cartilaginous fishes has been anecdotal.

Growth of the aquatic animal medicine field has resulted in a greater breadth of clinical experience with teleost and elasmobranch fishes. This has led to some generalities that can be applied to facilitate safe and effective immobilization and anesthesia.

Decisions on whether to manually or chemically immobilize an animal should be based on the invasiveness of the procedure planned, the duration of time the animal will need to be immobilized, the experience and capabilities of the staff involved, and human and animal safety. When chemical immobilization is deemed necessary, determination of what drug or drug combination should be used depends on the level and duration of sedation or anesthesia desired, the method and feasibility of delivery of the drug, and the ability to safely support and monitor the animal through recovery.

Anatomy and Physiology

The anatomy and physiology of cartilaginous fish has been well described in detail in other texts (Carrier et al. 2004, 2011; Hamlett 1999; Oetinger & Zorzi 1995; Smith et al. 2004; Mylniczenko 2021). Overall there is notable variability in the response of elasmobranchs to handling and anesthesia, which is due to physiology and anatomy. The animal's response to a drug is dependent on many factors, including drug receptor type, tissue distribution, method of administration, body temperature, hepatic biotransformation, blood distribution, renal function, and respiratory mechanism and function. These factors, among others, explain the frequent variation of drug effect seen in elasmobranchs both within and between species. This may be due to receptor binding differences (presence or lack of receptors to a specific drug), affinity to the receptor, different physiological response to the binding, and numbers of available binding sites for a small or great response. Drugs can also bind with blood proteins or other nontarget tissue, thus altering the amount of drug available and the effect on target tissue. In elasmobranchs, albumin is not present (Krol et al. 2014), which would impact a drug that requires albumin for transport. Additionally, naturally high levels of urea may impact the functionality of drugs.

Intramuscular injections may produce inconsistent responses due to the variable density of vasculature and location of associated myotomal muscle bodies (Bernal et al. 2001; Bernal & Graham 2001; Totland et al. 1981). As with some teleosts, sharks also have red and white muscles (Fig. 7.1a). The red (myotomal) muscles are slow contracting ("slow twitch") and aerobic, whilst the more predominant white muscles require less oxygen and are faster to contract ("fast twitch"). Relative abundance makes injections into the fast twitch muscles more likely. Anesthetic injections in the red muscle may result in more rapid induction times, as has been noted in some teleosts (Williams et al. 2004). Some drugs that produce a notable response when administered intravenously may produce little to no response when delivered intramuscularly or orally (Clauss et al. 2011; Mylniczenko, pers. exp.).

Active, pelagic sharks (e.g., hammerhead [*Sphyrna mokarran*] and blacktip [*Carcharhinus limbatus*]) have a

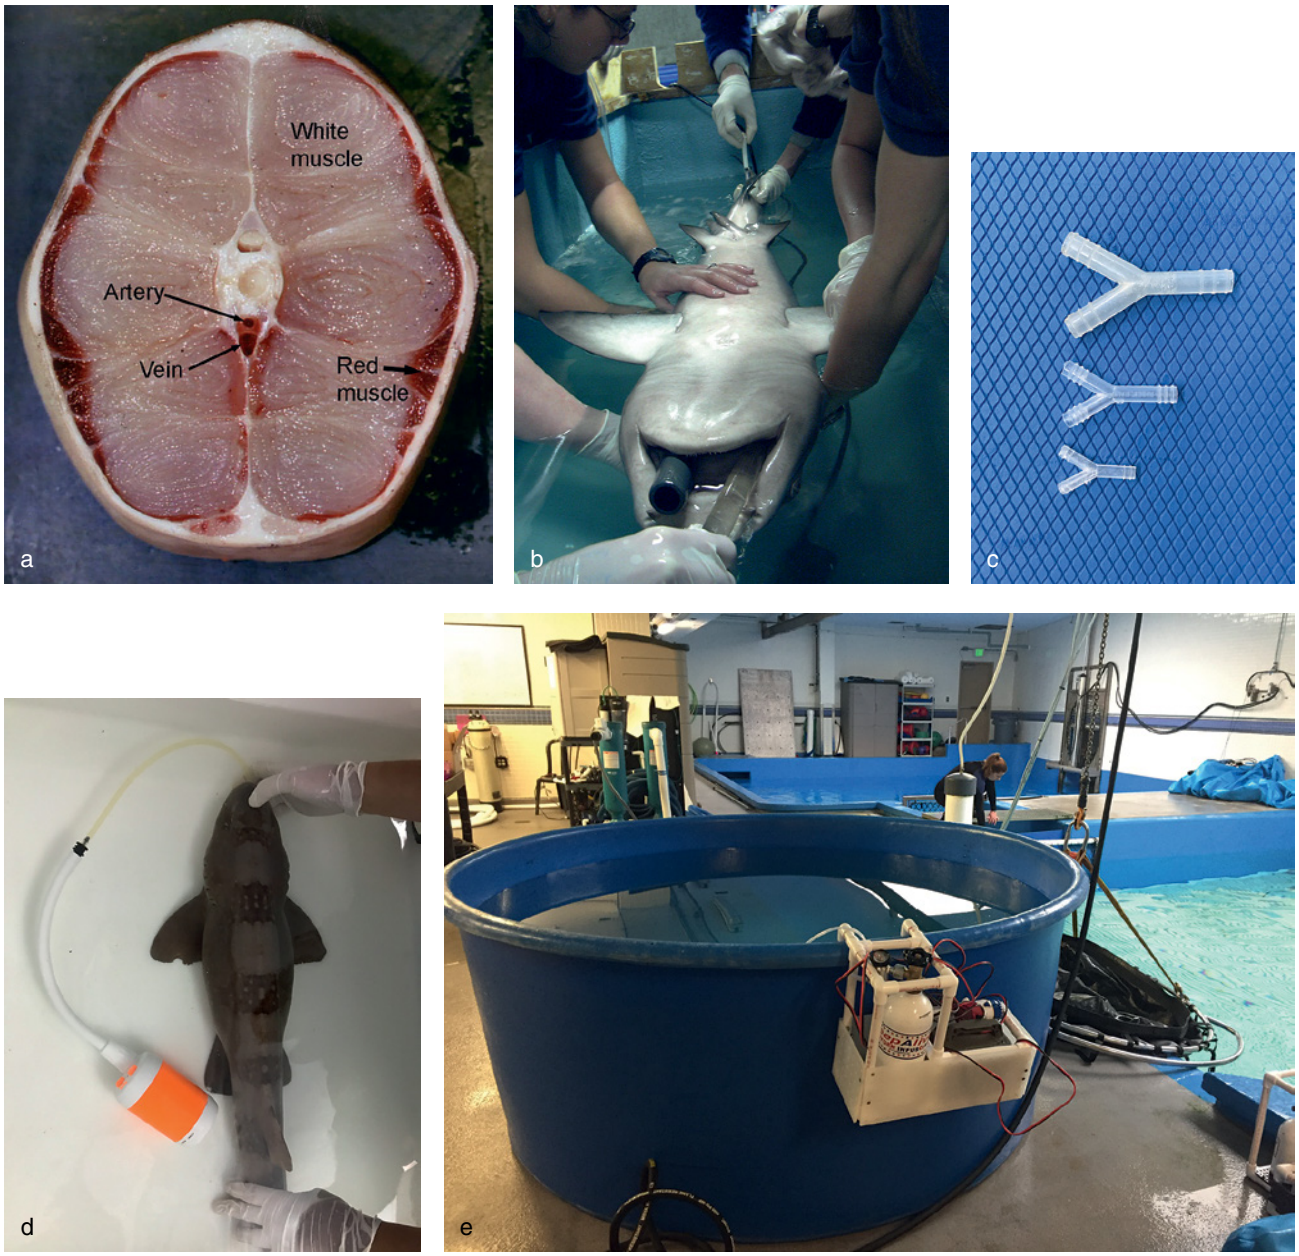

Figure 7.1 (a) Cross-section of the tail of a blacktip reef shark (*Carcharhinus melanopterus*) demonstrating the more vascular or "red" muscle in comparison to the "white" muscle. Note the location of the artery and vein in comparison to the vertebral column. (b) Assisted ventilation in a sandbar shark (*Carcharhinus plumbeus*). There is a PVC tube in place to keep the mouth open. A continuous flow pump is used to direct oxygenated water over the gills. Water flow out of the gill slits determines the appropriate positioning. (c) Variable "Y" pieces for ventilatory equipment that can distribute water flow to each gill series; these are size appropriate for smaller species. (d) Rechargeable, portable, underwater camp shower that can be used for ventilation of smaller elasmobranchs. (e) A portable oxygen tank and water-resistant battery pack to deliver oxygenated water via pump.

higher percentage of myotomal muscles (up to 22%) than less active sharks (e.g., nurse shark [*Ginglymostoma cirratum*] and epaulette [*Hemiscyllium ocellatum*]) (Bone 1999). Although more active sharks from the family Lamnidae (e.g., porbeagle [*Lamna nasus*], mako [*Isurus oxyrinchus*], white [*Carcharodon carcharias*]) and the common thresher shark from the Alopiidae family have a similar muscular plan to those previously mentioned, their myotomal framework is unique and more comparable to that of scombrid teleosts (e.g., tuna and mackerel). In these species, the red muscle is condensed into a solid piston-like muscle mass that is found closer to the vertebrae (Bernal et al. 2001; Carey et al. 1985; Graham & Dickson 2000, 2001; Graham et al. 1983; Sepulveda et al. 2005). In these highly active

elasmobranchs, the vascular supply to this red muscle is through a set of lateral vessels that give rise to a countercurrent heat exchange system (retia mirabilia). This allows conservation of metabolically derived heat, giving these sharks some endothermic abilities. The red muscle temperature may be elevated significantly above ambient (Bernal et al. 2003; Bone & Chubb 1983; Carey et al. 1982) and produce regional heterothermy. Environmental temperature may have little to no impact on the metabolic rates of these endothermic sharks. Ambient temperature, however, plays a major role in controlling the metabolic rates of the majority of elasmobranchs, which are ectothermic. Body temperature therefore must be considered as it impacts metabolic rates, determines enzyme activity, and may influence drug elimination and duration of effect.

In most studied animals, the liver metabolizes certain drugs to either active or inactive forms. Elasmobranch liver size and composition are species dependent but it is overall larger than in other animals and more lipid rich. In the normal animal, it can account for up to 23% of body weight and as much as 80% may be lipid (Holmgren & Nilsson 1999). Drug pharmacodynamics are dependent, in part, on their lipophilic or lipophobic solubility, as well as the amount of hepatic cellular exposure. This adds an additional layer of complexity to drug metabolism in elasmobranchs. Unfortunately, there is very little pharmacokinetic data in elasmobranchs, especially regarding anesthetics.

The kidney is very different to that of mammals, having a higher filtration rate (Lacy & Reale 1999) and is critical for the maintenance of the natural high osmolarity (Henderson et al. 1988) These differences may influence drug elimination rates. Like reptiles, elasmobranchs have a renal-portal system that allows blood from the caudal half of the animal to drain directly into the kidneys. Historically, injections in the caudal half of the body were avoided in reptiles and fish as theory suggested the renal portal system may enhance the nephrotoxicity or influence renal excretion of drugs. Studies in reptiles, however, found no significant difference in drug metabolism when injections were given in the fore or hind limbs, suggesting the renal portal system has little, if any, negative influence on drug metabolism (Beck et al. 1995; Holz 1999; Holz et al. 2002). Based on studies in reptiles, it is unlikely the renal portal system poses a threat to drug action or metabolism in elasmobranchs.

The basic function of the respiratory system is the exchange of gasses (oxygen and carbon dioxide). While simplistic in theory, elasmobranchs manage their metabolic exchange of these gasses differently. Elasmobranch respiration can be loosely based on their preference of habitat: pelagic (open water), intermediary, and benthic (bottom). Examples of these include (1) pelagic: black tip (*C. limbatus*) and blue shark (*Prionace glauca*); (2) intermediate: sand tiger shark (*Carcharhinus taurus*) and brown shark (*Carcharhinus plumbeus*); (3) benthic: Japanese wobbegong (*Orectolobus japonicus*) and the nurse shark (*G. cirratum*). Many pelagic elasmobranchs rely predominantly on ram ventilation, forcing water over their gills by swimming constantly. The nonpelagic animals can pump water over their gills via buccal pumping and can rest on the bottom for extended periods of time. These animals tend to have a higher tolerance for anaerobic conditions (Mylniczenko et al. 2007). Benthic animals are those that spend much of their active time on the sea bottom, while the intermediates swim more than they rest. The classifications are not strict. In general, benthic animals can buffer acidemia and/or manage hypoxemia more efficiently. This is critical because activity (such as capture) will significantly affect elasmobranch blood gasses and physiologic status. In general, there are few obligate ram ventilators in aquaria, but these animals need additional care during anesthesia and recovery to ensure adequate ventilation.

Most benthic sharks and batoids have a supplemental respiratory feature, the spiracle, located dorsally behind the eyes. This opening may serve as an alternate route for channeling water over the gills when the mouth of elasmobranchs is in contact with the sediment or substrate. It is suggested that the spiracle function is voluntary to prevent sand entry into the gills (Butler 1999). During anesthesia, ventilation may occur either via the mouth or through the spiracles. The advantage to ventilation via the mouth is flow may easily be directed over both gill sets simultaneously (Fig. 7.1b–d). Specific modifications are necessary to achieve simultaneous flow over both gill sets when water is directed through the spiracles. An example of this is a mouthpiece shaped as a "Y" (Fig. 7.1c). To facilitate a safe, portable, waterproof method of providing ventilation, a camp shower can be modified (Fig. 7.1d). Addition of oxygen pumped into the water can provide additionally ventilatory support (Fig. 7.1e).

Elasmobranchs possess a functional hypothalamic–pituitary–interrenal (HPI) axis based on the presence of adrenocorticotropic hormone (ACTH), which regulates interrenal production of 1α-hydroxycorticosterone (1α-OHB), a primary corticosteroid, which is produced only in elasmobranchs. Only recently, an assay developed for its measurement (Anderson 2012; Idler & Truscott 1966, 1967, 1968, 1969; Truscott & Idler 1968, 1972; Wheaton et al. 2018). Comparatively, cortisol is not present in elasmobranchs, while it is the primary corticosteroid in teleost fish (Skomal & Bernal 2011). Corticosterone (CS) is also found in some elasmobranch species (Rasmussen & Crow 1993; Rasmussen & Gruber 1990, 1993; Snelson et al. 1997), but 1α-OHB has been shown to be the dominant

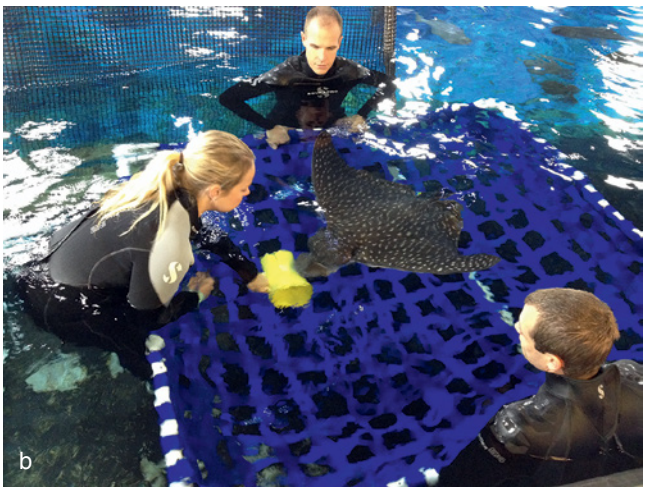
hormone. CS assays are often not accurate and there is cross-reaction (Anderson 2012; Skomal & Bernal 2011). The hormone has a proposed mixed role in mineralocorticoid and glucocorticoid responses, thus fluid shifts and energy utilization with a stress response can alter how the animal responds to handling as well as drug absorption and distribution.

There are few studies of the role of the HPI axis in regulating the elasmobranch primary stress response. Catecholamines increase immediately after a stressor and peak after the cessation of the event (Randall & Perry 1992). Manire et al. (2007) found both a short- and long-term CS response to capture and handling in bonnethead sharks (*Sphyrna tiburo*). These reports suggest a relationship between a stressful event and the activity of the interrenal gland. The secondary stress response has been studied more than the primary response, receiving a lot of attention in the last several years (Van Rijn & Reina 2010; Frick & Reina 2009; Karsten & Rice 2004; Mandelman & Farrington 2007; Mandelmann & Skomal 2009; Marshall et al. 2012; Naples et al. 2012; Renshaw et al. 2012). New data show a correlation of 1α-OHB with the secondary stress response (Wheaton et al. 2018). This information can be very useful in assessing elasmobranchs during the timeframe of a restraint; clinical applications will be discussed later in this chapter.

In addition to the stress response, other physiological or anatomical factors that may influence the drug response include gill health, lipid content, health status, and body condition changes associated with age, season, sexual maturity, and nutrition. There are many variables that need to be considered when anesthetizing elasmobranchs.

Capture

Many elasmobranchs housed in public aquaria share large systems with mixed species. Catching these animals can be challenging and even dangerous to both the people and animals involved. Retrieving these animals may be done either by behavioral conditioning, manually using a variety of techniques, or with chemical immobilization. Regardless of the method used, minimizing distress and maintaining safety should be primary goals.



Elasmobranchs are very responsive to behavioral conditioning and training techniques. The benefits of animal training programs include enrichment, better animal control and monitoring, reduced stress during handling, implementation of advanced husbandry techniques, enhanced education programs, and positive associations between animals and caretakers (Baker 1991). Operant conditioning is a process by which a subject produces a behavior in the presence of a cue on the condition of achieving desirable outcomes or avoiding undesirable consequences. While the training of sharks and rays may be somewhat limited, several facilities have achieved impressive results through operant conditioning and behavioral modification (Fig. 7.2).

Behaviors as seemingly simple as target training or station feeding can be invaluable and can facilitate shifting to different areas of an exhibit, stretcher trainer, morphometrics, and layouts for ultrasounds (Fig. 7.3a–e) (Sabalones, pers. exp.). A useful method is to swim or direct animals into a deflated swimming pool (which is then inflated once the animal is captured) or into a chute/restraint device for induction of anesthesia (Fig. 7.3f–i). Additionally, training animals to swim onto a ramp and then into a net or directly into a net (or stretcher) facilitates examinations and treatments (Fig. 7.3c–e). Behavioral management in some of the larger elasmobranchs is arguably a necessity as manually catching and restraining can be difficult, if not impossible, and has the potential to cause significant stress and possible injury to the staff and animal(s).

When animals are not conditioned to present behaviorally for examinations or other procedures, more active capture techniques must be used and may or may not involve administration of drugs. A shark 'sock' has gained popularity at aquaria (Fig. 7.4a). A clear vinyl bag is used which has the narrow end covered with a nylon mesh and the opposite to enable water flow to be directed at the head of the shark. Divers operate the bag, one at the closed end and two at the entrance. The animal (sedated or not, species dependent) is guided into the bag and the apparatus is then brought to the procedural area (Daly et al. 2007) (Fig. 7.4a,b). Unanesthetized large batoids (e.g., bowmouth (*Rhina ancylostoma*) (Fig. 7.4c) and giant guitarfish (*Rhynchobatus djiddensis*), sawfish (Fig. 7.4d,e) and other large elasmobranchs (Fig. 7.4f) can be caught using a large box net. The square PVC frame and attached knotless net is sunk to the exhibit floor. Divers in SCUBA corral the target animal over the net and people at the surface then haul the net up rapidly. The animal may then be restrained manually or chemically. Smaller sharks such as bonnetheads and blacktips may be caught via a hoop net when they approach a feeding station.

In some cases, a net draped across the width of a tank and pushed across the length of the enclosure (much like seine netting) can be used to both encourage animals into a medical pool and to limit the overall size of the area animals need to be captured in. This technique also allows the possibility to significantly reduce the depth of the area by bringing the bottom of the net to a more comfortable depth (Fig. 7.4g,h). Disadvantages include the number of staff/divers required to execute a "catch up" as well as catching multiple animals and nontarget animals. Animals

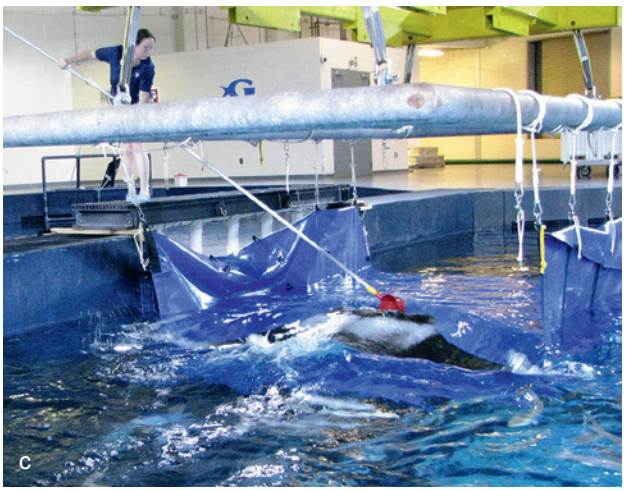


Figure 7.2 (a) A sandbar shark (*Carcharhinus plumbeus*) target feeding during a training session. (b) An eagle ray (*Aetobatus narinari*) targeting a stretcher in a training session. (c) Behaviorally conditioning a manta ray (*Manta alfredi*) to swim into and through a stretcher. Photo credit: Georgia Aquarium.

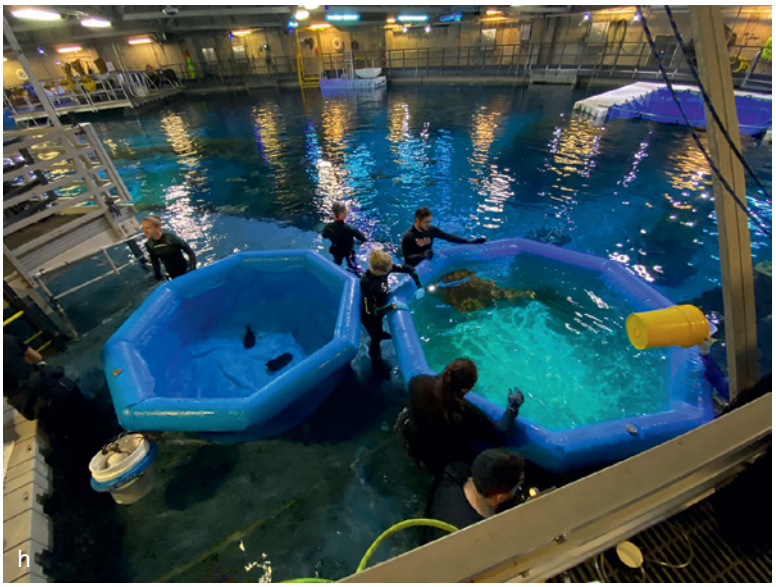
such as sawfish in these situations are difficult to manage and need to be excluded.



Drugs may also be used to assist in retrieving elasmobranchs from an exhibit or holding system. Immersion anesthetics are often impractical (but possible) due to tank size and the presence of other animals. However, divers may spray very concentrated immersion agents such as tricaine methanesulfonate (MS-222) or eugenol directly over the gills (into edge of mouth/face) to sedate it long enough to gain physical control. Injectable drugs may be delivered while the animal is swimming. This is usually done intramuscularly, but intravenous anesthetics have been delivered to a variety of rays and whale sharks by staff at the Okinawa Churaumi Aquarium in Okinawa, Japan (Makio, pers. comm.) and to whale sharks at the Osaka Aquarium Kaiyukan in Osaka, Japan (Takaomi, pers. comm.).

When dealing with more active or aggressive animals, diligent care must be taken when administering drugs via pole syringe, nearby darting apparatus, and especially when hand injecting. Animals when surprised, even if partially sedated, may turn around on a diver and inflict harm in their effort to ward off a threat. The speed of the animal and the trauma from their teeth or skin cannot be underestimated. Oral medications may also be delivered if the animal in question is target or station trained.

Oral doses required to sedate elasmobranchs are often quite high and the amount of drug required may be volume limiting or cause the animal to regurgitate the food item it is delivered in. As with injectable agents, the response to oral anesthetics is often unpredictable. Anesthetics and sedation will be discussed in greater detail later in this chapter.

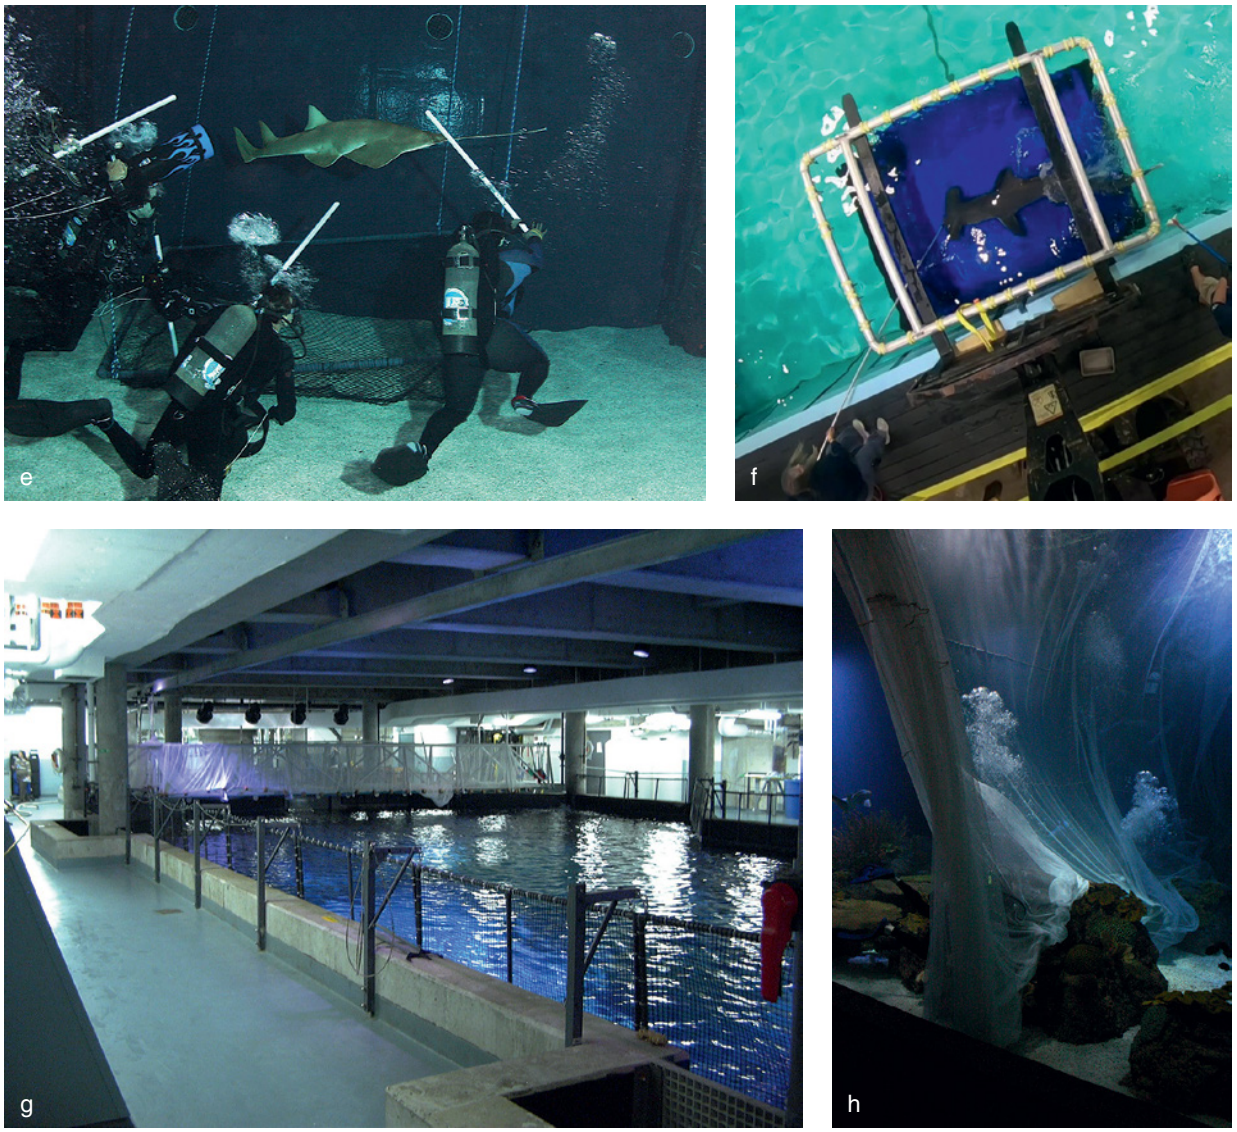

Figure 7.4 (Continued)

Physical Restraint

Tonic immobility (TI) or "hypnosis" is a defensive behavior resulting in a temporary state of "profound and reversible motor inhibition elicited by some forms of physical restraint" (Monassi et al. 1999). It is induced by placing an animal in dorsal recumbency. Once in TI, animals may exhibit either hypo- or hypertonicity and usually have a deep rhythmic respiratory pattern (Brooks et al. 2011; Kessel & Hussey 2015; Williamson et al. 2018; Mukharror et al. 2020). These animals, especially batoids, may go through a period of marked excitability during the initial catch and handling, but once in this hypnotic state, they are subdued. The level of restraint and duration of effect is highly variable between species.

When immobilized with TI, the blood pressure and heart rate of *C. melanopterus* decreased significantly. Branchial irrigation improved blood pressure in these animals, but heart rate was unchanged (Davie et al. 1993; Henningsen 1994). This indicates a vagal nerve response with the ability to have physiologic shifts based on ventilator support. Some aquaria report that pinching the dorsal fin will have a calming effect on some species, akin to reptile ocular–vagal responses, but this is anecdotal and not recommended as an initial stand-alone method of restraint. A controversial notion is that tonic mobility is appropriate as an anesthetic for surgical implantations (Kessel & Hussey 2015) but this warrants serious consideration for several reasons: no analgesia or hyperalgesia can occur and TI is frequently misunderstood and a true physiologic TI

state should be ensured (versus manual restraint). Animals should be ventilated appropriately to provide adequate oxygenation as respirations are altered. It may be that in field situations TI is chosen to allow an animal a more immediate recovery for return to the wild or that regulatory agencies will not approve the use of medications in animals being released. It is suggested that TI is "inherently a stressful experience". This is based on bloodwork changes in *Negaprion brevirostris* when they experience TI or when it is unsuccessful (Brooks et al. 2011).

Even when not utilizing manual restraint for an entire procedure, it is often necessary at the onset of a chemical immobilization. In those cases, rapid capture and restraint either by netting or by hand is recommended. Pursuing animals for prolonged periods frequently results in rapid elevations of lactate and acidemia. Only experienced staff should be involved with manual restraint of elasmobranchs. Even some of the smallest species are extremely strong, thus increasing the chances of injury to people and animals. Some additional human safety factors to consider include (1) abrasions from the placoid scales in sharks and some rays, (2) sharp teeth or crushing plates in the oral cavity, (3) barbs on stingrays, and (4) in some of the freshwater ray species, the surrounding epidermal bumps are venomous (Mylniczenko 2010). To mitigate these issues, under dangerous situations it is advisable to utilize baffles made of mesh and PVC or some other shielding device (Fig. 7.5a), to wear appropriate gloves that prevent bite and crush

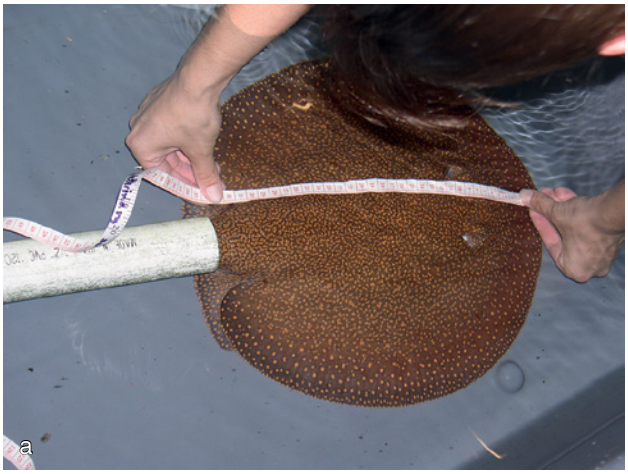

Figure 7.5 (a) A PVC safety tube placed over the tail of a freshwater stingray (family Potamotrygonidae). (b) Remote ventilation for a sand tiger shark (*Carcharhias taurus*) while recovering from anesthesia using a baffle during anesthetic recovery. (c) Remote ventilation for a brown (sandbar) shark (*Carcharhinus plumbeus*) while recovering from anesthesia in a smaller pool.

injuries (e.g., Kevlar gloves), and in some circumstances to wear suits or gloves that prevent bodily injury (e.g., chain mail suits specifically designed to work with dangerous aquatic animals) (Fig. 7.5b). Chain mail suits themselves can be very heavy and pose different safety concerns. Ideally, in case of traumatic injury, there should also be an emergency diver evacuation plan in place and access to first aid either by trained personnel or a nearby emergency response unit. A hands-off approach is possible as well, but requires more planning and facility modification (Fig. 7.5c).

Chimaerids offer unique handling challenges in that they are soft skinned and have ambient light restrictions (because they have an all-rod retina, they must minimize the amount of light that enters the retina). These animals should be handled with soft mesh or plastic nets and corralled under water as they are very sensitive to net trauma. Ideally procedures should be conducted in low light. They have a spine that precedes the first dorsal fin that contains weak venom, therefore staff should handle cautiously.

Vascular Access

Access to elasmobranchs vasculature is determined by the size and position of the animal rather than which vessel is most ideal. The largest blood vessel accessible with the animal in dorsal recumbency, in both sharks and rays, is the artery or vein that lies along the midline just ventral to the vertebral column (Figs 7.1a and 7.6a). These vessels are located by placing the needle just posterior to the base of the trailing edge of the first or second anal fins in sharks or just caudal to the vent in rays. The needle is directed anteriorly at angle of 30–90°, relative to the body, and inserted until the needle tip meets cartilage (approximately 4 cm for a 10-kg shark) to penetrate the vessel (Stoskopf et al. 1984). A lateral approach can be used as well (Fig. 7.6b). In large-bodied species and mature animals, needles may become plugged during penetration of the cartilage wall protecting the vessel. A spinal needle (with a removable stylet protecting the needle aperture) is used in these larger animals. However, longer needles may be difficult to place accurately on the midline, therefore careful threading is necessary. Abdominal vein access has also been described (Otway 2020).

There is a vascular plexus associated with the dorsal fin that is commonly referred to as the "dorsal sinus" (Fig. 7.6c). The first and second dorsal fins have this plexus and it can be found in most shark species as well as numerous batoids. The dorsal sinus is considered an access point to the secondary circulatory system, but it is a viable access port for blood collection as well as drug administration. The reader is cautioned with interpretation of blood work from this site as it does have variations compared to the central vasculature system (Mylniczenko et al. 2006). Regardless, various species have been successfully anesthetized using this route.

The pectoral fin vasculature in large sharks, such as whale sharks, as well as wing vessels in rays can be used for either blood collection or administration of intravenous drugs (Fig. 7.6c,d). The wing vessel in rays is found by palpating the ceratotrichia (cartilaginous rays) and then placing the needle in front of the cartilage, advancing the needle slowly with slight negative pressure in the syringe until a flash is obtained. The mesopterygial vessel can also be used (Westmoreland et al. 2019).

Catheterization of the ventral coccygeal vein dorsal sinus or wing veins is possible, but difficult to maintain. When successful it permits medications to be given in a direct, consistent manner over a long period of time.

Preanesthetic Considerations

Ideally, preanesthetic assessment will include a thorough history of the fish, information on water quality conditions and husbandry practices, remote observation (preferably in the original habitat), and familiarization with any unique characteristics of the species or individual. Fish often present to the clinician when they are already systemically ill. This represents an anesthetic risk, particularly since the etiology will likely be unknown until an examination is conducted.

Determining if water quality conditions may be a contributing factor in a disease process is important and evaluation prior to sedation can be helpful. If the fish has been transported to the clinician, the water quality variables of the transport vessel can be tested as well. Observation of fish in their primary habitat or even in a transport or holding vessel is useful for assessing swim patterns, posture, general appearance, and demeanor, as well as obtaining respiratory rates.

Even minimal handling can be stressful to healthy elasmobranch. A full clinical examination or blood work prior to anesthesia may therefore not be feasible or reasonable. The stress and potential trauma associated with manual restraint for diagnostics and morphometrics may be more risky than anesthetizing a fish without that information. When the body weight cannot be safely obtained prior to anesthesia, other methods exist for estimation, such as the length-to-weight ratio data for some species. When this information is not available, blind estimates may have to be made if oral or injectable anesthetics are used. However, this may greatly affect the quality and depth of the anesthesia. If this is the case, a weight and fork length should be taken once the animal is in hand and documented for future work.

Figure 7.6 (a) Collection of blood from a ventral tail vessel in a bonnethead shark (*Sphyrna tiburo*). (b) Collection of blood from a lateral approach to the ventral tail vessel in a sand tiger shark (*Carcharhias taurus*). (c) Collection of blood from the dorsal sinus in a vessel in a sand tiger shark (*Carcharhias taurus*). (d) Collection of blood from the wing vessel in an eagle ray (*Aetobatus narinari*). (e) Underwater collection of blood from the pectoral fin vasculature of a whale shark (*Rhincodon typus*) under behavioral control using a specialized feeding technique. As with most other animals, it is preferable that elasmobranchs be fasted prior to anesthesia so the anesthetic water and/or the procedure container are not fouled if regurgitation or elimination occurs. Caretakers should be instructed to bring additional water with them that may be used if the transport water is fouled and/or for recovery from anesthesia. Care should be taken to monitor water parameters such as temperature, pH, and dissolved oxygen of both the procedure water and recovery/clean water to maintain original habitat parameters.

Once an animal is removed from its primary habitat, all actions associated with transport, handling, and anesthesia should be swift and precise to minimize the stress response. Ideally, a preanesthetic meeting is conducted to ensure animal and human safety by outlining the goals of the capture, procedure, and recovery process as well as identifying the responsibilities for each person who is partaking in the event. Thorough preparation prior to an anesthetic procedure is essential in providing fish with the best opportunity for a full recovery.

Chemical Immobilization

The use of chemical restraint can provide a safer, less stressful procedure for the fish and staff involved. Minimization of movement and the ability to perform procedures with an elasmobranch out of the water often reduces handling time. Some diagnostic techniques and procedures cannot be adequately performed when animal movement occurs (e.g., magnetic resonance imaging, computed tomography, standard radiography) and thus chemical immobilization is essential. The authors have compiled cited and anecdotal dosages of the anesthetics used in various species of elasmobranchs (Table 7.1). Anesthetics may be delivered via immersion (inhalation), injection or per os.

Immersion (Inhalation) Anesthesia

Waterborne or immersion anesthesia is still the most widely used method for sedating or anesthetizing elasmobranchs and holocephalans. The chemical in aqueous solution is ventilated by the fish, passes into the blood via the gills and is delivered to the central nervous system. An extensive discussion of immersion anesthetics, including delivery techniques, mechanisms of action, metabolism, and clearance as well as advantages and disadvantages can be found in Chapter 8. The same principles used in bony fish also apply to elasmobranchs and holocephalans.

Immersion anesthetics are most commonly administered with the elasmobranch submerged in a specified concentration of the drug. Depending on clinician preference, a higher concentration of a drug may be used to induce anesthesia with a lower concentration being used to maintain the preferred plane of anesthesia. For balanced anesthesia, the authors use Aqui-S 20e™ as an induction agent and then move the animal to MS-222; this allows both drugs to be used at low doses with better recoveries than either drug alone. These chemicals have the advantage of being relatively safe to deliver and the concentration can be modified by addition or dilution of the solution. One disadvantage of immersion medications is the large amount of drug needed when immobilizing animals in large bodies of water. As previously mentioned, some waterborne anesthetics may be delivered in high concentration via direct administration to the gills. Gilbert and Kritzler (1960) anesthetized large sharks and rays with MS-222 (1 g/L) delivered through a hand pump sprayer while animals were free swimming. Care must be taken with this approach as some of these larger specimens are predatory and delivery requires the anesthetist to be in very close proximity to the mouth of the animal.

An alternative that facilitates the use of immersion anesthetics is training or conditioning the animal to shift into smaller bodies of water such as secondary systems or smaller containers. An example of the latter is an inflatable pool submerged, filled with tank water, and partially deflated in the main tank (Fig. 7.3f–h). Air is then added to the rim to fully inflate the pool once the animal is in the body of the pool. In large elasmobranchs, even after an animal is moved to a smaller container, the volume of drug needed for adequate immobilization can still be great. The technique of applying high concentrations of the anesthetic over the gills via the gill slits or through the spiracles, if present, can further reduce the volume of drug needed (Fig. 7.7).

Tricaine Methanesulfonate (MS-222, TMS)

This water-soluble, benzocaine derivative is used at a range of 50–150 mg/L to anesthetize both sharks and batoids (Larid & Oswald 1975). The concentration is varied with the species and procedures performed. If delivering via a hand pump, even higher concentrations will likely be necessary for induction (1–2 g/L). The drug is acidic and requires buffering. Sodium bicarbonate is the most used buffering agent and is usually mixed at a ratio of 2 parts buffer to 1 part drug based on the weight of the anesthetic. With that being said, recent studies have shown that sodium carbonate demonstrates a greater buffering capacity in a shorter time interval (N. Mylniczenko, pers. exp.; Waxman et al. 2021). Doses that exceeded this ratio resulted in blood gas abnormalities and clouding of the water. When the same anesthetic water is used to anesthetize multiple animals, it is wise to monitor the pH, oxygen, and carbon dioxide as shifts may occur. The authors recommend monitoring water quality or changing water after every third animal.

A direct linear relationship exists between MS-222 concentration and time to muscular relaxation (Dunn & Koester 1990). Levels of sedation and anesthesia (stages) have been described (Stoskopf 1986; Smith 1992). A wide variety of elasmobranch species will achieve a surgical plane of anesthesia (i.e., stage 3) using MS-222 (75–95 mg/L), but species-specific responses are common

Table 7.1 Anesthetic and immobilization drugs used in elasmobranchs.

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Acroteriobatus annulatus	Sandshark, lesser	Etorphine (M99) + midazolam		IM					No effect	Penning (2012)
Acroteriobatus annulatus	Sandshark, lesser	Medetomidine	0.1 mg/kg	IM		0.0.13			Fair	Penning (2012)
Acroteriobatus annulatus	Sandshark, lesser	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM		0.0.5			Fair to good	Penning (2012)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	Alfaxalone-alphadolone (Saffan)	0.35 mL/kg	IM	54	0.0.1			Tranquilization only achieved the deepest state within 1 hour with disorientation, slowed swimming, bumping into tank walls, net avoidance	Harvey et al. (1988)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	Eugenol (AquiS-20E)	15–25 mg/L	Immersion	2–94	10.9.0	Juvenile-adult	25	Typical recovery after a 30 minutes procedure on a healthy animal can be up to 30 minutes. Dilution after induction improves recovery speed.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	Medetomidine	0.1 mg/kg	IM	10–15	0.0.1			Good	Penning (2012)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM						Penning et al. (2017)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	Midazolam hydrochloride	4.6 mg/kg + 4.9 mg/kg	Oral		0.1.0	Adult		No effect first dose, supplemental dose mild sedation 15 minutes later	N.D. Mylniczenko (pers. exp.)
Aetobatus narinari	Eagle stingray, spotted (whitespotted)	MS-222 (Tricaine methanesulfonate)	40–75 mg/L	Immersion	2–94	10.9.0	Juvenile-adult	25	Juvenile specimens adequately sedated 40–65 mg/L, large females 50 mg/L	C.M. Burns & N.D. Mylniczenko (Personal experience)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Aetobatus ocellatus	Eagle stingray, ocellated	Eugenol (AquiS-20E)	15–75 mg/L	Immersion	2–75	4.8.7	Juvenile-adult	25	20–30 mg/L used to calm animal quicker, then dilute for longer procedure. Quick treatments can be done at high doses 75 mg/L for <5 minutes. Cardiac effects noted via U/S for long procedures.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Aetobatus ocellatus	Eagle stingray, ocellated	Eugenol (AquiS-20E) => MS-222	40–65 mg/L => 40–50 mg/L	Immersion	2–75	4.8.7	Juvenile-adult	25	AquiS-20e for induction within 5 minutes, then move to MS222 for maintanence for balanced anesthesia and short recovery time	C.M. Burns & N.D. Mylniczenko (Personal experience)
Aetobatus ocellatus	Eagle stingray, ocellated	MS-222 (Tricaine methanesulfonate)	45–80 mg/L, 100–125 mg/L	Immersion	2–75	4.8.7	Juvenile-adult	25	Up to 80 mg/L is used in routine or diagnostic examinations, for treatments or blood draws higher doses can be used for <10 minutes	C.M. Burns & N.D. Mylniczenko (Personal experience)
Atelomycterus marmoratus	Catshark, coral	Eugenol (AquiS-20E)	25–50 mg/L	Immersion	0.1–0.5	0.1.0	Juvenile-adult	25	High dose 50 mg/L can be used for short term (<10-minute) treatments or blood collection. Quick recovery.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Atelomycterus marmoratus	Catshark, coral	MS-222 (Tricaine methanesulfonate)	110 mg/L -> 75 mg/L	Immersion	0.1–0.5	0.1.0	Juvenile-adult	25	With frequent sedations, the patient needed increased doses for rapid induciton, but then dilution for longer duration procedures	C.M. Burns & N.D. Mylniczenko (Personal experience)
Atelomycterus marmoratus	Catshark, coral	MS-222 (Tricaine methanesulfonate)	60 mg/L	Immersion	0.1–0.5	0.1.0	Juvenile-adult	25	Varied with individuals, when animals were sedated more frequently concentration levels increased	C.M. Burns & N.D. Mylniczenko (Personal experience)
Atelomycterus marmoratus	Catshark, coral	MS-222 + propofol	150 mg/L + 1.5 mg/L	Immersion		0.0.6		21–24	Surgical plane of anesthesia	Levendosky (2020)
Bathytoshia lata	Brown (roughtail) stingray	Alfaxalone-alphadolone (Saffan)	0.2–0.3 mL/kg	IM	15	0.0.2			Deepest state within 1 hour: partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch	Harvey et al. (1988)

Bathytoshia lata (Dasyatis centroura)	Brown (roughtail) stingray	Alfaxalone-alphadolone (Saffan)	0.85 mL/kg	IM	18	0.0.1			Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance	Harvey et al. (1988)
Carcharhinus acronotus	Blacknose shark	Medetomidine + ketamine	70–100 µg/kg + 5.5–8.8 mg/kg	IM					Variable effects but did not achieve more than light sedation without supplementation of the same drugs. One animal death.	N.D. Mylniczenko (pers. exp.)
Carcharhinus acronotus	Blacknose shark	Medetomidine + ketamine	59.2–70.4 µg/kg + 2.8 mg/kg	IM		0.0.3	Juvenile	25.5	Mild to heavy sedation	M.A. Stamper (pers. exp.)
Carcharhinus albimarginatus	Silvertip shark	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM						Penning et al. (2017)
Carcharhinus brevipinna	Spinner shark	Medetomidine + butorphanol	0.1 mg/kg + 0.065 mg/kg	IM		0.0.5			Good, one later died (kidney)	Penning (2012)
Carcharhinus falciformis	Silky shark	MS-222 (Tricaine methanesulfonate)	100 mg/L	Immersion	9.5				Fair	N.D. Mylniczenko (pers. exp.)
Carcharhinus leucas	Bull shark	Medetomidine	0.1 mg/kg	IM		0.0.2	Adult		Excellent	Penning (2012)
Carcharhinus leucas	Bull shark	Medetomidine	200 µg/kg	IM	3.85		Subadult-adult	25	Stopped swimming, apnea, did not recover	M. Yanagisawa (pers. comm.)
Carcharhinus leucas	Bull shark	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM						Penning et al. (2017)
Carcharhinus leucas	Bull shark	Medetomidine + ketamine		IM		0.0.2			Poor	Penning (2012)
Carcharhinus leucas	Bull shark	Medetomidine + ketamine	100 µg/kg + 5 mg/kg	IM	4.0		1 year	25	Slow swimming, recovered but died the subsequent day	M. Yanagisawa (pers. comm.)
Carcharhinus leucas	Bull shark	Medetomidine + ketamine	150 µg/kg + 7.5 mg/kg	IM	3.9		1 year	25	Slow swimming, recovered but died the subsequent day	M. Yanagisawa (pers. comm.)
Carcharhinus leucas	Bull shark	Medetomidine + ketamine	200 µg/kg + 10 mg/kg	IM	–		1 year	25	Stopped swimming, apnea, did not recover	M. Yanagisawa (pers. comm.)
Carcharhinus limbatus	Blacktip shark	Alfaxalone-alphadolone (Saffan)	0.4 mL/kg	IM	21	0.0.1			Deepest state within 1 hour, partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch	Harvey et al. (1988)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Carcharhinus melanopterus	Blacktip reef shark	Eugenol (AquiS-20E)	30 mg/L =>70 mg/L MS222	Immersion	21.5	0.1.0	Adult	25	Good induction, good maintenance for endoscopic examination	N.D. Mylniczenko (pers. exp.)
Carcharhinus melanopterus	Blacktip reef shark	Midazolam hydrochloride	0.05–0.1 mg/kg	IM					Used as a premedication administered immediately after netting appeared to decrease stress or hyperexcitability during induction	N.D. Mylniczenko (pers. exp.)
Carcharhinus melanopterus	Blacktip reef shark	MS-222 (Tricaine methanesulfonate)	125 mg/L => 100–50 mg/L	Immersion		15.3.0		24–25.7	Induction -> maintenance dose. High dose induction around transport, then switched to manageable transport for examination to the low dose. Usually 100 to 50 mg/L	Naples et al. (2012)
Carcharhinus melanopterus	Blacktip reef shark	Propofol	2.5 mg/kg	IV	22.6	0.0.1	Adult		Pregnant; good plane at 4 minutes; 50 minutes swimming	Clauss & Hatcher (pers. comm.)
Carcharhinus melanopterus	Blacktip reef shark	Propofol	3 mg/kg	IV dorsal sinus	17.5	0.0.1	Adult		<1 minute initial effect; 40–60 minutes recovery; uteroscopy	Clauss & Hatcher (pers. comm.)
Carcharhinus plumbeus	Sandbar shark (brown)	Atipamezole	0.4 mg/kg	IM	30–70	0.3.0				C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Atipamezole	33, 36 mg/kg						12–30 minutes recovery	Lécu et al. (2017)
Carcharhinus plumbeus	Sandbar shark (brown)	Atipamezole + naltrexone	0.6 mg/kg + 0.15 mg/kg	IM	30–70	0.3.0				C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Dexmedetomidine + ketamine	0.03 mg/kg + 2 mg/kg	IM		0.1.0	3 years		Added saline to make 1 mL; mass removal	Boylan (pers. comm.)
Carcharhinus plumbeus	Sandbar shark (brown)	Dexmedetomidine + ketamine + midazolam	0.036 mg/kg + 7 mg/kg+ 0.5 mg/kg	IM	21				Able to swim animal into a net	Boylan (pers. comm.)
Carcharhinus plumbeus	Sandbar shark (brown)	Diazepam	1.2–1.6mg/kg	PO		0.0.1			Followed by MS222 staged anesthesia	N.D. Mylniczenko (pers. exp.)

Carcharhinus plumbeus	Sandbar shark (brown)	Etomidate	40 mg + 40 mg 15 min later	IM	~45	1.0.0	Adult	23–27	Procedure for diagnostics; induced TI at 29 minutes	Lécu et al. (2011)
Carcharhinus plumbeus	Sandbar shark (brown)	Eugenol	30 mg/L	Immersion	40	0.0.1		27	Induction 14 minutes, stage 3 anesthesia. Prolonged recovery 240 minutes.	Lécu et al. (2017)
Carcharhinus plumbeus	Sandbar shark (brown)	Eugenol (AquiS-20E)	10 mg/L	Immersion	30–70	0.3.0	Adult	25	Used at a low dose to transport animal short distance (<30 minutes), animal had periodic episodes of sitting on bottom	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Eugenol (AquiS-20E) => MS-222	10 mg/L => 60 mg/L	Immersion	70.00	0.1.0	Adult	25	Low dose for transport ~30 minutes, then examination in MS-222, quick recovery	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Eugenol 99%	30 mg/L	Immersion	40	1.0.0	Adult	23–27	Added with ethanol (1:8 ratio), Hook removal; stage II at 5 minutes, stage III at 10 minutes	Lécu et al. (2011)
Carcharhinus plumbeus	Sandbar shark (brown)	Ketamine + medetomidine	(2.76–4 mg/kg) + (25.4–34.5 µg/kg)	IM	12.4–15.7	4.1.0			One animal died 3 weeks after sedation suspected related to presedation muscle exertion	Lécu et al. (2017)
Carcharhinus plumbeus	Sandbar shark (brown)	Ketamine + xylazine	(10–25 mg/kg) + 6 mg/kg	IM	45–80	2.2.3			Stage 1 - plane 1 anesthesia, additional doses required to maintain sedation	Lécu et al. (2017)
Carcharhinus plumbeus	Sandbar shark (brown)	Medetomidine + ketamine	80 µg/kg + 4.8–5.3 mg/kg	IM	30–70	0.3.0	Adult	25	One attempt: sedated but reactive, enough to restrain, second attempt partial sedation for manual restrained, third attempt required additional supplements for safe restraint	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Medetomidine + ketamine + butorphanol	0.1 mg/kg + (4.0–4.5 mg/kg) + (0.07–1.0 mg/kg)	IM	30–70	0.3.0	Adult	25	Only notes from one sedation: partial sedation to baffle into net for restraint for further immersion sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	Medetomidine + ketamine + midazolam => MS-222	mg/kg + mg/kg + 2.25 mg/kg => mg/L	IM => immersion		0.1.0	Adult	25	Fair induction to move into immersion for further sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Carcharhinus plumbeus	Sandbar shark (brown)	Midazolam hydrochloride	0.05–0.1 mg/kg	IM					Premedication administered immediately after netting as animals became larger and more difficult to handle to decrease stress during induction	N.D. Mylniczenko (pers. exp.)
Carcharhinus plumbeus	Sandbar shark (brown)	MS-222 (Tricaine methanesulfonate)	50–100 mg/L	Immersion	30–70	0.3.0	Adult	25	Dilute with long procedures	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharhinus plumbeus	Sandbar shark (brown)	MS-222 (Tricaine methanesulfonate)	125 mg/L -> 50–100 mg/L	Immersion				24–25.5	High dose induction a round transport, then switched to a manageable transport for examination to the low dose. Usually 100 to 50 mg/L.	N.D. Mylniczenko (pers. exp.)
Carcharhinus plumbeus	Sandbar shark (brown)	Etomidate	10 mg/L	Immersion					Induced stage II anesthesia in approximately 2–4 minutes	Stoskopf (1986)
Carcharhinus plumbeus	Sandbar shark (brown)	Metomidate hydrochloride	10 mg/L	Immersion		1	Adult		Induced stage II anesthesia in approximately 2–4 minutes; 20 mg/L reduced induction time but not deeper sedation	Stoskopf (1986)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Atipamezole	0.3–0.4 mg/kg	IM	70–121	1.1.0				C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Atipamezole	120 mg/kg						1–4 minutes recovery	Lécu et al. (2017)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Atipamezole	5xs medetomidine dose	1/2 IV + 1/2 IM		0.0.4	Adult		Swam away 18 minutes after reversal, had no obvious post-immobilization sedation and resumed feeding within 24 hours of recovery	Snyder et al. (1998)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Atipamezole + doxapram	5xs medetomidine dose + 100 mg	IM + IV					Although both sharks resumed swimming, appeared to have incomplete reversal in that each remained sedated for several days and did not eat for 8–18 days following the immobilization	Snyder et al. (1998)

Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Atipamezole + naltrexone	0.5 mg/kg + 0.1 mg/kg	IM	70–120	2.2.0			C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Dexmedetomidine + ketamine => MS-222	0.03 mg/mL + 3 mg/L + 12.5 g/L	IM, spray to gills		1.0.0		Induction for transport, spray to gills when needed	J.M. Cavin & C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Dexmedetomidine + ketamine => MS-222	0.05 mg/kg + 10 mg/kg => 90–70 mg/L	IM, immersion		1.0.0		Induction, maintenance; plan to reduce to 70 mg/L MS-222	J.M. Cavin & C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Dexmedetomidine + ketamine => MS-222	0.03 mg/kg + 3.3mg/kg => 70–90 mg/L	IM, immersion		0.1.1		Rapid induction ~11 minutes, minute resp.; maintenance increased to 90 for one animal	J.M. Cavin & C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Dexmedetomidine => MS-222	0.03 mg/kg => 50 mg/L	IM		0.1.1		Good sedation - removed from tank after 20 minutes => transport bin	J.M. Cavin & C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Diazepam	0.1 mg/kg	IM			Adult	High individual variability. 20 minutes for induction to allow fin manipulation. If not sfficient sedation (after 30 minutes) 20% more drug was indicated. 5-hour duration.	McEwan (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Doxapram	100 mg	IV					Snyder et al. (1998)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Etomidate	1.2–1.6 mg/kg (high dose)	IM	76.5–87.5	1.2.0	Adult	More rapid and deeper level of sedation at the higher dosage, stage 2 - plane 2: slowed, came to a complete stop and did not struggle when handled. Sharks were caught immediately following administration of anesthetic.	Lécu et al. (2017)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Etomidate	0.38–0.53 mg/kg (low dose)	IM	52–77	2.2.0	Adult	Light sedation, stage 1 - plane 1. Sharks were caught immediately following administration of anesthetic.	Lécu et al. (2017)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Ketamine	10 mg/kg	IM	158.00					Tuttle (2008)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Ketamine + xylazine	15 mg/kg + 6 mg/kg	IM	200	0.2.0			For capture and transport, stage 1 - plane 1 anesthetic level, additional doses required to maintain sedation	Lécu et al. (2017)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine	0.1–0.16 mg/kg	IM	70–120	2.2.0	Adult	25	Mild to heavy sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine	0.1 mg/kg	IM		0.0.6			Good to excellent	Penning (2012)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine + butorphanol	0.1 mg/kg + 0.3 mg/kg	IM	160	1.0.0	Adult		4 minutes after injection, increased sedation. Able to guide shark for transport after 12 minutes. Sternal recumbency and ideal for transport in 20 minutes.	Larson (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine + butorphanol	0.1mg/kg + 1.0 mg/kg	IM		0.0.5			Excellent, one later died (kidney)	Penning (2012)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine + ketamine	50–100 μg/kg + 4.4–7.0 mg/kg	IM	70–120	2.2.0	Adult	25		C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine + ketamine	60.0–80.0 μg/kg + 5–10 mg/kg	IM		0.0.4	Adult	21–22	Smooth, deep narcosis within 4–18 minutes. Animals had scoliosis and lordosis; one animal was euthanized for medical reasons; not recovered.	Snyder et al. (1998)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Medetomidine + ketamine + butorphanol => MS-222	0.1 mg/kg + 5.2 mg/kg + 0.08 mg/kg => 25 mg/L	IM	70–120	2.2.0	Adult	25		C.M. Burns & N.D. Mylniczenko (Personal experience)

Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	MS-222 (Tricaine methanesulfonate)	50–80 mg/L	Immersion	70–120	3.2.0	Adult	25	Often higher dose for induction then diluting to maintanence	C.M. Burns & N.D. Mylniczenko (Personal experience)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	MS-222 (Tricaine methanesulfonate)	12.5 g/L	Spray to gills		1.0.0			Used at various times when needed	J.M. Cavin & C. Innis (pers. comm.)
Carcharias taurus	Sand tiger shark (grey nurse, ragged tooth)	Propofol	2.56–3.77 mg/kg	IV dorsal sinus	85–116.5		Adult		4–6 minutes adequate plane; 2–4 hours swimming	Clauss & Hatcher (pers. comm.)
Carcharinus obscurus	Dusky shark	Medetomidine	0.1 mg/kg	IM		0.0.6			Good, two later died	Penning (2012)
Carcharinus obscurus	Dusky shark	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM		0.0.2			Good	Penning (2012)
Cephaloscyllium ventriosum	Swellshark	MS-222 (Tricaine methanesulfonate)	100–125 mg/L=> 50 mg/L	Immersion		18		14	Induction high dose induction a round transport, then switched to a manageable transport for examination to the low dose. Usually 100 to 50 mg/L.	Naples et al. (2012)
Chiloscyllium plagiosum	Bamboo shark, whitespotted	Butorphanol	0.2 mg/kg	IV	1.6–3.0	0.2.0	Adult	25	0.2 mg/kg provided ~30 minutes of increased sedation during surgical/ invasive procedures in combination of MS-222 immersion	C.M. Burns & N.D. Mylniczenko (Personal experience)
Chiloscyllium plagiosum	Bamboo shark, whitespotted	Eugenol (AquiS-20E) => MS-222	30 mg/L => 55–65 mg/L	Immersion	2.5	0.1.0	Adult	25	AquiS-20e induction within 5 minutes then move to MS-222	C.M. Burns & N.D. Mylniczenko (Personal experience)
Chiloscyllium plagiosum	Bamboo shark, whitespotted	Medetomidine + ketamine	60 µg/kg + 3.0 mg/kg	IM						M.A. Stamper (pers. exp.)
Chiloscyllium punctatum	Bamboo shark, brownbanded	2-Phenoxyethanol (2PE)	200, 300–350, 400 mg/L	Immersion	2.3–3.9			26.1–26.9	Light sedation to deep narcosis, surgical anesthesia	M. Yanagisawa (pers. comm.)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Butorphanol	0.2–0.5 mg/kg	IV	0.8–1.5	0.2.0	Subadult-adult	25	0.2 mg/kg provided ~30 minutes of increased sedation during surgical/ invasive procedures in combination of MS-222 immersion	C.M. Burns & N.D. Mylniczenko (Personal experience)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Eugenol (AquiS-20E)	25 mg/L, 50–60 mg/L	Immersion	0.8–1.5	0.2.0	Subadult-adult	25	Sedation for treatments, increased dose for endoscopy	C.M. Burns & N.D. Mylniczenko (Personal experience)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Chiloscyllium punctatum	Bamboo shark, brownbanded	Eugenol (AquiS-20E) => MS-222	30–50 mg/L => 45–100 mg/L	Immersion	0.8–1.5	0.2.0	Subadult-adult	25	AquiS-20e induction within 5 minutes then move to MS-222	C.M. Burns & N.D. Mylniczenko (Personal experience)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Medetomidine + ketamine	(100–400 μg/kg) + (5–20 mg/kg)	IM	2.3–5.0			20–26.7	Varying doses provided increasesd anesthetic plane	M. Yanagisawa (pers. comm.)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Medetomidine + midazolam hydrochloride + butorphanol	0.1 mg/kg + 1 mg/kg + 1 mg/kg	IM + IV		0.0.4	Adult		No response from IM doses, IV dosages produced light sedation that allowed handling and minor procedures (transponder, blood draws, pin prick to evaluate)	N.D. Mylniczenko (pers. exp.)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Propofol	2.5, 4.0, 5.0 mg/kg	IV	4.86 -5.1			22.0–25.0	2.5–4.0 mg/kg provided adequate stages of anesthesia, 5.0 mg/kg animal became apneic	M. Yanagisawa (pers. comm.)
Chiloscyllium punctatum	Bamboo shark, brownbanded	Propofol + fentanyl citrate	(2.0–2.5 mg/kg) + (1.5–5.0 μg/kg)	IV	3.6–4			21–29	Provided apporiate levels of anesthesia	M. Yanagisawa (pers. comm.)
Chiloscyllium spp.	Bamboo shark sp.	2-Phenoxyethanol (2PE)	0.02 mL/L	Immersion		0.0.1			Sedated for radiographs	Larson (pers. comm.)
Chiloscyllium spp.	Bamboo shark sp.	MS-222 (Tricaine methanesulfonate)	50–100 mg/L	Immersion	0.17–3.0	1.7.0	Juvenile-adult	25		C.M. Burns & N.D. Mylniczenko (Personal experience)
Chiloscyllium spp.	Bamboo shark sp.	Tiletamine + zolazepam (Telazol)	5, 10, 15, and 20 mg/kg	IV, IM		0.0.8			Increased the duration of apnea with increased dosages. 15 mg/kg provided complete immobilization within 15 minutes lasting up to an hour with the least amount respiratory depression.	Adams & Krol (2015)

Dasyatidae spp.	Miscellaneous species	MS-222 (Tricaine methanesulfonate)	50–80 mg/L	Immersion	2.5–57	38.115.15	Subadult-adult	25–28	Average to good, typical dose around 60 mg/L	C.M. Burns & N.D. Mylniczenko (Personal experience)
Elasmobranchii	Miscellaneous species	2-Phenoxyethanol (2PE)	0.15 mL/L	Immersion					Suggested for group/tank sedation. Higher concentrations of 2-PE did not appear to have negative effects, but animals showed a more rapid and deeper sedation.	Vaughan et al. (2008); Penning (2012); Penning et al. (2017)
Elasmobranchii	Miscellaneous species	Atipamezole	5:1 ratio of atipamezole: medetomidine	IV						Lécu et al. (2017)
Elasmobranchii	Tiger shark	Atipamezole + naltrexone	0.5 mg/kg + 10 mg/kg	IM					Animals were typically left alone to recover. After 10–20 minutes, the elasmobranch was generally able to move, breathe and swim unaided.	Penning et al. (2017)
Elasmobranchii	Miscellaneous species	Eugenol	2–5 mg/L	Immersion					Used for mild sedation of elasmobranches during transport	Lécu et al. (2017)
Elasmobranchii	Miscellaneous species	Eugenol	20–40 mg/L	Immersion						Lécu et al. (2017)
Elasmobranchii	Miscellaneous species	Naltrexone	0.14–1.3 mg/kg	IV					Reversal	Clauss & Hatcher (pers. comm.)
Galeocerdo cuvier	Tiger shark	Medetomidine	0.1 mg/kg	IM		0.0.1			Excellent	Penning (2012)
Galeocerdo cuvier	Tiger shark	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM						Penning et al. (2017)
Galeocerdo cuvier	Tiger shark	Medetomidine + ketamine	100 µg/kg + 5 mg/kg	IM	250	0.0.1	Adult		15–20 minutes for induction; able to guide into PVC sock in 1 hour	Penning (2012)
Ginglymostoma cirratum	Nurse shark	Dexmedetomidine + ketamine => MS-222	0.05 mg/kg + ~9 mg/kg => 90 mg/L	IM		0.1.0			Induction, maintenance	J.M. Cavin & C. Innis (pers. comm.)
Ginglymostoma cirratum	Nurse shark	Dexmedetomidine + MS-222	0.03 mg/kg + 20 g/L	IM		0.1.0			Induction; minimal sedation after 30 minutes; 20 minutes of spraying gills in tank before sedation	J.M. Cavin & C. Innis (pers. comm.)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Ginglymostoma cirratum	Nurse shark	Medetomidine + ketamine	70–100 µg/kg + 8–10 mg/kg	IM		15	Adult		Poor to mild sedation; often ketamine was repeated at 5 mg/kg doses and medetomidine at 30 µg/kg	Kilbourn (pers. comm.)
Ginglymostoma cirratum	Nurse shark	Medetomidine + ketamine	75 µg/kg + 7.5 mg/kg	IM	20		Juvenile		No comments available	Mulican (pers. comm.)
Ginglymostoma cirratum	Nurse shark	Medetomidine + ketamine	90 µg/kg + 9.0 mg/kg	IM	68		Adult			M.T. Walsh (pers. comm.)
Ginglymostoma cirratum	Nurse shark	MS-222 (Tricaine methanesulfonate)	20 g/L	Spray to gills		0.1.0			5 minutes of spraying in stretcher	J.M. Cavin & C. Innis (pers. comm.)
Ginglymostoma cirratum	Nurse shark	Quinoline salts	0.075–0.1 mM	Immersion	4.0/21.0/4.5	1.2.0			Blood levels reached fairly constant value within 15 minutes	Brown et al. (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	10 mg/L	ICe	2–10				1 hour slowed activity, gilling, rights and swims	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	40 mg/L	ICe	2–10				25 minutes to anesthesia, gilling; 50 minutes loss of gilling; 7 hours return of gilling; 30 hours rights; 42 hours slowed activity	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	20 mg/L	IM	2–10				5 minutes slowed activity; 20 minutes weak gilling and swimming	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	40 mg/L	IM	2–10				2 minutes to anesthesia, weak gilling; 2 hours return of gilling; 24 hours rights and swims	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	60 mg/L	IP	2–10				3 minutes to anesthesia, gilling lost; 42 hours weak gilling; 54 hours rights and swims slowly	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	10 mg/L	IV	2–10				1 minute to anesthesia loss of gilling; 20 minutes return of gilling; 3 hour weakly rights	Walker (1972)
Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	20 mg/L	IV	2–10				1 minute to anesthesia loss of gilling; 3 hours return of gilling; 5 hours weakly rights	Walker (1972)

Ginglymostoma cirratum	Nurse shark	Sodium pentobarbital	60 mg/L	IV	2–10				Died	Walker (1972)
Hemiscyllium ocellatum	Epaulette shark	Tiletamine + zolazepam (Telazol)	20 mg/kg	IM		U	Adult		Allowed some manipulation (rolling over) but could not perform invasive procedures	Kilbourn (pers. comm.)
Hemiscyllium spp.	Carpet shark spp.	MS-222 (Tricaine methanesulfonate)	60–80 mg/L	Immersion	0.01–1.3	3.0.0	Juvenile-adult	25	Adequate sedation/anesthesia	C.M. Burns & N.D. Mylniczenko (Personal experience)
Heterodontus franscisci	Horn shark	MS-222 (Tricaine methanesulfonate)	125 mg/L => 100 mg/L	Immersion		1.1.1			Induction => maintenance	Naples et al. (2012)
Heterodontus portusjascksoni	Port Jackson shark	MS-222 (Tricaine methanesulfonate)	60–75 mg/L	Immersion	0.4–2.0	1.1.0	Juvenile-adult	25	Good anesthesia	C.M. Burns & N.D. Mylniczenko (Personal experience)
Himantura granulata	Whipray, mangrove	MS-222 (Tricaine methanesulfonate)	125 mg/L	Immersion		2.2.0				N.D. Mylniczenko (pers. exp.)
Himantura spp.	Miscellaneous species	MS-222 (Tricaine methanesulfonate)	50–75 mg/L	Immersion		0.0.6		25	Surgical anesthesia	C.M. Burns & N.D. Mylniczenko (Personal experience)
Himantura uarnak	Honeycomb stingray (reticulate whipray, leopard)	Eugenol (AquiS-20E)	15 mg/L	Immersion		0.0.2		25	Provided mild sedation for 30 minutes	C.M. Burns & N.D. Mylniczenko (Personal experience)
Hydrolagus colliei	Ratfish, spotted	MS-222 (Tricaine methanesulfonate)	125 mg/L => 100 mg/L	Immersion		2.2.0			Induction => maintenance	N.D. Mylniczenko (pers. exp.)
Hypanus americanus	Southern stingray	Atipamazole + flumazenil + naltrexone	(0.2–0.26 mg/kg) + 0.1 mg/kg + (0.2–0.3 mg/kg)	IV		0.5.0	Adult		Appeared to reduce sedative effects	Neiffer (Personal experience)
Hypanus americanus	Southern stingray	Atipamazole, atipamazole + flumazenil	0.42 mg/kg => 0.42 mg/kg + 0.1 mg/kg	IM, IV		0.1.0	Adult		Reversal with atipamazole IM, additional reversals supplemented IV 1 hour later	Neiffer (Personal experience)
Hypanus americanus	Southern stingray	Butorphanol	1.0 mg/kg	IV		0.1.0	Adult	25	Give IV during surgery, good effects	C.M. Burns & N.D. Mylniczenko (Personal experience)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Hypanus americanus	Southern stingray	Eugenol (AquiS-20E)	10–18 mg/L	Immersion		6.0.0	Subadult-adult	25–28	Adults can be maintained for extended period on 12–15 mg/L	C.M. Burns & N.D. Mylniczenko (Personal experience)
Hypanus americanus	Southern stingray	Guaifenisin	10–40 mg/kg	IV	20–25	0.5.0	Adult		Initial induction with MS222, then increased sedation with increasing dosage of guaifenisin to stage 2; notable period of asystole at onset of injection with rapid return to normal rhythm	Rosenberg et al. (2013)
Hypanus americanus	Southern stingray	Medetomidine + midazolam hydrochloride + butorphanol	0.05 mg/kg + 0.4 mg/kg + 0.4 mg/kg	IV		0.5.0	Adult		20 minute induction, highly variable responses	Neiffer et al. (2009)
Hypanus sabinus	Atlantic stingray	MS-222 + propofol	100 mg/L + 1.0 mg/L	Immersion		0.0.6		21–24	Surgical plane of anesthesia	M. Levendosky (2020)
Mobula hypostoma	Mobula (lesser devil ray)	AquiS-20E + midazolam	10 mg/L + 0.25 mg/kg	Immersion		0.1.0	Adult	25	Light anesthesia. Reversed flumazenil.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Mobula hypostoma	Mobula (lesser devil ray)	Butorphanol	0.2–0.6 mg/L	IV		0.1.0	Adult	25	Good response q20 minutes for coelomic surgery	C.M. Burns & N.D. Mylniczenko (Personal experience)
Mobula hypostoma	Mobula (lesser devil ray)	Eugenol (AquiS-20E)	10–19 mg/L	Immersion		0.4.0	Adult	25	Up to 19 mg/L with dilution over time	C.M. Burns & N.D. Mylniczenko (Personal experience)
Mobula hypostoma	Mobula (lesser devil ray)	Eugenol (AquiS-20E) => MS-222	15 => 60 mg/L	Immersion		0.4.0	Adult	25	Induction => maintenance, better recovery	C.M. Burns & N.D. Mylniczenko (Personal experience)
Mobula hypostoma	Mobula (lesser devil ray)	Flumazenil	0.025 mg/kg	IM					Seemingly appropriate dose	C.M. Burns & N.D. Mylniczenko (Personal experience)

Mobula hypostoma	Mobula (lesser devil ray)	MS-222 (Tricaine methanesulfonate)	50–125 mg/L	Immersion		2.4.0	Adult	25	Induced stage II anesthesia in approximately 2–4 minutes; 20 mg/L reduced induction time but not reliable depth of sedation. Rapid recovery.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Mustelus californicus	Smoothhound, gray	Eugenol (AquiS-20E)	35–55 mg/L	Immersion		0.0.3		20.1 ± 1.36	Anesthetic induction time twice as long and recovery time approximately three times as long as finfish species. Elasmobranch species exhibited a prolonged induction, with more of an excitement phase. One animal aborted pups at 24 hours.	Silbernagel & Yochem (2016)
Nebrius ferrugineus	Tawny nurse shark	Midazolam hydrochloride + propofol	0.75 mg/kg + 1.0 mg/kg	IM + IV					Stage 2, plane 2	M. Yanagisawa (pers. comm.)
Nebrius ferrugineus	Tawny nurse shark	Propofol	1.0–1.5 mg/kg	IV	7.25–10.8			28.6	Stage 2, plane 2 - stage 3, plane 1	M. Yanagisawa (pers. comm.)
Negaprion brevirostris	Lemon shark	Medetomidine + ketamine	90 µg/kg + 4.5 mg/kg	IM			Adult	26	Both animals blanched after drug adminstration; noted leakage from injection sites, undetermined amount, became recombant after handling	M.T. Walsh (pers. comm.)
Negaprion brevirostris	Lemon shark	Quinoline salts	0.075–0.15 mM	Immersion	5.7–7.0	4.1.0	Juvenile	26.5	Blood levels reached fairly constant value within 15 minutes, quickly produced anesthesia; drug enters brain rapidly	Brown et al. (1972)
Notorynchus cepedianus	Sevengill shark, broadnose	Ketamine	80 mg/kg	IM	29	1			5 minutes to first effects, then 45 minutes to slow swimming, 60 minutes easily caught in net and then moved to net	Vogelnest et al. (1994)
Orectobus maculatus	Spotted wobbegong	Eugenol	30 mg/L	Immersion	7.0–9.0	0.0.2		24.2–26.0	Good sedation	Lécu et al. (2017)
Orectolobus japonicus	Wobbegong, Japanese	MS-222 (Tricaine methanesulfonate)	125 mg/L => 100 mg/L	Immersion		0.0.3			Induction => maintenance	Naples et al. (2012)
Orectolobus japonicus	Wobbegong, Japanese	Propofol	2.2 mg/kg	IV		0.0.1			Spontaneous gill movement ceased at 3 minutes, returned at 55 minutes. Spontaneous movement at 148 minutes, full recovery at 153 minutes.	Larson (pers. comm.)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Pastinachus sephen	Cowtail stingray	MS-222 (Tricaine methanesulfonate)	65–75 mg/L	Immersion	0.53–0.67	1.0.0	Adult	25	Good sedation, diluted when necessary to improve anesthetic plane	C.M. Burns & N.D. Mylniczenko (Personal experience)
Potamotrygon motoro	Freshwater stingray	Ketamine	50 mg/kg	PO	0.093–0.1	4		(75–78 F)	Stage 2 at 10 minutes: loss of equilibrium, very slow swimming, decreased opercular movement, loss of muscle tone	Raines & Clancy (2009)
Potamotrygon motoro,	Freshwater stingray	Ketamine	20, 50 mg/kg	Oral	93–100 g	6		75–78 F	Induced a hypnotic sedation (stage 2) at 30 minutes	Raines & Clancy (2009)
Potamotrygon spp.	Freshwater stingray	Alfaxalone => MS222	0.11 mL/L	Immersion	39.5–103.6 g	0.0.8	Juvenile		Rapid induction (2 minutes) for MS-222 and 2.5 minutes for alfaxalone. Surgical anesthesia. Recovery 12 minutes for MS-222 and 24 minutes for alfaxalone.	Beckman et al. (2016)
Potamotrygon spp.	Freshwater stingray	MS-222 (Tricaine methanesulfonate)	125 mg/L	Immersion		4.2.0			Good sedation - removed from tank after 20 minutes => transport bin	N.D. Mylniczenko (pers. exp.)
Potamotrygon spp.	Freshwater stingray	MS-222 => alfaxalone	Not stated	Immersion	39.5–103.6 g	0.0.8	Juvenile		Rapid induction (2 minutes) for MS-222 and 2.5 minutes for alfaxalone. Surgical anesthesia. Recovery 12 minutes for MS-222 and 24 minutes for alfaxalone.	Beckman et al. (2016)
Potamotrygon wallacei (novel sp.)	Freshwater stingray	EOLA (*Lippia alba,* essential oil)	150, 175, 200 and 225 mg/L	Immersion	109.5 ± 30.7 g	0.0.48		26.01 ± 0.5	Recommendation over eugenol 200 mg/L EOLA (this was 'homemade' cultivated from plants at university)	de Lima (2021)
Potamotrygon wallacei (novel sp.)	Freshwater stingray	Eugenol oil	75, 100, 125 and 150 mg/L	Immersion	109.5 ± 30.7 g	0.0.48		26.01 ± 0.5	Highest concentration caused moderate to severe histological changes in the gills	de Lima (2021)

Pristis microdon	Sawfish, largetooth	2-Phenoxyethanol (2PE)	0.1–0.17 mL/L	Immersion		0.0.6			0.1 ml/L not adequate for transport; 0.145 ml/L markedly sedate, full recovery 90 minutes later	Larson (pers. comm.)
Pristis microdon	Sawfish, largetooth	Eugenol	20–30 mg/L	Immersion	11	0.0.1		24.5	Good sedation	Lécu et al. (2017)
Pristis microdon	Sawfish, largetooth	Propofol	2.0–3.0 mg/kg	IV dorsal sinus	64.7–112.5	0.0.6	Adult		2–8 minutes initial effect; 45–63 minutes full recovery; good for animal moves, examination, debridement of wounds	Clauss & Hatcher (pers. comm.)
Pristis zijsron	Sawfish, longcomb	Diazepam	0.4 mg/kg	PO					Premedication 1 hour prior to any attempted handling because the animal was considered dangerous to handlers	N.D. Mylniczenko (pers. exp.)
Pristis zijsron	Sawfish, longcomb	MS-222 (Tricaine methanesulfonate)	125 mg/L => 100 mg/L	Immersion		0.1.0			Induction => maintenance	N.D. Mylniczenko (pers. exp.)
Raja binoculata	Skate, big	Alfaxalone-alphadolone (Saffan)	0.25 mL/kg	IM	50	0.0.1			Deepest state within 1 hour: partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch	Harvey et al. (1988)
Raja erinacea	Skate, little	2-Phenoxyethanol (2PE)	0.11 mL/L	Immersion		0.0.1			Deep sedation for minor surgical procedure. Excellent sedation, fast recovery.	Larson (pers. comm.)
Rhina ancylostoma	Guitarfish, bowmouth (sharkray, mudskate)	Eugenol	30 mg/L	Immersion	17	0.0.1		24.6	Good sedation	Lécu et al. (2017)
Rhina ancylostoma	Guitarfish, bowmouth (sharkray, mudskate)	Eugenol (AquiS-20E)	15–30 mg/L	Immersion	48	1.1.0	Subadult-adult	25	Did not become sedate enough until 30 mg/L, recovery in 15 minutes	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhina ancylostoma	Guitarfish, bowmouth (sharkray, mudskate)	MS-222 (Tricaine methanesulfonate)	100–125 mg/L, 65–75 mg/L	Immersion	24–76	2.2.0	Juvenile-adult	25	Induction dose 125 mg/L, with maintenance dose of 65 mg/L. Recovery time ~30 minutes.	C.M. Burns & N.D. Mylniczenko (Personal experience)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Rhina ancylostoma	Guitarfish, bowmouth (sharkray, mudskate)	Propofol	2.22 mg/kg	IV		0.0.1			No comments	Larson (pers. comm.)
Rhincodon typus	Whale shark	Midazolam hydrochloride	3.0 mg/kg	IM	1500			29.9	Stage 2, plane 2 (animal in poor condition)	M. Yanagisawa (pers. comm.)
Rhincodon typus	Whale shark	Midazolam hydrochloride + propofol	6.0 mg/kg + 1.5 mg/kg	IM + IV	1300			28.9	Midazolam = slow swimming; propofol = stopped swimming. Stage 3, planes 2–4	M. Yanagisawa (pers. comm.)
Rhinobatos cemiculus	Guitarfish, blackchin	Eugenol	35 mg/L	Immersion	20–21	0.0.4		25–26	Good sedation	Lécu et al. (2017)
Rhinobatus lentiginosus	Guitarfish, Atlantic	Butorphanol	0.2, 0.6 mg/kg	IV		1.1.0	Adult	25	Used in conjunction with immersion anesthesia for a better surgical plane during more invasive procedures (0.2 mg/kg given q30 minutes, 0.6 mg/kg given once)	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinobatus lentiginosus	Guitarfish, Atlantic	Eugenol (AquiS-20E)	30 mg/L	Immersion		1.1.0	Adult	25	Good sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinobatus lentiginosus	Guitarfish, Atlantic	Eugenol (AquiS-20E) => MS-222	25–30 mg/L -> 50–60 mg/L	Immersion		1.1.0	Adult	25	Induction in AquiS20e, maintenance in MS222. Fin movement still occurs but animals were in a surgical plane of anesthesia.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinobatus lentiginosus	Guitarfish, Atlantic	MS-222 (Tricaine methanesulfonate)	60–80 mg/L	Immersion		1.1.0	Adult	25	Blood pH levels tend to decrease on MS222 alone	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinobatus typus	Guitarfish, giant shovelnose	Eugenol (AquiS-20E)	15–17 mg/L	Immersion		2.0.0	Juvenile-subadult	25	Mild sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)

Rhinobatus typus	Guitarfish, giant shovelnose	MS-222 (Tricaine methanesulfonate)	60–70 mg/L	Immersion		2.2.0	Adult	25	Mild to heavy sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinoptera bonasus	Cownose stingray	2-Phenoxyethanol (2PE)	0.2 mL/L	Immersion		0.0.2			Sedated for ultrasound	Larson (pers. comm.)
Rhinoptera bonasus	Cownose stingray	Butorphanol	0.2–1.0 mg/kg	IV		1.2.0	Adult	25	Supplemental dosing IV during surgical procedures, allows reduction of general anesthesia	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinoptera bonasus	Cownose stingray	Eugenol	25–75 mg/L in 50% ethanol	Immersion			Adult		Deep sedation not achieved at 25 mg/l. Recovery longer than with MS-222.	Grusha (2005)
Rhinoptera bonasus	Cownose stingray	Eugenol (AquiS-20E)	50–80 mg/L	Immersion	2–26		Juvenile-adult	25	Rapid induction for short procedures. Can be a "high" dose induction before placing in MS-222. Doses of 15–17 mg/L >30 minutes have prolonged induction and recovery.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhinoptera bonasus	Cownose stingray	MS-222 (Tricaine methanesulfonate)	50–150 mg/L	Immersion	2–26	0.0.38	Juvenile-adult	25	For short procedures, such as a barb trim or blood collection, can tolerate a dosage up to 125 mg/L. For longer procedures start with 150 mg/dL of MS-222 and move to 50–70 mg/L.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Rhynchobatus djiddensis	Guitarfish, giant	Medetomidine + butorphanol	0.1 mg/kg + 1.0 mg/kg	IM						Penning et al. (2017)
Sphyrna lewini	Hammerhead, scalloped	Etomidate + medetomidine	0.79 mg/kg + 1.3 µg/kg	IV	7.8	0.1.0			Quick recovery. Effects were short-lived.	Lécu et al. (2017)
Sphyrna lewini	Hammerhead, scalloped	Etomidate + medetomidine	1.3 mg/kg + 50 µg/kg	IM, IV	4	0.1.0			Rapid sedation with both IM and IV. Effects were short-lived.	Lécu et al. (2017)
Sphyrna lewini	Hammerhead, scalloped	Eugenol (AquiS-20E)	10 mg/L	Immersion	2.8–22	0.4.0	Juvenile	25	Used for transport (<30 minutes) with mild overt sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)

(*Continued*)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Sphyrna lewini	Hammerhead, scalloped	Eugenol (AquiS-20E)	55–75mg/L	Immersion		0.4.0		25	Recommend dilution after 15 minutes to a low dose 10 mg/L or switch to MS222. Excellent for induction and reduction of secondary stressors.	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna lewini	Hammerhead, scalloped	Eugenol (AquiS-20E) => MS-222	55–95 mg/L => 50–70 mg/L	Immersion	2.8–8.4	0.4.0	Juvenile	25	Good sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna lewini	Hammerhead, scalloped	MS-222 (Tricaine methanesulfonate)	150 mg/L => 40–65 mg/L	Immersion	2.8–8.3	0.4.0	Juvenile	25	At high dose of 150 mg/L animals very reactive, even lower doses result in significant excitatory phase; switch to eugenol for induction and then MS222 50–65 mg/L	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna tiburo	Bonnethead shark (shovelhead)	Eugenol (AquiS-20E)	100 mg/L	Immersion	0.5	0.0.3	Juvenile	25	Used for quick treatments <10 minutes (assist feeding, injections, etc.)	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna tiburo	Bonnethead shark (shovelhead)	Eugenol (AquiS-20E)	60 mg/L => 15 mg/L	Immersion	1.0–6.0	0.4.0	Adult	25	High dose, low dose recommended in this species	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna tiburo	Bonnethead shark (shovelhead)	Eugenol (AquiS-20E) => MS-222	50–60 mg/L -> 50–60 mg/L	Immersion	1.0–6.0	0.6.0	Adult	25	High dose, low dose recommended in this species	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna tiburo	Bonnethead shark (shovelhead)	MS-222 (Tricaine methanesulfonate)	100–125 mg/L -> 50–60 mg/L	Immersion	1.0–6.0	0.15.1	Adult	25	High dose, low dose recommended in this species; Aquis20E provided better induction	C.M. Burns & N.D. Mylniczenko (Personal experience)
Sphyrna tiburo	Bonnethead shark (shovelhead)	Propofol	4.0–5.0 mg/kg	IV dorsal sinus	1.4–4.65	4.9.0	Adult		1–3 minutes initial effect; 48–64 minutes swimming	Clauss & Hatcher (pers. comm.)

Squalus acanthias	Dogfish, spiny (spurdog)	Alfaxalone-alphadolone (Saffan)	0.3–0.5 mL/kg	IM	3/2	0.0.2			Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance	Harvey et al. (1988)
Squalus acanthias	Dogfish, spiny (spurdog)	Alfaxalone-alphadolone (Saffan)	1.5 mL/kg	IM	4	0.0.2			Deepest state within 1 hour: complete loss of equilibrium and cessation of swimming, no response to touch, marked depression of ventillation	Harvey et al. (1988)
Squalus acanthias	Dogfish, spiny (spurdog)	Azaperone	4 mg/kg	Spray to gills	1–5	10.11.0			Ideal for capture and confinement; still exhibit normal swimming	Latas (1987)
Squalus acanthias	Dogfish, spiny (spurdog)	Eugenol	120 mg/L	Immersion		0.0.1		9	Euthanasia: the lethal dose was triple concentration of eugenol to reach stage stage 4 anesthesia, cardiac arrest	Lécu et al. (2017)
Squalus acanthias	Dogfish, spiny (spurdog)	Hexobarbital	20 mg/kg	IV					Recovery of righting reflex - 3 hours	Adamson & Guarino (1972)
Squalus acanthias	Dogfish, spiny (spurdog)	Medetomidine + ketamine	200 µg/kg + 4 mg/kg	IM		0.0.15			Adequate for sedation, not for surgical anesthesia	Marancik et al. (2011)
Squalus acanthias	Dogfish, spiny (spurdog)	Metomidate hydrochloride	30 mg/kg	IM	3	0.0.1			Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance	Harvey et al. (1988)
Squalus acanthias	Dogfish, spiny (spurdog)	Propofol	5 mg/kg	IV		0.0.15			Good for surgical anesthesia	Marancik et al. (2011)
Squalus acanthias	Dogfish, spiny (spurdog)	Sodium pentobarbital	20 mg/kg	IV					Recovery of righting reflex - 6–8 hours	Adamson & Guarino (1972)
Squalus acanthias	Dogfish, spiny (spurdog)	Thiopental	20 mg/kg	IV					Recovery of righting reflex - 3 hours	Adamson & Guarino (1972)
Squatina californica	Angel shark	MS-222 (Tricaine methanesulfonate)	80–100 mg/L	Immersion				10–14	No comments	Ezcurra (pers. comm.)
Stegostoma tigrinum (fasciatum)	Zebra shark (sometimes leopard shark)	Midazolam hydrochloride + propofol	1.5 mg/kg + 1.0 mg/kg	IM + IV					Stage 2, plane 2	M. Yanagisawa (pers. comm.)
Stegostoma tigrinum (fasciatum)	Zebra shark (sometimes leopard shark)	MS-222 (Tricaine methanesulfonate)	50–80 mg/L	Immersion	3.0–7.6	1.1.0	Juvenile-adult	25	In this species some minimally invasive procedures can be performed without sedation using TI/stretcher	C.M. Burns & N.D. Mylniczenko (Personal experience)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Stegostoma tigrinum (fasciatum)	Zebra shark (sometimes leopard shark)	MS-222 (Tricaine methanesulfonate)	100–125 mg/L => 50–100 mg/L	Immersion		3.4.0			Induction => maintenance. High dose induction a round transport, then switched to a manageable transport for examination to the low dose. Usually 100 to 50 mg/L	Naples et al. (2012)
Taeniura lymma	Ribbontail stingray (bluespotted)	Butorphanol	0.2 mg/kg	IM						N.D. Mylniczenko (pers. exp.)
Taeniura meyeni	Round ribbontail stingray ray (blotched fantail ray)	Eugenol (AquiS-20E)	15–20 mg/L	Immersion	92	0.0.1	Adult	25	Mild sedation - light anesthesia, using AquiS-20E in this species did not show any benefit over MS-222	C.M. Burns & N.D. Mylniczenko (Personal experience)
Taeniura meyeni	Round ribbontail stingray ray (blotched fantail ray)	MS-222 (Tricaine methanesulfonate)	50–80 mg/L	Immersion	2–267	0.2.14	Newborn-adult	25	Younger rays need higher dose 65–80 mg/L, adults 50–65 mg/L	C.M. Burns & N.D. Mylniczenko (Personal experience)
Taeniura meyeni	Round ribbontail stingray ray (blotched fantail ray)	Propofol	3 mg/kg	IV	57		Adult		2 minutes initial effect; hook removal from esophagus; additional 1.5 mg/kg at 36 minutes due to movement; 88 minutes recovery	Clauss & Hatcher (pers. comm.)
Torpedo californica	Electric ray, Pacific	MS-222 (Tricaine methanesulfonate)	80–100 mg/L	Immersion	0.5			10–14	No comments	Ezcurra (pers. comm.)
Triaenodon obesus	Whitetip reef shark	Medetomidine + ketamine	90 μg/kg + 4.5 mg/kg	IM			Juvenile	27	Animal was abnormal; infection and scoliosis; stopped gilling unless touched	M.T. Walsh (pers. comm.)
Triaenodon obesus	Whitetip reef shark	MS-222 (Tricaine methanesulfonate)	100–125 mg/L => 50–100 mg/L	Immersion		0.0.7		24–25.6	High dose induction a round transport, then switched to a manageable transport for examination to the low dose. Usually 100 to 50 mg/L	Naples et al. (2012)

Triakis semifasciata	Leopard shark	Eugenol (AquiS-20E)	35–55 mg/L	Immersion		0.0.2		20.1 ± 1.36	Anesthetic induction time twice as long and recovery time approximately three times as long as finfish species. Elasmobranch species exhibited a prolonged induction, with more of an excitement phase. One animal aborted pups at 24 hours.	Silbernagel & Yochem (2016)
Triakis semifasciata	Leopard shark	Ketamine + xylazine	7, 15, 20 mg/kg + 3, 6, 10 mg/kg	IM	447.5 ± 1.2 g	2.6.0			No effects were seen at lower doses. Ketamine at 20 mg/kg and Xylazine at 10 mg/kg induced sedation within 5–9 minutes. Atipamezole was not used and recovery occurred at 10–18 minutes after sedation was induced.	Lécu et al. (2017)
Triakis semifasciata	Leopard shark	Midazolam hydrochloride	0.2 mg/kg	IM		2.0.0			No effect	C.M. Burns & N.D. Mylniczenko (Personal experience)
Triakis semifasciata	Leopard shark	MS-222 (Tricaine methanesulfonate)	45–100 mg/L	Immersion	4.6–9.0	4.4.0	Adult	25	Single anesthetic doses have been used up to 100 mg/L, however improved responses to anesthesia using high induction of 100 mg/L then titrating it down	C.M. Burns & N.D. Mylniczenko (Personal experience)
Triakis semifasciata	Leopard shark	MS-222 (Tricaine methanesulfonate)	100–125 mg/L => 50–100 mg/L	Immersion				14	High dose induction a round transport, then switched to a manageable transport for examination to the low dose. Usually 100 to 50mg/L	Naples et al. (2012)
Triakis semifasciata	Leopard shark	MS-222 (Tricaine methanesulfonate)	150 mg/L to 75 mg/L	Immersion				19	Comparative study with propofol 2.5 mg/L for I-stats/lactates	
Triakis semifasciata	Leopard shark	Propofol	2.5 mg/L	IV		0.0.1		18	2 minutes initial effect; hook removal from esophagus; additional 1.5 mg/kg at 36 minutes due to movement; 88 minutes recovery	
Triakis semifasciata	Leopard shark	Xylazine	6, 12, 18 mg/kg	IM	0.310–1.350	1.5.0			No anesthetic effect was noted at any dose	Lécu et al. (2017)

Table 7.1 (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Weight (kg, unless stated otherwise)	Sedations	Age Class	Water Temperature (°C)	Comments	Reference
Trygonorrhina fasciata	Fiddler ray, eastern	MS-222 (Tricaine methanesulfonate)	90 mg/L	Immersion					Blood and morphometrics	Clauss & Hatcher (pers. comm.)
Urobatis halleri	Haller's round stingray	MS-222 (Tricaine methanesulfonate)	60–70 mg/L	Immersion	0.3–1.2	0.0.2			Slightly light to good	N.D. Mylniczenko (pers. exp.)
Urobatis jamaicensis	Yellow stingray	Butorphanol	0.5 mg/kg	IV	2	1.0.0	Adult	25	IV during surgical procedure q30minutes	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urobatis jamaicensis	Yellow stingray	Eugenol (AquiS-20E)	15 mg/L	Immersion	2	1.0.0	Adult	25	Good sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urobatis jamaicensis	Yellow stingray	MS-222 (Tricaine methanesulfonate)	50–80 mg/L	Immersion	0.5–2.0	2.2.0	Subadult-adult	25	Good sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urogymnus asperrimus	Procupine ray	Butorphanol	0.2–0.3 mg/L	IV	63	0.1.0	Adult	25	IV immediately when placed in anesthetic bath provided a better plane of anesthesia in 70 mg/L for 30 minutes without prolonged recovery	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urogymnus asperrimus	Porcupine ray	MS-222 (Tricaine methanesulfonate)	70–90 mg/L	Immersion	23–63	0.1.0	Adult	25	Species induction can be erratic, high dose and dilution recommend or a longer wait for induction at lower doses	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urotrygon chilensis	Chilean stingray (thorny or blotched roundray)	Eugenol (AquiS-20E)	15–30 mg/L	Immersion	0.08–0.60	0.3.0	Juvenile-adult	25	Mild to heavy sedation, at higher doses <10 minutes and then dilute	C.M. Burns & N.D. Mylniczenko (Personal experience)
Urotrygon chilensis	Chilean stingray (thorny or blotched roundray)	Eugenol (AquiS-20E) => MS-222	25–30 mg/L, 55 mg/L	Immersion	0.15–0.60	0.3.0	Adult	25	Heavy sedation	C.M. Burns & N.D. Mylniczenko (Personal experience)

Urotrygon chilensis	Chilean stingray (thorny or blotched roundray)	MS-222 (Tricaine methanesulfonate)	50–70 mg/L	Immersion	0.08–0.60	0.3.0	Juvenile-adult	25	Mild sedation to light anesthesia	C.M. Burns & N.D. Mylniczenko (Personal experience)
Zapteryx brevirostris	Guitarfish, lesser	Eugenol (K-Dent)	21.25, 42.5, 85, 170 mg/L	Immersion	541.16 ± 119.18 g	11.10.0	Adult	25 ± 2	K-Dent is a dental product; according to the author 21.25 mg/L never achieved an anesthetic rating of >2, caused prolonged hyperexcitability, 42.5 was ok for procedure but took longer for sedation, 85 was ideal and 170 mf/L was excessive with prolonged recovery	Takatsuka et al. (2018)
Mustelus henlei	Smoothhound, brown	Xylazine	40 mg/kg	IM		0.0.6			No anesthetic effect noted at 1, 2, 3, 24, and 48 hours	Lécu et al. (2017)

ICe, Intracoelomic; IM, intramuscular; IP, Intraperitoneal; IV, intravenous; PO, per os.

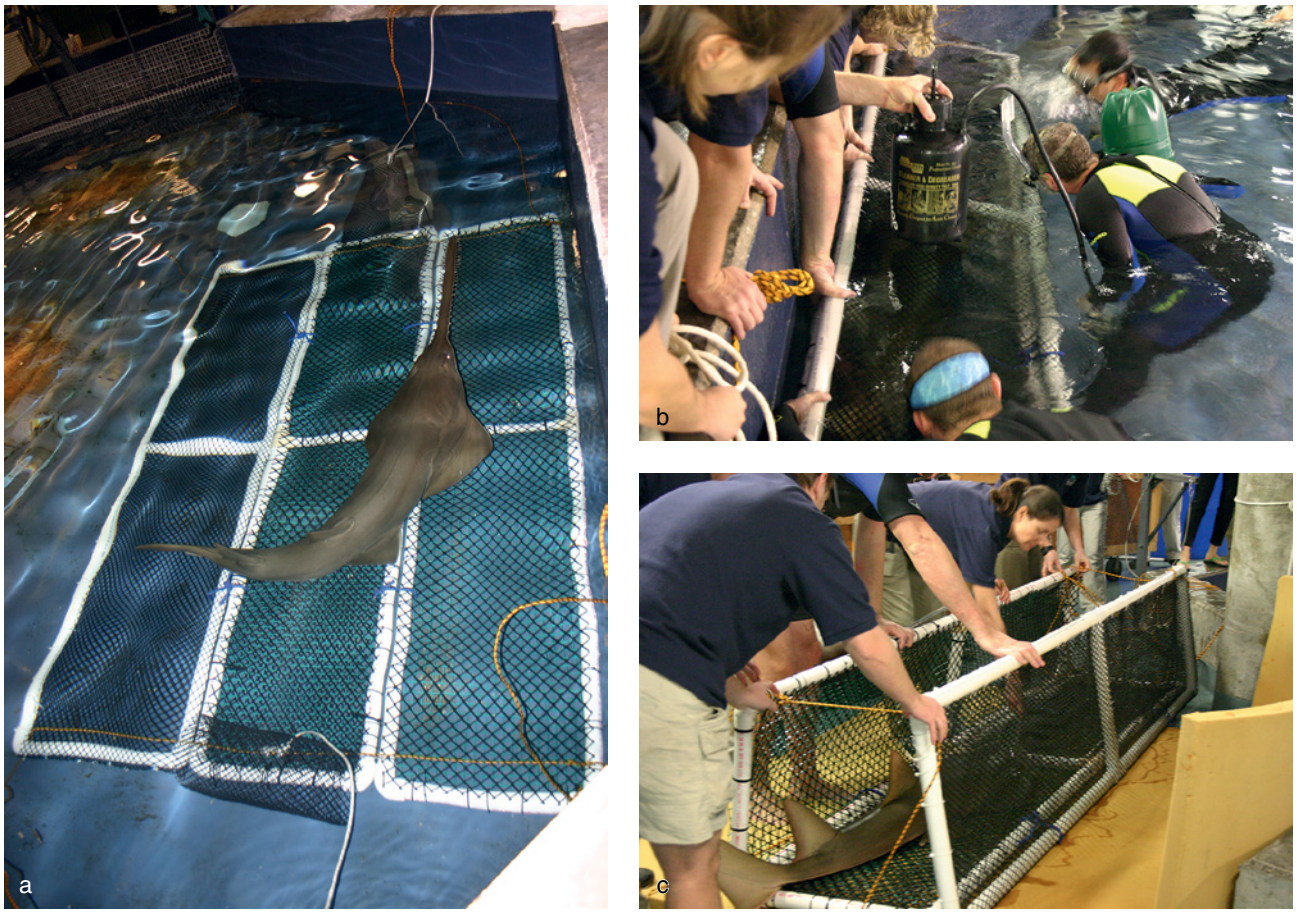

Figure 7.7 (a) Target training a green sawfish (*Pristis zijsron*) to swim over a foldable restraint device. (b) The same animal, within the folded restraint device, now in the shape of a prism with the animal's head at the far end of the photo. Divers are administering high-dose MS-222 over the gills of the animal through the device. (c) The same animal, fully anesthetized and pulled from the water, ready for examination.

(Dunn & Koester 1990). Some species of sharks have been anesthetized using a low concentration (50 mg/L) as a "preanesthetic" (sedative-type) dose followed by higher concentrations (≤85 mg/L) for maintenance anesthesia (Davis, pers. comm.). The "preanesthetic" concentration appears to reduce the excitement phase and lowers the maintenance level of MS-222. Conversely, the authors typically prefer high-dose induction (150 mg/L), especially in pelagic animals, with removal to a lower maintenance dose (50–75 mg/L). This regimen has resulted in rapid anesthesia, decreased excitement phase, better blood gas measurements, and better planes of anesthesia. Higher than 150 mg/L MS-222 will cause physical irritation to the patient.

Gilbert & Wood (1957) describe a field technique of bringing large lemon sharks (*Negaprion brevirostris*) up to the water surface with a hook and line and then applying a high concentration of MS-222 (1 g/L) with a pump handsprayer. Effects were noted within 15 seconds and the animals were anesthetized within 1 minute. It is recommended that the patient's head remain out of the water and only buffered MS-222 be applied to the gills if utilizing this technique.

MS-222 anesthesia is the preferred anesthetic for holocephalans. In the authors' experience, 80–110 mg/L buffered MS-222 provides excellent anesthesia and good recovery. There is one report of *Hydrolagus collier* being anesthetized at 0.1% MS-222 (1000 mg/L) for research purposes (Lovejoy et al. 1993).

Eugenol (Clove Oil and Aqui-S 20E™)

The active ingredient in clove oil is the phenolic compound eugenol. It is commercially available, inexpensive, and has a distinct odor of clove. Aqui-S™ (isoeugenol) is commercially produced by Aqui™ New Zealand Ltd and is not commercially available in the United States. Aqui-S 20E™ (10% eugenol) is available under an Investigation

New Animal Drug program with the Aquatic Animal Drug Approval Partnership (purchased through Aquatactics Fish Health, Kirkland, WA, USA). It is water dispersible, has a neutral pH, and reduces excitation/irritability in fish during induction. The authors favor this as an immersion drug for shorter procedures and for induction for longer procedures.

The use of eugenol and isoeugenol is useful in fractious elasmobranchs or those prone to acidemia, resulting in less frenzied swimming. Once induced, moving the patient to a low dose of MS-222 provides excellent balanced anesthesia. Disadvantages include longer induction times and if kept in it for periods greater than 15 minutes, longer recoveries. Doses used are available in Table 7.1.

Clove oil (25–50 mg/L) has been used to anesthetize epaulette sharks (*H. ocellatum*) and shovelnose rays (*Rhinobatus typus*) without complication (Grusha 2005). Controlled studies with cownose rays (*R. bonasus*) using eugenol (25, 50, and 75 mg/L) dissolved in 50% ethanol, as well as MS-222 (100 mg/L), showed similar effects for all treatment groups (Grusha 2005). The animals anesthetized with 25 mg/L eugenol, however, did not reach a plane of deep sedation. Recovery times were generally longer for the animals anesthetized with 50 and 75 mg/L eugenol compared with the rays anesthetized with MS-222. In a study with southern stingrays (*D. americana*), eugenol (20 mg/L), isoeugenol (15.7 mg/L), and MS-222 (55–65 mg/L) were compared. Minor variations were noted, but overall, all the agents provided adequate anesthesia for short-term immobilizations and minor procedures (Neiffer et al. 2009). MS-222 is considered a good induction agent as the excitatory phase is muted and induction is rapid. Once induced, moving the patient to a low dose of MS-222 provides excellent balanced anesthesia.

Disadvantages with eugenol/isoeugenol include dose-dependent longer induction times and longer recoveries if animals are maintained in it for periods greater than 15 minutes. Doses used are available in (Table 7.1). Lécu et al. (2011, 2017) used 20–40 mg/L in multiple species with good success. They also use 2–5 mg/L for transport. Since a high concentration of eugenol was used in their trials (99%) they diluted it in ethanol at 1:8 and vigorously shook the mixture for dispersal. In *Zapteryx brevirostris,* 85.0 mg/L was elected the best dose in a range from 21 to 170 mg/L) (Takatsuka et al. 2018).

2-Phenoxyethanol

2-phenoxyethanol (2-PE), a glycol ether, is a clear or straw-colored oily liquid. It has a faintly aromatic odor and is moderately water-soluble. 2-PE was used initially in aquaculture to treat ichthyophonus and other fungal, bacterial, and parasitic diseases. 2-PE has been widely used for sedation, particularly in fish transportation, as well as for general anesthesia (Ross 2001). One advantage is that it causes no pH change when added to seawater.

At uShaka Marine World in Durban, South Africa, 2-PE was mixed with dechlorinated seawater in plastic containers and poured directly into the water of two marine systems in an effort to translocate all of the teleost and elasmobranch fishes to new exhibits. Concentration increments of 0.05 mL/L were added every 30 minutes to the shark tank to a final concentration of 0.150 mL/L. Excitation events were recorded and the fishes were removed according to their effective induction to anesthesia based on loss of equilibrium. No excitation was noted in the eight sand tiger sharks (*C. taurus*), but excitation was noted at 0.100 mL/L in the two Zambezi sharks (*C. leucas*). Members of both species were guided into stretchers at the first signs of anesthesia to prevent physical injury due to collision with walls or viewing windows. Anesthesia at 0.150 mL/L lasted 70 minutes in both species. All sharks recovered well (Vaughan et al. 2008).

According to Oswald (1978), 2-PE may cause hypoventilation and it has poor analgesic properties. Sustained regular exposure can cause a neurophysiological syndrome in some individuals, thus staff handling 2-PE are advised to wear personal protective gear such as gloves and masks. Consequently, frequent use in elasmobranchs warrants caution as it is unknown if similar effects can occur. In the authors' experience, smaller sharks can be lightly sedated with an apparent wide safety margin for prolonged procedures (although doses are highly variable). However, for pelagic animals, induction length and quality of induction do not provide an advantage compared to other drugs already discussed. In general, at the doses tried, deep sedation is not achieved.

Metomidate and Etomidate

Etomidate and metomidate are GABA agonists and reportedly provide a more rapid induction and recovery than MS-222. Etomidate is more effective in alkaline water and higher water temperature, but is not affected by total hardness. In adult sandbar sharks (*C. plumbeus*), 10 mg/L of either drug induced stage II anesthesia in approximately 2–4 minutes. This stage was characterized by an absence of response to positional changes, decreased respiratory rate to approximately normal, total loss of equilibrium, no righting response, decreased muscle tone, some response to strong tactile and vibrational stimuli, and adequate restraint for external sampling (e.g., gill biopsy). Increasing

the dose to 20 mg/L reduced induction time to ≤1 minute, but anesthetic depth was more difficult to control.

Although etomidate is considerably more potent than metomidate in freshwater teleosts, this difference was not observed in sandbar sharks. Recovery from stage II plane 2 took approximately 3–5 minutes for metomidate. Recovery from deeper planes was considerably prolonged (>1 hour), speculated to be due to decreased cardiac output (Stoskopf 1986). Overall there were no advantages with immersion of either of these drugs when compared to other available water-miscible products.

Propofol

Immersion propofol has been tested in the Atlantic stingray (*H. sabinus*) and coral catshark (*A. marmoratus*) with 1 and 1.5 mg/L considered to provide surgical planes of anesthesia (Levendosky 2020).

Gas Anesthetics for Immersion Anesthesia

Halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) is an inhalation anesthetic typically used in air-breathing animals, including previous use in humans. Dunn & Koester (1990) used halothane (1.5% for induction, then 0.5–0.8% for maintenance) in nitrous oxide (100–200 mL/min) and oxygen (200–300 mL/min) for anesthesia of guitarfish (*Rhinobatas* sp.) and skates (*Raja* sp.). A precision vaporizer was used to add halothane to a mixture of nitrous oxide and oxygen that was then introduced into the water through an aerator. This combination provides easy control of anesthetic depth, shorter recovery, and a very high survival rate. A major disadvantage is contamination of the working environment room with halothane and nitrous oxide. Isoflurane (1-chloro-2,2,2-trifluoroethyl difluoromethyl ether) and sevoflurane (fluoromethyl 2,2,2-trifluoro-1-(trifluoromethyl) ethyl ether) can presumably be used in the same manner. The advantages and disadvantages of isoflurane and sevoflurane are similar to those noted for halothane and hence use of anesthetics requiring gas vaporizers is not common practice in aquatic medicine.

Gas Narcosis (Oxygen, Carbon Dioxide, Nitrogen)

Narcosis is defined as "a reversible state of arrested activity ... resulting from exposure to a xenobiotic", and narcosis and anesthesia are often used interchangeably. Most popularly, oxygen is used for "sedation" in aquaria, but its use is largely anecdotal with scant available references. As such, the border between oxygen narcosis and oxygen toxicity is not established for fish. Oxygen narcosis is used for transport or minor procedures. Hyperoxygenated (>100%, where *generally* 100% = 10 mg/dL, 120% = 11 g/dL, 140% = 13 mg/dL, etc. at 17°C; Kaill & Frey 1973) water is flushed across the gills via a power head or ventilation system. Reported signs of oxygen sedation or narcosis include decreased respiratory effort, behavioral changes including subdued activity, slower rate to recovery, and, in some cases, loss of equilibrium (Stamper, pers. exp.). Since the oxygen is not provided under pressure, supersaturation ("gas bubble disease") does not occur.

Prolonged exposure to elevated oxygen will depress ventilation and produce hypercapnia (likely the cause of narcosis) and potentially life-threatening acidemia (Spotte 1992). The use of oxygen narcosis for immobilization should therefore be limited in duration and monitoring of blood gas variables is recommended. Hyperoxygenation, even in short bursts, can also result in elevated plasma cortisol levels (Sundh et al. 2009). Chronic exposure in fish also increased the permeability of cell membranes and pathogen susceptibility (Sundh et al. 2009). Oxygen toxicity, when administration of oxygen levels exceeds biotransformation and clearance, can occur (Manning 2002). Consequently, the positive and negative aspects of hyperoxygenation must be considered in balance.

Other gasses can also cause narcosis. Carbon dioxide anesthesia is described in teleosts (Oberg et al. 2015) but not elasmobranchs. While CO_2 has some advantages (availability, inexpensive, no tissue residues) its capacity to be toxic, cause acidosis, and result in sudden death make it less ideal. Elevation of CO_2 (as with long procedures and transports) can cause sedation, although dosing and oxygen supplementation will mitigate some of those effects.

Injectable Anesthesia

Injectable anesthetics are an alternative when waterborne anesthesia is impractical due to large water volume or, as mentioned previously, when sedation is necessary to safely capture animals from complex primary exhibits. The popularity of injectable anesthesia has grown as more controlled studies offer clinicians a better understanding of the effects the drugs may have on various species. Intramuscular (IM) delivery is the most common, but intravenous (IV) and intracoelomic (ICe) administration are used in some situations.

IM delivery is typically achieved by hand injection, pole syringe, Hawaiian sling (Chapter 9), or remotely through either an underwater laser aimed dart gun (Fig. 7.8) (Aquadart; Harvey et al. 1988; Runnells & Mylniczenko 2014) or other similar remote injection devices. Additionally, the standard zoo air-charged pistols and rifles have been used from the surface with the tip of the barrel underwater aimed

Figure 7.8 An underwater dart system with laser apparatus (AQUADART; Harvey et al. 1988). See Chapter 9 for modified dart and pole syringe options.

at the patient. This method requires practice to achieve appropriate placement and discharge of the dart.

A "home-made set-up" is described for immobilizing large fishes and may prove useful for large elasmobranchs as well (Garcia-Parraga et al. 2007). When setting up a dart on a pole or extension, an air-charged dart as used in regular zoo practice is placed against a barrier at the caudal end. This is then attached to a sturdy pole (Chapter 9).

Whether an animal is free swimming or manually restrained, IM injections should be delivered quickly, ensuring reduced contact or handling time. This in turn reduces the chance of injury to the animal and people involved. The safety precautions taken when injecting free-swimming animals are described above. The challenges of underwater darting include judgment of distance, refraction from the facemask (making targeting less accurate), and getting a full discharge of darts under water (reduces gas pressure in the dart), making it less reliable than on land. With the above-mentioned laser-aimed dart gun these issues are eliminated.

As mentioned previously, many sharks have both red and white muscle (Fig. 7.1). The red, oxidative myotomal muscles usually comprise less than 10% of the body mass and consist of relatively small, well-vascularized, myoglobin-rich fibers. White myotomal muscles comprise approximately 50% of body mass and consist of less-vascularized, myoglobin-poor fibers. In fishes other than the scombrids, lamnid sharks, and the common thresher shark, the red muscle usually occurs as a relatively thin layer directly beneath the skin, gradually becoming more abundant in the posterior regions of the body (Greer-Walker & Pull 1975). Injection into different muscles will theoretically affect drug absorption. Some of the variability in response to IM drugs within a species may be due to this anatomical variation in blood supply. Skeletomuscular movement helps blood circulate (Gruber & Keyes 1981) and has a direct impact on IM drugs. Animals that are sedentary may not adequately absorb the drug through their muscles. There is also a limit to the amount of drug that can be injected in one muscle body. In rays, the musculature and cartilaginous fin rays prevent retention of high volumes.

An elasmobranch's protective denticles and epidermis make needle penetration of the integument difficult and often require the use of a heavy needle (20–22 gauge in small species, 16–18 gauge in larger species) for IM injections. Unfortunately, shark skin does not have a great degree of contractibility and muscle is at a positive resting potential. Injection site leakage is a problem. To minimize leakage, use small volumes and angle the needle either anteriorly or posteriorly to deposit the drug away from the injection site. If remotely injected darts are used to administer a drug, the dart should be left in the animal until it has become sedated, thus preventing drug leakage. Barbed or collared needles can be used. In some situations, bone wax (mix of beeswax and isopropyl palmitate), Ilex® skin protectant paste or other water-insoluble substances may be used to cover or plug the injection site when the needle is removed.

The recommended site for IM injection in a shark and elongated batoids (sawfish, guitarfish) is the dorsal saddle (Fig. 7.9). This area surrounds the first dorsal fin and extends laterally to just above the lateral line, from the posterior gill slit caudal to a point halfway between the first

Figure 7.9 Intramuscular injection into the dorsal saddle just ventrolateral to the first dorsal fin in a giant guitarfish (*Rhynchobatus djiddensis*). Photo credit: Georgia Aquarium.

and second dorsal fins (Stoskopf et al. 1984). In "flat" rays, there is adequate area for muscular injection throughout the disc, but the coelom should be avoided. Since the wings are rich with vessels, pulling back on the plunger prior to injection is indicated. IV injection is the most reliable anesthetic delivery route, providing more rapid induction and often a shorter duration of effect. Locations for vascular access are described above. Walker (1972) calculated a circulation time of 1–2 minutes for indigo cyanine green injected in the caudal tail vein of nurse sharks (*G. cirratum*). Slow circulation in elasmobranchs may delay the onset of effect of an IV drug when compared to onset times of other classes of animals. The main disadvantage with IV administration is most animals must be appropriately restrained for drug delivery. Some exceptions were previously described in which a diver swims next to an animal while administering a drug via the vasculature associated with the dorsal or pectoral fins.

ICe (into the body cavity) injection is an additional option. It requires drugs to pass through the serosal membranes of the coelomic cavity organs, making the anesthetic induction time erratic. Needle insertion at an acute angle directed anteriorly to the pelvic girdle on the right side of the abdominal wall minimizes the possibility of puncturing any internal organs, particularly the liver, which is easily damaged. In addition to unpredictable induction times and the possibility of organ puncture, other disadvantages of ICe administration include the risk of peritonitis as well as the need to place an animal in dorsal recumbency to administer the injection. The coelom is considered excretory in function (Donnelly et al. 2019) and coelomic fluid can be expelled via the coelomic pores, so volume is important to consider and can be limiting.

Injectable Anesthetics in Batoids

There are few reports on batoid injectable anesthesia, but procedures using a combination of midazolam, medetomidine, and butorphanol were successful in producing sedation adequate for minimally invasive procedures (Neiffer, pers. comm., 2011). The protocol included initial immersion in isoeugenol (15.7 ppm), followed by midazolam (0.2–0.3 mg/kg IV), medetomidine (0.035–0.05 mg/kg IV), and butorphanol (0.2–0.3 mg/kg IV) and immediate transfer to isoeugenol-free saltwater for the remainder of the anesthetic event. Recovery was complete after administration of reversal with flumazenil (0.01 mg/kg IV), atipamezole (0.228 mg/kg IV), and naltrexone (0.280 mg/kg IV). IV propofol has also been used successfully in sawfish (*Pristis microdon* and *zijsron*), cownose rays (*Rhinoptera bonasus*), and round ribbontail rays (*Taeniura meyeni*). Delivery can be via the caudal tail vein, a wing vessel, or a dorsal fin sinus of the sawfish. Dose ranges for batoids are 2.0–4.0 mg/kg and produce intermittent apnea, mild coloration changes, and expected shifts in acid-base balance. Recovery times correlate to anesthetic doses and subsequent planes of anesthesia. The longest recorded return to normal swimming in a ray was 88 minutes; this animal received two doses of propofol during a lengthy procedure to remove an embedded circle hook (Clauss, pers. comm.). An alternative in cases where anesthesia is long or depth of anesthesia needs to be increased, an elasmobranch can be placed into a low-dose immersion anesthetic for maintenance anesthesia after injectables are used. Such an example is described later using MS-222 and guaifenesin in southern stingrays.

Acepromazine

Intrasinus administration of acepromazine (0.5 and 4 mg/kg), a phenothiazine derivative, in *S. tiburo* resulted in no clinical responses (Clauss, pers. exp.).

Alfaxalone

Alfaxalone has become available again since the last publication of this chapter, but there are no reported uses. There is one abstract available (Beckman et al. 2016) on its use in Potamotrygon rays, with few details.

Historically, alfaxalone-alfadolone (Alfathesin®), a steroid anesthetic (no longer marketed in the United States), was used in the piked dogfish (1.5 mL/kg), the brown ray (*Raja miraletus*, 0.2–0.3 mL/kg), the skate (*Dipturus batis*, 0.2 mL/kg), the blacktip shark (*C. limbatus*, 0.4 mL/kg), and the spotted eagle ray (*Aetobatus narinari*, 0.3 mL/kg) (Harvey et al. 1988). The anesthetic response was highly variable, from minimal effect in the eagle ray to immobilization in the dogfish.

Azaperone

Azaperone, a butyrophenone, reduces response to environmental stimuli without motor impairment or sedation. Preliminary studies in piked dogfish (*Squalus acanthias*) showed the most efficacious application of azaperone is directly over the gills rather than by injection. No effect was noted when animals were injected with the drug IM. However, an effect was observed when the drug (4 mg/kg) was deposited on the gill filaments and the animal held out of water for several seconds (Latas 1987). At 4 hours, drugged animals, compared to control animals, showed no flight response. Blood glucose levels were unaffected. Tranquilized animals were more likely to feed compared to control animals, which exhibited several days of anorexia

after blood collection. They could negotiate tank walls and returned to normal behavior within 24 hours. The advantages of using azaperone include uninterrupted swimming patterns, normal gill ventilation, and normal cardiovascular function (Latas 1987).

When administered intrasinus (via the first dorsal fin sinus) to *S. tiburo*, a range of responses were seen. These include variable induction times (10–40 minutes), ability to handle animals, and highly varied recovery times. At the higher dosages, bottom settling was noted as well as a slow, coordinated swim pattern with obstacle avoidance. If given IM, there were no responses at 12 mg/kg, but higher dosages were not tried (volume limiting) (Clauss, pers. exp.).

Butorphanol Tartrate

Butorphanol is a systemic partial opiate agonist/antagonist used or tested as an analgesic and in combination with other injectable anesthetics (see table 8.1, Davis et al. 2006). The authors (Burns & Mylniczenko) have found that an IV dose of 0.2 mg/kg periprocedurally and perioperatively is a very useful adjunct for analgesia and for improved depth of anesthesia for short durations (~20–30 minutes). The positive effects included lower anesthetic immersion doses, cessation of movement during computed tomography scans, and elimination of reaction under surgery. Higher dosages (0.4–0.6 mg/kg) subjectively had a longer duration of obvious effects (40–50 minutes).

Carfentanil Citrate

Carfentanil citrate, an ultra-potent opioid, failed to achieve any effect in a nurse (*G. cirratum*) and a lemon shark (*Negaprion brevirostris*) at a high dosage (compared to mammals) of 0.25 mg/kg (Stoskopf 1986, 1993). This lack of response seems unusual as sharks do possess μ opioid-like receptors and peptides (Li et al. 1986; Lorenz et al. 1986). It is conceivable that as with amphibians (Wright & Whitaker 2001) the amount of receptor binding required is much higher than that reported for other animals.

Chloral Hydrate

Chloral hydrate is a hypnotic sedative whose mechanism of action is not well understood. When given intrasinus to bonnethead sharks (*S. tiburo*) at 60–80 mg/kg, reactions were variable from intermittent incoordination with little obstacle avoidance to settling on the bottom and tolerance of handling. Additionally, the drug caused minor skin reaction at the injection site (Clauss, pers. exp.).

Detomidine Hydrochloride

Dormosedan® (detomidine hydrochloride) is an alpha-2 agonist. Two trials using relatively high amounts of detomidine (115 μg/kg IM)/ketamine (4.5 mg/kg IM) in a single bull shark (*Carcharhinus leucas*) showed little effect (Stamper, pers. exp.).

Dexmedetomidine

This alpha-2 agonist gained more popularity when medetomidine could only be purchased at compounding pharmacies in concentrated form. It has been used in *C. plumbeus*, *C. taurus*, *S. tiburo*, and *G. cirratum* at dosages of 0.03 mg/kg either alone or in combination with ketamine 0.025–0.1 mg/kg IM (Gaskins & Boylan 2019).

Diazepam

Diazepam in sand tiger sharks (*C. taurus*) at a dosage of 0.1 mg/kg IM provided satisfactory sedation in one institution, but more research is indicated to define dosages (McEwan, pers. comm., 2011). The authors feel diazepam does not provide sufficient sedation at multiple dosages, but can be used for mild tranquilization in some species to facilitate capture and restraint.

Etomidate

Etomidate (0.4–1.3 mg/kg IM) has been used as an induction agent for *C. taurus* and *C. plumbeus* by either darting or pole syringe. The higher dosages resulted in more rapid induction and easier handling. The drug formulation is very thick and can result in leakage from the injection site. Anesthetic effects were noted as variable, but resulted in animals that would allow manual restraint (Lécu, pers. comm., 2017).

Guaifenesin

The mechanism of action of guaifenesin is unknown, but it is believed to depress or block nerve impulse transmission and has sedative qualities. It is commonly used for continuous-rate infusions in hoofstock species to maintain muscle relaxation and offer rapid recoveries. Guaifenisin IV was used in southern stingrays after a 5–10-minute induction in buffered MS-222 (50 ppm), which was enough to allow the animal to be turned over for IV administration of the drug (Rosenberg et al. 2013). The drug was given as a bolus at dosages of 10–40 mg/kg to observe effects in hopes of identifying a continuous-rate infusion dose for longer procedures. At the low

dosages, this drug provided very little effect and only showed sedation (stage 2) at the higher dosages, with rapid recoveries at all dosages. The only negative effect was a brief cessation of cardiac rhythm and asystole (identified by continual observance via ultrasound), which rapidly returned to a normal rhythm. One other institution has used the drug (20 mg/kg) for treatment of a suspected muscular condition and showed minor sedative effects as well (Rosenberg et al. 2013).

Haloperidol

Haloperidol lactate is a neuroleptic butyrophenone used as a tranquilizer in mammals. It is used to facilitate the transport of flighty animals and to decrease stress. Its calming effects make it a possible desirable drug for elasmobranchs. During trials in bonnethead sharks (*S. tiburo*) using the lactate form (2–10 mg/kg) intrasinus, only one animal out of five showed a response (incoordination and hyperexcitability) at the higher dosage. There was also considerable skin reaction to the drug. In general, haloperidol was not considered successful for sedation or adequate tranquilization at the dosages tested (Clauss, pers. exp.). The use of haloperidol decanoate has not been documented in elasmobranchs.

Ketamine Hydrochloride

Ketamine hydrochloride is an analgesic and cataleptic cyclohexamine. Ketamine provides good peripheral analgesia (pain relief) in mammals through suppression of dorsal horn cell activity in the spinal cord, but provides little visceral analgesia. It has been used as a single anesthetic at very high doses (50–80 mg/kg) in elasmobranchs. Seizure-like muscle spasms due to spinal reflex firing have occasionally been noted (Stoskopf 1993). Recovery is often prolonged and animals are disoriented for long periods of time. For these reasons it is preferably used in combination with other anesthetics.

Medetomidine

Medetomidine, an alpha-2 agonist, is available only via compounding at 10 and 40 mg/mL concentrations. It has been used in combination with ketamine in several shark species, including sand tiger shark (*C. taurus*), blacknose shark (*Carcharhinus acronotus*), sandbar shark (*Carcharhinus plumbeus*), and nurse shark (*G. cirratum*), to ameliorate muscle spasms that can occur with ketamine alone (Snyder et al. 1998; Tuttle & Dunn 2003). See medetomidine in multiple combinations (below and Table 7.1) for effects.

Midazolam

As a benzodiazepine receptor agonist, midazolam can result in sedation and anxiolytic activity. When used at dosages of 1–5 mg/kg IM as a sole agent in *S. tiburo, C. melanopterus*, and *C. plagiosum*, the authors have not found the drug to be useful. However, when used in combination with other drugs, induction times did seem to decrease as did the physical excitement phase (Mylniczenko, pers. exp.). When administered intrasinus in *S tiburo*, there was notable hyperexcitability and ataxia at 4–5 mg/kg in two animals, while at 8 mg/kg death occurred in one animal (Clauss, pers. exp.). In whale sharks, *Rhincodon typus*, 4.5 mg/kg IV or IM, was efficacious for sedation. It is also efficacious in manta rays (*M. birostris*) at 0.50–2.5 mg/kg IV or IM (Ueda et al. 2017). The same group also found that propofol at 1.5 mg/kg IV after the midazolam provided good general anesthesia.

Propofol

Propofol is a sedative-hypnotic that has been used in multiple species (Table 7.1). Dosage range is typically 1.0–5.0 mg/kg IV at a slow to moderate infusion rate to achieve a surgical anesthetic level within 5–10 minutes (Claus, pers. exp.). Apnea is more profound in shark species than batoids, but consistent, spontaneous respiration and righting responses usually return within 60–90 minutes. Ventilatory support should always be provided when using propofol in elasmobranchs. When administered in *S. tiburo* at 2.5 mg/kg intrasinus, slight incoordination was noted but no anesthesia. At 5 mg/kg, however, induction was rapid, a surgical plane of anesthesia was achieved, and marked respiratory suppression occurred. These bonnet heads returned to gilling >35 minutes post induction. The animals returned to swimming >65 minutes after induction. Additional work with *S. tiburo* suggests that 4.0 mg/kg is an ideal dose for moderate anesthesia for 45–60 minutes (Clauss, pers. exp.). In the spiny dogfish (*S. acanthias*) a minimum of 5 mg/kg IV was necessary to achieve a surgical plane of anesthesia (Cavin et al. 2007). With blacktip sharks (*C. limbatus*) 2.5–3.0 mg/kg delivered intrasinus resulted in rapid induction (<1 minute) and a surgical plane of anesthesia with persistent shallow, irregular spontaneous ventilation. Sharks returned to normal gilling 35–45 minutes post induction and to normal swimming in 55–75 minutes (Cavin et al. 2007; Clauss, pers. exp.). Propofol administered IV in batoids and sharks produces reliable, dose-dependent anesthesia and recoveries. The disadvantage is the IV delivery requires the animal to be in hand or for a diver to administer it underwater.

Sodium Pentobarbital

Sodium pentobarbital (10 mg/kg) produced satisfactory general surgical anesthesia in nurse sharks (*G. cirratum*) when administered rapidly IV (Walker 1972). Slow injection resulted in an erratic response. Intraperitoneal absorption was slow and response was variable, while IM injection resulted in only slightly improved response. Serum half-life was approximately 15 seconds with a second half-life of several days due to an inability of the animals to excrete the drug through their gills or kidneys. An anesthetic IV dose (10 mg/kg) resulted in loss of ventilatory movements (gilling) within 1 minute. Gilling returned after 10 minutes and a weak righting response was observed at 3 hours. A higher IV dose (20 mg/kg) resulted in a rapid loss of gilling that did not return by 3 hours. A weak righting response was only observed after 5 hours. A high IV dose (60 mg/kg) resulted in death. Larger, more active sharks require smaller doses per kilogram than smaller, sedentary specimens. For example, sandbar and bull sharks dosed at 6 mg/kg IV responded similarly to the nurse shark dosed at 10 mg/kg IV (Walker 1972).

Tiletamine/Zolazepam

Tiletamine/zolazepam (12 mg/kg) administered to a lemon (*Negaprion brevirostris*) and a sand tiger (*C. taurus*) shark produced irritability, rapid swimming, and unrestrained biting (Stoskopf 1986, 1993). Dosages of 5–20 mg/kg IM in *C. plagiosum* showed very little response even at the high dosage (some animals permitted being turned over for a few seconds) (Kilborne, unpubl. data) but a different study using the same dosage trials in *C. plagiosum* and *C. punctatum* (Adams & Krol 2015) showed that when administered IV, 15 mg/kg showed complete immobilization, but there was variability in anesthetic depth and prolonged apnea.

Xylazine

Xylazine in boney fish (teleosts) is a convulsant and causes major changes in the electrocardiogram (Oswald 1978). Used in combination with ketamine (12 mg/kg), xylazine (6 mg/kg) in sand tiger shark (*C. taurus*), lemon shark (*Negaprion brevirostris*), sandbar shark (*C. plumbeus*), and nurse shark (*Ginglymostoma cirratum*) variably ameliorated the muscle spasms that can occur with ketamine alone (Stoskopf 1993). Yohimbine hydrochloride administered IV to a nurse shark immobilized with xylazine/ketamine caused arousal (Stoskopf 1986). Lécu et al. (2017) noted no anesthetic effect at any dose of xylazine administered up to 50 mg/kg even with the addition of ketamine.

Injectable Anesthetic Combinations

Balanced anesthesia involves drug combinations, for example combinations of IM xylazine (6–7.5 mg/kg) and ketamine (12–16.5 mg/kg) have been used to produce light to moderate anesthesia in multiple species (Stoskopf 1986; Andrews & Jones 1990). Current practice, however, favors medetomidine and ketamine at varying dosages (Table 7.1) with dosages ranging from 90 to 100 μg/kg medetomidine and 4 to 5 mg/kg ketamine. Usually initial effects take 20–40 minutes, but results can be erratic. The effects vary from complete anesthesia with recumbency (some within 5 minutes), animals showing partial signs with no recumbency (despite additional dosing), and animals showing almost no sedative effects. There also appears to be a great variation between species in their responses to similar dosages under the same conditions. Additionally, recoveries are highly variable, with reports of immediate recoveries to some deaths several days later. Anorexia is a common complaint post procedure.

Penning and team have successfully used medetomidine and butorphanol for multiple procedures in several elasmobranchs. Medetomidine (0.1 mg/kg IM) and butorphanol (0.65 mg/kg IM) proved very successful with several *Carcharinus* species. Moderate success was achieved with giant guitarfish (*R. djiddensis*) by increasing the butorphanol dosage to 1 mg/kg. Inductions started at approximately 20 minutes, but animals were not handled until 45 minutes, which was considered a minimum time to avoid stimulation for successful sedation. The animals were then guided into a plastic sock (described above) and transported. In some instances, the sharks lay on the bottom of the tank, while others continued to glide very slowly. Reversals were given for rapid and full recoveries. The team noted that the addition of ketamine seemed to increase the frequency of phantom biting or biting at the stimulating activities. In these situations, they offered a bite stick for the animal to hold onto (Penning, pers. comm.).

In bamboo sharks (*C. plagiosum*), midazolam (1–5 mg/kg), medetomidine (80–90 μg/kg), and butorphanol (0.5–1 mg/kg) had little to no effect IM, but minor sedative effects IV. With the latter route the animals tolerated being turned over and stayed dorsally recumbent for several seconds to several minutes (Mylniczenko, pers. exp.).

Oral

Oral sedation of elasmobranchs is not widely practiced and is rarely reported (Raines & Clancy 2009; Clauss et al. 2011), in part because few feasible, effective options exist. Oral administration holds potential for the management of

animals in large aquaria and for improving the capture of animals for further immobilization if reliable medications can be identified.

In one study, four ocellated river stingrays (*Potamotrygon motoro*) were offered ketamine-injected earthworms at a dosage of 20 mg/kg; within 15 minutes the animals were easily netted and placed into dorsal recumbency, but did not reach anesthetic depths. In a different study, multiple sedatives were used with bonnethead sharks (*S. tiburo*), comparing oral (via capsule in food) and IV injectable drugs (Clauss, pers. exp.). The oral drugs produced little effect, even at doses considered high for other species. These drugs included chloral hydrate (no sedative response at 300 mg/kg), ketamine (no sedative response at 30 mg/kg), and haloperidol lactate (no sedative response at dosages up to 50 mg/kg). Haloperidol showed no sedative effects at 10 mg/kg in *Triakis semifasciata,* but did show behavioral modifying effects (decreased stereotypy) (Mylniczenko, pers. exp.). The authors have also used diazepam at dosages from 1 to 40 mg/kg (most in the 1–10 mg/kg range) with variable anxiolytic effects or appetite stimulation effects. There were no overt sedative effects in a variety of species: sawfish (*Pristis zijsron*), brown sharks (*C. plumbeus*), blacktip reef shark (*C. melanopterus*), leopard shark (*Triakis semifasciata*), blotched fantail ray (*Taeniura meyeni*), bowmouth (*Rhina ancylostoma*), and whale sharks (*Rhincodon typus*). More research is indicated to evaluate the usefulness of oral sedation in elasmobranchs.

Reversal Agents and Nonspecific "Reversal" Drugs

Atipamezole is a potent, selective alpha-2 reversal agent, exhibiting activity at both central and peripheral receptor sites. It has been developed specifically as an antidote to medetomidine and is able to reverse behavioral, cardiovascular, gastrointestinal, neurochemical, and hypothermic sedative effects (Swann 1993). It also reverses dexmedetomidine and detomidine. An IM dose is usually dependent on the dose of the anesthetic drug, for example five times the medetomidine dose and 10 times the dexmedetomidine dose (Gaskins & Boylan 2019). Yohimbine is a historical alpha-2 reversal agent that is still on the market and less expensive than atipamezole. Dosages of 0.125 mg/kg can be used successfully to reverse the effects of ketamine–xylazine combinations.

Naltrexone is an opioid reversal agent (Grimm & Lamont 2007). Reversal is typical after 10–20 minutes and the elasmobranchs were generally able to move, respire, and swim unaided (Penning et al. 2017).

Doxapram hydrochloride, while not a reversal, has been used to facilitate recovery in elasmobranchs. It has been noted to produce dramatic arousal and stimulation in anesthetized elasmobranchs and should be used with caution because animals can become extremely excited and dangerous (Stoskopf 1986).

Monitoring

In captive animals, a quiet environment without predatory tank mates should be used for anesthetic induction and maintenance. Several baseline physiological variables should be monitored. Ventilation rates are recorded if the animal is actively pumping water through the gills and not ram-ventilating. Gill ventilation rate and rhythm can be monitored visually. Caudal fin strokes are measured to determine the onset of drug effect; this activity is usually the first to be reduced throughout anesthetic procedures. When an animal becomes ventrally recumbent, the righting reflex, respiration, and heart rate should be closely monitored. If respiration becomes erratic, slows significantly, or ceases, the animal must be manually ventilated by directing water flow over the gills.

Although animals may appear to be ventilating well in some anesthetic situations, bradycardia and an increased resistance to gill capillary flow (as erythrocytes accumulate within the capillary bed and become swollen) has been noted to cause hypoxemia (Tyler & Hawkins 1981), therefore the authors strongly advise assisted ventilation even with voluntary gill movement and equate this with a good standard of practice.

Ventilatory effectiveness is best assessed with periodic blood gas analysis to determine pH, bicarbonate, and lactate levels. Large changes in blood chemistry can occur during the stress of capture and handling of elasmobranch fishes (Naples et al. 2012; Frick & Reina 2009; Mandelmann & Skomel 2009). Respiratory, metabolic, and lactic acidemia are common. In elasmobranchs, lactic acid is produced in large quantities during hypoventilation and/or muscle exertion; the resultant acidemia is usually corrected by hydrogen ions buffering or through gill excretion (a much slower process), therefore lactate levels will continue to rise in elasmobranchs for up to 12 hours after the inciting event (Piiper & Baumgarten 1969). Experiments with larger spotted dogfish (*Scyliorhinus stellaris*) indicated arterial partial pressure of carbon dioxide ($PaCO_2$) was increased immediately after exercise, but returned to baseline within 1 hour. The pH gradually decreased, reaching a minimum in the second hour and returned to baseline within 8 hours. Lactate concentrations increased slowly to very high levels, reaching a maximum of 220 mg% within 6–8 hours after exercise (Piiper & Baumgarten 1969). The

pH may therefore correct itself in an animal that has sufficient buffering capacity, but this is largely determined by the animal's respiratory mode and method of oxygen metabolism (Piiper & Baumgarten 1969; Cliff & Thurman 1984; Manire et al. 2001; Chapman & Renshaw 2009; Frick & Reina 2009). Benthic animals tolerate and correct acidemia more readily than pelagic animals.

Handheld analyzers offer rapid analysis at poolside or on a boat, and some automatically adjust calculations for lower body temperature. If they do not, then correction for ambient water temperature is necessary or, alternately, evaluation or trends should be followed rather than actual values. The pH is a critical variable to monitor. For the authors, animals with corrected values under 7.0 indicated an animal in crisis that needs attention (ventilatory and/or chemical), even when chemical restraint is not utilized. Lactate levels are useful for anticipating problems that may occur later or for evaluating handling/anesthetic events; repeated increasing lactate levels suggest a continued problem. These values vary by species and by method of restraint. Under circumstances of continued pH decline and/or lactate elevation, the authors have treated animals with fluids solely or in combination with sodium bicarbonate and/or acetate therapy. Adjustments to ventilation may also be warranted with consideration to direction over gills, flow rate, and oxygen saturation of the water).

Another factor to consider when evaluating blood gas variables is the location used for blood collection. In larger specimens, the dorsal sinus was historically used for blood collection due to ease of access. However, several variables have been shown to be inaccurate for the animal's baseline state in samples from this location. Not only is hematocrit lower at this site compared to the tail (Mylniczenko et al. 2006), but blood gas values are also different. The pH and lactate are not accurate or "real time" when measured in blood samples collected from the dorsal sinus (Naples et al. 2012). Blood collected from the ventral tail vein can be a mixed venous–arterial sample due to the close proximity of the vasculature. The collected sample from the tail is likely to be arterial if the needle tip is moved just off the cartilage as the vessel abuts the vertebrae.

Heart rate is monitored using either a Doppler flow detection probe (Fig. 7.10a) or ultrasound (Fig. 7.10b) placed over the heart, which is located along the ventral midline just cranial to the pectoral girdle. The heart rate will vary between species and in response to stress and temperature. Most unanesthetized fish will have a heart rate between 30 and 70 beats per minute, depending on animal size, species, and condition (Lewbart 2001). In addition to heart rate, the contraction quality and rhythm are important to examine. Changes such as weak contractions and dysrhythmias may indicate the animal is doing poorly under anesthesia. Dilution of immersion drugs or recovery should be considered. If contractions appear to be weak, evaluation of the animal's calcium is warranted, particularly ionized calcium, which can be monitored with a handheld analyzer. Normally, this value is greater than the readable limit of some portable units (>2.5 mmol/L). If it is reading below this value, and the animal has weak contractions, then the animal should be recovered and/or calcium administered to manage the relatively lower calcium levels (Mylniczenko, pers. exp.).

Figure 7.10 Heart rate can be monitored using either a Doppler flow probe (7.10a) or ultrasound probe (7.10b) placed directly over the heart.

Anesthetic stages in elasmobranchs are like mammals and teleost fish (Chapter 9; Stoskopf 1986). Stages are gauged by activity, reactivity to stimuli, equilibrium, muscle tone, respiratory rate, and heart rate (Ross & Ross 1999). The period between respiratory and cardiac arrest, however, is greater because the respiratory capillaries can exchange oxygen and carbon dioxide when water flow over the gills is maintained via assisted ventilation. Stages of anesthesia are highly variable between animals (both intra- and interspecies) and between drugs.

As a reminder, during an immobilization procedure, it is also important to monitor and control the water quality of the anesthesia or restraint system as poor or altered water parameters may negatively impact the animal(s) involved. Temperature fluctuations may occur easily if the water volume is small and should be controlled as hyper- or hypothermia can impact metabolism and recovery. Dissolved oxygen should be maintained close to 100% and may require the addition of supplemental air stones with or without supplemental oxygen. Any fouling of the system by the patient can lead to an excess of nitrogenous waste. Waterborne anesthetics, in particular MS-222, can lower the pH of the water and thus may require buffering.

Recovery Considerations and Postanesthetic Challenges

All safety precautions exercised for induction and maintenance should continue to be a priority during recovery from anesthesia. When recovering an animal from an anesthetic event, an isolated environment is preferable (Fig. 7.11a). Ideally the recovery container or tank will be easily accessible for the staff, but will also be large enough to allow the animal space to swim as it progresses through stages of recovery. Water in recovery containers should be well aerated and maintained at an appropriate dissolved oxygen level (100–120%, 10–12 mg/dL). The water flow should be aimed toward the fish's mouth if the animal is respiring spontaneously but still sedated from anesthesia. Assisted ventilation directly over the gills may be necessary if the fish is not respiring (Fig. 7.11b) or the respiration rate continues to be slow or irregular. It is not recommended to pull the fish forward through the water with its mouth open. In the authors' experience, this method is inferior to the use of a ventilation system, indicated by differences in the quality of blood gas results.

Careful observation is important, and staff should be readily available to intervene if the fish becomes distressed or the recovery process halts. It is important to have experienced personnel involved when making judgment calls on the release of a recuperated animal. If an animal is released too early it may not be able to maneuver appropriately in the water column, and it may swim briefly and then fall to the bottom of the recovery pool. Although this is not considered a respiratory issue with buccopharyngeal breathers, it can be problematic with pelagic animals; the animal must be retrieved and continue to be supported through recovery. As a fish recovers from anesthesia, the respiratory rate should return to normal and the rhythm should become more consistent. Muscle tone and fin movements should return, followed by progressively better coordination.

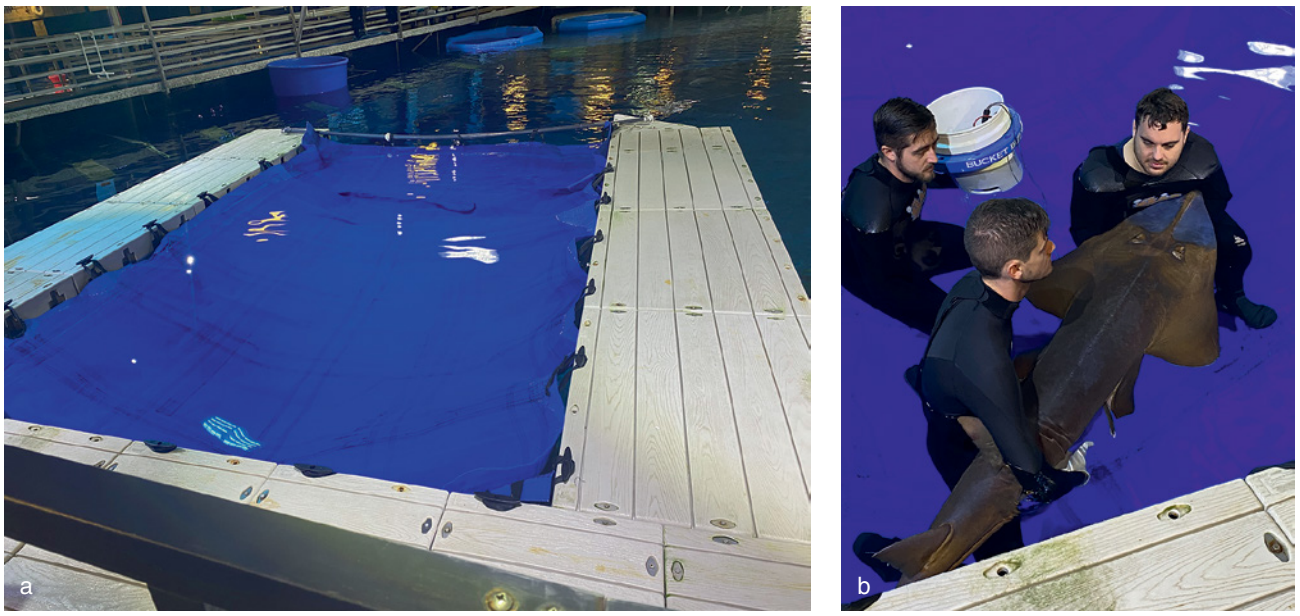

Figure 7.11 (a) Floating docks and tarp to create a recovery and isolation area in a large aquarium system. (b) Recovery of a shovelnose guitarfish (*Rhinobatus productus*) using the tarped area and a floating bucket for maintaining ventilatory equipment safely. The ventilation is being provided ventrally, out of the view of the photograph.

Recovery from immersion anesthesia begins when the fish is placed in anesthesia-free water. During the recovery process, the water in the tank may need to be changed as anesthetics and their metabolites may be excreted from the fish into the water and potentially reabsorbed, although this is rarely indicated. The same process is theoretically possible with oral or parenteral drugs as they too may be excreted into the water and reabsorbed. Recovery from oral or parenteral anesthetics technically begins after the drug is administered and fully metabolized. Faster recovery in some cases is facilitated by administering reversal agents. However, there is no reversal for some drugs and in those situations it is up to the fish to fully metabolize and clear the drug(s) for full recovery to occur. Recovery time from oral and parenteral agents is dependent on the route of administration, rate of metabolism, use of reversal agents, health status of the patient, and species. Extended recovery periods may occur with excessive anesthetic dosages, medically compromised animals, long procedures, or for unknown pharmacokinetic reasons.

Prolonged recoveries and other unpredictable scenarios can also be attributed to the immensely variable responses to anesthesia, as extrapolation of doses is challenging. At the New England Aquarium, two sand tiger sharks (*C. taurus*) anesthetized with dexmedetomidine (0.03 mg/kg) and ketamine (3.0 mg/kg), followed by MS-222 (70–90 mg/L) immersion, had markedly different recovery times. Even after reversal with atipamezole, one shark began to swim 6 hours after reversal and returned to the exhibit tank. The other shark did not begin to swim until 24 hours after reversal (Cavin & Innis, pers. comm.). At the Living Seas with Nemo and Friends® (Walt Disney World, Orlando, FL, USA) highly variable responses to a similar drug combination were noted and ranged from no response to rapid induction, with recoveries that were also highly variable. This included a quick return to normal to exhibition of abnormal behavior, including swim gait abnormalities, anorexia, and prolonged lethargy for up to 7 days in the same species.

Recovery or resuscitation attempts should not be abandoned prematurely in apneic fish as respiratory arrest may precede cardiac arrest by extended periods of time. In the authors' experience, anesthetics such as propofol may produce respiratory arrest for periods in excess of 30 minutes followed by full recovery when the sharks are artificially ventilated. Fifteen bonnethead sharks (*S. tiburo*) at the Georgia Aquarium were anesthetized with propofol (4.0–5.0 mg/kg) administered into the first dorsal sinus. Spontaneous respirations ceased within 3–5 minutes. The sharks were artificially ventilated with a submersible pump and vitals monitored closely as well as blood gasses. Gilling resumed in all 15 animals within 36–52 minutes after propofol administration. Fish with persistent apnea or bradypnea that also experience bradycardia, abnormal blood gases, or other physiological challenges may be given doxapram. The authors have observed positive responses to doxapram (5 mg/kg IV, IM, intracoelomic or over the gills) in several cases of respiratory arrest. Caution should be used when administering doxapram as it may cause hyperexcitability, especially in sharks.

In some situations, it may be necessary to provide supportive care and/or emergency drugs such as atropine, corticosteroids, fluids, or other therapeutics. In cases of shock or physiological collapse, corticosteroids such as methylprednisolone, prednisolone, or dexamethasone may be given with the caveat that it is unknown if steroid therapy is effective in elasmobranchs. In the authors' experience, corticosteroid administration has been subjectively helpful in many cases and no adverse effects have been noted.

Emergency fluid therapy should take into account the animal's osmotic balance as well as any imbalances or deficiencies that may be present. Elasmobranchs are hyperosmotic to their environment with urea, NaCl, and trimethylamine oxide being the major osmoregulatory plasma components (Olson 1999). Elasmobranch Ringers solutions should be used and recipes are available (Mylniczenko & Clauss 2017). Thorough summaries on the osmoregulation of elasmobranchs as it is currently understood can be found in the literature (Hammerschlag 2006; Anderson et al. 2007). Greenwell et al. (2003) provide an overview of the clinical implications involved with elasmobranch osmoregulation, including additional guidelines on the principles of fluid administration. The fluids are ideally administered through a needle or catheter placed in the caudal vein or the dorsal sinus, but may also be administered intracoelomically or orally. No rates of fluid administration have been published based on scientific studies, but the authors use maintenance doses of 7–10 mL/kg. Some elasmobranchs appear to respond to oral freshwater administration at 1–3% of body weight in less severe situations. When metabolic acidemia occurs, if the fish is unable to compensate and does not respond to increased oxygen supplementation and fluid therapy, it may be beneficial to administer an alkalinizing agent such as sodium bicarbonate or sodium acetate. Care should be taken not to overcorrect, causing an alkalemia or electrolyte imbalance. In these cases, monitoring with a point-of-care analyzer is extremely helpful and can guide clinical decisions.

As with other classes of animals, administration of emergency medications varies by case and should be governed by individual animal needs. Table 7.2 lists emergency and supportive care therapeutics the authors have used that have been valuable when working with elasmobranchs and holocephalans.

Table 7.2 Drugs used for emergency and supportive care in elasmobranchs.

Drug	Dosage	Route	Indication
Atropine	0.1 mg/kg	IV, IM, IP	Bradycardia, arrythmia, organophosphate poisoning
Glycopyrrolate	0.01 mg/kg	IV, IM	Bradycardia, arrythmia
Epinephrine	0.2 mL/kg	IV, IM, IP	Bradycardia, cardiac arrest
Doxapram	2–10 mg/kg	IV, IM, over gills; may cause hyperexcitability	Apnea, respiratory arrest
Erythropoietin	100–150 u/kg	IM	Anemia
Furosemide	2 mg/kg	IV, IM, IP	Excessive coelomic fluid, generalized edema
Dexamethasone	1 mg/kg	IV, IM, IP	Stress, shock, trauma
Methyl-prednisolone acetate	30 mg/kg initial, 15 mg/kg subsequent dosage		
Midazolam	0.5 mg/kg	IV, IM	Seizures
Diazepam	1–2 mg/kg		
Calcium gluconate	50–150 mg/kg	IV, IP	Muscle fasiculations, tetany, dysrhythmias, decreased myocardial contractility
Calcium lactate/calcium glycerophosphate	10 mg/kg	IV, IM, IP	
Iron dextran	10 mg/kg	IM	
Sodium bicarbonate	1 mEq/kg	IV, IM, IP	Acidosis
Sodium acetate	1 mEq/kg diluted ~ 1:10 with fluids	IV, IP	
Hank's balanced salt solution + 8 g/L NaCl and 21 g/L urea	5–10 mL/kg	IV, ICe, PO	Dehydration, shock, fluid loss, hypovolemia, hypotension
0.9% NaCl + 8 g/l NaCl and 21 g/l urea	5–10 mL/kg		
Blood transfusion	Blood: up to 10 mL/kg Heparin : 1 mL (1:1000 IU/mL) per 10 mL of blood	IV	Shock, anemia, hypovolemia

ICe, intracoelomic; IM, intramuscular; IP, Intraperitoneal; IV, intravenous; PO, per os.

Field Immobilization

Immobilization of elasmobranchs in the field has been in practice for many years. Live-release biological assessments and subsequent tagging and tracking provide valuable information on factors such as the population dynamics, spatial patterns, foraging behavior, and health status of free-ranging animals. These activities have become increasingly common practice as scientists try to understand the causes and significance of changing or declining populations and relationships to ocean health.

Generally, animals are manually restrained after hook and line, long-line, or trawl net capture, but other techniques may be employed as warranted. In these situations, naïve animals are being placed under the rigors of extreme exercise and are particularly vulnerable to exertional rhabdomyolysis, hypoxemia and lactic acidemia, hook and handling trauma. and stomach eversion. Pelagic (ram-ventilating) species are especially susceptible to stress and exhaustion. and can have a poor chance of survival, but this is highly species dependent (Mandelman & Skomal 2008). The location of release may also have an impact on survivability. Predatory fish, including other elasmobranchs, may take the opportunity to predate a tired, recently released animal, particularly if the area has been chummed to attract additional specimens for capture. Often, however, there is no control over the matter as the animals are mainly caught and released in open water. Capture–release scenarios that result in the least impact to the animal are imperative.

Experienced handlers are required as the space on a boat or dock is limited, areas on deck are potentially unstable or wet, and animals are strong and often very agitated (see previous comments in this chapter about manual restraint

and safety). If the animals are out of the water for any length of time, it is advised that they are safely ventilated with the water they were just pulled from. If animals are to be maintained in live wells, consider the time in the well, volume of water, oxygen delivery to the water, swim-glide pattern (usually nonexistent under these circumstances), and number of animals in the well (more animals means more consumption of oxygen, crowding, and excretion of biological end products).

In some scenarios with animals too large to be hauled onto the deck, they must be restrained in the water along the side of the boat or dock (Fig. 7.12). Under these circumstances, even more expertise and potentially specialized equipment is important for human and animal safety. When capture and immobilization involves extremely large specimens, such as white sharks, whale sharks or manta rays, specialized watercraft is also necessary.

It is rare to use anesthesia for field immobilization procedures for several reasons: speed, efficiency, space, and, most importantly, regulations governing using drugs in potential food fish (Aquatic Animal Drug Approval Partnership 2010). It is important to note that if elasmobranchs are to be retained under managed care for extended periods of time, there may be restrictions against release or there may be special permitting required, but this is highly variable by state in the United States.

When health assessments occur during field immobilization projects, additional considerations include having portable equipment that can connect and operate on generators or batteries, or plug into the vessel's electrical system as well as having adequate, safe storage and preservation capacity for biological specimens. Weather and water conditions may change rapidly and in turn may complicate sample collection, processing, and safe handling. Having seaworthy staff experienced in biological sample processing is beneficial.

Figure 7.12 Collection of blood from a free-ranging sand tiger shark (*Carcharias taurus*) during a population health assessment project in Delaware Bay. Photo credit: Georgia Aquarium.

With any field immobilization technique, speed and precision are essential to reduce the stress on the animal and improve viability on release. Ultimately, limited handling or limited time in a live well is best. Some researchers have developed techniques for collecting samples and attaching tracking or identification devices without physically restraining the animals. These methods usually involve less stress or physical exertion for the animal, but may present a different set of safety hazards for the people involved.

Some studies have assessed the impacts of catching elasmobranchs for science, sport or accidentally as by-catch. Blood acid-base status can be utilized to gauge the magnitude of the stress response, which is dependent on the nature of the capture and the metabolic capacity of the animal in question (Mandelman & Skomal 2008). Changes in blood glucose, electrolytes, osmolality, and hematocrit have also been documented in various species of elasmobranchs after capture (Wells et al. 1986; Wendelaar Bonga 1997; Hoffmayer & Parsons 2001; Manire & Hueter 2001; Moyes et al. 2006). Regardless of collection technique, captured fish experience distress caused by the cumulative impacts of physical trauma and physiological stress (Skomal 2007). The importance of swift and meticulous capture, handling, and release cannot be underestimated and can greatly improve survivability in field immobilization activities.

Euthanasia

The goal of euthanasia should be the rapid loss of consciousness. This can be accomplished by an overdosage of immobilization drugs. Inhalant (immersion) drugs at five to 10 times the anesthetic concentration for a particular species can be chosen (Ross & Ross 2009). Elasmobranchs, however, may require sedation first with parenteral drugs then euthanasia with a drug such as pentobarbital, following all the previously stated techniques. Use of Doppler flow probes, ultrasonography, or electrocardiography is recommended to confirm asystole. Severing the spinal cord at the brain stem (decapitation) or exsanguination are alternatives to chemotherapeutic euthanasia and can be performed once the fish is anesthetized. The reader is directed to review euthanasia principles for fish as outlined by the American Veterinary Medical Association

(Underwood & Anthony 2020). Unacceptable methods of euthanasia include asphyxiation and hypothermia.

Acknowledgments

Portions of this chapter have previously been published in Smith M, Warmolts D, Thoney D and Hueter R (eds) 2004. *The Elasmobranch Husbandry Manual: Captive Care of Sharks, Rays and their Relatives*. Special publication of the Ohio Biological Survey, 580 pp. The authors would like to acknowledge M. Andrew Stamper, Ilze Berzins, Mike Walsh, Lisa Naples, Don Neiffer, Lynda Leppert, Nicholas Parnell, and Nicole Hatcher for their assistance in preparing this chapter. Special thanks to the animal health and care staff at the Georgia Aquarium (Atlanta, GA, USA), John G. Shedd Aquarium (Chicago, IL, USA), and The Seas with Nemo and Friends at Epcot, Walt Disney World (Orlando, FL, USA).

Bony Fish (Lungfish, Sturgeon, and Teleosts)

Natalie D. Mylniczenko, Charlene Burns, Whitney Greene, and Tonya Clauss

Introduction

Do fish require anesthesia? This becomes a debate in aquaria and loops in the conversations about mitigation of fish welfare and analgesia via the use of anesthetics. The subjects of welfare and pain have been taken into account in multiple other publications, including the previous version of this chapter (Braithwaite & Boulcott 2007; Chatigny et al. 2018; Posner 2009; Sneddon 2009, 2012; Mylniczenko et al. 2014). Similarly, stress is another topic of debate for the use of anesthesia. Acute and chronic stress negatively affects fish health, but does anesthesia dampen the response or create it? Fish display robust neuroendocrine and physiologic stress responses to noxious stimuli. Consequently, there is a need to identify and reduce these stressors in individuals and groups. Although examination and sample collection can be performed using manual restraint for many minor procedures, chemical immobilization may be safer for both fish and handlers in some situations. In addition, many procedures are performed out of water, which may result in fish struggling (Harms & Bakal 1995). This chapter will highlight methods for handling fish with and without anesthesia that have minimal impact on the animal and ultimately reduce stress when performed properly.

Chemical immobilization is routinely used to reduce excitement and trauma related to hyperactivity that can occur during routine handling for medical procedures, vaccinations, hormonal implants or injections, roe or milt collection, sorting, tagging, and transportation of fish (Cooke et al. 2004; Harms 1999; Kumlu & Yanar 1999; Myszkowski et al. 2003; Ross 2001). In addition to acute trauma causing mortality and morbidity, integument damage results in acute to chronic osmoregulatory disturbances and increased susceptibility to pathogens (Kumlu & Yanar 1999; Ross 2001). Chemical immobilization during transport reduces metabolism, leading to decreased oxygen demand and waste (i.e., CO_2 and ammonia) production (Cooke et al. 2004; Crosby et al. 2006; Guo et al. 1995; Hoskonen & Pirhonen 2004; Ross & Ross 1999).

Invasive or surgical procedures require anesthesia to prevent movement and remove any doubt in the debate over pain (Harms & Bakal 1995; Myszkowski et al. 2003; Ross 2001). At the very least, movement and physiologic changes in response to nociception are minimized.

There are approximately 33,000 species of fish that comprise more than 40% of all extant chordates. Of these, teleosts (Teleostei: class Actinopterygii) comprise about 96% of living fish species. Other groups include other members of class Actinopterygii or ray-finned fishes (sturgeon, gar, bichir, paddlefish, and bowfin), class Sarcopterygii or lobe-finned fishes (lungfishes and coelacanths), class Agnatha or jawless fish (hagfishes and lampreys), and class Chondrichthyes (elasmobranchs and chimeras) (Bond 1996; Harms 2003).

The majority of immobilization studies involve only a handful of teleosts. Extrapolation to all species is potentially harmful without consideration of the wide range of anatomic, physiologic, and behavioral differences. For example, benzocaine kills Atlantic cod (*Gadus morhua*) at the same dosage that is safe and effective in Atlantic salmon (*Salmo salar*) (Hansen et al. 2003; Mattson & Riple 1989). Even within families there can be marked variation in preferred environmental parameters. Consequently, knowledge of taxonomy and natural history is essential for developing anesthetic regimens in fish. Despite that, we are often limited geographically or under law to a handful of available anesthetics, therefore careful but diligent use of drugs in new species is necessary.

An ideal anesthetic for teleosts should have the following qualities: (1) induce anesthesia rapidly with minimal hyperactivity or stress; (2) be easy to administer and should maintain the animal in appropriate anesthetic state; (3) allow for rapid recovery; (4) be effective at low

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.
© 2025 John Wiley & Sons, Inc. Published 2025 by John Wiley & Sons, Inc.

doses with a wide margin of safety; (5) not produce any long-lasting physiological effects with rapid clearance from the body; (6) have high solubility in fresh and saltwater; (7) be readily available, cost-effective, and nontoxic to humans (Priborsky & Velisek 2018; Ross & Ross 1999, 2009). A final notion worth considering is the aversion fish may have to an anesthetic, which reflects the welfare perspective. Traditionally, 'excitation' is considered as a phase of anesthesia, but it may be a profound reaction to the actual nature of the drug, such as the popular MS-222, which can produce a profound negative reaction (Readman et al. 2013).

Stress and Anesthesia

Fish restraint activates the hypothalamic–pituitary–interrenal (HPI) axis, resulting in cortisol release causing various secondary stress responses (Bressler & Ron 2004; Myszkowski 2003; Ross & Ross 1984; Small 2003; Small & Chatakondi 2005). Details can be found in previous versions of this chapter (Mylniczenko et al. 2014). Mitigation of these responses is key and although anesthesia can minimize handling stress, it is inherently stressful (Bressler & Ron 2004) and a strong potentiator of catecholamine release, especially in salmonids (Rothwell et al. 2005; Zahl et al. 2010). Anesthesia-associated catecholamine release is due to hypoxemia rather than acidemia or direct drug effects (Ross & Ross 1984; Rothwell et al. 2005). If unbuffered, some immersives ("inhalants" or baths, e.g., tricaine methanesulfonate or MS-222) induce a stress response, possibly due to the pH change; additionally, some anesthetics are simply irritating to the gills and skin even when buffered. Hypoxemia is usually due to drug-induced hypoventilation (decreased buccal movement) or lack of appropriate oxygen infusion into the water. In air-breathing fish, hypoxemia can be exacerbated by preventing anesthetized fish access to the water's surface (Rantin et al. 1993, 1998). Hypoventilation with decreased water flow in the buccal cavity often leads to reflex bradycardia and dorsal aortic hypotension, which produces progressive hypoxemia (Ross 2001), thus emphasizing the importance of ventilation.

Despite the above-mentioned effects, well-managed chemical sedation or anesthesia produce a lower stress response when compared to drug-free handling and transport. This conclusion is based on a comparison of circulating cortisol levels, as well as secondary indicators such as blood glucose, hematocrit (HCT), hemoglobin (Hgb), lactate, and osmolarity (Bressler & Ron 2004; Crosby et al. 2006; Hseu et al. 1996; Small & Chatakondi 2005).

Of the commonly used drugs, only metomidate consistently and significantly blocks HPI activation (Davis & Griffin 2004; Iversen et al. 2003; Zahl et al. 2010) in a broad range of species (Mylniczenko et al. 2014). The effect of clove oil (eugenol and isoeugenol) on cortisol secretion in fish is variable and dependent on circumstance (water quality, dose, environment). MS-222 has highly variable effects on stress which are dependent on dosage, handling circumstance, and species. Limited information on the effects of injectable drugs on the HPI response exists. In bonito (*Sarda chiliensis*) ketamine/medetomidine did not significantly alter HCT, Hgb, or glucose although baseline values were not provided (Williams et al. 2004).

In addition to affecting the stress response, some anesthetics are immunosuppressive. This effect may be caused by direct interaction with immune components or indirectly through the nervous system. For example, in gilthead seabream (*Sparus aurata*) both humoral and cellular immune responses were significantly depressed by benzocaine (Bressler & Ron 2004). However, clove oil does not cause significant immunosuppression in the same species, demonstrating the variability between species and drug effects (Bressler & Ron 2004). Metomidate-associated blockade of the HPI axis is thought to prevent immunosuppression (Davis & Griffin 2004).

Taxonomy, Anatomy, Physiology, and Behavior

Respiration

All fish have gills although the degree of reliance on these structures for respiration varies across class, order, and family. Most fish force water over the gills through rhythmic movements of their lower jaw and opercula (buccopharyngeal respiration). However, some species utilize ram ventilation (forcing water over the fish gill by swimming through the water column) with minimal opercular movement. Some teleosts (e.g., tuna, family Scombridae) are obligate ram ventilators, with gilling alone not providing sufficient ventilation to meet metabolic demands. These species swim forward continuously with their mouth slightly agape to develop the pressure necessary for sufficient water flow over the gills. Failure to perfuse the gills during anesthesia results in suffocation (Brill & Bushnell 2001; Bushnell & Jones 1994). Tuna also rely on constant forward speed to produce lift from their pectoral fins for hydrostatic equilibrium (Brill & Bushnell 2001). Consequently, during recovery of ram-ventilating species, it is necessary to hold the fish with sufficient water flow over the gills via a pump mechanism until adequate voluntary forward motion of the sedated animal returns. Walking the animal or pulling the animal manually

through the water to ventilate is a favored option amongst fish enthusiasts; however, this does not always provide adequate oxygenation and mechanical ventilation is strongly encouraged to move water over the gills, particularly with pelagic fish species.

In response to hypoxic environments or other selective pressures, many species have evolved anatomical, physiologic, and behavioral adaptations to meet their ventilatory needs (Graham 1997). In addition to elaboration of the basic gill design for improved oxygen extraction, a diverse array of accessory respiratory organs has evolved, with a number of species capable of utilizing atmospheric air (Mylniczenko 2021). For many species, increased aerial gas exchange surface area exists in portions of the alimentary canal (i.e., buccal and pharyngeal cavities) either as a direct proliferation of the respiratory surface or as a single or a pair of pouches extending from it (Ishimatsu & Itazawa 1993). Alternatively, branchial diverticulae may develop as in anabantoids (gouramis, bettas, climbing gouramis) (Graham 1997).

Many species take in atmospheric air with a behavior termed aquatic surface respiration (ASR). The fish position their mouths to skim the air:water interface, which is richer in oxygen. Some species (e.g., pacu, *Piaractus mesopotamicus*) respond to hypoxic conditions by developing temporary dermal swellings of the lower jaw to facilitate ASR (Rantin et al. 1993, 1998). Others (e.g., channids [snakeheads], anabantoids) employ alternate filling of an air-breathing chamber (labyrinth organ in anabantoids) with air and water during aerial ventilation (Ishimatsu & Itazawa 1993). Air-breathing fishes pose unique risks for anesthesia as they may be difficult to induce via immersion (shifting oxygen exchange away from gills to accessory air organs). :is also a theory that they may "drown" by not allowing access to air but this may also happen with deoxygenation of the water; either should be monitored (Graham 1997). Not all are obligate air breathers, some are facultative and less susceptible to environmental oxygen pressure.

Lungfish (the sister group to tetrapods) and polypterids (bichirs and reedfish) possess true lungs with ventrally situated pneumatic duct openings in the alimentary canal instead of a traditional gas or "swim" bladder (Graham 1997). Of these, the African (*Propterus* sp.) and South American lungfish (*Lepidosiren* sp.) are obligatory air-breathers (Bassi et al. 2005; Graham 1997). The Australian lungfish (*Neoceratodus fosteri*) possesses gills as well as a lung (Lenfant et al. 1966). Although anatomically challenging, it is theoretically possible to cannulate the pneumatic duct of lungfish for administration of inhalant anesthesia. Conceivably, chamber induction with gas (while somewhat submerged) may be possible but has not been reported. The Australian lungfish is the only facultative breather in the group but when placed in immersive anesthetics will attempt to breathe air and not respirate through its gills; drowning is a risk (both from lack of oxygen in the air and from water infiltrating the air space) (Farrell & Randall 1978). Immersion anesthesia with MS-222, benzocaine, and eugenol has been used in lungfishes. Oxygenation should be ensured once sedated via oxygen gas (or oxygenated water in animals with gills) (Christensen et al. 2015; Delaney et al. 1976; Lederoun et al. 2019; Lenfant et al. 1966; Monteiro et al. 2018; Mylniczenko, pers. exp.).

Understanding the anatomical and physiologic range of fish respiration is important for anesthesia for two reasons. First, immersion uptake and induction rate are linked to oxygen demand. For fish that depend primarily or entirely on dissolved oxygen in water, induction rates are shorter compared to those of air-breathing species. Responding to confinement or hypoxic anesthetic baths, the latter pull air from the water surface and reduce opercular movement. Some may temporarily stop opercular activity (Hseu et al. 1997). Injectable anesthetics can be used for induction of species capable of aerial respiration (e.g., anabantoids) (Bruecker & Graham 1993). Second, although many fish that utilize an accessory respiratory organ retain gills for aquatic gas exchange, effective gill tissue is so reduced in some species (e.g., channids, lepidosirenid lungfish, and clariids or walking catfish) they will succumb or "drown" if denied access to atmospheric air (Ishimatsu & Itazawa 1993; Peters et al. 2001). Perianesthetically, these species are maintained in very shallow water, or on a moist substrate, until capable of reaching the air:water interface regardless of the anesthetic route used.

Arapaima (*Arapaima gigas*) and other osteoglossids are also obligate air-breathing fishes that use a modified swim bladder for respiration (Brauner et al. 2004). Focused spraying of immersion drugs, like benzocaine and eugenol, on the gills is an effective method of induction (Honczaryk & Inoue 2010). Full immersion with benzocaine has been used in this species for anesthesia/euthanasia (Buzete Gardinal et al. 2019). One of the authors (Mylniczenko) has experience using high-dose MS-222 (1 g/L) over the gills to sedate larger species as well as low-dose immersion MS-222 (25 ppm) in combination with valium (10 mg/kg PO) for transport. Ketamine has been successful orally in this species for transport (Raines & Clancy 2009). There is also concern that these fish are at high risk for not recovering their air-breathing reflexes once anesthetized (Chu-Koo et al. 2009) or drowning during recovery (Pelster et al. 2020), though the authors have not experienced this.

Although notable exceptions exist (e.g., tarpon, *Megalops atlanticus*), few marine species have evolved adaptations

for hypoxic environments other than surface piping or migrating from the area. Consequently, marine species may be less tolerant of hypoxic conditions during anesthesia in comparison to the freshwater species discussed above (Rothwell et al. 2005).

Metabolism

Most fish are ectothermic and dependent on ambient temperature. Though exceptions exist for some cold-adapted species, lower temperatures are usually associated with prolonged induction and recovery times during either immersion or parenteral anesthesia (Gelwicks et al. 1998). This effect is reversed at higher temperatures (Detar & Mattingly 2004; Gomes et al. 2001; Peters et al. 2001; Stehly & Gingerich 1999). During immersion anesthesia, this relationship is primarily related to altered respiratory rate. Blood acid-base status is temperature dependent, with increased temperatures leading to acidemia and hypercapnia that stimulate hyperventilation. This decreases induction and recovery times for drugs taken up or eliminated from the gills (Aguiar et al. 2002; Stehly & Gingerich 1999).

Some fish (e.g., family Scombridae, tuna) have evolved various degrees of endothermy. They have the capacity to conserve metabolic heat in slow-twitch muscle, viscera, brain, and eyes, and to elevate body tissue temperature above ambient (Bushnell & Jones 1994). Tuna gills have large surface areas and thin epithelia compared to other fish (Brill & Bushnell 2001; Bushnell & Jones 1994) with a net result of enhanced oxygen uptake. Red cells with elevated hemoglobin levels are circulated by proportionally large hearts with high cardiac outputs (Blank et al. 2004; Bushnell & Jones 1994) to well-vascularized tissues. High myoglobin levels and aerobic enzymes enhance tissue oxygen extraction. Enzyme activity is particularly high in muscle; aerobic oxidation rates are three to five times greater than other teleosts (Bushnell & Jones 1994). Elevated enzymatic activity and counter-current heat exchangers raise muscle temperatures (Cooper et al. 1994). Endothermy leads to increased rate of anesthetic uptake and metabolism compared to similarly sized ectothermic species. More primitive Scombrids (e.g., bonitos, seerfishes, and mackerels) are not endothermic and lack physiologic characteristics of tuna such as the vascular countercurrent heat exchange mechanism. However, aerobic enzyme activity is similar and these scombrids represent a transition between ectothermy and tuna endothermy (Brill & Bushnell 2001; Williams et al. 2004).

Teleost fish have an anatomic separation between aerobic, slow-oxidative muscles (red muscle) and anaerobic, fast-twitch, glycolytic muscles (white muscle). In many species, a distinct pattern of highly oxygenated slow-oxidative muscle runs along the midline of the body. Given the increased capillaries, injection of anesthetic agents into this region may result in more rapid induction times compared to injections administered elsewhere (Williams et al. 2004), but in reality this layer is very thin and has large variation in thickness and location, making consistent injections difficult.

Integument

Although most fish possess scales, marked variation in distribution and structure exists. This has implications for administration of parenteral drugs by hand and remote injection. Species that have large, hard scales (e.g., tarpon, arapaima) are difficult to dart or pole syringe, while large cobia (*Rachycentron canadum*), with smaller scales, are relatively easy to inject.

For many fish, the skin is a respiratory organ and may be responsible for up to 30% of oxygen uptake in some species (Bruecker & Graham 1993). Most marine species have well-vascularized skin capable of significant cutaneous gas exchange (Ishimatsu & Itazawa 1993). Though scaleless species (e.g., catfish, Siluriformes) are better designed for cutaneous respiration, capacity often varies with age. Younger fish, regardless of size, tend to have thinner skin and less-developed scales, which results in greater oxygen uptake (Myszkowski et al. 2003). Fish species that produce larvae lacking gills require skin respiration until full differentiation of secondary gill lamellae occurs (Oikawa et al. 1994). Like other respiratory organs, skin is a route for immersion drug uptake and presumably excretion (Ferreira et al. 1984). Some scaleless types of common carp with high skin lipid content are much more efficient at cutaneous anesthetic uptake than rainbow trout (*Oncorhynchus mykiss*) with their small, densely packed scales and comparatively lower lipid content (Ferreira et al. 1984). In some instances, skin may be more efficient than other respiratory organs. In the electric eel (*Electrophorus electricus*), quinaldine uptake across the skin was higher than for the gills (Walsh & Pease 2002).

Size

Minimum effective anesthetic concentration is directly correlated with increasing body mass (Oikawa et al. 1994). This relationship is also true for toxic concentrations. For example, MS-222 LC_{50} increases with growth in rainbow trout, brown trout (*Salmo trutta*), lake trout (*Salvelinus namaycush*), largemouth bass (*Micropterus salmoides*), and channel catfish (*Ictalurus punctatus*) (Oikawa et al. 1994).

Environmental and Other Factors

Temperature

In addition to metabolism, dissolved oxygen (DO) concentrations are influenced by temperature. At higher temperatures, DO decreases and this exacerbates any anesthetic induced hypoxia. Warmer temperatures also promote solubilization of immersion anesthetics while cooler temperatures promote precipitation.

pH

The pH of immersion solutions will influence efficacy, possibly by affecting the ratio of charged to uncharged molecules. In general, decreased efficacy is seen as the pH drops due to increased ionization, which interferes with absorption. Unfortunately, most immersion anesthetics (e.g., MS-222 and quinaldine) in solutions are acidic, requiring buffering agents (e.g., sodium bicarbonate) to neutralize the pH. In addition to promoting immersion anesthetic efficacy (Ferreira et al. 1984), buffers can help prevent metabolic acidemia, a condition precipitated by anesthetic-induced hypoxemia and anaerobic metabolism. Saltwater, with its higher pH and greater natural buffering capacity compared to freshwater, has been shown not to require addition of buffering agents in some studies (Harms & Bakal 1995; Harms 1999; Oikawa et al. 1994; Ross & Ross 1984; Ross 2001), but in the authors' experience at least MS-222 requires buffering and produces much more favorable results when that occurs. At some institutions, it is common practice to buffer marine water with sodium bicarbonate at a 2:1 ratio (2 parts bicarbonate, 1 part MS-222 based on weight). An alternative to automatic addition of a buffer is to test the pH of the anesthetic water and adjust the pH accordingly. It has recently been found that sodium carbonate is a better buffer than bicarbonate (Burns, pers. exp.; Waxman et al. 2021). Regardless of the method used, one should keep in mind that pH shifts may have metabolic effects on the fish not solely related to anesthetic efficacy, especially if exposure is prolonged. That said, in an unpublished study by one of the authors (Clauss) with crevalle jacks (*Caranx hippos*), there was no significant short-term difference in blood gas values from fish anesthetized in buffered or unbuffered MS-222. Regardless, species differences exist and without a controlled study, it is advised to buffer or measure water pH. Bicarbonate itself is considered an anesthetic (due to the secondary effects of carbon dioxide narcosis) at 50–100 g/L and has been used in freshwater fishes (Avillanosa & Marlowe 2019; Caipang et al. 2021) (see also under the CO_2 section).

Nitrogenous Compounds

Buildup of nitrogenous compounds, particularly ammonia and nitrite, can damage or induce changes in gill morphology that affect uptake and clearance of immersion anesthetics. In addition, compromised oxygen uptake affects metabolism, including that of parenteral and immersion anesthetic agents, and can lead to acidemia. When anesthetic immersion water is used for an extended period of time for one animal or is reused for consecutive procedures, there is risk of nitrogenous compound elevations. Water changes during an extended procedure or between procedures will ameliorate these effects. Additionally, measuring the water's ammonia content during the procedure will alleviate concerns and guide actions.

Drug Concentration or Dosage

At a given temperature, higher concentration immersions or drug dosages generally decrease induction and increase recovery times. However, recovery time from some immersions is independent of concentration (Hseu et al. 1997, 1998).

Drug Exposure Time

Increased immersion anesthetic exposure time usually results in increased recovery time. This effect is often associated with progressive hypoxemia and metabolic acidemia due to prolonged hypoventilation. Some immersion drugs (e.g., MS-222) continue to increase in brain and muscle despite blood equilibration. Therefore, an initially satisfactory drug dosage can produce progressively deeper anesthesia and respiratory arrest, even during recovery when the fish is in anesthetic-free water (Ross 2001). Thus, using graded anesthesia, higher dose rapid induction, and lower dose maintenance levels is sound practice. This practice has shown to reduce overall levels of physiologic stress in some species (Matsche 2011). Additionally, dilution of the anesthetic water in a longer procedure while maintaining the anesthetic plane is a good method to reduce recovery time.

Vascular Access

Most fish fall under a similar body plan and accessing their blood vessels is fairly straightforward. The caudal tail vein is accessible via the ventral midline or with a lateral approach (Fig. 8.1). Cardiac puncture is sometimes the only viable option in species where the tail is either covered by large, thick scales (e.g., parrot fish, arowana, and

Figure 8.1 (a) Midline caudal tail venipuncture at a slight oblique angle in a green moray eel (*Gymnothorax funebris*) restrained in a plastic bag with mild sedation. (b) Lateral approach to caudal vein in a sedated green moray eel (*Gymnothorax funebris*).

arapaima) that prevent access without removal of scales, or where removal would result in significant skin exposure (Fig. 8.2a,b). In large fish, spinal needles may be required due to the depth of the vessels. Cardiac puncture can be achieved by moving the operculum and inserting the needle through the skin that is cranial to the bulbus arteriosus/ventricle or ventrally through the body wall. Access to the dorsal aorta is also available through the oral cavity, midline, and immediately posterior to the hard palate (Fig. 8.2c). There is a periorbital sinus that can be reached through the oral cavity (e.g., Australian lungfish). A vessel can be found in some species along the gill arch and can be another area to draw blood (Fig. 8.2d).

Intravenous catheterization of fishes is possible but not common (Ostrander 2000; Vergneau-Grosset & Benedetti 2022). In certain settings, typically research, dorsal aorta cannulation can be performed, but it requires anchoring specialized tubing through the roof of the mouth and through the rostrum, and fixing to the dorsal fin or muscle of the fish (Smith & Bell 1964; Sovio et al. 1972). The ventral aorta is cannulated in a similar fashion but using the lower jaw. The caudal vein can be catheterized as well and uses similar tubing as described above or with standard catheters (Ostrander 2000; Smith & Bell 1964; Sovio et al. 1972; Vergneau-Grosset & Benedetti 2022). The apparatus must be affixed to the animal to prevent slippage of the catheter. In fast-moving fishes, maintaining such catheters is nearly impossible, therefore confinement may be necessary, which carries its own obvious stressors (Sumpter et al. 1986). Additionally, the shape of the oral cavity and location of the vessel make some of these approaches impossible.

Immobilization Methods and Techniques

Manual Restraint

Manual restraint, when managed appropriately, can be used for doing simple, short procedures or when preparing the animal for induction of anesthesia. For procedures lasting longer than several minutes, it is best to use chemical immobilization. Animals that are habituated or domesticated tend to tolerate handling and restraint better than nonacclimated fish. See also the operant conditioning section in this chapter.

Considerations for human safety with manual restraint should include bites, stings, abrasions, and physical trauma due to thrashing. Even with chemical immobilization, the following should be considered so that appropriate safety precautions are utilized. Venom can occur in the dorsal or pectoral spines of scorpionfish, toadfish, rabbitfish, and a number of other fishes (Williamson et al. 1996). Sharp spines or other protuberances, such as with the acanthuridae (tangs, surgeonfish) or some tetraodontidae (porcupine pufferfishes), can cause significant damage without protective clothing. Teeth have vast anatomic variety and can crush, puncture, and/or macerate. In some species, pharyngeal teeth located deep in the oral cavity can cause trauma, particularly if the handler is unaware of their presence. Finally, there is the unique group of electric animals (electric eels, Mormyridiformes, Gymnotiformes) that pose varying risks. An electric eel can produce 550 V (~1 amp), which can be fatal to a human (Harms 2003), while some mormyrids produce <1000 Hz, used for communication and electrolocation (von der Emde 1999). Wearing gloves

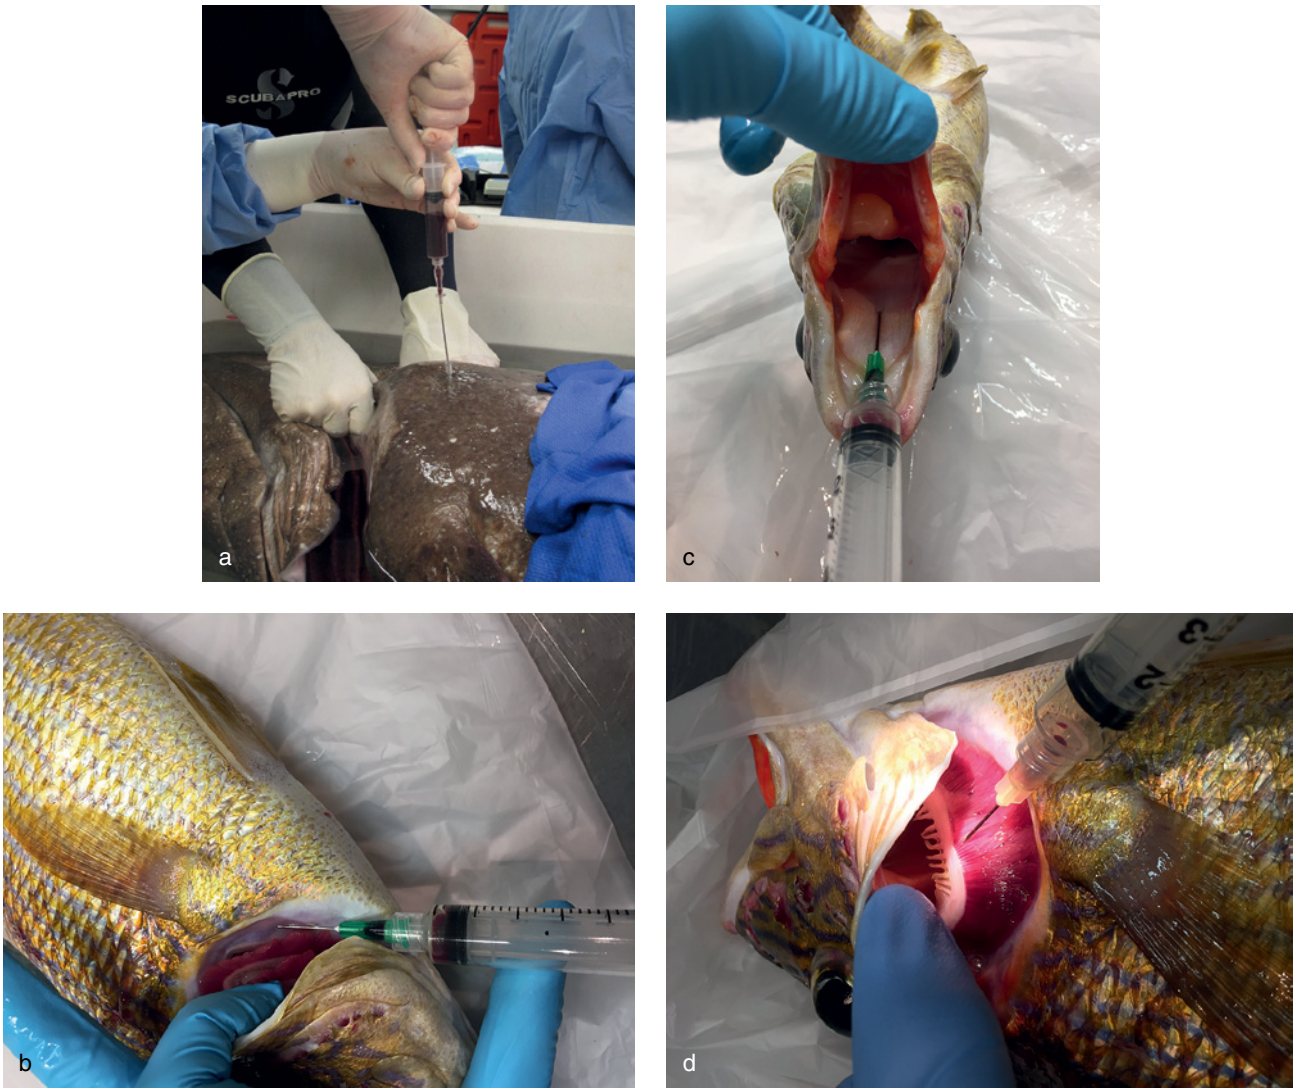

Figure 8.2 (a) Cardiac venipuncture in a giant grouper (*Epinephelus lanceolatus*) using a 16-gauge spinal needle. (b) Cardiac venipuncture in a French grunt (*Haemulon flavolineatum*). that do not transmit electric current is beneficial. Several case reports have been published highlighting some best practices with these species (Poll et al. 2014; Wenger et al. 2016, 2018).

Regarding animal safety, the tubular, soft-bodied fishes are particularly challenging to hold without crushing them. Furthermore, the mucus on the skin of fishes is very slippery and, in some species, copious. This can make it challenging to securely restrain the animal and can lead to long-term consequences should the mucus be removed. Wearing disposable gloves that have been rinsed free of powder (an irritant to fish) helps with minimizing damage to fish skin and mucus, but can make secure handling more challenging. Wet materials such as cloth diapers, flannel, bubble wrap, and chamois used for automobiles are both soft and smooth, and can be useful in restraining some fish without damaging or altering the skin and mucous layer. Some fishes are scaleless and require more delicate handling to avoid abrading the skin. Additionally, keeping some basic facts in mind (such as fish lack eyelids) will help in avoiding simple mistakes. Handling can result in microabrasions and ports of entry for foreign bacteria (Foster et al. 2020). The empirical treatment of adding a topical like sodium hyaluronate is helpful to prevent progression of these minor traumas.

Nets of varying sizes and configurations (dip, seine, and box) are the first-choice tool for catching and restraining many fishes. For delicate-skinned fish, nets made of plastic or very soft fine mesh should be used (Fig. 8.3a,b), but alternately, clear plastic bags can be used. In some

Figure 8.3 (a) Soft rubber net with clear plastic. (b) Large soft rubber net.

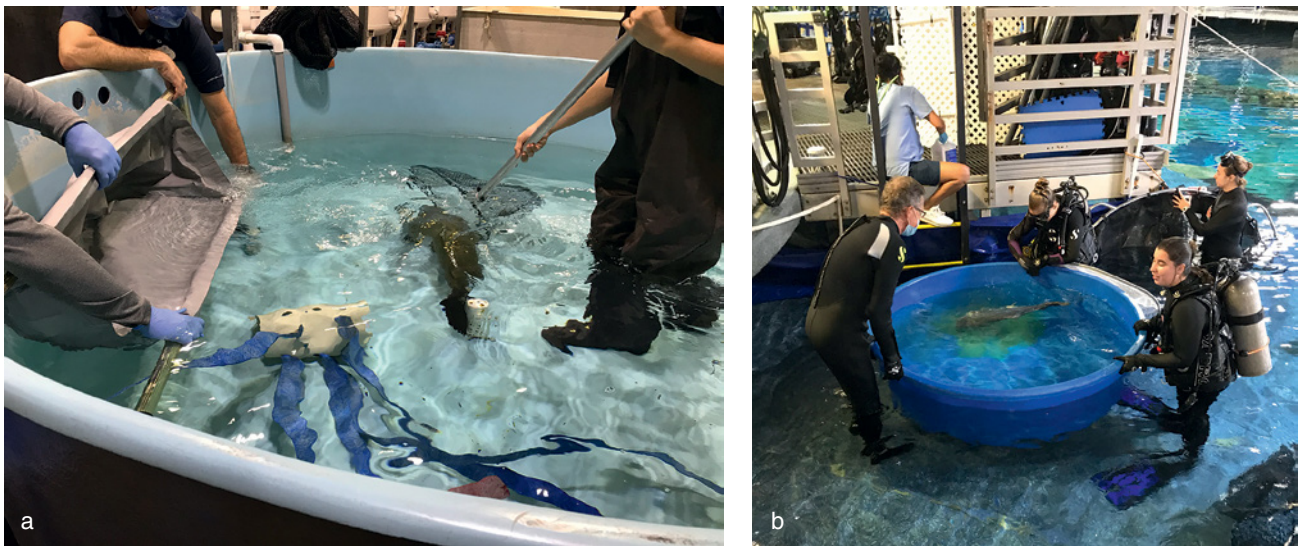

Figure 8.4 (a) Corralling a black pacu, tambaqui (*Colossoma macropomum*), fish into a sling for transfer. (b) A pool within a pool to facilitate sedation of large fish in smaller immersion volumes. The yellow tinge to the water is eugenol.

circumstances, as in large exhibits, even the hook and line approach has been successfully used. It is important to note, however, that as with wild fishes, hook traumas can pose risks to the fish and the process can be fatal as a result of exhaustive exercise.

Animals that struggle should be sedated. The concept of "learned helplessness", as with mammals, is not an appropriate parallel to draw. The fish that "gives up" is stressed and depleted of energy. Anticipation of how a fish will manage manual restraint is crucial.

Larger fish can be netted and placed in a sling (Figs 8.4 and 8.5a) but care needs to be taken when lifting; the integrity of the net must be solid and it should have drainage holes. These animals should only be moved for purposes of sedation and no further manipulation should occur due to human and animal safety concerns. One method more recently introduced for elasmobranchs handling and anesthesia (see Chapter 7) is also an effective method for larger teleosts such as grouper. This technique entails the use of a large vinyl bag with a narrow end that is open to allow water flow and a larger opening to catch the animal; this technique is best used in trained, partially sedated or sedated animals. At the Seas, Walt Disney World, Orlando, FL, a goliath grouper (*Epinephelus itajara*) was pre-sedated with oral valium, moved into the bag, and then further sedated with high doses of tricaine methanesulfonate in a 6-million-gallon aquarium and safely brought to the surface.

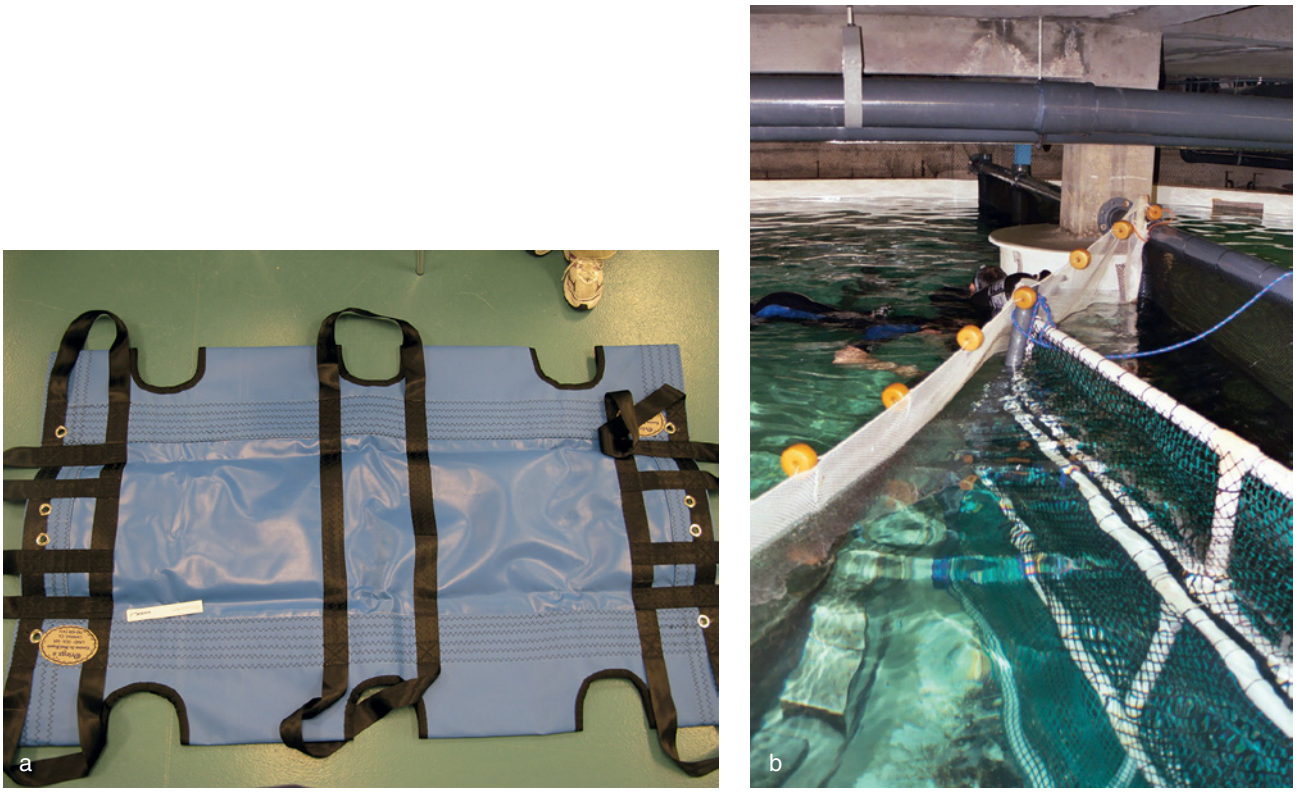

Figure 8.5 (a) Sling designed to lift large aquatic animals. (b) Squeeze device designed from polyvinyl pipe and plastic mesh. To the left of the squeeze is a net that reduces the space of the tank. The animal was corralled into the right side of the polyvinyl/mesh (animal is the far-right bottom corner).

An additional important consideration for manual restraint is time out of the water. In several studies, exposure to air increased mortality rates of angler-caught fishes (Ferguson & Tufts 1992; Gingerich et al. 2007; Veldhuizen et al. 2018). In another study, while there were no mortalities, there was significant morbidity (Schreer et al. 2005). Severity is species variable, as fishes that require oxygen-rich environments (e.g., trout) are more profoundly affected by air exposure and become acidotic with even short exposure times to air.

Operant Conditioning

Operant conditioning in fish is not a new concept and is critical to accomplish several husbandry behaviors and reduce stress (Alderman & Clayton 2021; Benhaïm et al. 2017; Bloch et al. 2019; Clayton & Mcdermott 2021; Couvillon 1984; Salena et al. 2021; Sison & Garlai 2010; Wright & Eastcott 1982). Many fish can be trained to move into certain areas of their enclosure, to swim into nets, crates, or pools. The size of the animal is not a restriction and schools of fish can be trained as well. In larger animals, operant conditioning can be an invaluable tool to isolate animals for brief examinations, treatments, or for facilitating chemical administration for inducing anesthesia (Fig. 8.6).

For induction of anesthesia, it is best to reduce the area where an animal can swim so that immersion anesthetics can be used in smaller volumes, injections are more achievable, or so that high-dose immersion agents (discussed later) can be administered with ease. Corralling animals into smaller areas with baffles, bringing them over slings (Fig. 8.4) and allowing the sling to come up around the animal's body, moving them into small inflatable pools, and finally, "squeeze" areas (Fig. 8.5) are all methods that facilitate examination, minor procedures (e.g., praziquantel immersion treatments) as well as anesthetic induction. Training animals to shift into containers like a PVC box or a plastic bin or over/into stretchers are also good options to achieve closer contact.

Fish cognitive abilities allow individuals or groups to respond to visual, auditory, or olfactory cues, and as such they can be trained or conditioned much like you would train any higher vertebrate (Alderman & Clayton 2021; Benhaïm et al. 2017; Bloch et al. 2019; Clayton & McDermott 2021; Couvillon 1984; Sison & Garlai 2010; Wright & Eastcott 1982; Salena et al. 2021).

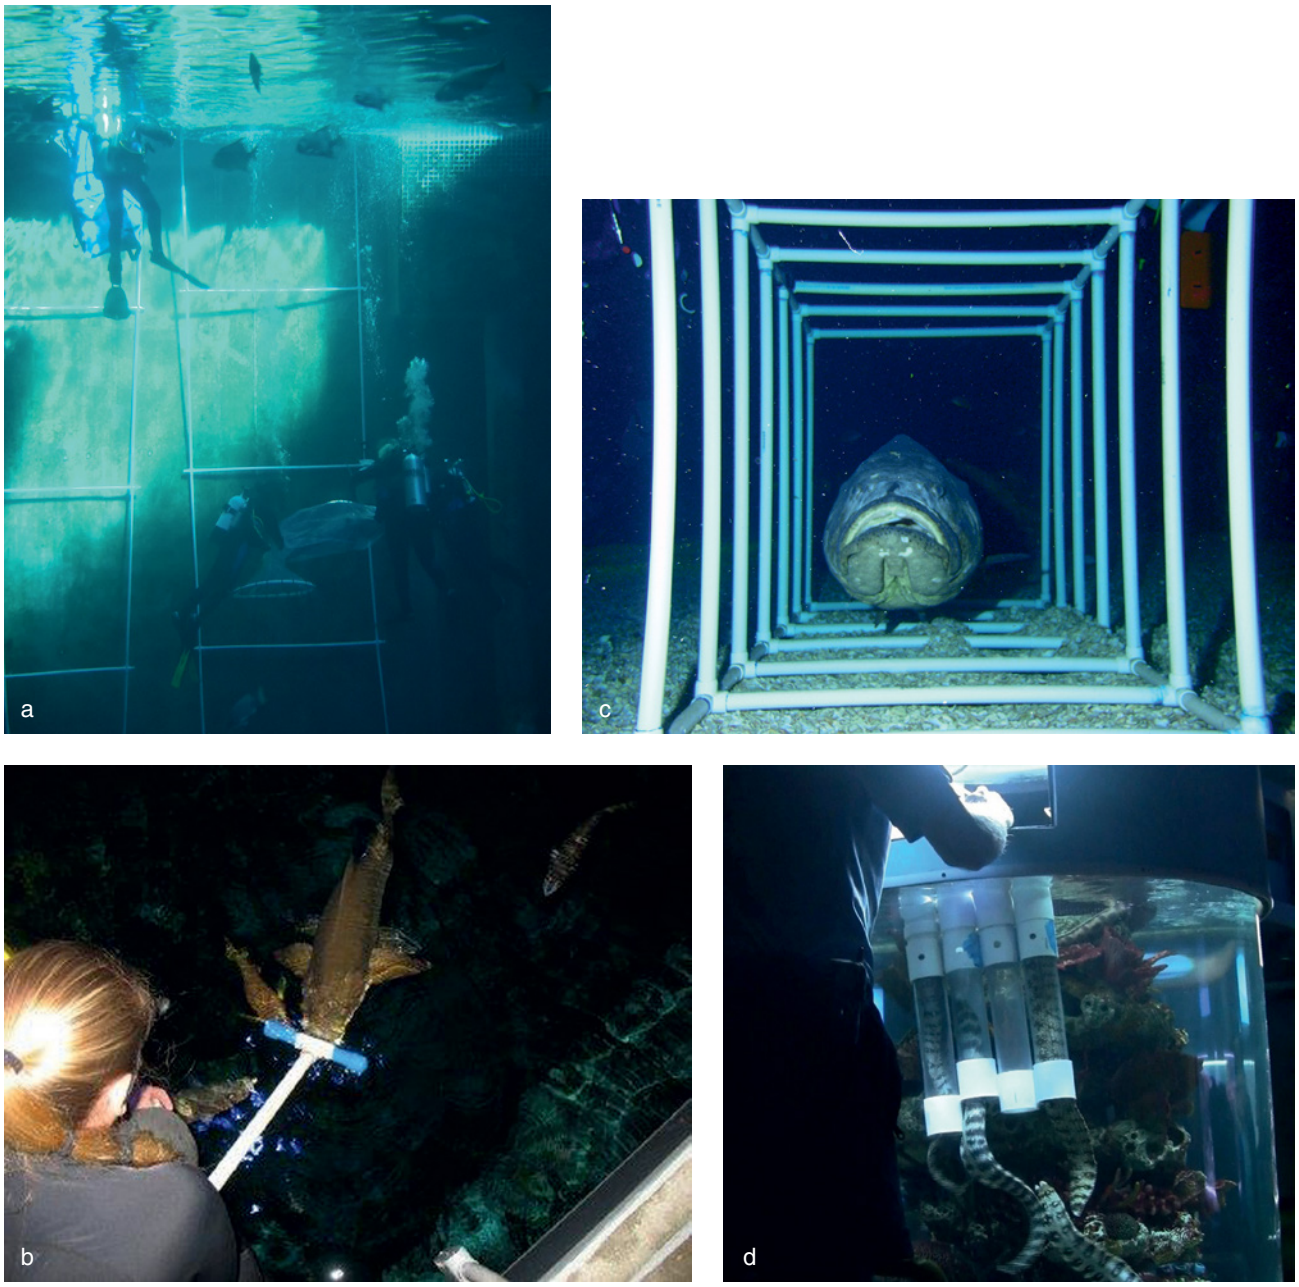

Figure 8.6 (a) Underwater image of a grouper (*Epinephelus itajara*) being transported in a vinyl sock to the surface after initial induction of high dose MS-222 delivered by a power sprayer. (b) Operant conditioning of a cobia (*Rachycentron canadum*). Note the animal is targeting a T-shaped piece of polyvinyl pipe. (c) Operant conditioning of a goliath grouper (*Epinephelus itajara*). The animal swims into a polyvinyl pipe box which can then be closed/secured to reduce the functional swimming space of the animal. (d) Operant conditioning of eels to enter a clear plastic tube for target feeding.

General Suggestions for Anesthesia

Before anesthetizing an unfamiliar species the anesthesiologist should perform a review of the available literature. Despite limited fish anesthesia publications, a literature search using the scientific name along with words or phrases such as "physiology", "anatomy", "site fidelity", "fecundity", "population assessment", etc., will identify studies that required sedation or anesthesia. Table 8.1, while listing anesthetic regimens for representatives of many families, is far from exhaustive and was accomplished, in part, as suggested above. Careful review of age class and body size in the literature should be considered when using these dosages and regimens because many studies utilize young or small fish. For example, drug

Protopterus aethiopicus	Lungfish, marbled	MS-222 (tricaine methanesulfonate)	0.50%	Immersion	2–14 kg				Used for catheter placement into the branchial arch.	Delaney et al. (1976)	
Protopterus annectens	Lungfish, West African	Medetomidine + ketamine	0.053 mg/kg + 5.26 mg/kg	Immersion	1.3 kg				Recommend higher dose.	D.L. Neiffer (pers. exp.)	Mild sedation, insuffiicient for diagnsotic workup.
Protopterus annectens	Lungfish, West African	Clove oil (100% pure)	0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1 ml/L	Immersion	50.3 ± 5.5 g			26.3 ± 1.2	The optimum concentration of benzocaine is between 1.8 and 2.6 ml/L.	Lederoun et al. (2019)	Clove oil > benzocaine and is effective at lower concentrations.
Protopterus annectens	Lungfish, West African	Benzocaine	0.85, 0.9, 0.95, 1.2, 1.5, 1.8, 2.1, 2.4, 2.5, 2.6, 2.7 ml/L	Immersion	50.3 ± 5.5 g			26.3 ± 1.2	The optimum concentration of benzocaine is between 1.8 and 2.6 ml/L.	Lederoun et al. (2019)	
Class Actinopterygii											
Order Acanthuriformes											
Family Acanthuridae											
Acanthurus bahianus	Surgeonfish, ocean	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion	~60 g				Sedation rated fair to good. Examinations performed.	D.L. Neiffer (pers. exp.)	Fair to good sedation level.
Acanthurus chirurgus	Doctorfish	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion	0.8–1.2			25	Provided surgical anesthesia for enucleation.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for enucleation.
Acanthurus chirurgus	Doctorfish	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion				25	Diagnostic examination, radiographs, surgery.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination, radiographs, surgery.
Acanthurus coeruleus	Surgeonfish, blue tang	MS-222 (tricaine methanesulfonate)	85 mg/L	Immersion				25	Sedation rated excellent. Examination and topical treatment performed.	D.L. Neiffer (pers. exp.)	Sedation rated excellent.
Acanthurus coeruleus	Surgeonfish, blue tang	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion			Adult	25	Diagnostic examination, laceration repairs.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination, laceration repairs.
Acanthurus japonicus	Tang, powder-brown	MS-222 (tricaine methanesulfonate)	50–70 mg/L	Immersion				25	Diagnostic examination.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination.

Acanthurus leucosternon	Surgeonfish, powder-blue	MS-222 (tricaine methanesulfonate)	50–70 mg/L	Immersion		25	Sedation rated excellent. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated excellent.
Acanthurus lineatus	Surgeonfish, lined	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion		25	Diagnostic examination, radiographs.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination, radiographs.
Acanthurus sohal	Surgeonfish, sohal	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion		25	Sedation rated good. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Good sedation.
Naso brevirostris	Unicornfish, spotted	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	~400 g	25	Go high and dilute down to prevent damage to horn.	C.M. Burns (pers. exp.)	Recommend high to low dose to prevent damage to horn.
Naso lituratus	Unicornfish, orangespine	MS-222 (tricaine methanesulfonate)	70–120 mg/L	Immersion	~300 g	25	Diagnostic examination, radiographs.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination, radiographs.
Naso unicornis	Unicornfish, bluespine	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion		25	Go high and dilute down to prevent damage to horn.	C.M. Burns (pers. exp.)	Recommend high to low dose to prevent damage to horn.
Paracanthurus hepatus	Tang, regal blue	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion		25	Diagnostic examination, laceration repairs, surgery.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination, laceration repairs, surgery.
Zebrasoma flavescens	Tang, yellow	MS-222 (tricaine methanesulfonate)	50–70 mg/L	Immersion	16–40 g	25	Diagnostic examination.	C.M. Burns (pers. exp.)	Sufficient sedation for diagnostic examination.
Family Ephippidae									
Chaetodipterus faber	Spadefish, Atlantic	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion	0.22–2.32		Effect varied from mild sedation at lower doses to surgical anesthesia at 100 mg/L, $N = 11$.	D.L. Neiffer (pers. exp.)	Variable effects ranging from mild sedation to surgical anesthesia.
Platax orbicularis	Batfish, orbicular	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion	2			C.M. Burns (pers. exp.)	
Platax teira	Batfish, longfin	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion	2			C.M. Burns (pers. exp.)	
Platax pinnatus	Batfish, pinnate	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion	2			C.M. Burns (pers. exp.)	
Family Lobotidae		MS-222 (tricaine methanesulfonate)							
Lobotes surinamensis	Tripletail	MS-222 (tricaine methanesulfonate)	70–90 mg/L	Immersion	21	25	Light to good plane of anesthesia for diagnostic examination/debridng wounds.	C.M. Burns (pers. exp.)	
Family Sciaenidae		MS-222 (tricaine methanesulfonate)							
Sciaenops ocellatus	Drum, red	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion		26–27	Anesthesia induced in 2.5–6 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8.	Thomas & Robertston (1991)	Sufficient sedation for handling and phlebotomy.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Sciaenops ocellatus	Drum, red	Metomidate hydrochloride	7 mg/L	Immersion				26–27	Anesthesia induced in 3–7 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8.	Thomas & Robertston (1991)	Sufficient sedation for handling and phlebotomy.
Sciaenops ocellatus	Drum, red	Quinaldine sulfate	20 mg/L	Immersion				26–27	Anesthesia induced in 2–4 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8.	Thomas & Robertston (1991)	Sufficient sedation for handling and phlebotomy.
Atractoscion nobilis	Weakfish, white	Isoeugenol	15, 25, 35, 55, 75, 100 mg/L	Immersion		0.0.75	Juvenile	22 ± 0.64	We found that a dose range of 25–55 mg/L provided an effective plane of anesthesia (stage II, plane II) for a 10-minute procedure in our cultured WSB with no associated postanesthetic mortality.	Silbernagel & Yochem (2016)	
Family Zanclidae											
Zanclus cornutus	Idol, moorish	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Sedation rated as excellent. Examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated as excellent.
Order Acipenseriformes											
Family Acipenseridae											
Acipenser baerii	Sturgeon, Siberian	Clove oil	50, 100, 200, 400 mg/L	Immersion			Prolarvae	19–20	Reached anesthesia between 50 and 280 seconds.	Kim & Nam (2018)	Prolarvae treated with clove oil reached anesthesia <5 seconds.
Acipenser baerii	Sturgeon, Siberian	Lidocaine	50, 100, 200, 400 mg/L	Immersion					Reached anesthesia between 35 and 100 seconds.	Kim & Nam (2018)	
Acipenser baerii	Sturgeon, Siberian	MS-222 (tricaine methanesulfonate)	50, 100, 200, 400 mg/L	Immersion					MS-222 also showed dose-dependent decrease of anesthetic times, 15–125 seconds.	Kim & Nam (2018)	MS-222 showed dose-dependent decrease of anesthetic times.
Acipenser baerii	Sturgeon, Siberian	MS-222 (tricaine methanesulfonate)	80, 100, 120, 140, 160 mg/L	Immersion	30–50 g		Juvenile	~16	Concentration of MS-222 for juveniles is between 80 and 120 mg/L.	Feng et al. (2011)	
Acipenser baerii	Sturgeon, Siberian	Clove oil (85% eugenol)	60, 90, 120, 150, 180 mg/L	Immersion	30–50 g		Juvenile	~16	Concentration of clove oil for juveniles is between 60 and 90 mg/L.	Feng et al. (2011)	
Acipenser gueldenstaedtii	Sturgeon, Russian	Clove oil	0.20–0.75 g/L	Immersion		0.0.44	Larvae	18	Sedated 3 minutes, recovery in 5 minutes at 0.20 g /L.	Akbulut et al. (2011)	Effective anaesthetic in larvae; higher doses had prolonged the recoveries.
Acipenser gueldenstaedtii	Sturgeon, Russian	Isoeugenol	50 mg/L	Immersion	22.25 ± 7.64	0.0.23	Adult	24.3–25.1	Time to reach handling 1 minute and 30 seconds, sedation 2 minutes and 30 seconds with ~6 minutes sedation and recovery of 9 minutes.	Cassle et al. (2021)	

Acipenser oxyrinchus oxyrinchus	Sturgeon, Atlantic	MS-222 (tricaine methanesulfonate)	100, 150, 200, 250 mg/L (induction), 70, 85, 100 mg/L (maintenance)	Immersion	~4		Juvenile	14 ± 24	Minimum 85 mg/L. Surgical dosing was 250 mg/L induction then to 70–100 mg/L. 45-minute procedure.	Matsche (2011)	Reccomended dose: 85 mg/L. Surgical dosing: 250mg/L.
Acipenser persicus	Sturgeon, Persian	Clove oil (80% eugenol)	25, 50, 75, 100 mg/L	Immersion	6.88 ± 0.9 g	0.0.15	Juvenile	21.5 ± 1.3	Useful concentrations of anesthetics tested were between 25 and 50 mg/L.	Adel et al. (2016)	Recommended dose: 25 and 50 mg/L for clove oil, less than 1 mg/L for propofol, 330 mg/L for 2-PE, and none for ketamine HCl.
Acipenser persicus	Sturgeon, Persian	Propofol (Rapinovet®)	1, 1.25, 2.5, 5 mg/L	Immersion	6.88 ± 0.9 g	0.0.15	Juvenile	21.5 ± 1.3	Useful concentrations of anesthetics tested were less than 1 mg/L for propofol.	Adel et al. (2016)	Recommended dose: between 25 and 50 mg/L for clove oil, less than 1 mg/L for propofol, 330 mg/L for 2-PE, and none for ketamine HCl.
Acipenser persicus	Sturgeon, Persian	2-phenoxyethanol	110, 330, 550, 770 mg/L	Immersion	6.88 ± 0.9 g	0.0.15	Juvenile	21.5 ± 1.3	Useful concentrations of anesthetics tested were 330 mg/L for 2-PE.	Adel et al. (2016)	Reommended dose: between 25 and 50 mg/L for clove oil, less than 1 mg/L for propofol, 330 mg/L for 2-PE, and none for ketamine HCl.
Acipenser persicus	Sturgeon, Persian	Ketamine hydrochloride	1250, 2500, 3750, 5000 mg/L	Immersion	6.88 ± 0.9 g	0.0.15	Juvenile	21.5 ± 1.3	None of the tested concentrations for ketamine HCl were clinically useful.	Adel et al. (2016)	Recommended dose: between 25 and 50 mg/L for clove oil, less than 1 mg/L for propofol, 330 mg/L for 2-PE, and none for ketamine HCl.
Acinpenser pxyrinchus desotoi	Sturgeon, Gulf	MS-222 (tricaine methanesulfonate)	250 mg/L (induction), 87.5mg/L (maintenance)	Immersion	13–17	0.0.17	5–8 years	18–21	Time to induction was 7–11 minutes. Recovery <13 minutes on endoscopic procedure.	Hernandez-Divers et al. (2004)	
Acinpenser pxyrinchus desotoi	Sturgeon, Gulf	Medetomidine + ketamine, atipamezole	.06 mg/kg + 6 mg/kg, reverse 0. mg/kg	IM	~4		4 years	21.6 ± 3.1	Light plane of anesthesia for minor diagnostic procedures within 10 minutes. Mild bradycardia and respiratory depression noted. Atipamezole administered 30 minutes after immobilizing agents. Full recovery by 30 minutes. No mortality.	Fleming et al. (2003)	Mild bradycardia and respiratory depression. No mortality.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Acinpenser pxyrinchus desotoi	Sturgeon, Gulf	Propofol	6.5 mg/kg	IV	~4		4 years	21.6 ± 3.1	Light plane of anesthesia for minor diagnostic procedures within 5 minutes. Mild bradycardia and respiratory depression noted, with latter persisting for 60 minutes. Fish remained quiet and unresponsive for 40 minutes. At 60 minutes 70% were struggling at pre-injection levels. All fish fully recovered within 120 minutes. No mortality.	Fleming et al. (2003)	Mild bradycardia and respiratory depression. Longer recoveries with no mortality.
Acipenser transmontanus	Sturgeon, white	Clove oil	50–100 mg/L	Immersion	206–363 g				Induction 3–6 minutes. Exposed for 10 minutes. Recovery 4.5–8.5 minutes. No mortality. A dosage of 25 mg/L was effective in anesthetizing all species for 120 minutes without mortality.	Taylor & Roberts (1999)	Recommended dose: 25 mg/L.
Acipenser transmontanus		Ketamine	77–88 mg/kg	IM	5–7.7				Induction 4–7 minutes. Effect lasted 6 hours.	Williams et al. (1988)	Long-lasting effect.
Acipenser ruthenus × *Huso huso*	Sturgeon, hybrid	MS-222 (tricaine methanesulfonate)	100–125 mg/L	Immersion	1.36–2.34	0.0.10			Variable effect from mild sedation to light anesthesia.	Clauss (pers. exp.)	Variable effect from mild sedation to light anesthesia.
Acipenser naccarii × *Acipenser baerii*	Sturgeon, hybrid	Clove oil	100 mg/L	Immersion					MS-222 (3.2 minutes) compared with CLO (4.7 minutes) and MK (5.4 minutes). Recovery time was significantly longer inMK anesthetized fish (16 minutes) in comparison with CLO. (5.8 min) and MS-222 (3.8 min).	Di Marco et al. (2011)	
Acipenser naccarii × *Acipenser baerii*	Sturgeon, hybrid	MS-222 (tricaine methanesulfonate)	150 mg/L	Immersion					MS-222 (3.2 minutes) compared with CLO (4.7 minutes)and MK (5.4 minutes). Recovery time was significantly longer inMK anesthetized fish (16 minutes) in comparison with CLO. (5.8 min) and MS-222 (3.8 min).	Di Marco et al. (2011)	
Acipenser naccarii × *Acipenser baerii*	Sturgeon, hybrid	Medtomidine + ketamine	0.04 mg/kg + 4 mg/kg	IV					Induced within 5 minutes, recovery within 15 minutes. Can use atipamezole.	Di Marco et al. (2011)	Safe and effective anaesthetic protocol; atipamezole can be used.

Huso huso	Sturgeon, beluga	Clove powder	175, 225, 275, 350 mg/L	Immersion	~30 g	0.0.180	Juvenile		Exposure was 10 minutes at each dose, no concentration tested had long-lasting effects on blood parameters.	Mohammadizarejabad et al. (2010)	No concentration tested had long-lasting effects on blood parameters.
Acipenser gueldenstaedtii	Sturgeon, Russian	MS-222 (tricaine methanesulfonate)	100–150 mg/L	Immersion	~20		Adult		Varies for procedure type, longer procedures induce 150 mg/ml dilute to lower dose.	C.M. Burns (pers. exp.)	Consider dilutions for longer procedures.
Acipenser spp.	Sturgeon	Isoeugenol	20–80 mg/L	Immersion					Concentrations of 40–60 mg/L rapidly anesthetize coldwater species to the handleable stage in <3–5 minutes whereas 60–80 mg/L is necessary to anesthetize cool and warm-water species in a comparable amount of time.	Javahery et al. (2012)	Recommended dose: 40–60 mg/L (cold-water species), 60–80 mg/L (cool- and warm-water species).
Order Anabantiformes											
Family Osphronemidae											
Colisa labiosus	Gourami, thick lipped	MS-222 (tricaine methanesulfonate)	200 mg/L –> 80 mg/L	Immersion	8 g				Induction 90 seconds. Total anesthesia time 47 minutes. Flow rate of maintenance fluid 12.1 ml/min. Gill motion throughout procedure. Full recovery by 23 minutes. Surgical mass removal.	Harms et al. (1995)	
Trichogaster trichopterus	Gourami, three spot	MS-222 (tricaine methanesulfonate)	400 mg/L	Immersion	19 ± 3 g			23–25	Induction within 2 minutes. Level sufficient for deep IM injection and phlebotomy. Recovery within 2 minutes. pH 7.4–7.6.	Yanong et al. (2005)	
Trichogaster trichopterus	Gourami, three spot	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion				28–29	Level sufficient to induce light sedation within 4 minutes.	Crosby et al. (2006)	
Trichogaster trichopterus	Gourami, three spot	Metomidate hydrochloride	0.8 mg/L	Immersion				28–29	Level sufficient to induce light sedation within 4 minutes.	Crosby et al. (2006)	
Trichogaster trichopterus	Gourami, three spot	Quinaldine	5 mg/L	Immersion				28–29	Level sufficient to induce light sedation within 4 minutes.	Crosby et al. (2006)	
Trichogaster trichopterus	Gourami, three spot	Metomidate hydrochloride	0.1, 0.2, 0.3, 0.4 mg/L	Immersion		0.0.330		22.9–24.7	Use of metomidate hydrochloride as a transport sedative for three-spot gourami should be considered with caution and may be problematic at the concentrations tested. Study parameters included marketability.	Crosby et al. (2012)	Use with caution as a transport sedative due to behavioral changes and high glucose.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Order Anguilliformes											
Family Anguillidae											
Anguilla anguilla	Eel, European	Eugenol	50 mg/L	Immersion	~150 g	0.0.20		~12	Recovery noted but no other anesthetic information provided.	Renault et al. (2011)	Eugenol as an aesthetic in ecotoxicological studies measuring gene expression or plasma cortisol concentration is not appropriate. Electro-narcosis did not seem to have any impact on the parameters taken into consideration in this study.
Anguilla japonica	Eel, Japanese	2-phenoxyethanol	1–16 ml/L	Immersion		0.0.8		25	Exposure to 2-PE at any dose induced a loss of equilibrium within 3 minutes.	Chiba et al. (2006)	Exposure to 2-PE at any dose induced a loss of equilibrium within 3 minutes, while the dose of MS-222 needed to induce a similar effect was more than 200 mg/L.
Anguilla japonica	Eel, Japanese	MS-222 (tricaine methanesulfonate)	50–800 mg/L	Immersion					Dose needed to induce a similar effect of 2-PE was more than 200 mg/L.	Chiba et al. (2006)	
Anguilla japonica	Eel, Japanese	Electroanesthesia	100 V, 2A -AC power or 240 V, 6A -AC, 30 s	Immersion						Chiba et al. (2006)	Electrofisher Model 12-A (Smith-Root, Vancouver, WA, USA) was also used to shock the fish with 500 V or 1000 V at 5 A pulsating DC for 30 seconds.
Anguilla reinhardtii	Eel, speckled longfin	Benzocaine	60–80 mg/L	Immersion			Adult	17–25	Dissolved in ethanol (1:10). Induction within 6 minutes.	Walsh & Pease (2002)	
Anguilla reinhardtii	Eel, speckled longfin	Clove oil	100 mg/L	Immersion			Adult	17–25	Induction within 6 minutes. Recovery within 4 minutes.	Walsh & Pease (2002)	
Anguilla rostrata	Eel, American	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Sedation rated excellent. Examination performed.	D.L. Neiffer (pers. exp.)	Excellent sedation.
Family Muraenidae											
Echidna nebulosa	Eel, snowflake	MS-222 (tricaine methanesulfonate)	80–200 mg/L	Immersion			Juvenile-adult	25	Air gulpers, make sure animal is completely submerged. Prolonged inductions can be attributed to this. Induce high, especially in healthier specimens.	C.M. Burns (pers. exp.)	Air gulpers, make sure animal is completely submerged. Higher doses recommend for faster induction.
Echidna nebulosa	Eel, snowflake	Isoeugenol	40–70 mg/L	Immersion			Juvenile-adult	25	Sedate enough for morphometrics, blood draw. Apply to give treatments at 70, with anesthesia time <20 minutes.	C.M. Burns (pers. exp.)	Sedate enough for morphometrics, blood draw.

Gymnomuraena zebra	Moray, zebra	MS-222 (tricaine methanesulfonate)	80–200 mg/L	Immersion		0.0.2	Adult	25	Sick animal sedated at 80, up to 200 mg/L for healthy animals (induction).	C.M. Burns (pers. exp.)	Wide dose range; 80 mg/L used in debilitated animals up to 200 mg/L.
Gymnomuraena zebra	Moray, zebra	Isoeugenol	50 mg/L	Immersion		0.0.1	Adult	25	Sedate enough for morphometrics, blood draw.	C.M. Burns (pers. exp.)	
Gymnothorax funebris	Moray, green	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion	22–30		Adult		Suitable for examination. Animals that gulp air at surface may take longer to induce. Make sure animal is enclosed in a confined area since prone to leaping.	E.J. Chittick (pers. exp.)	Air gulper, may take longer to induce. Prone to jumping.
Gymnothorax funebris	Moray, green	MS-222 (tricaine methanesulfonate)	125–150 mg/L –> 75–100 mg/L	Immersion	22–30		Adult		Long procedures lower induction dose to below 100 mg/L. For short procedures 125 ppm is suitable for entire time.	C.M. Burns (pers. exp.)	Long procedures lower dose (<100 mg/L) recommended; use higher dose (125 ppm) for shorter procedures.
Gymnothorax funebris	Moray, green	Isoeugenol	25–30 mg/L	Immersion			Adult		Fast induction, dilute for longer procedures.	C.M. Burns (pers. exp.)	Fast induction. Recommend dilution for longer procedures.
Gymnothorax vicinus	Moray, purplemouth	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion			Adult		Suitable for examination. Animals that gulp air at surface may take longer to induce. Make sure animal is enclosed in a confined area since prone to leaping.	E.J. Chittick (pers. exp.)	Air gulper, may take longer to induce. Prone to jumping.
Family Ophichthidae											
Myrichthys maculosus	Eel, tiger snake	MS-222 (tricaine methanesulfonate)	175–200 mg/L	Immersion			Adult		Very active species, more profound air gulping, make sure animal is submerged. Decrease dose for longer procedures.	C.M. Burns (pers. exp.)	Very active species, ensure full submersion.
Order Atheriniformes											
Family Melanotaeniidae											
Melanotaeniidae spp.	Ornamentals	Metomidate hydrochloride	40, 60, 100, 250, 100 mg/L	Immersion				22–24	Some species were euthanized at a concentration of 40 mg/L metomidate hydrochloride for a total exposuretime of 38 minutes. Most species tested were successfully euthanized with metomidate hydrochloride at a concentration of 100 mg/L, with total exposure times ranging from 35 to 96 minutes. A few catfish species were refractory and recovered after 100 mg/L. However, *Otocinclus* sp. were successfully euthanized at 250 mg/L and bronze corydoras were euthanized at 1000 mg/L.	Yanong (2021)	Wide range of doses and time until effect.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Melanotaenia australis	Rainbowfish, western	Isoeugenol	40, 60, 80, 100, 120 mg/L	Immersion				27	For stage four anesthesia of the western rainbowfish *Melanotaenia australis* the most efficacious concentration of Aqui-S® was found to be 80 mg/L.	Young (2009)	
Order Batrachoidiformes											
Family Batrachoididae											
Opsanus beta	Toadfish, gulf	MS-222 (tricaine methanesulfonate)	670 mg/L buffered with NaOH	Immersion			Adult	24–26	Once fish were induced they were wrapped in anesthetic solution-soaked paper towels for 30-minute surgical placement of venous cannula. Species is considered tolerant of air exposure and it was not necessary to irrigate gills.	Gilmour et al. (1998)	
Opsanus tau	Toadfish, oyster	MS-222 (tricaine methanesulfonate)	50–250 mg/L	Immersion	675 ± 46 g		Adult	20	Slight sedation at 50 mg/l. Decreasing respiratory rate and ability to maintain equilibrium from 100 to 250 mg/l. Cessation of voluntary respiratory activity at 300 mg/l. These later fish resumed gilling 14 minutes after anesthetic withdrawal and all fish regained equilibrium within 23 minutes of anesthetic withdrawal.	Palmer & Mensinger (2004)	
Opsanus tau	Toadfish, oyster	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion	1.38		Adult	25	Sedated for up to 1 hour during CT starting with high dose and diluting down when necessary.	C.M. Burns (pers. exp.)	
Opsanus tau	Toadfish, oyster	Isoeugenol (Aqui-S® 20e)	0.0005–0.0060%	Immersion	281.5± 72.8 g	10.16.0	Adult	19–21	Effective in inducing the surgical plane of anesthesia. It is not recommended for acute neural preparations due to its depression of neural activity. The depression of lateral line sensitivity at low concentrations could play a role in reducing the stress response during fish transport.	Putland et al. (2020)	Increasing the concentration significantly decreased spontaneous and evoked firing rates of the anterior lateral line.

Order Beryciformes											
Family Holocentridae											
Holocentrus ascensionis	Squirrelfish	MS-222 (tricaine methanesulfonate)	70–85 mg/L	Immersion	160–500 g				Variable sedation (mild to heavy) for examination.	D.L. Neiffer (pers. exp.)	
Myripristis jacobus	Soldierfish	MS-222 (tricaine methanesulfonate)	55–75 mg/L	Immersion	140–390 g					C.M. Burns (pers. exp.)	
Neoniphon sammara	Squirrelfish, sammara	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion						T.M. Clauss (pers. exp.)	
Sargocentron spp.	Squirrelfish	MS-222 (tricaine methanesulfonate)	70–75 mg/L	Immersion	27–335 g					C.M. Burns (pers. exp.)	
Order Beloniformes											
Family Adrianichthyidae											
Oryzias dancena	Medaka, Merine	Clove oil	50 , 75, 100, 125, 150 mg/L	Immersion	334.9 ± 60.0 mg	0.0.50		26	Both drugs tested in salinities of 0 to 40 ppt. Anesthetic time increased as salinity increased.	Park et al. (2017)	10 ppt had fastest time to effect.
Oryzias dancena	Medaka, Merine	Clove oil (85%)	50, 75, 100, 125, 150, 175 mg/L	Immersion	11.0 ± 1.31, 324.3 ± 58.6 mg	0.0.40	20–40 phd, 100–160 phd	23, 26, 29	Exposure to 125 mg/L at 23°C, 100 mg/L at 26°C, and 75 mg/L at 29°C were considered the optimal concentrations.	Park et al. (2011)	Recommended dose: 125 mg/L at 23°C, 100 mg/L at 26°C, and 75 mg/L at 29°C.
Oryzias dancena	Medaka, Merine	Lidocaine-HCl	50 , 75, 100, 125, 150 mg/L	Immersion	334.9 ± 60.0 mg	0.0.50		26	Both drugs tested in salinities of 0 to 40 ppt. Anesthetic time increased as salinity increased.	Park et al. (2017)	
Oryzias dancena	Medaka, Merine	Lidocaine HCL	300, 400, 500, 600, 700, 800 mg/L	Immersion	11.0 ± 1.31, 324.3 ± 58.6 mg	0.0.40	20–40 phd, 100–160 phd	23, 26, 29	Exposure to 800 mg/L at 23°C and 700 mg/L at 26 and 29°C were considered the optimal concentrations for anesthesia within 1 minute.	Park et al. (2011)	Recommended dose: 800 mg/L at 23°C and to 700 mg/L at 26 and 29°C.
Oryzias latipes	Medaka, Japanese	Menthol	3.0 mM	Immersion	1.6 ± 0.2 cm			25 ± 1	Applied by injection to one side of a gill (50 μL), oral cavity (50 μL), and one side of the body surface (100 μL) of medaka fish and goldfish (100, 100, and 300 μL, respectively) by injection with a 1-ml syringe, and the peritoneal cavity (10 μL for medaka fish and 30 μL for goldfish) was injected with a 100-μL Hamilton microsyringe.	Kasai et al. (2014)	Menthol (d-, l-, dl-types) at 0.4 mM produced surgical anesthesia in medaka, goldfish, and zebrafish.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Order Blenniiformes											
Family Tripterygiidae											
Enneapterygius rufopileus	Triplefin, redcap	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion				18	Induction within 3 minutes. Recovery within 10 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Induction within 3 minutes. Recovery within 10 minutes. Sufficient for handling and measurement.
Order Carangiformes											
Family Carangidae											
Caranx bartholomaei	Jack, yellow	MS-222 (tricaine methanesulfonate)	55–80 mg/L	Immersion				25	Examination, quarantine checkouts.	C.M. Burns (pers. exp.)	
Caranx crysos	Blue runner	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion				25	Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good for diagnostic examination.
Caranx crysos	Blue runner	Alphaxalone + alphadolone	0.3 ml/kg	IM	1.5				Anesthesia with marked depression of ventilation.	Harvey et al. (1988)	Produced stage 3 anesthesia.
Caranx hippos	Jack, crevalle	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion				25	Transport, unable to obtain blood.	C.M. Burns (pers. exp.)	
Caranx latus	Jack, horse-eye	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion			Adult	25	Fast sedation prior to injectable euthasol for euthanasia.	C.M. Burns (pers. exp.)	
Caranx latus	Jack, horse-eye	Isoeugenol + MS-222 (tricaine methanesulfonate)	25–40 mg/L induction –> 70 mg/L maintenance	Immersion			Adult	25	40 mg/L was a deep anesthesia prior to moving to MS-222.	C.M. Burns (pers. exp.)	
Caranx latus	Jack, horse-eye	MS-222 (tricaine methanesulfonate)	50–80 mg/L	Immersion				25	Sedation rated as good to excellent. Examinations performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good-excellent for diagnostic examination.
Carangoides ruber	Jack, bar	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion	70 g			25	Sedation rated as good. Adequate for examination and enucleation.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Adequate for examination and enucleation.
Carangoides ruber	Jack, bar	MS-222 (tricaine methanesulfonate)	45–80 mg/L	Immersion			Juvenile-adult	25	Examination, quarantine checkouts.	C.M. Burns (pers. exp.)	
Caranx stellatus	Bluefin trevally	Alphaxalone + alphadolone	0.4 ml/kg	IM	18				Sedation with partial loss of equilibrium within 2–5 minutes. More than one dart used to deliver total dose. Able to be netted, but responsive. Recovered within 30 minutes.	Harvey et al. (1988)	Produced stage 1 anesthesia.
Caranx stellatus	Bluefin trevally	Metomidate hydrochloride	10–100 mg/kg	IM	16–35				Light sedation with partial loss of equilibrium. Directed net avoidance.	Harvey et al. (1988)	Produced stage 1–2 anesthesia.

Selene vomer	Lookdown	MS-222 (tricaine methanesulfonate)	75–125 mg/L	Immersion				25	Varied effect from mild sedation to light anesthesia (125 mg/L) for examinations.	D.L. Neiffer (pers. exp.)	Varied effect from mild sedation to light anesthesia (125 mg/L) for examination.
Selene vomer	Lookdown	MS-222 (tricaine methanesulfonate)	50–70 mg/L	Immersion			Juvenile-adults	25	Species places head in corner/against wall during sedation. Careful of eyes.	C.M. Burns (pers. exp.)	
Seriola dumerili	Amberjack, greater	Alphaxalone + alphadolone	0.3 ml/kg	IM	8				Sedation with partial loss of equilibrium within 2–5 minutes. Able to be netted, but responsive. Recovered within 30 minutes.	Harvey et al. (1988)	Produced stage 2 anesthesia.
Seriola dumerili	Amberjack, greater	Metomidate hydrochloride	10–100 mg/kg	IM	9				Sedation with partial loss of equilibrium. Able to be netted, but responsive.	Harvey et al. (1988)	Produced stage 2 anesthesia.
Seriola lalandi	Amberjack, yellowtail	Isoeugenol	25, 35, 55, 75 mg/L	Immersion		0.0.50	Juvenile	20.7 ± 0.37	In cultured YT species, the safe and effective dose range was narrower, 25–35 mg/L, with significant mortality noted at 55 mg/L and above.	Silbernagel & Yochem (2016)	Safe and effective dose range was narrow: 25–35 mg/L. Significant mortality noted at 55 mg/L and above.
Seriola lalandi	Amberjack, yellowtail	Tiletamine-zolazepam	8–9 mg/kg (avg. 70 mg per jack)	Oral	6–9	0.0.15	Adult, juvenile		Used dry form of drug for oral sedation. Within 6–8 hours of ingestion, fish receiving an intended 70-mg dose began to show signs of sedation consisting of dark coloration, altered swim patterns, and loss of righting ability. Maximum sedative effect of oral tiletamine-zolazepam was 8–12 hours. Recovery from sedation, defined as return of normal swimming patterns and equilibrium, ranged from 12 to 48 hours.	Steers & Sherrill (2001)	10 out of 14 (71.4%) animals were transported, with the remaining as mortalities.
Trachinotus carolinus	Pompano, Florida	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion				25	Provided sedation to light anesthesia for examinations, tagging, and ocular surgery.	D.L. Neiffer (pers. exp.)	
Trachinotus falcatus	Permit	MS-222 (tricaine methanesulfonate)	100–125 mg/L => 70–90 mg/L	Immersion	3.8–18		Adult	25	If adult start at high dose and dilute to lower dose as needed. Juveniles can start at a lower dose if desired.	C.M. Burns (pers. exp.)	
Trachinotus goodei	Pompano, great	MS-222 (tricaine methanesulfonate)	70–100 mg/L					25	Light to heavy sedation for surgery.	C.M. Burns (pers. exp.)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Family Rachycentridae										
Rachycentron canadum	Cobia	Medetomidine + ketamine	0.122–0.240 mg/kg + 6–13.5 mg/kg	IM	24–40 kg	Adult	5	Injected using spring-loaded pole syringe. Dose resulted in mild sedation. Supplemental dose of 0.100 mg/kg medetomidine and 2.8 mg/kg ketamine necessary for final capture.	D.L. Neiffer (pers. exp.)	Supplemental dose of 0.100 mg/kg medetomidine and 2.8 mg/kg ketamine.
Rachycentron canadum	Cobia	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion	9–40 kg	Adult	25	Transport, diagnostic examination, treatments.	C.M. Burns (pers. exp.)	
Order Characiformes										
Family Characidae										
Brycon cephalus	Matrinxã/ brycon, red-tailed	MS-222 (tricaine methanesulfonate)	150 mg/L	Immersion	31.56 ± 8.08 g	Juvenile	25	Buffered with $CaCO_3$ time to anesthesia: ~6 minutes, duration 10 minutes, recovery <10 minutes. Zero mortality at 150 mg/L.	Roubach et al. (2001)	Mortality: 0% at 150 mg/L, 16.7% at 200 mg/L, and 33.3% at 300 mg/L. Pronounced stress response at 200 and 300 mg/L.
Colossoma macropomum	Tambaqui/ cachama	Benzocaine	100–150 mg/L	Immersion	9.32 ± 3.7 g	Juvenile	24	Dissolved in acetone (10 g/100 ml). Induction: 0.11–1.01 minutes. Recovery following exposure for 10 minutes: 2.32–9.04 minutes. Recovery following exposure for 30 minutes: 30 ± 20 minutes.	Gomes et al. (2001)	Fish exposed to ≥ 220 mg/L exhibited stress response. Mortality 30% at 350 mg/L.
Colossoma macropomum	Tambaqui/ cachama	Eugenol	65 mg/L	Immersion	56.6 ± 7.7 g, 1100 ± 90.7 g	Juveniles to subadults	26–27	Dissolved in alcohol to make 1:2 stock solution. Handling at 1.45 minutes, surgical stage in 2.54 minutes, recovery <10 minutes. Exposure for 30 minutes was not associated with mortality. Dose up to 100 mg/L considered safe.	Roubach et al. (2005)	Exposure for 30 minutes was not associated with mortality. Dose up to 100 mg/L was considered safe.
Colossoma macropomum	Tambaqui/ cachama	MS-222 (tricaine methanesulfonate)	30 mg/L	Immersion		Adult		In-tank sedation, then transport.	Mylniczenko (pers. exp.)	
Colossoma macropomum	Tambaqui/ cachama	Medetomidine, butorphanol, midazolam	100 μg/mkg + 1 mg/kg + 1 mg/kg	IM		Adult		Used in combination prior to euthanasia with MS-222. Very light sedation.	Mylniczenko (pers. exp.)	Used in combination prior to euthanasia with MS-222. Very light sedation.

Colossoma macropomum	Tambaqui/ cachama	Tea tree oil + clove oil	10.4 mg/L	Immersion	65.2 ± 1.20g	0.0.300	Juvenile	27 ± 1.7	Favorable results for 15- and 36-hour transportations using combined tea tree and clove essential oils at 10.4 mg/L for sedation.	Santos et al. (2020)	Good for 15- and 36-hour transports.
Colossoma macropomum	Tambaqui/ cachama	Alphaxalone + alphadolone	0.3–0.8 ml/kg	IM	6–10				Deepest stage within 1 hour 0–3.	Harvey et al. (1988)	
Colossoma macropomum	Tambaqui/ cachama	Metomidate hydrochloride	20–165 mg/kg	IM	4–9				Deepest stage within 1 hour 0–3.	Harvey et al. (1988)	
Colossoma macropomum	Tambaqui/ cachama	Gallamine triethiodide (Flaxedil)	1.3–1.4 mg/kg	IM	7–13				Deepest stage within 1 hour 2–3.	Harvey et al. (1988)	
Hyphessobrycon spp.	Tetra	Clove oil	0.05 ml (50 mg), 0.10 ml (100 mg), and 0.20 ml (200 mg) per 500 ml of water	Immersion		0.0.40			Most effective dose is 0.05 ml for recovery. 0.20 ml is recommended for studies that require fish euthanization.	Fernandes et al. (2016)	Recommended dose: 0.05 ml for recovery procedures.
Piaractus brachypomus	Pirapitinga	MS-222 (tricaine methanesulfonate)	100–125 mg/L	Immersion	18		Adult	25	Diagnostic examination, radiographs, recovered quickly.	C.M. Burns (pers. exp.)	Quick recovery.
Piaractus brachypomus	Pirapitinga	MS-222 (tricaine methanesulfonate)	100, 200 mg/L	Immersion	500–727 g		4-year-old adults	20–23	Induction: 100 mg/L, average 550 seconds; 200 mg/L, average 350 seconds. Recovery 300–500 seconds. pH 5.5–7.0.	Sladky et al. (2001)	
Piaractus brachypomus	Pirapitinga	Eugenol	0, 25, 50, 75, 100, 125 mg/L	Immersion	0.87 ± 0.20, 17.14 ± 3.27 g	0.0.120	Juveniles I, II		Able to induce deep anesthesia at 50–100 mg/L for both size classes.	Ferreira et al. (2021)	
Piaractus brachypomus	Pirapitinga	Menthol	0, 25, 50, 75, 100, 125 mg/L	Immersion	0.83 ± 21, 16.83 ± 2.78 g	0.0.120	Juveniles I, II		Able to induce deep anesthesia at 25–100 mg/L for juvenile I and between 50 and 25 mg/L for juvenile II.	Ferreira et al. (2021)	
Piaractus mesopotamicus	Pacu	Benzocaine	99 mg/L	Immersion	315.2–745.2 g		Adult	15–35	Used for surgical implantation of ECG electrodes, and buccal and opercular catheters.		Used for surgical implantation of ECG electrodes, buccal and opercular catheters.
Pygocentrus cariba	Piranha, black spot	MS-222 (tricaine methanesulfonate)	70–90 mg/L	Immersion			Adult		Good anesthesia for mass removal, ocular aspirations, and assisted feeding.	T.M. Clauss (pers. exp.)	Good anesthesia for mass removal, ocular aspirations, and assist feeding.
Pygocentrus nattereri	Piranha, red	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion			Adult		Good anesthesia for minor and surgical procedures.	N.D. Mylniczenko, T.M. Clauss (pers. exp.)	Good anesthesia for minor and surgical procedures.
Astyanax altiparanae	Lampari	Eugenol	50, 75, 100, 125, 150 mg/L	Immersion	~0.6 g		Fry		50 mg/L is an efficient and safe concentration.	Pereira da Silva et al. (2009)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Family Erythrinidae											
Hoplerythrinus unitaeniatus	Aimara	Urethane	1% solution	Immersion						Farrell & Randall (1978)	
Hoplerythrinus unitaeniatus	Aimara	MS-222 (tricaine methanesulfonate)	0.01% solution	Immersion						Farrell & Randall (1978)	
Hoplias lacerdae	Characin	Benzocaine	50 mg/L	Immersion	375 ± 47 g		Adult	25 ± 1	Provided light anesthesia for brief procedures.	Rantin et al. (1993)	
Hoplias malabaricus	Trahira	Benzocaine	50 mg/L	Immersion	312 ± 47 g		Adult	25 ± 1	Provided light anesthesia for brief procedures.	Rantin et al. (1993)	
Family Prochilodontidae											
Prochilodus nigricans	Prochilodus, black	Eugenol	25, 50, 100, 200 mg/L	Immersion	221.34 ± 9.0 g	0.0.50		29.47 ± 0.30	The concentration of 50 mg/L surgical anesthesia induction ~3 minutes.	Viegas et al. (2020)	
Order Cichliformes											
Family Cichlidae											
Aulonocara spp.	Cichlid, peacock	Alfaxalone	5 mg/L	Immersion		0.0.11				Zellar et al. (2018)	
Aulonocara spp.	Cichlid, peacock	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion		0.0.11				Zellar et al. (2018)	Buffered with 200 mg/L bicarbonate.
Astronotus ocellatus	Oscar	Alfaxalone	5 mg/L	Immersion		0.0.6	Subadult	25.1	Induction time <15 minutes, recovery up to 55 minutes. OpR and RR decreased over time in anesthetic but HR remained the same.	Bugman et al. (2016)	Respirations decreased over time but heart rate remained steady.
Amphilophus citrinellus	Cichlid, midas	MS-222 (tricaine methanesulfonate)	150 mg/L for induction;	Immersion	800 g				Induction in 8 minutes. Flow rate of maintenance solution 3 L/min. Procedure 71 minutes.	Lewbart et al. (1994)	
Amphilophus citrinellus	Cichlid, midas	Ketamine	30 mg/kg	IV	206 ± 36 g			22 ± 2	Fish sedated first in buffered MS-222 (100–125 mg/L) for 8–10 minutes, at which point fish became unresponsive. Fish removed from bath and ketamine injected. Induction <10 seconds. In some fish complete cessation of ventilation occurred, while in others intermittent coughing or rapid ventilation was noted. Anesthesia lasted 1–41 minutes with balance regained at 57–263 minutes.	Bruecker & Graham (1993)	Sedated first in buffered MS-222 then injected with ketamine. Wide range in effect.

Cichlidae spp.	Misc. species	Metomidate hydrochloride	40, 60, 100, 250, 100 mg/L	Immersion		22–24	Some species were euthanized at a concentration of 40 mg/L metomidate hydrochloride for a total exposuretime of 38 minutes. Most species tested were successfully euthanized with metomidate hydrochloride at a concentration of 100 mg/L, with total exposure times ranging from 35 to 96 minutes. A few catfish species were refractory and recovered after 100 mg/L. However, *Otocinclus* sp. were successfully euthanized at 250 mg/L and bronze corydoras were euthanized at 1000 mg/L.	Yanong (2021)	Wide range in anesthetic doses and duration until effect.
Cichlasoma nigrofasciatum	Cichlid, convict	Quinaldine sulphate	3.25, 6.5, 9.75, 13, 27, 40, 54 mg/L	Immersion	~54 g	26	Introduction of diazepam in combination with QS helped eliminate the undesired effects of QS during sedation. The combination of QS + D is a potent anesthetic for convict cichlids. For light anesthesia: 9.75 ppm QS + 0.5 ppm D. For deep anesthesia: 9.75 ppm QS + 1.0 ppm D.	Bircan-Yildirim et al. (2010)	Addition of diazepam with QS helped eliminate undesired effects.
Cichlasoma nigrofasciatum	Cichlid, convict	Quinaldine sulphate + diazepam	Above with added 0.5 and 1.0 mg/L	Immersion				Bircan-Yildirim et al. (2010)	
Haplochromis obliquidens	Cichlid, Lake Victoria	Clove oil	5–30 µL/L	Immersion			18–20 µL/L suggested a narrow margin of safety as this concentration range induced mortality.	Kaiser et al. (2006)	Narrow margin of safety and this concentration range induced mortality.
Sarotherodon linellii	Cichlid, blackfin	MS-222 (tricaine methanesulfonate)	1000 mg/L	Immersion			Euthanasia: After a 60-minute immersion in the euthanasia solution, the presence of an audible heartbeat was identified in 90% or more of the cichlids, indicating that they were not reliably euthanized. A two-step protocol is therefore recommended in cichlids for euthanasia: heavy anesthesia via immersion followed by an IV or intracardiac injection of euthanasia solution or other secondary method of euthanasia.	Bradley et al. (2021)	Euthanasia methods utilized in this study were not reliable.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Sarotherodon linellii	Cichlid, blackfin	2-phenoxyethanol	2 ml/L	Immersion						Bradley et al. (2021)	
Sarotherodon linellii	Cichlid, blackfin	Clove oil	500 mg/L	Immersion						Bradley et al. (2021)	
Oreochromis spp.	Tilapia	Isoeugenol	20–80 mg/L	Immersion					Concentrations of 40–60 mg/L rapidly anesthetize cold-water species to the handleable stage in <3–5 minutes whereas 60–80 mg/L is necessary to anesthetize cool- and warm-water species in a comparable amount of time.	Javahery et al. (2012)	Recommended dose: 40–60 mg/L (cold-water species); 60–80 mg/L (cool- and warm-water species).
Oreochromis spp.	Tilapia, red hybrid	Sodium bicarbonate	50, 100 g/L	Immersion	1–4.5 g		Juvenile	26–29	Fish that were reared in brackishwater (20 ppt) took a longer time to be fully anesthetized than those reared in freshwater for either concentration. The concentration of the anesthetic has an effect on the time to induce anesthesia of the fish. In addition, the time to full recovery of the fish was not significantly different in both rearing environments and was not affected by the dose of anesthetic.	Avillanosa et al. (2019)	Fish that were reared in brackishwater (20 ppt) took a longer time to be fully anesthetized than those reared in fresh water at either concentration.
Oreochromis macrochir	Tilapia, longfin	Sodium bicarbonate	5.0, 10.0, 15.0, 20.0 and 30.0 g/L	Immersion	160 ± 10 g	0.0.90	Adult	25 ± 0.5	5.0 g/L produced no anesthetic effects. The induction for this study varied up to 11 minutes and recovery times varied up to 22 minutes.	Hasimuna et al. (2020)	5.0 g/L produced no anesthetic effects.
Oreochromis mossambicus	Tilapia, Mozambique	2-phenoxyethanol	600 mg/L	Immersion	3.83 ± 0.55 g		Juvenile	30	Induction: 7.43 + 13.25 minutes. Recovery (fish placed in fresh water immediately after induction): 1.38 + 1.77 minutes.	Hseu et al. (1997)	
Oreochromis mossambicus	Tilapia, Mozambique	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion			Juvenile, adult			N.D. Mylniczenko (pers. exp.)	
Oreochromis mossambicus	Tilapia, Mozambique	MS-222 (tricaine methanesulfonate)	110–150 mg/L	Immersion					Light sedation at low range.	T.M. Clauss (pers. exp.)	Light sedation at low range.

Oreochromis mossambicus	Tilapia, Mozambique	Lidocaine	100–750 mg/L	Immersion					Although both induced anesthesia, the mixture was more effective for induction and recovery (titrated at 50-mg doses).	Carrasco et al. (1984)	
Oreochromis niloticus	Tilapia, Nile	Propofol	0.15, 0.30, or 0.60 ml/L	Immersion	30–50 g			25	We found that low concentrations of propofol at 0.15, 0.30, and 0.60 ml/L induce anesthesia in ~17. 9, 7.2, and 5.6 minutes, respectively.	Valenca-Silva et al. (2014)	
Oreochromis niloticus	Tilapia, Nile	Saturated nitric oxide (NO)	Solubility of NO was 136 ml/1000 ml	Immersion		0.0.72		20	No treatment resulted in shorter euthanasia time (~20 minutes), less stress than CO_2.	Wang et al. (2017)	No treatment resulted in shorter euthanasia time; less stress than CO_2.
Oreochromis niloticus	Tilapia, Nile	Eugenol (99%)	30 mg/L	Immersion	35 ± 2.3 g	0.0.18		24 ± 2	Induction 5.75 ± 3.32 minutes, anesthesia 56.25 ± 21.6 minutes, recovery 33.6 ± 13.9 minutes.	Zahran et al. (2021)	
Oreochromis niloticus	Tilapia, Nile	Propofol	2.5 mg/L	Immersion	35 ± 2.3 g	0.0.18		24 ± 2	Induction 2.5 ± 1.3 minutes, anesthesia 19.87 ± 3.4 minutes, recovery 45.6 ± 12.02 minutes.	Zahran et al. (2021)	
Oreochromios niloticus	Tilapia, Nile	2-phenoxyethanol	0.5, 1, 2 ml/L	Immersion	61 ± 3 g			26	4 minutes in 2-phenoxyethanol (0.5 ml/L). Fish from an aquarium were anesthetized in less than 1 minute in 2-phenoxyethanol (1 or 2 ml/L). The use of higher concentrations of 2-phenoxyethanol (1 or 2 ml/L) provided anesthetized fish in less than 1 minute.	Auperin et al. (1997)	
Oreochromisb niloticus	Tilapia, Nile	Benzocaine	1.5, 3.25, 6.5, 13, 26 ml/L	Immersion	22.85 ± 2.57 g	0.0.40	Juvenile	24.5 ± 0.16	Propofol is a more powerful anesthetic than benzocaine in Nile tilapia, with longer duration and deeper effect. Immersion propofol is efficient as an anesthetic in fish and could be adopted as a protocol in experimentation as well aquaculture management. Best results seen were 6.5 ml/L of benozocaine and 0.3ml/L of propofol.	Gonçalves and Giaquinto (2020)	Propofol is a more powerful anesthetic than benzocaine, with longer duration and deeper effect.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Oreochromisb niloticus	Tilapia, Nile	Propofol (Diprivan 1%)	0.075, 0.15, 0.3, 0.6, 1.2 ml/L	Immersion	22.85 ± 2.57 g	0.0.40	Juvenile	24.5 ± 0.16		Gonçalves and Giaquinto (2020)	
Oreochromisb niloticus	Tilapia, Nile	Ethanol	500 µL/L	Immersion	224.05 ± 67.56 g	0.0.40		28.05	Ethanol did not elicit any anesthetic effect or sedation in the fish. Induction of deep anesthesia was faster in the OA group (126 seconds), than PE (152 seconds) and LA (170 seconds). OA or LA essential oils at 500 µL/L were effective in inducing deep anesthesia with unconsciousness duration of 126–180 seconds, allowing time for bleeding.	Rucinque (2021)	Ethanol did not elicit any anaesthetic effect or sedation in the fish.
Oreochromisb niloticus	Tilapia, Nile	2-phenoxyethanol	500 µL/L	Immersion	224.05 ± 67.56 g	0.0.40		28.05		Rucinque (2021)	
Oreochromisb niloticus	Tilapia, Nile	*Ocimum americanum* (Basil)	500 µL/L	Immersion	224.05 ± 67.56 g	0.0.40		28.05		Rucinque (2021)	
Oreochromisb niloticus	Tilapia, Nile	*Lippia alba* (Verbena)	500 µL/L	Immersion	224.05 ± 67.56 g	0.0.40		28.05		Rucinque (2021)	
Oreochromis niloticus	Tilapia, Nile	Cooling treatment –> carbon dioxide (CO_2)	Reduction in temperature from 30°C to 15°C (at a rate of 3.5°C/h, by adding slurry ice) moved to 15°C hyperoxic (1.0–0.2 L/min)	Immersion	500–550 g			30 ± 2 to 15	Cooling followed by hyperoxic CO_2 anesthesia would be suitable for handling tilapia in a short-time air exposure procedure. Fish were deeply sedated within 69 seconds, completely anesthetized within 276 seconds and recovered within 308 seconds without any mortality.	Guan et al. (2017)	
Oreochromis niloticus	Tilapia, Nile	Eugenol plant	30, 60, 120, 180, 240, 300 mg/L	Immersion	~600 g	0.0.12			60 mg/L concentration required more time to reach the desired stage of profound anesthesia (206.3 seconds), while the 300 g/L concentration reached this stage more rapidly (77.8 seconds).Results suggest that the optimal concentration of eugenol for biometry procedures is 120 mg/L and that increased anesthetic dosage results in reduced opercular beat rate.	Moreira et al. (2010)	Recommended dose: 120 mg/L. Increased anesthetic dosage results in reduced opercular beat rate.
Oreochromis niloticus	Tilapia, Nile	Propofol (1%)	2.5, 5, 7.5, 10, 12.5 mg/L	Immersion	5–200 g	300.0.0		29.7 ± 0.9	Except for the 2.5 mg/L dosage, all concentrations induced full and smooth anesthesia in <5 minutes in all the Nile tilapia size classes. A <10-minute recovery time only occurred in a few sizes, most >10-minute however recovery was complete for all fish.	Obirikorang et al. (2020)	Except for the 2.5 mg/L dosage, all concentrations induced full and smooth anaesthesia.

Oreochromis niloticus	Tilapia, Nile	Menthol	50–300, 500 mg/L	Immersion	13.70 g			~27	Surgical anesthesia 250 mg/L, brief handling 150–200 mg/L, doses at 500 mg/L showed no mortalities.	Simoes & Gomes (2009)	Doses at 500 mg/L showed no mortalities.
Oreochromis niloticus	Tilapia, Nile	Clove oil	100, 150, 200, 250, 350 mg/L	Immersion	670.00 ± 75.28 g	0.0.70		26.98 ± 1.41	The concentration of 250 mg/L of clove oil was adequate to induce lower opercular movement in adult tilapia. For anesthesia for biometrics and brief management, the recommended concentration is 100 mg/L clove oil is an effective anesthetic for the management of adult tilapia as a routine procedure in fish farming.	Simoes et al. (2010)	Recommended dose: 100 mg/L for the management of adult tilapia as a routine procedure in fish farming.
Pterophyllum scalare	Angelfish, freshwater	Eugenol	0 (control), 10.6, 15.9, 21.2, 31.8,42.4, 53.0 or 63.6 mg/L (each concentration diluted 1:10 with ethanol)	Immersion	0.80 ± 0.08 g	0.0.56	Juvenile		The minimum effective concentration for sedation and anesthesia occurred with 15.9 and 53.0 mg/L eugenol. It is concluded that 15.9 and 53.0 mg/L eugenol are effective concentrations for sedation andanesthesia in juveniles.	de Oliveira et al. (2019)	Recommended dose: 15.9 and 53.0 mg/L eugenol were effective concentrations for sedation andanesthesia in juveniles.
Pterophyllum scalare	Angelfish, freshwater	Eugenol	15.9 mg/L	Immersion	1.75 ± 0.17 g	0.0.40	Juvenile		Simulated transport with evaluations at 4- and 7-hour marks. 15.9 mg/L eugenol has the potential to be used for the transportation of freshwater angelfish for up to 7 hours.	de Oliveira et al. (2019)	Eugenol has the potential to be used for the transportation of freshwater angelfish for up to 7 hours.
Order Clupeiformes											
Family Clupeidae											
Alosa pseudoharengus	Alewife	MS-222 (tricaine methanesulfonate)	87.5–112.5 mg/L (adult), 62.5,75, 87.5, 100 mg/L (juvenile), 37.5, 50.0, 62.5, 75.0, 87.5 mg/L (larval)	Immersion	27.5 ± 8.9, 200 g		Adult, juvenile, larval	15–17	Optimal doses: 75–100 mg/L MS-222 for all sizes.		Metomidate hydrochloride may be better for longer sedation.
Alosa pseudoharengus	Alewife	Clove oil	25–40 mg/L (adult), 2.5, 5, 20, 25, 30, 35, 40 mg/L (juvenile), 20, 25, 30, 35, 40 mg/L (larval)	Immersion					Optimal doses: 40 mg/L clove oil for all sizes.		

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Alosa pseudoharengus	Alewife	Metomidate hydrochloride	0.5–5.0 mg/L (adult), 0.25, 0.50, 3.0, 4.0, 5.0, 6.0, 7.0 mg/L (juvenile/larval)	Immersion					Optimal doses: 5–7 mg/L metomidate hydrochloride. Noting metomidate hydrochloride may be better for longer sedation.		
Alosa pseudoharengus	Alewife	2-phenoxyethanol	500 mg/L (adult), 300, 350, 400, 450, 500 mg/L (juvenile/larval)	Immersion					Optimal doses: 500 mg/L 2-PE.		
Alosa pseudoharengus	Alewife	MS-222 (tricaine methanesulfonate)	87.5–112.5 mg/L	Immersion			Adult, juvenile, larval		Optimal doses for anesthesia: 75–100 mg/L MS-222.	Berlinsky et al. (2016)	
Alosa pseudoharengus	Alewife	Clove oil	25–40 mg/L	Immersion					Optimal doses for anesthesia: 40 mg/L clove oil.	Berlinsky et al. (2016)	
Alosa pseudoharengus	Alewife	Metomidate hydrochloride	0.5–5.0 mg/L	Immersion					Optimal doses for anesthesia: 5–7 mg/L metomidate hydrochloride.	Berlinsky et al. (2016)	
Alosa pseudoharengus	Alewife	2-phenoxyethanol	125–550 mg/L	Immersion					Optimal doses for anesthesia: 500 mg/L 2-PE.	Berlinsky et al. (2016)	
Alosa pseudoharengus	Shad, hickory	MS-222 (tricaine methanesulfonate)	50, 75, 100 mg/L	Immersion		64.64.27		11.5–13.0	75–100 mg/L MS-222 is effective in anesthetizing in <2 minutes to a level of anesthesia sufficient for handling.	Matsche (2017)	Muscle spasms, coughing, decreased respiration were evident at 400 mg/L.
Alosa pseudoharengus	Shad, hickory	2-phenoxyethanol	25, 100, 400 mg/L	Immersion					400 mg/L PhE anesthetizes in <2 minutes to a level of anesthesia sufficient for handling. External signs of stress were evident in fish during anesthesia with the highest concentration of PhE.	Matsche (2017)	
Alosa pseudoharengus	Shad, hickory	Isoeugenol	25, 50, 100 mg/L	Immersion					50–100 mg/L eugenol is effective in anesthetizing in <2 minutes to a level of anesthesia sufficient for handling (stage III, plane 1).	Matsche (2017)	
Order Cypriniformes											
Family Cyprinidae											
Carassius auratus	Goldfish	2-phenoxyethanol	0.25–0.35 ml/L	Immersion	3.93 ± 1.99 g			24	Provided light sedation.	Kaiser & Vine (1998)	Provided light sedation.
Carassius auratus	Goldfish	2-phenoxyethanol	0.45 ml/L	Immersion					Provided anesthesia with loss of equilibrium.	Kaiser & Vine (1998)	Provided anesthesia with loss of equilibrium.

Carassius auratus	Goldfish	2-phenoxyethanol	0.3, 0.4, 0.5 ml/L	Immersion	2.15 ± 0.05, 9.19 ± 0.17 g		20, 25, 30	At temperatures at and below 25°C, 0.4 ml/L was needed to induce anesthesia. Above 25°C, 0.5 ml/L was required.	Weyl et al. (1996)	At temperatures at and below 25°C, 0.4 ml/L was needed to reach effect within 15 minutes; above 25°C, 0.5 ml/L was required to induce anesthesia.
Carassius auratus	Goldfish	Alfaxalone	0.15, 0.5, 2.0, 5.0 and 7.5 mg/L	Immersion		0.0.30	23–25	Lowest concentrations to induce sedation were 0.5 and 5 mg/L.	Bauquier et al. (2013)	
Carassius auratus	Goldfish	Alfaxalone	6, 7, 9 mg/L	Immersion		0.0.30	2.24–25	Immersion of 6 mg/L provided best induction of anesthesia.	Leonardi et al. (2019)	Recommended dose: 6 mg/L.
Carassius auratus	Goldfish	Alfaxalone	10 mg/L (induction), 5 mg/L (maintenance)	Immersion	460 g			Administered for analgesia 0.4 mg/kg IM. 60 minutes surgical event with 35 minutes of recovery.	Fernández-Parra et al. (2017)	Used for analgesia at 0.4 mg/kg IM.
Carassius auratus	Goldfish	Butorphanol mg/kg	0.1, 0.2, 0.4 mg/kg	IM				Fish were anesthetized with MS-222 for injectioms in concentrations >120 ppm. Morphine and ketoprofen decrease anesthetic needs in goldfish and may provide analgesia.	Ward et al. (2012)	Morphine and ketoprofen decreased anesthetic needs in goldfish and may provide analgesia.
Cyprinus carpio	Goldfish	Eugenol (99%)	6.25, 12.5, 25, 50, 75, 100, 125, 150, 200 mg/L; 43 mg/L (5 min); 10 mg/L (3 h)	Immersion	110 ± 5.65 g	0.0.98	25.3 ± 1.25	Eugenol anesthetized the fish within 600–900 seconds (with recovery time of 190–380 seconds) at concentrations of 25–150 mg/L.	Yousefi et al. (2018)	Anesthesia in 600–90 seconds with recovery times of 190–380 seconds.
Carassius auratus	Goldfish	Fentanyl + (MS-222 + gallamine)	10 µg/g + 100 mg/L + 100, 500, 2500 µg/g	IM	30–70 g	0.0.16		Animals were only anesthetized to stop moving for fentanyl injection, returned to nonanesthetic water. Gallamine was given to stop animals from moving for experiment. Recovery not noted due to euthanization after experiment.	Cordova & Braurn (2007)	Gallamine was given to stop animal from moving for experiment; no recovery data.
Carassius auratus	Goldfish	Ketamine	50, 67, 100, 200 mg/kg	PO	3–20 g	0.0.22	70–73F	Ketamine can be safely administered orally and in food up to at least 500 mg/kg in less primitive teleost fish and 50 mg/kg in elasmobranchs to induce a hypnotic sedation plane.	Raines & Clancy (2009)	Ketamine can be administered orally up to 500 mg/kg in fish and 50 mg/kg in elasmobranchs.
Carassius auratus	Goldfish	Medetomidine	0.01, 0.015, 0.025 mg/kg	IM				Fish were anesthetized with MS-222 for injectioms in concentrations >120 ppm. Morphine and ketoprofen decrease anesthetic needs in goldfish and may provide analgesia.	Ward et al. (2012)	Morphine and ketoprofen decrease anesthetic needs in goldfish and may provide analgesia.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Carassius auratus	Goldfish	Morphine sulfate 15 mg/ml, Baxter Healthcare Corporation, Deerfield, Illinois, 60015, USA	10, 20, 40 mg/kg	IM					Fish were anesthetized with MS-222 for injectioms in concentrations >120 ppm. Morphine and ketoprofen decrease anesthetic needs in goldfish and may provide analgesia.	Ward et al. (2012)	Morphine and ketoprofen decrease anesthetic needs in goldfish and may provide analgesia.
Carassius auratus	Goldfish	Propofol	1, 5, 10 mg/L	Immersion	0.02–0.03	0.0.38	Adult	23.1–23.3	Propofol at 1 mg/L did not produce anesthesia. Propofol at 5 and 10 mg/L produced anesthesia, and anesthetic needs were similar following repeated procedures.	Balko et al. (2017)	Propofol at 1 mg/L did not produce anesthesia while 5 and 10 mg/L did.
Carassius auratus	Goldfish	Propofol	25 mg/L	Immersion	0.02–0.04	0.0.6	Adult	23.1–23.3	Euthanasia: 30 minutes in 25 mg/L.	Balko et al. (2018)	Very light sedation after 30 minutes in 25 mg/L.
Cyprinus carpio	Goldfish	Thymol (98.5%)	6.25, 12.5, 25, 50, 75, 100, 125, 150, 200 mg/L; 52 mg/L (5 min); 20 mg/L (3 h)	Immersion	110 ± 5.65 g	0.0.98		25.3 ± 1.25	Thymol induced anesthesia within 850–60 seconds at concentrations of 25–200 mg/L.	Yousefi et al. (2018)	
Carassius auratus	Goldfish	Tricaine methansulfonate	150, 200, 300, 400, 500 mg/L	Immersion	230 ± 25 mg	0.0.5		25.6	Recommended ideal concentration was 200 mg/L at 12 ppt.	Küçük & Çoban (2016)	Recommended dose: 200 mg/L at 12 ppt.
Carassius auratus	Goldfish	Tricaine methanesulfonate	500 mg/L	Immersion	0.02–0.04	0.0.6	Adult	23.1–23.3	Euthanasia: at 15 and 30 minutes in 500 mg/L.	Balko et al. (2018)	Very light sedation at 15 and 30 minutes in 500 mg/L.
Carassius auratus	Goldfish	Tricaine methanesulfonate	1,000 mg/L	Immersion	0.02–0.04	0.0.6	Adult	23.1–23.3	Euthanasia: at 15 minutes in 1000 mg/L.	Balko et al. (2018)	Very light sedation at 15 minutes in 1000 mg/L.
Carassius carassius	Carp, Crucian	Benzocaine	25, 50, 100 mg/L	Immersion	~370 g	0.0.36		~22	100 mg/L benzocaine produced a fast induction anesthesia time.	Heo & Shin (2010)	Quick induction with low circulating cortisol and glucose concentrations.
Ctenopharyngodon idella	Carp, grass	MS-222 (tricaine methanesulfonate)	100 mg/L –> 75mg/L	Immersion	1.0–2.5 kg			22	Induction within 5 minutes. Allowed for surgical implantation of radio transmitters. Recovery took 5–25 minutes. Mortality occurred with 100 mg/L at temperatures >31°C.	Schramm & Black (1984)	Mortality occurred with 100 mg/L at temperatures >31°C.
Ctenopharyngodon idella	Carp, grass	2-phenoxyethanol	0.2 ml/L	Immersion	3–12 kg		Brood stock	25	Mixed with 500 ml of tank water and added to chamber. Induction to light sedation in 2–3 minutes. Females stripped of ova with this dose.	McCarter (1992)	Mixed with 500 ml of tank water and added to chamber.

Ctenopharyngodon idella	Carp, grass	2-phenoxyethanol	0.4 ml/L	Immersion					Induction to anesthesia in 5–10 minutes. Males stripped of milt with this dose.	McCarter (1992)	
Ctenopharyngodon idella	Carp, grass	Etomidate	1.0–3.0 ml/L	Immersion			Spawners	23	Propiscin applied in a water bath can provide up to 1 hour of general anesthesia.	Kazuñ & Siwicki (2012)	
Ctenopharyngodon idella	Carp, grass	MS-222 (tricaine methanesulfonate)	100 mg/L (control group)	Immersion	107.78 ± 22.11 g	0.0.165	Juvenile	18–21	Induction time in MS-222 139 seconds.	Khara et al. (2020)	MS-222 had fastest induction followed by ketamine then tobacco.
Ctenopharyngodon idella	Carp, grass	Ketamine	5.5, 8, 11, 18.5, 22 mg/L	Immersion	107.78 ± 22.11 g	0.0.165	Juvenile	18–21	Induction time in 18.5 mg/L of ketamine 140.	Khara et al. (2020)	
Ctenopharyngodon idella	Carp, grass	Tobacco extract	10, 13.33, 20, 26.27, 40 mg/L	Immersion	107.78 ± 22.11 g	0.0.165	Juvenile	18–21	Induction time in 40 mg/L tobacco 174 seconds.	Khara et al. (2020)	
Ctenopharyngodon idella	Carp, grass	Benzocaine	30, 40, 50, 60, 70 mg/L	Immersion	12 g	0.0.350	Juvenile	15	Optimal concentration was 0.3 mg/L for xylazine, more effective in deep anesthesia and recovery times.	Shakeri et al. (2016)	Recommended dose: 0.3 mg/L for xylazine and 50 mg/L for benzocaine. Xylazine was more effective in deep anesthesia and recovery times.
Ctenopharyngodon idella	Carp, grass	Xylazine	0.1, 0.2, 0.3, 0.4, 0.5 mg/L	Immersion	12 g	0.0.350	Juvenile	15	Optimal concentration was 50 mg/L for benzocaine.	Shakeri et al. (2016)	Recommended dose: 0.3 mg/L for xylazine and 50 mg/L for benzocaine. Xylazine was more effective in deep anesthesia and recovery times.
Cyprinus carpio	Carp, common	Alphaxalone-alphadolone	0.3 ml/kg	IM	2 kg				Sedation with partial loss of equilibrium. Able to be netted, but responsive.	Harvey et al. (1998)	Sedation with partial loss of equilibrium. Able to be netted, but responsive.
Cyprinus carpio	Carp, common	Alphaxalone	10 mg/L then 1–2.5 mg/L	Immersion	0.292–0.405			17–19	10 mg/L to immobile, maintained 1 or 2.5 mg/L.	Bailey et al. (2014)	
Cyprinus carpio	Carp, common	Alphaxalone	10 mg/L –> 1 mg/L or 2.5 mg/L	Immersion	292.0–405.0 g	0.0.6	Adult	17.4–18.5	Maintenance dose of 2.5 mg/L was sufficient to prevent response to noxious stimuli.	Minter et al. (2014)	The maintenance dose of 2.5 mg/L was sufficient for nociception but showed clinically relevant respiratory depression. No mortalities.
Cyrpinus carpio	Carp, common	Alphaxalone + alphadolone	0.3 ml/kg	IM	2				Achieved level 2 sedation.	Hansen et al. (2003)	Achieved level 2 sedation
Cyprinus carpio	Carp, common	Isoeugenol	20, 40, 60, 80, 100, 150, 200, 500 mg/L	Immersion		0.0.216	Juvenile		40–80 mg/L induced anesthesia within 4–11 minutes. 500 mg/L caused death in 50% of the study.	Gladden et al. (2010)	Recommended dose: 40 to 80 mg/L induced anesthesia. 500 mg/L = 50% mortality.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Cyprinus carpio L.	Carp, common	Etomidate	1.0 ml/L	Immersion			Fingerlings, 2yro	17–19	Propiscin applied in a water bath can provide up to 1 hour of general anesthesia.	Kazuñ & Siwicki (2012)	
Cyprinus carpio	Carp, common	Lidocaine	100–750 mg/L	Immersion					Although both induced anesthesia, the mixture was more effective for induction and recovery, and was able to achieve the required time for the fish to be out of water (titrated at 50-mg doses).	Carrasco et al. (1984)	A combination of lidocaine and sodium carbonate was better than the drugs in isolation.
Cyprinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	75–150 mg/L	Immersion	340–5000		Juvenile-adult		125 mg/L used frequently, surgeries start 150 mg/L titrate down.	C.M. Burns (pers. exp.)	125 mg/L used frequently, surgeries start 150 mg/L titrate down.
Cyprinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	100, 150 mg/L	Immersion	62–402 g	0.0.50	1–2 years	18–19	100 and 150 mg/L represent safe anesthetic concentrations.	Parker-Graham et al. (2020)	150 mg/L had changes in blood gases, acid-base balance, and electrolyte concentrations.
Cyprinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	100–200 mg/L	Immersion	123 ± 53 g			22–27	Utilized for exploratory celiotomy.	Harms et al. (2005)	Utilized for exploratory celiotomy.
Cyprinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	200 mg/L	Immersion	144 ± 44 g			23–25	Induction within 2 minutes. Level sufficient for deep IM injection and phlebotomy. Recovery within 2 minutes.	Yanong et al. (2005)	Quick induction and recovery. Level sufficient for deep IM injection and phlebotomy.
Cyprinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	150 mg/L (high dose), 100–125 mg/L (low dose)	Immersion		0.0.8				Hanley et al. (2010)	
Cyrpinus carpio	Carp, common	MS-222 (tricaine methanesulfonate)	500 mg/L + 10 mEq/kg	Immersion + IC, ICe, topical over gills, or none		0.0.28			For euthanasia: koi were left in 500 mg/L for 10–12 minutes before removing and performing IC, ICe, or topical treatment of KCl. In cardiac arrest in anesthetized koi.	Louis et al. (2020)	Used for euthanasia.
Cyprinus carpio	Carp, common	Propofol	1, 2.5, 5, 10 mg/L	Immersion	325 ± 81 g	0.0.10	Adult	23.1–23.3	5 mg/L provided anesthetic induction.	Oda et al. (2014)	Recommended dose: 5 mg/L for anesthetic induction.
Cyprinus carpio	Carp, common	Xylazine	11.4 ml of xylazine (2% solution) in 10 L of water	Immersion	40–91 g			25	Xylazine alone induced a state of sedation and anesthesia in the fish in 5–12 minutes.	Al-Hamdani et al. (2010)	Xylazine and ketamine combined took longer for induction, but duration was longer.
Cyprinus carpio	Carp, common	Ketamine hydrochloride	14.4 ml of ketamine (5% solution) in 10 L of water	Immersion					Ketamine alone induced similar effects in 7.2–9.7 minutes.	Al-Hamdani et al. (2010)	Xylazine and ketamine combined took longer for induction, but duration was longer.

Cyprinus carpio	Carp, common	Xylazine + ketamine	11.4 ml xylazine + 14.4 ml ketamine in 10 L	Immersion					Xylazine and ketamine combined took longer (14–22.8 minutes) to induce sedation and anesthesia, but duration was longer.	Al-Hamdani et al. (2010)	Xylazine and ketamine combined took longer for induction, but duration was longer.
Cyprinus carpio	Carp, common	Calamus oil (*Acorus calamus*)	1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5 mg/L	Immersion	37.6 ± 4.27 g			28 ± 2	A concentration of 2.5 mg/L calamus oil showed rapid anesthetic and recovery times.		Reocmmended dose: 2.5 mg/L calamus oil.
Cyprinus carpio	Carp, common	Clove powder	200, 300, 400 mg/L	Immersion	60 ± 10		Juvenile	28 ± 1		Abdulrahman et al. (2018)	
Cyprinus carpio	Carp, common	Clove powder	200, 300, 400 mg/L	Immersion	60 ± 10 g	0.0.117		9 ± 1, 27 ± 1, 33 ± 1	Multiple parameters tested including water temperature/DO. Complete anesthesia at 137 seconds in 400 mg/L clove powder.	Hassan et al. (2016)	
Cyprinus carpio	Carp, common	Mustard powder	200, 300, 400 mg/L	Immersion					No anesthetic events noted in any of the mustard oil or powder concentrations.	Hassan et al. (2016)	
Cyprinus carpio	Carp, common	Clove oil	1, 1.5, 2 ml/L	Immersion					Complete anesthesia at 93 seconds in 2 ml/L clove oil.	Hassan et al. (2016)	No anesthetic events noted in any of the mustard oil or powder concentrations.
Cyprinus carpio	Carp, common	Mustard oil	1, 1.5, 2 ml/L	Immersion					No anesthetic events noted in any of the mustard oil or powder concentrations.	Hassan et al. (2016)	
Cyrpinus carpio	Carp, common	Cineole oil	200, 400, 600, 800, 1000, 1200 µL/L	Immersion	56.7 ± 1.88 g	0.0.60	Juvenile	20.3 ± 1.52	Anesthesia with 1000 µL/L cineole proved suitable for rapid sampling.	Hoseini et al. (2020)	1000 µL/L cineole proved suitable for rapid sampling.
Cyprinus carpio	Carp, common	Clove buds (*Eugenia caryophyllata*)	3 ml extract/L	Immersion					Obtained S4 within 5.5 minutes and recovered in 15 minutes.	Ramanayaka et al. (2006)	Obtained S4 within 5.5 minutes, recovery 15 minutes.
Cyprinus carpio	Carp, common	Clotalaria (possible misspell in paper, suspect Crotalaria)	2.5 ml/L	Immersion					Obtained S4 within 4.3 minutes and recovered in 40minutes.	Ramanayaka et al. (2006)	Obtained S4 within 4.3 minutes, recovery >40 minutes.
Cyprinus carpio	Carp, common	Kalawel (*Derris scandens*)	2 ml/L	Immersion					Obtained S4 within 8.7 minutes and recovered in >40 minutes.	Ramanayaka et al. (2006)	Obtained S4 within 8.7 minutes, recovery >40 minutes.
Cyprinus carpio	Carp, common	Kukuru (nuts/ fruits)	3.75 ml/L	Immersion					Obtained S4 within 20 minutes and recovered in 60 minutes.	Ramanayaka et al. (2006)	Obtained S4 within 20 minutes, recovery 60 minutes.
Cyprinus carpio	Carp, common	Welan, Medella (*Barringtonia raecemosa*)		Immersion					Each showed some anesthetic properties less effective (long induction/ recovery).	Ramanayaka et al. (2006)	Each showed some anesthetic properties less effective (long induction/ recovery).
Cyprinus carpio	Carp, common	Thiththawel (*Anamirla coculus*), Thala (*Corypha ambraculifera*), Daluk (*Euphorabhia antiqurum*)		Immersion					Showed no anesthetic properites and were toxic.	Ramanayaka et al. (2006)	Showed no anesthetic properites and was toxic.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Cyprinidae spp.	Carp	Isoeugenol	20–80 mg/L	Immersion					Concentrations of 40–60 mg/L rapidly anesthetize cold-water species to the handleable stage in <3–5 minutes whereas 60–80 mg/L is necessary to anesthetize cool- and warm-water species in a comparable amount of time.	Javahery et al. (2012)	Recommended dose: 40–60 mg/L (cold-water species); 60–80 mg/L (cool- and warm-water species).
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	250 mg/L	Immersion		0.0.10	Larvae		Euthanasia: the heartbeat was not lost in any larvae held in any euthanasia solution.	Collymore et al. (2016)	The heartbeat was not lost in any larvae held in any euthanasia solution, indicating a lack of efficacy for all chemical methods tested.
Danio rerio	Zebrafish	Lidocaine hydrochloride	400, 500, 600, 700, 800, 900, or 1000 mg/L	Immersion		0.0.70	Larvae		Euthanasia: no fish in the lidocaine hydrochloride groups recovered.	Collymore et al. (2016)	
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	250 mg/L	Immersion		0.0.10	Adult		Euthanasia: one fish recovered.	Collymore et al. (2016)	One fish in the MS-222 group recovered from euthanasia. Overall, the time to death was significantly reduced with lidocaine hydrochloride at all doses compared with MS-222 in adult fish.
Danio rerio	Zebrafish	Lidocaine hydrochloride	400, 500, 600 mg/L	Immersion		0.0.30	Adult		Euthanasia: no fish in the lidocaine hydrochloride groups recovered.	Collymore et al. (2016)	
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	1.7, 5.1, 17 mM	Immersion				27 ± 2	Euthanasia:	Davis et al. (2015)	
Danio rerio	Zebrafish	Clove oil	0.01%, 0.03%, 0.1%	Immersion					Euthanasia:	Davis et al. (2015)	
Danio rerio	Zebrafish	Lidocaine gel	4%	Topical		0.0.175	Adult	27 ± 0.3	Each fish was touched gently with a cotton ball (soaked in lidocaine gel) at each lateral line for <30 seconds. Demonstrated that local bilateral lidocaine application evokes overt behavioral effects in zebrafish, suppressing locomotor activity and top exploration.	de Abreu et al. (2019)	

Danio rerio	Zebrafish	Lidocaine hydrochloride	1, 5, 10 mg/L	Immersion				Immersible lidocaine had similar effects to topical application at the 10 mg/L dose.	de Abreu et al. (2019)	Immersible lidocaine had similar effects to topical application at the 10 mg/L dose.
Danio rerio	Zebrafish	Diazepam	1–10 mg/L	Immersion				Diazepam causes a disinhibition of motor activity at doses of 1 and 5 mg/L. Diazepam 20 mg/L has a depriving effect. Diazepam acts in a higher dose range (1–10 mg/L) than phenazepam (0.1–1 mg/L) in *Danio rerio*.	Devyashin et al. (2020)	Diazepam causes a disinhibition of motor activity at doses of 1 and 5 mg/L.
Danio rerio	Zebrafish	Alfaxalone, unpreserved	10 mg/L	Immersion	0.0.10			Immersion anesthesia using 10 mg/L of either formulation of alfaxalone resulted in anesthesia of similar quality and duration in laboratory zebrafish.	Farry et al. (2019)	10 mg/L of either formulation had a similar quality and duration in laboratory zebra fish.
Danio rerio	Zebrafish	Alfaxalone, preserved	10 mg/L	Immersion	0.0.10				Farry et al. (2019)	
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	205 mg/L	Immersion	0.0.12			Rapid cooling induced a faster loss of equilibrium, response to a painful stimuli, and ceassation of opercular movements than other treatments.	Ferreira et al. (2018)	Rapid cooling induced a faster loss of equilibrium, response to a painful stimuli, and ceassation of opercular movements than other treatments.
Danio rerio	Zebrafish	Propofol + lidocaine	20 mg/L + 100 mg/L	Immersion	0.0.12				Ferreira et al. (2018)	
Danio rerio	Zebrafish	Etomidate	6 mg/L	Immersion	0.0.12				Ferreira et al. (2018)	
Danio rerio	Zebrafish	Clove oil	50 mg/L	Immersion	0.0.12				Ferreira et al. (2018)	
Danio rerio	Zebrafish	Rapid cooling	Ice	Immersion	0.0.12		2–4o	Rapid cooling induced a faster loss of equilibrium, response to a painful stimuli, and ceassation of opercular movements than other treatments.	Ferreira et al. (2018)	
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	100, 120, 140, 160, 180, 200 mg/L	Immersion		Adult	28.5		Huang et al. (2010)	The combined use of MS-222 with isoflurane effectively extended the time of anesthesia, and fish recovered faster.
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	50–80 mg/L + 50–80 mg/L	Immersion		Adult	28.5	The combined use of MS-222 with isoflurane effectively extended the time of anesthesia, and the zebrafish recovered faster than when anesthetized with the traditional MS-222.	Huang et al. (2010)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Danio rerio	Zebrafish	Ketamine choridrate solution 10%	2, 20, 40 mg/L	Immersion		0.0.36	4–6 months	27 ± 1	Ketamine (2 mg/L) increased aggression-related phenotypes, while 20 and 40 mg/L reduced aggression and elicited stereotypic behaviors by causing hyperlocomotion, altering motor patterns, and increasing circling behavior at the higher concentration tested. 100 mg/L induced anesthesia in zebrafish, opted for lower doses to see neuro effects.		Ketamine (2 mg/L) increased aggression while 20 and 40 mg/L reduced aggression and elicited stereotypic behaviors.
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	300, 600, 900 mg/L	Immersion			14 days	27.8 ± 1.2	Euthanasia: MS-222 and eugenol were ineffective methods for euthanasia at this stage of development.	Strykowski & Schech (2015)	MS-222 and eugenol were ineffective methods for euthanasia at this stage of development.
Danio rerio	Zebrafish	Isoeugenol	500 ,1000, 1500 μL/L	Immersion					Euthanasia: MS-222 and eugenol were ineffective methods for euthanasia at this stage of development.	Strykowski & Schech (2015)	
Danio rerio	Zebrafish	Isoeugenol	540 mg/L	Immersion		0.0.1409	7–27 months	28	Euthanasia:	Von Krogh et al. (2021)	
Danio rerio	Zebrafish	Clove oil	0.10%	Immersion					Euthanasia:	Von Krogh et al. (2021)	
Danio rerio	Zebrafish	2-Phenoxyethanol	3.0 ml/L	Immersion					Euthanasia:	Von Krogh et al. (2021)	
Danio rerio	Zebrafish	MS-222 (tricaine methanesulfonate)	0.5 g/L, 1.0 g/L	Immersion					Euthanasia:	Von Krogh et al. (2021)	
Danio rerio	Zebrafish	Benzocaine	1.0 g/L	Immersion					Euthanasia: having high efficacy, 1 g/L benzocaine was too aversive to be recommended for zebrafish euthanasia.	Von Krogh et al. (2021)	1 g/L benzocaine was too aversive to be recommended for zebrafish euthanasia.
Danio rerio	Zebrafish	Lidocaine HCl	1.0 g/L	Immersion					Euthanasia: 1 g/L lidocaine HCl buffered with 2 g/L $NaHCO_3$ and 50 ml/L 96% ethanol as a humane, reliable, and effective method for induction of euthanasia by overdose in adult zebrafish.	Von Krogh et al. (2021)	Recommended dose: 1 g/L lidocaine HCl buffered with 2 g/L $NaHCO_3$ and 50 ml/L 96% ethanol for humane, reliable, and effective method for induction of euthanasia.

Danio rerio	Zebrafish	Etomidate	50 mg/L	Immersion					Effect as an anesthetic but maintained reflexes >10 minutes.	Von Krogh et al. (2021)	Effect as an anaesthetic but maintained reflexes >10 minutes.
Danio rerio	Zebrafish	Rapid cooling	From 28 to 0–4	Immersion			3–90 dpf	0–4	Euthanasia: <14 dpf requires >12 hours, those 16 to 28 dpf of age require 5 minutes, and >28 dpf require 30 seconds of minimal exposure to rapid cooling for reliable euthanasia.	Wallace et al. (2018)	Variable times needed for exposure to rapid cooling for reliable euthanasia; influenced by age.
Pethia nigrofasciata	Barb, black ruby	Lidocaine	40, 60, 80, 100, 120, 140 mg/L	Immersion		66.66.130	immature, mature		Immature barbs have optimal dose of lidocaine at 80mg/L, adults 100 mg/L.	Priyangika et al. (2007)	Lower concentration of both lidocaine and clove oil required for the induction of anaesthesia compared to other species. May have a limited safety margin.
Pethia nigrofasciata	Barb, black ruby	Clove oil	2, 4, 6, 8, 10, 12, 14 mg/L	Immersion		66.66.130	immature, mature		Immature 8 mg/L and adults 10 mg/L of clove oil.	Priyangika et al. (2007)	
Dawkinsia filamentosa	Barb, blackspot	Alfaxalone	5 mg/L	Immersion		0.0.11		25.5–26.6		Zellar et al. (2018)	
Dawkinsia filamentosa	Barb, blackspot	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion		0.0.11			Buffered with 200 mg/L bicarbonate.	Zellar et al. (2018)	Buffered with 200 mg/L bicarbonate.
Epalzeorhynchos bicolor	Sharkminnow, redtail	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	1.4 ± 0.4 g		Juveniles	25.5	Anesthesia sufficient for handling.	Russo et al. (2006)	Anesthesia sufficient for handling and vaccination.
Hypselobarbus kurali		2-phenoxyethanol	300, 400, 500, 600 µL/L	Immersion		0.0.80			The lowest induction time (<180 seconds) was observed at 500 µL/L and therefore this was considered the lowest effective concentration for anesthesia. At 500 µL/L, recovery time was 133 ± 16 seconds.	Nair & Williams (2015)	The lowest induction time (<180 seconds) was observed at 500 µL/L.
Hypophthalmichthys molitrix	Carp, silver	2-phenoxyethanol	0.2 ml/L	Immersion	3–12 kg		Brood stock	25	Induction to light sedation in 2–3 minutes.	McCarter (1992)	Induction to light sedation in 2–3 minutes.
Hypophthalmichthys molitrix	Carp, silver	2-phenoxyethanol	0.4 ml/L	Immersion					Induction to anesthesia in 5–10 minutes.	McCarter (1992)	Induction to anesthesia in 5–10 minutes.
Hypophthalmichthys molitrix	Carp, silver	Carbon dioxide (dry ice state)	25 kg dry ice/100,000 L (low) to 50 kg/100,000 L (high)	Immersion				9.5–9.7	Solid state CO_2 was used in ice-covered ponds with the three species (two invasive, one noninvasive) together. Fathead minnows were less susceptible to CO_2 exposure than the carps, with 26–96% survival in low-treatment ponds and 4–68% survival in high-treatment ponds.	Cupp et al. (2018)	Minnows were less susceptible to CO_2 than carp.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Hypophthalmichthys nobilis	Carp, bighead	Carbon dioxide (dry ice state)	25 kg dry ice/100,000 L (low) to 50 kg/100,000 L (high)	Immersion				9.5–9.7	Solid state CO_2 was used in ice-covered ponds with the three species (two invasive, one noninvasive) together. Fathead minnows were less susceptible to CO_2 exposure than the carps, with 26–96% survival in low-treatment ponds and 4–68% survival in high-treatment ponds.	Cupp et al. (2018)	Minnows were less susceptible to CO_2 than carp.
Phoxinus erythrogaster	Dace, southern redbelly	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion	0.35–4.46 g		Adult, juvenile		Induction to total loss of equilibrium in 5–13 minutes. Recovery <2 minutes with faster recovery at higher temperatures. Mortality 0%.	Detar & Mattingly (2004)	Induction in 5–13 minutes. Recovery <2 minutes, faster at higher temperatures. Mortality 0%.
Phoxinus erythrogaster	Dace, southern redbelly	Clove oil	40–60 mg/L	Immersion	0.35–4.46 g		Adult, juvenile		Induction to total loss of equilibrium within 3 minutes. Recovery: <5 minutes with faster recovery at higher temperatures. No mortality.	Detar & Mattingly (2004)	Faster recovery at higher temperatures. No mortality.
Phoxinus cumberlandensis	Dace, blackside	Clove oil	40 mg/L	Immersion			Adult, juvenile		Used for anesthesia in the field during elastomer tag placement and fin clipping.	Detar & Mattingly (2004)	Used for anesthesia in the field during elastomer tag placement and fin clipping.
Rhinichthys atratulus	Dace, blackside	MS-222 (tricaine methanesulfonate)	300–500 mg/L	Immersion			Adult		Light anesthesia within 3 minutes. Allowed for handling. Recovery following 9 minutes exposure 4–7 minutes. Exposure to this dose range beyond 15 minutes associated with mortality.	MacAvoy & Zaepfel (1997)	Exposure to this dose range beyond 15 minutes associated with mortality.
Rutilus rutilus	Roach	Clove oil	4 mg/L	Immersion	71 g			15	Provided sedation for 6 hours without loss of equilibrium, at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen & Pirhonen (2004)	Considered useful for transport. No mortality.
Tinca tinca	Tench	2-phenoxyethanol	0.5 g/L	Immersion	0.08–1.82 g		Juvenile	25	Induction time 2.2–12.6 minutes. Recovery after 15 minutes of exposure 1.1–3.3 minutes. Recommended for short-term anesthesia.	Myszkowski et al. (2003)	Recommended for short-term anesthesia.

Pimephales promelas	Fathead minnow	Carbon dioxide (dry ice state)	25 kg dry ice/100,000 L (low) to 50 kg/100,000 L (high)	Immersion				9.5–9.7	Solid state CO_2 was used in ice-covered ponds with the three species (two invasive, one noninvasive) together. Fathead minnows were less susceptible to CO_2 exposure than the carps, with 26–96% survival in low-treatment ponds and 4–68% survival in high-treatment ponds.	Cupp et al. (2018)	Minnows were less susceptible to CO_2 than carp.
Pimephales promelas	Fathead minnow	Carbon dioxide (gas state)	12 h continuous flow-through CO_2 exposure at 5, 15, and 25°C water temperatures	Immersion	2.6 ± 1.0 g	0.0.18	Adult		CO_2 toxicity can differ by species and water temperature. Bluegill were more sensitive than fathead minnow at all water temperatures.	Cupp et al. (2020)	CO_2 toxicity can differ by species and water temperature; bluegill were more sensitive than fathead minnow at all water temperatures.
Rutilus frisii kutum	Kutum, Caspian	Clove essence	50, 200, 400 ppm	Immersion		30.0.0		18	No mortalities occurred at any doses.	Farahi et al. (2011)	No mortalities occurred at any doses.
Carassius auratus, *Danio rerio*	Goldfish, zebrafish	Menthol (dl-menthol Nacalai Tesque Inc., Japan)	0.1–3.0 mM	Immersion				25 ± 1	Applied by injection to one side of a gill (50 μL), oral cavity (50 μL), and one side of the body surface (100 μL) of medaka fish and goldfish (100, 100, and 300 μL, respectively) by injection with a 1-ml syringe, and the peritoneal cavity (10 μL for medaka fish and 30 μL for goldfish) was injected with a 100-μL Hamilton microsyringe.	Kasai et al. (2014)	Menthol (d-, l-, dl-types) at 0.4 mM produced surgical anesthesia in medaka, goldfish, and zebrafish. GABAA mediated.
Family Leuciscidae											
Gila elegans	Bonytail	Metomidate hydrochloride	0.2, 0.5, 1.0, 2.5, 3.0, 3.5, 4.0 mg/L	Immersion	193.9 g	0.0.20		16.4–29.98	Aqui-S® 20e had better survivability during 4-, 8-, and 12-hour transport.	Tennant et al. (2019)	
Gila elegans	Bonytail	MS-222 (tricaine methanesulfonate)	55.0, 60.0, 65.0, 70.0 mg/L	Immersion						Tennant et al. (2019)	
Gila elegans	Bonytail	Isoeugenol	10.0, 15.0, 17.0, 20.0 mg/L	Immersion						Tennant et al. (2019)	
Order Cyprinodontiformes											
Family Poeciliidae											
Poecilia velifera	Molly, sailfin	2-phenoxyethanol	600 mg/L	Immersion	1.56 ± 0.27 g		Adult	23	Induction: 7.50 ± 11.97 minutes. Recovery (fish placed in fresh water immediately after induction): 1.28 ± 2.53 minutes.	Hseu et al. (1997)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Xiphophorus maculatus	Platyfish, southern	MS-222 (tricaine methanesulfonate)	30 mg/L	Immersion	1.71 ± 0.36 g		Adult		Provides light sedation.	Guo et al. (1995)	
Xiphophorus maculatus	Platyfish, southern	Metomidate hydrochloride	1 mg/L	Immersion	1.71 ± 0.36 g		Adult		Provides light sedation.	Guo et al. (1995)	
Xiphophorus maculatus	Platyfish, southern	Quinaldine sulphate	10 mg/L	Immersion	1.71 ± 0.36 g		Adult		Provides light sedation.	Guo et al. (1995)	
Xiphophorus maculatus	Platyfish, southern	2-phenoxyethanol	220 mg/L	Immersion	1.71 ± 0.36 g		Adult		Provides light sedation.	Guo et al. (1995)	
Poecilia spp.	Mollies	Sodium bicarbonate	1, 100 g/L	Immersion				27–29	Sedation in 100 g/L took 83.2–104.6 seconds and recovery 47–62.5 seconds. 1 week after exposure author noted a 40–60% survival rate. Simulated transport of fish for 6 hours in water containing 1 g/L of sodium bicarbonate showed survival ranging from 70% to 100% a week after transport.	Caipang et al. (2021)	
Poeciliidae spp.	Ornamentals	Metomidate hydrochloride	40, 60, 100, 250, 100 mg/L	Immersion				22–24	Euthanasia: euthanized at a concentration of 40 mg/L metomidate hydrochloride for a total exposure time of 38 minutes. Most species tested were successfully euthanized with metomidate hydrochloride at a concentration of 100 mg/L, with total exposure times ranging from 35 to 96 minutes.	Yanong (2021)	
Order Elopiformes											
Family Megalopidae											
Megalops Atlanticus	Tarpon	Diazepam => MS-222 (tricaine methanesulfonate)	5–22.5 mg/kg => 25–40 mg/L	PO, immersion		0.0.4			Given oral diazepam, MS-222 immersion to new system, did well for transfer.	C.M. Burns, N.D. Mylniczenko (pers. exp.)	
Megalops Atlanticus	Tarpon	MS-222 (tricaine methanesulfonate)	40–60 mg/L	Immersion		0.0.6			Good sedation, prolonged procedures in 60 deep anesthesia.	C.M. Burns, N.D. Mylniczenko (pers. exp.)	
Order Gadiformes											
Family Gadidae											
Gadus morhua	Cod, Atlantic	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion	84 ± 5 g			8.4	Anesthesia within 4 minutes. Exposure time 2.8–3.4 minutes. Recovery time 3.7–7.1 minutes.	Mattson & Riple (1989)	

Gadus morhua	Cod, Atlantic	Benzocaine dissolved in ethanol	40 mg/L	Immersion	101 ± 6 g	9.5	Anesthesia reached within 3 minutes. Exposure time 2.1–3.2 minutes. Recovery time 3.9–10.8 minutes. Mortality 50% at 75–100 mg/L.	Mattson & Riple (1989)
Gadus morhua	Cod, Atlantic	Metomidate hydrochloride	5 mg/L	Immersion	101 ± 6 g	9.6	Anesthesia reached within 4 minutes. Exposure time 4.8–10.8 minutes. Recovery time 8.2–19.2 minutes. Used for sorting and handling broodstock.	Mattson & Riple (1989)
Gadus morhua	Cod, Atlantic	Benzocaine	25–35 mg/L	Immersion	10, 100, 1000 g	8, 16	Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)
Gadus morhua	Cod, Atlantic	MS-222 (tricaine methanesulfonate)	55–60 mg/L	Immersion			Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)
Gadus morhua	Cod, Atlantic	Metomidate hydrochloride	3–6 mg/L	Immersion			Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)
Gadus morhua	Cod, Atlantic	2-phenoxyethanol (Sigma-Aldrich AS, Oslo, Norway)	0.25 mg/L	Immersion			Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Gadus morhua	Cod, Atlantic	Metomidate hydrochloride + benzocaine	1.0–3.0 + 15–22 mg/L	Immersion					Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)	
Gadus morhua	Cod, Atlantic	Metomidate hydrochloride + MS-222	0.5–2.0 + 37.5–45 mg/L	Immersion					Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)	
Gadus morhua	Cod, Atlantic	2-phenoxyethanol + benzocaine	0.1–1.5 + 15–20 mg/L	Immersion					Induction and recovery times varied in relation to water temperature and were generally shorter at 16°C for all weight groups and treatments compared to 8°C. Concentrations varied by size and no suitable dose for found for benzocaine at 8°C in 1000 g of fish.	Zahl et al. (2009)	
Gadus morhua	Cod, Atlantic	Benzocaine (Benzoak Vet, A.C.D Pharmaceuticals, Leknes, Norway)	20 mg/L	Immersion	400 g	0.0.114		~9	Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	
Gadus morhua	Cod, Atlantic	MS-222 (tricaine methanesulfonate)	55 mg/L	Immersion					Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	
Gadus morhua	Cod, Atlantic	Metomidate hydrochloride	3 mg/L	Immersion					Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	
Family Lotidae											
Lota lota	Burbot	Etomidate	0.5 ml/L	Immersion	0.5–5000 g	0.0.1600	Spawners	5	When applied in immersion did not cause a change in pH or CO_2 content. Propiscin applied in a water bath can provide up to 1 hour of general anesthesia.	Kazuñ & Siwicki (2012)	

Order Gobiiformes									
Family Gobiidae									
Afurcagobius tamarensis	Goby, Tammar river	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Sufficient for handling and measurement.
Bathygobius cocosensis	Goby, cocos frill	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Sufficient for handling and measurement.
Favonigobius lateralis	Goby, southern longfin	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Sufficient for handling and measurement.
Gobiidae spp.	Ornamentals	Metomidate hydrochloride	40, 60, 100, 250, 100 mg/L	Immersion		22–24	Some species were euthanized at a concentration of 40 mg/L metomidate hydrochloride for a total exposure time of 38 minutes. Most species tested were successfully euthanized with metomidate hydrochloride at a concentration of 100 mg/L, with total exposure times ranging from 35 to 96 minutes. A few catfish species were refractory and recovered after 100 mg/L. However, *Otocinclus* sp. were successfully euthanized at 250 mg/L and bronze corydoras were euthanized at 1000 mg/L.	Yanong (2021)	Wide range in doses and time till effect.
Nemateleotris decora	Firefish, elegant (purple cap)	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion			Deep anesthesia used for parasite removal.	C.M. Burns (pers. exp.)	
Synchiropus splendidus	Mandarinfish	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion			For skin scrape/gill clips.	C.M. Burns (pers. exp.)	Approprate for skin scrape/gill clips.
Order Gonorynchiformes									
Family Chanidae									
Chanos chanos	Milkfish	2-phenoxyethanol	400 mg/L	Immersion	24 ± 1.07 g	28	Provided total loss of equilibrium, allowing phlebotomy.	Hseu et al. (1996)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Chanos chanos	Milkfish	2-phenoxyethanol	80 mg/L	Immersion			Juvenile	15–17, 20–22, 25–27	The study showed that a temperature of 20–22°C in combination with anesthetic (2-phenoxyethanol) application was the optimum condition for long-duration confinement of milkfish juveniles in transport bags.	Failaman et al. (2021)	
Order Gymnotiformes											
Family Gymnotidae											
Electrophorus electricus	Eel, electric	MS-222 (tricaine methanesulfonate)	300 mg/L	Immersion	18				Animal sedated in two separate events at the same dose. Aerated water containing MS-222 was applied over the gills every 2–5 minutes.	Wenger et al. (2016, 2018)	Supplemented with 0.11 mg/kg medetomidine and 2.2 mg/kg ketamine IM.
Electrophorus electricus	Eel, electric	Medetomidine (Dorbene) + ketamine (Narketan)	0.11 mg/kg + 2.2 mg/kg	IM						Wenger et al. (2016, 2018)	
Electrophorus electricus	Eel, electric	MS-222 (tricaine methanesulfonate)	150 mg/L	Spray over gills						Wenger et al. (2016, 2018)	
Electrophorus electricus	Eel, electric	Atimpamezole	0.28 mg/kg	IM						Wenger et al. (2016, 2018)	
Electrophorus electricus	Eel, electric	MS-222 (tricaine methanesulfonate)	205–300 mg/L => 100–150 mg/L	Immersion					Anesthesia involved forced immersion in high concentration, buffered MS-222 (250–300 ppm) in oxygenated water and maintenance out of water at lower concentrations (100–150 ppm) with mechanical gill ventilation, oral oxygen supplementation, and temperature regulation. During induction strong electric pulses ceased before the weaker background sensory pulses (about 10 V) and both ceased when the eel was fully anesthetized, allowing for safe handling.	Poll et al. (2014)	

Order Istiophoriformes										
Family Sphyraenidae										
Sphyraena barracuda	Barracuda, great	MS-222 (tricaine methanesulfonate)	30, 50 mg/L	Immersion			Adult		Lower dose for whole-tank sedation, higher dose for transport. Once transported, blood was drawn from the animal.	N.D. Mylniczenko (pers. exp.)	Lower dose for whole-tank sedation, higher dose for transport.
Sphyraena barracuda	Barracuda, great	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion			Juvenile		Excellent sedation for physical examination and treatments.	N.D. Mylniczenko (pers. exp.)	Excellent sedation for physical examination and treatments.
Order Kurtiformes										
Family Apogonidae										
Pterapogon kauderni	Cardinalfish, banggai	MS-222 (tricaine methanesulfonate)	70–90 mg/L	Immersion				25		C.M. Burns (pers. exp.)	
Sphaeramia nematoptera	Cardinalfish, pajama	MS-222 (tricaine methanesulfonate)	65–90 mg/L	Immersion		0.0.15		25	Good to heavy sedation.	C.M. Burns (pers. exp.)	
Order Labriformes										
Family Labridae										
Bodianus anthioides	Hogfish, lyretail	MS-222 (tricaine methanesulfonate)	70 mg/L	Immersion	0.04–0.13				Good sedation, diagnostic examination, debridement.	C.M. Burns (pers. exp.)	Used for a diagnostic examination.
Bodianus rufus	Hogfish, Spanish	MS-222 (tricaine methanesulfonate)	70 mg/L	Immersion					Diagnostic examination.	C.M. Burns (pers. exp.)	Used for a diagnostic examination.
Bodianus pulchellus	Hogfish, spotfin	MS-222 (tricaine methanesulfonate)	70 mg/L	Immersion					Diagnostic examination.	C.M. Burns (pers. exp.)	Used for a diagnostic examination.
Cheilinus fasciatus	Wrasse, redbreasted	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion	0.2–0.4				Good sedation for diagnostic examination.	C.M. Burns (pers. exp.)	
Cheilinus undulatus	Wrasse, humphead	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion					Induction at 100 mg/L, maintenance at 50 mg/L. Excellent for transport and physical examination.	N.D. Mylniczenko (pers. exp.)	Induction at 100 mg/L, maintenance at 50 mg/L. Excellent for transport and physical examination.
Choerodon fasciatus	Tuskfish, harlequin	MS-222 (tricaine methanesulfonate)	60–65 mg/L	Immersion	0.16–0.36				Good sedation for diagnostic examination.	C.M. Burns (pers. exp.)	
Clepticus parrae	Wrasse, creole	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion	0.04–0.05				Good sedation, diagnostic examination, and wound care.	C.M. Burns (pers. exp.)	
Epibulus insidiator	Wrasse, sling-jaw	MS-222 (tricaine methanesulfonate)	45–75 mg/L	Immersion	0.04–0.2				Light to very deep, used for diagnostic examination and radiographs.	C.M. Burns (pers. exp.)	
Gomphosus varius	Wrasse, bird	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion					Deep anesthesia. Take care during sedation to not injury beak.	C.M. Burns (pers. exp.)	
Halichoeres radiatus	Wrasse, puddingwife	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion					Sedation rated as good. Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)	Used for a diagnostic examination. Sedation rated as good.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Lachnolaimus maximus	Hogfish	MS-222 (tricaine methanesulfonate)	25, 50, 100, 125, and 150 mg/L	Immersion	0.2–1.2 kg, 5–50 g		Adult, juvenile		For adult hogfish, Tricaine-S® was effective at inducing light anesthesia at 100–150 mg/L and was preferred over the effective range of Aqui-S® 20e doses (100–200 mg/L) based on fish behavioral observations while undergoing anesthesia.	Shopnitz et al. (2022)	Tricaine-S® preferred over Aqui-S® 20e based on fish behavioral observations while undergoing anesthesia.
Lachnolaimus maximus	Hogfish	Eugenol	50, 75, 100, 200, 300, 400, 500 mg/L	Immersion					For adult hogfish, Tricaine-S® was effective at inducing light anesthesia at 100–150 mg/L and was preferred over the effective range of Aqui-S® 20e doses (100–200 mg/L) based on fish behavioral observations while undergoing anesthesia.	Shopnitz et al. (2022)	
Lachnolaimus maximus	Hogfish	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion			Juvenile		Diagnostic examination.	C.M. Burns (pers. exp.)	Used for a diagnostic exam.
Thalassoma duperreyi	Wrasse, saddle	MS-222 (tricaine methanesulfonate)	90 mg/L	Immersion					Sedation rated as good. Diagnostic examinations performed.	C.M. Burns (pers. exp.)	Used for a diagnostic exam. Sedation rated as good.
Thalassoma lunare	Wrasse, moon	MS-222 (tricaine methanesulfonate)	30 mg/L	Immersion	0.9				Animal compromised.	C.M. Burns (pers. exp.)	
Family Scaridae											
Sparisoma aurofrenatum	Parrotfish, redband	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Provided surgical anesthesia for enucleation.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for enucleation.
Scarus coelestinus	Parrotfish, midnight	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Provided light anesthesia for diagnostic examination.	D.L. Neiffer (pers. exp.)	Used for a diagnostic examination.
Scarus guacamaia	Parrotfish, rainbow	MS-222 (tricaine methanesulfonate)	50–80 mg/L	Immersion	2.03–7.45 kg				Effect varied from moderate sedation to light anesthesia. Diagnostic examinations performed. $N = 4$.	D.L. Neiffer (pers. exp.)	Used for a diagnostic examination. Effect varied from moderate sedation to light anesthesia.
Scarus vetula	Parrotfish, queen	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion					Provided mild to heavy sedation. Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)	Used for a diagnostic examination. Provided mild to heavy sedation.
Sparisoma viride	Parrotfish, stoplight	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion	0.48				Diagnostic eye examination, treatments.	C.M. Burns (pers. exp.)	Used for a diagnostic examination and treatments.

Order Lepisosteiformes											
Family Lepisosteidae											
Lepisosteus platostomus	Shortnose gar	Isoeugenol	240–250 mg/L	Immersion	0.0.15			Stage V surgerical anesthesia. Fish given 240 and 250 mg/L of sedative remained anesthetized for the entire time they were held in the surgery trough.		Gar were induced via a method that did not allow air gulping at high dosages and this facilitiated induction.
Order Lophiiformes											
Family Antennariidae											
Antennarius commerson	Frogfish, Commerson's	MS-222 (tricaine methanesulfonate)	50–80 mg/L	Immersion		Adult	25	Anesthesia was up to 95 minutes for surgery in one case.	C.M. Burns (pers. exp.)	
Antennarius maculatus	Frogfish, warty	MS-222 (tricaine methanesulfonate)	50–60 mg/L	Immersion				Heavy sedation for radiographs and swim bladder aspiration.	T.M. Clauss (pers. exp.)	
Antennarius maculatus	Frogfish, warty	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion		Juvenile-adult	25	Diagnostic examination, radiographs, surgery, treatments.	C.M. Burns (pers. exp.)	
Antennarius striatus	Frogfish, striated	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion		Adult		Diagnostics performed.	Yanong et al. (2003)	
Antennarius striatus	Frogfish, striated	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion	200 g			Negatively buoyant, air aspiration.	D.L. Neiffer (pers. exp.)	
Fowlerichthys ocellatus	Frogfish, ocellated	MS-222 (tricaine methanesulfonate)	30–80 mg/L	Immersion	350–450 g			Sedation rated fair to excellent (higher doses better). Examination and topical treatments performed.	D.L. Neiffer (pers. exp.)	
Histrio histrio	Sargassumfish	MS-222 (tricaine methanesulfonate)	30 mg/L	Immersion				Sedation adequate for examination and injections.	D.L. Neiffer (pers. exp.)	
Order Mugiliformes											
Family Mugilidae											
Mugil cephalus	Mullet, flathead grey	2-phenoxyethanol	400 mg/L	Immersion	38.49 ± 3.85 g		31	Provided total loss of equilibrium, allowing phlebotomy.	Hseu et al. (1996)	Provided total loss of equilibrium, allowing phlebotomy.
Myxus elongates	Mullet, sand grey	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion			18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	
Order Osteoglossiformes											
Family Mormyridae											
Gnathonemus petersii	Fish, elephantnose	Alphaxalone/ alphadolone acetate	2 mg/L for induction and 1.5 mg/L for maintenance	Immersion	~15 g		23	Loss of equilibrium and cessation of opercular movement at 20 minutes. Recovery took an average of 17 minutes following 2.5 hours of exposure.	Peters et al. (2001)	Recovery took average of 17 minutes following 2.5 hours of exposure.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Family Osteoglossidae											
Arapaima gigas	Arapaima/ pirarucu	Chloroform	3 ml in a 2-L gas mask supplied with atmospheric air	Inhalation	~400 g	0.0.10	Adult	28	Anesthetic induction occured shortly after chloroform inhalation (10 ± 3 seconds). Therecovery time recorded for chloroform was 15 ± 4 minutes. This study demonstrates theusefulness of chloroform-induced anesthesia in air-breathing fish.	Carreiro et al. (2011)	
Arapaima gigas	Arapaima/ pirarucu	Urethane	1% solution	Immersion					Arapaima did not recover from anesthesia unassisted. Revived via artifically ventilting the bladder with air until the fish could surface and breath unassisted.	Farrell & Randall (1978)	Arapaima were artifically air ventilated until the fish could surface and breath unassisted.
Arapaima gigas	Arapaima/ pirarucu	MS-222 (tricaine methanesulfonate)	25, 50, 75, 100 mg/L	Immersion		0.0.6	Juvenile		Efficient anesthetic effects in juvenile paiches at a concentration of 100 mg/L.	Hinostroza & Serrano-Martinez (2013)	
Arapaima gigas	Arapaima/ pirarucu	Benzocaine	25, 50, 75, 100 mg/L	Spray on gills					Benzocaine sprinkled directly in the gills of pirarucu shown to be an efficient anesthetic both for juveniles and adult fish. Absence of movements was observed for 2 minutes, time enough for most handling procedures. No mortality occurred even 1e month after experiments.	Honczaryk & Inoue (2009)	No mortality occurred up to 1 month after experiments.
Arapaima gigas	Arapaima/ pirarucu	Eugenol	30, 60 mg/L	Spray on gills						Honczaryk & Inoue (2009)	
Arapaima gigas	Arapaima/ pirarucu	MS-222 (tricaine methanesulfonate)	500 mg/L (euthanasia)	Immersion	4.75 ± 0.07 g	0.0.41	2–3 weeks, 3–4 months	27–30	Animals were euthanized for this study.	Pelster et al. (2020)	
Arapaima gigas	Arapaima/ pirarucu	Ketamine	10 mg/kg	PO	664 ± 38 g	0.0.1	Adult	68–74F	Placed in whole trout, 27 minutes later sedated sufficiently for transportation. Permitted being placed in a sling.	Raines & Clancy (2009)	Longer induction produced sufficient level for transportation.

Order Ovalentaria										
Family Grammatidae										
Gramma loreto	Gramma, royal	MS-222 (tricaine methanesulfonate)	65–90 mg/L	Immersion				Sedation rate was good. Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)	Sedation rate as good. Diagnostic examinations performed.
Family Plesiopidae										
Calloplesiops altivelis	Comet	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion	0.03			Good sedation.	C.M. Burns (pers. exp.)	
Paraplesiops meleagris	Blue devil, southern	MS-222 (tricaine methanesulfonate)	65–90 mg/L	Immersion		0.0.2	25	Light to good for diagnostic examination, treatments.	D.L. Neiffer (pers. exp.)	
Family Pomacentridae										
Abudefduf saxatilis	Sergeant major	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion			25	Provided surgical anesthesia for kidney culture.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for kidney culture.
Amphiprion melanopus	Clownfish, fire	MS-222 (tricaine methanesulfonate)	50–70 mg.L	Immersion			25	Provided light to good sedation.	C.M. Burns (pers. exp.)	Provided light to good sedation.
Amphiprion ocellaris	Anemonefish, clown	MS-222 (tricaine methanesulfonate)	60–70 mg/L	Immersion			25		C.M. Burns (pers. exp.)	
Amphiprion percula	Clownfish, orange	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion			25	Provided mild to heavy sedation for examinations.	D.L. Neiffer (pers. exp.)	Sedation level varied from mild to heavy.
Amphiprion sebae	Anenomefish, sebae	Clove oil derivative (prepared from dry clove)	10.0, 17.5, 25.0, 40.0, 50.0, 75.0, and 100.0 mg/L	Immersion		0.0.110	25	To determine the optimum concentration of clove extract to anesthetize and transport the fish under packed conditions. Optimal dosage with no mortalities 17.5 mg/L.	Balamurugan et al. (2016)	Recommended dose: 17.5 mg/L. No mortalities.
Chromis cyanea	Chromis, blue	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion			25	Sedation rated as good. Examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Diagnostic examination performed.
Chromis multilineata	Chromis, brown	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion			25	Sedation rated as good. Examination and transport.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Examination and transport.
Chromis viridis	Chromis, blue-green	MS-222 (tricaine methanesulfonate)	50–65 mg/L	Immersion			25	Good for diagnostic examination, surgeries.	C.M. Burns (pers. exp.)	
Dascyllus melanurus	Humbug, blacktail	MS-222 (tricaine methanesulfonate)	90 mg/L	Immersion			25	Sedation rated as good. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Diagnostic examination performed.
Dascyllus trimaculatus	Dascyllus, threespot	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion			25	Provided heavy sedation for examinations.	D.L. Neiffer (pers. exp.)	Provided heavy sedation for examinations.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Pomacentridae spp.	Misc species	Metomidate hydrochloride	40, 60, 100, 250, 100 mg/L	Immersion				22–24	Some species were euthanized at a concentration of 40 mg/L metomidate hydrochloride for a total exposuretime of 38 minutes. Most species tested were successfully euthanized with metomidate hydrochloride at a concentration of 100 mg/L, with total exposure times ranging from 35 to 96 minutes. A few catfish species were refractory and recovered after 100 mg/L. However, *Otocinclus* sp. were successfully euthanized at 250 mg/L and bronze corydoras were euthanized at 1000 mg/L.	Yanong (2021)	Wide dose range for euthanasia and exposure time to effect.
Premnas biaculeatus	Anenomefish, spinecheek	MS-222 (tricaine methanesulfonate)	60–90 mg/L	Immersion				25	Light to good sedation. Examination, tissue biopsy.	C.M. Burns (pers. exp.)	Light to good sedation. Dignostic examinations and biopsy performed.
Order Perciformes											
Family Caesionidae											
Caesio cuning	Fusilier, redbelly yellowtail	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion	0.06				Light to good to excessively deep.	C.M. Burns (pers. exp.)	
Family Centrarchidae											
Lepomis macrochirus	Bluegill	Carbon dioxide (gas state)	12-h continuous flow-through CO_2 exposure at 5, 15, and 25°C water temperatures	Immersion	2.7 ± 1.0 g	0.0.18	Juvenile	5, 15, 25	CO_2 toxicity can differ by species and water temperature. Bluegill were more sensitive than fathead minnow at all water temperatures.	Cupp et al. (2020)	Bluegill were more sensitive than fathead minnow at all water temperatures.
Lepomis macrochirus	Bluegill	Electric handling gloves	FHGs vs. PES vs. handling	Electroanesthesia		0.0.36			(1) Lower-voltage, non-pulsed-DC fish-handling gloves that tend to only sedate fish while the gloves are touching the animal. (2) A comparatively high-voltage, pulsed-DC portable electrosedation system.	Abrams et al. (2018)	

Lepomis macrochirus	Bluegill	Isoeugenol	20 mg/L	Immersion	213 ± 118 g	Juveniles-young adults	12 ± 2	Induction within 3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures.	Stehly & Gingerich (2001)	Useful for basic handling procedures.
Lepomis macrochirus	Bluegill	Isoeugenol	20 mg/L	Immersion	0.54 ± 0.2 g	Fry-fingerling		Induction within 4.1 minutes. Total exposure time ≤15 minutes. Recovery within 5 minutes. Useful for basic handling procedures.	Stehly & Gingerich (2001)	Useful for basic handling procedures.
Micropterus salmoides	Bass, largemouth	Clove oil	5–9 mg/L	Immersion		Fingerling, subadult	21	Time to deep sedation 368 seconds. Sufficient for transport (reduced activity while maintaining equilibrium). Recovery 417 seconds.	Cooke et al. (2004)	
Micropterus salmoides	Bass, largemouth	Clove oil	15–20 mg/L	Immersion				Time to moderate anesthesia 651 seconds. Recovery 1699 seconds.	Cooke et al. (2004)	
Micropterus salmoides	Bass, largemouth	MS-222 (tricaine methanesulfonate)	50 mg/L => 25 mg/L	Immersion				Induction to maintenance. Provided sufficient sedation for transport.	Cooke et al. (2004)	Provided sufficient sedation for transport.
Micropterus salmoides	Bass, largemouth	Electroanesthesia	FHGs vs. PES vs. handling	Electroanesthesia	0.0.37			(1) Lower-voltage, non-pulsed-DC fish-handling gloves that tend to only sedate fish while the gloves are touching the animal. (2) A comparatively high-voltage, pulsed-DC portable electrosedation system.	Abrams et al. (2018)	
Micropterus salmoides	Bass, largemouth	Electric handling gloves	4mA at 30 and 120 s	Electroanesthesia			12–19	After a 30-minute post-treatment retention period, blood chemistry and ventilation rates were similar between fish held with fish-handling gloves and those held with bare hands. This study supports the notion that electric fish-handling gloves are a safe and effective tool for practitioners who need to temporarily immobilize fish for handling, enumeration, or performing various scientific procedures.	Ward et al. (2017)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Family Centropomidae											
Centropomus undecimalis	Snook, common	MS-222 (tricaine methanesulfonate)	50–60 mg/L	Immersion					Provided mild sedation for diagnostic examinations.	D.L. Neiffer (pers. exp.)	
Family Chaetodontidae											
Forcipiger longirostris	Butterflyfish, longnose	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion					Sedation was rated good and provided good anesthesia for examination and radiographs.	C.M. Burns (pers. exp.)	
Chaetodon spp.	Butterflyfish spp.	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion						C.M. Burns (pers. exp.)	
Chelmon rostratus	Butterflyfish, copperband	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion						C.M. Burns (pers. exp.)	
Hemitaurichthys polylepis	Butterflyfish, pyramid	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion						C.M. Burns (pers. exp.)	
Hemitaurichthys zoster	Butterflyfish, brown and white	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion						C.M. Burns (pers. exp.)	
Heniochus acuminatus	Coralfish, pennant	MS-222 (tricaine methanesulfonate)	90 mg/L	Immersion					Sedation rated as good. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Diagnostic examination performed.
Heniochus sp.	Bannerfish	MS-222 (tricaine methanesulfonate)	90 mg/L	Immersion					Provided heavy sedation for diagnostic examinations.	D.L. Neiffer (pers. exp.)	Provided heavy sedation for diagnostic examinations.
Family Gerreidae											
Eucinostomus gula	Mojarra, jenny	MS-222 (tricaine methanesulfonate)	70–90 mg/L	Immersion					Light to deep anesthesia.	C.M. Burns (pers. exp.)	
Gerres cinereus	Mojarra, yellow fin	MS-222 (tricaine methanesulfonate)	70–90 mg/L	Immersion					Light to deep anesthesia.	C.M. Burns (pers. exp.)	
Family Haemulidae											
Anisotremus virginicus	Porkfish	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion					Provided surgical anesthesia for enucleation and kidney culture.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for enucleation and kidney culture.
Anisotremus surinamensis	Margate, black	MS-222 (tricaine methanesulfonate)	90–100 mg/L	Immersion					Good sedation for diagostic examination.	C.M. Burns (pers. exp.)	
Haemulon aurolineatum	Grunt, tomtate	MS-222 (tricaine methanesulfonate)	80–100 mg/L	Immersion					Sedation rated good. Examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated good. Examination performed.
Haemulon carbonarium	Grunt, caesar	MS-222 (tricaine methanesulfonate)	60–85 mg/L	Immersion					Diasnostic examination, skin scrapes/gill clips.	C.M. Burns (pers. exp.)	Diasnostic examination, skin scrapes/gill clips.
Haemulon chrysargyreum	Grunt, smallmouth	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion					Provided surgical anesthesia for kidney culture.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for kidney culture.

Haemulon flavolineatum	Grunt, french	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion				Provided surgical anesthesia for enucleation and kidney culture.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for enucleation and kidney culture.
Haemulon melanurum	Grunt, cottonwick	MS-222 (tricaine methanesulfonate)	70–110 mg/L	Immersion				Sedation rated as good. Examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Examination performed.
Haemulon plumieri	Grunt, white	MS-222 (tricaine methanesulfonate)	85–100 mg/L	Immersion				Sedation rated good. Examinations performed.	D.L. Neiffer (pers. exp.)	Sedation rated good. Examinations performed.
Haemulon sciurus	Grunt, bluestriped	MS-222 (tricaine methanesulfonate)	70–110 mg/L	Immersion				Most sedations rated as good. Diagnostic examinations, injections, and enucleation (one case) performed.	D.L. Neiffer (pers. exp.)	Most sedations rated as good. Diagnostic examinations, injections, and enucleation.
Plectorhinchus spp.	Sweetlips	MS-222 (tricaine methanesulfonate)	60–80 mg/L	Immersion	2.7–3.7		25	Good anesthesia for diagnostic examination, blood draw.	C.M. Burns (pers. exp.)	
Family Kyphosidae										
Girella elevata	Drummer, black	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion			18	Induction within 3 mininutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Sufficient for handling and measurement.
Microcanthus strigatus	Tang, convict	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion				Provide heavy sedation.	D.L. Neiffer (pers. exp.)	Provided heavy sedation.
Scorpis lineolatus	Sweep, silver	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion			18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.
Family Lateolabracidae										
Lateolabrax japonicus	Sea bass, Japanese	2-phenoxyethanol	400 mg/L	Immersion	48.98 ± 3.47 g		29	Provided total loss of equilibrium, allowing phlebotomy.	Hseu et al. (1996)	Provided total loss of equilibrium allowing phlebotomy.
Lateolabrax japonicus	Sea bass, Japanese	2-phenoxyethanol	400 mg/L	Immersion	4.4 ± 0.86 g	Juvenile	28	Induction 2.13 + 0.45 minutes. Recovery (fish placed in fresh water immediately after induction) 0.69 + 0.15 minutes.	Hseu et al. (1997)	
Lateolabrax japonicus	Sea bass, Japanese	2-phenoxyethanol	400 mg/L	Immersion	4.8 ± 1.46 g	Juvenile	24	Induction 1.75 ± 0.16 minutes. Recovery (fish placed in non-medicated water immediately after induction) 0.49 ± 0.08 minutes.	Hseu et al. (1997)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Lateolabrax maculatus	Sea bass	Eugenol (98.5%)	20, 30, 40, 50, 60 mg/L	Immersion	533.92 ± 20.88 g			20.0 ± 2.0	Based on ideal induction (<3 minutes) and recovery (<10 minutes), the lowest effective concentrations for spotted sea bass were 60 mg/L for eugenol, 120 mg/L for clove oil, and 140 mg/L for MS-222 at around 20°C.		
Lateolabrax maculatus	Sea bass	Clove oil (85%)	100, 110, 120, 130, 140 mg/L	Immersion	533.92 ± 20.88 g			20.0 ± 2.0	Based on ideal induction (<3 minutes) and recovery (<10 minutes), the lowest effective concentrations for spotted sea bass were 60 mg/L for eugenol, 120 mg/L for clove oil, and 140 mg/L for MS-222 at around 20°C.		The lowest effective concentrations were 60 mg/L for eugenol, 120 mg/L for clove oil, and 140 mg/L for MS-222.
Lateolabrax maculatus	Sea bass	MS-222 (tricaine methanesulfonate)	120, 130, 140, 150 and 160 mg/L	Immersion	533.92 ± 20.88 g			20.0 ± 2.0	Based on ideal induction (<3 minutes) and recovery (<10 minutes), the lowest effective concentrations for spotted sea bass were 60 mg/L for eugenol, 120 mg/L for clove oil, and 140 mg/L for MS-222 at around 20°C.		Based on ideal induction (<3 minutes) and recovery (<10 minutes), the lowest effective concentrations for spotted sea bass were 60 mg/L for eugenol, 120 mg/Lfor clove oil, and 140 mg/L for MS-222 at around 20°C.
Family Latidae											
Lates calcarifer	Barramundi	Clove oil	6–9 mg/L		42 ± 9.74 g			29–30	Dissolved in boiled water induction 1.8–4.5 minutes. Exposed to clove oil for 4 minutes. Recovery 0.5–5.0 minutes. No mortality though some distal gill filament necrosis noted with repeated exposure to 9 mg/l.	Afifi et al. (2001)	
Family Lutjanidae											
Lutjanus sp.	Snapper sp.	Metomidate hydrochloride	50 mg/kg	IM	14 kg				Anesthesia with marked depression of ventilation. Two or more darts used to deliver total.	Harvey et al. (1988)	Anesthesia with marked depression of ventilation. Two or more darts used to deliver total.
Lutjanus apodus	Snapper, schoolmaster	MS-222 (tricaine methanesulfonate)	70–125 mg/L	Immersion					Provided surgical anesthesia for kidney culture.	D.L. Neiffer (pers. exp.)	Provided surgical anesthesia for kidney culture.

Lutjanus argentimaculatus	Snapper, mangrove red	2-phenoxyethanol	400 mg/L	Immersion	39.21 ± 2.08 g		29	Provided total loss of equilibrium, allowing phlebotomy.	Hseu et al. (1996)	Provided total loss of equilibrium, allowing phlebotomy.
Lutjanus bohar	Snapper, two-spot red	Metomidate hydrochloride	50 mg/kg	IM	14			Level 3 sedation.	Harvey et al. (1988)	
Lutjanus coeruleolineatus	Snapper, blueline	MS-222 (tricaine methanesulfonate)	70–85 mg/L	Immersion				Diagnostic and quarantine examinations.	C.M. Burns (pers. exp.)	
Lutjanus griseus	Snapper, grey	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion				Diagnostic examination, good sedation.	C.M. Burns (pers. exp.)	
Ocyurus chrysurus	Snapper, yellowtail	MS-222 (tricaine methanesulfonate)	75–85 mg/L	Immersion	50–120 g			Effect varied from mild to heavy sedation. Examinations performed. $N = 17$.	D.L. Neiffer (pers. exp.)	Effect varied from mild to heavy sedation. Examinations performed.
Ocyurus chrysurus	Snapper, yellowtail	Medetomidine + ketamine	1.1–1.7 + 27–42 mg/kg	IM	2.35–3.65 0.0.6			All fish injected by dives using a jab stick. Initial effect seen in 4–12 minutes. For complete injections, mild to moderate sedation achieved. Fish netted and transferred to MS-222 bath for phlebotomy. Fish culled as part of disease surveillance and thus no reversal agent given.	D.L. Neiffer (pers. exp.)	All fish injected by divers using pole syringe. For complete injections, mild to moderate sedation achieved.
Ocyurus chrysurus	Snapper, yellowtail		(ratio M:K averages 24:1)							
Symphorichthys spilurus	Snapper, sailfin	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion				Diagnostic examination, good sedation.	C.M. Burns (pers. exp.)	
Family Moronidae										
Dicentrarchus labrax	Sea bass, European	Quinaldine sulphate + diazepam	7.5 mg/L + 2 mg/L	Immersion	8–9 g	Juvenile	24–25	Induction time 1–2 minutes. Recovery time 4–6 minutes. Provides deep anesthesia suitable for marking, surgery, and handling. Note: Quinaldine sulfate alone at 15 mg/L associated with 10% mortality and at 20–25 mg/L associated with 30–100% mortality. pH 7.9–8.2.	Yanar & Kumlu (2001)	Quinaldine sulfate alone at 15 mg/L associated with 10% mortality and at 20–25 mg/L associated with 30–100% mortality. pH = 7.9–8.2.
Dicentrarchus labrax	Sea bass, European	Quinaldine sulphate + diazepam	5 mg/L + 2 mg/L	Immersion	8–9 g	Juvenile	24–25	Induction time 1–2 minutes. Recovery time 3–5 minutes. Provides light anesthesia suitable for transportation. pH 7.9–8.2.	Yanar & Kumlu (2001)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Morone saxatilis	Bass, striped	Benzocaine dissolved in 100% ethanol at 1 g/30 ml	55–80 mg/L	Immersion	0.118–3.5		Juvenile, adult	22	Induction 3 minutes. Recovery 1.5–14.25 minutes.	Gilderhus et al. (1991)	
Morone saxatilis	Bass, striped	MS-222 (tricaine methanesulfonate)	20 mg/L	Immersion	48–81 cm		Adult	21	Prior to placement in bath, gills were sprayed twice with MS-222 solution (3200 mg/L). Procedure: mock intracoelomic transmitter placement. Induction 38–58 seconds. Recovery after 5 minutes of exposure to drug 156–272 seconds. No mortalities. Note from author (D.N.): species appears to be sensitive to MS-222.	Jennings & Looney (1998)	Species appears to be sensitive to MS-222.
Morone saxatilis × *M. chrysops*	Hybrid striped bass	Ketamine	125, 300, 500 mg/kg	Oral	13–31 g	0.0.6			Offering varying doses of ketamine (125, 300, and 500 mg/kg) injected into pieces of earthworm due to ways species fed. 125 mg/kgresulting in light sedation and 300 mg/kg induced a deeper stage of anesthesia.	Raines & Clancy (2009)	
Morone saxatilis x M. chrysops	Bass, hybrid striped	MS-222 (tricaine methanesulfonate)	25 mg/L	Immersion	87 ± 24.4 g			23	Light sedation.	Davis & Griffin (2004)	Light sedation.
Morone saxatilis x M. chrysops	Bass, hybrid striped	Clove oil	8 μL/L	Immersion	87 ± 24.4 g			23	Light sedation.	Davis & Griffin (2004)	Light sedation.
Morone saxatilis x M. chrysops	Bass, hybrid striped	Isoeugenol	3.6 mg/L	Immersion	87 ± 24.4 g			23	Light sedation.	Davis & Griffin (2004)	Light sedation.
Morone saxatilis x M. chrysops	Bass, hybrid striped	Quinaldine sulphate	8.3 mg/L	Immersion	87 ± 24.4 g			23	Light sedation.	Davis & Griffin (2004)	Light sedation.
Morone saxatilis x M. chrysops	Bass, hybrid striped	Metomidate hydrochloride	1.5 mg/L	Immersion	87 ± 24.4 g			23	Light sedation.	Davis & Griffin (2004)	Light sedation.
Micropterus salmoides, *Morone saxatilis* × *M. chrysops*	Bass, largemouth; hybrid striped	Isoeugenol	20–80 mg/L	Immersion					Concentrations of 40–60 mg/L rapidly anesthetize cold-water species to the handleable stage in <3–5 minutes whereas 60–80 mg/L is necessary to anesthetize cool- and warm-water species in a comparable amount of time.	Javahery et al. (2012)	Recommended dose: 40–60 mg/L (cold-water species); 60–80 mg/L (cool- and warm-water species).

Family Mullidae										
Parupeneus multifasciatus	Goatfish, manybar	MS-222 (tricaine methanesulfonate)	30–70 mg/L	Immersion				Light to heavy sedation for examination.	C.M. Burns (pers. exp.)	Light to heavy sedation for examination.
Pseudupeneus maculates	Goatfish, spotted	MS-222 (tricaine methanesulfonate)	30–50 mg/L	Immersion				Heavy sedation.	D.L. Neiffer (pers. exp.)	Heavy sedation.
Family Percidae										
Perca flavescens	Perch, American yellow	Isoeugenol	20 mg/L	Immersion	126 ± 50.1 g	Juvenile-young adult	12 ± 2	Induction within 3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH 8.1.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Perca flavescens	Perch, American yellow	Isoeugenol	20 mg/L	Immersion	1.1 ± 0.22 g	Fry-fingerling	12 ± 2	Induction within 4.1 minutes or less. Total exposure time ≤15 minutes. Recovery within 5 minutes. Useful for basic handling procedures. pH 8.1.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Perca flavescens	Perch, American yellow	MS-222 (tricaine methanesulfonate)	80, 120 mg/L	Immersion	2.7 ± 1.4		18.9 ± 0.2	Treatment periods 4.0–10.5 minutes for yellow perch.	Bowker et al. (2017)	
Perca flavescens	Perch, American yellow	MS-222 (tricaine methanesulfonate)	100, 150, 200, 250, 300 mg/L	Immersion	~7 g		22 ± 0.5	Exposed to 250 mg/L MS-222 combined with bicarbonate buffer at three ratios (w/w 1:0.5, 1:1, and 1:2) showed significantly ($P < 0.05$) reduced anesthesia induction and recovery times. The shortest times of anesthesia induction and recovery were observed in treatments using the 1:1 MS-222 to buffer ratio (dose maybe optimal for minimizing handling disturbance).	Zhai et al. (2018)	
Perca flavescens	Perch, American yellow	MS-222 (tricaine methanesulfonate)	150 mg/L (high dose), 100–125 mg/L (low dose)	Immersion	0.0.10		17		Hanley et al. (2010)	
Perca fluviatilis	Perch, European	Clove oil dissolved in 95% ethanol at 1:10 ratio.	6 mg/L	Immersion	17 g		15	Provided sedation for 6 hours without loss of equilibrium, at which time fish were removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen & Pirhonen (2004)	Provided sedation for 6 hours and useful for transport. No mortality.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Perca fluviatilis L.	Perch, European	Etomidate	1, 2 ml/L	Immersion	162.98 ± 29.40 g	0.0.20		19.7 ± 0.1	Taking into consideration the anesthesia recovery rates of the fish and recovery times, the low intensity of stress reactions, and the 100% fish survival rate following the procedure, it is justified to recommend using a propiscin solution at a concentration of 2 ml/L during rearing procedures that require anesthetizing this species.	Rożyński et al. (2018)	
Sander vitreus	Walleye	MS-222 (tricaine methanesulfonate)	150 mg/L –>100–125 mg/L	Immersion		0.0.5				Hanley et al. (2010)	
Stizostedion vitreum	Walleye	Isoeugenol	50 mg/L	Immersion	58.3 ± 12.2 g		Fry-fingerling	12 ± 2	Induction averaged 4.3 minutes. Total exposure time <15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH 8.1.	Stehly & Gingerich (1999)	
Family Pomacanthidae											
Centropyge bicolor	Angelfish, bicolor	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion				25	Sedation rated excellent. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated excellent. Diagnostic examination performed.
Holacanthus passer	Angelfish, king	MS-222 (tricaine methanesulfonate)	60–75 mg/L	Immersion	0.5			25	Good sedation, diagnostic examination.	C.M. Burns (pers. exp.)	Good sedation. Diagnostic examination performed.
Pomacanthus arcuatus	Angelfish, gray	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion	0.2–1.7 kg	0.0.16		25	Provided mild to heavy sedation. Diagnostic examinations and topical treatments performed.	D.L. Neiffer (pers. exp.)	Provided mild to heavy sedation. Diagnostic examination and topical treatments performed.
Pomacanthus asfur	Angelfish, Arabian	MS-222 (tricaine methanesulfonate)	60–90 mg/L	Immersion				25	High end sedation for swim bladder surgery.	C.M. Burns (pers. exp.)	Good sedation for surgery.
Pomacanthus annularis	Angelfish, bluering	MS-222 (tricaine methanesulfonate)	75–85 mg/L	Immersion	0.5			25	Good sedation, diagnostic examination.	C.M. Burns (pers. exp.)	Good sedation. Diagnostic examination performed.
Pomacanthus imperator	Angelfish, emperor	MS-222 (tricaine methanesulfonate)	75–85 mg/L	Immersion				25	Good sedation, diagnostic examination.	C.M. Burns (pers. exp.)	Good sedation. Diagnostic examination performed.
Pomacanthus paru	Angelfish, French	MS-222 (tricaine methanesulfonate)	60–90 mg/L	Immersion	0.40–1.95 kg	0.0.10		25	Good sedation, diagnostic examination.	D.L. Neiffer (pers. exp.)	Provided mild to heavy sedation. Diagnostic examinations performed.
Pomacanthus semicirculatus	Angelfish, semicircle	MS-222 (tricaine methanesulfonate)	60–85 mg/L	Immersion		0.0.4		25	Variable sedative effect (fair to excellent). Diagnostic examinations and treatments performed.	D.L. Neiffer (pers. exp.)	Variable sedative effect (fair to excellent). Diagnostic examination and treatments performed.

Family Priacanthidae											
Priacanthus arenatus	Bigeye, Atlantic	MS-222 (tricaine methanesulfonate)	60–90 mg/L	Immersion	0.3–0.6	0.0.9		25	Diagnostic examination, exopthalmia treatments. Care taken regarding the eyes during sedation.	C.M. Burns (pers. exp.)	
Family Serranidae											
Centropristis striata	Sea bass, black	Ketamine + dexmedetomidine + midazolam	1-2 mg/kg + 0.025–0.1 mg/kg + 0.2 mg/kg	IM	0.148–0.374			20–22	The protocol was effective in black sea bass, and the fish were consistently sedated and easily handled when anesthetised. Reversals given of atipamezole ranging from 0.25 to 1.0 mg/kg based on dexmed dose.	Christiansen et al. (2014)	
Cephalopholis cruentata	Graysby	MS-222 (tricaine methanesulfonate)	75–100mg/L	Immersion	2.00			25	Examination to surgical dosing.	C.M. Burns (pers. exp.)	
Cromileptes altivelis	Grouper, humpback	MS-222 (tricaine methanesulfonate)	65–70 mg/L	Immersion	0.60			25	Examination and blood draw.	C.M. Burns (pers. exp.)	
Epinephelus itajara	Grouper, Atlantic goliath	MS-222 (tricaine methanesulfonate)	75–95 mg/L	Immersion	7.7–106.2 kg	0.0.5		25	Provided mild to heavy sedation. Diagnostic examinations, injections, and topical treatments performed.	D.L. Neiffer (pers. exp.)	Provided mild to heavy sedation. Diagnostic examination, injections, and topical treatments performed.
Epinephelus itajara	Grouper, Atlantic goliath	MS-222 (tricaine methanesulfonate)	95–125 mg/L	Immersion	3.4–10 kg	0.0.6		25	Effect varied from heavy sedation to anesthesia (swim bladder surgeries and sampling).	D.L. Neiffer (pers. exp.)	Effect varied from heavy sedation to anesthesia.
Epinephelus lanceolatus	Grouper, giant	MS-222 (tricaine methanesulfonate)	1 g/L, 75 mg/L	Immersion			Adult		Induction with high-dose power sprayer over gills, following by maintenance in lower dose.	N.D. Mylniczenko (pers. exp.)	Induction with high dose via pump sprayer over gills, followed by maintenance in lower dose.
Epinephelus morio	Grouper, red	MS-222 (tricaine methanesulfonate)	70–95 mg/L	Immersion	0.51–8.64 kg	0.0.7		25	Effect ranged from mild sedation to light anesthesia. Examinations performed.	D.L. Neiffer (pers. exp.)	Effect ranged from mild sedation to light anesthesia.
Epinephelus ongus	Grouper, white-streaked	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion	610 g				Good for diagnostics (clips and scrapes).	T.M. Clauss (pers. exp.)	Good sedation. Diagnostic examination performed.
Epinephelus polyphekadion	Grouper, camouflage	Clove oil	10 mg/L	Immersion					Suitable for sampling and transportation.	Afifi et al. (2001)	Suitable for sampling and for transportation.
Mycteroperca bonaci	Grouper, black	MS-222 (tricaine methanesulfonate)	80–100 mg/L	Immersion	183–800 g	0.0.5		25	Provided adequate sedation for examination.	D.L. Neiffer (pers. exp.)	
Mycteroperca venenosa	Grouper, yellowfin	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion				25	Provided adequate sedation for examination.	D.L. Neiffer (pers. exp.)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Paralabrax maculatofasciatus	Bass, spotted sand	Isoeugenol	45 –> 35 mg/L	Immersion	40–160 g	0.0.6		20.1 ± 1.36	Mean anesthetic exposure time was 6 minutes and 54 seconds for wild finfish. Induction to maintenance.	Silbernagel & Yochem (2016)	
Paralabrax nebulifer	Bass, barred sand	Isoeugenol	45 –> 35 mg/L	Immersion	40–160 g	0.0.6			Mean anesthetic exposure time was 6 minutes and 54 seconds for wild finfish. Induction to maintenance.	Silbernagel & Yochem (2016)	
Pseudanthias bicolor	Anthias, bicolor	MS-222 (tricaine methanesulfonate)	60–70 mg/L	Immersion	0.02–0.04			25		C.M. Burns (pers. exp.)	
Pseudanthias pleurotaenia	Basslet, square-spot fairy	MS-222 (tricaine methanesulfonate)	60–70 mg/L	Immersion	0.02			25		C.M. Burns (pers. exp.)	
Pseudoanthias sp.	*Anthias* sp.	MS-222 (tricaine methanesulfonate)	77 mg/L	Immersion			Adult		Sedation rated excellent. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)	Sedation rated excellent. Diagnostic examination performed.
Family Siganidae											
Siganus lineatus	Spinefoot, golden-lined	Clove oil	100 mg/L	Immersion	7–39 g		Juvenile	27–29	Time to anesthesia <3 minutes. Time to recovery <5 minutes. Suitable for examination. No mortality observed.		Diagnostic examination performed. No mortality observed.
Family Sparidae											
Acanthopagrus schlegelii	Seabream, blackhead	2-phenoxyethanol	400 mg/L	Immersion	11.55 ± 3.47 g			29	Provided total loss of equilibrium, allowing phlebotomy.	Hseu et al. (1996)	Provided total loss of equilibrium, allowing phlebotomy.
Calamus calamus	Porgy, saucereye	MS-222 (tricaine methanesulfonate)	70–75 mg/L	Immersion				25	Diagnostic examination, treatments.	C.M. Burns (pers. exp.)	
Calamus penna	Porgy, sheepshead	MS-222 (tricaine methanesulfonate)	70–75 mg/L	Immersion	1.7			25	Diagnostic examination, treatments, phlebotomy.	C.M. Burns (pers. exp.)	
Calamus pennatula	Porgy, pluma	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion					Suitable for evaluation of exophthalmia though 100 mg/L excessive in one case.	D.L. Neiffer (pers. exp.)	100 mg/L suitable for examination but dose was high in one case.
Chrysophrys auratus	Seabream, silver	Isoeugenol	120 mg/L => 60 mg/L	Immersion	861.3 ± 64.6 g			11 ± 0.2	Time to surgical anesthesia was 20–25 minutes. During surgery (cannula placement) 60 mg/L oxygenated solution flushed continuously over gills. Poor survival with possible relation to prolonged surgery and/or hypoxemia.	Rothwell et al. (2005)	Poor survival with possible relation to prolonged surgery and/or hypoxemia.

Lagodon rhomboides	Pinfish	MS-222 (tricaine methanesulfonate)	60 mg/L	Immersion	0.6–0.7		25	Good sedation for treatments, tube feeding, blood draw.	C.M. Burns (pers. exp.)	
Pagrus major	Seabream, red	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	320 g	595 days old	20	Induction 3–5 minutes. 100% recovery after 30 minutes of exposure. Observations: maintained stage III anesthesia.	Oikawa et al. (1994)	Stage III anesthesia
Pagrus pagrus	Porgy, red	Ketamine + dexmedetomidine + midazolam	1 mg/kg + 0.025 mg/kg + 0.2 mg/kg	IM	0.05–0.307		20–22	The response of red porgy was extremely variable, and even at the lowest dose tested multiple fish exhibited a severe, often fatal lactic acidosis.	Christiansen et al. (2014)	Variable response with multiple fish exhibiting a severe, often fatal lactic acidosis.
Rhabdosargus sarba	Seabream, goldlined	2-phenoxyethanol	400 μL/L	Immersion	3.2 ± 0.15 g	Juvenile	27–29	Induction 1.25 ± 0.08 minutes. Recovery 0.51 ± 0.04 minutes. No mortality.	Hseu et al. (1998)	
Rhabdosargus sarba	Seabream, goldlined	Benzocaine dissolved in 95% ethanol	50 mg/L	Immersion	3.2 ± 0.15 g	Juvenile	27–29	Induction 1.94 ± 0.03 minutes. Recovery 0.52 ± 0.04 minutes. No mortality.	Hseu et al. (1998)	
Rhabdosargus sarba	Seabream, goldlined	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	3.2 ± 0.15 g	Juvenile	27–29	Induction 1.31 ± 0.06 minutes. Recovery 0.63 ± 0.03 minutes. No mortality.	Hseu et al. (1998)	
Rhabdosargus sarba	Seabream, goldlined	Quinaldine dissolved in 95% ethanol	9 μL/L	Immersion	3.2 ± 0.15 g	Juvenile	27–29	Induction 1.19 ± 0.11 minutes. Recovery 0.40 ± 0.03 minutes. No mortality.	Hseu et al. (1998)	
Rhabdosargus sarba	Seabream, goldlined	Quinaldine sulphate	20 mg/L	Immersion	3.2 ± 0.15 g	Juvenile	27–29	Induction 2.40 ± 0.11 minutes. Recovery 0.51 ± 0.02 minutes. No mortality.	Hseu et al. (1998)	
Sparus aurata	Seabream, gilthead	2-phenoxyethanol	0.15, 0.3, 0.45, 0.6, 0.75 ml/L	Immersion				Optimal doses for deep anesthesia for ongrowing gilthead seabrea was determined to be 0.45 ml/L for 2-PE.	Pires (2017)	
Sparus aurata	Seabream, gilthead	2-phenoxyethanol (99%)	35 μL/L	Immersion	48.5 ± 3.9 g	Juvenile	18		Toni et al. (2015)	EOLA did not produce anesthesia in under 30 minutes for 35 μL/L or less; 50–200 μL/L produced anesthesia and quicker recovery thus an effective anesthetic, but it was unable to prevent a stress response.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Sparus aurata	Seabream, gilthead	Benzocaine dissolved in 100% ethanol (1:20)	22.5 µL/L	Immersion	220 ± 15 g			24 ± 0.5	Used for diagnostic sampling. Loss of sensation and equilibrium within 8 minutes. Recovery within 90 seconds of transfer to anesthetic-free water. No mortality.	Bressler & Ron (2004)	Used for diagnostic sampling. Loss of sensation and equilibrium within 8 minutes. Recovery within 90 seconds of transfer to anesthetic-free water. No mortality.
Sparus aurata	Seabream, gilthead	Clove oil	0.2, 0.4, 0.6, 0.8, 1.0 ml/L	Immersion					Optimal dose for deep anesthesia for ongrowing gilthead seabream was determined to be 0.6 ml/L for clove oil.	Pires (2017)	
Sparus aurata	Seabream, gilthead	Clove oil	2.5, 5, 10, 20, 40, 60 mg/L	Immersion	42.7 ± 6.8 g	0.0.160	Juvenile	19	Optimal clove oil was 60 mg/L.	Jerez-Cepa et al. (2019)	Recommended dose: 80 mg/L (MS-222), 60 mg/L (clove oil). No mortality.
Sparus aurata	Seabream, gilthead	Clove oil dissolved in 100% ethanol (1:5)	44.5 µL/L	Immersion	220 ± 15 g			24 ± 0.5	Used for diagnostic sampling. Loss of sensation and equilibrium within 8 minutes. Recovery within 90 seconds of transfer to anesthetic-free water. No mortality.	Bressler & Ron (2004)	
Sparus aurata	Seabream, gilthead	Etomidate (dissolved in 1:3 96°-ethanol (EtOH))	0.15, 0.3, 0.5, 1.0, 1.5, 2.0 mg/L	Immersion					Etomidate was more effective to minimize stress responses in seabream juveniles transported for 6 hours (in 0.15 mg/L).	Jerez-Cepa et al. (2021)	
Sparus aurata	Seabream, gilthead	Isoeugenol	2, 5, 8, 15, 30, 60 mg/L	Immersion	65.1 ± 5.3 g	0.0.170	Juvenile	19	Aqui-S® resulted more suitable in short-term procedures where deep anesthesia (at 60 mg/L) is required.	Jerez-Cepa et al. (2021)	Aqui-S® better for short-term deep anesthesia while etomidate was more effective to minimize stress responses.
Sparus aurata	Seabream, gilthead	*Lippia alba* oil (EOLA , extracted)	25, 35, 50, 100, 200, 300 µL/L	Immersion		0.0.54				Toni et al. (2015)	
Sparus aurata	Seabream, gilthead	MS-222 (tricaine methanesulfonate)	5, 10, 25, 50, 70, 80, 100 mg/L	Immersion						Jerez-Cepa et al. (2019)	
Sparus aurata	Seabream, gilthead	MS-222 (tricaine methanesulfonate)	50, 100, 150, 200, 250 mg/L	Immersion	151 ± 4.3 g	0.0.108		22 ± 1	Optimal dose for deep anesthesia for ongrowing gilthead seabream was determined to be 150 mg/L for MS-222.	Pires (2017)	Recommended dose: 0.45 ml/L (2-PE), 150 mg/L (MS-222), and 0.6 ml/L (clove oil).

Sparus aurata	Seabream, gilthead	Quinaldine sulphate (plus diazepam)	5 mg/L	Immersion	6–7 g	Juvenile	25–26	Use for light anesthesia and transportation. Induction 1–2 minutes. Recovery 2–4 minutes. Observations: opercular rate 150/min, which is less than the opercular rate when quinaldine sulfate is used alone to reach the same level of anesthesia. Mortality 0%.	Yanar & Kumlu (2000)	
Sparus aurata	Seabream, gilthead	Quinaldine sulphate (plus diazepam)	7.5 mg/L	Immersion	6–7 g	Juvenile	25–26	Light anesthesia achieved. Induction 0–1 minute. Recovery: 3–5 minutes. Observations: opercular rate 190/min. All fish remained sensitive to external stimuli. Mortality 0% at light sedation dose, but 30–100% at deep sedation dose of 15–20 mg/L. In these cases the opecular rate increased to 190/min and then ceased.	Yanar & Kumlu (2000)	Mortality: 0% at light sedation dose, but 30–100% at higher dose.
Sparus aurata	Seabream, gilthead	Quinaldine sulphate	1 mg/L	Immersion	6–7 g	Juvenile	25–26		Yanar & Kumlu (2000)	
Sparus aurata	Seabream, gilthead	Quinaldine sulphate	10 mg/L	Immersion	6–7 g	Juvenile	25–26		Yanar & Kumlu (2000)	
Family Terapontidae										
Bidyanus bidyanus	Perch, silver	Benzocaine	20 mg/L	Immersion	682 ± 99 g			Used for sedation during transport.	Kildea et al. (2004)	
Bidyanus bidyanus	Perch, silver	Clove oil	15, 50 mg/L	Immersion	682 + 99 g			15 mg/L sufficient for light handling, tagging, and harvesting (exposure time 60 minutes). 50 mg/L produced anesthesia suitable for surgical procedures (exposure time 30 minutes).	Kildea et al. (2004)	Recommended dose: 15 mg/L (light handling, tagging, and harvesting); 50 mg/L (surgical anesthesia).
Bidyanus bidyanus	Perch, silver	Isoeugenol	15 mg/L	Immersion	682 + 99 g			Sufficient for light handling, tagging, and harvesting (exposure time 60 minutes).	Kildea et al. (2004)	Sufficient for light handling, tagging, and harvesting (exposure time 60 minutes).
Family Toxotidae										
Toxotes jaculatrix	Archerfish, banded	MS-222 (tricaine methanesulfonate)	90–100 mg/L	Immersion					N.D. Mylniczenko, T.M. Clauss (pers. exp.)	

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Order Pleuronectiformes											
Family Achiridae											
Trinectes maculatus	Sole, hogchoker	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion					Good anesthesia for examination, cultures.	C.M. Burns (pers. exp.)	
Family Paralichthyidae											
Paralichthys lethostigma	Southern flounder	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Provided adequate sedation for examination.	D.L. Neiffer (pers. exp.)	Provided adequate sedation for examination.
Family Pleuronectidae											
Hippoglossus hippoglossus	Halibut, Atlantic	Benzocaine	40 mg/L	Immersion	200 g	0.0.180		~9	Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Hippoglossus hippoglossus	Halibut, Atlantic	Metomidate hydrochloride	20–30 mg/L	Immersion	2915 $\pm$ 592 g			10	Induction to anesthesia 189–310 seconds. Dose allowed for handling and phlebotomy. Recovery time 220–320 seconds.	Malmstrøm et al. (1993)	
Hippoglossus hippoglossus	Halibut, Atlantic	Metomidate hydrochloride	3 mg/kg	IV				10.5	Metomidate hydrochloride rapidly immobilized the fish, with respiratory depression, reduced heart rate, and loss of balance /motor control within 1 minute (mean). Recovery was slow, with resumed balance /motor control after 26.4 minutes. Opercular respiration movements were resumed more rapidly with a recorded mean of 1.7 minutes. Oral administration was demonstrated to be a way of immobilizing fish, for example in large aquariums, without exposing them to unwanted stress.	Hansen et al. (2003)	Rapid induction, slow recovery.

Hippoglossus hippoglossus	Halibut, Atlantic	Metomidate hydrochloride	9 mg/L	Immersion		10.5	Metomidate hydrochloride rapidly immobilized the fish, with respiratory depression, reduced heart rate, and loss of balance /motor control within 1 minute (mean). Recovery was slow, with resumed balance /motor control after 26.4 minutes. Opercular respiration movements were resumed more rapidly with a recorded mean of 1.7 minutes. Oral administration was demonstrated to be a way of immobilizing fish, for example in large aquariums, without exposing them to unwanted stress.	Hansen et al. (2003)	Rapid induction, slow recovery.
Hippoglossus hippoglossus	Halibut, Atlantic	Metomidate hydrochloride	3 mg/L	Immersion			Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Hippoglossus hippoglossus	Halibut, Atlantic	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion			Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Hippoglossus hippoglossus	Halibut, Atlantic	MS-222 (tricaine methanesulfonate)	250 mg/L	Immersion	2915 + 592 g	10	Induction to anesthesia 250–282 seconds. Dose allowed for handling and phlebotomy. Recovery time 495–649 seconds.	Malmstrøm et al. (1993)	
Paralichthys californicus	Flounder, California	Isoeugenol	45 –> 35 mg/L	Immersion	40–160 g 0.0.6		Mean anesthetic exposure time was 6 minutes and 54 seconds for wild finfish. Induction to maintenance.	Silbernagel & Yochem (2016)	
Family Scophthalmidae									
Scophthalmus maximus	Turbot	Metomidate hydrochloride	3 mg/kg	intravenous		18	Metomidate hydrochloride rapidly immobilized the fish, with respiratory depression, reduced heart rate, and loss of balance /motor control within 1 minute (mean). Recovery was slow, with resumed balance /motor control after 26.4 minutes. Opercular respiration movements were resumed more rapidly with a recorded mean of 1.7 minutes. Oral administration was demonstrated to be a way of immobilizing fish, for example in large aquariums, without exposing them to unwanted stress.	Hansen et al. (2003)	Rapid induction, slow recovery.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Scophthalmus maximus	Turbot	Metomidate hydrochloride	9 mg/L	Immersion				18	Metomidate hydrochloride rapidly immobilized the fish, with respiratory depression, reduced heart rate, and loss of balance /motor control within 1 minute (mean). Recovery was slow, with resumed balance /motor control after 26.4 minutes. Opercular respiration movements were resumed more rapidly with a recorded mean of 1.7 minutes. Oral administration was demonstrated to be a way of immobilizing fish, for example in large aquariums, without exposing them to unwanted stress.	Hansen et al. (2003)	Rapid induction, slow recovery.
Scophthalmus maximus	Turbot	Metomidate hydrochloride	7 mg/kg	Oral				18	Metomidate hydrochloride rapidly immobilized the fish, with respiratory depression, reduced heart rate, and loss of balance /motor control within 1 minute (mean). Recovery was slow, with resumed balance /motor control after 26.4 minutes. Opercular respiration movements were resumed more rapidly with a recorded mean of 1.7 minutes. Oral administration was demonstrated to be a way of immobilizing fish, for example in large aquariums, without exposing them to unwanted stress.	Hansen et al. (2003)	Rapid induction, slow recovery.
Scophthalmus maximus	Turbot	Medetomidine	0.063–420 nM	Immersion	0.25–0.80 g		Juvenile	14	Used as an antifoaling drug.	Hilvarsson et al. (2007)	Used as an antifoaling drug.
Order Salmoniformes											
Family salmonidae											
Coregonus lavaretus	Whitefish, European	Clove oil dissolved in 95% ethanol at 1:10 ratio.	3 mg/L	Immersion	31–44 g			15	Provided sedation for 6 hours without loss of equilibrium, at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen & Pirhonen (2004)	Considered useful for transport for up to 6 hours. No mortality.

Hucho hucho	Huchen	Etomidate	1.0–1.5 ml/L	Immersion		Spawners	4.5–5.0		Kazuñ & Siwicki (2012)	
Oncorhynchus kisutch	Salmon, coho	Clove oil	25 mg/L	Immersion	5.47–12.72 kg			Induction 2.5–3.5 minutes. Exposed for 10 minutes. Recovery 7.5–13 minutes. No mortality.	Taylor & Roberts (1999)	
Oncorhynchus kisutch	Salmon, coho	Ketamine	30 mg/kg	IV	1.857 ± 0.102 kg		15	Injected into dorsal aorta via cannula. Caused immediate cessation of ventilation for 10–300 seconds with loss of equilibrium. Ventilation rate recovered within 1–2 hours.	Graham & Iwama (1990)	Injected into dorsal aorta via cannula. Caused immediate cessation of ventilation for 10–300 seconds with loss of equilibrium.
Oncorhynchus kisutch	Salmon, coho	Alphaxalone-alphadolone	0.5–1.0 ml/kg	IM	2–3 kg			Sedation with partial loss of equilibrium. Able to be netted, but responsive.	Harvey et al. (1988)	Sedation with partial loss of equilibrium. Able to be netted, but responsive.
Oncorhynchus mykiss	Trout, rainbow	2-phenoxyethanol	0.2 ml/L	Immersion				Concentrations chosen so stage 3 anesthesia would be induced in 4–7 minutes.	Iwama et al. (1989)	
Oncorhynchus mykiss	Trout, rainbow	2-phenoxyethanol	0.2 ml/L	Immersion	56 ± 5 g	0.0.100	12	Fish were deeply anesthetized with 2-PE at 165 ± 22 seconds and recovered at 209 ± 26 seconds.	Soltanian et al. (2018)	
Oncorhynchus mykiss	Trout, rainbow	Alphaxalone-alphadolone	130, 150 mg/kg	ICe or ⅔ ICe+ ⅓ IM	100–500 g		10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).	Oswald (1978)	Doses of 18 mg/kg produced anesthesia but also apnea and long recoveries. Lower doses only produced sedation.
Oncorhynchus mykiss	Trout, rainbow	Benzocaine	20 mg/L	Immersion	100–500 g		10	Provided adequate sedation within 30 seconds to permit weighing and injections.	Oswald (1978)	Provided adequate sedation within 30 seconds to permit weighing and injections.
Oncorhynchus mykiss	Trout, rainbow	Benzocaine	30 mg/L	Immersion	~400 g			Concentrations chosen so stage 3 anesthesia would be induced in 4–7 minutes.	Iwama et al. (1989)	
Oncorhynchus mykiss	Trout, rainbow	Benzocaine dissolved in ethanol at 1 gram /30 ml to make stock solution	25–40 mg/L	Immersion	2–500 g	Juvenile	Oct-13	Induction 1.25–5.5 minutes. Recovery following 15 minutes of exposure 4–16 minutes. Provided light to heavy sedation.	Gilderhus (1989)	Provided light to heavy sedation.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Oncorhynchus mykiss	Trout, rainbow	Benzocaine dissolved in ethanol at 1 gram /30 ml to make stock solution	30–45 mg/L	Immersion	0.68–2.04 kg		Adult		Induction 2.25–4.5 minutes. Recovery following 15 minutes of exposure 5.5–13.5 minutes. Provided light to heavy sedation.	Gilderhus (1989)	
Oncorhynchus mykiss	Trout, rainbow	Benozocaine (10%)	25, 65 mg/ml	Immersion	900–1000 g	0.40.0		10.1–10.4		Saunders et al. (2020)	Following multiple anesthetizations with TMS, the methemoglobin increased by 90%, 5%, and 1% in brook trout, rainbow trout, and Atlantic salmon, respectively.
Oncorhynchus mykiss	Trout, rainbow	Clove oil dissolved in ethanol at a ratio of 1:10	2–5 mg/L	Immersion	20.46 ± 0.73 g		6 months	9.1 ± 0.2	Recommended for sedation suitable for 6–8 hours of transport.	Keene et al. (1998)	Recommended for sedation and suitable for 6–8 hours of transport.
Oncorhynchus mykiss	Trout, rainbow	Clove oil (80%)	25 mg/L	Immersion	56 ± 5 g	0.0.100		12	Fish were deeply anesthetized with clove oil at 110 ± 18 seconds and recovered at 170 ± 22 seconds.	Soltanian et al. (2018)	
Oncorhynchus mykiss	Trout, rainbow	Clove oil dissolved in ethanol at a ratio of 1:10	40–60 mg/L	Immersion	20.46 ± 0.73 g		6 months	9.1 ± 0.2	Provided deep anesthesia following 3–6 minutes of exposure.	Keene et al. (1998)	
Oncorhynchus mykiss	Trout, rainbow	Clove oil	60 mg/L	Immersion	91.1 ± 3.0, 288.8 ± 9.8 g			11.5 ± 0.5	Fish exposed to MS-222 had significantly higher cortisol levels at 1 hour. These findings show that few differences exist between the anesthetic effects of clove oil and MS-222 on the physiological response of fish to stress. However, clove oil is more effective at reducing the short-term stress response induced by handling and blood sampling, and is recommended as an alternative anaesthetic.	Wagner et al. (2003)	Clove oil was more effective at reducing the short-term stress versus MS-222.
Oncorhynchus mykiss	Trout, rainbow	Clove oil	20, 30, 40, 50, 60 mg/L	Immersion	30.5 ± 11.4 g		Juvenile	15	Basal effective concentrations determined were 40 mg/L for clove oil.	Mohammadi & Khara (2014)	Recomended dose: 40 mg/L (clove oil), 150 mg/L (MS-222), 1 mg/L (ketamine), and 30 mg/L (tobacco). Fish were anesthetized more rapidly with clove oil followed by tobacco extract, ketamine, and MS-222.

Oncorhynchus mykiss	Trout, rainbow	Etomidate	0.5–1.0 ml/L	Immersion		Spawners, commerical fish	4.5–7.0		Kazuñ & Siwicki (2012)	
Oncorhynchus mykiss	Trout, rainbow	Isoeugenol	40, 60 mg/L	Immersion	2.3 ± 0.9		15.2 ± 0.4	Treatment periods 2.25–8.75 minutes for rainbow trout.	Bowker et al. (2017)	
Oncorhynchus mykiss	Trout, rainbow	Isoeugenol	20 mg/L	Immersion	754 ± 145 g	Juveniles-young adults	12 ± 2	Induction within 3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Oncorhynchus mykiss	Trout, rainbow	Isoeugenol	20 mg/L	Immersion	4.1 ± 1.4 g	Fry-fingerling		Induction within 4.1 minutes or less. Total exposure time ≤15 minutes. Recovery within 5 minutes. Useful for basic handling procedures.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Oncorhynchus mykiss	Trout, rainbow	Ketamine	0.5, 1, 1.2, 1.5, 1.7 mg/L	Immersion	30.5 ± 11.4 g	Juvenile	15	Basal effective concentrations determined were 1 mg/L for ketamine.	Mohammadi & Khara (2014)	
Oncorhynchus mykiss	Trout, rainbow	Ketamine	50 mg/L	IM	100–500 g		10	Induction generally within 5–10 minutes. Anesthesia persisted for 20 minutes at 130 mg/ and 50–80 min at 150 mg/kg. Apnea requiring assisted ventilation occurred in 30% of fish. Recovery took up to 90 minutes and was characterized by excitement and ataxia.	Oswald (1978)	Apnea in 30% fish. Recovery took up to 90 minutes and was characterized by excitement and ataxia.
Oncorhynchus mykiss	Trout, rainbow	Ketamine	30 mg/kg	IV	365 ± 26 g			Injected into dorsal aorta via cannula. Caused immediate cessation of ventilation for 10–300 seconds with loss of equilibrium. Ventilation rate recovered to preanesthesia values within 1–2 hours.	Graham & Iwama (1990)	Immediate cessation of ventilation for 10–300 seconds with loss of equilibrium. Ventilation rate recovered within 1–2 hours.
Oncorhynchus mykiss	Trout, rainbow	Ketamine	100 mg/L	Immersion	18–257 g	0.0.40		The result shows that ketamine can produce anesthesia in the fish as a water-soluble drug and it is safe and effective.	Ganjoor et al. (2021)	Ketamine produced anesthesia in the fish as a water-soluble drug and it is safe and effective.
Oncorhynchus mykiss	Trout, rainbow	Metomidate hydrochloride	5 mg/L	Immersion				Concentrations chosen so stage 3 anesthesia would be induced in 4–7 minutes.	Iwama et al. (1989)	
Oncorhynchus mykiss	Trout, rainbow	Medetomidine	5–20 mg/L	Immersion	300–400 g		10 ± 0.2	Exposure for 10 minutes. Considered to be a good sedative, but not anesthetic.	Horsberg et al. (1999)	Considered to be a good sedative, but not anesthetic.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Oncorhynchus mykiss	Trout, rainbow	Atipamezole	30–80 mg/L (6× medetomidine dose)	Immersion					Exposed to atipamezole for 7–10 minutes. Exposure to 80 mg/L atipamezole resulted in panic-like reactions.	Horsberg et al. (1999)	
Oncorhynchus mykiss	Trout, rainbow	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion	56 ± 5 g	0.0.100		12	Fish were deeply anesthetized with MS-222 at 94 ± 10 seconds and recovered at 138 ± 16 seconds.	Soltanian et al. (2018)	
Oncorhynchus mykiss	Trout, rainbow	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion			Adult			Tubio et al. (2010)	
Oncorhynchus mykiss	Trout, rainbow	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion	0.6–2 kg		Adult		70–75 ppm provides excellent anesthesia for invasive procedures.	N.D. Mylniczenko (pers. exp.)	Recommended dose: 70–75 ppm for surgical procedures.
Oncorhynchus mykiss	Trout, rainbow	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion					Concentrations chosen so stage 3 anesthesia would be induced in 4–7 minutes.	Iwama et al. (1989)	
Oncorhynchus mykiss	Trout, rainbow	MS-222 (tricaine methanesulfonate)	50, 100, 150, 200, 250 mg/L	Immersion	30.5 ± 11.4 g		Juvenile	15	Basal effective concentrations determined were 150 mg/L for MS-222.	Mohammadi & Khara (2014)	
Oncorhynchus mykiss	Trout, rainbow	Propofol 1%	2.5, 5 mg/L	Immersion	~300 g	0.0.36		15	Stage 4 anesthesia was achieved in ~5 minutes with 2.5 mg/L and in ~3 minutes with 5mg/L. Recovery time was between 3 and 9 minutes.	Prieto et al. (2017)	
Oncorhynchus mykiss	Trout, rainbow	Tobacco extract	20, 25, 30, 35, 40 mg/L	Immersion	30.5 ± 11.4 g		Juvenile	15	Basal effective concentrations determined were 30 mg/L for tobacco.	Mohammadi & Khara (2014)	
Oncorhynchus mykiss	Trout, rainbow	Carbon dioxide (CO_2)	50% (balance O_2)	Immersion					Concentrations chosen so stage 3 anesthesia would be induced in 4–7 minutes.	Iwama et al. (1989)	
Oncorhynchus nerka	Salmon, sockeye	Clove oil	50 mg/L	Immersion			Adult	9-Oct	Fish could be handled within 3 minutes for measurement, esophageal implants, and fin clips. Recovery within 10 minutes following 15 minutes of exposure.	Woody et al. (2002)	

Oncorhynchus nerka	Salmon, sockeye	Sodium bicarbonate + acetic acid	40 g + 15 ml (yielded CO_2 328–195 mg/L)	Immersion	1.5–3.5	Mature		The mean time to stage 4 anesthesia was 6.35 minutes. Mean time for recovery after removal to fresh water was 7.48 minutes. Researchers wishing to use our technique will have to modify the amount of acetic acid used to achieve stage 4 anesthesia if the pH of their water differs.	Prince et al. (1995)	
Oncorhynchus tshawytscha	Salmon, chinook	Alphaxalone-alphadolone	0.3–0.5 ml/kg	IM	3			1	Harvey et al. (1988)	
Oncorhynchus tshawytscha	Salmon, chinook	Benzocaine dissolved in ethanol at 1 gram/30 ml	25–35 mg/L	Immersion	80 g	Juvenile	Oct–13	Induction 1–3.25 minutes. Recovery following 15 minutes of exposure 2.25–18.5 minutes. Provided light to heavy sedation.	Gilderhus (1989)	Provided light to heavy sedation.
Oncorhynchus tshawytscha	Salmon, chinook	Clove oil (82%)	40 mg/L	Immersion	~350 g Female	Adult		Only exposed 3 minutes perform blood taken.	Young et al. (2019)	
Oncorhynchus tshawytscha	Salmon, chinook	Clove oil in 1:10 ratio with 95% ethanol.	20 mg/L	Immersion	40.2 ± 0.6 g	Juvenile		Provided deep anesthesia within 2 minutes.	Cho & Heath (2000)	Provided deep anesthesia within 2 minutes.
Oncorhynchus tshawytscha	Salmon, chinook	Isoeugenol	40 mg/L	Immersion	~350 g Female	Adult		Only exposed 3 minutes perform blood taken.	Young et al. (2019)	
Oncorhynchus tshawytscha	Salmon, chinook	Isoeugenol	60 mg/L	Immersion	844–1562 g		12.5 ± 2.5	Sedation with partial loss of equilibrium. Suitable for handling.	Rothwell et al. (2005)	Sedation with partial loss of equilibrium. Suitable for handling.
Oncorhynchus tshawytscha	Salmon, chinook	Isoeugenol	120 mg/L	Immersion	844–1562 g		12.5 ± 2.5	Resulted in surgical anesthesia within 10 minutes for placement of vascular cannula. Recovery within 5–8 minutes.	Rothwell et al. (2005)	
Oncorhynchus tshawytscha	Salmon, chinook	Metomidate hydrochloride	42 mg/kg	IM	9			Light sedation with partial loss of equilibrium. Directed net avoidance.	Harvey et al. (1988)	2
Oncorhynchus tshawytscha	Salmon, chinook	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion	40.2 ± 0.6 g	Juvenile		Provided deep anesthesia within 2 minutes.	Cho & Heath (2000)	Provided deep anesthesia within 2 minutes.
Oncorhynchus tshawytscha	Salmon, chinook	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	844–1562 g		12.5 ± 2.5	Resulted in light anesthesia. Recovery following 5 minutes of exposure occurred within 5 minutes.	Rothwell et al. (2005)	Resulted in light anesthesia. Recovery following 5 minutes of exposure occurred within 5 minutes.
Salmo munzuricus	Trout (novel species)	2-phenoxyethanol	0.2, 0.3, 0.4, 0.5 ml/L	Immersion	100–200 g			Most appropriate concentrations were determined as 0.4 ml/L at weights of 100–400 g.	Can et al. (2017)	Recommended dose: 0.4 ml/L (weights of 100–400 g), 0.5 ml/L (weights of 400–600 g).

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Salmo munzuricus	Trout (novel species)	2-phenoxyethanol	0.2, 0.3, 0.4, 0.5 ml/L	Immersion	200–400 g				Most appropriate concentrations were determined as 0.4 ml/L at weights of 100–400 g.	Can et al. (2017)	
Salmo munzuricus	Trout (novel species)	2-phenoxyethanol	0.2, 0.3, 0.4, 0.5 ml/L	Immersion	400–600 g				Most appropriate concentrations were determined as 0.4 ml/L at weights of 100–400 g and 0.5 ml/L at weights of 400–600 g for 2-phenoxyethanol in *Salmo munzuricus* broodstock.	Can et al. (2017)	
Salmo salar	Salmon, Atlantic	Benzocaine 20%	30–100 mg/L	Immersion	31–44 g			15	Provided sedation for 6 hours without loss of equilibrium, at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen & Pirhonen (2004)	Considered useful for transport up to 6 hours. No mortality.
Salmo salar	Salmon, Atlantic	Benzocaine	40 mg/L	Immersion	420 g	0.0.1444		~9	Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Salmo salar	Salmon, Atlantic	Clove oil dissolved in 95% ethanol at 1:10 ratio.	5 mg/L	Immersion	31–44 g			15	Provided sedation for 6 hours without loss of equilibrium, at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen & Pirhonen (2004)	Considered useful for transport up to 6 hours. No mortality.
Salmo salar	Salmon, Atlantic	Clove oil dissolved in 95% ethanol at 1:10 ratio.	8 mg/L	Immersion	44.7 ± 12.8 g		1-year-old smolt	5.4 ± 0.2	Anesthesia attained in 2.2–8.1 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)	Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.
Salmo salar	Salmon, Atlantic	Clove oil dissolved in ethanol at 1:10 ratio	30–100 mg/L	Immersion	44.7 ± 12.8 g		1-year-old smolt	5.4 ± 0.2	Anesthesia attained in 2.2–8.1 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)	Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.
Salmo salar	Salmon, Atlantic	Isoeugenol	5.4 mg/L	Immersion					Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Salmo salar	Salmon, Atlantic	Isoeugenol	17 mg/L	Immersion	2.39 ± 0.62	0.0.8		7.2–7.9	Not approved for food fish, but met all requirements in experiment related to fish welfare.	Erikson (2011)	Not approved for food fish, but met all requirements in experiment related to fish welfare.

Salmo salar	Salmon, Atlantic	Isoeugenol	30–100 mg/L	Immersion	44.7 ± 12.8 g		1-year-old smolt	5.4 ± 0.2	Anesthesia attained in 2.2–6.2 minutes.	Iversen et al. (2003)	
Salmo salar	Salmon, Atlantic	Metomidate hydrochloride	2–10 mg/L	Immersion	44.7 ± 12.8 g		1-year-old smolt	5.4 ± 0.2	Anesthesia attained in 3.0–17.4 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)	Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.
Salmo salar	Salmon, Atlantic	Metomidate hydrochloride	3 mg/L	Immersion					Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Salmo salar	Salmon, Atlantic	Metomidate hydrochloride	1, 2, 3, 5, 10 mg/L		58, 1130 g	0.0.180, 0.0.18	Parr, adult	5, 7.7	Anesthetic was more potent in the adult salmon acclimated to sea water than in freshwater parr. Recommended concentration of 3 mg/L.	Olsen et al. (1995)	Recommended dose: 3 mg/L. Anaesthetic was more potent in the adult salmon acclimated to sea water than in freshwater.
Salmo salar	Salmon, Atlantic	MS-222 (tricaine methanesulfonate)	55 mg/L	Immersion					Concentrations based on manufacturers' recommendations.	Zahl et al. (2010)	Concentrations based on manufacturers' recommendations.
Salmo salar	Salmon, Atlantic	MS-222 (tricaine methanesulfonate)	65 mg/ml	Immersion	150 g	0.40.0				Saunders et al. (2020)	
Salmo salar	Salmon, Atlantic	Nitrogen		Immersion		0.0.4			The fish treated with nitrogen showed the strongest aversive reactions, produced the most stressed fish, and fish that did not appear to be sedated.	Erikson (2011)	The fish treated with nitrogen showed the strongest aversive reactions, lack of sedation, and the most stress.
Salmo salar	Salmon, Atlantic	Carbon dioxide (CO_2)	low 70–80, medium 180–250, high > 400 mg CO_2/L	Immersion		0.0.24			No level of carbon dioxide rendered the fish unconscious.	Erikson (2011)	No level of carbon dioxide rendered the fish unconscious.
Salmo trutta	Trout, sea	Alphaxalone-alphadolone	12–18 mg/kg	ICe or ⅔ ICe + ⅓ IM	100–500 g			10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).	Oswald (1978)	Lower doses only produced sedation. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Salmo trutta	Trout, sea	Benzocaine	50 mg/L	Immersion	100–500 g			10	Induction generally in 5–10 minutes. Anesthesia persisted for 20 minutes at 130 mg/ and 50–80 minutes at 150 mg/kg. Apnea requiring assisted ventilation occurred in 30% of fish. Recovery took up to 90 minutes and was characterized by excitement and ataxia.	Oswald (1978)	Apnea in 30%. Recovery took up to 90 minutes with excitement and ataxia.
Salmo trutta	Trout, sea	Clove oil dissolved in 95% ethanol at 1:10 ratio.	8 mg/L	Immersion	100–500 g			10	Provided adequate sedation within 30 seconds to permit weighing and injections.	Oswald (1978)	
Coregonus lavaretus	Trout, sea	Etomidate	0.5–1.0 ml/L	Immersion			Commercial	7		Kazuñ & Siwicki (2012)	
Salmo trutta	Trout, sea	Ketamine	130, 150 mg/kg	IM	100–500 g			10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).	Oswald (1978)	Lower doses only produced sedation. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).
Salvelinus alpinus	Artic char	Carbon dioxide (CO_2)	CO_2 until near saturation (>1 h)	Immersion	478–1286 g			4.6 ± 0.2	Exposure to water saturated with CO_2 triggered aversive struggling and escape responses for several minutes before immobilization. Fish exposed to an electric current immobilized close to instant. It took 5 minutes for the fish to recover from electrical stunning. Fish stunned with CO_2 did not recover. However, the electrically stunned fish had more than double the plasma levels of cortisol compared with fish stunned with CO_2.	Gräns et al. (2016)	Exposure to water saturated with CO_2 triggered aversive struggling and escape responses and poor/lack of recovery.

Salvelinus fontinalis	Trout, brook	Isoeugenol	40 mg/L	Immersion						Durhack et al. (2020)	
Salvelinus fontinalis	Trout, brook	Eugenol + lidocaine 2%	40 mg/L + 6 mg/kg	Immersion						Lamglait & Lair (2021)	
Salvelinus fontinalis	Trout, brook	MS-222 (tricaine methanesulfonate)	60 mg/L + 6 mg/kg	Immersion	1098 ± 191 g					Lamglait & Lair (2021)	
Salvelinus fontinalis	Trout, brook	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion	25.8 ± 7.5 g	0.0.480	Juvenile		Aqui-S® and electro-immobilization may provide suitable alternatives to MS-222 for field research (which has longer clearance times).	Durhack et al. (2020)	
Salvelinus fontinalis	Trout, brook	MS-222 (tricaine methanesulfonate)	65 mg/ml	Immersion	380–770 g	16.24.0				Saunders et al. (2020)	
Salvelinus fontinalis	Trout, brook	Electric handling gloves	Electro + 6 mg/kg	Elecroanesthesia						Lamglait & Lair (2021)	Rapid immobilization, suboptimal for surgeries. Equipment: Smith-Root EFHGs.
Salvelinus fontinalis	Trout, brook	Electric handling gloves	10–14 pulses of 150 V direct current (D/C), 60 Hz frequency, and 15% duty cycle for duration of 0.20 ± 0.02 min	Elecroanesthesia						Durhack et al. (2020)	Considered appropriate for fieldwork, no withdrawal time. Equipment: PES®.
Salvelinus namaycush	Trout, lake	Isoeugenol	20–50 mg/L	Immersion	167–1399 g		Juveniles-young adult	12 ± 2	Induction in 2.5–3.9 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH 8.1.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Thymallus thymallus	Grayling	Etomidate	0.5–1.0 ml/L	Immersion			Spawner	7		Kazuñ & Siwicki (2012)	
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Benzocaine	50 mg/L	Immersion	100–500 g			10	Animals were placed in benzocaine immersion for 30 seconds in to give IP/IM/IP + IM injections. Animals were reversed from brief immersion before going into induction with injected drug (5–10 minutes).	Oswald (1978)	Rapid induction to allow other anesthetic injections.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Ketamine	130, 150 mg/kg	IM		0.0.6			At 130 mg/kg, anesthesia only persisted for 20 minutes but at 150 mg/kg, it lasted between 50 and 80 minutes. The recovery period was prolonged, taking up to 90 minutes before completion.	Oswald (1978)	Dose-dependent length of anesthesia. Recovery prolonged.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Etorphine HCl/ acetylpromazine maleate(Large Animal Revivon, Reckitt)	1.25–10 mg/kg	IM or IP (unclear)		0.0.3			Rates of 8–10 mg/kg were found to be effective. Animals remained immobile for 30–60 minutes until reversal was given by deep IM (divided into two doses). Within 5 minutes of reversal regained equilibrium.	Oswald (1978)	Good anesthesia reported. Rapid reversal with diprenorphine hydrochloride. Human safety concerns.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Propanidid	80–500 mg/kg	IM or IP (unclear)		0.0.7			The optimal dosage lies between 300 and 350 mg/kg. At 300 mg/kg, the sleep time was variable, lasting from 30 to 120 minutes. At 325 mg/kg reliably produced a sleep time of 2.5 hours, with minimal respiratory effects. Highest dose produce apneic response during anesthesia (180 minutes) but animal recovered.	Oswald (1978)	Variable duration, no respiratory depression.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Xylazine HCl	100–140 mg/kg	IM or IP (unclear)					The minimal anesthetic dose was found to be 100 mg/kg and this consistently produced apnoea. Xylazine also caused gross ECG disturbances, including changes in duration of P, QRS and T waves. Atropine (0.5 mg) partially corrected this.	Oswald (1978)	Apnea, convulsive activity reported. ECG disturbances.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Alphaxalone-alphadolone	18–36 mg/kg	IM/IP		0.0.12			Fish were injected by IP or a combination of 2/3 IP, 1/3 IM. Doses of 18 mg/kg and over produced anesthesia, but lower doses produced sedation only. Sleep times ranged from 1 to 3 hours at 24 mg/kg to 4–6 hours at 36 mg/kg. Doses of 24 mg/kg and over always provoked apnoea. In most cases, recovery was complete within 2 hours.	Oswald (1978)	Duration 1–3 hours longer with higher doses.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Chlorpromazine HCl	50, 100 mg/kg	ICe		0.0.2			Ineffective.	Oswald (1978)	No effect.

Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Pentobarbitone sodium	30–72 mg/kg	ICe		0.0.4		Doses of 30 mg/kg produced sedation only, without loss of equilibrium. Recovery prolonged, with persistent ataxia noted in 48, 72 mg/kg.	Oswald (1978)	Recovery prolonged, with persistent ataxia noted in 48 and 72 mg/kg.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Lignocaine hydrochloride	0.1 ml	Spinal nerve block	120–150 g	0.0.2		A 25-gauge needle was introduced downwards from the dorsal midline surface at a point about 1 cm posterior to the occipital process. The needle tip was moved until a gap between the vertebrae was found, after which it was gently advanced until a twitch indicated contact with the spinal cord. 0.1 ml of lignocaine hydrochloride was deposited and the fish returned to water. The onset of anesthesia was very rapid, with immobilization occurring in 5 minutes.	Oswald (1978)	Rapid immobilization in 5 minutes. Recovery 45 minutes.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow and brown	Benzocaine	120 mg/kg	ICe		0.0.1		No effect.	Oswald (1978)	No effect.
Oncorhynchus mykiss, *Salmo trutta* L.	Trout, rainbow	Electroanesthesia	4–25 mA	Electroanesthesia		0.0.105		An amperage level of 16 mA produced the desired effect (category 3) most often for rainbow trout (80% of the time).		Equipment: Smith-Root Fish Handling Gloves™ desired effect 80% of the time.
Salvelinus namaycush		Electroanesthesia	5–25 mA	Electroanesthesia		0.0.105		An amperage of 25 mA produced the desired result most often for lake trout (60% of the time).		25 mA produced the desired result 60% of the time.
Order Scombriformes										
Family Scombridae										
Sarda chiliensis	Bonito, eastern Pacific	Ketamine + medetomidine	4 mg/kg + 0.4 mg/kg	IM	2.7 ± 0.6 kg		19.5–20.5	Injections placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction 8.9 ± 2.1 minutes. Anesthesia time 19.0 ± 3.8 minutes. Recovery following injection of atipamezole 7.7 ± 8.5 minutes. Mortality in fish receiving atipamezole dose <5× medetomidine dose. pH 7.8–7.9.	Williams et al. (2004)	Mortality in fish receiving atipamezole dose <5× medetomidine dose.

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Sarda chiliensis	Bonito, eastern Pacific	Atipamezole	2 mg/kg	IM	2.7 ± 0.6 kg			19.5–20.5	Injections placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction 8.9 ± 2.1 minutes. Anesthesia time 19.0 ± 3.8 minutes. Recovery following injection of atipamezole 7.7 ± 8.5 minutes. Mortality in fish receiving atipamezole dose <5× medetomidine dose. pH 7.8–7.9.	Williams et al. (2004)	Mortality in fish receiving atipamezole dose <5× medetomidine dose.
Scomber japonicus	Mackerel, chub	Ketamine + medetomidine	53–228 mg/kg + 0.6–4.2 mg/kg	IM	0.33–0.40 kg			19.5–20.5	Injected placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction 4–21 minutes (mean 9 minutes) for 37 fish, 45–56 minutes for eight fish. Anesthesia time 1–52 minutes (mean 16 minutes). Recovery following atipamezole 2–12 minutes (mean 5 minutes). pH 7.8–7.9.	Williams et al. (2004)	Mortality in fish receiving atipamezole dose <5× medetomidine dose.
Scomber japonicus	Mackerel, chub	Atipamezole	5× medetomidine dose	IM	0.33–0.40 kg			19.5–20.5	Injected placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction 4–21 minutes (mean 9 minutes) for 37 fish, 45–56 minutes for eight fish. Anesthesia time 1–52 minutes (mean 16 minutes). Recovery following atipamezole 2–12 minutes (mean 5 minutes). pH 7.8–7.9.	Williams et al. (2004)	Mortality in fish receiving atipamezole dose <5× medetomidine dose.

Thunnus thynnus	Tuna, Atlantic bluefin	MS-222 (tricaine methanesulfonate)	90 mg/L	Immersion					Oxygenated water over gills at 12–20 L/min following induction until recovery. Minor surgical procedures, ultrasonographic examinations, and serial blood sampling.	Cooper et al. (1994)	
Thunnus thynnus	Tuna, Atlantic bluefin	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Induction rapid and deep. For short procedures, fish captured and dosed in vinyl bag with supplemental oxygen provided. For longer procedures fish captured in stretcher and transferred to large pool containing MS-222. Once induced, fish transferred to examination table with oxygenated anesthetic water directed over gills.	Cooper et al. (1994)	
Family Stromateidae											
Pampus argenteus	Silver pomfret	MS-222 (tricaine methanesulfonate)	10, 25, 50, 75, 100, and 125 mg/L	Immersion	11.2 ± 1.5 g	0.0.250	Fingerling/ 4 months	29 ± 0.5	Lowest effective dose established at 75 mg/L. Per author longest safe time under deep anesthesia was 10 minutes.	Yu et al. (2020)	Lowest effective dose established at 75 mg/L; per author: longest safe time under deep anesthesia was 10 minutes.
Order Scorpaeniformes											
Family Anarhichadidae											
Anarhichas lupus	Wolffish, Atlantic	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion					Physical examination, blood draw.	N.D. Mylniczenko (pers. exp.)	
Anarrhichthys ocellatus	Eel, wolf	MS-222 (tricaine methanesulfonate)	90–100 mg/L						Lower than 90 not adequate for blood draw.	T.M. Clauss (pers. exp.)	Lower than 90 not adequate for blood draw.
Family Anoplopomatidae											
Anoplopoma fimbria	Sablefish	Metomidate hydrochloride	62 mg/kg	IM	6				Light sedation with partial loss of equilibrium. Directed net avoidance.	Harvey et al. (1988)	Light sedation with partial loss of equilibrium. Directed net avoidance.
Anoplopoma fimbria	Sablefish	Alphaxalone-alphadolone	0.3–0.4 mg/kg	IM	3–5				Light to heavy sedation with some fish exhibiting directed net avoidance. Recovery within 90 minutes.	Harvey et al. (1988)	Light to heavy sedation with some fish exhibiting directed net avoidance.
Family Cyclopteridae											
Cyclopterus lumpus L.	Lumpfish	MS-222 (tricaine methanesulfonate)	100, 200, 400, 800, 1600 mg/L	Immersion	10–20, 200–400, 600–1300 g			6, 12	Deep narcosis: 200 mg/L metacaine. Lighter anesthesia: 100 mg/L can be used.	Skar et al. (2017)	Recommended dose: 200 mg/L (deep narcosis).

(*Continued*)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Cyclopterus lumpus L.	Lumpfish	Isoeugenol	10, 20, 40 mg/L	Immersion	10–20, 200–400, 600–1300 g			6, 12	Deep narcosis: 200 mg/L metacaine. Lighter anesthesia: 100 mg/L can be used.	Skar et al. (2017)	Isoeugenol not recommended for lumpfish.
Cyclopterus lumpus L.	Lumpfish	Benzocaine	100, 200, 400, 800 mg/L	Immersion	10–20, 200–400, 600–1300 g			6, 12	Deep narcosis: 200 mg/L metacaine. Lighter anesthesia: 100 mg/L can be used.	Skar et al. (2017)	Benzocaine is less efficient than metacaine and is not suitable for larger fish >600 g.
Family Sebastidae											
Sebastes spp.	Rockfish sp.	MS-222 (tricaine methanesulfonate)	80–110 mg/L	IN					Good sedation for invasive procedures (ocular surgery).	N.D. Mylniczenko, T.M. Clauss (pers. exp.)	Good sedation for invasive procedures (ocular surgery).
Sebastes caurinus	Rockfish, copper	Gallamine triethiodide	1.0–4.0, 30 mg/kg	IM	1–3		0.0.6		Up to 2 hours until effect noted. Effect ranged from sedation (fish could be netted but were responsive) to anesthesia with marked depression of ventilation.	Harvey et al. (1988)	Up to 2 hours until effect, highly varied effects: sedation to anesthesia with marked depression of ventilation.
Sebastes caurinus	Rockfish, copper	Metomidate hydrochloride	100 mg/kg	IM	2		0.0.2		Anesthesia with marked depression of ventilation. Recovery taking several hours.	Harvey et al. (1988)	Anesthesia with marked depression of ventilation. Recovery taking several hours.
Sebastes carnatus	Rockfish, gopher	Carbon dioxide (CO_2)		Immersion					Given the prolonged recovery times of $NaHCO_3$ and CO_2, electroanesthesia is the preferable method for rapid induction, recovery, and immediate release of gopher rockfish following surgery at sea (acoustic implants).	Duryea (2014)	Given the prolonged recovery times of $NaHCO_3$ and CO_2, electroanesthesia is the preferable method for rapid induction, recovery, and immediate release.
Sebastes carnatus	Rockfish, gopher	Sodium bicarbonate ($NaHCO_3$)	2.66 g/L solutions activated with 18.95 ml of glacial acetic acid	Immersion						Duryea (2014)	Given the prolonged recovery times of $NaHCO_3$ and CO_2, electroanesthesia is the preferable method for rapid induction, recovery, and immediate release.
Sebastes carnatus	Rockfish, gopher	Electroanesthesia, pulsed direct current (pDC)	150 V, 60 Hz, 12% duty cycle, 3-s exposure	Electroanesthesia						Duryea (2014)	Given the prolonged recovery times of $NaHCO_3$ and CO_2, electroanesthesia is the preferable method for rapid induction, recovery, and immediate release.

Sebastes carnatus	Rockfish, gopher	MS-222 (tricaine methanesulfonate)	175 mg/L unbuffered solution	Immersion				Duryea (2014)	Given the prolonged recovery times of $NaHCO_3$ and CO_2, electroanesthesia is the preferable method for rapid induction, recovery, and immediate release.
Family Scorpaenidae									
Pterois sp.	(Dwarf lionfish)	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion		25	Sedation rated as good. Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Diagnostic examinations performed.
Pterois volitans	Lionfish, red	MS-222 (tricaine methanesulfonate)	75–85 mg/L	Immersion	0.34–0.38	25	Good anesthesia, diagnostic examination, radiographs.	C.M. Burns (pers. exp.)	Sedation rated as good. Diagnostic examinations performed.
Pterois radiata	Firefish, radial	MS-222 (tricaine methanesulfonate)	60–70 mg/L	Immersion	~0.13	25	Good anesthesia, diagnostic examination.	C.M. Burns (pers. exp.)	Sedation rated as good. Diagnostic examinations performed.
Taenianotus triacanthus	Scorpionfish, leaf	MS-222 (tricaine methanesulfonate)	50–90 mg/L	Immersion		25	Provided mild to good sedation. Diagnostic examination performed. $N = 3$.	D.L. Neiffer (pers. exp.)	Provided mild to good sedation. Diagnostic examination performed.
Dendrochirus biocellatus	Turkeyfish, two-spot	MS-222 (tricaine methanesulfonate)	85 mg/L	Immersion	0.0.4	25	Good sedation for diagnostic examination and computed tomography.	C.M. Burns (pers. exp.)	Provided mild to good sedation. Diagnostic examination performed.
Dendrochirus brachypterus	Lionfish, dwarf	MS-222 (tricaine methanesulfonate)	75–90 mg/L	Immersion	0.0.2	25	Good sedation for examination.	C.M. Burns (pers. exp.)	Provided mild to good sedation. Diagnostic examination performed.
Order Siluriformes									
Family Clariidae									
Clarias gariepinus	Catfish, north African	Alphaxalone-alphadolone	24 mg/kg	IM	~1150 g	24	Preanesthetized by squirting a few milliliters of 2-PE on gills, which induced almost immediate immobility. Once alphaxalone-alphadolone injected, the gills were rinsed with fresh water. Surgical anesthesia at 26 ± 8 minutes. Artificial respiration required by pumping gills. If the investigators ensured that either the fish could reach the water surface from time to time during recovery or the fish were placed in shallow water (<15 cm), the fish survived. If these precautions were not taken, mortality occurred.	Peters et al. (2001)

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Clarias gariepinus	Catfish, north African	Avocado pear (*Pyrus communis*) leaf extract	100, 130, 160, and 190 ml/L	Immersion	395 g	0.0.60	Adult		Aqueous extracts of avocado pear leaf at concentrations ranging from 130–190 ml/L induced general anesthesia. The effective concentration of avocado pear leaf extracts that best sustained the gonadectomy was 190 ml/L, with a recovery time of 12 minutes.	Adebayo et al. (2010)	Recommended dose: 190 ml/L.
Clarias gariepinus	Catfish, north African	Etomidate (Propiscin) 0.2%	0.5–1 ml/L	Immersion					Propiscin did not cause a change in pH or CO_2 content. Propiscin applied in a water bath can provide up to 1 hour of general anesthesia.	Kazuñ & Siwicki (2012)	
Clarias gariepinus	Catfish, north African	Propofol	2 mg/L	Immersion	300 ± 0.87 g	0.0.30	Juvenile	20 ± 0.3	Anesthesia was achieved in 5.3 ± 0.74 minutes at 2 mg/L of propofol. Recovery time in this study was recorded as 3.2 ± 0.48 minutes. Since blood studies were included, the author indicates a potential use as an anesthetic for aquaculture in the future.	Adeola et al. (2018)	
Family Ictaluridae											
Ictalurus furcatus	Catfish, blue	MS-222 (tricaine methanesulfonate)	60–120 mg/L	Immersion					Low range good for minimally invasive procedures.	T.M. Clauss (pers. exp.)	Low range, good for minimally invasive procedures.
Ictalurus furcatus	Catfish, blue										
Ameiurus nebulosus	Catfish, brown bullhead	Alphaxalone-alphadolone	24 mg/kg	IM	56–255 g			18	Injection given just behind first dorsal fin. Induction within minutes. Gradually lost balance and eventually ventilation ceased. Artificial respiration required by pumping water over gills at ~100 ml/min. Surgical anesthesia required on average 20 minutes. Time until recovery of opercular movements averaged 207 minutes.	Peters et al. (2001)	

Ameiurus melas	Catfish, black bullhead	Alphaxalone-alphadolone	24 mg/kg	IM			18	Injection given just behind first dorsal fin. Event very similar to brown bullhead above.	Peters et al. (2001)	
Ameiurus melas	Catfish, black bullhead	Clove oil	100 mg/L	Immersion	3–810 g	Juvenile to adult	26		Small (2003)	
Ameiurus melas	Catfish, black bullhead	Clove oil	100–150 mg/L	Inhalant	19.12 ± 4.32 g	Fingerling	23	No ethanol added directly to water and aerated strongly prior to addition of fish. Induction within 1 minute. Recovery following 10 minutes of exposure to 100 mg/L, recovery occurred within 4 minutes. Recovery prolonged (>10 minutes) after exposure to 150 mg/L. Exposure to 100 mg/L for >20 minutes associated with increasing mortality. Exposure to 300 mg/L for 10 minutes resulted in 50% mortality.	Waterstrat (1999)	Recovery prolonged (>10 minutes) after exposure to 150 mg/L. Exposure to 100 mg/L for ≥20 minutes associated with increasing mortality. Exposure to 300 mg/L for 10 minutes resulted in 50% mortality. pH = 7.6.
Ictalurus punctatus	Catfish, channel	Eugenol	100, 150 mg/L		1.5 ± 0.5		26.3 ± 0.3	Treatment periods 2.5–12.0 minutes for channel catfish.	Bowker et al. (2017)	
Ictalurus punctatus	Catfish, channel	Isoeugenol	2.5 mg/L	Immersion	50–75 g	Juvenile	26	Sedation achieved in all fish. No mortality with exposure from 30 minutes to 24 hours. pH 8.6.	Small (2004)	
Ictalurus punctatus	Catfish, channel	Isoeugenol	20, 40, 60 mg/L	Immersion	1.1 ± 0.04 kg	Mature	14.5	On average, all the fish lost equilibrium at 8.0, 3.9, and 3.7 minutes when anesthetized in 20, 40, and 60 mg Aqui-S®/L, respectively. Recovery time in fresh water was 2.1, 2.8, and 5.3 minutes for fishanesthetized in 20, 40, and 60 mg/L Aqui-S®, respectively.	Small & Chatakondi (2005)	
Ictalurus punctatus	Catfish, channel	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	1.1 ± 0.04	Adult	14.5	Anesthesia 4.5 ± 0.8 minutes. Fish immediately transferred to anesthetic-free water with recovery time of 1.7 ± 0.2 minutes. Survival 100% at 24 hours. Dose considered useful for basic handling procedures.	Small & Chatakondi (2005)	Dose considered useful for basic handling procedures.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Ictalurus punctatus	Catfish, channel	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion	3–810 g		Juvenile-adult	26		Small (2003)	
Ictalurus punctatus	Catfish, channel	MS-222 (tricaine methanesulfonate)	100 mg/L	Immersion					Stage III sedation was attained within 120 seconds with MS-222. These results suggest that MS-222 is an appropriate anesthetic to use during the initial 5 minutes of sedation.	Smith et al. (2015)	Reduced cortisol.
Ictalurus punctatus	Catfish, channel	Metomidate hydrochloride	1.5 mg/L	Immersion	62 ± 11.3 g		Juvenile	26	Sedation achieved in all fish. No mortality with exposure from 30 minutes to 24 hours. pH 8.6.	Small (2004)	Sedation achieved in all fish. No mortality with exposure from 30 minutes to 24 hours.
Ictalurus punctatus	Catfish, channel	Metomidate hydrochloride	0.5, 1, 2, 4, 6, 8, 16 mg/L	Immersion	3–810 g		Juvenile-adult	26	The minimum desirable concentration for anesthesia, that which resulted in a total loss of equilibrium in all fish within 3 minutes, was determined to be 6 ppm. No mortalities at 8 mg/L or less. 16 mg/L had 65% mortalities.	Small (2003)	No mortalities at 8 mg/L or less. 16 mg/L had 65% mortalities.
Ictalurus punctatus	Catfish, channel	Metomidate hydrochloride	12.5 mg/L	Immersion	~12 g			26	Stage III sedation was attained within 90 seconds with metomidate hydrochloride and might be more appropriate for longer periods of sedation.	Smith et al. (2015)	Reduced cortisol. Good for longer sedation.
Ictalurus punctatus	Catfish, channel	Quinaldine	30 mg/L	Immersion	3–810 g		Juvenile-adult	26		Small (2003)	
Ictalurus punctatus	Catfish, channel	Lidocaine	100–750 mg/L	Immersion					Although both induced anesthesia, the mixture was more effective for induction and recovery, and was able to achieve the required time for the fish to be out of water (titrated at 50-mg doses).	Carrasco et al. (1984)	Lidocaine effective for anesthesia.
Ictalurus punctatus	Catfish, channel	Lidocaine-sodium bicarbonate	250 mg/L + 1 g/L	Immersion					Although both induced anesthesia, the mixture was more effective for induction and recovery, and was able to achieve the required time for the fish to be out of water (titrated at 50–mg doses).	Carrasco et al. (1984)	Lidacaine and bicarbonate combination, more effective than lidocaine alone.

Family Pangasiidae										
Pangasius sp.	Catfish, Pangasius	Isoeugenol (Aqui–S®)	20 mg/L	Immersion	335 ± 92.0 g	Juvenile-young adult	12 ± 2	Induction in 5.3 minutes. Total exposure time <15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH 8.1.	Stehly & Gingerich (1999)	Useful for basic handling procedures.
Family Siluridae										
Kryptopterus bicirrhis	Catfish, glass	Alphaxalone-alphadolone	4.8 mg/L for induction	Immersion	2–7 g		23–27	Opercular movements disappeared after 5 minutes of exposure, at which time fish transferred to maintenance. Artificial respiration given by pumping water through mouth and across gills at 7–10 ml/min. Recovery in ~30 minutes after being placed in clean water.	Peters et al. (2001)	Recovery in ~30 minutes after being placed in clean water.
Silurus asotus	Catfish, Amur	Clove oil	200, 300, 400, 500, 600 mg/L	Immersion	50.1 ± 0.0.40 5.91, 302.1 ± 15.22 g	Larval-adult		The results showed significant relationships between the concentration of the anesthetic and the body size of the fish. Based on an optimal anesthetic time of approximately 1 minute, the preferred concentrations of the anesthetics were 500 ppm for clove oil and 600 ppm for MS-222.	Park (2019)	Recommended dose: 500 ppm (clove oil), 600 ppm (MS-222). Significant relationship between the concentration of the anesthetic and the body size of the fish.
Silurus asotus	Catfish, Amur	MS-222 (tricaine methanesulfonate)	200, 300, 400, 500, 600 mg/L	Immersion	50.1 ± 5.91, 302.1 ± 15.22 g	Larval-adult		The results showed significant relationships between the concentration of the anesthetic and the body size of the fish. Based on an optimal anesthetic time of approximately 1 minute, the preferred concentration of the anesthetic was 600 ppm for MS-222.	Park (2019)	Recommended dose: 500 ppm (clove oil), 600 ppm (MS-222). Significant relationship between the concentration of the anesthetic and the body size of the fish.
Order Syngnathiformes										
Family Syngnathidae										
Hippocampus barbouri	Seahorse, Barbour's	MS-222 (tricaine methanesulfonate)	50–60 mg/L	Immersion		Adult		Diagnostic examination.	C.M. Burns (pers. exp.)	
Hippocampus erectus	Seahorse, lined	MS-222 (tricaine methanesulfonate)	60–100 mg/L	Immersion		Adult		Low end dose adequate for radiographs and minimally invasive procedures.	N.D. Mylniczenko (pers. exp.)	Low end dose adequate for radiographs and minimally invasive procedures.

Table 8.1 (Continued)

Species	Common Name	Drug		Route of Administration	Body Weight	Population	Age Class	Water Temp. (C°)	Comments	Reference	Comments
Hippocampus erectus	Seahorse, lined	MS-222 (tricaine methanesulfonate)	5, 10, 20, 40, 60, 80 mg/L	Immersion	0.72 ± 0.08 g			26 ± 2.0	Effectively anesthetized into stage II at concentrations of 20–60 mg/L MS-222.	Qin et al. (2016)	Recommended dose: 10–30 mg/L (clove oil), 20–60 mg/L (MS-222).
Hippocampus erectus	Seahorse, lined	Clove oil	2, 5, 10, 20, 30, 40 mg/L	Immersion					Effectively anesthetized into stage II at concentrations of 10–30 mg/L clove oil.	Qin et al. (2016)	Recommended dose: 10–30 mg/L (clove oil), 20–60 mg/L (MS-222).
Hippocampus procerus	Seahorse, high-crown	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion			Juvenile-adult		Diagnostic examination, radiographs.	C.M. Burns (pers. exp.)	
Hippocampus reidi	Seahorse, longsnout	MS-222 (tricaine methanesulfonate)	50–90 mg/L	Immersion		0.0.30	Juvenile-adult		Diagnostic examination, radiographs.	C.M. Burns (pers. exp.)	
Hippocampus reidi	Seahorse, longsnout	MS-222 (tricaine methanesulfonate)	75–100 mg/L	Immersion			Adult		Good sedation for blood draw, assist feed and injectable treatments.	N.D. Mylniczenko (pers. exp.)	Good sedation for blood draw, assisted feeding and injectable treatments.
Micrognathus crinitus	Pipefish, banded	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion					Depth good for miminally invasive procedures on low end.	C.M. Burns (pers. exp.)	
Phycodurus eques	Seadragon, leafy	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion			Adult		Under 60 mg/L very light sedation and not sufficient for assisting feeding or oral examination. Above 80 mg/L occasionally noted longer recoveries.	N.D. Mylniczenko, T.M. Clauss (pers. exp.)	Under 60 mg/L very light sedation. Above 80 mg/L occasionally noted longer recoveries.
Phyllopteryx taeniolatus	Seadragon, weedy	MS-222 (tricaine methanesulfonate)	50–100 mg/L	Immersion					Same as above.	N.D. Mylniczenko, T.M. Clauss (pers. exp.)	Under 60 mg/L very light sedation. Above 80 mg/L occasionally noted longer recoveries.
Syngnathus scovelli	Pipefish, gulf	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion					Sedation rated as good. Topical treatments performed.	D.L. Neiffer (pers. exp.)	Sedation rated as good. Topical treatments performed.
Order Tetraodontiformes											
Family Balistidae											
Balistes capriscus	Triggerfish, grey	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion	~2.7			25	Good sedation to deep anesthesia.	C.M. Burns (pers. exp.)	
Balistes vetula	Triggerfish, queen	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion	0.4–1.0			25	Good sedation for diagnostic examination, treatments.	C.M. Burns (pers. exp.)	
Canthidermis maculata	Triggerfish, rough	MS-222 (tricaine methanesulfonate)	45–75 mg/L	Immersion	1.3			25	Provided mild to heavy sedation. Diagnostic examinations performed. $N = 3$.	D.L. Neiffer (pers. exp.)	
Pseudobalistes fuscus	Triggerfish, yellow-spotted (blue-line)	MS-222 (tricaine methanesulfonate)	75 mg/L	Immersion	0.19			25	Good sedation for diagnostic examination.	C.M. Burns (pers. exp.)	

Xanthichthys auromarginatus	Triggerfish, gilded (golden-edged)	MS-222 (tricaine methanesulfonate)	70 mg/L	Immersion	0.08		25	Good sedation for diagnostic examination with blood draw.	C.M. Burns (pers. exp.)
Canthidermis sufflamen	Triggerfish, ocean	MS-222 (tricaine methanesulfonate)	80 mg/L	Immersion	1.2		25	Good sedation for diagnostic examination.	C.M. Burns (pers. exp.)
Melichthys niger	Durgeon, black	MS-222 (tricaine methanesulfonate)	70–100 mg/L	Immersion	1.2		25	Good sedation, 100 mg/L induction for surgerical procedure then lowered.	C.M. Burns (pers. exp.)
Rhinecanthus aculeatus	Triggerfish, white-banded (humuhumu)	MS-222 (tricaine methanesulfonate)	50–75 mg/L	Immersion	0.07		25	Good sedation to deep anesthesia for abscess debridement.	C.M. Burns (pers. exp.)
Family Diodontidae									
Diodon holocanthus	Porcupinefish, long-spined	MS-222 (tricaine methanesulfonate)	75–80 mg/L	Immersion	0.38–1.16 kg	0.0.5		Sedative effect rated fair to good. Diagnostic examination and topical treatments performed.	D.L. Neiffer (pers. exp.)
Diodon holocanthus	Porcupinefish, long-spined	MS-222 (tricaine methanesulfonate)	100–125 mg/L	Immersion	0.38–0.42 kg			Provided surgical anesthesia for removal of fungal granulomas from integument and resection of coelomic musculature.	D.L. Neiffer (pers. exp.)
Diodon hystrix	Porupinefish, spot-fin	MS-222 (tricaine methanesulfonate)	75–80 mg/L	Immersion		0.0.2		Mild to moderate sedation. Diagnostic examination performed. $N = 2$.	D.L. Neiffer (pers. exp.)
Family Monocanthidae									
Aluterus scriptus	Filefish, scrawled	MS-222 (tricaine methanesulfonate)	50–60 mg/L	Immersion	0.44–2.35			Sedation rated as good to excellent. Diagnostic examinations performed.	D.L. Neiffer (pers. exp.)
Aluterus scriptus	Filefish, scrawled	MS-222 (tricaine methanesulfonate)	75–100 mg/L	Immersion	0.44–2.35			Heavy sedation with cessation of gilling.	D.L. Neiffer (pers. exp.)
Meuschenia trachylepis	Filefish	Clove oil in ethanol at ratio 1:5	40 mg/L	Immersion			18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
Monacanthus tuckeri	Filefish, slender	MS-222 (tricaine methanesulfonate)	50 mg/L	Immersion				Provided mild sedation. Diagnostic examination performed.	D.L. Neiffer (pers. exp.)
Cantherhines macrocerus	Filefish, American white-spotted	MS-222 (tricaine methanesulfonate)	70 mg/L	Immersion	0.9		25	Good sedation for diagnostic examination.	C.M. Burns (pers. exp.)
Family Ostraciidae									
Acanthostracion quadricornis	Cowfish, scrawled	MS-222 (tricaine methanesulfonate)	60–80 mg/L	Immersion	~0.4		25	Good to deep anesthesia.	C.M. Burns (pers. exp.)

dosages used in salmon smolts may not be effective in ocean ranging adults.

Regardless of available information, the anesthetic regimen for an untested species should be tried using one or a small group of fish. Start at the low end of the recommended dosage range and work up to the desired effect (Harms 1995; Neiffer & Stamper 2009; Ross 2001; Stetter 2001). However, in a species whose anesthetic tolerance is known, using a high dosage for a smoother and more rapid induction is most appropriate. Once induced, a lower immersion maintenance dosage is recommended (Harms 1999). Rapid capture or in-enclosure anesthesia will reduce stress and facilitate smoother inductions. Utilizing graded anesthesia (high induction, low maintenance dose) is a stress-reducing method of anesthesia (Matsche 2011).

Preanesthetic Preparations and Considerations

Whenever possible, the following should be performed prior to induction:

1) Baseline behavioral parameters (i.e., ventilation, caudal fin stroke rate, and overall activity level) should be recorded for comparison during anesthesia.
2) Although aspiration pneumonia is not a concern, it is not uncommon for fish to regurgitate material that clogs gill rakers and contributes to water quality degradation. Additionally, if the regurgitant is fine and covers the gill lamellae, then suffocation can theoretically occur (sestonosis). Fasting for 12–24 hours (one feeding cycle) limits regurgitation and decreases nitrogenous waste production (Harms & Bakal 1995; Stetter 2001).
3) Containers with adequate water for transportation, induction, maintenance, and recovery should be available (Harms 1999; Stetter 2001). This is particularly important when water is used for immersion anesthesia. If the procedure occurs next to the animal's tank it can be used for recovery. This assumes monitoring is possible and other specimens will not traumatize or predate the fish during recovery.
4) The physical (e.g., temperature) and chemical (e.g., pH, salinity) variables of all water used should be matched to those of the fish's source water. Smaller water volumes used for anesthetic procedures will warm or chill to the temperature of the room air, thus water temperature should be monitored during the procedure and maintained as consistently as possible. Dissolved oxygen is maintained >5 ppm (mg/L) with 6–10 ppm ideal (Harms 1999; Stetter 2001); in the authors' practices, 9–12 ppm is a targeted range.
5) For out-of-water procedures, it is important to prevent drying of the skin, fins, and eyes. This can include coverage with clear plastic drapes, bubble wrap, soft cloth (chamois or microfiber), and regular rinsing of tissues with water from a syringe or a small portable atomizer (Harms 1999; Ross 2001).
6) Capture techniques should be considered and the procedure discussed with all staff involved, especially with large fishes.

Immersion (Waterborne, Bath or Inhalant) Anesthesia

Immersion anesthesia via immersion in the water is analogous to gaseous anesthesia in terrestrial animals. The anesthetic in solution is ventilated by the fish, enters the bloodstream through the gills, accessory respiratory organs, and the skin, and passes rapidly to the central nervous system. When returned to drug-free water, drugs or their metabolites are excreted mostly via the gills and presumably accessory respiratory organs. Some elimination also occurs through the kidneys, liver, and presumably the skin (Ross 2001; Walsh & Pease 2002). Unlike in terrestrial vertebrates, any water-soluble drugs or metabolites excreted from fish will be continuously absorbed through the body surface and gills, while being simultaneously metabolized and eliminated (Oikawa et al. 1994). This is problematic for assessing dosage effects and performing pharmacokinetic studies unless flowthrough systems or closed systems with inline carbon filters are utilized. This is significant when considering reusing the same water for multiple fishes. It is unknown how much drug is metabolized per volume of anesthetic water; it is in the authors' experience that with multiple animals, there is degradation of water quality and as a result, inductions are longer. This is highly variable though and based on the number of fish, size of the animals, and volume of water used.

Immersion drugs must be water-soluble or utilize a water-soluble solvent as a vehicle. For simple, short procedures the required drug concentration is made up in an aerated container to which fish are transferred or drugs are added directly to the water containing the fish. In the latter situation, a buffer (e.g., sodium bicarbonate or carbonate) is added. It is always preferable to use water from the fish's environment to make the anesthetic solution prior to drug administration to minimize acute drops in pH or other water-quality parameters (Harms 1999; Ross 2001).

For large fish, where immersion is impractical or dangerous to handlers, drugs in solution may be applied directly to the gills. Inexpensive plastic pump spray bottles (e.g., unused bug sprayers) are ideal for this application. When used by divers, the addition of a harmless dye (e.g., food coloring) helps identify distribution of the anesthetic.

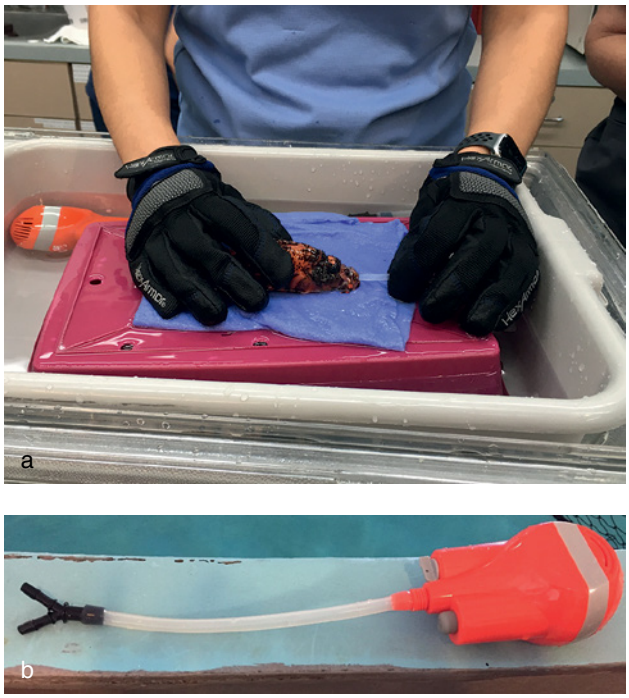

Figure 8.7 (a) A dwarf lionfish (*Dendrochirus brachypterush*) ventilated with an outdoor submersible camp shower (behind the tub). (b) An outdoor submersible camp shower, rechargeable and submersible for ventilation of fishes in a recirculating system.

Regardless of application, anesthetic solutions are most accurately made using a measured volume of a standard stock solution. However, preparing stock solutions of expensive powdered anesthetic drugs (e.g., MS-222) is not economical if used infrequently because potency decreases over time (Ross 2001). Alternatively, preweighed drug packets are recommended. Waterproof quick reference charts and known volume containers are useful for procedure set up. More importantly, they enable quick modification of drug dosage level.

Ventilation, even in animals that are apparently ventilating on their own, is an important standard of practice. It is akin to providing oxygen to sedated mammals. Simply, a syringe and plastic tubing can ventilate each side of the animal's gills. Otherwise, an aquarium pump with flow control or modified camp shower pump will work (Fig. 8.7). With longer procedures (>10 minutes), debilitated fish, species that are slow to recover, and all but the shortest out-of-water procedures, an artificial ventilation system should be used (Fig. 8.8). The animal is placed in shallow water or on a fenestrated surface in lateral recumbency or in dorsal recumbency in a soft holder (foam, soft cloth, sponge).

Aerated anesthetic solution is delivered across the gills from a bifurcated pipe or mouthpiece placed in the buccal cavity (Fig. 8.9) using a nonrecirculating or recirculating system. In its simplest form, a nonrecirculating system uses an intravenous (IV) fluid bag and drip set. Resealable bags are easier for preparation but used sealed bags with an opening cut in the end will suffice. Flow rate is controlled by the drip set valve. Aeration of the anesthetic water with an air stone in the IV bag ensures near saturation of oxygen and removal of dissolved CO_2. Used water is collected, but not recycled (Harms 1999; Ross 2001; Stetter 2001). This system is suitable for small to medium-sized fish depending on reservoir volume, drip set tube diameter, and the rate at which fluid can be delivered.

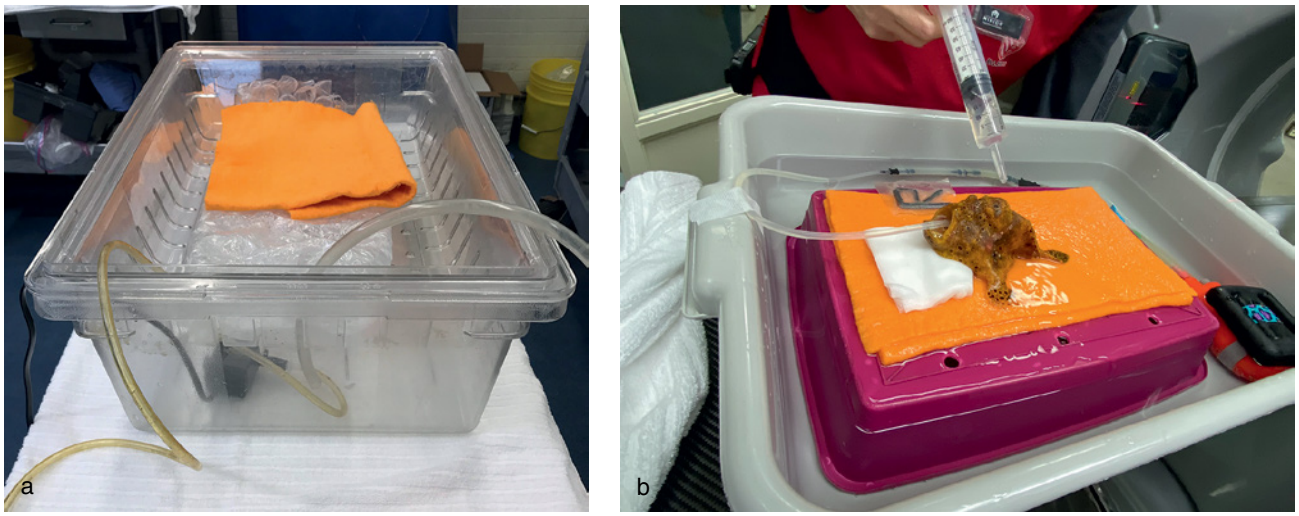

Figure 8.8 (a) A simple recirculating system which enables delivery of anesthetic water from a reservoir to the gills and recycling of the effluent back to the fish by use of a submersible pump. (b) A simple recirculating system which elevates the patient, a frogfish (*Antennarius maculatus*), out of water for CT scan.

Figure 8.9 Goliath grouper (*Epinephelus itajara*) positioned in dorsal recumbency in a foam holder during anesthesia with MS-222. Note the bifurcated (Y) mouthpiece being placed in the oral cavity for delivery of oxygenated anesthetic water to both sets of gills.

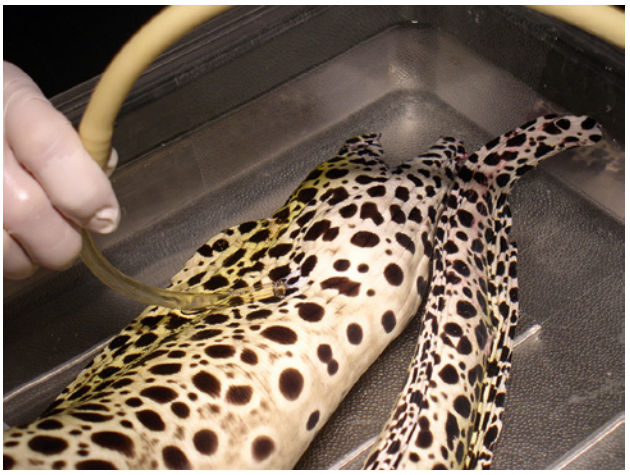

Figure 8.10 Retrograde flow over through gill slit in a laced moray eel (*Gymnothorax favagineus*) that is having oral surgery.

Recirculating systems enable delivery of anesthetic water from a reservoir to the gills and recycling of the effluent back to the fish. This recycling is either done manually (refill elevated reservoir with collected effluent) or with a submersible pump. When using pumps, electrical safety for the operator must be considered. Flow rate can be controlled by a valve on the tube leading to the mouth. Minimum effective flow rate during fish anesthesia has not been determined; 1–3 L/min/kg seems appropriate. Low delivery rates fail to keep the gills on both sides wet, thereby reducing gas exchange. High flow rates similarly prevent gas exchange and can result in alimentary anesthetic delivery and gastric dilatation, which may also occur due to depth of anesthesia and low sphincter tone. Both scenarios can be alleviated with the use of a "Y" or "T" plastic piece that equally distributes water over both gill arches. Oxygenation is provided as described above. Recirculating systems are used in large fish where cost and wastewater concerns make conservation of anesthetics and water paramount (Harms 1999; Ross 2001; Stetter 2001).

Regardless of the method used, adjusting the delivered drug concentration in response to anesthetic depth is difficult. One option is to prepare measured volumes of anesthetic-free water and concentrations of anesthetic solution. These solutions are placed in separate reservoirs and used in either recirculating or nonrecirculating systems. Alternatively, a syringe or turkey baster is used to rapidly deliver small amounts of fluid directly to the gills without disconnecting the fish from the system (Harms 1999).

The flow is usually normograde to achieve optimal gas and anesthetic exchange. During oral surgery, flow can be reversed if needed to allow for surgical access. However, retrograde flow nullifies the normal countercurrent exchange mechanism and may damage the gills, but in some circumstances may be required (oral surgery). The size or anatomy of some fish (e.g., filefish [Monocanthidae], triggers [Balistidae], or eels [Muraenidae]) (Fig. 8.10) make placement of a bifurcated buccal tube difficult. In these species, some retrograde flow is used to ensure all gill tissue is adequately perfused.

In some circumstances, whole-tank anesthesia is required to move fishes out of their systems. When this occurs, sufficient supportive staff for induction, transport, and recovery will be necessary. Using lower doses that tranquilize the animals enough for safely moving into transports would be sensible versus full sedation, but this will be species-specific not animal-specific (individual temperament, disease state, and size). This method has been shown to result in the least amount of stress when compared to capturing animals out of the tank and transferring to an induction tank (Tubio et al. 2010).

Enteral and Parenteral Anesthesia

In addition to immersion, anesthetics are delivered orally, intravenously, intramuscularly, and intracoelomically. Oral administration is rarely used because precise dosing is difficult and the rate and degree of absorption is uncertain (Harms 2003). However, a few examples of successful use of oral drugs exist (Hansen et al. 2003; Harms & Bakal 1995; Harvey et al. 1988; Raines & Clancy 2009; Steers & Sherrill 2001). IV injection is the fastest delivery method, with rapid induction and usually short duration of effect. However, this route has limited clinical use because it requires either manual restraint or prior administration of

drugs by another route to allow IV access (Fleming et al. 2003; Hansen et al. 2003).

Intramuscular (IM) delivery is the most common parenteral route. The major consideration with this route is that muscle is composed of both red and white muscle, with the white muscle taking up a majority of the muscle mass. In comparison to white muscle, the red muscle is aerobic and fast twitch, most likely the ideal set of muscles for appropriate metabolism and pharmacokinetics. However, because of location and low percentage of muscle mass, it is unlikely that an injection will be in the correct location, particularly if it needs to be administered quickly. Additionally, not all fish have both types of muscle; some species have all white muscle. Scale presence, size, and shape are also considerations with IM delivery. Intracoelomic (ICo) delivery has an increased risk of visceral damage and drugs must pass through the serosal surface, making induction time erratic. Both IM and ICo routes are used in larger fish because many are kept in large-volume aquariums or pens where adding waterborne anesthetics is impractical and because injection-site trauma is less problematic in larger specimens (Harms 1999; Harvey et al. 1988; Williams et al. 1988). Sedated fish will stop swimming and begin to drop through the water column with or without obvious gilling. However, when approached by divers with a net, they will often arouse and swim with directed movement, which signifies that more time is needed for the drug to have full effect and/or supplemental drug injections may need to be administered. Regardless of ease of capture, parenteral anesthetics are unpredictable and often do not provide adequate sedation or anesthesia, requiring supplemental anesthesia. Additionally, hypoxemia during induction is a concern as ventilatory ability is compromised. Ventilatory support is necessary during maintenance of parenteral immobilization drugs and particularly during recovery if prolonged (Harms 1999), but there is a period where safety for the staff and anesthetic depth are not always compatible. Injections are delivered by hand syringe, pole syringe (or modified pole syringe, Fig. 8.11), or a darting system (Runnells & Mylniczenko 2014).

Examples of darting systems include a modified Hawaiian sling (Fig. 8.12), pneumatic spear guns, a traditional dart gun system (Dan Inject Dart Guns, Austin, TX, US, https://dan-inject.com/) and a laser-aimed underwater gun (Harms 1999; Harvey et al. 1988; Runnells & Mylniczenko 2014; Williams et al. 1988).

The latter propels darts from a distance of 1–2 m (4–7 feet) that inject pneumatically on impact and remain attached after jettisoning the lightweight spear shaft. Hawaiian sling and pneumatic spear guns should be used with caution. They are used mostly for euthanasia as they

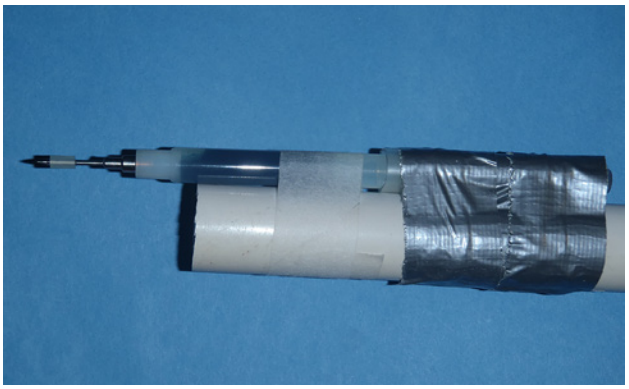

Figure 8.11 "Handmade" pole syringe system using an air charged dart capable of injecting 5 ml. The dart is backed into a plastic case that is taped to a polyvinyl pipe. The setup is secured with paper tape that will easily fall off after the animal is injected. Filtered food dye has been added to the contents of the syringe so injection success can be judged.

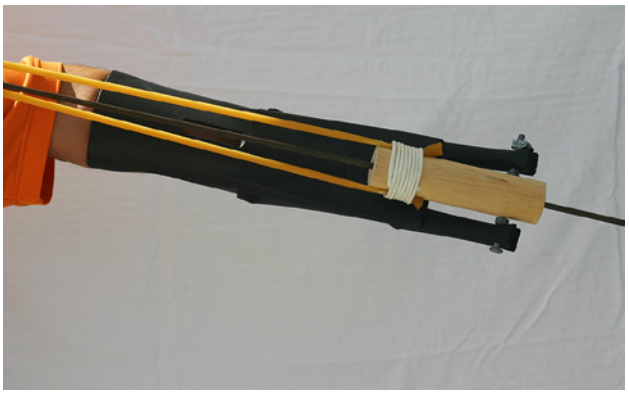

Figure 8.12 An example of a Hawaiian sling. It is recommended that this only be used for long distances or euthanasia by skilled users. Special thanks to Forrest Young, Dynasty Marine Associates, Marathon, FL.

are very powerful and it is difficult to control the force of the impact on the animal. Dart guns can be used from the surface, but skill is required to adequately propel and aim the dart. Both barbless and barbed needles are used for large, active, and heavily scaled or sluggish fish (Harvey et al. 1988). A complication of dart use is injection-site trauma and scale loss, with some fish requiring local or systemic wound treatment. IM injections will often result in leakage of some injected drug as the needle falls out or is withdrawn and the surrounding muscles contract (Harms 1995; Peters et al. 2001). Some scaled fish have very large and/or thickened scales that can deflect a dart or result in incomplete needle insertion. Consideration to injection volume is important as fish cannot retain much fluid due to muscle inelasticity. A final thought is that when divers are underwater, there is refraction between the diver's mask and the water, thus affecting the aim.

If the fish is in hand for injection, the needle is placed directly on the dorsal midline between epaxial muscles, and then laterally inserted into a muscle bundle to reduce drug loss (Harms 1995). Filtered food dye can be added to the contents of the syringe so injection success can be judged. Alternatively, fluorescein stain or methylene blue dye is used (Harvey et al. 1988).

A first consideration when using parenteral anesthetics is human safety. The large dosages and drug volumes required make accidental injection a possibility for handlers (Harvey et al. 1988). The authors recommend reference to drug exposure protocols for hoofstock when using doses that may be large enough to adversely affect the handler.

Monitoring

Anesthetic Depth

Various schemes are used to describe anesthetic depth in fish with no consensus (Detar & Mattingly 2004; Myszkowski et al. 2003; Oikawa et al. 1994). This makes comparison of regimens between and within species difficult when reviewing the literature. Common criteria used in defining anesthetic depth or level include activity, reactivity to stimuli, equilibrium (righting reflex), muscle tone, and respiratory and heart rates. Broad stages include sedation, narcosis or loss or equilibrium, and anesthesia; each stage is subdivided further into light and deep planes (Harms 2003; Stetter 2001). Depending on the species, drug, and dosage used, some stage components are unrecognized (Harms 1999; Neiffer & Stamper 2009; Stetter 2001). Conversely, some signs attributed to drug effects are instead responses to stress. For example, Gulf sturgeon (*Acipenser oxyrinchus desotoi*) often turn into a ventral/dorsal position when stressed (Fleming et al. 2003). Therefore, loss of the righting reflex is not used to determine the anesthetic stage in this species.

For most fish, induction occurs in 5–10 minutes with immersion drugs, but may be prolonged when using other routes. During induction, swimming, respiratory rate, and reaction to stimuli decreases. As the fish becomes anesthetized, there is loss of equilibrium and response to stimuli. At a surgical anesthetic plane, there is total loss of muscle tone and a further decrease, but not cessation, in respiratory rate. A firm squeeze at the base of the tail or insertion of a needle into the peduncle is used to determine response to stimuli; if the animal does not respond, general anesthesia has been achieved (Harms 2003; Stetter 2001; Storms & Mylniczenko 2004). Some species go through excitement during immersion induction and may traumatize themselves (Harms 1999; Stetter 2001).

Cardiopulmonary

Respiratory and cardiac rate changes are useful in assessing anesthetic depth. Both usually decrease with increased anesthetic dosage and anesthetic time. Respiratory rates are determined in the perianesthetic period by observing opercular movement (Harms 1999, 2003; Stetter 2001). However, in some species (e.g., scombrids) opercular movement is minimal to nonexistent, and potentially nondetectable in some species due to anatomy (frogfish, cowfish, etc.). Additionally, passage of oxygenated water over the gills of any anesthetized fish with ceased opercular movement will maintain adequate ventilation, at least in the short term. This is accomplished because of the large differential between respiratory and cardiac arrest. The heart will still supply fresh arterial blood to the gills, allowing for adequate gas exchange.

In species with thin pliable body walls and proportionally large hearts, the heartbeat may be observed directly, but for most it is neither visible nor palpable (Harms 1995, 1999). In these species, heart rate is monitored using cardiac ultrasonography, Doppler flow probes, or electrocardiography (Harms 1995, 1999; Ross 2001). During cardiac ultrasonography the probe is placed into the opercular slit of medium to large fish, or directly over the heart in smaller or small scaled/scaleless species (Fig. 8.13). Doppler probes

Figure 8.13 Ultrasonography is a useful tool for monitoring heart rate in fish. In this goliath grouper (*Epinephelus itajara*) the probe is placed directly over the heart in smaller specimens or small scaled/scaleless species.

are placed in the same locations (Fig. 8.14). Regarding electrocardiograms, electrodes can be clamped lightly to the surface of the fins, with the pectoral and anal fins being a good combination (Ross 2001). Subcutaneous placement of needle electrodes minimizes skin trauma, reduces the chance of grounding out the ECG signal by contact with a wet external surface, and improves signal quality (Harms 1999). In some species, use of human electrodes may work as well (Fig. 8.15). Pulse oximetry is not effective for measuring hemoglobin saturation in fish (Harms 1999; Ross 2001).

If the animal is stable, respiratory and heart rates are measured and recorded every 5 minutes. Trends are key because normal rates are not known for most species. Additionally, assessing quality of the rhythm and, if using ultrasound, contractility can be helpful, particularly if a baseline has been observed. Anesthetized fish generally have slower heart rates than terrestrial animals of similar size (Stetter 2001).

Figure 8.14 Doppler flow is also used for monitoring heart rate in fish. This figure demonstrates placement of the probe onto the area of the heart in a laced moray eel (*Gymnothorax favagineus*).

Figure 8.15 While not always practical, is it possible to monitor the ECG of fish as with this laced moray eel (*Gymnothorax favagineus*).

Other variables that are visually or palpably monitored include equilibrium, jaw tone, color of fin margin (pallor = hypoxemia, hypotension or peripheral vasoconstriction), response to touch or surgical stimuli, and gill color (pallor = hypoxemia, hypotension, hypovolemia, or asystole) (Harms 1995, 2001; Stetter 2001). Because of the relatively low blood pressure of fishes, blood pooling can occur normally and often occurs in the dependent portions of the body, particularly when animals are not in the water, where hydrostatic forces keep this pooling from occurring (Sandblom & Axelsson 2007).

An effective way to monitor respiratory efficiency is periodic blood gas sampling to determine lactate, carbon dioxide, and pH. Venous samples are easier to collect and useful information about physiological trends is obtained. Other blood variables used to assess metabolic status include HCT, bicarbonate, and glucose. Lactate is a critical metabolite that has been instrumental in evaluating fish responses to hypoxia and exertion (Heming 1989; McDonald & Milligan 1992). Point-of-care units are convenient but limited in their accuracy for some of these parameters (Harrenstein et al. 2005). There are species variations in tolerance of both hypoxia and exertion that must be taken into account; regardless, changes in blood gas values indicate a potentially unstable anesthetic event, depending on the degree of derangement. Small size or debilitation may prohibit collection of even a single blood sample from some individuals.

Water Quality

After cardiorespiratory function, water quality monitoring is critical to reducing anesthetic morbidity and mortality. Assuming aeration, DO, and temperature are appropriate and constant, ammonia concentration is of greatest concern. Ammonia concentrations will rise and buffering capacity will decrease during prolonged procedures and when multiple fish are sequentially anesthetized in the same system. Marine systems have an alkaline water pH, which enhances ammonia toxicity. Ammonia concentrations are easy to measure with tank side kits. Another indicator of deteriorating water quality is surface foam formation due to increased protein from fish "slime" or the mucus coat (Harms 1999). Some species (e.g., Gulf toadfish, *Opsanus beta*) are facultatively ureotelic and ureogenic. In contrast to most teleosts, which are obligate ammonioteles, the toadfish switches to ureotelism in response to moderate stressors (e.g., anesthesia),

excreting the majority of its nitrogenous waste as urea (Gilmour et al. 1998). Consequently, ammonia level measurement as a guide to water quality is inaccurate for this and similar species.

Declining water quality during anesthesia is corrected with a partial water change. The handler either adds water containing a known anesthetic concentration or, when reducing anesthetic depth, a known volume of clean water to the system.

Recovery

Recovery from immersion anesthesia begins when the fish is placed in drug-free water (Ross 2001). Even when using oral or parenteral drugs, moving to clean water is important as some of these drugs and their metabolites may be excreted into the water and be reabsorbed across the gills and/or skin. The recovery water is aerated with the fish's mouth oriented toward water flow. In an artificial ventilation system, clean drug-free water is passed over the gills until spontaneous ventilation and movement return. Alternatively, if the fish is not spontaneously ventilating it can be pulled forward through the water with its mouth open, but assisted ventilation is preferred. Dragging the animal backwards through water may cause gill damage and should be avoided. Most fish recover within 5–15 minutes from immersion anesthetics when the procedure is short, but this duration can be highly variable. Recoveries extending >10 minutes indicate either excessive anesthetic dosage or a medically compromised animal (Ross 2001; Stetter 2001). In comparison, recovery from parenteral agents is often greater. The time is dependent on route, rate of drug metabolism, and if a reversal agent is available and used. As the fish recovers, respirations increase, muscle tone returns, fin movements start, and the fish swims with progressively less ataxia until full equilibrium is regained. Some fish go through an erratic porpoising phase and escape from the tank must be prevented (Harms 1999). Certain individuals may need to be manually restrained during this period to prevent damage to eyes and body.

Resuscitation

Marked hypoventilation or apnea is usually not alarming. If cardiac output is maintained and oxygenated water is flowing appropriately over the gills, tissue gas exchange is probably adequate. Decreasing the anesthetic concentration or moving the fish to anesthetic-free water until respirations resume (Stetter 2001) are recommended. If involved in a major procedure (e.g., exploratory coeliotomy), the latter is not possible. In either scenario, the anesthetist takes advantage of the buccal flow/heart rate reflex: increasing water flow through the buccal cavity accelerates heart rate. The subsequent increase in gill blood flow more rapidly eliminates immersion drugs and hastens recovery. However, too rapid a flow may not allow adequate exchange, thus a balance must be achieved. Unresponsive fish are given standard mammalian emergency drugs such as doxapram, corticosteroids, and fluids. The authors' have observed positive responses to doxapram administration (5 mg/kg IV, IM [or both at the same time], ICe or even over the gills) in several cases of erratic respirations or respiratory arrest. Controversy over the use of epinephrine versus norepinephrine in fish exists and is an area in need of further investigation. At this time, epinephrine appears to be an effective drug for critical situations.

Anesthetic Drugs

General Comments

Anesthesia is "a biological state induced by an external agent which results in the partial or complete loss of sensation or loss of voluntary neuromotor control through chemical or non-chemical means" (Bressler & Ron 2004).

Rather than listing a few cross-taxa dosage recommendations for several commonly used drugs, the authors have taxonomically arranged cited and anecdotal dosages for representative species from most orders (Table 8.1).

Immersion (Waterborne, Bath or Inhalant) Drugs

Tricaine Methanesulfonate (MS-222, TMS)

Tricaine methanesulfonate (MS-222) is a benzocaine derivative with a sulfonate radical, which accounts for its water solubility and increased acidity over the parent compound (Harms 1999; Oikawa et al. 1994; Topic Popovic et al. 2012). It is absorbed through gills and skin and is metabolized in the liver, kidneys, blood, and muscle. The main action is by blocking sodium channels in muscle and potassium pathways in nerve membranes (Priborsky & Velisek 2018). It is cleared primarily through the gills as free and acetylated forms, with additional metabolites eliminated in urine and bile (Harms 1999). Tricaine powder is directly mixed into the anesthetic chamber or administered as a stock solution of 10 g/L (10,000 mg/L). The latter is unstable in light and is kept in a dark container. Oily residues in buffered stock solutions indicate the presence of a de-sulfonation product and decreased potency.

MS-222 is acidic and is more effective and safe in its neutralized form. Solutions are buffered to the pH of the holding water before immersing the fish. Although sodium bicarbonate has been used most predominantly, other buffers include imidazole, sodium hydrogen phosphate, sodium hydroxide, and calcium carbonate. Sodium carbonate was recently found to be a better medium than bicarbonate for buffering (Waxman et al. 2021). Exact amounts of buffer can be measured out or the powdered buffer incrementally mixed into the anesthesia chamber until the solid no longer dissolves and saturation is reached (Harms 1999; Oikawa et al. 1994; Roubach et al. 2001; Stetter 2001). The latter can cause supersaturation and may result in blood gas abnormalities (author's personal experience), so measuring precise amounts of buffer is strongly encouraged.

There has been some dispute in the literature regarding the susceptibility of some sturgeon to MS-222, suggesting they are refractory to standard doses (Fleming et al. 2003), however other groups have used MS-222 with no resistance at typical inductive doses (Feng et al. 2011; Hernandez-Divers et al. 2004; Matsche 2011). The reasons for this discrepancy can include subspecies variations and environmental parameters (e.g., temperature) which may affect metabolism. In one study of sturgeon anesthesia, it was found that when compared to medetomidine/ketamine and even clove oil, MS-222 resulted in much higher negative physiologic effects (Di Marco et al. 2011).

The margin of safety is narrower with young fish in warm, soft water, and there are species variations (Harms 1999; Topic Popovic et al. 2012; Roubach et al. 2001). In all age groups, MS-222 can be associated with hypoxemia resulting from drug-induced hypoventilation (Davis & Griffin 2004; Harms 1995; Oikawa et al. 1994). MS-222 is a suspected carcinogen (Detar & Mattingly 2004) and in fish and humans may cause reversible retinal deficits (Berstein et al. 1997). A chronically exposed ichthyologist developed decreased vision, photophobia, and photopsia that resolved after terminating MS-222 contact for 7 months (Berstein et al. 1997). Personnel with regular occupational exposure should wear personal protective equipment to prevent systemic absorption of this retinotoxic drug.

MS-222 is the only US Food and Drug Administration (FDA)-approved anesthetic for fish in the United States and consequently is widely used in aquaculture. However, there is a 21-day withdrawal period prior to human consumption or release to the wild. This makes its use impractical or incompatible with some farming operations and field work (Detar & Mattingly 2004; Sladky et al. 2001; Waterstrat 1999).

Benzocaine

Benzocaine, the parent compound to MS-222, is similar in pharmacology, but is much less water soluble. Consequently, a stock solution in ethanol or acetone (100 g in 1 L) or propylene glycol is prepared prior to its use. The stock solution is kept in a dark bottle and held at room temperature (Harms & Bakal 1995). Its relative insolubility may account for its usefulness in species sensitive to MS-222. For example, striped bass (*Morone saxatilis*) are very sensitive to MS-222 but are effectively anesthetized in benzocaine solutions (55–80 mg/L) (Hseu et al. 1998).

Other advantages include low toxicity to humans at the concentrations used, and it can be removed from aquaculture facility effluents using activated carbon filtration. Even if not filtered, breakdown in water is approximately 4 hours, making it less likely to cause environmental contamination. Exposure also does not impair fish growth or reproductive capacity (Gomes et al. 2001; Hseu et al. 1998).

Efficacy and sensitivity to benzocaine are species and dosage related (Gomes et al. 2001; Heo & Shin 2010), and it can stimulate the stress response as discussed previously. The only other major concern is its fat solubility, which may result in prolonged recovery in older and gravid fish. It is one of the few drugs shown to be effective for safe anesthesia of arapaima (Honczaryk & Inoue 2009). A paper in Crucian carp (*Carassius carassius*) noted it to be a safe rapid agent with low increases in stress biomarkers (glucose and cortisol) (Heo & Shin 2010). In Atlantic cod, induction and recovery times were found to increase with increasing body weight. Additionally, it was found that recovery times were longer with benzocaine versus MS-222, even at half the dose of MS-222. In combination with metomidate, however, induction times did decrease (but not as much as metomidate and MS-222) (Zahl 2009). In a recent study it was found that methemoglobin levels increase in several salmonids when anesthetized with both MS-222 and benzocaine at varying levels with no obvious clinical effects (Saunders et al. 2020).

Lidocaine Hydrochloride

Anesthesia with lidocaine baths showed moderate species differences in dose and effect (Carrasco et al. 1984). Lidocaine is a Na^+ channel blocker with local and central action reported. In 10 mg/L sedation was noted in zebrafish with parallel reduction of brain acetylcholinesterase (de Abreu et al. 2019). In immature black ruby barbs 80–100 mg/L was considered optimum (Priyangika et al. 2007). Surgical anesthesia was achieved in zebrafish at 325 mg/L but had a low margin of safety at 350 mg/L (Collymore et al. 2014). In carp it produced reliable, rapid induction and fast recoveries for short procedures at 100 mg/L (Cagiltay et al. 2017).

Clove Oil, Eugenol, Isoeugenol, and Aqui-S® 20e

Clove oil is a mixture of compounds, of which the phenol, eugenol, comprises 85–95%. Isoeugenol and methyleugenol make up the remaining 5–15% of active ingredients. Commercially available clove oil has approximately 84% eugenol, but it is possible to purchase 100%, even at local natural product stores. There are several modes of action: inhibiting voltage dependent ion channels, potentiation of gamma-aminobutyric acid A (GABA) receptors, and inhibition of N-methyl-D-aspartate (NMDA) receptors (Javahery et al. 2012; Zahl et al. 2012).

Clove oil and isoeugenol are "generally recognized as safe" (GRAS) by the FDA as a food additive for humans. Eugenol is similarly approved for use in animal feeds and is used in dental cement for temporary fillings (Harper 2003). However, clove oil, any component of clove oil, and Aqui-S® (isoeugenol, no longer available in the US) are not approved for use as a fish anesthetic in food fish in the United States due to concerns of carcinogenicity in a few animal models (Silbernagel & Yochem 2016). Aqui-S® 20e is currently an Investigational New Animal Drug (https://www.fws.gov/fisheries/aadap/inads.html).

Clove oil and eugenol are incompletely water soluble, particularly at cold temperatures. A 1:10 mixture in 95% ethanol yields a 100 mg/ml stock solution. Concentrations are wide and range from 25 to 120 mg/L (the contribution of ethanol to the anesthetic effect is nil at these concentrations) (Harms 2003; Silbernagel & Yochem 2016). Aqui-S® 20e is completely water soluble, pH neutral, and has no foaming effects as reported with Aqui-S®. Doses for Aqui-S® 20e are 25–55 mg/L with mortalities occurring in several teleost species at >75 mg/L; the reader should review the literature for available species-specific effective doses and if not available, the authors recommend starting at 25 ppm and increasing as warranted by level of sedation achieved (see Table 8.1 for some recommendations).

For tide pools and reef surveys, a section is covered with a mesh net covered in turn by a nylon cloak. A solution of clove oil mixed with ethanol is then pumped into the netted area to temporarily immobilize all fish (as a reminder, clove is not an FDA-approved drug). This application of clove oil may be of use in managed exhibits, which often have elaborate rock or coral work, making removal of fish for medical or maintenance reasons difficult.

Clove oil at doses of >75 mg/L had mortalities in some species (*Astyanax altiparanae*) (Pereira-da-Silva et al. 2009). This may be a function of the physical properties of eugenol oil, increased duration of exposure, or peri-anesthetic management (ventilation, capture stress, etc.). As an oil, eugenol coats anatomic structures and its persistence on gill epithelia may block gaseous diffusion (Sladky et al. 2001). In addition, mild gill necrosis due to repeated exposure to low-dose eugenol (9 mg/L) has been reported (Afifi et al. 2001). With Aqui-S® and Aqui-S® 20e there appears to be a wider safety margin than other clove oil products and fewer mortalities (Bowker et al. 2017; de Oliveira et al. 2019; Gladden et al. 2010; Silbernagel & Yochem 2016; Tennant et al. 2019).

Clove oil has also been used for long-term transports (up to 48 hours) in the cichlid, *Haplochromis obliquidens,* with some mortalities at the higher end (Kaiser et al. 2006). Aqui-S® 20e and eugenol have been effectively used in transports (Cupp et al. 2017). Compared to other immersion anesthetics, clove oil results in more rapid induction times and consistent anesthesia (Abdulrahman et al. 2018; Balamurugan et al. 2016; Bressler & Ron 2004; Detar & Mattingly 2004; Sladky et al. 2001). Additionally, it is less aversive than anesthetics like MS-222 (Wong et al. 2014). In the authors' experience this tends to be true with many anesthetics. In beluga sturgeon (*Huso huso*) that were exposed to clove oil at doses of 500–3000 mg/L it was noted that cortisol, glucose, and lactate levels were lower at the higher dosages with faster inductions (Hoseini et al. 2011). The stress response is variable with suppression in some cases and activation in others, and the reader is directed to the literature (Small & Chatakondi 2005; Wagner et al. 2003) for more detail.

A more practical approach has been to utilize clove powder rather than oil. In sturgeon, the powder has been used in juvenile beluga sturgeon from 175 to 350 mg/L with negative side effects being limited to increases in hematocrit, hemoglobin, and total erythrocyte count but with a return to normal within 24 hours (Mohammadizarejabad et al. 2010). In common carp (*Cyprinus carpio*), 190 mg/L (range 120–230 mg/L) was considered a safe and effective dose with no adverse side effects (Abdulrahman et al. 2018). In convict cichlid (*Amatitlania nigrofasciata*), both clove powder and lavender essential oil successfully worked as anesthetics, however the overall effect was different between the two methods (Raisi et al. 2020).

Although the analgesic effects of eugenol in humans result from the inhibition of prostaglandin H synthase (Keene et al. 1998), proof of analgesia in fish does not exist (Sladky et al. 2001). In red pacu (*Piaractus brachypomus*), fish anesthetized with eugenol were more likely to react to a hypodermic needle puncture than fish anesthetized with tricaine methanesulfonate raising the question of appropriateness of clove oil or related compounds for invasive or markedly noxious procedures. The effect of clove oil and its components on the stress response is variable, with suppression in some cases and activation in others. There has been recent interest in the potential of other essential oils to expedite zero withdrawal for market fish such as basil, thyme, mint, rosemary, lavender, citronella, verbena,

eucalyptus, and camphor as sedatives and anesthetics in different fish species (Aydin & Barbas 2020; Soldatov 2021; Souza et al. 2019) but more research is needed.

Alfaxalone

A combination steroid anesthetic, Alfaxalone (alphaxalone)/alphadolone (A/A), was marketed as Saffan™ and found to induce surgical anesthesia in fish when used as an immersion anesthetic (Peters et al. 2001). It mainly depresses central nervous system (CNS) activity while leaving the integumentary sensory system operational. This makes it very valuable for research in sensory physiology, including mechanoreceptors (Peters et al. 2001). Unfortunately, the main solvent in the drug, Cremophor EL, was associated with histamine release in cats and dogs and subsequently removed from the market (Sear 1996). A newer formulation of alfaxalone has been released without alphadolone, Alfaxan™ (alfaxalone); it is a controlled substance. Alfaxan™ is solubilized in hydroxypropyl-beta cyclodextrin and has not been associated with histamine release.

Alfaxalone has been studied as an immersion anesthetic in goldfish (*Carassius auratus*) (Bauquier et al. 2013; Leonardi et al. 2019), koi (*Cyprinus carpio*) (Minter et al. 2014), and Oscar fish (*Astronotus ocellatus*) (Bugman et al. 2016). Similar to A/A, species and individual variation should be anticipated with the use of alfaxalone (Zellar et al. 2018). In a comparison between MS-222 and alfaxalone of two fish species, black spot barbs (*Puntius filamentosis*) had significantly faster induction times when treated with both drugs, and a faster recovery time from 5 mg/L alfaxalone compared to peacock cichlids (*Aulonocara* spp.). However, shorter induction and longer recovery times were observed for both species treated with 5 mg/L alfaxalone, compared to MS-222 (Zellar et al. 2018). In zebrafish (*Danio rerio*), it produced similar anesthetic results as MS-222 (Farry et al. 2019) and another study in goldfish found it to reach an appropriate level of anesthesia with no adverse effects (Fernández-Parra et al. 2017).

Metomidate and Etomidate

Metomidate and etomidate are nonbarbiturate imidazoles that act through modulation of the inhibitory GABA type A receptors (Martins et al. 2019). Metomidate is labeled currently as Aquacalm™ (Syndel, WA) at doses of 0.1–1.0 mg/L (sedation) and 1.0–10.0 mg/L (anesthesia). It is readily water soluble and is stored in tight, light-protected containers. In addition to immersion, the drug can be given orally (Hansen et al. 2003; Harvey et al. 1988). Etomidate is not widely used in teleost fishes, possibly because of its overall availability and because it is an aqueous solution, requiring ethanol dilution to use. It has been suggested as the best anesthetic for zebrafish, a popular research fish (Readman et al. 2013), and recent use in perch (*Perca fluviatilis*) suggests it is appropriate for this species (Rożyński et al. 2018).

Metomidate and etomidate suppress cortisol response to anesthesia in many (not all) fishes. They block adrenocorticotropic hormone stimulation of steroidogenesis, even when exogenous ACTH is injected intracoelomic. This occurs by a direct effect on the interrenal gland and the mitochondrial cytochrome P_{450}-dependent enzymes that catalyze the synthesis of cortisol (Davis & Griffin 2004; Small & Chatakondi 2005). Cortisol synthesis blockade may cause the immobilized fish to transiently turn very dark. This may be due to reduced cortisol production terminating the negative feedback loop on ACTH synthesis. As ACTH synthesis is linked to melanocyte-stimulating hormone production, both compounds increase with the associated color change occurring (Harms 1995, 1999).

In addition to sedation and anesthesia for minor procedures, metomidate is useful for limiting transport trauma. Fish transported while immobilized can sustain damage if in contact with the container sides and bottom. Metomidate dosages that suppress the cortisol stress response still allow maintenance of equilibrium (Davis & Griffin 2004; Harms 1999; Kilgore et al. 2009).

Metomidate is a hypnotic that more technically induces a sleep-like state rather than general anesthesia. This is reflected in maintenance of opercular respiration for twice as long at the effective concentration as other immersions (Mattson & Riple 1989). Additionally, muscle fasciculations occur at low dosages, indicating incomplete relaxation (Harms 1999). Metomidate is probably a poor analgesic and should not be used alone for major surgical or noxious procedures (Hansen et al. 2003; Harms 1999). It was recently evaluated for use as a euthanasia agent as it shows no aversive effects to exposure of the drug at 100 mg/L, but several caveats were iterated: cessation of reactivity to stimuli and not cessation of ventilation after 30 minutes of exposure and buffering, and higher doses were required in some species (Yanong 2021).

In some marine species, metomidate has a wider therapeutic range compared to benzocaine (Hansen et al. 2003). Among freshwater tropical fish, three-spot gouramis (*Trichogaster trichopterus*) are very sensitive to metomidate and its use in cichlids (Cichlidae) in water of pH <5 is contraindicated (Harms 1999). As a result of the gourami study, it has been recommended not to use this product in air-breathing fishes (Martins et al. 2019). In Atlantic cod, recovery times were found to increase with increasing body weight, but not induction times. When metomidate was used in combination with MS-222 or benzocaine, overall

reduction of dose of both MS-222 and benzocaine was possible with marked reduction of both induction and recovery time (Zahl et al. 2009). The authors have found that while the drug is useful for light sedation, induction times and depth of anesthesia (or sleep) did not show an advantage over other immersion drugs other than a consideration for the low cortisol response in published species and lack of aversion to this drug (Weber et al. 2017).

Quinaldine and Quinaldine Sulfate

Quinaldine sulfate (QS) is a strongly acidic, highly water-soluble powder that must be buffered. Rather than adding powder directly to the water, QS is administered as a stock solution (10 g/L). Its parent compound, quinaldine, is a yellowish oily liquid and must be dissolved in acetone or alcohol prior to mixing in water. Due to high lipid solubility, quinaldine tends to accumulate in the brain more than QS (Harms 1999; Hseu et al. 1998; Ross 2001). Like MS-222 and most immersions, quinaldine and QS depress the CNS sensory centers. Unlike MS-222, neither drug is metabolized by fish and is excreted entirely unchanged (Harms 1999; Hseu et al. 1998).

Though not approved for use in the United States (Harms 1999), QS is common in aquaculture elsewhere because of its relatively low cost. This has also made quinaldine a popular tool for collection of fishes from tidal pools and small lagoons (Ross & Ross 1984). Other reported advantages include effectiveness at very low concentrations, purported low toxicity and wide safety margin, and short fish recovery time (Kumlu & Yanar 1999).

Despite claims of safety, mortality occurs in some species. For example, in gilt-head seabream low-dosage QS (15–20 mg/L) resulted in 30–100% mortality (Kumlu & Yanar 1999). In addition, quinaldine can be an irritant and has caused corneal damage in salmonids (Harms & Bakal 1995; Ross & Ross 1984). Also of importance are studies that demonstrate that fish exposed to quinaldine or QS alone retain a strong reflex response to being touched, even when they have totally lost equilibrium and are deeply anesthetized. This, along with the potential lack of analgesia makes it inappropriate for transportation, handling, and surgical or similarly noxious procedures (Cullen 1996; Harms 1999; Kumlu & Yanar 1999).

To reduce toxicity, and increase efficacy and analgesia, some researchers have combined diazepam with QS. As demonstrated in gilt-head seabream, sea bass (*Dicentrarchus labrax*), and cichlids, addition of diazepam to the QS bath results in fish entering a deeper anesthetic plane at lower QS dosages. This occurs with lower to no mortality, improved muscle relaxation, and reduced excitement in confined spaces (e.g., transport boxes) (Kumlu & Yanar 1999; Yanar & Kumlu 2001; Bircan-Yildirim et al. 2010). Nondepolarizing neuromuscular blocking agents (gallamine triethiodide, tubocurarine chloride, and pancuronium bromide) IM eliminate the reflex responses in fish anesthetized by quinaldine alone (Kumlu & Yanar 1999). However, these combinations do not provide analgesia. Given the more advantageous properties of other immersives, this drug is not in favorable use in most managed-care situations, but is being investigated in other countries.

2-Phenoxyethanol

2-phenoxyethanol (2-PE) is a clear or straw-colored oily liquid. It has a faintly aromatic odor and is moderately water soluble. The mode of action is related to inhibition of NMDA receptors, which have been related to analgesic effects but analgesia appears to be incomplete (Martins et al. 2019). 2-PE was used initially in aquaculture to treat ichthyophonus and other fungal, bacterial, and parasitic diseases. Historically less expensive than many anesthetics, 2-PE has been widely used for sedation, particularly in fish transportation, as well as general anesthesia (Hseu et al. 1996, 1997; Martins et al. 2019; Priborsky & Velisek 2018; Ross 2001). Another advantage is that it causes no pH change when added to seawater (Hseu et al. 1998).

In addition to the poor analgesic properties, 2-PE also produces hypoventilation (Oswald 1978). Additionally, 2-PE may not completely cease involuntary movements, so muscle twitching is possible. Other negative aspects to the drug include no block of the stress response and cardiovascular activity is significantly reduced (Fredricks et al. 1993; Molinero & Gonzalez 1995) although low doses (such as for light sedation and transport) showed no effect on cortisol secretion (Martins et al. 2019). Also, sustained and regular exposure to 2-PE solution causes a neuropsychological syndrome in some handlers (Hseu et al. 1998) although a recent article shows it to be relatively safe (Dreno et al. 2019).

Over 102 species (30 families) of a variety of sizes and ages of fish were moved from one aquarium to another using 2PE exclusively at an average dosage of 0.15 ml/L with maintenance in the immersion for up to 330 minutes. In general, the procedure was smooth, with very little excitation noted in most of the species (Vaughan et al. 2008).

Isoflurane

There are limited published studies evaluating chlorofluorocarbon-based anesthetics in fish, and they have limited applicability (Cagiltay et al. 2017). Isoflurane is considered safe and effective in freshwater and marine fish at concentrations ranging from 0.4 to 0.75 ml isoflurane/L H_2O for induction and 0.25 ml isoflurane/L H_2O for maintenance (Stetter 2001). Isoflurane liquid is vaporized and bubbled

through the water or is directly added to the anesthetic chamber. The latter involves spraying the drug through a 25-gauge needle beneath the surface of the anesthetic chamber. This allows small drug droplets to be distributed in the water (Stetter 2001). Anesthetic depth is difficult to control and, due to insolubility in water, localized areas of higher concentrations may occur, resulting in overdosage. In addition, volatilization and difficulty in scavenging waste gas is a hazard to personnel (Harms 1999; Ross 2001). This is addressed, to some extent, by attaching a funnel system to a standard scavenging system and placing it immediately above the anesthetic chamber (Stetter 2001). Given the disadvantages associated with its use, a number of researchers and clinicians recommend use of isoflurane or similar drugs only as a last resort anesthetic, for euthanasia, or not at all (Harms 1999; Ross 2001). A recent study utilized emulsified gas anesthetics compared to propofol, finding that isoflurane and sevoflurane when emulsified induced general anesthesia in Amur carp (*Cyprinus rubrofuscus*), with faster recovery times compared to propofol (Natalini 2021). In zebrafish isoflurane bubbled into a concentration of 0.5 ml/L resulted in mortalities without providing stage 3 anesthesia (Collymore et al. 2014). Using isoflurane and halothane in carp at 1.5 mg/L resulted in deaths in the isoflurane group of small fish in the study (Cagiltay et al. 2017).

Propofol

Propofol produced anesthesia when used as an immersion in goldfish at 5 and 10 mg/L. Anesthetic needs were similar following repeated exposure and it was safe, but it was not suitable to test MAC reduction (Balko et al. 2017). Propofol has been used as an immersion anesthetic in other species, including silver catfish (*Bagrus bajad*) (GholipourKanani and Ahadizadeh 2013), Nile tilapia (*Oreochromis niloticus*) (Gressler et al. 2012; Goncalves and Giaquinto 2020), koi (Oda et al. 2014, 2018), Persian sturgeon (*Acipenser persicus*) (Adel et al. 2016), and goldfish (Valenca-Silva et al. 2014) with reported efficacy.

In goldfish, a concentration of 1 mg/L resulted in sedation but not anesthesia while 2.5–10 mg/L resulted in dose-dependent decreases in induction times and conversely longer recoveries (Balko et al. 2017). In another study, a dose-dependent response was similarly seen, but body size also influenced induction and recovery times (larger fish had longer induction and faster recoveries) (Obirikorang et al. 2020). Dose of 2 mg/L was effective in African catfish (*Clarias gariepinus*) with no adverse effects on hematologic parameters (Adeola et al. 2018).

Ketamine, Xylazine, and Telazol

Traditionally used intramuscularly or intravenously, the drugs ketamine and xylazine can also be used as an immersion. In a study conducted by Hamdani et al. (2010), these drugs utilized in various combinations as a bath for carp resulted in smooth inductions with sufficient anesthetic time to perform minor procedures. In rainbow trout, 100 mg/L ketamine was considered safe and easy (very water soluble) (Ganjoor et al. 2020). Conversely, in Persian sturgeon there were no clinical effects at 500 and 750 mg/L; even with doses of 5000 mg/L, induction was still long (>5 minutes) (Adel et al. 2016). In addition to species variable responses, other disadvantages are the cost and DEA regulations. In a study on grass carp, xylazine was more effective in deep anesthesia and recovery times compared to benzocaine (Shakeri et al. 2016).

Medetomidine

Medetomidine is an antifouling agent used for barnacle control (Koning et al. 2021). The drug is incorporated into marine paints and prevents the settling of barnacle and tubeworm larvae on surfaces coated with the paint. To assess the potential for effects on nontarget species in the vicinity of such paints, studies have been performed with low-dose long-term immersion baths. In one of these studies, 0.5–50 nM medetomidine baths were used; mostly fry was affected and side effects noted were body paleness, decreased oxygen consumption, and decreased respirations (Lennquist et al. 2010). Sedative effects were not noted as it was not the scope of the study, but all side effects were reversible when animals were removed to clean water.

Carbon Dioxide

Carbon dioxide for immobilization is obtained from three sources: CO_2 gas, sodium bicarbonate ($NaHCO_3$), or carbonic acid (H_2CO_3) (Gelwicks et al. 1998; Prince et al. 1995). Use of carbon dioxide gas involves diffusing compressed CO_2 gas through air stones into water. The $NaHCO_3$ (baking soda) method involves mixing a specific amount of the drug with water to release CO_2. Carbonic acid immobilization involves mixing equal volumes of sulfuric acid (H_2SO_4) and $NaHCO_3$ solutions in water to form carbonic acid and liberate CO_2 (Gelwicks et al. 1998; Prince et al. 1995).

Carbon dioxide gas and $NaHCO_3$ methods are popular, but cumbersome for many field applications (Gelwicks et al. 1998; Prince et al. 1995). In comparison, the materials needed for carbonic acid immobilization are compact and concentrations are easily controlled, making it more applicable to field work (Gelwicks et al. 1998). The carbonic acid method has its own disadvantage in that $NaHCO_3$ and H_2SO_4 solutions are designed to react completely and accuracy is essential. If one solution is mixed incorrectly, water chemistry (i.e., pH) will be significantly affected. Safe handling of concentrated H_2SO_4 requires protective gloves, clothing, and glasses, and work should be performed under

a fume hood (Gelwicks et al. 1998). The acid is added to the water, not the reverse.

Regardless of method, CO_2 use has many disadvantages. Concentrations in water are difficult to control and oxygen must be maintained at high levels. Blood gases and acid-base balance are markedly altered (Harms 1999; Prince et al. 1995). To address the latter concern, some handlers use $NaHCO_3$ with CO_2 gas for its buffering effect (Prince et al. 1995). Alternatively, some handlers mix $NaHCO_3$ with glacial acetic acid to yield carbon dioxide concentrations sufficient for immobilization while limiting acid-base shifts (Prince et al. 1995).

Following immersion in water with a high CO_2 concentration, there is a rapid decrease in blood pH and increase in blood CO_2 concentration. Low blood pH results in less efficient oxygen transport to tissues, including the brain. The resulting cerebral hypoxia causes an overall inhibition of spontaneous activity of the CNS and the observed "anesthetic" effect (Gelwicks et al. 1998; Harms & Bakal 1995). When fish are returned to freshwater, CO_2 diffuses out of the gills, blood pH rapidly returns to normal levels and fish recover. One may expect these changes in blood pH and subsequent cerebral hypoxia to produce morbidity. However, rainbow trout appear tolerant of these changes in blood pH. Recent studies provide conflicting evidence regarding the effectiveness and safety of carbonic acid (Gelwicks et al. 1998).

Although touted to decrease the stress response, CO_2 has questionable analgesia (Prince et al. 1995; Ross 2001) and is not appropriate for invasive procedures. Additionally, fish are aversive to CO_2 in their environment (Robb et al. 2000; Tix et al. 2018).

In the United States the primary advantage of using CO_2 is that it is "generally regarded as safe, and there are no restrictions on its use, which is appealing to both aquaculture and field work" (Gelwicks et al. 1998; Harms 1999). However, many handlers feel it should be used for immobilization or euthanasia as a last resort (Harms 1999).

Other Immersion Agents

There are more esoteric plant-based essential oils that have been tried in fishes, with a dearth in the extant literature (for a review, see Aydin & Barbas [2020] and Table 8.1). This is owing to financial reasons, lack of residues (no withdrawal), availability, and ease of use. Of additional interest is the use of diazepam as an immersion anesthetic, and while not overtly sedative, it does show evidence of anxiolytic effects which may prove useful in other combinations (Bencan et al. 2009; Grebauer et al. 2011). Similarly, many psychoactives (e.g., gabapentin, tramadol) are trialed in fish due to wastewater exposure (Cunha et al. 2019) but these are not at doses that would likely be used for sedation or anesthesia.

Some historical drugs include chloral hydrate, urethane, chlorobutanol, and diethyl ether, none of which are recommended for use in fish any longer (McFarland & Klonz 1969).

Oral Anesthetics

Metomidate

In addition to being used as an immersion, metomidate has been administered orally by high-pressure syringe as a supplement in fish partially immobilized by remote injection (Harvey et al. 1988) and to turbot (*Scophthalmus maximus*) via stomach tube for rapid and complete immobilization (Hansen et al. 2003).

Diazepam

In addition to being combined with QS for immersion anesthesia (Yanar & Kumlu 2001), diazepam-impregnated pellets have been fed to American shad (*Alosa sapidissima*), resulting in a slow anesthetic induction (Harms & Bakal 1995). The authors regularly use oral diazepam as an oral pre-sedative in larger fishes at dosages of 0.5–4.0 mg/kg.

Ketamine

Ketamine, when gavaged orally to goldfish and hybrid striped bass, showed notable sedative effects and animals allowed themselves to be netted; furthermore, an arapaima sedated by this method tolerated slinging (Raines & Clancy 2009).

Tiletamine-Zolazepam

Though designed to be used as an injectable drug combination, successful sedation and translocation of >70% of a population of captive yellowtail jacks (*Seriola lalandi*) was performed using per os tiletamine-zolazepam. The powder was packed in gelatin capsules and placed in food items. Mortalities did occur and were attributed to anesthetic overdosage from fish consuming more than one medicated food item (Steers & Sherrill 2001).

Injectable Anesthetics

Alfaxalone

In a collection of marine and freshwater species A/A was effective IM, but not consistent for capture of free-swimming individuals (Harvey et al. 1988). In several catfish species, IM A/A provided surgical anesthesia lasting several hours (Peters et al. 2001). In rainbow and brown trout, A/A produces similar long sleep times, but it is difficult to give a dose that simultaneously abolishes locomotion yet preserves ventilation (Oswald 1978). With the new formulation of alfaxalone, immersion works well, but

intramuscular dosages of 1.0–10.0 mg/kg were tested in koi with variable responses (mostly inadequate sedation at the low doses) and 33% mortality in the 10 mg/kg dosage (Bailey et al. 2014).

Ketamine Hydrochloride

Ketamine is used alone or in combination with alpha-2 agonists (Harms 1999). Intramuscular injection is the most common route and requires high dosages in teleosts and sturgeons when used alone (Bruecker & Graham 1993; Fleming et al. 2003; Williams et al. 1988). When available in the lyophilized form, a concentrated solution permitting a smaller volume IM injection can be prepared (Oswald 1978). IV administration, though rarely reported, uses dosages a third to a half of those used IM.

Ketamine has been used for capture and manipulation of a number of marine and freshwater species (Williams et al. 1988) and for short-duration procedures and transport (Bruecker & Graham 1993; Oswald 1978). Ketamine IV in coho salmon (*Oncorhynchus kisutch*), rainbow trout, and Midas cichlids (*Heros citrinellum*) reduces the oxygen demand during handling (Bruecker & Graham 1993; Oswald 1978). Tested protocols of IM ketamine (K), dexmedetomidine (D), and midazolam (M) in red porgy (*Pagrus pagrus*) and black sea bass (*Centropristis striata*) showed variable and poor (fatal consequences) responses in porgy but were effective in black sea bass (see Table 8.1 for doses) (Christiansen et al. 2014).

Regardless of administration route, ketamine alone has a species-specific effect in fish often characterized by incomplete anesthesia, periods of apnea, and prolonged recovery with excitement (Bruecker & Graham 1993; Graham & Iwama 1990; Oswald 1978). To reduce dosage and apnea, and improve anesthesia, ketamine is often combined with the reversible alpha-2-adrenergic agonist medetomidine. This combination provides safe and effective anesthesia in some species (Williams et al. 2004), but respiratory depression, bradycardia (Fleming et al. 2003) and incomplete immobilization are noted in others. For the latter reason, either ketamine or a ketamine/medetomidine (K/M) combination is more appropriate as an aid to restraint, rather than as a substitute for immersion anesthesia during major procedures. K/M can be useful in capture of fish from large-volume aquaria. Following reduction of reflexes or sedation with K/M, staff are able to net the fish and transfer them to an MS-222 bath for maintenance and evaluation. In sturgeon (*Acipenser* hybrids), IV medetomidine 0.04 mg/kg and ketamine 4.0 mg/kg had slower inductions and longer recoveries than MS-222 or cove oil, but interestingly had fewer physiologic effects than the MS-222 or clove oil (Di Marco et al. 2011).

Lidocaine

Lidocaine is suggested as an effective injectable local anesthetic in fish, with some question recently on actual analgesic properties (see Chatigny et al. 2017; Harms & Bakal 1995; Park et al. 2011; Sneddon 2012). It has been reported in several fishes as the primary local anesthetic with rare instances of novocaine addition (Chatigny et al. 2017). Immersion at a low dose is suggested for analgesia at 2.0–5.0 mg/L in a postoperative holding aquarium but there are confounding factors and interpretation of success is left to the reader; theoretically topical and possible central effects are possible, but dose and species dependent (Schroeder & Sneddon 2017). At the very least, there have been mortalities reported with local use up to doses of 15.0 mg/kg (see review in Chatigny et al. [2017]).

Medetomidine and Dexmedetomidine

Medetomidine is usually combined with ketamine and reversed with atipamezole. However, it can be used alone as an immersion in rainbow trout to produce sedation, but not analgesia. Bradypnea was observed during immobilization, with an increase in respiration occurring after addition of atipamezole to the recovery water at six times the medetomidine concentration (Horsberg et al. 1999). One of the authors (Mylniczenko) found that in black pacu (or tambiqui), *Colossoma macropomum*, medetomidine (100.0 ug/kg IM) in combination with midazolam (1.0 mg/kg IM) and butorphanol (1.0 mg/kg IM) did not produce ataxia or adequate anesthesia to allow any invasive testing or significant animal manipulation, but it did allow sedation for removal into a small transport. Dexmedetomidine has been used with mixed results (see Table 8.1) (Christiansen et al. 2014).

Propofol

Propofol IV has been used successfully for rapid induction in Gulf of Mexico sturgeon, but caused significant respiratory depression. This complication was addressed by ventilating the fish via the passage of oxygenated water across the gills. In addition to respiratory depression, uncomplicated bradycardia was noted (Fleming et al. 2003). At one facility, propofol in an African lungfish (*Protopterus annectens*) was associated with mortality. It is not certain if this was directly drug related or due to an obligate air-breathing fish being recovered in water that was too deep to allow surface access (Mylniczenko et al. 2014).

Tiletamine-Zolazepam

IM administration of tiletamine-zolazepam (TZ) was used in one study at dosages of 5.0–20.0 mg/kg in multiple saltwater species (not noted in the abstract). Even at dosages of 60.0 mg/kg this group did not experience any mortalities.

At higher dosages, animals had prolonged recoveries, some up to 72 hours (Garcia-Parrage et al. 2007). The greatest advantage of using TZ was lower volumes of drug required as the drug is purchased as a powder and can be reconstituted to high concentrations with good effect and no supersaturation.

Xylazine

In rainbow and brown trout the lowest effective dose of xylazine (100.0 mg/kg) consistently produced apnea. Convulsant activity occurred during induction and recovery, making it difficult to ensure artificial ventilation because the convulsions frequently dislodged the water supply. In addition, gross ECG disturbances were detected. Consequently, xylazine is not recommended in salmonids (Oswald 1978). Given the proven usefulness of medetomidine in other teleost species, xylazine is not the preferred alpha-2 agonist for any fish.

Miscellaneous Drugs

Gallamine triethiodide IM has been used for capture and handling of large tank fish, providing a smooth induction of paralysis following injection (Harvey et al. 1988). If used it is suggested for noninvasive procedures or as an adjunct to other anesthetic agents. A combination of etorphine-acetylpromazine (Large Animal Immobilon™) has been used in trout for anesthesia but given the human accidental exposure risks (Oswald 1978) and availability of other agents, its use is not recommended. Ethanol is an anesthetic of last resort. Anesthetic depth is variable and difficult to control. However, in nonclinical situations or for euthanasia, ethanol is sometimes available when other drugs are not (Harms & Bakal 1995).

Nonchemical Anesthesia

Electroanesthesia (galvanonarcosis) is a common fisheries tool for group immobilization to tag, survey, or remove animals from an area. Anesthesia may not be an accurate descriptor as animals are not truly anesthetized. The process results in electronarcosis or stunning, but when the intensity of the current is too high, it can result in severe muscle tetany and spinal injuries (Schreck et al. 1976). There are two main methods currently used to sedate fish using electricity: (1) lower-voltage, nonpulsed-DC fish-handling gloves (EFHGs), which tend to only sedate fish while the gloves are touching the animal, and (2) a comparatively high-voltage, pulsed-DC portable electrosedation system (PES) that leads to galvanonarcosis (Abrams et al. 2018).

Electroanesthesia can be used appropriately and successfully, with reports of shorter induction and recovery times (Hudson et al. 2011; Roth et al. 2003), however results have indicated that physiological responses are often varied between species and individuals (Abrams et al. 2018) and there are a few deleterious effects. One author (Mylniczenko) has experienced long-term immunocompromise and resulting secondary infections in animals collected by PES. Additionally, the acute effects can be very dramatic and mimic exhaustive exercise. Finally, this method does not have much practical application for the aquarium but may be a tool used to collect specimens coming into quarantine or utilized during field work. A study comparing EFHGs with immersion anesthesia found that a lower plane of anesthesia and inconsistent immobilization made surgeries with EFHGs more challenging to perform than surgeries conducted using immersion anesthesia (Lamglait & Lair 2021). Lastly, there should be caution for human safety when using electricity in water and for collateral damage of nontarget animals in the vicinity of the shock.

Hypothermia is not an appropriate method of anesthesia but has been used historically to induce light anesthesia and for transport; the physiologic effects are too great for its consideration as an anesthetic.

Analgesia

The importance of animal welfare and whether fish feel pain has received increased attention over recent years. The topic of analgesia is beyond the scope of this chapter but the reader is referred to the numerous contemporary articles on the topic of analgesia in fishes (Chatigny 2019; Chatigny et al. 2018; Martins et al. 2019; Sneddon et al. 2018; Sneddon 2019; Woodruff 2018). Most sources define analgesia as the absence of pain in the presence of stimuli that would normally be painful without the loss of consciousness. The less-used definition seems more universally acceptable as it includes absence of noxious stimulation as well as pain in the definition (Blood & Studdert 1988; Thurmon et al. 1996). Putting aside the question of pain perception, fish have pain receptors throughout the brain, making it reasonable to expect some effect of treatments in fish experiencing noxious stimuli (Harms et al. 2005). Additionally, beneficial effects on behavior and physiologic parameters have been reported in many instances, especially associated with morphine administration (Chatigny et al. 2018). The empirical evidence in fish demonstrates that pain-related behaviors are conserved across vertebrates and that fish experience pain. Additionally, where tested, the lack of adverse effects in those drugs does not put the clinician in a risky situation with their patient. Thus, it is important to minimize and

alleviate pain or noxious stimuli in fish whenever possible (Chatigny 2019; Sneddon 2019).

Euthanasia

Euthanasia can be difficult in fishes as determination of death can be difficult. Cessation of opercular movement and cardiac movement are not always sufficient to correlate to brain (telencephalon) death (Louis et al. 2020). As such a secondary method is always recommended (severing the spinal cord from the brain). Typically, overdosage of an immersion immobilization drug is used. However, the most recent AVMA euthanasia guidelines (Leary et al. 2020) for immersion euthanasia recommend that "finfish should be left in the anesthetic solution for a minimum of 10 minutes after cessation of opercular movement" and state that an MS-222 "concentration of 250–500 mg/L, or 5 to 10 times the anesthetic dosage, is effective for most species." MS-222 is most common but injectable agents can also be used. However, several papers recently have shown that MS-222 at five to 10 times the anesthetic dosage may be ineffective at euthanizing certain species. Up to 96% of goldfish exposed to higher doses and longer exposure periods than the current recommended guidelines made complete recoveries with no signs of morbidity or mortality. Additionally, myocardial contractions continued for up to 4 hours in decapitated goldfish and immersion in propofol at a concentration of 25 mg/L for 30 minutes did not reliably euthanize goldfish (Balko et al. 2018). Other studies have evaluated other substances for teleost euthanasia but are out of scope for discussion here (Chu et al. 2020; Collymore et al. 2016; Louis et al. 2020; von Krogh et al. 2021; Yanong 2021).

Many fish in large exhibits require induction first with parenteral drugs (e.g., medetomidine/ketamine), then euthanasia in an MS-222 bath. Alternatively, in fish too large for a bath, the solution is poured directly over the gills (Harms & Bakal 1995). Cessation of opercular movement sometimes indicates a fish has expired but is not definitive and should not be used as the sole parameter for confirmation of death. Cardiac asystole usually lags behind brain death since fish myocardial cells utilize local glycogen stores for energy and do not need blood glucose (Stetter 2001). Use of Doppler flow probes, ultrasonography, or electrocardiography is recommended to confirm asystole. To be certain, additional anesthetic drugs, KCl or pentobarbital are administered IV into the heart or caudal vein (Louis et al. 2020; Ross 2001). Alternatively, cranial concussion, decapitation, spinal transection, or exsanguination may be performed once the fish is deeply anesthetized (Harms & Bakal 1995). These physical forms of euthanasia can result in instantaneous death when applied correctly, thus it is imperative to use the proper equipment and trained personnel who are regularly monitored for proficiency (Leary et al. 2020).

While euthanasia with baking powder or Alka Seltzer™ tablets has been utilized, CO_2 release is very aversive and may not be ideal for the welfare of the fish without a multimodal anesthetic protocol. The reader is directed to review euthanasia principles for fish in other documents (Leary et al. 2020; Posner et al. 2019; Kilgore et al. 2009; Yanong 2021). Unacceptable methods of euthanasia include asphyxiation and hypothermia. Though there are reports of success using these methods, variability has been reported (Wallace et al. 2018) and the animal welfare implications are unknown at this time.

Field Immobilization

Immobilization of fishes in the field is a commonplace event. Considerations for immobilizing fish in remote areas include having portable equipment that can connect to car batteries or portable generators/batteries. It is important to consider guidelines for approved drugs (US Fish and Wildlife Service, The Aquatic Animal Drug Approval Partnership 2022) and to observe withdrawal periods. Alternatively, there are tags available that state "do not consume" that are affixed to the fish. Typically for field procedures, unless invasive, animals are not anesthetized with chemicals and are only physically restrained. Hook and line, net, trawl, and electroanesthesia fishing are methods used to capture free-range fish. Each technique carries its own risk to the animal, including hypoxia, trauma, exhaustion, and major physiologic disturbances. These must be considered for long-term management or survival of the animals.

When using source water, clarity must be considered as some water bodies may have turbid water, algal blooms or high tannins. This can complicate visualization of induction or recovery in these animals. Temperature shifts throughout the course of the day will greatly modify temperatures in holding vats. Manual restraint and air exposure can also affect physiology (see earlier comments in this chapter).

Postanesthetic Challenges

Once animals are placed into recovery water, ensuring adequate ventilation is critical. The authors prefer using an electronic pump to facilitate oxygenated water flow over the gills, but many aquarists prefer moving the animal through the water column. Determining when to release the animal requires skilled staff that are aware of

normal swimming behavior. Staff should be prepared to retrieve the animal if it falls to the bottom of the water column (or if aggressed upon) rather than showing normal behavior or swimming away and recovering. Observation of the animal for the next 24–48 hours is recommended for observing any morbidity or mortality associated with the procedure. As with all anesthetic procedures in animals, restraining a compromised animal with either manual or chemical methods carries a risk for increased morbidity or mortality.

Acknowledgements

Special thanks to Donald L. Neiffer for his significant contributions to the first versions of this chapter, and to M. Andrew Stamper, Jane Capobianco, Karen Echeverria, DeAnne Fanta, and Dr. Beth Nolan from Walt Disney World, Orlando, FL. and Lynda Leppert from the Georgia Aquarium, Atlanta, GA for their assistance with chapter preparation.

Amphibians

Amy B. Alexander and Eric Baitchman

Introduction

Amphibians are native to all continents, except Antarctica, and occupy a wide variety of aquatic, semi-aquatic, and terrestrial habitats. Amphibians are found from the equatorial rainforest to Canada, where they may remain frozen through the winter. There are more than 6800 species within the Orders Anura (frogs and toads), Caudata (salamanders and newts), and Gymnophiona (caecilians) (IUCN 2020). Although new species of amphibians continue to be discovered, amphibians are considered the most threatened class of vertebrates, with one-third being listed as threatened. Threats include infectious disease, particularly chytrid fungus, *Batrachochytrium dendrobatidis* (Bd), as well as climate change and habitat destruction, which can also exacerbate susceptibility to infectious diseases (Catenazzi 2015; IUCN 2020; Pessier 2018). There is significant concern about worldwide amphibian decline and its implications for global ecosystem health.

Amphibians are routinely maintained in human care as pets, in laboratories, and in zoos for education, as well as conservation and reintroduction projects. Veterinarians are most likely to be involved with anurans or caudates. It is not uncommon for amphibians to require sedation or anesthesia for diagnostics, surgery, or research.

Anatomy and Physiology

Amphibians have several unique and clinically relevant anatomical characteristics. The first is that many go through metamorphosis and change from strictly aquatic larval forms (i.e., tadpoles) to terrestrial adults. These metamorphoses include dramatic anatomical changes; growth of legs, loss of gills, resorption of tails (anurans), and formation of lungs. As a completely aquatic tadpole with gills they have very similar respiration to fish.

The respiratory physiology of amphibians is unlike that of any other animal taxa. Four different types of respiration are employed: branchial, cutaneous, pulmonary, and buccopharyngeal. All species utilize branchial respiration (gills) as larvae, and some paedomorphic species, such as axolotl (*Ambystoma mexicanum*), mudpuppies (Proteidae), and sirens (Sirenidae), retain gills as adults (Duellman & Trueb 1994). All adult amphibians utilize cutaneous respiration to varying degrees and this may account for a significant portion of an animal's total oxygen exchange.

The largest family of salamanders, the Plethodontidae or lungless salamanders, perform nearly all respiration via cutaneous gas exchange. Even those caudates that do possess lungs primarily utilize cutaneous gas exchange (Baitchman & Herman 2015; Duellman & Trueb 1994). A unique adaptation in cryptobranchid salamanders (hellbenders and giant salamanders) is intradermal capillaries concentrated along lateral skin folds that increase surface area for gas exchange (Baitchman & Herman 2015; Pessier 2018).

Adult anurans and caecilians possess lungs, but the majority of oxygen intake is usually via pulmonary exchange, while the cutaneous route still accounts for the majority of carbon dioxide exchange (Clayton & Mylniczenko 2015; Duellman & Trueb 1994; Hillman et al. 2009; Wright & Whitaker 2001). Lungs are inflated by positive pressure ventilation achieved through buccal pumping. Small amounts of gas exchange may also occur across buccopharyngeal mucus membranes. Central respiratory drive to increase respiratory frequency or tidal volume is stimulated by either a decrease in PO_2 or increase in PCO_2 (Branco & Glass 1995; Fonseca et al. 2012; Hillman et al. 2009).

Amphibian skin is highly permeable and well vascularized. In addition to respiratory gas exchange, it is the primary route of water exchange and actively participates in electrolyte balance. Smooth-skinned animals, adapted to moister environments, have higher permeability and are

susceptible to dehydration through insensible water loss. In most species the ventral pelvic region, often referred to as the pelvic patch or drink patch, is the area of highest water uptake. It is especially well developed in terrestrial species, showing increased surface area and vascularity in this region (Fig. 9.1).

Vascular Access and Injection Sites

Vascular access is limited by animal size. Fine-gauge needles or catheters (24-gauge or smaller) may be needed. Useful access sites include the ventral abdominal vein on the caudal ventral midline (Fig. 9.2), the femoral vein behind the stifle, the axillary venous plexus (Fig. 9.3), the sublingual plexus, and the ventral tail vein in caudates. Other sites, such as the brachial vein or lateral abdominal veins, may be accessible in larger species. Transillumination is a useful technique for highlighting the pathways of major vessels (Fig. 9.4).

Intramuscular injections can be administered in the large muscles of the hind limbs. However, as amphibians have a renal portal system, injections are ideally administered in the cranial limbs to prevent possible first-pass effect. Subcutaneous injections should be considered intralymphatic/intravascular in anurans, as the subcutaneous space along the dorsum consists of extensive lymphatic

sacs. In caudates, the dermis is firmly adhered to the underlying tissue, limiting subcutaneous access (Pasmans & Martel 2019; Pessier 2018).

General Anesthetic Considerations

The aquatic nature and skin permeability of amphibians makes topical use of anesthetic agents a convenient means of achieving systemic effects. Amphibian anesthesia is very similar to fish anesthesia in the methodology and drugs used (Stetter 2001). Anesthetic compounds may be delivered in water and absorbed across the animal's skin or gills. Inhalant anesthetic agents may be used either topically or in solution. When gas anesthetics are delivered into a chamber or bubbled through water, induction can be prolonged or unsuccessful. Some amphibians can be intubated awake and administered an inhalant anesthetic for induction. Parenteral or injectable anesthetics are often unreliable, have a low margin of safety, may be associated with prolonged recovery, and have species-specific doses (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Caution is recommended when using an anesthetic agent in a new species.

Aquatic amphibians can be kept out of water for extended periods of time if the skin is kept moist to prevent damage or dehydration and ensure dermal respiration is maintained (Wright & Whitaker 2001). When working with entirely aquatic species (e.g., African clawed frog, *Xenopus laevis*), tank water from the animal's environment is used to prevent abrupt environmental changes (e.g., temperature, pH, etc.). All water used for anesthesia is tested using standard reagent test kits to ensure there are no elevated deleterious variables such as ammonia (Wright & Whitaker 2001). Toxin-free (dechlorinated) water within the animal's preferred body temperature range (usually 15–23°C, 59–73°F) is used (Wright & Whitaker 2001). Bottled spring water at room temperature is often convenient to use or amphibian Ringer's solution may be prepared.

The container used as an anesthetic chamber must be thoroughly cleaned and rinsed. Since amphibians absorb chemicals across their skin, cleaning solutions or other chemicals left in a container can be toxic. In addition, some amphibians secrete toxins from their skin and it is important to rinse containers well between patients. Sealable plastic bags are efficient containers for anesthetic bath induction chambers and can be discarded when the procedure is complete. Other potential induction chambers include small plastic containers with lids or small fish aquariums. Many amphibians exhibit an excitement phase during induction, making it important to have a closed container to prevent the patient leaping out. The interior should be smooth and padded, if possible, to prevent injury (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). When a water bath is being used for anesthetic application, there should be an interface with the air at the surface (i.e., do not fill the container completely to the lid). Animals with lungs should be positioned with nostrils elevated out of the water to prevent aspiration during induction.

When using a bath solution to induce anesthesia, the induction dose received is dependent on the surface area of the animal, that is, smaller animals with greater surface area are exposed to larger amounts of anesthetic than larger animals with smaller surface area relative to body size. Consideration should be given to adjusting solution concentrations based on body size (Goulet et al. 2010, 2011).

Moistened gloves are worn when handling amphibians to protect their skin as well as to protect the handler from potentially toxic secretions (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Rinsed nonlatex, nonpowdered gloves are recommended for handling adults, and only washed vinyl gloves have been found safe for handling amphibian larvae. Mortality was seen in tadpoles exposed to latex, nitrile, and unwashed vinyl gloves (Cashins et al. 2008; Gutleb et al. 2001). Small towels moistened with tank water can help restrain aquatic species, as well as prevent damage to their mucus layer.

Amphibians are not commonly fasted prior to anesthesia. Their larynx remains tightly closed even under general anesthesia and the chance of aspiration is low (Wright & Whitaker 2001). Regurgitation or gastric prolapse has been reported in studies using isoflurane or eugenol in *Xenopus laevis* or eugenol in *Rana pipiens* (Goulet et al. 2011; Lafortune et al. 2001; Smith & Stump 2000). Regurgitation was also observed in a lesser siren (*Siren intermedia*) during induction via alfaxalone bath (D. Heard, pers. comm.). While no lasting adverse effects were appreciated in those animals, consideration might be given to fasting for 24 hours when feasible, particularly if the amphibian's diet includes large prey items or if the anesthetic procedure is to include coelomic surgery.

Respiratory ventilation is usually reduced or absent during amphibian anesthesia. The dermis is kept moist to allow for efficient dermal respiration. Cutaneous oxygen exchange, however, may be low in some species (Hillman et al. 2009) and supplemental oxygen should be considered to avoid hypoxemia and acidemia (Andersen & Wang 2002). While some amphibians can tolerate anoxia for long periods, reoxygenation is a significant stress and risks free-radical injury to tissues (Bickler & Buck 2007). For long surgical procedures the patient can be placed in a shallow water bath with oxygen bubbled into it. Intubation is also a safe option to provide supplemental oxygen (G. Crawshaw & D. Mader, pers. comm.). Small species

may be intubated with modified intravenous catheters or noncuffed Cole tubes may be used in larger species. The larynx is usually tightly closed, even in anesthetized animals, and the tube may need to be gently forced (G. Crawshaw, pers. comm.). The trachea is very short and the tip of the tube should be placed just past the larynx (Stetter 2003). Amphibian lungs are composed of thin-walled membranes and manual or mechanical ventilation must be done gently. Larger species can be ventilated at a pressure of 5 cmH_2O, with a breath every 10 seconds (D. Mader, pers. comm.).

Monitoring

The skin under the mandible and along the ventral cervical region is the gular region; movement in this area is a primary means of respiration. As a patient becomes anesthetized, gular respirations decrease and there is a diminished withdrawal reflex (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Light anesthesia is associated with loss of righting reflex and an absence of abdominal respirations. Surgical anesthesia is indicated by a loss of withdrawal reflex and cessation of gular respiration (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). When the patient has ceased movement and appears to be anesthetized, the animal may be placed in dorsal recumbency to assess righting reflex. For procedures requiring light anesthesia (e.g., blood sampling, radiographs, physical examinations, etc.) the patient is removed from the container and quickly rinsed with anesthetic-free water before the procedure begins. If surgical anesthesia is required, an aggressive toe pinch of the rear leg will help determine if there is loss of withdrawal reflex and nociception.

Anesthetized amphibians usually become apneic; abdominal and gular respirations cease. This can be very disconcerting for the anesthetist who relies on respiratory rate for assessing anesthesia. Consideration should be given to intubation or other means of supplementing oxygen, as discussed above.

Heart rate is a useful indicator for anesthetic monitoring (Crawshaw 2003; Wright & Whitaker 2001). In most anesthetized patients in dorsal recumbency, the heart is seen contracting on the midline just caudal to the pectoral girdle. Direct visualization, a Doppler monitor, or ultrasound is used to measure heart rate (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Although normal heart rates for species are not extensively published, a significant decrease in baseline heart rate is of concern and indicates excessive anesthetic depth. Pulse oximetry has not been validated in amphibians, but may show trends in hemoglobin saturation for long procedures and can assist with monitoring pulse (Fig. 9.5). Intermittently monitoring withdrawal reflex will determine if the patient is transitioning from surgical to light anesthesia. A patient that regains its withdrawal reflex, or gular respirations, requires supplementation if a surgical plane of anesthesia is still required. For supplementation, a 10–50% concentration of the induction solution is applied topically via syringe or partial water bath (Fig. 9.6). When the animal reaches an adequate level of anesthesia the application is discontinued.

During recovery, animals should be kept moist and well oxygenated, ideally at the preferred optimal temperature for the species. Recovery is considered complete when the

animal is responsive, respiring normally, and has regained all reflexes (Wright & Whitaker 2001).

Analgesia

Excellent discussions on nociception in amphibians can be found in Machin (1999) and Stevens (2011). Amphibians share the same array of nociceptive afferent nerves, spinal cord neurotransmitters, and endogenous opioid peptides as mammals. While the perception of pain in an amphibian is unknown, all the same nociceptive pathways are conserved as in higher phylogenetic classes of vertebrates. Analgesia should be considered for any noxious procedures in amphibians.

Analgesic drugs and dosages are summarized in Table 9.1. Anesthetic drugs and dosages are summarized in Table 9.2.

Opioids

All mammalian opioid receptors, mu, delta, and kappa, are present in the central nervous system of amphibians. While receptor selectivity is less than in mammals, the relative analgesic potency mu > delta > kappa, is the same (Stevens 1996, 2004). In a study comparing alfaxalone-butorphanol versus alfaxalone-morphine via immersion in oriental fire-bellied toads (*Bombina orientalis*), only the group that received morphine had adequate antinociception. Both groups had cardiac and respiratory depression, but recoveries were smooth. Irrigation with naloxone did not speed recovery (Adami et al. 2016a). In general, opioid dosages tend to be much higher in amphibians compared to mammals and onset to peak analgesic effect is longer at 60 minutes or greater when given systemically (Stevens et al. 1994). Planning analgesia for procedures should take this delay of onset into account.

Alpha-2 Adrenergic Agonists

In amphibians, alpha-2 adrenergic agonists provide analgesia without sedation. Normal movement, including righting, corneal, and hindlimb withdrawal reflexes, all remain intact. Onset of effect is rapid and long lasting, with peak effect occurring by 60 minutes and lasting for 6–8 hours or more (Brenner et al. 1994). In *Bombina orientalis*, the addition of dexmedetomidine to an alfaxalone immersion protocol did provide some analgesia, but seemed to lighten the anesthetic depth, making the combination unsuitable for surgical anesthesia in this species (Adami et al. 2016b).

Nonsteroidal Anti-inflammatory Drugs

Although often used empirically, little data exists to support the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for analgesia in amphibians. Flunixin meglumine is reported

to provide significant analgesia. The dosages used in two studies, however, are extremely high (25 mg/kg) compared to typical doses in other taxa, and one animal that died during the trial had histopathologic evidence of renal congestion and inflammation (Coble et al. 2011). Meloxicam reduced circulating prostaglandin E2 in *Rana catesbeiana*, implying it can suppress the inflammatory response and may therefore provide an analgesic effect (Minter et al. 2011). No significant analgesic effect was seen, however, when using meloxicam in trials with *Xenopus laevis* (Coble et al. 2011). Plasma concentrations of meloxicam were not reliably detectable after subcutaneous or topical administration in smoky jungle frogs (*Leptodactylus pentadactylus*). Ketoprofen administered subcutaneously and topically did have detectable plasma concentrations for at least 24 hours, with the subcutaneous route having the more predictable plasma concentrations (Balko et al. 2018). Mild analgesia is reported from a study with two uncommon NSAIDs, indomethacin and ketorolac (Stevens et al. 2001).

Anesthetic Drugs

Tricaine Methanesulfonate (Ms-222 Or Finquel®)

This is the most commonly used anesthetic for amphibians (Cooper 2003; Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). It is effective in all species and all developmental stages, and it has a wide margin of safety.

Tricaine methanesulfonate is a white powder that readily dissolves in water. Its mechanism of action, like other local anesthetics, is as a sodium channel blocker inhibiting nerve conduction. Used systemically, it creates anesthesia via central nervous system depression (Cakir & Strauch 2005). In aqueous solution, it is very acidic, especially at higher concentrations and with waters that have a low buffering capacity (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). This acidic solution is not only irritating to the patient, but the drug is also in a more ionized form and

therefore less effective as an anesthetic at low pH levels. It is important to buffer the solution to keep the pH at 7.0–7.4 (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). This is easily accomplished by adding sodium bicarbonate to the mixture. Common baking soda (powdered sodium bicarbonate) is added to the solution until saturation (powder no longer dissolves) is achieved, usually a 1:1 ratio. Amphibian ringer's solution also provides some buffering capacity as it contains sodium bicarbonate. Since the patient is being induced in an anesthetic water bath, rather than a dosage based on body weight, the anesthetic solution concentration is determined by the level of sedation or anesthesia required along with relative life stage (larvae vs. adult) and species of amphibian (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). In general, lower concentrations are required for younger larval stages, species with external gills, and the more aquatic frogs compared to the terrestrial toads. Hellbenders are unique in that they also require lower concentrations (Junge 2012; S. O'Brien, pers. comm.). Skin disease is common in amphibians, with lesions including ulceration and hyperkeratosis, which can affect anesthetic absorption, osmoregulation, cutaneous respiration, and metabolism. These lesions should be taken into consideration when determining an anesthetic plan, as concentrations may need to be adjusted. Refer to Table 9.2 for general recommendations of concentrations.

For a desired volume of solution, the exact amount of tricaine methanesulfonate is weighed out, dissolved in water, and the buffer is added until neutral pH is achieved. The solution is not stable over long periods of time and is discarded after each use. Anesthetic solution is added to the induction chamber at a level sufficient to cover approximately the ventral half of the patient's body. Additional anesthetic solution can be diluted to 10–50% of the induction concentration to be used as a maintenance solution for longer procedures. Specific areas to focus supplementation for more rapid effect are the ventral drink patch in anurans and the lateral folds in hellbenders.

Although induction times are variable, initial effects can be seen within a few minutes, with a surgical plane of anesthesia achieved in up to 30 minutes. The general comments in the above sections apply to induction and monitoring in tricaine anesthesia. Loss of gular respiration is expected at a surgical plane of anesthesia and excessive anesthetic depth will cause cardiac depression on a dose-dependent basis (Cakir & Strauch 2005).

Eugenol

Eugenol is the active compound in clove oil, wherein eugenol concentration can vary widely, from 47% to 88% (Chaieb et al. 2007). It is worth noting that when dosing clove oil, the percentage of eugenol may not be known, nor is the possible presence of other active or inactive compounds. Interpretation of published dosages of clove oil as an anesthetic should take this variability into consideration. Simple side-by-side comparison of protocols using clove oil is not straightforward. Purified eugenol can be obtained for use as an anesthetic, allowing more accurate and consistent dosing. As more published reports using purified eugenol are produced, species and dosage comparisons can be made more easily. The terms "clove oil" and "eugenol" are not used interchangeably in this chapter.

Eugenol has been used as a topical anesthetic in humans, as well as a general anesthetic in invertebrates, fish, and amphibians. Its mechanism of action is as a local anesthetic, creating analgesia and anesthesia by blocking sodium voltage-gated channels as well as vanilloid receptor TRPV1 and activating inhibitory $GABA_A$ receptors (Goulet et al. 2010).

Eugenol or clove oil induction is most effective via an immersion bath solution. Eugenol solutions do not need to be buffered. Surgical anesthesia has been reliably achieved in multiple reports with *R. pipiens* and *X. laevis*. Regurgitation or gastric prolapse has been observed in these studies as a fairly common side effect during induction or recovery, though apparently without adverse consequence (Goulet et al. 2011; Guenette et al. 2007; Lafortune et al. 2001). Clove oil anesthesia has been reported in one caudate species, *Ambystoma tigrinum*, where a surgical plane of anesthesia was achieved in 67% (8/12) at a higher dose than required for *R. pipiens* (Mitchell et al. 2009).

Toxicity studies in *Xenopus* indicate that smaller animals have a higher incidence of toxic effects. Smaller animals have a higher surface area and therefore are likely to absorb anesthetics at a higher dosage per body weight relative to larger animals in the same bath concentration. Smaller *Xenopus* are also less mature than larger animals, so the mechanism of toxicity could be either dose- or age-dependent (Goulet et al. 2010, 2011). Histopathologic findings in small animals (28.2 ± 13.7 g) 24 hours after receiving anesthetic doses (350 μL/L) of eugenol included apoptosis of distal tubular cells in the renal medulla, followed by regeneration 1 week after anesthesia. Animals that were anesthetized daily for three consecutive days had tubular apoptosis ranging from mild to severe, followed by tubular regeneration, massive hepatic necrosis, and hemorrhage of coelomic fat bodies 1 week later (Goulet et al. 2011). Large female *Xenopus* (111.7 ± 18.3 g) showed no histopathologic abnormalities 24 hours after anesthesia in the same bath concentration (Guenette et al. 2007). Cardiovascular depression is also seen with smaller animals in a surgical plane of anesthesia, but not in larger animals (Goulet et al. 2010; Guenette et al. 2007). Cutaneous necrosis has been reported in *Xenopus* receiving topical applications of

eugenol at concentrations of 60 mg/mL or greater (Ross et al. 2006).

Isoeugenol (Aqui-S®), an isomer of eugenol, has been used as an anesthetic in fish and produces similar anesthetic effects as eugenol, but at lower concentrations. Southern brown tree frog tadpoles (*Litoria ewingii*) were safely anesthetized using 20 µL/L immersion and the animals did not show signs of irritation or excitement and recovered uneventfully. Repeated dosing and histopathology were not performed (Speare et al. 2014).

Inhalant Agents

Isoflurane is a safe and effective anesthetic in amphibians and may be familiar and useful to the practitioner who does not keep tricaine methanesulfonate in stock (Barbon et al. 2019; Stetter 2001). Topical applications of liquid isoflurane or bath immersion in isoflurane solution are the most reliable means of induction. Isoflurane gas can also be delivered in the traditional vaporized form via a chamber or by bubbling vaporized isoflurane and oxygen from an anesthetic system into a water bath (Barbon et al. 2019; Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). In both cases a sealed container is used to minimize human exposure and increase isoflurane concentrations in the induction chamber. While these methods can be effective in some cases, they are associated with slow induction times and rapid recoveries once the patient is removed from the chamber. Frogs in a gas induction chamber can cease ventilation, thereby significantly increasing induction times (Barter et al. 2007). The aquatic frog *Xenopus* was not anesthetized by bubbling vaporized isoflurane into a water chamber (Smith & Stump 2000). Intubation and maintenance of large amphibian patients with isoflurane gas may be performed with an uncuffed endotracheal tube (Wright 2006). Mountain chicken frogs (*Leptodactylus fallax*) were induced with isoflurane via chamber induction and removed once they lost their righting reflex. They were then intubated with a modified cuffed endotracheal tube (2.5–3.5 mm) and manually ventilated at 2% isoflurane to achieve and maintain a surgical anesthetic plane. Manual ventilation with room air was continued until the animals regained the righting reflex (Rodrigeuz 2019).

The most effective and longest lasting methods of isoflurane anesthesia are application of concentrated liquid isoflurane to the skin or immersion in an isoflurane bath solution (Stetter 2001). For the immersion bath, a syringe is used to add the liquid isoflurane directly into the water. The syringe tip is placed below the surface of the water and the isoflurane liquid is injected and mixed into the bath. A concentration of 2–3 mL/L is most commonly used (Crawshaw 2003; Stetter 2001).

When applying concentrated liquid isoflurane directly to the skin, a carrier solution or barrier is created to increase dermal contact time prior to the isoflurane evaporating. A gel mixture is created using 3 mL of liquid isoflurane, 1.5 mL of water, and 3.5 mL of K-Y® Jelly (Stetter 2001). These three ingredients are placed in a 10 mL empty serum vial and vigorously shaken until a uniform gel is established. This isoflurane gel can now be applied to the patient's dorsum at dosages of 0.025–0.035 mL/g body weight (Stetter 2001). Lower dosages are used for more aquatic species and higher dosages for thicker-skinned terrestrial species (e.g., toads). After the isoflurane gel is mixed in the vial the indicated volume is withdrawn through a syringe and needle and the gel deposited on the patient's dorsum. Once applied, the patient is placed in a small sealed container until induction is complete. After induction, the anesthetic gel preparation should be rinsed from the patient's skin. Patients anesthetized with topical isoflurane gel will remain under anesthesia for 45–80 minutes. Shorter anesthetic times with a more rapid recovery are seen with the liquid isoflurane in water method (Stetter 2001), or the isoflurane and water solution can be dripped on the skin at a rate needed to maintain anesthetic depth, similar to the method for maintenance with tricaine methanesulfonate.

Topical application of concentrated isoflurane liquid was successful for anesthetizing *Xenopus* frogs using an absorbent pad with a plastic backing. Isoflurane at 0.03–0.06 mL/g body weight is used to saturate the absorbent pad, which is cut to size to cover the animals' dorsum and placed against the skin with the plastic backing facing up (Smith & Stump 2000).

Sevoflurane, compounded into a gel as described above, has shown good absorption across skin in *Rana catesbeiana* and reliable loss of righting reflex in *Bufo marinus* (Ardente et al. 2008; Stone et al. 2013). When applied topically as compounded gels to American green tree frogs (*Hyla cinerea*), both isoflurane and sevoflurane had similar induction rates, but the sevoflurane-anesthetized animals had a more rapid return of the righting reflex, with the isoflurane frogs taking 4.5 times longer to recover (Zec et al. 2014). Cane toads (*Rhinella marina*) were induced in a chamber with isoflurane, sevoflurane, or desflurane, which has a lower tissue solubility. All three anesthetics had similar induction rates, but the recovery rate was approximately twice as long with isoflurane and sevoflurane compared to desflurane (Morrison et al. 2016).

Adverse complications are few when using isoflurane by the above methods. In the study comparing topical compounded isoflurane and sevoflurane gels in *Hyla cinerea*, skin lesions and death secondary to septicemia were noted in some of the isoflurane-treated frogs. The dose used in the

study was significantly higher than what is recommended in this chapter, reinforcing that caution is always required when using anesthetic drugs in different amphibian species (Zec et al. 2014). The dose of sevoflurane was also significantly higher than in a previous study in *Bufo marinus*, which may indicate a wider safety margin for sevoflurane (Stone et al. 2013; Zec et al. 2014). Regurgitation was observed in *Xenopus* frogs fed within 1 day of isoflurane induction. Injectable administration of isoflurane (intracelomic, subcutaneous, or intramuscular) is not recommended due to variable results and high mortality (Smith & Stump 2000).

Human exposure to vaporized volatile gas anesthetics is of concern during protocols involving these drugs in their liquid form. Procedures should be performed within a fume hood or beneath an active scavenging system.

Miscellaneous Topical Anesthetic Drugs

A variety of drugs traditionally used for local analgesia in mammals have been evaluated for general anesthetic use in amphibians. Benzocaine has been used with good results in a variety of anuran and caudate amphibians (Andersen & Wang 2002; Cakir & Strauch 2005; Crawshaw 2003; Wright & Whitaker 2001). Benzocaine powder is not readily soluble in water and should be dissolved in ethanol first. The volume of ethanol in the final anesthetic solution should not exceed 1% (Wright & Whitaker 2001). A commercially available topical gel product, Orajel®, containing 10–20% benzocaine, has been successfully utilized topically in caudates and anurans in its original form and in solution as an immersion bath (Brown et al. 2004; Cecala et al. 2007; Guenette & Lair 2006). At least one study found unexpected mortality in *Bufo fowleri* with a 1 g/L Orajel® bath (equivalent to 0.2 g/L benzocaine; Cecala 2007). No mortality, however, was seen in another bufonid, *Bufo marinus*, using 1 g/L pure benzocaine dissolved in ethanol and water (Andersen & Wang 2002).

A topical xylocaine spray (10% solution) produced satisfactory anesthesia in two *Rana* species (Garcia Aguilar et al. 1999). High mortality was seen in *Rana pipiens* exposed to a commercial product containing lidocaine 2.5% and prilocaine 2.5% cream (Guenette & Lair 2006). Lidocaine administered subcutaneously in bullfrogs (*Lithobates catesbeianus*) resulted in dose-dependent sedation, with respiratory depression and loss of righting reflex, but did not provide local antinociception at the hindlimb injection site (Williams et al. 2017).

Injectable Anesthetic Drugs

Alfaxalone is a neuroactive steroid that potentiates GABA receptors. There have been a few studies in recent years evaluating its use as an anesthetic in amphibians. Generally, only sedation and light anesthesia are achieved, with intramuscular administration having more consistent results than immersion. As there are no antinociceptive properties, alfaxalone alone may be useful for restraint or noninvasive procedures, such as radiographs or blood collection, but is not appropriate as a single agent for surgical procedures (Adami et al. 2015; Posner et al. 2013; Sladakovic et al. 2014). A surgical anesthetic plane via immersion was achieved in oriental fire-bellied toads (*Bombina orientalis*) when morphine was added to alfaxalone in an immersion bath, and this combination could be considered in other species (Adami et al. 2016b). Surgical anesthesia via immersion was also described in a case report in an axolotl. Induction in a 5 mg/L immersion bath was followed with maintenance by irrigation of the external gills with the same solution, supplemented as necessary with additional drops of 10 mg/L solution (McMillan & Leece 2011). Most studies found that alfaxalone was safe and did not significantly affect heart rates. The most common adverse effects were decreased respiration and prolonged recoveries, particularly with higher doses (Adami et al. 2013; Posner et al. 2013; Sladakovic 2014). An increase in heart rate was observed in bullfrogs (*Lithobates catesbeianus*) administered intravascular and intramuscular alfaxalone (Williams et al. 2018).

Propofol is a short-acting intravenous anesthetic in mammals and reptiles that also potentiates GABA receptors. In amphibian species, intravenous administration is a challenge and the effects of propofol when given by alternate routes are highly variable. In *Rana pipiens* 10 mg/kg perivascularly in the sublingual plexus produced brief and light anesthesia following a short induction time (Lafortune et al. 2001). *Xenopus laevis* were induced to a brief light plane of anesthesia in an 88 mg/L immersion bath, but all animals died when exposed to bath concentrations of 175 mg/L or higher (Guenette et al. 2008). Surgical anesthesia was not achieved in either of these studies. Intracoelomic administration of 35 mg/kg in *Ambystoma tigrinum* did produce very brief surgical anesthesia after prolonged induction times (Mitchell 2009). Given the variability of reported dosages and routes of administration, and potential mortality at higher concentrations, recommendations for its use in amphibians are not possible. Differences in GABA receptor density between species may introduce further variability in the effect of these drugs among amphibians (Guenette et al. 2008).

Alpha-2 adrenergic agonists such as medetomidine and dexmedetomidine do not produce sedation in amphibians. Dexmedetomidine, when added to an alfaxalone immersion protocol, did provide some analgesia, but resulted in lightening of the anesthetic depth in

oriental fire-bellied toads (*Bombina orientalis*) (Adami et al. 2016b). Imidazole-based, nonbarbiturate hypnotic drugs, metomidate and etomidate, have been shown to achieve anesthesia in amphibians, but complications such as extremely prolonged recoveries in *Rana pipiens* and pruritus, myoclonus, and prolonged recoveries in *Bombina orientalis* make these drugs unsuitable as a sole anesthetic agent in these animals (d'Ovidio et al. 2015; Doss et al. 2014). They may be effective in gilled animals, as etomidate does produce anesthesia in fish and *Xenopus laevis* tadpoles (Plumb et al. 1983; Paris et al. 2007).

A variety of other injectable anesthetic agents, including ketamine, tiletamine/zolazepam, and various barbiturates, have been used. These agents are not recommended because they are less reliable than the topical and inhalant anesthetic agents. They are associated with large species variability in effect and produce significantly higher mortality rates.

Tortoises, Turtles, and Terrapins (Chelonians)

Alessio Vigani and Darryl Heard

Introduction

The order Chelonia includes almost 300 species of tortoises, turtles, and terrapins. They inhabit many different habitats, from tropical rain forests to deserts, from freshwater swamps to oceans. The wide variety of environments, dietary preferences, and activity levels explains the substantial differences in metabolic rate among chelonian species. They also differ significantly in body size, from the 0.1-kg adult Cape tortoise (*Homopus* spp.) to the 1000-kg adult leatherback sea turtle (*Dermochelys* coriacea) (Raphael 2003). Most tortoises are generally shy, harmless animals, but there are differences in temperament among chelonians. Many aquatic species are natural predators and often respond with aggression to potential threats. These species can be dangerous and require caution when handled.

Interventions in the field for research purposes and the management of patients in the hospital setting represent the main conditions where sedation and general anesthesia are needed. It follows the choice of the anesthetic protocol will depend on the invasiveness of the procedure and the environment where it will take place. Collection of diagnostic samples in the field generally only requires mild to moderate sedation and, ideally, wild animals should return to the wild without the risk of any residual anesthetic effect. For this purpose, sedative protocols that include short-acting and reversible agents are particularly suitable.

Invasive surgical procedures should be performed under general anesthesia in the controlled environment of a veterinary hospital. The facility should be equipped with specific anesthesia equipment and monitoring devices. Prior to anesthesia the patient should be thoroughly evaluated and acclimatized, homeostasis should be restored, and thermoregulation should be supported to optimize the response of the patient to the anesthetic. Appropriate analgesia should be provided to any patient that is to undergo a painful procedure. New information on the ability of reptiles, chelonians included, to feel pain underlines the responsibility of every veterinarian to properly prevent and manage pain in these species.

Furthermore, independently from the operative setting, prerequisites to the design of a safe anesthetic protocol are a good knowledge not only of the anatomy and physiology, but also of the species-specific differences in response to anesthetic drugs and dosages. Multiple studies have evaluated the efficacy of a variety of single or combined anesthetic and analgesic drugs in different chelonian species.

The perfect anesthetic agent does not exist for any species. There is no anesthetic drug devoid of side effects and even the most recently marketed agents produce dose-related toxicity. For this reason the use of combinations of small doses of multiple drugs has become popular in anesthesia (Turner et al. 2021). This anesthetic technique is referred to as *balanced anesthesia* and has been shown to be superior to single-agent anesthesia in humans and many veterinary species (Kushiro et al. 2005; Sanders et al. 2008). The explanation of its success is that the use of small doses summates the advantages, but not the disadvantages of the individual components of the mixture. It follows that the safety of the anesthetic protocol largely depends on the right choice of drugs, used at the adequate dose for the patient.

Anatomy and Physiology

Cardiovascular

The cardiovascular system is characterized by many morphological and functional peculiarities. The heart is three-chambered and valentine-shaped. It is located within the pericardial sac, at midline, above the cranial portion of the plastron, immediately cranial to the liver. The large right and left atria are distinct and open independently into an anatomically single but functionally divided ventricle. The

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

right atrium receives deoxygenated blood from the systemic venous circulation via a preatrial muscular, thin-walled chamber called the *sinus venosum*. The latter represents the confluence site of blood from the left and right precaval veins, the postcaval vein, and the left hepatic vein.

The cardiac muscle constituting the *sinus venosum* acts also as the pacemaker of the heart. This electrical activity is detectable on the electrocardiogram by the presence of an "SV wave" preceding atrial depolarization.

The left atrium receives oxygenated blood from the pulmonary circulation via the left and right pulmonary veins. The ventricular muscle is internally organized in a series of ridges that divide the ventricle into three functional chambers: *cavum pulmonale*, *cavum venosum*, *and cavum arteriosum*. Blood coming from the right atrium enters first the *cavum venosum* and then the *cavum pulmonale*, which has a direct pulmonary arterial output into the pulmonary trunk. Left atrial blood enters the *cavum arteriosum* and secondarily the *cavum venosum*, which opens into the systemic arterial systems via the left and right aortas (Farrell et al. 1998). It follows the *cavum venosum* receives both deoxygenated (directly from right atrium) and oxygenated blood (indirectly from the left atrium), with the potential for mixing of the two.

The ventricular anatomy is such that, in physiologic conditions of normal ventilation, there is a high degree of separation between the systemic and pulmonary circulations, with minimal mixing between venous and arterial blood. During ventilation, systemic ventricular output matches with the pulmonary ventricular output and intracardiac shunting is low. With the animal at rest, the physiological cardiac shunting in is bidirectional with coexistence of right-to-left and left-to-right components (Farrell et al. 1998).

The extraordinary adaptability of chelonians is fully displayed during apnea. The dive reflex induces complex physiologic changes, including modulation of intracardiac shunting (Hicks & Malvin 1992). During breath holding, the arterial tension of oxygen progressively decreases. This induces vasoconstriction of the pulmonary arterial vasculature and causes a substantial decrease in pulmonary blood flow (Crossley et al. 1998). During apnea in turtles, the increased pulmonary arterial pressure causes the systemic venous return to be preferentially directed into the systemic circulation (R-L shunt), bypassing the lungs. This mechanism produces an oxygen-sparing effect in the lungs (Jackson 2000). Aquatic, and to a lesser extent terrestrial, chelonians have been shown to develop right-to-left intracardiac shunting in hypoxic conditions (Hicks et al. 1996). During ventilatory periods, the cardiovascular changes are the reciprocals of those occurring during apnea: the heart rate increases, the pulmonary vascular resistance falls, and pulmonary blood flow is maximized. Blood flow measurements indicate a net formation of a left-to-right shunt during ventilation which increases hemoglobin oxygen saturation of pulmonary arterial blood (Shelton & Burggren 1976). Low rates of elimination of inhalant anesthetics, such as isoflurane or sevoflurane, can be expected whenever cardiac shunting exists.

Hypoxemia and the subsequent right-to-left shunt trigger a generalized hypometabolic state (Hicks & Wang 1999). This hypometabolic condition significantly decreases the hepatic function with a potential detrimental effect on the clearance of drugs (Platzack & Hicks 2001). Therefore, it is important to provide ventilation and oxygenation during anesthesia to maintain a steady cardiovascular and metabolic state. Once cardiac shunting is present, it may be difficult to provide oxygen supplementation.

The direction (right-to-left vs. left-to-right) and size of shunting in chelonians are influenced by multiple factors that control cardiac function. These include both adrenergic and cholinergic innervation. Stimulation of the vagus nerve in tortoises results in an increase in pulmonary arterial pressure and net formation of right-to-left shunt (Hicks & Comeau 1994). In contrast, epinephrine or the stimulation of the cardiac sympathetic nerves abolish right-to-left shunting and induce vasodilation of the pulmonary vasculature. In *Trachemys scripta* it has been shown the infusion of epinephrine increases the blood flow in the pulmonary circulation (left-to-right shunt) and eliminates the systemic venous admixture in the aortic arches (Hicks & Malvin 1992).

An additional important factor that modulates cardiac shunting is thermoregulation. Variation of body temperature from the physiologic optimal conditions has major effects on the circulatory system (Krosniunas & Hicks 2003). At normal body temperature the intracardiac shunting is relatively stable, with a small right-to-left shunt. Interestingly, both heating and cooling result in the development of an increased R-L intracardiac shunt (Galli et al. 2004). The ability to selectively shunt blood flow away from the pulmonary circulation is likely the cause of prolonged recoveries from inhalant anesthesia. Therefore, during anesthesia the maintenance of steady physiologic thermal conditions is important to provide optimal gas exchange, including inhaled anesthetics.

The renal portal system (RPS) maintains sufficient blood flow to the renal tubules at times when a decreased effective circulating volume generates a low glomerular blood flow. The portal vein is a large vessel that enters the kidney and originates at the confluence of the epigastric and external iliac veins. It contains muscular valves capable of shunting blood from the caudal half of the body directly to

the kidney. Hydration status seems to play a primary role in the activity of the RPS and affects the degree of shunting. Dehydration causes an increased diversion of blood. The blood in the RPS is exposed to the renal tubular surface and this may result in increased clearance of drugs normally excreted through the tubules into the urine. Angiographic studies have also shown a large amount of venous blood from the hindlimbs is directed to the liver (Holz et al. 1997b), therefore renal and hepatic levels of some drugs injected into the caudal limbs may be unpredictable. It has been demonstrated, however, that the injection site is unlikely to have any influence over the activity of most drugs and the caudal half of a chelonian is available for drug administration (Holz et al. 1997a). For example carbenicillin, a drug largely excreted by tubular secretion, was injected into the hindlimbs of turtles. The systemic blood levels of the drug obtained were just slightly lower compared to the forelimb injection (Holz et al. 1997b). Whether the same scenario applies to drugs injected into the dorsal venous sinus of the chelonian tail remains unclear. In green iguanas (*Iguana iguana*), the venous flow from the tail was found to directly enter the kidney through the renal portal circulation (Benson & Forrest 1999). Until adequately investigated, it is advisable not to use the dorsal venous sinus for drug administration in dehydrated chelonians.

Respiratory System

Chelonians are obligate nasal breathers. Open-mouth breathing indicates decreased airflow through the nasal cavities, possibly due to pathology. The external nares open into a keratinized vestibule divided symmetrically by a cartilaginous septum into right and left nasal chambers. The nasal chambers lie above the hard palate and extend aborally into the oropharynx through a ventral recess. Turbinates, sinuses, and soft palate are absent. The glottis is located at the base of the tongue, with species-specific differences in morphology. In aquatic species in particular, it is characterized by a strong muscular component needed to provide efficient sealing of the distal airways during immersion. The trachea is composed of complete rings, is relatively short, and bifurcates in paired bronchi at the level of the mid-cervical region (McArthur et al. 2004). It is therefore easy to unilaterally intubate most chelonians.

The lungs are located dorsally in the coelomic cavity and their dorsal surface is attached to the carapace. All chelonians have multichambered lungs with paired unbranched intrapulmonary bronchi reinforced by cartilage over their entire length. In sea turtles, the intrapulmonary bronchi are supported by cartilaginous rings, are broad cranially, and taper caudally. In other chelonians, the bronchi are uniform in diameter for their entire length, and the supporting cartilage forms a network instead of separate rings. Each bronchus opens into three to 11 chambers from which multiple subcompartments, referred to as "niches", originate. The chelonian analogues of mammalian alveoli are termed "faveoli", "ediculae", and " trabeculae" and represent the parenchymal gas exchange units (Perry 1998).

The presence of the carapace impedes the costal component of ventilation, therefore muscle-induced movements of the viscera and limbs are responsible for alterations in intrapulmonary pressure. Chelonians do not possess a functional muscular diaphragm. A horizontal septum, or pseudodiaphragm, separates the lungs form other intracoelomic organs. In some chelonians, such as sea turtles, the horizontal septum is extensive and attaches the liver and stomach to the ventral surface of the lung. This attachment maximizes the transmission of the movement of the body wall and limb girdles through the visceral mass to the lungs. Limb movements stretch the septum downward, causing expansion of the lungs. The lung expansion generates a negative intrapulmonary pressure and facilitates the passive inflow of air during inspiration. The "muscle pump" mechanism is abolished by immobility; subsequently ventilation is profoundly depressed during anesthesia. Ventilatory artificial support by intermittent positive pressure ventilation (IPPV) is therefore always recommended in anesthetized chelonians. IPPV can be provided either manually or mechanically with a ventilator.

Chelonians are unable to cough and lack effective ciliary clearance of respiratory material. This explains why their ability at clearing secretions and foreign material from their lower respiratory tract is very poor. Consequently, inflammatory exudates tend to accumulate in dependent area of the lungs with severe effects on respiratory function and gas exchanges. The innate resilience of chelonians, however, allows them to withstand extreme physiologic perturbations, such as severe hypoxemia or hypercapnia, and clinical signs of respiratory distress occur late in the course of the primary disease (McArthur et al. 2004).

Reptiles, compared to avian and mammalian species, have a relatively large lung volume which is distributed a relatively small respiratory surface area. The multichambered lungs of chelonians, however, represent the advantage of a more complex surface elaboration compared to the single-chambered lungs of other reptiles. Studies in red-eared sliders (*Trachemys scripta*) showed the septa that divide the pulmonary chambers provide a 40% larger surface area used for gas exchanges compared to the outer wall of the lungs. This yields effective gas exchange to cover metabolic requirements (Perry 1998).

Respiration is characterized by intermittent breathing patterns with ventilatory periods alternated with nonventilatory

pauses. The respiratory cycle in terrestrial species consists of a passive inspiratory followed by an active expiratory phase. The latter is reversed in aquatic species. These peculiarities, along with the high compliance values of chelonian lungs, produce a significantly lower work of breathing compared to mammals. In regard to anesthesia, however, the chelonian highly compliant lungs are extremely easy to inflate and hence highly sensitive to barotrauma (Herman et al. 1997). It is therefore recommended that low peak inspiratory pressures be used during IPPV.

The need to maintain the low-energy requirements of ventilation is also reflected by the adaptive mechanisms that chelonians operate in response to increased metabolic stress. Increasing tidal volume is ineffective and represents a major energy expense in chelonians. This explains why most tortoises and turtles during activity increase their minute ventilation by increasing respiratory rate and not tidal volume. In regard to the diving mechanisms of ventilation, hypoxemia and hypercarbia affect the length of respiratory cycles differently. Hypoxemia induces bradypnea while hypercapnia causes tachypnea. The explanations of these opposite effects are oxygen preservation and the elimination of carbon dioxide, respectively. Conversely, the artificial induction of either hyperoxia or hypocapnia independently from one another causes persistent cessation of spontaneous ventilation (Wang et al. 1998). Therefore, the maintenance of blood gas variables within physiologic range is critical during anesthesia to avoid long-lasting alteration of ventilatory function.

Many chelonians can perceive a low oxygen environment and develop a cardiorespiratory response similar to the dive reflex described in mammals. They become apneic, bradycardic, and convert to anaerobic metabolism. These physiological changes, combined with cardiac shunting, facilitate diving and hibernation, but complicate the use of inhaled anesthetic agents. The alterations in respiratory circulation typical of the chelonian dive reflex can affect the uptake and excretion rates of inhalant anesthetics.

Pain and Nociception

Pain and nociception are often mistakenly considered synonymous. Pain is inherently subjective, and in animals is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. Pain represents the interpretation by the cerebral cortex of a noxious stimulus and consciousness, therefore, is a prerequisite to feel pain. Nociception instead refers to the physiologic or neuroanatomical components necessary to sense and transmit the noxious stimuli to the brain (IASP 1994). Any organism that has developed these neuroanatomical structures is defined as sentient. In a sentient animal, therefore, nociception persists during unconsciousness and anesthesia unless analgesic interventions are provided (Giordano 2005).

Multiple studies in different reptile species have demonstrated the presence of the neuroanatomical apparatus for sentience and nociception (Liang & Terashima 1993; ten Donkelaar and de Boer-van Huizen 1987). It has been shown that environmental stimuli elicit impulse transmission from sensory receptors, through the spinal cord, to the animal's brain. Furthermore, the reptile cerebral structures are operationally sophisticated enough to convert the impulses into perceived sensations (Giordano 2005). The opioid receptor gene family is highly conserved across multiple vertebrate orders, and new information is now available on opioid receptors and their modulation in chelonians (Reiner 1987; Li et al. 1996). For example, mu (μ) and delta (δ) opioid receptors are located throughout the brain in aquatic turtles, with δ opioid receptors being more abundant than μ opioid receptors (Xia & Haddad 2001). With respect to endogenous opioid related neurotransmitters, proenkephalin and other neuropeptides (i.e., neuropeptide FF) are present in the brain of turtles with a distribution similar to that in mammals and birds (Munoz et al. 2008). New information is also now available on the role of the different opioid receptors in nociception and analgesia in chelonians (Sladky et al. 2009). For example, kappa (κ) opioid receptors are significantly less involved in nociception and pain compared to μ opioid receptors. κ receptor agonists do not produce any detectable analgesic effect in turtles whereas agents with μ agonist activity significantly increase the nociceptive threshold (Wambugu et al. 2010).

In nonverbal species, suffering is expressed in the form of behavioral changes that are often not obvious to the observer (Holton et al. 2001; Holsti et al. 2008). Chelonians are not an exception. It follows, independently from the inability of these animals to show evident expressions of pain, veterinarians should consider chelonians are capable of suffering when a noxious stimulus in applied, and therefore they should be provided with appropriate analgesia.

Perianesthetic Considerations and Patient Management

Preanesthetic Assessment

A complete history provides crucial information regarding the patient's environment, husbandry, and diet, and helps to determine duration and severity of clinical signs of the medical condition. The observation of the unstressed patient is important to determine the level of activity of the patient unbiased by any restraint.

Ideally, prior to anesthesia, the patient should be acclimatized to the new environment and the room temperature and humidity should be set within the ideal range for the species. This obviously does not apply to emergency cases where immediate intervention is required. As with all ectotherms, chelonian body temperature is reliant on the environmental temperature. The preferred optimal temperature zone (POTZ) refers to the ideal environmental temperature range selected by a particular species. Each species has its own POTZ and it is only when the animal is in its POTZ that its physiology is functioning at its best. For most chelonians, data regarding optimal environmental temperature and humidity can be found in the literature. If the specific POTZ is uncertain, exposure to a room temperature range of 24–28°C during preanesthetic stabilization seems to be appropriate for most chelonian species (McArthur et al. 2004).

Body temperature should be measured prior to anesthesia. Oscillations in body temperature in ectothermic species are common and it is important to identify and correct wide variations from the normal range. All chelonians have what is referred to as an active temperature range (ATR). This is the body temperature range where they are capable of normal, voluntary activity. Each species has a different ATR (McArthur et al. 2004). Critically ill patients are often hypothermic and the prompt restoration of normothermia is of critical importance to maximize the chance of patient stabilization. On the other hand, overheating should also be carefully avoided. Hypothermia and hyperthermia have significant effects on metabolic rate (drug clearance), acid base status, intracardiac shunting (respiratory gas exchanges and inhalant anesthetic uptake and clearance), and inhalant agent potency (decreased minimum alveolar concentration [MAC] during hypothermia). Therefore, attention to maintaining normothermia in the perianesthetic period is a priority for the anesthetist.

The preanesthetic physical examination consists of the assessment of systems and organs, and should include a preliminary visual examination aimed at determining body condition, nutritional and hydration status, and presence of trauma. Body weight must be recorded to ensure accurate dosing of anesthetics.

A basic assessment of the cardiovascular system of the patient should be performed prior to anesthesia. Heart rate and pulse rate and strength can be evaluated noninvasively with a Doppler flow detector. Pencil and flat probes are selected based on the size of the animal and the location where the probe must be placed. For cardiac auscultation a pencil probe can be placed lateral to the neck at the level of the coelomic (thoracic inlet) (Fig. 10.1). For pulse assessment, a flat probe can detect blood flow in vessels directly beneath the probe. Suitable arteries for pulse assessment are the carotid and femoral artery (McArthur 2007). Several formulas to determine the normal heart rate based on body

Figure 10.1 (a) Appropriate positioning of a Doppler pencil flow probe in the coelomic inlet to assess blood flow and heart rate in a semi-awake wood turtle (*Glyptemys insculpta*). (b) An anesthetized freshwater turtle with a Doppler pencil flow probe placed in the coelomic inlet for continuous blood flow and heart rate monitoring. Note also the use of a soft mouth gag and a portable ECG.

weight in reptiles have been given by different authors. However, the absence of validation studies and the significant physiologic differences between species often make those equations clinically inadequate for predicting heart rate.

Baseline respiratory rate and depth are measured before induction. Identification of even mild signs of respiratory disease should be considered as an expression of potentially severe respiratory illness. Chronic respiratory disease is fairly common, and chelonians are able to withstand extensive injury to the respiratory system before showing signs of distress.

Ideally when planning elective procedures, a venous blood sample should be collected prior to anesthesia for hematologic and plasma biochemical evaluation. Blood should be collected into lithium heparin tubes as EDTA causes lysis of reptilian erythrocytes. As a general rule, the sample size should not be larger than 1% of the body weight of the subject. Abnormalities in the laboratory variables of special interest for the anesthesiologist are represented by, but not limited to, the presence of anemia or hemoconcentration, hypoproteinemia, hypoglycemia, hyperuricemia, and electrolytes and acid-base imbalances. The presence of any of the above abnormalities warrants further investigation to identify the underlying cause and properly treat prior to anesthesia.

The patient's hydration status should be assessed based on history, physical examination, and laboratory findings. At present, however, the evaluation of hydration status is still somewhat subjective. Indications of dehydration are sunken eyes, reduced skin turgor, and hematological and plasma biochemical alterations such as hemoconcentration and hyperproteinemia (McArthur 2004). Ion pump activation and significant fluid reabsorption by the lower urinary and digestive tracts complicate the use of many variables as indicators of hydration. In most reptiles, approximately 75% of body weight is water. In chelonians, the presence of the carapace reduces the value closer to that found in mammals, which is approximately 66%. However, in contrast to mammals, the total body water is equally distributed between the intra- and extracellular fluid compartments and 30% of the extracellular fluid volume exists in the intravascular space (Smits & Kozubowski 1985). These differences should be considered to accurately plan and administer fluids to chelonians.

Differences in response to various inhaled and injectable sedatives and anesthetics have also been shown between chelonian species. The drugs and doses effective and safe in one species may not apply to other chelonians.

Handling of Dangerous Chelonians

Chelonians generally do not need significant restraint during examination and most herbivorous animals can be handled with no real risk of danger to the personnel. However, aggressive and potentially dangerous species represent exceptions. Snapping turtles (*Chelydra* spp.), soft-shell turtles (*Trionyx* spp.), and marine chelonians may show unpredictable, aggressive reactions and these large animals can inflict serious injuries with their beaks and claws. These species should be handled with extreme caution. Wearing heavy-duty gloves is recommended, but serious bite injuries can still occur despite their use. These animals can be examined more safely after they have bitten or locked on nontraumatic objects such as a PVC pipe. Alternatively, a suitably sized container can be placed over the head to prevent biting when injecting into the pectoral muscles. When working with aggressive species, the help of an assistant is often necessary.

Smaller marine, snapping, and soft-shell turtles can be held with a hand on either side of the carapace, with the head directed away from the operator and other people (Fig. 10.2). Turtles of the genera *Chelydra* and *Trionyx* are able to extend their head up to the level of their hindlimbs. It is important to determine the "safe zone" around the animal. Medium-sized (10–40 kg) marine and snapping turtles are better controlled with one hand around the nuchal scute (cranial carapace above the neck) and the other on the caudal carapace (Fig. 10.3). Very large individuals of these species are capable of incredible strength and stretchers or canvas slings should be used during maneuvering procedures. Marine chelonians should never be picked up by their flippers. This is due to the risk of causing luxations and fractures. The handler should also be prepared for a

Figure 10.2 Appropriate physical restraint of a medium-size (15 kg) alligator snapping turtle (*Macrochelys temminckii*). Note the position of the hands on either side of the shell. The use of reinforced gloves provides additional protection from the claws.

Figure 10.3 Physical restraint of a large (30-kg) alligator snapping turtle (*Macrochelys temminckii*). The animal is controlled with one hand on the nucal scute and the other on the caudal carapace. The head of the animal is directed away from the operator.

rapid burst of struggling and flipper flapping when a marine turtle is first lifted out of water or its enclosure.

While necessary in some cases, chemical immobilization should be considered as a last resort in a simple physical examination procedure. Whenever sedation is used, an aquatic animal must not be reintroduced into water until it is fully recovered to avoid the risk of drowning.

Venipuncture and Intravenous Catheterization

Venipuncture and venous catheterization for phlebotomy and drug or fluids administration purposes are difficult. The diversity in morphology of turtles and tortoises precludes any single dependable venipuncture site for all species. Therefore, it is important to know the location of multiple potential sites and select the most appropriate for the individual species. Venipuncture sites previously described include the jugular veins, dorsal cervical sinus, subcarapacial (subvertebral) sinus, and the dorsal coccygeal vein (Lloyd & Morris 1999). Other peripheral venipuncture sites, where only small blood samples can be obtained, are the radio-humeral venous plexus and the femoral vein. These sites may be more yielding in larger animals.

It is recommended blood collection be from the jugular veins when possible. Samples taken from the jugular site are least likely to be lymph diluted (Jacobson et al. 1992). The external and internal jugular veins are located on either side of the neck in many chelonian species. The external jugular veins lie higher on the neck compared to mammals. Either can be used for venipuncture. The external jugular vein is larger and located in a lateral to dorsolateral position. It runs approximately in a line from the dorsal edge of the tympanic membrane parallel to the dorsal plane of the neck in the direction of the thoracic inlet (Fig. 10.4). Extension of the neck is needed to allow the jugular vein to be raised and seen. This is possible in many small chelonians, but in large individuals (>10 kg) or aggressive species such as snapping turtles, it is often impossible without adequate chemical restraint. Should the jugular site prove impractical, the subcarapacial sinus or the dorsal coccygeal vein may represent good alternatives, particularly for intravenous (IV) drug administration.

The subcarapacial venous sinus can be easily accessible in small chelonians (<10 kg) (Fig. 10.5). It is located under the carapace, on the dorsal midline, at the junction of the common intercostal and the caudal branch of the external jugular veins, just cranial to the eight cervical vertebra (Hernandez-Divers & Hernandez-Divers 2002). Although the presence of clear liquid in the syringe at this site has often been attributed to lymph, it is most likely to be cerebrospinal fluid. Consequently, the subcarapacial vein is not recommended for injection of anesthetic drugs, except for euthanasia (Quesada et al. 2010).

The dorsal coccygeal vein is a safe and dependable venipuncture site in snapping turtles (Fig. 10.6). The dorsal coccygeal vein runs in the dorsal midline from the tip of the tail to the carapace. Blood samples from this site can be unpredictably lymphodiluted, therefore, when clear fluid

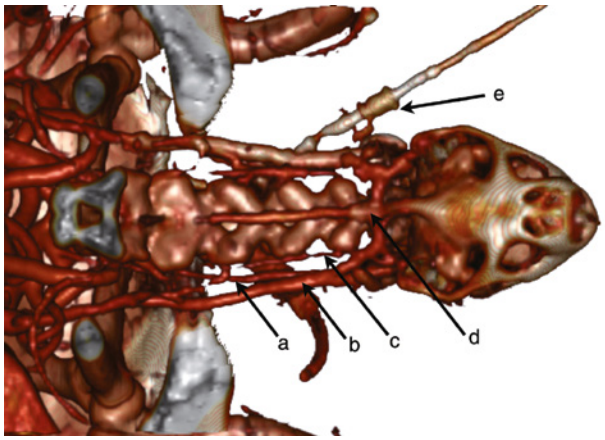

Figure 10.4 CT-scan 3D reconstruction of the neck of the Gopher tortoise (*Gopherus polyphemus*). The vascular structures are identified as follows: (a) carotid artery, (b) external jugular vein, (c) internal jugular vein, (d) occipital venous sinus. (e) indicates an intravenous catheter placed in the left external jugular vein.

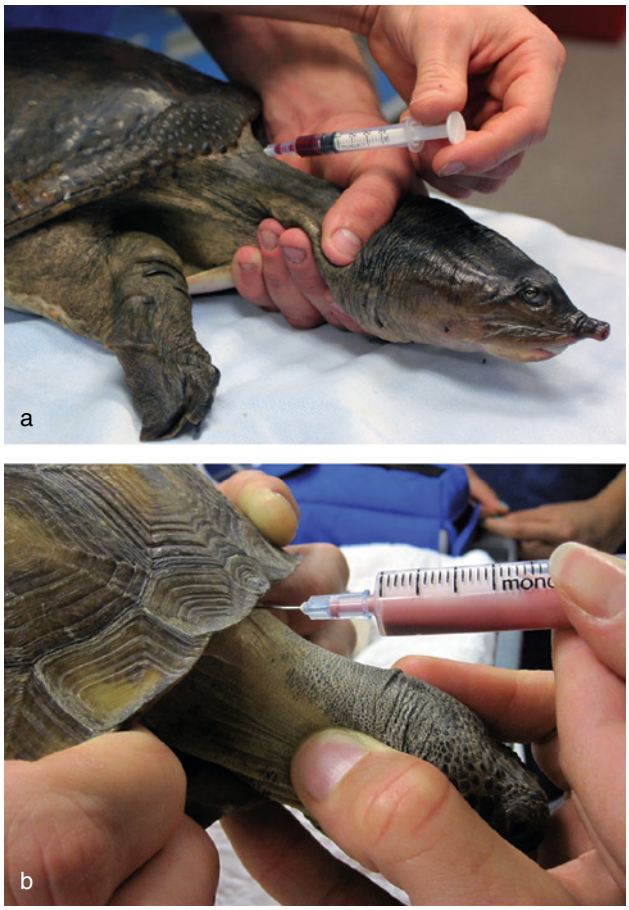

Figure 10.5 Use of the subcarapacial venous sinus for (a) blood withdrawal in a Florida soft-shell turtle (*Apalone ferox*) and (b) intravenous injection of propofol in a gopher tortoise (*Gopherus polyphemus*). The needle is inserted on the midline of the neck, at the junction between the skin and the carapacial nucal scute. The needle is advanced caudally while maintaining gentle negative aspiration on the syringe until blood is flowing into the chamber.

is sampled, another attempt should be made at a different site. The vessel is occasionally more superficial then expected and a needle which is inserted between the vertebrae too deep has the potential to enter the vertebral canal, therefore accurate disinfection of the skin of the tail is mandatory before attempting venipuncture.

In marine turtles the dorsal cervical sinus is a reliable venipuncture site and it is popular with those working with these chelonians. It is useful both for blood withdrawal and IV injections. The paired sinuses are parallel to the midline and are located on either side, 0.5–1 cm away from the dorsal spinous processes of the proximal cervical vertebrae. They are found 0.5–3 cm deep depending on the size of the animal.

Suitable anatomical locations for IV catheter placement are limited; the jugular veins are usually the only option.

Figure 10.6 Venipunture in an alligator snapping turtle (*Macrochelys temminckii*) using the dorsal approach to access the dorsal coccygeal vein. The main advantage of this venipuncture site is represented by its location in the "safe zone" around the animal. For safety, an assistant should restrain the animal during the venipuncture procedure.

Figure 10.7 A single-lumen jugular catheter placed in the external jugular vein of a green sea turtle (*Chelonia mydas*). The catheter was inserted using an over-the-wire technique. The winged proximal portion is secured to the skin with sutures.

Jugular catheter placement can be performed with either a venous cut-down or percutaneously. Prior sedation is recommended and often necessary for a successful catheter placement. In general, over-the-needle, 22–18-gauge, 2–4-cm long IV catheters can be used for short-term placement. When long-term venous access is required, indwelling polyurethane or silicon central venous catheters should be used (Fig. 10.7). This author (A. Vigani) recommends the use of the standard Seldinger technique (over-the-wire) for percutaneous placement of long-term catheters (Fig. 10.8) (Pardo & Divers 2016).

Figure 10.8 Placement of a long-term jugular catheter in an Aldabra tortoise (*Aldabrachelys gigantea*). In the anesthetized animal, the external jugular vein is identified by palpation of the dorso-lateral aspect of either side of the neck. A hollow needle is advanced through the skin until blood is aspirated. The catheter is then inserted using the Seldinger technique: a blunt guidewire is passed through the needle (a), then the needle is removed. A dilating device may be passed over the guide wire to slightly enlarge the vessel. Finally, the central line itself is then passed over the guidewire, which is then removed. All the lumens of the line are aspirated and flushed. The catheter is finally secured with sutures to the skin (b).

Intraosseous catheterization is very difficult to impossible in most chelonians due to the density of their bones and the small intramedullary spaces. In giant tortoises, however, the best site for placement of an intraosseous catheter appears to be the gular scutes at the front of the plastron (Heard, pers. comm.). This area was originally identified using a CAT scan. A small hole sufficient to accommodate a 2–3-inch (5–8-cm), 22-gauge spinal needle is first drilled through outer gular scute. The needle is then placed and secured to the shell with glue or putty (e.g., Loctite All Purpose Repair Putty). Once it hardens the latter provides excellent adhesion to the shell.

Fluid Therapy

When a fluid deficit is clearly identified or the hydration status of the patient is unknown, perianesthetic fluid therapy is indicated to replace the deficit in active circulating volume and restore tissue perfusion and homeostasis. Hypotonic fluids such as 5% dextrose in water (D5W) generally diffuse primarily in the intracellular space whereas isotonic crystalloids contain a sodium concentration similar to that of the extracellular space, making them the ideal solution for replacing extracellular volume deficits.

There is still debate on the best type of fluids to administer to reptiles given their blood is hypotonic compared to birds and mammals. There are several guidelines for fluid replacement in reptiles, but most of the standard crystalloids, such as lactated or acetated Ringer's, and normal saline solutions can safely be used. Two recipes of isotonic solution are diluted saline (9 parts 0.9% NaCl and 1 part sterile water) and Reptile Ringer's (2 parts 2.5% dextrose/0.45% saline with 1 part lactated Ringer's). It is generally accepted a rate of 25 mL/kg every 24 hours is appropriate as a rehydrating rate. In chelonians, total fluids given at one time should not exceed 2–3% of total body weight (Norton 2005). Constant rate infusion is preferable over intermittent boluses. Fluids can be administered orally, intravenously, or intracoelomically. Oral rehydration is recommended for clinically stable, mildly to moderately dehydrated patients, whereas the IV route is preferred in severely dehydrated patients. Intracoelomic fluids should be avoided in patients with present or suspected respiratory disease, intracoelomic space-occupying lesion, obstipation, and egg retention (McArthur 2004).

Traumatized patients that have suffered severe hemorrhage should be promptly fluid resuscitated. In these cases the IV route is considered ideal for fluid administration. In these patients, however, the low intravascular volume and vasoconstriction often limit IV access.

In the presence of life-threatening hypovolemia, the IV administration of hypertonic solutions (i.e., 7.5% NaCl) and colloids (hydroxyethyl starches and dextrans) is indicated to provide selective intravascular volume expansion. The recommended doses of hypertonic solutions and colloids in mammals are 2–4 and 5–10 mL/kg, respectively. The safety of such indications has not been proved in chelonians. Thus, the author (A. Vigani) recommends starting with lower initial volumes (1–2 mL/kg) and then reassessing the response of the patient.

Analgesia

Sladky (2023) provides an excellent review of the current literature on pain assessment and analgesia in reptiles.

A survey of the use of analgesics by reptile veterinarians almost 20 years ago indicated analgesia is withheld in more than 50% of the patients by more that 60% of the responders (Read 2004). This finding may be partially explained by our inability to detect pain in reptiles due to the lack of definitive information on behaviors proven to be pathognomonic of pain. Ultimately, pain assessment is made even more difficult by the evidence reptiles seem to voluntarily suppress pain-related behaviors when they are observed (Fleming & Robertson 2006; Sladky 2023). Sadly, for all these reasons, pain control in reptiles has been largely overlooked. The current knowledge and better understanding of pain perception in reptiles support the importance of providing appropriate analgesia whenever an invasive procedure is performed. Sladky (2023) provides an excellent review of the current literature on pain assessment and analgesia in reptiles.

Opioids

Among opioid analgesics, morphine has been shown to provide analgesia in chelonians whereas butorphanol, even at dosages largely exceeding the mammalian therapeutic doses, did not have any effect on thermal threshold (Sladky et al. 2007). The analgesic action of morphine (1.5 mg/kg) in chelonians appears to have a time of onset of 2–8 hours post administration and duration of more than 24 hours. Unfortunately, this analgesic effect is coupled with a significant, long-lasting respiratory depression (Sladky et al. 2007). Meperidine, a synthetic μ pure agonist, induced significant decrease in the duration of limb retraction after formalin injection in Speke's hinged tortoise (*Kinixy's spekii*) at a dose of 20 mg/kg. This drug appears to provide a degree of analgesia equivalent to morphine (Wambugu et al. 2010). Pharmacokinetic data of buprenorphine in red-eared sliders (*Trachemys scripta elegans*) established the subcutaneous administration of 0.075–0.1 mg/kg every 24 hours is sufficient to maintain plasma drug concentrations considered analgesic for humans (Kummrow et al. 2008). The analgesic effect of buprenorphine in chelonians has not been evaluated. Tramadol, an atypical synthetic opioid, has been recently shown to provide long-lasting analgesia in chelonians with minimal respiratory depression. In red-eared sliders (*Trachemys scripta elegans*), the oral administration of 10–25 mg/kg increased thermal threshold for up to 96 hours (Baker et al. 2011). These dosages are much higher than those generally used in clinical practice (0.5–4 mg/kg). Preservative-free morphine can also be administered intrathecally for prolonged analgesia of 24–48 hours' duration (Mans 2014).

Nonsteroidal Anti-inflammatory Agents

Nonsteroidal anti-inflammatory agents (NSAIDs) are widely used in reptiles based on their proven potent analgesic activity in mammals. Interestingly, there is no proven scientific evidence of the analgesic activity of NSAIDs in chelonians. This could be due to our incapacity to effectively assess pain. To the authors' knowledge a limited number of studies evaluated pharmacokinetics and pharmacodynamics of NSAIDs in chelonians. In green iguanas (*Iguana iguana*) the oral administration of meloxicam at 0.2 mg/kg resulted in plasma concentrations considered analgesic for mammals (Divers et al. 2010). In loggerhead sea turtles (*Careta careta*), it was shown that the clearance of meloxicam was significantly higher than reported for the iguana, suggesting the need for more frequent dose intervals to maintain effective plasma concentrations (Soloperto et al. 2012). This may not, however, correlate with analgesia because the plasma concentration of NSAIDs does not directly correlate with clinical effect.

The safety of the use of NSAIDs in reptiles has been evaluated in studies involving repeated daily administrations. No significant biochemical abnormalities or histopathological lesions were seen with meloxicam (Hernandez-Divers et al. 2004). Despite this, it is still possible NSAIDs can cause severe side effects, as reported in mammals. Normal hydration status and renal function should always be ensured prior to NSAID administration. Although the clinical use of NSAIDs in reptiles does not appear to delay wound healing, it has been shown that the administration of selective NSAIDs cyclooxygenase-2 inhibitors to geckos after tail amputation significantly retards the regenerative process (Sharma & Suresh 2008).

Local and Regional Anesthesia

Local anesthesia represents an irreplaceable component of a multimodal anesthetic approach. Local anesthetics prevent the transmission of nerve impulses by interrupting the sodium influx into the neurons. In sensory nerve fibers, the signal from a noxious stimulus is then stopped at its origin and is prevented from reaching the central nervous system. Local anesthetic agents vary in potency and duration of action. Lidocaine and bupivacaine represent the most commonly used agents in veterinary practice. Bupivacaine is more potent and longer acting compared to lidocaine, but the actual duration of action in reptiles is undetermined. In chelonians, the local injection of local anesthetics is useful for facilitating minor surgical interventions, but local anesthesia alone is not sufficient to provide analgesia for more invasive procedures. The infiltraton around the surgical site (local block) represents the most

diffuse use of local anesthetics in chelonians, but more advanced techniques have also been described (Hernandez-Divers et al. 2009).

Brachial nerve blockade for forelimb surgery has been evaluated (Mones et al. 2021, 2023) in eastern box turtles (*Terrepene carolina carolina*). Unfortunately, the technique was unreliable in producing brachial plexus motor and sensory blockade, and further research is required to identify an effective and consistent technique (Mones et al. 2023).

Mans (2014) summarizes intrathecal administration of preservative-free local anesthetics and opioids for surgical anesthesia of the hind end and for prolonged analgesia, respectively. Lidocaine (2%) injected intrathecally at an approximate dose of 1 mL per 25 kg in hybrid Galapagos tortoises (*Geochelone nigra*) was sufficient to perform phallectomy (Rivera et al. 2011). The technique provided adequate analgesia, without the need for supplemental systemic analgesics. The ambulatory function returned to normal within 60 minutes after administration in all the animals in the study.

The short analgesic effect limits the single administration use of local anesthetics to the perioperative period. To provide prolonged analgesia using local anesthetics, repeated administrations are required. For this purpose, the placement of long-term intrathecal catheters is possible in chelonians (Fig. 10.9).

Spinal anesthesia was used for surgical removal of cutaneous fibropapillomas in green sea turtles (*Chelonia mydas*) (Futema et al. 2020). Animals were administered 2% lidocaine (0.2 mL/10 cm of carapace) in the epidural/subarachnoid space of the tail. The technique was effective for all animals, with fast onset of motor and sensory blockade (3 ± 1.76 minutes) and relatively fast recovery time (83.9 ± 16.2 minutes). Fibropapillomas were removed from all animals with no signs of pain (i.e., no behavioral response during surgical procedure, such as head and forelimb movement, showing discomfort).

Although the authors are unaware of any toxicity studies in chelonians, the safe dosages for local anesthetics (lidocaine <10 mg/kg and bupivacaine <2 mg/kg) appear similar to those of mammals. The analgesic agents for which pharmacokinetic and pharmacodynamic data are currently available in chelonians are listed in Table 10.1 and summarized by Sladky (2023).

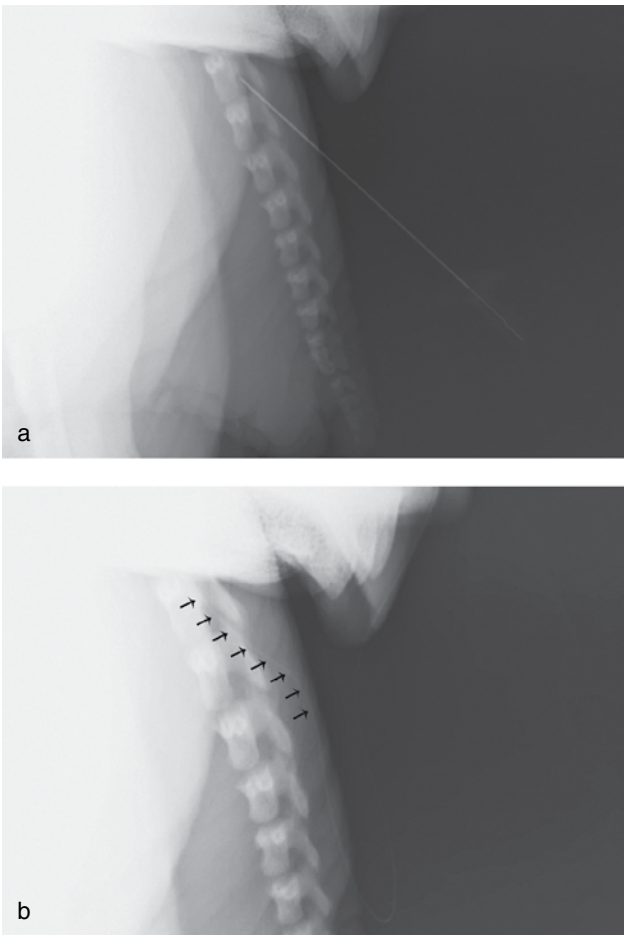

Figure 10.9 Lateral radiographic views of the placement of an inthathecal catheter in a Galapagos tortoise (*Chelonoidis nigra*). A Tuohy needle is slowly advanced between the spinous processes of two consecutive coccygeal vertebrae and placed in the vertebral canal (a) into the intrathecal space (space between dura mater and leptomeninx). The catheter is threaded through the needle and advanced a few centimeters into the vertebral canal (b). The needle is then withdrawn over the catheter. The catheter is secured to the skin with sutures to prevent it becoming dislodged. The catheter can be used for repeated administrations of analgesics and local anesthetics. The small black arrows indicate the catheter placed into the intrathecal space. Courtesy of the University of Florida.

Anesthetic Induction and Maintenance

Generally, induction and maintenance of anesthesia are relatively simple, but at times they can be particularly challenging and frustrating to the anesthetist.

Mask induction with inhaled anesthetics can be used, but is associated with pronged induction times and is not recommended for use alone. Aquatic species are well adapted to the episodic breathing pattern and able to stay apneic for very extensive periods of time, preventing the adequate delivery of inhaled anesthetic (Bienzle & Boyd 1992). Inducing respiration by gently moving the forelimbs forwards and backwards may reduce induction times.

Awake intubation and induction is more effective, but stressful to the animal. The mouth is forcibly opened and

Table 10.1 Analgesic agents used in chelonian species.

Drug	Dose (mg/kg)	Route	Analgesic Activity	Comments	Source
Buprenophine	0.075–0.1	IV, IM	Not established	Elevated drug plasma concentrations up to 24 hours	Kummrow et al. (2008)
Butorphanol	2.8–28	IM, IV	None	No analgesic effect even at high doses; at high doses prolonged respiratory depression	Sladky et al. (2007)
Lidocaine	0.8	Intrathecal	Good	Duration of analgesia up to 60 minutes; temporary paraparesis can occur	Rivera et al. (2011)
Lidocaine	1	SQ (local infiltration)	Moderate	Used alone not sufficient analgesia for celioscopy	Hernandez-Divers et al. (2009)
Meloxicam	0.2	SQ	Not established	Anecdotal evidence of clinical efficacy	McArthur (2004)
Meperidine	20	IV, IM	Good	Analgesic efficacy similar to morphine	Wambugu et al. (2010)
Morphine	1.5	IV, IM	Good	Dose-dependent respiratory depression	Sladky et al. (2007)
Tramadol	5–10	PO	Good	Long-lasting analgesic effect up to 96 hours	Baker et al. (2011)
Tramadol	10–25	SQ	Good	Slower onset and shorter duration of analgesia compared to PO administration	Baker et al. (2011)

IM, intramuscular; IV, intravenous; PO, per os; SC, subcutaneous.
Where possible recommended dosages are based on published pharmacokinetic and pharmacodynamic data. Sladky (2023) gives a comprehensive review of reptile analgesia.

the endotracheal tube inserted through the glottis. This allows controlled ventilation to deliver the inhaled anesthetic. Large tortoises, however, are unbelievably powerful animals and are impossible to forcibly intubate without sedation. Furthermore, strong laryngeal sphincter muscles seal the glottis of aquatic species, making awake intubation difficult. Repeated attempts to force open the closed glottis are not recommended due to risk of causing severe tissue damage. Instead, gentle manipulation and patience in waiting for the animal to voluntarily open the glottis often facilitate the intubation. A short piece of PVC pipe used as mouth gag facilitates intubation and protects the endotracheal tube (Fig. 10.10).

Injectable sedative and anesthetic agents are commonly administered intramuscularly due to the difficulty of gaining IV access without previous sedation. Intramuscular (IM) administration of ketamine combined with benzodiazepines or alpha-2 adrenergic agonists often produce adequate sedation and muscle relaxation. The pectoral muscles are a preferred site for IM injections. Alternatively, the triceps muscle may be used when accessible in larger animals. Reported parenteral drug combinations and dosages are given in Table 10.2, and recommended induction and anesthesia protocols are discussed at the end of the chapter.

Figure 10.10 A piece of PVC pipe used as an oral speculum facilitates intubation and protects the endotracheal tube. Both the mouth-gag and the endotracheal tube are secured with tape to the head of the animal to prevent dislodgment.

In some species the presence of easily accessible veins and venous sinuses facilitates direct IV administration of anesthetics. In sea turtles, the cervical venous sinus is an easily accessible site for injection (Moon & Hernandez

IM, intramuscular; IV, intravenous.

Foester 2001). It is often used for induction, but limited information is available on the rate of distribution of anesthetics using this route. If the desired effect is not achieved at the recommended dosage of a drug, it is recommended not to repeat the administration to avoid over-dosage (Wood et al. 1982).

The dorsal coccygeal vein is in the present authors' experience a safe and reliable site for IV injection in unsedated snapping turtles (*Chelydra* spp. and *Macrochelys temminckii*). The subcarapacial venous sinus is easily accessible for injections in small chelonians, however extravasation of drug is likely when this access is used. The subcarapacial sinus runs close to the subdural space where the cervical vertebrae join the carapace. As described above, deaths in gopher tortoises (*Gopherus polyphemus*) have been associated with the inadvertent injection of propofol into this space while attempting subcarapacial injection (Quesada et al. 2010).

When the IV route is utilized, propofol titrated to effect is a good choice for induction of anesthesia. Di Giuseppe et al. (2018) showed major differences in induction times and effects between occipital sinus, subcarapacial sinus, and dorsal coccygeal vein injection (5 mg/kg). Although occipital and subcarapacial injections provided the fastest inductions, we do not recommend these routes for injection other than for euthanasia. Di Giuseppe et al. (2018) also found limited to no effect from the coccygeal vessel injection. In the present authors' experience the induction times for this site can be prolonged and the authors may not have waited long enough for peak effect (sometimes 30 minutes or more). Used as a single agent, propofol requires doses between 4 and 8 mg/kg to produce anesthesia.

Alternatively, the combination of ketamine (5 mg/kg) and medetomidine (0.05 mg/kg) given intravenously appears to be safe in many aquatic and terrestrial species. Although no longer available, alfaxalone/alfadolone at 24 mg/kg given intracoelomically was shown to produce surgical anesthesia in red-eared sliders (Lawrence & Jackson 1983). A new formulation of alfaxalone (Alfaxan®) is now available, but it does not produce analgesia. It can be administered intravenously or intramuscularly for short surgical procedures, at the same dosages described for the previous mixture. The low concentration (10 mg/mL), however, precludes IM, as well as subcutaneous, injection in large tortoises. It can be used at a low dosage (and volume) as part of a multidrug anesthetic combination.

Soft-shell aquatic turtles appear to possess an amphibian-like modality of fluid absorption across nonenteral surfaces (e.g., skin and mucous membranes beside the enteral mucosa) (Bagatto et al. 1997). In spiny and Florida soft-shell turtles (*Apalone apinifera* and *Apalone ferox*, respectively), tricainemethane sulfonate (MS-222) has been tested as an immersion anesthetic. A concentration of 1 g/L provided a quick onset of surgical anesthesia. All the animals in the study survived and the technique was considered safe by the authors (Bagatto et al. 1997). Lidocaine-hydrochloride diluted in bicarbonate-buffered water was also used as anesthetic in soft-shelled turtles (*Pelodiscus sinensis*). Immersion at 700 mg/L produced anesthesia within 6 minutes after exposure. Recovery time was short after removal of the animal from the anesthetic solution (Park et al. 2006).

Succinylcholine and other neuromuscular blocking agents alone have been used in the past for immobilization of chelonians. This class of drugs does not have any anesthetic or analgesic properties and the patient is completely conscious while paralyzed. The depolarization before muscle relaxation associated with succinylcholine also causes pain, lactic academia, and hyperkalemia. For these reasons, the use of neuromuscular blocking agents alone for immobilization is considered unacceptable.

Endotracheal intubation is facilitated by the use of a tongue depressor to better expose the glottis. In aquatic turtles there is abundant soft tissue at the base of tongue, which can make visualization of the glottis difficult (Fig. 10.11).

Gentle upwards pressure on the skin surface between the mandibular branches helps to expose the glottis. The size of endotracheal tube can be estimated either by external palpation of the trachea or by visualizing the glottal diameter during inspiration. The glottal opening is usually smaller than the tracheal diameter. Cuffed endotracheal tubes can be used, but overinflation of the cuff can potentially cause tracheal injury. The trachea is relatively short, particularly in sea turtles, and the selective intubation of a bronchus is possibly if a long endotracheal tube is inserted too far.

Immobility has a substantial negative impact on ventilation due to the important role of limb movement for lung expansion (Taylor et al. 2010; Gatten 1974a). The respiratory drive is also depressed by the direct effect of anesthetic agents on the respiratory centers. This predisposes the patient to hypoxemia and hypercapnia. Hypoventilation also prevents the constant delivery of anesthetic when inhalation anesthesia is used. Manual or mechanical intermittent positive pressure ventilation (IPPV) is therefore recommended for general anesthesia. Tidal volumes are highly variable and influenced by species and body position. Sea turtles have much higher tidal volumes compared to terrestrial tortoises (Lutcavage & Lutz 1996). The lung compliance is also much lower in dorsal recumbency compared to ventral recumbency (Lutcavage et al. 1989). Concerns exist to the possible

Figure 10.11 Glottal apparatus of an alligator snapping turtle (*Macrochelys temminckii*) during breath-holding (a) and inspiration (b). Note the perfect seal of the closed glottis. Waiting for the animal to voluntarily open the glottis facilitates the endotracheal intubation.

detrimental effect of positive pressure ventilation on the cardiovascular system. However, examination of the effect of artificially manipulating lung volume on blood flows and heart rate in the freshwater turtle (*Trachemys scripta elegans*) showed increases in lung volume have no effect on pulmonary blood flow (Herman et al. 1997).

It is difficult to assess effective artificial ventilation in the clinical setting. Current recommendations for IPPV are 2 to 6 breaths per minute using tidal volumes ranging from 15 to 20 mL/kg, with peak airway pressures less than 10 cmH_2O. In intubated chelonians Heard used a capnograph to monitor adequacy of ventilation, as well as spontaneous ventilation. End-tidal CO_2 usually starts around 20 mmHg. Values below 10 or above 30 mmHg appear to be indicative of either hypocapnia (excessive ventilation) or hypercapnia (too little ventilation). Return to spontaneous ventilation is very difficult to visually assess in chelonians. Hence, capnography can be a sensitive monitor to determine normal respiration, especially in the recovery period.

For pronged procedures, anesthesia can be maintained by use of supplemental doses of the drug combination used for induction or more commonly by use of inhaled anesthetics. Gaining familiarity with multiple anesthetic agents and protocols in different species allows prediction of the patient response and the duration of effect of each specific anesthetic agent or combination.

Important aspects of patient care during anesthesia include continuous patient monitoring, appropriate fluid therapy, maintenance of the specie's preferred body temperature, appropriate analgesia, and lubrication of the eyes. In giant tortoises the protection of the limbs and the phallus (frequently prolapsed in males during anesthesia) is also critical for avoiding severe crushing injuries caused by the weight of the anesthetized animal.

Monitoring

The extreme physiologic resilience of reptiles should never be considered an excuse to overlook constant assessment of an anesthetized patient. Information is now available on the application of several types of monitoring equipment in chelonian anesthesia (Bailey & Pablo 1998; Mosley et al. 2004; Hernandez-Divers 2004). The accuracy and reliability of much of this equipment, however, is only beginning to be determined and for the most part has not been validated. This underlines the importance of the role of the anesthesiologist in the constant direct assessment of anesthetic depth, cardiopulmonary function, body temperature, and other physiologic parameters.

Anesthetic Depth

The accurate assessment of anesthetic depth is challenging. Several authors have previously proposed guidelines for the assessment of the stage of anesthesia in chelonians (McArthur 2004). Stages 1 and 2 are associated with minimal muscle relaxation, persistence of head withdrawal reflex, and voluntary response to painful stimuli. These anesthetic stages are indicated for noninvasive or minimally invasive procedures.

Stage 3 (surgical anesthetic stage) is characterized by immobility, absence of head withdrawal reflex, marked muscle relaxation occurring cranio-caudally as anesthetic depth increases, and no voluntary muscle response to noxious stimulation. This is considered a suitable stage for performing invasive surgical or diagnostic procedures.

The deepest anesthetic stage (stage 4) represents severe medullary depression due to anesthetic overdose. This stage is associated with life-threatening, severe cardiovascular

depression and is clinically detected by the loss of all reflexes, including the vent and corneal reflexes.

In chelonians, hypoventilation and apnea are common during anesthesia, even at lighter stages. Therefore, the visual assessment of external signs of respiration does not represent a good indicator of anesthetic depth and ventilatory support should be provided to all anesthetized chelonians. Alternatively, intubated chelonians should be monitored with a capnograph. Heart rate is influenced by multiple factors, including temperature and oxygenation, making this an unreliable parameter for the assessment of anesthetic depth (McArthur et al. 2004; Krosniunas & Hicks 2003).

Cardiovascular Function

The main aim of cardiovascular monitoring is to ensure adequate blood flow to the tissue. Monitored variables include heart rate and rhythm, pulse, and changes in intravascular volume caused by blood loss. It has been reported that baseline heart rate in reptiles, maintained within its preferred optimal temperature zone, can be estimated using the formula $33.4 \times (Wt_{kg}^{-25})$ based on allometric scaling (Sedgwick 1991). However, insufficient data is available on the reliability of this calculation in chelonians. Furthermore, given heart rate is highly affected by variations in body temperature, any kind of approximation is of limited significance and potentially misleading during anesthesia.

Direct auscultation of cardiac sounds is a simple method of basic assessment of heart rate and rhythm. In anesthetized patients, an esophageal stethoscope can be placed into the thoracic esophagus to the level of the heart for direct auscultation. Since it may cause reflux of gastric contents, the trachea should be intubated prior to its placement. The stethoscope tubing has to be slowly advanced until the maximal sound intensity is reached. It can be connected to a standard stethoscope headpiece for intermittent monitoring or to a portable amplified speaker for continuous assessment.

The electrocardiogram (ECG) detects the electrical activity of the heart. It should be noted the presence of normal electrical activity does not indicate normal cardiac function. Myocardial conduction can continue despite absence of myocardial contraction, which is referred to as pulseless electrical activity, therefore the monitoring of cardiovascular function should not rely solely on an ECG. The ECG can be used as a standard three limb lead configuration, but the thick scaly skin limits its sensitivity in this configuration and requires the use of a hypodermic needle for effective lead attachment (Bailey & Pablo 1998). A base-apex ECG configuration represents a good alternative during anesthesia. Esophageal base-apex ECG lead configurations are commercially available in different sizes and are often combined on the same tubing with an esophageal stethoscope. For anesthetic monitoring, the ECG is usually viewed in lead II. The reptilian ECG tracing comprises three primary complexes: P wave, QRS complex, and T wave. An SV wave may precede the P wave and represents the depolarization of the sinus venosus (Fig. 10.12). As in mammalian species, the P wave and the QRS complex represent atrial depolarization and ventricular depolarization, respectively. The T wave indicates ventricular repolarization. In chelonians, this repolarization phase is physiologically prolonged (Holz & Holz 1995). Due to the paucity of research, there is still limited understanding regarding ECG interpretation in chelonians and reptiles in general (Kik & Mitchell 2005).

The use of an 8-Hz Doppler ultrasonic flow probe is a good alternative to direct auscultation to detect blood flow. It also allows the detection of pulse in major vessels. For these reasons many authors promote the Doppler as the most useful and reliable cardiovascular monitoring device in reptiles (McArthur 2004; Schumacher 2007). Several types of probes are available: adult and pediatric flat probes and pencil probes. In chelonians the pencil probe is most useful for the detection of cardiac blood flow. It is placed on either side of the neck on the ventral aspect of the thoracic inlet (Fig. 10.13). Flat probes can also be taped over the carotid arteries (ventro-lateral aspect of the neck), the coccygeal artery (base of the tail), and femoral arteries for continuous assessment of pulse rate and quality. Pediatric probes are preferred over adult probes due to the higher sensitivity in detecting flow in small vessels.

Determination of peripheral pulse rate and rhythm can also be obtained with the use of a pulse oximeter. As discussed in the next section, pulse oximetry is more often used as a respiratory monitor. Unfortunately, the use of pulse oximetry in chelonians for detecting pulse is limited by placement sites for the probe. Reflectance probes placed

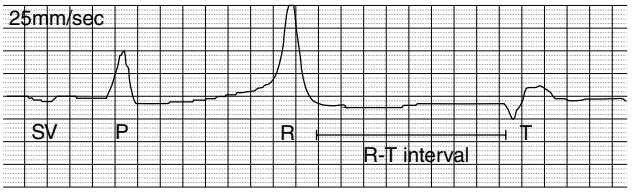

Figure 10.12 Electrocardiographic tracing of an anesthetized Galapagos tortoise (*Chelonoidis nigra*). On the tracing the following waves are identified: sinus venosus depolarization (SV), atrial depolarization (P), ventricular depolarization (R), ventricular repolarization (T). Note that systolic phase of the cardiac cycle is physiologically prolonged (the R-T interval is approximately 1.6 seconds).

Figure 10.13 Cardiovascular monitoring of a juvenile alligator snapping turtle (*Macrochelys temminckii*) during anesthesia. An 8-Hz Doppler pencil probe is placed on the side of the neck with the detecting crystal directed towards the thoracic inlet. The ECG is used in a standard three-limb lead configuration.

in the oral cavity or the cloaca may be a better choice. Some pulse oximetry units are extremely sensitive, and the presence of a strong pulsatile signal does not necessarily correlate with adequate blood flow to the tissues. When the probe is correctly applied, less than 10% of normal blood flow is required for pulse oximeters to detect a pulse (Bailey & Pablo 1998).

During surgery hemorrhage is common and monitoring blood loss is always indicated to determine the need for intervention. In small patients (<1 kg) any detectable blood loss can produce a significant decrease in circulating blood volume and consequent deterioration of patient homeostasis.

Respiratory Function

As discussed above, the direct visualization of respiratory movements such as thoracic excursions can be difficult. The presence of respiratory movements does not indicate adequate ventilation. The use of respiratory monitoring, therefore, is essential.

Arterial blood gas analysis is the ideal method for assessment of respiratory gas exchange, directly measuring the degree of oxygenation (arterial oxygen concentration, PaO_2) and ventilation (arterial carbon dioxide concentration, $PaCO_2$). Unfortunately, the clinical applicability of blood gas analysis in chelonians is limited. Arterial blood sampling in chelonians is difficult and impractical. Additionally, multiple blood draws can represent a significant blood loss in very small patients. Reptiles tend to tolerate alterations in $PaCO_2$ and PaO_2 much more than mammals and thus normal values for mammals may not be applicable (Hernandez-Divers 2004). In mammalian species, venous blood gas analysis can be used for assessing ventilation (venous CO_2 concentration approximates arterial concentration) but not oxygenation. However, the reliability of venous blood gas analysis in chelonians has not been demonstrated. For all of these reasons, the value of routine blood gas analysis in chelonians remains questionable. Other monitoring devices of respiratory function are capnometry and pulse oximetry.

Capnometry measures carbon dioxide concentration in expired gases ($PetCO_2$). In mammalian species capnometry is a noninvasive monitoring tool for assessing ventilation due to the good correlation between the end-tidal concentration of CO_2 and arterial CO_2 concentration. In chelonians this correlation is not consistent due to cardiac shunting. The absolute values of $PetCO_2$ therefore may not be a reliable indicator of arterial CO_2 due to the unpredictable gradient between end-tidal and arterial carbon dioxide (Hernandez-Divers 2004). Capnometry is best used over time to assess trends and to identify potential anesthetic complications. For this purpose, devices with graphing capability (capnograph) that display a continuous waveform (capnogram) are more useful than standard capnometers. Any large, sudden decrease in $PetCO_2$ requires further investigation. These drops are commonly associated with obstruction or kinking of the endotracheal tube, but can also be indicative of an abrupt decrease in cardiac output.

Mainstream and sidestream capnometry devices are commercially available. Mainstream analyzers use a detecting window inserted into the anesthetic circuit. A sensor mounted on the detecting window measures $PetCO_2$. Sidestream analyzers continuously aspirate gas from the anesthetic circuit, and the sensor for the analysis is located away from the ventilator circuit. There are some concerns when capnometry is used in small species. A large detecting window (mainstream) or sampling chamber (sidestream) attached to the endotracheal tube adds significant mechanical dead space. Pediatric connectors can reduce this added dead space. The sensor of mainstream devices may add an excessive amount of weight on the endotracheal tube, causing possible kinking. Sidestream devices require the continuous removal of gas from the circuit (100–200 mL/min) and in very small animals this sampling rate can be similar to or higher than the tidal volume of the patient. Veterinary designed sidestream capnometers such as the Capnovet-10 (Vetronic Services, Devon, UK) use smaller sampling volumes and are suitable for use in patients weighing less than 100 g (Stanford 2004).

Pulse oximetry is used to noninvasively measure the oxygen saturation of arterial hemoglobin (SpO_2). A plethysmograph (to detect pulsatile blood flow) and a combined

spectrophotometer (to measure changes in light absorbance) constitute the functional components of a pulse oximeter. Although pulse oximetry is one of the most commonly used anesthetic monitoring devices in reptiles, its technical limitations and high susceptibility to measurement errors and artifacts should be considered. Pulse oximetry has been designed for use in mammals, meaning it detects typical mammalian pulse and is calibrated using the mammalian oxygen hemoglobin dissociation curve. In reptiles, the characteristics of these variables are markedly different when compared with mammals (Frische et al. 2001). In green iguanas it was shown the absorbencies for oxyhemoglobin (660 nm) and deoxyhemoglobin (990 nm) were in agreement with mammalian references, indicating that pulse oximetry could be reliable in certain reptile species (Diethelm et al. 1998). Unfortunately, the transmittance probes used in mammals do not provide consistent readings when applied to the skin of reptiles. Reflectance probes are more easily placed inside the esophagus or the cloaca to maximize the chance of reading. In the green iguana a reflectance pulse oximeter probe placed in the esophagus and was inaccurate (Mosley et al. 2004). Reptile blood generally contains higher physiologic concentrations of methemoglobin than mammals, which can cause artifacts in SpO_2 readings. Therefore, as for capnography, pulse oximetry is best used to look at the trends in measurements, rather than at the absolute saturation values.

Body Temperature

As in all ectothermic animals, normal thermoregulation in chelonians results from the direct interaction between the animal and the external environment. A series of behavioral patterns and modulations of the cardiovascular system tightly regulate the amount of heat derived from the environment (Galli et al. 2004). During anesthesia, all of these mechanisms are blunted or even abolished and hypothermia is a common occurrence. The direct effect on the cardiovascular system is a progressive decrease in cardiac output and an increase in intracardiac shunting (Krosniunas & Hicks 2003). The anesthetist, therefore, is responsible for appropriately monitoring and modulating body temperature in anesthetized chelonians. The aim is to minimize variations from the species' preferred body temperature range allowing better patient homeostasis (Gatten 1974b). Intraoperatively, this goal is accomplished by appropriately insulating and actively warming the patient (Fig. 10.14).

Patient temperature can be continuously monitored using cloacal or esophageal probes. The patient should not be in direct contact with cold surfaces and should be covered with plastic drapes during prolonged surgical procedures to decrease the dispersion of internal heat. Warm water bottles, circulating warm water blankets, and forced warm air blowers, in ascending order of efficiency, also represent suitable tools for actively increasing and maintaining normothermia. When active warming is provided, attention should be paid to not overheating the patient. Increasing the temperature above the ATR increases oxygen consumption and the animal breathing room air (e.g., during the recovery period) may be unable to meet the increased oxygen demand. It should be noted that body temperatures above 38°C are lethal for most chelonian species.

Figure 10.14 Active warming the patient with a forced warm air blower (Bair Hugger®, Arizant Healthcare Inc., Eden Prairie, MN, USA). The maintenance of the patient's temperature within the preferred body temperature range is an important aspect of patient care in chelonians. Unpredictable disarrangement of the chelonian's homeostasis can occur in response to sudden changes in body temperature.

As mentioned in a previous section, the preferred body temperature or ATR in chelonians is species-dependent. For example, many freshwater turtles will tolerate temperatures between 20 and 25°C whereas sea turtles and land tortoises are better adapted to temperatures between 25 and 30°C (George 1996; McArthur et al. 2004).

Suboptimal temperatures are associated with decreased metabolic rate and consequent unpredictably prolonged clearance of anesthetic agents. When body temperature declines, recovery times are commonly prolonged while inhaled anesthetic requirements are reduced.

Blood Glucose

Monitoring blood glucose in juvenile patients and debilitated patients or during prolonged anesthesia is recommended to detect hypoglycemic episodes. However, the

occurrence of hypoglycemia in anesthetized chelonians has not been documented and the need for repeated glucose checks is debatable.

Recommended Sedatives and Anesthetic Agents

Injectable Drugs

Combinations of parenteral drugs belonging to different classes permit a reduction in the required dosages of each agent, therefore reducing their potential side effects. It has been shown multiple drug combinations provide better sedation, muscle relaxation, and shorter induction and recovery times compared to the use of single agents. The administration of specific antagonists for some classes of sedatives makes it possible to modulate the duration of their effect.

Alpha-2 Adrenergic Agonists

Alpha-2 adrenergic agonists are extensively used sedatives in chelonian anesthesia (Lock et al. 1998; Sleeman & Gaynor 2000; Holz & Holz 1994). The rapid onset of action, the potent sedation, and the possibility to reverse their sedative effect with specific antagonists are the major advantages of alpha-2 agonists compared to other sedatives. They are also characterized by a mild analgesic activity (Greer et al. 2001a). Alpha-2 adrenergic agonists are part of many anesthetic protocols owing to their synergistic effect with other agents, such as ketamine (Greer et al. 2001a; Chittick et al. 2002). Xylazine when combined with ketamine produced moderate sedation in freshwater turtles (*Trachemys*) (Holz & Holz 1994). Xylazine (1.5 mg/kg), administered intramuscularly, followed by IV induction with propofol (5 mg/kg), also produced moderate sedation for 2.5 hours in Amazonian turtles (*Podocnemis expansa*) (Santos et al. 2008). In loggerhead sea turtles (*Caretta caretta*), medetomidine (0.05 mg/kg) combined with ketamine (5 mg/kg) was shown to produce rapid induction (Chittick et al. 2002). Wild leatherback sea turtles (*Dermochelys coriacea*) were effectively immobilized for measurement of physiologic variables with a combination of medetomidine (0.03–0.08 mg/kg) and ketamine (3–8 mg/kg) (Harms et al. 2007). In Galapagos tortoises (*Geochelone nigra*) medetomidine (0.1 mg/kg) and ketamine (10 mg/kg) given intravenously as a combination produced a surgical plane of anesthesia sufficient to perform celioscopy for about 45 minutes (Knafo et al. 2011). In adult Aldabra tortoises (*Aldabrachelys gigantea*), IM medetomidine (0.02–0.03 mg/kg), ketamine (2–3 mg/kg), and midazolam (0.1 mg/kg), have been used by the author as an induction and maintenance anesthetic protocol for both diagnostic and minor surgical procedures.

Pronounced cardiopulmonary side effects, however, are common after administration of alpha-2 adrenergic agonists in chelonians and appear to be similar to those seen in mammals (Dennis & Heard 2002). The effect of alpha-2 adrenergic agonists on the cardiovascular system appears to be dose-unrelated. Bradycardia and hypoxemia were described in desert tortoises (*Gopherus agassizii*) sedated with medetomidine (0.15 mg/kg) (Sleeman & Gaynor 2000). Medetomidine (0.1 mg/kg) produced good sedation, but also moderate bradycardia in leopard tortoises (*Geochelone pardalis*) and yellow-foot tortoises (*Geochelone denticulata*) (Lock et al. 1998). Similar effects were seen in Aldabra tortoises (*Aldabrachelys gigantea*) at a dose of 0.025–0.08 mg/kg (Lock et al. 1998). In gopher tortoises, the combination of medetomidine (0.1 mg/kg) and ketamine (5 mg/kg) produced moderate hypertension, hypercapnia, and hypoxemia (Dennis & Heard 2002). For these reasons, the use of supplemental oxygen is highly recommended when alpha-2 adrenergic agonists are used.

Severe cardiovascular changes can be also caused by the IV administration of reversal agents. The antagonist atipamezole (0.5 mg/kg) given IV was demonstrated to produce severe hypotension and even undetectable carotid pulse in gopher tortoises (*Gopherus polyphemus*) (Dennis & Heard 2002). Based on these findings, it is recommended to utilize the IM route for injection of the reversal agent of alpha-2 agonists.

The stereoisomer dexmedetomidine is now commonly used in veterinary anesthesia. Its potency in mammals appears to be twice as high as that of medetomidine (Kuusela et al. 2001). There are no published studies on the sedative effect of dexmedetomidine in chelonians. Medetomidine is still commercially available as a compounded preparation at high concentrations (10, 20, and 40 mg/mL). In large chelonians (>100 kg), these concentrated solutions are a good choice for IM administration to significantly reduce the volume of injection.

Ketamine

Ketamine is a dissociative anesthetic commonly utilized in many reported anesthetic protocols for chelonians. Ketamine has a large margin of safety due to its supportive cardiovascular effects and its lower respiratory depression when compared to other induction agents, such as barbiturates and propofol. Used alone, ketamine requires very high dosages to produce general anesthesia in chelonians (30–50 mg/kg), does not produce adequate muscle relaxation, and is associated with prolonged induction and recovery times of up to 24 hours (Holz & Holz 1994). The combination of ketamine with other sedatives produces a

synergistic effect at reducing the doses of the single agents. Benzodiazepines, alpha-2 adrenergic agonists, opioids, and potentially alfaxalone improve the anesthetic profile of ketamine, producing better muscle relaxation and making it possible to obtain a plane of anesthesia more suitable for surgical interventions (Chittick et al. 2002). Benzodiazepines are primarily added to produce muscle relaxation (Bienzle & Boyd 1992). Alpha-2 adrenergic agonists are often used to significantly decrease the ketamine dose and to achieve deeper anesthetic planes (Greer et al. 2001b; Lock et al. 1998; Harms et al. 2007). Medetomidine and xylazine added to ketamine is a very common induction protocol for both aquatic and terrestrial species. Several dosing regimens have been reported in different chelonians, showing significant interspecies variability in dose and sedative effect (see Table 10.2). Ketamine also has intrinsic analgesic properties due to its antagonist effect on N-methyl-D-aspartate receptors. The presence of this type of receptor has been demonstrated in chelonians (Bickler et al. 2000). The analgesic effect of ketamine is mild and short-lived for treatment of surgical pain and superior analgesia is provided by the use of a multimodal approach. The addition of more potent systemic analgesics, such as opioids, and the use of local anesthetics are recommended for management of acute surgical pain.

Tiletamine/Zolazepam

The moderately potent and long-acting dissociative anesthetic tiletamine is usually combined with the long-acting benzodiazepine zolazepam. It has usually been avoided for use in chelonians because of the potential for prolonged recoveries. In Heard's experience, however, chelonians are surprisingly resistant to the effects of this combination, requiring relatively high dosages and only showing a relative short period of immobilization. For example, immobilization of the African spurred tortoise requires up to 30 mg/kg IM.

Propofol

Propofol is a fast-acting hypnotic agent formulated for IV injection only. Several reports describe the safety of propofol as an induction agent in several chelonian species (McArthur 2007; Ziolo & Bertelsen 2009; Smith et al. 2000) (see Table 10.2). Propofol produces induction of general anesthesia within 1–2 minutes after injection (Santos et al. 2008). The duration of effect is usually 30–45 minutes at the typical dosages of 2–10 mg/kg. Large species appear to require lower doses compared to small chelonians (McArthur 2004). In a study in loggerhead sea turtles (*Caretta caretta*), propofol (5 mg/kg) produced an adequate plane of anesthesia for laparoscopic sex determination. The duration of effect lasted 30 minutes (MacLean et al. 2008). Prolonged apnea following induction with propofol is a common complication in chelonians and prompt intubation and manual ventilation are therefore required. Dose-dependent hypotension can be severe following rapid administration. Slow injection over 1 minute allows the anesthetist to titrate the administration to the desired effect, minimizing the cardiovascular depression. Propofol does not have any analgesic activity and it should always be combined with analgesics when performing surgical procedures. Propofol given as a constant rate infusion (0.2–0.4 mg/kg/min) or as incremental boluses (0.5–1 mg/kg) is suitable for maintenance of anesthesia in mammals, but the safety and the appropriate rates of infusion in reptiles have not been determined. The fast induction and recovery time and the possibility of modulating the effect by adjusting the dose make propofol the author's (A. Vigani) anesthetic of choice whenever the IV route is accessible.

Midazolam

Midazolam is a benzodiazepine with similar potency to diazepam. Compared to diazepam, the more hydrosoluble molecule of midazolam produces more constant absorption and better bioavailability after IM injection. Midazolam used alone, even at dosages 10 times higher than the therapeutic doses for mammals, was repeatedly shown not to produce significant sedation in some chelonian species (Harvey-Clark 1993). In sliders (1.5 mg/kg IM) provided moderate sedation with minimal cardiovascular and respiratory changes (Oppenheim & Moon 1995). In snapping turtles (*Chelydra serpentina*), the combination of midazolam and ketamine appeared to produce better sedation and muscle relaxation compared to use of single agents (Bienzle & Boyd 1992). General anesthesia, however, could not be achieved even at high dosages. The recommended dosages for chelonians range between 0.1 and 1 mg/kg. When midazolam is used in chelonian anesthesia, it is suggested to combine it with other agents, such as ketamine or propofol, to produce adequate anesthetic depth (Holz & Holz 1994; Wood et al. 1982). The sedative effect of midazolam can be reversed by the specific antagonist flumazenil (0.01–0.04 mg/kg).

Alfaxalone

Alfaxalone is a neuro-steroid that exerts its anesthetic effect by binding to GABA receptors. It was originally introduced in the 1970s as a mixture with alfadolone for induction of anesthesia. The trade name of the compound in the veterinary market was Saffan®. This formulation was later withdrawn from the market because of the occurrence of lethal anaphylactoid reactions in small animals.

These adverse effects were induced by the presence in the compound of Cremophor EL® as a solubilizing agent.

Recently alfaxalone, as a new water-soluble formulation, has been reintroduced to the veterinary market under the brand name of Alfaxan®. The water solubility of this preparation is due to the binding of the alfaxalone molecule to a cyclodextrine molecule. This mixture does not cause histamine release, unlike the old formulation. The physiological effects of alfaxalone are identical to those of propofol and include dose- and rate-dependent cardiopulmonary depression and hypotension.

Unlike propofol, alfaxalone can also be administered via the IM route, providing a possible alternative of anesthetic induction when vascular access is not available. It should be noted, however, that the use of the IM route requires higher dosages compared to the IV route. In chelonians alfaxalone given IM produced anesthesia at a dosage of 10–20 mg/kg (Lawrence & Jackson 1983). Alfaxan® is available at a concentration of 10 mg/mL and its use in large chelonians (>10 kg) therefore may be limited by the very large volume of drug which then must be injected intramuscularly. It can, however, be used at a low dosage and relatively low volume (0.5–1 mg/kg) for its sedative effects as part of a multidrug induction combination.

Alfaxalone (3–10 mg/kg) IV in yearling loggerhead sea turtles (*Caretta caretta*) produced rapid induction (Phillips et al. 2017). The recoveries, as would be expected, were dose-dependent (up to 90 minutes). Similarly, the severity of cardiopulmonary effects increased with dosage. Hypoxemia and hypercapnia, associated with apnea in many animals, were most severe at the recommended induction dosage of 10 mg/kg. In red-eared sliders (*Trachemys scripta scripta*) alfaxalone IV had similar physiological effects as in loggerhead sea turtles, but the recommended dosages for good immobilization/relaxation were higher (10–20 mg/kg) (Shepard et al. 2013). Not surprisingly, the cooler (18–20°C) temperature turtles required a lower dosage to achieve the same effect as in warmer animals (22–25°C).

Neuromuscular Blocking Agents

The use of nondepolarizing neuromuscular blocking agents (NNMBAs) has been recently described to facilitate endotracheal intubation in chelonians (Kaufman et al. 2003). Nondepolarizing neuromuscular blockers have a much safer toxicological profile compared to depolarizing agents such as succinylcholine. NNMBAs do not have any anesthetic or analgesic activity, therefore they should never be utilized alone for immobilization. They must be considered only as complementary to a balanced anesthetic technique. Rocuronium is a NNMBA with rapid onset and intermediate duration of action. Rocuronium (0.2 mg/kg IM) has been shown to permit endotracheal intubation in Gulf Coast box turtles (*Terrapene carolina major*) and in Amazon turtles (*Podocnemis expansa*) within 15 minutes after administration (Kaufman et al. 2003; Scarpa Bosso et al. 2009). The effects of NNMBAs can be antagonized with neostigmine. In the studies mentioned above, recovery time (time to walking) from rocuronium occurred within 30 minutes after administration of neostigmine (0.04–0.07 mg/kg IM). Glycopyrrolate (0.01 mg/kg) can be coadministered with neostigmine to prevent its potential parasympathetic effects.

Inhaled Anesthetics

Currently, the inhalants isoflurane and sevoflurane are favored for maintenance of anesthesia in reptiles (Shaw et al. 1992). High concentrations of inhaled anesthetics and awake endotracheal intubation are required when these agents are used for induction. The potency of inhaled anesthetics is conventionally expressed as the minimal alveolar concentration (MAC). The values of MAC for isoflurane and sevoflurane in green iguanas (*Iguana iguana*) were 1.8% and 3.1%, respectively (Barter et al. 2006). Specific values of MAC for chelonian species have not been determined yet, but clinical evidence suggests the inspired concentrations required for surgical anesthesia are similar to the ones reported for other reptiles. Sevoflurane, by virtue of its low solubility in blood, is associated with faster anesthetic induction and recovery times when compared to isoflurane in mammals. Similar findings were shown in reptiles. In green iguanas (*Iguana iguana*), recovery time was significantly longer in animals anesthetized with isoflurane (35 ± 27 minutes) when compared to sevoflurane (7 ± 4 minutes) (Hernandez-Divers et al. 2005). Recovery times after 2 hours of anesthesia with 2% isoflurane averaged 4 hours in Kemp's ridley sea turtles, whereas prolonged anesthesia in desert tortoises, induced and maintained with sevoflurane, was associated with recovery times averaging 30 minutes (Moon & Stabenau 1996; Rooney et al. 1999). However, the high intracardiac shunting typical of aquatic chelonians may have contributed to these significant differences.

Interestingly, it has been shown in green iguanas that the MAC of inhalants tends to decrease over time, most likely reflecting limitations to anesthetic uptake and distribution. The progressive decrease in anesthetic requirements could also suggest that for any given end-tidal anesthetic concentration, the plane of anesthesia may deepen over time during prolonged procedures (Brosnan et al. 2006). For this reason, it is important to constantly monitor the depth of anesthesia and to titrate the concentration of inhalant to decrease the risk of overdose.

Chelonians can voluntarily breath-hold and successful use of inhaled anesthetics requires controlled ventilation for adequate drug uptake and elimination. Pure oxygen is the carrier gas usually utilized with inhalants. However, experimental evidence suggests hyperoxia depresses ventilation in both terrestrial and aquatic chelonians (Glass et al. 1978). Hypoxia, however, appears to be a common anesthetic complication in chelonians, supporting the use of high inspired oxygen concentrations. Consequently, the ideal carrier gas mixture that would provide adequate oxygenation and maintain appropriate ventilation is still undetermined.

Inhalants do not provide any analgesia and therefore appropriate addition of analgesics is required for any surgical procedure. Intraoperative pain management and use of balanced anesthetic techniques will also decrease the requirements of inhalant and hence side effects. For example, the cardiovascular depression associated with inhalant anesthesia in reptiles, as in mammals, has been shown to be dose-dependent (Mosley et al. 2004). For this reason, the multimodal approach to chelonian anesthesia using injectable and inhaled agents has gained the favor of many investigators (Shaw et al. 1992; Moon & Hernandez Foester 2001; McArthur 2004; Chittick et al. 2002) (see Table 10.2).

Recovery

Recovery time from anesthesia appears to be prolonged in chelonians when compared to mammals exposed to the same anesthetic agent. This difference may be due to the lower efficiency of the metabolic pathways of reptiles (McArthur et al. 2004). Additionally, temperature significantly affects the metabolic rate and the cardiovascular physiology of chelonians (Krosniunas & Hicks 2003). Both represent critical factors affecting a timely and successful recovery from anesthesia. For instance, hypothermia is associated with a decrease in metabolic function, which could delay the clearance of many injectable agents. Additionally, the amplification of intracardiac shunting, occurring when body temperature is below the ATR, can decrease the elimination of inhaled anesthetics through the lungs. Warming the patient above the preferred temperature for the species is also discouraged owing to the risk of increased oxygen demand (Galli et al. 2004). Consequently, the maintenance of body temperature within the ATR is recommended. Respiratory depression also persists during the recovery period. Noticeably, chelonians can occasionally take spontaneous breaths in the early postoperative period, but these should not be misinterpreted as signs of complete recovery from anesthesia. It is recommended to maintain the patient intubated until consistent spontaneous ventilation and voluntary movements are present.

When using inhalation anesthesia it is important to adjust the vaporizer setting in relation to how soon a procedure will be ending, as well as the effects of the induction drugs. In some cases there will be little to no need to supplement anesthesia with an inhalant, but the chelonian should be intubated, monitored with a capnograph and ventilation adjusted based on end-tidal CO_2. The animals are recovered in either an incubator or warmed environment and extubation can occur when there is evidence of apparently adequate spontaneous respiration and/or the animal is ambulating.

There is evidence that catecholamines modulate cardiac shunting in chelonians (Overgaard et al. 2002). Particularly in *Trachemys*, epinephrine was shown to increase pulmonary blood flow by directly reversing the presence of right-to-left shunting. Several studies in alligators (Gatson et al. 2017) and chelonians (Balko et al. 2018; Goe et al. 2016; Greunz et al. 2018) have now shown epinephrine administered intramuscularly hastens recovery after inhalation anesthesia. Interestingly, this also seems to be true after total parenteral anesthesia (Heard, pers. obs.). This may be secondary to increased cardiac output, alterations of shunting, and better delivery to the routes of elimination/excretion. Goe et al. (2016) also showed electrical stimulation of the acupuncture site GV-26 hastened recovery in common snapping turtles (*Chelydra serpentina*). In addition to reversal of alpha-2 adrenergic agonists and midazolam with atipamezole and flumazenil, Heard also routinely uses epinephrine during recovery from anesthesia in chelonians and other reptiles without any observed adverse effects.

Recommended Anesthetic Protocols

Chelonians can be crudely divided into groups based on their response to anesthetic drugs, as well as their size. See Table 10.2 for published and recommended anesthetic regimens. Based on known effective drug dosages, the giant tortoises (Galapagos and Aldabra) and sea turtles appear very to moderately sensitive (Turner et al. 2001). As discussed below, the exception is the African spurred tortoise (Turner et al. 2001). Other dry-land tortoises (e.g., *Gopherus* spp.) seem similar and require the lower end of the drug dosages (McGuire et al. 2014). The freshwater aquatic turtles appear to require the highest drug dosages for a similar predictable immobilization. Box turtles appear to fall between the dry-land tortoises and freshwater turtles.

There is no single best drug for parenteral induction and maintenance in chelonians, rather a combination of drugs and techniques is used to promote a more rapid recovery and less adverse physiological effects (Table 10.2). Analgesia (Table 10.1) is also an essential component of any protocol for painful procedures and can be attained with a multimodal approach proportionate to the procedure and need (i.e., opioids, NSAIDs, and local/regional anesthesia).

The African spurred tortoise is the largest land tortoise from Africa. It has become a common chelonian in captivity because of its size and fecundity; hatchlings are also readily available for sale and they are easy to care for. Despite this, they pose a major challenge for veterinarians. In awake animals it is virtually impossible to access vessels for either collection of blood or for IV injection. Consequently, to work with this species in a clinical setting it is usually necessary to anesthetize them. Unfortunately, they are unusually resistant to the effects of anesthetic drugs and it is very difficult to even administer an IM, let alone an IV, injection. Surprisingly the best and most consistent anesthetic combination is tiletamine/zolazepam (10–30 mg/kg). Alternatively, an intramuscularly administered combination of medetomidine (dexmedetomidine) (50 μg/kg), ketamine (5–8 mg/kg), and midazolam (0.2 mg/kg) ± hydromorphone (0.2 mg/kg) can be used. When using either drug protocol it may take up to 30–45 minutes for peak effect after IM injection. Even then, there may be a narrow window of 10–15 minutes of relaxation sufficient to allow intubation.

Snakes and Lizards (Squamates)

Catherine J.A. Williams, Tobias Wang, and Mads F. Bertelsen

Introduction

Sedation and anesthesia are essential to the veterinary care of lizards and snakes. They are required for surgery and other painful or invasive procedures, to facilitate handling, and to enhance the quality or safety of diagnostic procedures while minimizing stress and discomfort. The field of reptile anesthesia has undergone a gradual and continuing evolution from hypothermia and manual restraint to contemporary balanced and well-controlled anesthesia. However, there is still much to be learned and there continues to be value in defining, exploring, and improving protocols. Several excellent reviews on reptile anesthesia are available (Bertelsen 2019; Mans et al. 2019a,b; Perpiñán 2018; Schnellbacher et al. 2019; Schnellbacher & Shepard 2019; Sladky & Mans 2012a), but controlled clinical studies remain relatively scarce. In general, squamates are rather resilient or "tough" and life-threatening anesthetic complications are rare, but should obviously be avoided or at least minimized.

Taxonomy and Biology

The nomenclature and taxonomy of the class Reptilia remains controversial and continues to be revised (Burbrink et al. 2019; Pyron et al. 2013). The order Squamata is by far the most speciose group within Reptilia and contains more than 50 families and approximately 10,600 species of amphisbaenians (worm lizards), lizards, and snakes. While squamates thrive in very different habitats, range across a broad geographical distribution from the tropics to the near-Arctic, and vary tremendously in size from a few centimeters to 8 m, most anatomical and physiological features as well as reactions to anesthetic drugs are surprisingly uniform.

Anatomy and Physiology

Reptiles are ectothermic vertebrates with relatively low metabolic rates, usually some five to 10 times lower than that of a mammal at the same temperature (Nagy 2005). The low rates of oxygen consumption are reflected in the anatomy and physiology of their cardiorespiratory systems. Lizards, snakes, and other reptiles generally have low blood pressures as well as low heart and ventilation rates compared to mammals. Despite the anatomical differences, there are striking similarities in the regulation of pulmonary ventilation and cardiovascular functions that reflect the common evolutionary roots of reptiles and mammals (Taylor et al. 2010, 2014; West 2011).

Cardiovascular System

All reptiles possess two atria divided by a complete atrial septum (Jensen et al. 2019). Each atrium opens into the ventricle through a separate atrio-ventricular ostium guarded by valves, such that oxygen-poor blood enters the ventricle from the right atrium separately from the oxygen-rich blood that enters the ventricle from the left atrium. The ventricular wall of lizards and snakes has a thin compact layer and most of the myocardium is trabeculated, giving it a spongy appearance. The spongy myocardium accounts for most of the mass and allows a high ejection fraction (Jensen et al. 2014; Williams et al. 2019a). The ventricular anatomy is complicated and the lumen is divided into three major compartments by septa, primarily the vertical septum and muscular ridge. The three compartments are called the cavum arteriosum (contains the blood which is ejected into the systemic arteries), cavum pulmonale (which holds the blood destined for the pulmonary circulation), and the smaller cavum venosum. The atrioventricular valves play an important role in directing blood flows

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.
© 2025 John Wiley & Sons, Inc. Published 2025 by John Wiley & Sons, Inc.

when these cava are filled during diastole (Jensen et al. 2014). Thus, the oxygen-rich blood that enters from the left atrium is primarily directed into the cavum arteriosum on the left side of the heart, whereas the oxygen-poor blood runs through the cavum venosum into the cavum pulmonale. During cardiac contraction (systole), the oxygen-rich blood enters the two aortic arches through the cavum venosum, whilst the oxygen-poor blood enters the pulmonary artery directly from the cavum pulmonale.

Since the three chambers remain in contact with each other during cardiac contraction, there are equal systolic blood pressures in the systemic and pulmonary arteries. Two exceptions, the python and varanid lizards, are discussed below. The normal arterial pressures of lizards and snakes are considerably lower than those of mammals, but may increase drastically during stress or restraint (Stinner & Ely 1993; Wang et al. 2001a) while large intraspecies pressure differences may correlate with the species' general activity level.

While the admixture of oxygen-rich and oxygen-poor blood flows entering the ventricle can be greatly reduced by the ventricular septa, the squamate heart has a large potential for intracardiac mixing and shunting of blood (Hicks 1998). This may occur as an overall left-to-right (L-R) shunt or a right-to-left (R-L) shunt; during normal conditions, shunting actually happens in both directions (Ishimatsu et al. 1996, 1988). An L-R shunt represents oxygenated pulmonary venous blood re-entering the pulmonary circulation, while an R-L shunt is deoxygenated systemic venous blood that bypasses the lungs and returns into systemic circulation. R-L shunting results in large reductions in the partial pressure of oxygen in the arterial blood (PaO_2) and hence results in very large alveolar-arterial PO_2 differences (Hlastala et al. 1985; Wang et al. 1998a). The effects of R-L shunts on arterial PCO_2 are much smaller (Malte et al. 2017).

The resistances in the systemic and pulmonary circulations largely determine the magnitude and direction of cardiac shunts. Thus, increased pulmonary vascular resistance diverts blood flows into the systemic circulation (R-L shunts) and vice versa (Galli et al. 2007). Any anesthetic that alters vascular resistances in the systemic or the pulmonary circulation is therefore likely to affect the cardiac shunt pattern. Systemic vasodilatation will tend to produce R-L shunts (Greunz et al. 2018), whilst systemic constriction, for example following alpha-adrenergic stimulation, will result in L-R shunts (Goe et al. 2016).

The cardiac shunt pattern of reptiles is highly regulated, where vagal innervation of smooth muscle in the pulmonary artery allows pulmonary vasoconstriction and promotes large R-L shunts (Filogonio et al. 2020; Taylor et al. 2009). Therefore, when vagal tone is high during breath holding, a low heart rate, low pulmonary perfusion, and large R-L intracardiac shunts result (Wang et al. 2001b). In contrast, periods of pulmonary ventilation are characterized by decreased pulmonary resistance, increased pulmonary blood flow, small R-L shunt, and tachycardia (Filogonio et al. 2016; Krosniunas & Hicks 2003). The functional significance of cardiac shunts remains unresolved, despite many proposed hypotheses (Burggren et al. 2020; Hicks 2002).

In contrast to most lizards and snakes, where large cardiac shunts are common, the vertical septum and muscular ridge (the two major septa that divide the squamate ventricle) are so well-developed in varanid lizards and pythons that the level of cardiac shunting is very small (Jensen et al. 2014). Contrary to all other squamates, these two separate groups also have high systemic arterial blood pressures and low pulmonary arterial pressures, i.e., ventricular pressure separation (Burggren & Johansen 1982; Jensen et al. 2010; Joyce et al. 2016; Wang 2003).

Respiratory System

The squamate glottis is located at the base of the tongue, quite rostrally in the oral cavity. The glottis is closed during most of the respiratory cycle, opening only during inspiration and expiration. This closed glottis breath-hold allows reptiles to have a super-atmospheric pressure in the lung, which combined with the high lung compliance leads to a relatively large volume of air available for gas exchange in these periods. This volume will be lost on intubation, as the glottis is held open. The trachea of squamates has incomplete cartilaginous rings, while those of chelonians and crocodilians have complete tracheal rings (Kardong 1972a,b; Perry 1998). Most squamates have paired unicameral lungs where the gas exchange surface is enlarged by deep, narrow faveoli. Lizards and more basal snakes have two roughly symmetrical lungs, while the left lung is reduced in size or absent in more derived snakes and in amphisbaenians the right lung is reduced. The gas exchange surface of some snake lungs lie along the trachea (van Soldt et al. 2015) and gas exchange occurs in the cranial portion of the snake lung, while the caudal portion is typically reduced to an air sac-like structure. In iguanas and monitor lizards, the airflow has been found to be unidirectional during normal breathing, potentially allowing greater efficiency of gas exchange (Cieri & Farmer 2016).

Both the relative lung volume and the compliance of the reptilian lung far exceeds that of mammals, but the surface available for gas exchange is considerably smaller due to the structure of faveoli in comparison with the alveoli of mammals. The barrier between the air and blood is also

thicker than in the mammalian lung, so the pulmonary diffusion capacity for both O_2 and CO_2 is considerably smaller than in mammals (Glass 1991; Perry 1983; Starck et al. 2015).

The basic breathing pattern of most species of lizards and snakes consists of single breaths, each starting by opening of the glottis and an exhalation driven by elastic recoil that, in some species, may be assisted by active contraction of the hypaxial musculature. Inhalation is always active, and is typically followed by a period of breath-holding that may last a few seconds to many minutes or even hours depending on metabolism (Milsom 1991). The breathing pattern varies enormously amongst squamates. In many species, the breathing pattern consists of single individual breaths, whereas other species cluster their breaths into ventilatory episodes of numerous (typically three to 15) breaths and longer nonventilatory periods (Milsom 1991; Wang et al. 1998b). A given species may change between these breathing patterns when metabolism changes in response to altered body temperature, digestion, physical activity, or disturbance.

Reptiles, most notably freshwater turtles, are remarkably resistant to ambient hypoxia. While green iguanas can breath-hold dive *in extremis* up to 4.5 hours (Moberly 1968), chelonians may survive complete environmental anoxia for hours or days at their normal body temperatures and weeks to months at the low temperatures of winter hibernation (Belkin 1963; Ultsch 1985). An increase in body temperature leads to increased metabolic oxygen consumption, and consequently to requirement for increased ventilation.

Implications for Inhalational Anesthesia

The large R-L shunts of most squamates mean that systemic arterial PO_2 (PaO_2) is much lower than that of the lungs. In rattlesnakes, for example, Wang et al. (1998a) documented a PO_2 difference of almost 100 mmHg at 15°C that could be attributed to R-L shunt. There is probably also a contribution from V/Q inhomogeneity and pulmonary shunts (Powell & Hopkins 2004). In comparison, the pulmonary to arterial difference created by a small physiological shunt in mammals and birds is minor. The consequence of R-L shunting may be that induction and recovery from inhalational anesthesia is slower and less predictable than in mammals and birds. These effects are most pronounced in chelonians, where flow patterns may be altered by drugs reducing the resistance of pulmonary arteries, therefore reducing R-L shunt (e.g., atropine) (Filogonio et al. 2014, 2016; Greunz et al. 2018), or those increasing systemic resistance and cardiac output (e.g., adrenaline) (Goe et al. 2016).

Vascular Access Sites

The most reliable vascular access site is the ventral tail vessels, located immediately ventral to the coccygeal vertebrae. In snakes, these vessels are mostly approached from the ventral midline, but in many lizards a lateral approach is often more convenient. The palatine veins may be accessed in larger anesthetized snakes (Fig. 11.1). Indwelling catheters may be placed in the cephalic, femoral, abdominal, or ventral cervical vessels using cut-down techniques. Fluids and certain drugs may be administered by the intraosseus route. In lizards, intraosseus catheterization may be performed in the humerus, femur, or tibia following local analgesia of the cannulation site. Cardiac puncture for drug administration as well as for obtaining mixed arterial/venous blood samples is an option in snakes, but minor damage to the myocardium following cardiac puncture has been documented in ball pythons (Isaza et al. 2004; McFadden et al. 2011) the procedure is likely stressful and these authors see the approach as a last resort.

Preanesthetic Considerations

Body weights vary markedly, and an accurate weight should be obtained prior to administering drugs to the reptilian patient. The hydration status of the subject should be assessed and abnormalities corrected. Animals should be subjected to a physical examination prior to anesthesia and if time, budget, and facilities allow, a blood sample for packed cell volume, complete blood count, and plasma biochemistry profiles, as well as ultrasonographic or radiographic imaging may aid in preanesthetic evaluation.

Figure 11.1 Placement of an over-the-needle catheter in the palatine vein of an anesthetized Burmese python (*Python bivittatus*). Care must be taken to avoid the palatine teeth. It is recommended the catheter be removed prior to recovery.

Withholding food prior to surgery is not generally indicated, but large quantities of feed in the stomach may theoretically impair pulmonary function. In infrequently feeding snakes, massive increases in oxygen consumption and cardiac output follow feeding (Enok et al. 2016; Overgaard et al. 1999; Secor et al. 2000), as do increases in organ weights (Andersen et al. 2005; Secor & Diamond 1997). As these factors are all likely to increase the risk of anesthetic complications, elective procedures should be avoided in recently fed snakes. That said, no effect on recovery times was found in garter snakes anesthetized 1, 2, 3 and 10 days post feeding (Preston et al. 2010).

Maintaining Body Temperature

Induction time, anesthetic dose, and recovery time (Arena et al. 1988; Dohm & Brunson 1998; Green et al. 1981; Preston et al. 2010) as well as general metabolism are all temperature dependent and maintaining the animal's body temperature within the preferred optimum zone (POZ) is highly beneficial. This can be achieved by placing the animal on heating pads, circulating water blankets, water bottles, beanbags etc. For most temperate and tropical species, a body temperature of 25–35°C during induction, anesthesia, and recovery will be appropriate. In garter snakes anesthetized with methohexital, recovery time at 21°C was twice as long as at 31°C (Preston et al. 2010), and warming animals toward the high end of the POZ once the procedure is over may be attempted to hasten recovery. This approach, however, requires that the increased oxygen consumption be met by providing appropriate ventilation and potentially by oxygen supplementation to the inspired air.

Monitoring Physiological Function

Most monitoring modalities for domestic species can be applied to reptiles. Body temperature should be monitored with a cloacal or esophageal thermometer or temperature probe able to measure low temperatures. Heart rate and rhythm may be monitored using ECG or Doppler flow detection units. The latter offers simple audible monitoring. In most snakes, heart rate can usually be determined by visual inspection of the ventral scales approximately 25% of the snake's length from the head, and the heart rate may be visually observed in the jugular groove of many lizards. Blood pressure may be measured invasively only following cut-down procedures, limiting usefulness to research settings. Commercially available oscillometric devices applied to the tail of snakes or the femoral region of lizards unfortunately seem to have limited value, but may perhaps provide trend information (Chinnadurai et al. 2009, 2010). Respiration may be assessed visually and in intubated animals main stream or side stream capnography provides useful information, although incomplete gas mixing, cardiac shunting, and dilution as a consequence of excessive sampling rates of the devices used may give rise to erroneous or systematically low end-tidal carbon dioxide readings (Hernandez-Divers et al. 2005).

The use of pulse oximetry in reptiles remains controversial and problematic (Diethelm & Mader 1999; Hernandez-Divers et al. 2005; Mosley et al. 2004) as values obtained may not correlate with measured arterial oxygenation. However, continuous monitoring with pulse oximetry may provide information on trends that reflect changes in oxygenation over time. Regional tissue oxygenation evaluation may be a useful additional technique (Cushing et al. 2020).

Arterial blood gas analysis provides valuable information on oxygenation and acid-base status, especially in relation to whether the lungs are properly ventilated. Cost-effective portable equipment is increasingly available with internal temperature correction and options for species correction. In some cases, automated blood gas analyzers have been calibrated for specific species of reptiles (Malte et al. 2014). However, arterial samples are normally not easy to obtain and most vascular sampling sites yield venous blood. Cardiac puncture likely results in an unknown mixture of arterial and venous blood. Venous blood samples are readily available (Ratliff et al. 2019), but their relationship to arterial values varies wildly and oxygen levels are exquisitely sensitive to tissue extraction. In anesthetized iguanas, for example, arterial and venous oxygen pressures were very close and carbon dioxide pressures only slightly different. This may suggest very low tissue metabolism and oxygen consumption during anesthesia (Mosley et al. 2004). However, venous O_2 was similar in bearded dragons anesthetized with either 21% or 100% inspired oxygen. This indicates venous oxygen levels do not reflect arterial oxygen partial pressure in the arteries or the lungs (Ratliff et al. 2019). The use of venous blood gas samples in conscious animals will reflect not only tissue metabolism and respiratory status, but also will be influenced by shunt and therefore are expected to vary widely and may not be suitable for diagnostic value.

Depth of Anesthesia

The clinical signs associated with induction of general anesthesia in reptiles are fairly consistent. Generally, muscle relaxation in lizards and snakes starts at mid-body and moves forward, then backwards so that tail tone is lost last

(Bonath 1977; James et al. 2018). In varanids induced with inhalation anesthetics, the front limbs lose tone first, followed by the hind limbs and the neck approximately simultaneously. Then righting reflex is lost, and finally the tail tone (Bertelsen et al. 2005a). The tongue retraction "reflex" in snakes and varanids persists beyond the loss of tail tone and righting reflex (Schumacher et al. 1997) and often is present at the surgical plane, as is the corneal reflex (lizards) (Arena et al. 1988; Bertelsen & Sauer 2011). Loss of these reflexes may indicate excessive anesthetic depth. Animals retain the ability to react to painful stimuli even after the loss of righting reflex and tail tone. The response to toe or tail pinching or surgical incision should therefore be evaluated before deciding surgical anesthesia has been achieved.

Endotracheal Intubation

Due to the large oral cavities and rostral position of the glottis, lizards and snakes are easily intubated. The glottis is visualized at the bottom of the mouth, immediately caudal to the tongue (Fig. 11.2a). A noncuffed endotracheal tube of appropriate size is inserted and taped in place, allowing positive pressure ventilation either manually or using mechanical ventilators (Fig. 11.2b). Snakes and some lizards may be intubated awake following the application of topical analgesics to the glottis, however premedication, for example with midazolam, may aid intubation and lower the minimum anaesthetic concentration of inhaled anaesthetics required (Larouche et al. 2019). It is common practice to induce with a swiftly acting injectable, for example alfaxalone or propofol, and maintain on inhalation anaesthesia (Hansen & Bertelsen 2013; Knotek 2017; Morici et al. 2018; Perrin & Bertelsen 2017; Rasys et al. 2019). Endotracheal tubes are commercially available down to 1 mm internal diameter (ID), but for the smallest subjects over-the-needle intravenous (IV) catheters (12–25 gauge) may be used. The adapter from a commercially available 3-mm ID endotracheal tube will usually fit the connector for an over-the-needle catheter (Heard, pers. comm.). When using very small tubes care should be taken to ensure the end does not become obstructed by mucous, and air can move freely back and forth into the trachea.

A piece of rubber tubing, a folded gauze pad, or a wooden mouth gag, depending on the size of the subject, may be used to prevent the animal from biting on the tube. In small reptiles, taping the animal, the endotracheal tube, and the breathing system to the table, a board, or a tongue depressor may prevent tube displacement and injury.

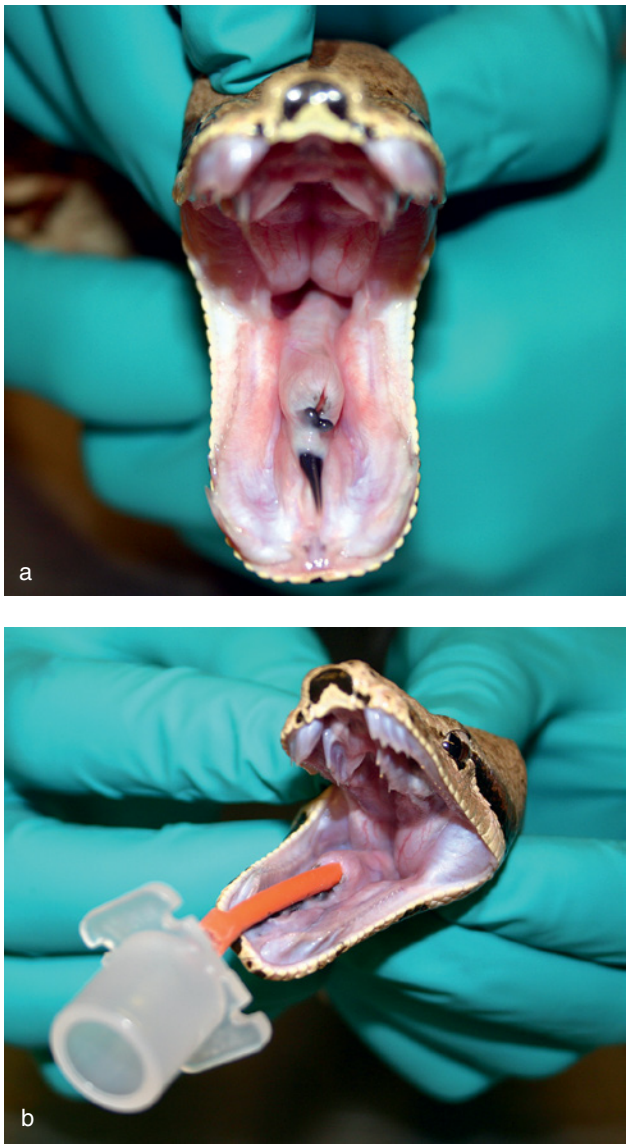

Figure 11.2 (a) The oral cavity of a boa constrictor (*Boa constrictor*). Note the rostral location of the partly open glottis. (b) The oral cavity of a boa constrictor showing the endotracheal tube within the glottis after intubation.

Ventilation

The combination of very low metabolic rates and extreme resilience to hypoxemia allows anesthetized reptiles to experience long periods of apnea without overtly deleterious effects. Although the consequences of apnea during anesthesia are largely unknown, supplementary external ventilation is recommended during deep or prolonged anesthesia, that is, conditions when spontaneous ventilation is usually lost in reptiles. Apart from preventing hypoxemia and hypercapnia, external ventilation ensures delivery and removal of inhalational anesthetics anesthetic

agents, thus providing anesthetic stability and reducing recovery times (Bertelsen et al. 2015; Jakobsen et al. 2017).

Following endotracheal intubation, external ventilation may be achieved by manually "bagging" the animal or by means of a mechanical ventilator of appropriate size. For many species, specialized laboratory animal or very small animal equipment is necessary to avoid over-ventilation, and even with this equipment it may be hard to achieve sufficiently low respiratory rates. When artificially ventilating lizards and snakes, the larger tidal volume and lower minute ventilation compared to mammals should be taken into consideration and, if available, capnography should be used to monitor the level of ventilation. A minute ventilation of 50–75 mL/kg and a frequency of 0.5–2 breaths per minute will be adequate in most species, with end tidal pressures of 10–12 cmH_2O (Bertelsen et al. 2015; Jakobsen et al. 2017; Sladky & Mans 2012b).

Inhalation Anesthesia

Inhalational anesthesia is commonly used for induction and maintenance of reptile anesthesia. As in other species, the advantages of inhalational anesthetics include superior control of anesthetic depth, wide safety margins, excellent muscle relaxation, faster recovery, and "built-in" oxygen supplementation. As mentioned above, induction and recovery times in reptiles tend to be longer and more variable than in mammals and birds due to breath-holding, intracardiac shunting, and slow circulatory time.

Anesthetic Potency

Minimum alveolar concentration or minimum anesthetic concentration (MAC) is the standard measure of potency of inhalational anesthetic agents (Quasha et al. 1980) MAC is defined as the anesthetic concentration that prevents gross purposeful movement in 50% of an anesthetized population subjected to a supramaximal noxious stimulus, traditionally a surgical incision. Apart from permitting comparison of anesthetic agent potency, the value allows standardization and comparison of various depths of anesthesia as multiples of MAC. Using MAC values also provides a way of assessing the synergism between two anesthetics. Other terms essentially equivalent to MAC are sometimes reported in birds and reptiles (e.g., minimum anesthetic dose, effective dose 50, minimum infundibular concentration). Generally, MAC for a given agent varies little across mammalian species (Quasha et al. 1980) and the limited number of reports available indicate that the same applies to reptiles, although evolutionary differences in cardiopulmonary performance may give raise to greater variability among reptiles (Bertelsen et al. 2005b; Larouche 2019; Larouche et al. 2019).

As MAC only "accounts for" 50% of the population, vaporizer settings of 1.3 MAC are recommended to achieve surgical anesthesia. As a likely consequence of R-L intracardiac shunting and low minute ventilation, the equilibrium between inhaled substances and body occurs more slowly in reptiles. Consequently, effective MAC decreases over time in iguanas (and probably other reptiles), indicating that inhaled gas levels should be decreased toward the end of lengthy procedures (Barter et al. 2006; Brosnan et al. 2006; Williams et al. 2019a).

Equipment

Inhalant anesthetics are delivered either by agent-specific vaporizers using oxygen or a mix of oxygen and nitrous oxide as the carrier gas. Standard anesthetic machines fitted with non-rebreathing (Bain's) or circle systems are used, and for smaller specimens laboratory animal equipment has great potential. Commercially available small animal face masks, as well as masks home-made from plastic bottles or syringe cases work well.

Due to low metabolic rates, oxygen consumption is low (<1 mL/kg/min; Perry 1989) and flowrates may be reduced considerably compared to mammalian settings. In practice, the flow rate is often determined by the performance of flow meters and vaporizers, and rates of 250–1000 mL/min will be appropriate for most reptiles.

Induction

Unlike in chelonians, where inductions may be prohibitively prolonged, mask induction is generally feasible in lizards and snakes (Fig. 11.3). Animals may also be induced in chambers or plastic bags filled from a vaporizer at maximal setting, or simply by adding a small volume of the concentrated agent on a piece of cotton wool (e.g., ~1 mL isoflurane per liter of chamber volume). With the latter approach, close attention should be paid as inductions may be quite rapid and toxic levels could be reached if animals are left too long. Care should be taken to ensure that the anesthetic does not come into direct contact with the animal.

Early Inhalants

One of the first reports of anesthesia in reptiles is that of John Tait describing the surgical removal of venom glands from rattlesnakes under chloroform anesthesia, which was also used for immobilization of snakes for artistic purposes 100 years earlier (Bause 2016; Tait 1938). Later, prolonged

Figure 11.3 Mask induction of a monitor lizard with isoflurane. Note the use of a standard small animal face mask.

induction and recovery periods were described in several snake species anesthetized with methoxyflurane (Burke & Wall 1970; Gandal 1968). There are no recent reports on the use of either agent, and other drugs have long superseded them.

Ether anesthesia is associated with very long induction (40–60 minutes) and recovery periods in lizards and snakes (Bonath & Zschege 1979; Brazenor & Kaye 1953). While still occasionally used in physiological research and venom production, the agent must be considered obsolete in a clinical setting. It is also flammable and potentially explosive, therefore it is a hazardous chemical to store and use.

Halothane

Halothane delivered at 3–6% results in moderate sedation to profound anesthesia in lizards and snakes. At halothane concentrations of 5.8% the mean induction time at 22–25°C has been reported to be 24 minutes in lizards ($n = 38$) and 35.3 minutes in snakes ($n = 12$) (Bonath 1977, 1979; Bonath & Zschege 1979). Shorter induction times (5–19 minutes) were reported using 5% halothane in a 3:1 nitrous oxide/oxygen mixture (Custer & Bush 1980) A transient initial excitement stage has been described in rattlesnakes at very high concentrations (Hackenbrock & Finster 1963).

In snakes, halothane significantly decreases respiration rate and tidal volume, leading to respiratory acidemia, while heart rate decreases mildly or remains unchanged (Bonath 1977, 1979; Bonath & Zschege 1979; Custer & Bush 1980). Recovery times following brief anesthetic events are relatively short (24–35 minutes), while recovery times from deeper anesthesia are reported to be much longer (Bonath 1977, 1979; Bonath & Zschege 1979). No information exists on the potency of halothane in reptiles, and data on cardiopulmonary function during halothane anesthesia are limited to that described above. In the clinical setting, halothane has been replaced by isoflurane and sevoflurane.

Isoflurane

Isoflurane is used extensively in reptiles. In lizards, the time to initial relaxation and loss of righting reflex breathing 5% is typically 4–9 minutes (Hernandez-Divers et al. 2005; Mauthe von Degerfeld 2004; Schildger et al. 1993; Spelman et al. 1996) while the time to complete relaxation is 13–20 minutes depending on the species (Bertelsen et al. 2005a; Mosley 2000). In snakes, induction times with mask induction tend to be slightly longer (Schildger et al. 1993), but direct intubation of the awake snake followed by mechanical ventilation with the drug leads to rapid induction. As mentioned, faster inductions may be achieved using higher inspired concentrations by adding isoflurane directly to the induction chamber or by use of an injectable agent prior to intubation.

Isoflurane causes a moderate (~25%) reduction in heart rate (Hernandez-Divers et al. 2005; Maas & Brunson 2002) and a severe reduction in respiratory rate (Maas & Brunson 2002) when compared to values in manually restrained animals. It should be considered, however, that values in manually restrained subjects are significantly higher than in undisturbed animals (Bertelsen et al. 2005a). During anesthesia, a dose-dependent reduction in systemic blood pressure is observed (Chinnadurai et al. 2010; Mosley et al. 2004). At low concentrations animals continue breathing (Spelman et al. 1996), but at levels adequate for surgical anesthesia mechanical ventilation is usually necessary.

The minimum alveolar concentration at 30–35°C has been reported to be 1.11% (95% confidence interval 0.94–1.28%) in ball pythons (Larouche et al. 2019), $1.9 \pm 0.59\%$ in rat snakes (Maas & Brunson 2002), $1.8 \pm 0.3\%$ to $2.1 \pm 0.6\%$ in iguanas (Barter et al. 2006; Mosley et al. 2003a) and $1.54 \pm 0.17\%$ in monitors (Bertelsen et al. 2005b). These values indicate vaporizer settings of 2–2.5% will be appropriate to maintain surgical anesthesia in most subjects. As a likely consequence of R-L intracardiac shunting at the beginning of anesthesia, MAC decreases over time in iguanas (Barter et al. 2006), indicating inhaled gas levels should be decreased toward the end of lengthy procedures. The MAC decreases with decreasing body temperature (Dohm & Brunson 1998). In an attempt to determine the cardiac anesthetic index, seven iguanas were subjected to up to 9.2% isoflurane without any apparent signs of cardiac arrest, suggesting a very wide margin of safety (Mosley et al. 2003b).

Recovery time depends on the depth and duration of anesthesia, and is relatively short (2–12 minutes) following brief, shallow anesthetic events (Schildger et al. 1993; Spelman et al. 1996), intermediate (30–40 minutes) following light surgical anesthesia, and more prolonged (50–70 minutes) following deep anesthesia (Bertelsen et al. 2005a; Mosley 2000). In general, recovery times appear longer and more variable in snakes than in lizards.

Sevoflurane

Induction times using sevoflurane are slightly shorter than with isoflurane (Bertelsen et al. 2005a; Hernandez-Divers et al. 2005). In lizards induced with 8%, the time to initial relaxation and loss of righting reflex is around 6 minutes (Hernandez-Divers et al. 2005) while the time to complete relaxation is approximately 11 minutes (Bertelsen et al. 2005a). As for isoflurane, direct intubation of the awake animal followed by mechanical ventilation with the drug leads to rapid induction. The addition of 66% nitrous oxide will speed up inductions slightly (Bertelsen et al. 2005a).

Sevoflurane induction has been subjectively judged as smoother and associated with less breath-holding than with isoflurane (Hernandez-Divers et al. 2005), but the respiratory rate during induction appears to be similar or even marginally lower with sevoflurane (Bertelsen et al. 2005a). Sevoflurane causes a moderate reduction in heart rate and a severe reduction in respiratory rate compared to values in manually restrained animals (Hernandez-Divers et al. 2005; Maas & Brunson 2002). The hemodynamic effects of sevoflurane in iguanas are similar to those with isoflurane (Barter et al. 2006).

The minimum alveolar concentration at 30–35°C has been reported to be 2.42 ± 0.57% in rat snakes (Maas & Brunson 2002), 2.51 ± 0.46% in monitor lizards (Bertelsen et al. 2005c), and 3.1 ± 1.0% in iguanas (Barter et al. 2006), indicating vaporizer settings of 3–3.5% will be appropriate to maintain surgical anesthesia in most subjects. In a study of monitor lizards, the coadministration of 66% nitrous oxide resulted in a 25% reduction in sevoflurane MAC (Bertelsen et al. 2005c) and similar reductions are likely to occur in other species and with other inhalants, as shown with isoflurane in ball pythons (Larouche et al. 2019).

With modern inhalant anesthetics, the length of the recovery period appears to be influenced more by the duration and depth of anesthesia (and the extent of intracardiac shunting) than by the agent used (Brosnan et al. 2006). After a short time, relatively superficial anesthesia sevoflurane will result in faster recoveries than for isoflurane (Hernandez-Divers et al. 2005), but following prolonged, deep anesthesia that difference is marginal (Bertelsen et al. 2005a).

Desflurane

Desflurane is the least soluble of the volatile anesthetics, and thus theoretically has the fastest inductions and recoveries. However, it may cause airway irritability, requires specialized heated vaporizers, and is rarely used in veterinary practice. The minimum alveolar concentration at 34–35°C has been reported to be 8.9 ± 2.1% in iguanas, with hemodynamic effects being similar to those of isoflurane and sevoflurane (Barter et al. 2006).

Nitrous Oxide

Nitrous oxide (N_2O) may be used as a supplemental anesthetic (at 50–66% with oxygen) during induction with inhalational agents (Bennett 1998; Custer & Bush 1980; Larouche et al. 2019), resulting in marginally shorter induction times (Bertelsen et al. 2005a). Sixty-six per cent N_2O delivered with sevoflurane reduced the latter's MAC 25% in monitor lizards (Bertelsen et al. 2005c) and that of isoflurane by 17% in ball pythons (Larouche et al. 2019). Assuming that a relationship of simple linear additivity between sevoflurane and nitrous oxide exists, the MAC for N_2O in varanids can be estimated to be 244%. Apart from reducing the concentration of the primary agent, which may improve cardiopulmonary function, the use of N_2O likely provides improved analgesia over delivery in 100% oxygen.

Carbon Dioxide

Inhalation of carbon dioxide (CO_2) is occasionally used as a cheap and easy way to immobilize venomous snakes during venom extraction (Wang et al. 1993). Unconsciousness is thought to be mediated through central nervous system acidosis and is accompanied by temporarily very low oxygen levels in the arterial blood (Wang et al. 1993). This procedure is not recommended in clinical practice.

Small amounts of CO_2 can be added to the inhaled gases to avoid the respiratory alkalemia that often develop when the minute volume of mechanical ventilation exceeds the reptile's normal and low rate. As an example, it can be suitable to add 1–3% of CO_2, which then allows for high rates of mechanical ventilation that ensures high oxygenation of the lungs (Crossley et al. 1998; Overgaard et al. 2002). Also, use of a 10% CO_2 mixture has been suggested to stimulate respiration during recovery (Malley 1997), but the ventilatory response to hypercapnia is complex in squamates as intrapulmonary chemoreceptors may inhibit ventilation (Milsom 1991).

Parenteral Anesthesia

Numerous injectable anesthetics have been used in snakes and lizards with varying success. These include etorphine hydrochloride (Hinsch & Gandal 1969; Wallach & Hoessle 1970), pentobarbital sodium (Arena et al. 1988; Betz 1962; Karlstrom & Cook 1955), thiopental sodium (Karlstrom & Cook 1955), methohexital (Preston et al. 2010; Wang et al. 1977), MS-222 (Green & Precious 1978; Karlstrom & Cook 1955), urethane (Calderwood 1971), nicotine (Calderwood 1971), decamethonium iodide (Brazenor & Kaye 1953), 2,2,2-tribromoethanol (Rasys et al. 2019), procaine hydrochloride (Livezey 1958), and the muscle relaxant tubocuraine chloride (Brazenor & Kaye 1953). While still occasionally used in experimental settings, these agents must be considered obsolete in clinical practice.

Propofol

Provided vascular access is available, propofol is these authors' agent of choice for anesthetic induction. Administered intravenously or intraosseously at dosages of 5–10 mg/kg, propofol will cause induction in 1–5 minutes (Anderson et al. 1999; Bennett et al. 1998; Bertelsen et al. 2015; McFadden et al. 2011). Propofol administered perivascularly is ineffective, but unlike barbiturates does not cause tissue damage. Administration via the ventral tail vessels is generally feasible in patients larger than 250 g, although there are significant species differences.

In lizards and snakes, propofol causes a slight decrease in heart rate from handled levels and a marked respiratory depression (Anderson et al. 1999; Bennett et al. 1998). The respiratory depression is dose dependent and appears to be affected by the duration of administration: low doses given slowly cause less apnea than high doses administered as a bolus.

The duration of anesthesia depends on dosage: 5 mg/kg results in 20–30 minutes of anesthesia, while anesthesia and recovery times are longer following 10 mg/kg dosage. Anesthesia may be maintained by inhalation or by continuous propofol infusion. An infusion rate of 0.5 mg/kg/min proved excessive in green iguanas (Bennett et al. 1998) and rates of 0.2–0.4 mg/kg/min are likely more appropriate. For most species, a dose of 5–10 mg/kg given slowly is appropriate for short procedures or as induction for inhalational anesthesia.

Alfaxalone

The steroid anesthetic alfaxalone is highly insoluble in water and was originally formulated in combination with alphadalone and a cremaphor solubilising agent. Alfaxalone soon found some use in reptiles (Calderwood & Jacobson 1979; Lawrence & Jackson 1983), but its use was discontinued as cremaphor was associated with allergic reactions in domestic animals. More recently, alfaxalone has been solubilized with 2-hydroxypropylbeta-cyclodextrin (Estes et al. 1990). When given intravenously, this formulation has much the same effects as propofol. In veiled chameleons and leopard geckos, a surgical plane of anesthesia lasting for 5–10 minutes was achieved 2 minutes following 5 mg/kg IV (Knotek et al. 2011; Morici et al. 2018) and enabled tracheal intubation in agamid lizards 1 minute after administration (Knotek 2017). In green iguanas, 5 mg/kg IV resulted in about 15 minutes of anesthesia with minimal effect on heart rate and respiratory rate (Knotek et al. 2013), while in bearded dragons 12 mg/kg IV provided "surgical anesthesia" in five out of eight animals, lasting approximately 15 minutes (Perrin & Bertelsen 2017). Interestingly, unlike propofol, alfaxalone is effective when administered intramuscularly or subcutaneously at higher dosages. In iguanas, 10 mg/kg provides light sedation, 20 mg/kg provides a level suitable for minor procedures or for endotracheal intubation and supplementation with inhalational anesthesia, and 30 mg/kg provides an anesthetic plane suitable for surgical procedures of limited duration (up to 40 minutes) (Bertelsen & Sauer 2011). In iguanas there is an initial dose-dependent depression of respiration followed by a significant increase in frequency over time (Bertelsen & Sauer 2011). In accordance with principles of metabolic scaling, smaller individuals require higher dosages. A dosage of 5 mg/kg IV via the jugular vein was sufficient for tracheal intubation in leopard geckos, while 15 mg/kg intramuscular (IM) in combination with midazolam provided sufficient sedation for venipuncture (Doss et al. 2017; Morici et al. 2018). In contrast, 20 mg/kg IM alfaxalone after 10 mg/kg butorphanol premedication did not result in surgical level anesthesia in bullsnakes (Sadar & Ambros 2019).

In pythons, both IM and subcutaneous administration cranial to the heart resulted in faster inductions and a deeper plane of anesthesia than alfaxalone administered more caudally, probably due to the hepatic metabolism of caudally administered drug (James et al. 2018; Yaw et al. 2018). Alfaxalone in combination with dexmedetomidine was found to be sufficient for celiotomy in brown anoles (Rasys et al. 2019), and as a sole agent was preferable to ketamine in galliwasps (Kleinschmidt et al. 2018). In both ball python and bearded dragons, alfaxalone-induced animals have been reported to have increased reaction to external stimuli, so reducing external stimulation may aid smooth recoveries (James et al. 2018; Perrin & Bertelsen 2017).

Ketamine

Ketamine hydrochloride has been used extensively in reptiles, primarily snakes, since its introduction in the late 1960s (Glenn et al. 1972; Schumacher et al. 1997).

The effective dosage depends on body temperature (Arena et al. 1988): at lower body temperatures lower doses are required, but both induction and recovery are prolonged (Arena et al. 1988; Green et al. 1981). Effects are highly species dependent (Arena et al. 1988; Cooper 1974; Hill & Mackessy 1997; Ogunranti 1987; Schildger et al. 1993), but large individual variation is also observed (Cooper 1974; Hill & Mackessy 1997).

Reported dosages range from 12–44 mg/kg for sedation (Bennett 1998; Glenn et al. 1972; Schildger et al. 1993; Spelman et al. 1996) to 55–88 mg/kg for surgical anesthesia (Bennett 1998; Glenn et al. 1972; Schildger et al. 1993), while yet higher doses (100–220 mg/mL) are occasionally reported (Arena et al. 1988; Harding 1977). The time to peak effect following IM injection is approximately 30 minutes (Cooper 1974; Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981).

In snakes and lizards, moderate ketamine dosages are associated with increased heart rates (Arena et al. 1988; Schumacher et al. 1997), hypertension (Schumacher et al. 1997), and respiratory depression, peaking at 30–60 minutes (Arena et al. 1988; Ogunranti 1987; Schumacher et al. 1997). At increasing dosages, ketamine will induce apnea, bradycardia, and eventually death (Cooper 1974; Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981).

The very extended recovery periods represent the main problem with ketamine anesthesia in reptiles. Reported recovery times range from 6–24 hours at 15 mg/kg (Hill & Mackessy 1997) to 2–3 days at 40–80 mg/kg and 6–7 days at 100–130 mg/kg (Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981).

Ketamine may be combined with sedatives, such as benzodiazepines and alpha-2 agonists, for better muscle relaxation, a reduction in required dose, and shorter recovery times (Bennett 1998; Budden et al. 2018; Fink et al. 2018; Heard 2001; Malley 1997), and may provide long-term anaesthesia for extended procedures (Barrillot et al. 2018a). Due to the variable effects, long recovery periods, and the availability of alternative protocols, the authors rarely use dissociative agents.

Zolazepam-Tiletamine

The potent cyclohexamine tiletamine combined with the benzodiazepine zolazepam has found some use in reptile anesthesia (Boever & Caputo 1982; Gray et al. 1974; Read 2004), but very little published information exists. The onset of effects is faster than with ketamine (Mauthe von Degerfeld 2004), while cardiopulmonary effects are likely similar to those produced by ketamine. In early studies, dosages of 30–40 mg/kg administered to iguanas resulted in surgical anesthesia lasting 8–16 hours, while variable effects were seen with doses of up to 88 mg/kg in snakes (Boever & Caputo 1982). In Komodo dragons, dosages of 5.5 mg/kg caused repetitive head and neck movements 10–25 minutes before resulting in sedation (Spelman et al. 1996). In iguanas 10 mg/kg resulted in a brief period of excitement followed by good relaxation (Mauthe von Degerfeld 2004). Despite its long duration of action and variable effects, low doses (2–5 mg/kg) may be useful for sedation prior to handling or intubation, particularly of larger animals.

Sedatives

Sedative and tranquilizing drugs such as benzodiazepines and alpha-2 agonists may be used in squamates, and can reduce MAC and provide additional anesthetic depth (Bisetto et al. 2018; Doss et al. 2017; Larouche et al. 2019; Rasys et al. 2019). Reversal with atipamezole can make alpha-2 agonists attractive sedative agents for fast recoveries, and their administration in combination with ketamine or midazolam is gaining use (Barrillot et al. 2018b; Cushing et al. 2020; Rasys et al. 2019; Sadar & Ambros 2019; Yaw et al. 2020). Due to the difficulty in accessing the vascular system and airways, sedatives have gained popularity in turtles and tortoises, and as information gained in chelonians can probably be extrapolated to snakes and lizards, readers are also referred to Chapter 10.

Other Techniques

Hypothermia, once used as a means of immobilizing reptiles (Broeckhoven et al. 2017; Calderwood 1971; Kaplan 1969; Keifer & Zheng 2017) is considered an unacceptable clinical practice, as is electro-immobilization.

Recovery

As mentioned above, recovery times in reptiles are prolonged compared to birds and mammals. Body temperature critically affects speed and quality of recovery so animals should be kept within their preferred temperature zone. If mechanical ventilation is used, animals should gradually be weaned off ventilation. The easiest way to do so is by manual ventilation every 1–5 minutes using an Ambu-bag or similar to allow carbon dioxide to build up. A capnograph is useful in detecting spontaneous respirations during recovery. Breath holds of 5–10 minutes with inflated lungs will not cause deleterious effects.

Despite previous clinical concern over the effect of hyperoxia on respiration in reptiles based on past physiological data (Glass & Johansen 1976) there appears to be little effect of recovery in room air (21% oxygen) as opposed to 100% oxygen. While faster recoveries were experienced when ventilating iguanas with 21% oxygen following short-term isoflurane anesthesia (Diethelm & Mader 1999), no difference could be demonstrated following longer anesthetic events (Bertelsen et al. 2005a). Reversal of any alpha-2 agonists allows faster recovery from combination injectable anaesthesia, but will also remove any analgesic effect, while flumazenil may be used to reverse benzodiazepines (Doss et al. 2017; Yaw et al. 2020). IM administration of epinephrine may reduce recovery times without apparent adverse effects (Heard, pers. comm.).

Complications

Complications are relatively rare using the protocols suggested above, but respiratory depression or apnea and prolonged recoveries are commonly encountered (Read 2004). These problems may be reduced by providing adequate mechanical ventilation and by maintaining body temperature within physiological limits.

Analgesia

Since the first edition of this book, pain perception and modulation have received an increasing amount of attention in reptiles (d'Ovidio & Adami 2019; Mans et al. 2019b; Mosley 2011; Perry & Nevarez 2018; Sladky & Mans 2012a, 2019; Williams et al. 2019b). A slower return to normal feeding in ball pythons experiencing a surgical incision under isoflurane than in those anesthetized without incision underlines the need for perioperative analgesia in reptiles (James et al. 2017). However, there is a continuing need for well-controlled analgesic studies. While thermal and chemical nociceptive models have provided well-tested methodologies and are the basis for many of the following recommendations, they may not replicate the effect of treatment in spontaneously painful conditions, where published trials are still lacking.

In anoles, the administration of the μ-receptor opioid morphine (5 mg/kg IM) caused an increased latency of the tail-flick response (Mauk et al. 1981). Similarly, morphine (10–20 mg/kg) increased thermal withdrawal latency in red-eared sliders (Sladky & Miletic 2007) and bearded dragons (Sladky et al. 2008), but appears to be ineffective in corn snakes at dosages up to 40 mg/kg (Sladky et al. 2008) and at 10 mg/kg in ball pythons (Williams et al. 2016). Morphine causes severe respiratory depression, but another μ-receptor opioid, tramadol, appears to have similar effects on thermal withdrawal latency (10–15 mg/kg PO, SC) in turtles with much less respiratory depression (Baker et al. 2011). Similarly, another μ-receptor opioid, hydromorphone (0.5 mg/kg IM), increased thermal withdrawal time in sliders (Mans et al. 2012). Fentanyl patches have been seen to provide plasma levels that would be expected to be effective in skinks and snakes (Darrow et al. 2017; Gamble 2008; Kharbush et al. 2017), but despite clinical experience of analgesia in patients with chronically painful conditions (snakes with arthritis), fentanyl patches were not effective in a thermal nocioceptive test and significantly depressed respiration (Kharbush et al. 2017).

The predominant κ-receptor opioid butorphanol (20 mg/kg SC) was ineffective in bearded dragons and sliders, and only effectively increased thermal withdrawal latency in corn snakes at exceptionally high doses, which have extreme sedative effects and are unsuitable in clinical patients (Sladky & Miletic 2007; Sladky et al. 2008). In iguanas, butorphanol (1 mg/kg IM) failed to decrease the minimum anesthetic dose of isoflurane and did not provide demonstrable analgesia in a heat pad test (Fleming & Robertson 2012; Mosley et al. 2003a).

Nonsteroidal anti-inflammatory drugs (NSAIDs) have, perhaps mistakenly, been expected to behave much the same across species, although tissue concentrations of COX-1 and -2 in inflamed tissue varies among reptiles (Royal et al. 2012; Sadler et al. 2016). Nevertheless, clinical evidence supports the efficacy of NSAIDs in reptiles and they appear widely used (Hernandez-Divers 2006; Read 2004). A pharmacokinetic trial of meloxicam in iguanas showed excellent bioavailability following PO administration, and suggested that administration of meloxicam at a dose of 0.2 mg/kg IV or PO results in plasma concentrations of >0.1 μg/mL for approximately 24 hours (Divers et al. 2010). Furthermore, daily administration of high doses (1 or 5 mg/kg) for 12 days did not induce any histologic changes in gastric, hepatic, or renal tissues (Divers et al. 2010). Similarly, daily administration of meloxicam (0.2 mg/kg IM for 10 days) in iguanas failed to demonstrate any significant clinical, biochemical, or hematological abnormalities (Trnkova et al. 2007). In an attempt to evaluate the effect of meloxicam (0.3 mg/kg IM) and butorphanol (5 mg/kg IM), the postoperative physiological stress response in ball pythons was evaluated and failed to demonstrate an effect of either drug (Olesen et al. 2008). However, even in the saline-treated control group there was only minimal measurable physiological response to surgery, questioning the validity of the model. COX-2 expression in inflamed skin did not change in experimental lesions in pythons (Sadler et al. 2016), so further study

is required to investigate whether a less selective NSAID would be more effective in snakes.

Despite the lack of current comprehensive documentation, analgesics should be part of any anesthetic regimen that involves potentially painful procedures. μ-receptor opioids and NSAIDs are the most relevant candidates for successful treatment, and suggested dosages of selected drugs are given in Table 11.1. Future directions include preliminary work suggesting that alpha-2 agonists may provide thermal antinociception in pythons (Bunke et al. 2018).

As in any species, preemptive analgesia offers intraoperative as well as postoperative analgesia, and likely will reduce the amount of anesthetic needed (Ong et al. 2005; Page et al. 1998). Local analgesics (e.g., lidocaine, bupivicaine) are commonly used in reptiles, using doses extrapolated from the mammalian literatures (Chatigny et al. 2017; James et al. 2017; Sladky & Mans 2012b). Given their action on sodium channels, central to nociception in reptiles, they are expected to be effective given both locally as infiltrations and as nerve blocks and regional protocols (Mans et al. 2019b; Wellehan et al. 2006). In small subjects, diluting the drugs (e.g., 1:10 in sterile saline) prior to administration will help to allow sufficient volume to provide analgesia to the surgical area while avoiding overdosing. Intrathecal lidocaine administered under alfaxalone has been shown to provide antinociception, but requires skills in administration (Ferreira & Mans 2018). Systematic research into the duration of action and the effects of dilution and mixing (e.g., bupivacaine and lidocaine coadministration) on the efficacy of local anaesthetics is currently still lacking in reptiles for local administration, but its use is recommended by these authors on clinical grounds.

Selected Protocols

For most snakes and lizards the authors recommend one of three approaches (Table 11.2): induction with propofol (5–10 mg/kg IV) or alfaxalone (5 mg/kg IV, 20–30 mg/kg

Table 11.1 Selected anesthetic, sedative and analgesic drugs used in snakes and lizards.

Generic Name	Dosage (mg/kg)	Reversal Agent	Reference
Propofol	5–10 IV/IO	None	Bennett et al. (1998); Anderson et al. (1999); McFadden et al. (2011)
Alfaxalone	5–10 IV 10–40 IM (cranial administration preferred) 5–30 SC (cranial administration preferred)	None	Knotek et al. (2011); Bertelsen and Sauer (2011); James et al. (2018); Rasys et al. (2019); Yaw et al. (2018)
Midazolam	0.5–2	Flumazenil	Larouche et al. (2019); Sadar and Ambros (2019)
Medetomidine	0.05–0.2	Atipamezole	Barrillot et al. (2018); Wightman et al. (2015)
Dexmedetomidine	0.025–0.2	Atipamezole	Bisetto et al. (2018); Cushing et al. (2020); Fink et al. (2018); Rasys et al. (2019); Sadar and Ambros (2019); Yaw et al. (2020); Budden et al. (2018); Bunke et al. (2018); Doss et al. (2017)
Ketamine	10–40[a]	None	Glenn et al. (1972); Custer and Bush (1980); Schumacher et al. (1997); Barrillot et al. (2018b); Cushing et al. (2020); Fink et al. (2018); Rasys et al. (2019); Sadar and Ambros (2019)
Zolazepam-tiletamine	2–10	Flumazenil for zolazepam	Mauthe von Degerfeld (2004)
Meloxicam	0.1–0.3	None	Divers et al. (2010); Hernandez-Divers (2006)
Morphine	5–15	Naltrexone, naloxone	Sladky et al. (2008); Williams et al. (2016)
Tramadol	10–15	Naltrexone, naloxone	Baker et al. (2011)
Lidocaine	1–5		Chatigny et al. (2017)
Bupivicaine	1–2		Chatigny et al. (2017)

IM, intramuscular; IO, intraosseous; IV, intravenous; SC, subcutaneous.
[a] Dosages up to 220 mg/kg have been reported (Arena et al. 1988).

Table 11.2 Recommended anesthetic protocols for snakes and lizards (refer to text for details).

Type	Premedication	Induction	Maintenance
Small snake	None	Propofol 5–10 mg/kg IV Chamber induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Large snake	None or Alfaxalone 10 mg/kg, cranial administration IM/SC or Telazol 5–10 mg/kg IM	Propofol 2–7 mg/kg IV Direct intubation[a] followed by ventilation with isoflurane or sevoflurane Chamber induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Venomous snake	None	Propofol 5–10 mg/kg IV[b] Chamber induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Small lizard	None	Propofol 5–10 mg/kg IV Alfaxalone 20–40 mg/kg IM/SC administered cranial to liver Chamber induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Large lizard	None or Telazol 5–10 mg/kg	Propofol 3–10 mg/kg IV Mask with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube

IM, intramuscular; IV, intravenous; SC, subcutaneous.
[a] Desentization of the glottis with a drop or spray of local analgesic recommended.
[b] If properly restrained.

IM, cranial half of animal) followed by isoflurane or sevoflurane anesthesia for longer duration, or mask or chamber induction with isoflurane or sevoflurane. For large and aggressive specimens, injection with low doses of ketamine (e.g., 5 mg/kg IM) or tiletamine/zolazepam (e.g., 3 mg/kg IM), with or without (dex-) medetomidine (e.g., 50–100 μg/kg IM) or midazolam (e.g., 1 mg/kg IM), may be used to allow safe handling. Dosages of commonly used drugs are presented in Table 11.1. These anesthetic regimes are supplemented by the use of local anesthesia, NSAIDs, and opiate administration where nociception is expected.

Field Techniques

For fieldwork, when equipment must be kept to a minimum, the protocols using parenteral drugs are recommended. Depending on the size of the animal and the invasiveness of the procedure, IM alfaxalone (10–40 mg/kg, cranial half of animal) or IV propofol (5–10 mg/kg) may be employed. Liquid isoflurane or sevoflurane administered directly into a small airtight container or plastic bag containing the animal is another straightforward means of induction even in the field and remains popular in telemetry studies, but care should be taken to ensure effective breathing of the animals once removed from the container.

Venomous Reptile Restraint and Handling

Frederick B. Antonio

Introduction

This chapter presents information and recommendations for the restraint of venomous reptiles in either a clinical environment or field conditions. For simplicity, a venomous reptile refers to venomous snakes. A section at the end of the chapter will review the management of venomous lizards of the family Helodermatidae (Gila monsters and beaded lizards). Envenomation will be referred to as snakebite, although it is recognized that helodermids can also inflict a serious bite.

It is intended that the use of the techniques described in this chapter will greatly reduce the probability of snakebite. There is always some inherent risk, however, when handling and restraining venomous reptiles. The combination of planning, training, and gaining experience for the skills necessary for proper handling will significantly reduce the probability for error.

In recent years captive venomous reptiles have increased in popularity in the private sector. They are the topics of numerous television series, and are portrayed as both exciting and dangerous, often by actors and commentators that inspire young viewers to engage in interactions with venomous species. Many private collectors, researchers, and zoo professionals have only a vague notion of the potential lethality of their charges. Their ignorance includes both the potential physiological effects of venoms and the behaviors that make venomous snakes difficult to restrain (Altimari 1998). Some states within the United States prohibit personal possession of venomous reptiles while others lack any regulation. Florida annually issues over 500 venomous reptile permits for personal possession. Many private collections are "underground" and reptile clinicians should expect to examine virtually any species of native or exotic venomous reptile. Safe handling of these animals requires veterinarians, researchers, and support staff to be familiar with and use proper methods. The following presents current procedures and techniques designed to limit unrestrained contact with venomous reptiles and thereby promote safety during examinations, clinical procedures, and fieldwork.

General Characteristics

Snake venoms evolved primarily to aid in prey acquisition and secondarily for defense. More than 2700 snake species are currently recognized within about 18 families and 420 genera (Greene 1997). Of these, 250–500 species may induce serious physiologic effects in humans. These belong primarily to the families Elapidae (cobras, kraits, mambas, coral snakes, and seasnakes) and Viperidae (true vipers and pitvipers).

Almost every colubrid snake family has at least one species whose venom has the potential to produce either morbidity or mortality in humans. These include Colubridae (*Dispholidus*, *Thelatornis*), Dipsadidae (*Hydrodynastes*, *Xenodon*, *Waglerophis*), Atractaspididae (A*tractapis*, *Homoroselaps*), Homalopsidae (*Cerberus*, *Enydris*, *Homalopsis*), Natricidae (*Macropisthodon*, *Rhabdophis*), Psammophiidae (*Malpolon*, *Psammophis*, *Rhamphiophis*), and Pseudoxyrhophiidae (*Leioheterodon*, *Madagascarophis*) (Fry 2006). Of these, the most commonly imported are the boomslang, *Dispholidus typus*; African twigsnake, *Thelotornis capensis*; Blanding's treesnake, *Boiga blandingi*; road guarder, *Conophis lineatus*; Japanese water snake, *Rhabdophis tigrinus*; and false pitvipers, *Xenodon* spp.

The evolution of reptilian venom systems (Fry et al. 2006) demonstrates some extant "nonvenomous" snake taxa and certain lizards of Varanidae (monitor lizards) and Iguania to have toxin-secreting oral glands. A thorough review of nonfront-fanged colubroid snakes (Weinstein et al. 2011)

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

analyzes documented case reports of bites inflicted by approximately 100 species and discusses clinical management of medically significant species, most commonly referred to as "rear-fanged" snakes. Studies of this kind confirm toxic salivary secretions in extant reptiles, usually products of the Duvernoy's gland, that present a continuum of toxicity from mild to severe. Their presence and effects in human victims require further study to build clinical evidence as to their potential severity. Thus, it is prudent for the clinician to treat suspect or unusual species, especially opisthoglyphs, with the same precautions as they do recognized venomous species.

Venom delivery systems originate from modified salivary glands. These vary from mucous-producing oral glands to well-developed encapsulated glands with separate compressor musculature to express venom through a duct to individual hollow fangs. There are four dental patterns in snakes (Greene 1997): aglyphous, undifferentiated maxillary teeth (present in primitive snakes and some colubrids), opisthoglyphous (enlarged teeth, which may be grooved to facilitate induction of salivary secretions) located on the posterior ends of the maxillary bones (present in rear-fanged snakes), proteroglyphous, enlarged true hollow fangs located on the anterior end of the maxillary bones that have restricted movement (present in elapids), and solenoglyphous, elongated hollow fangs located on highly movable maxillary bones, and folded back along the roof of the mouth when not in use (present in vipers and pitvipers). These four basic dental morphologies represent a progression in efficiency for venom induction when biting.

One impressive variation in fang structure with management implications is found in the elapid species referred to as spitting cobras. Eye injuries by spitting snakes (Chippaux 2006) include African species (*Naja nigricollis, N. katiensis, N. mossambica, N. pallida, N. crawshayi* and *Hemachatus hemachatus*) and some populations of Asian cobras (*Naja sputatrix*). These species have a fang structure and discharge orifice to defensively eject venom aimed at the eyes of an intruder. Target accuracy and the distance of ejection are from 1 to 5 m (Russell 1980). Full-face shields (Fig. 12.1) are recommended at all times when working these species. If venom comes in contact with an eye, wipe remaining venom away from the eyes and begin immediate copious irrigation with sterile saline solution (Boyer & Murphy 1999). A long-sleeved lab coat or protective garment is recommended to shield skin. Venom may also be expressed on the inside of a restraint tube. Expelled venom must be treated with extreme caution during both the procedure and the clean-up process. Dried venom on glass can be aerosolized during cleaning and cause injury to eyes and mucous membranes.

Figure 12.1 Full-face shields and protective garments are recommended when working with all species of spitting cobras. Red spitting cobra, *Naja pallida*, Central Florida Zoo and Botanical Gardens.

Snake Behavior

Handling and restraint should be approached every time as a novel experience that may be significantly different from previous procedures. Planning the procedure with the total focus of all persons involved is required. Complacency or a casual approach, no matter how experienced the handler, can result in an unexpected and disastrous outcome.

Every species exhibits different behaviors when manipulated. Defensive behaviors vary with the individual temperament of each snake, and the handler must observe and read these behaviors to adjust their response and modify techniques if needed. Altimari (1998) describes the temperaments of many captive venomous snake species. Viperids tend to defensively coil and may strike out in any direction. Elapids are more dangerous to manipulate and may initially attempt to flee. However, they can turn and strike at any time, or strike first then look for an escape route. Striking distances are approximately two-thirds of the total body length. For some species, however, when traveling and lunging while striking it is difficult to determine a safe working distance in an open environment. Always overestimate the strike range.

Snakebite

In the United States prior to 1950, exotic venomous snakes were primarily found in zoos. Increased interest in reptiles during the latter part of the 20th century has resulted in the United States becoming the major importer of reptiles, representing 80% of the world trade or approximately 2,000,000

reptiles imported annually (Keyler 2006). The vast majority of snakebites occur in private collections comprising a large variety of genera and species (Seifert 2006a). Of these, nearly half are elapid bites. The incidence of non-native envenomations has increased significantly over the past decade. Statistics on snakebite in clinical situations are difficult to obtain, as many are not reported to data surveillance systems. Toxic Exposure Surveillance System (TESS) data for 2002 showed the number of exotic snakebites in the United States to be 125 (Keyler 2006), and around 100 exotic bites are reported to the American Association of Poison Control Centers annually (Lai et al. 2006).

In a survey of 40 academic institutions that used venomous reptiles in research projects (Ivanyi & Altimari 2004) 18 facilities reported 42 envenomations and six dry bites from 20 species. The majority of these bites (87.5%) were the result of inappropriate capture techniques and inadequate restraint methods, including free handling snakes, pinning, handling with gloves, and improper use of restraint tubes. Card and Roberts (1996) surveyed North American zoos to determine the incidence of venomous reptile bites received by staff. Out of 30 reptile collections that maintained venomous reptiles, 21 zoos reported a staff member bitten during a 25-year period with a total of 31 incidents. Of these, 15 envenomations occurred during routine handling, five during physical restraint, and one during a veterinary procedure. In a survey of 32 venom extraction facilities worldwide (Powell et al. 2006) envenomation averaged one per facility every 2 years. Although records of envenomation in veterinary medicine are lacking, the potential is ever present when a client presents a venomous reptile for examination and treatment. In many cases this is a novel experience for the practitioner, who lacks behavioral knowledge of the species, handling expertise, and proper equipment.

Antivenom

Antivenom is the only product recommended for treatment of snakebite. The goal of this immunotherapy is to neutralize venom components with antibodies and prevent them from reaching their sites of action. All snakebites are medical emergencies requiring effective response protocols and knowledgeable case approach by the treating physicians once the victim arrives in the emergency room. Treatment of snakebite is outside the scope of this chapter, but it remains the responsibility of the veterinary clinician or researcher to either possess the appropriate antivenin or know the nearest local source for the species to be restrained.

The appropriate foreign antivenom for exotic snake species should be present when working with these species as it is not stocked in hospital pharmacies. Ideally it should be provided by the client and accompany the snake during transport to the clinician. Antivenom for native species is usually stocked at local hospitals for venomous species found in that region. It is recommended to contact local hospital pharmacies to periodically check on current inventories as antivenom can be difficult to obtain and supplies may be limited.

Treatment of envenomations is a challenge to physicians as most have never treated a snakebite victim. Case approaches, the appropriate use of antivenom, and patient support have also been controversial. Locating and obtaining appropriate antivenom may be difficult, resulting in critical delays (Seifert 2006b). Species-specific antivenom should be sought unless there is evidence for cross-species efficacy. Most private collectors do not routinely maintain exotic antivenoms (Keyler 2006). Lack of sufficient appropriate antivenin can be a determining factor in choosing not to accept cases or engage in specific research projects that involves the handling of venomous snakes.

In the United States, foreign manufactured antivenin can be imported by facilities or individuals under an Investigational New Drug license issued by the Food and Drug Administration, Department of Health and Human Services. These products may be species-specific or polyvalent. Some antivenoms have shown cross-species neutralization (Minton 1999), but evidence must be available for efficacy before relying on this strategy. The appropriate antivenom should be provided by a responsible owner or researcher and travel with the snake to the clinic. If the owner does not have the appropriate antivenom, the nearest source should be located prior to arrival. For long-term studies, the acquisition and stocking of the appropriate antivenom is recommended.

An Online Antivenom Index (OAI), developed by the Association of Zoos and Aquariums (AZA) and the American Association of Poison Control Centers, lists specific antivenoms for the treatment of exotic snakebite and their locations across the country. This antivenom inventory can be accessed by calling Poison Control (US phone: 1-800-222-1222) to locate the nearest source for specific antivenom appropriate for the species. In most cases the source is an AZA facility that logs their institutional inventory on the OAI site. Poison control centers have access to this information and should be consulted when locating a potential source of antivenom for projects or procedures involving venomous snakes.

An additional source for foreign antivenoms is the Miami-Dade Fire Rescue Antivenin Bank (formerly the Florida Antivenin Bank, Inc.), which stocks a significant inventory of antivenoms. Information on their holdings and procedures for requesting antivenom can be found on their website (www.venomousreptiles.org). A phone call can arrange an emergency response (Emergency Envenomation, phone

786-336-6600 or nonemergency 786-331-4444) to arrange antivenom transport to the attending hospital. This service can be a critical element in the treatment of snakebite when quantities of appropriate antivenom are lacking.

Management Guidelines

Strict protocols for handling venomous reptiles, routine husbandry, and staff training promote safety for staff and animals. Written protocols for snakebite response must be in place prior to receiving venomous reptiles. Snakebite protocols and case approaches for attending physicians should be established with the local hospital and emergency room physicians to help ensure swift and consistent treatment. A list of consulting physicians who are experts in treating snakebite should be readily available as a resource for local treating physicians because few will be familiar with proper clinical management of snakebite.

The following venomous reptile handling protocols serve as a baseline for establishing best practices and may be expanded to incorporate unique aspects of facilities or research projects.

1) Venomous reptiles should not be handled by anyone except designated personnel.
2) Staff should be thoroughly trained, knowledgeable, and comfortable with handling procedures.
3) Always review techniques and procedures with staff. Set up the workspace in advance and clear the area of unnecessary objects or obstacles. Have all appropriate tools readily available.
4) Never work with venomous reptiles when in a hurry, mentally distracted, or on medication that may impair alertness, reflexes, or response time.
5) Two qualified personnel should always be present. Assistance is often needed and a second person is crucial should snakebite occur.
6) Cages should remain locked until they are ready to be opened. Always announce a cage is to be opened so the attention of support staff is immediately focused on the procedure.
7) All cages should be clearly marked "VENOMOUS". An additional label should state the name of the species (common and scientific name), the number of animals in the enclosure, the type of antivenom to be administered, and the typical number of vials recommended for a moderate envenomation.
8) Never handle a reptile that appears dead directly with your hands. Always use a tong or snake hook to test for movement. The mouth of a dead specimen should be carefully taped closed to avoid unintentional contact with the fangs.

Equipment and Methods

Venomous reptiles can be managed safely by using the proper tools and techniques. Training and experience play a significant role in developing expertise. A working knowledge of snake behavior and the reaction of snakes to stimuli will aid in strategizing the best methods to use for a particular procedure. An organized and methodical approach to handling and restraint increases control and is reassuring to support staff that may be unfamiliar with working venomous reptiles. The equipment and methods described here are proven techniques. Innovations can produce further modifications for specific procedures. Historic methods such as pinning a snake behind the head for manual restraint (Fig. 12.2) are dangerous manipulations and should be discouraged.

Snake Hooks

The manipulation of venomous snakes using snake hooks (Fig. 12.3), as opposed to tongs, lowers the potential of injury to the animal. Reptiles have a single occipital condyle supporting their skulls on the cervical spine. Rough handling or improper restraint can cause spinal injury (Frye 1991) when the snake twists or thrashes. Vertebral morphology and the limitations of movement by vertebrae and axial musculature have been reviewed by Gasc (1976). Using tongs for restraint may also induce the snake to bite itself. This can result in self-inflicted fang penetration and envenomation. Although the effects of self-envenomation are usually minimal due to immunity, mechanical damage due to fang penetration can have a serious outcome.

Figure 12.2 Pinning behind the head for manual restraint is not recommended. Snakes when struggling can move fangs independently while dislodging the mandible to succeed with envenomation. Eyelash viper, *Bothriechis schlegeli*, The Orianne Society.

Figure 12.3 Snake hooks (top to bottom): wide-blade python hook, extension hook, double-handled hook, various styles, L hook or pinning hook.

The choice of snake hook is dependent on the size and species. Hooks come in a variety of sizes and configurations, and can be homemade or purchased from specialty suppliers (e.g., Midwest Tongs and Animal Capture Equipment Inc.). Two main design aspects need to be considered when choosing the appropriate hook. First, the length of the hook handle must be longer than the striking distance to the hand. In most species this is usually two-thirds of the length of the snake or more. The second is that the terminal end of the hook, which supports the snake, should be of sufficient diameter to comfortably hold the weight of the snake. Large, heavy animals require the wider support surface found on larger diameter hooks. Python hooks have wide flattened surfaces of 3–6 cm for added comfort to the snake during lifting. This results in a more consistent manipulation of large vipers (genus *Agkistrodon, Bitis, Crotalus, Lachesis*, and *Vipera*). The main disadvantage of python hooks is they usually lack sufficient shaft length for large specimens. A hook with a terminal L-shaped end is not recommended. The snake will slide down the shaft if it is lifted higher than the handle of the hook. Hooks are relatively simple tools that can be made and tailored to problematic species or individuals.

Basic steps when using a hook:

1) Always set up all required equipment first (transfer or holding containers, and a clear work area) and review the procedure steps with personnel. It is desirable to have a second potential handler with a hook should assistance be required.
2) Always open bags, containers, and cages using proper safety methods.
3) The hook tip is initially inserted under the anterior portion of the snake and slid caudally to the midpoint or its approximate center of gravity, on the body side facing the handler.
4) Once the hook is at the desired location, lift the snake in one motion, just high enough for the head and tail to clear the surface. This will induce the snake to hold and balance. If it is still moving and not balanced, gently set the animal down and repeat the process.
5) Once balanced, lift and move the snake to the desired location. Prevent the head and tail from touching objects during transfer. This will often startle the snake and induce it to come off the hook.
6) Gently set the snake down and remove the hook. Be prepared to use the hook to keep the snake under control or to further manipulate it for the intended procedure.

Longer-handled hooks for larger and more agile snakes may have a second grip located above the base grip of the hook. Using two hands on the hook, with the second (anterior) grip as a pivot point, aids in lifting heavier specimens while increasing dexterity and control of the specimen. Care must always be taken that the position of the second grip (hand closest to the snake) is outside the striking range of the snake.

Some snakes require double-hooking to distribute their weight at two points. This includes very large specimens where support on a single surface will cause discomfort or injury. Snakes with medical problems (e.g., fused vertebrae or a recent surgery) are also supported this way. Active snakes and arboreal prehensile-tailed species are also handled with greater control when double-hooked.

The use of two snake hooks requires more finesse than the use of one.

1) Hold a hook in each hand and insert them under the middle portion of the snake, on the same side of the body that is facing the handler.
2) Move the hooks away from each other to points dividing the snake's length into thirds. While the hooks are being moved to these locations, each hook should be lifted slightly testing the snake's tendency to balance.
3) Once the hooks are appropriate for balance, lift the snake and determine if it is stable. If so, transfer the snake in a smooth, deliberate movement.
4) When lifting, the outward pressure (away from the snake's midpoint) of the hooks will help keep tension on the snake and not draw the hooks together if the snake tries to progress forward.

This technique requires practice, but is not difficult. Each snake reacts differently to the double-hooking process. For specimens that benefit from double hooking, this is an excellent technique and should be used routinely.

Tongs and Forceps

Various styles of snake tongs and forceps (Fig. 12.4) are available from reptile equipment dealers (e.g., Midwest Tongs and Animal Capture Equipment). They should not be used as a primary method of restraint due to their potential to injure. Many snakes will thrash or bite the tongs when held tight enough for restraint. If tongs are used directly for restraint, the contacting surface of the tongs should be padded to create a firm but soft restraint. This style of tong can be very useful when working in the field, primarily with small to medium-sized specimens. In captivity, tongs should only be used as a last resort or in an emergency. Their use is not an acceptable substitute for lack of training or skill with a snake hook (Altimari 1998).

Long-handled tongs are ideal when used for feeding, removing cage items, manipulating container lids, holding restraint tubes, and lifting holding bags. Tong length must always be longer than the maximum striking distance of the snake.

Elongated forceps (Fig. 12.4) are used for feeding small snakes, removing retained shed or ectoparasites, and assessing the depth of anesthetized animals. Forceps length may range from 30 to 45 cm. They must be used cautiously when working in close proximity to the head, allowing for potential movement and strike ability.

Protective Gloves

Wearing protective gloves for handling venomous snakes (Fig. 12.5) has been used by a limited number of researchers. While this method does have its advocates, extreme caution must be used as it places the handler in close proximity to the snake. Defensive strikes may not only target the gloves, but also the handler's arms and body that are not protected. Some snakes appear not to recognize gloves as strike targets as they do bare fingers and hands. This gives the impression that the snake is tame and not prone to biting. That condition can change quickly and the snake should always be handled so that its strike range is limited to the padded/protective areas of the gloves. A popular manufacturer, HexArmor, produces the Hercules™ R6E glove made with SuperFabric® that may offer sufficient protection for most small to medium-sized species. The company does not offer any guarantees in regard to protection from snakebite. The condition of the gloves with prolonged use needs to be monitored as the integrity of the material may break down over time (R. Keszey, pers. comm.).

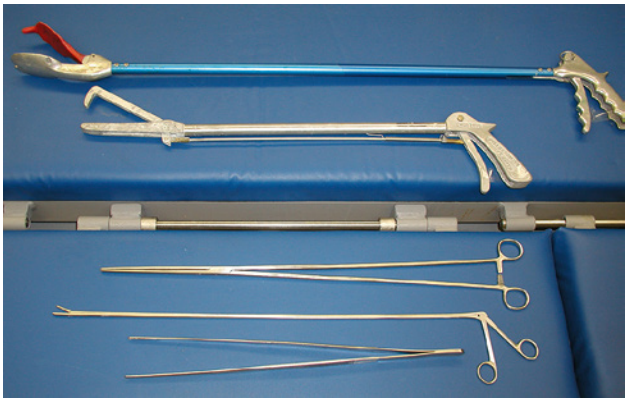

Figure 12.4 Tongs and forceps (top to bottom): Midwest Tong®, Pilstrom Tong®, hemostatic forceps, endoscopic forceps, and tissue forceps.

Figure 12.5 Puncture-resistant gloves can offer protection from snakebites of small to medium-sized species, but all handling precautions must be met as this method requires the handler to work in very close proximity to the snake. Tiger rattlesnake, *Crotalus tigris*, Glades Herp Farm.

Shift Boxes

Most snakes will enter boxes, where they can seek visual and tactile security. Shift boxes are placed either inside the enclosure or attached to the outside. Box size need only be large enough for the snake to lie comfortably in a resting coil. Many snakes prefer to wedge into a tight-fitting space for physical and tactile security. Normally, the snake's head when residing in a shift box is pointed toward the opening (entrance hole) awaiting the passing of potential prey. They will commonly strike out at any movement in front of the opening. Training some elapids to enter shift boxes (Kipp et al. 2006) is achieved with classical conditioning techniques. This is a very useful management tool for long-term captive animals requiring routine handling.

Shift boxes are most appropriate for large, swift elapids. They can be designed to attach directly to the cage (Fig. 12.6). In snake collections requiring multiple

Figure 12.6 Shift box and interfacing cage for an arboreal snake. Not shown are the transparent top and side panels of shift box. Used for Gold's tree cobra, *Pseudohaje goldii*, Central Florida Zoo and Botanical Gardens.

enclosures, the openings in cages, shift boxes, and the points of attachment are standardized so boxes can be interchanged. Cages are also designed with a center divider that allows the handler to shift the snake from one side to the other to facilitate safe servicing. The divider slide space should be sufficiently narrow to prevent escape when the divider is removed.

Shift boxes within a cage (Fig. 12.7) should be solid, with a bottom and locking door (Rossi 1995). They are easily fabricated from plywood and sealed with polyurethane to facilitate cleaning. A horizontal sliding door is designed to be closed with a hook once the animal is enclosed. A locking pin or mechanism for the shift box door is secured prior to removing from the cage and when transporting the snake.

Many styles and designs for shift boxes that attach to the outside of enclosures have been used to facilitate safe cage servicing or to aid with restraint and immobilization for veterinary procedures. Historically in zoos and research facilities, boxes have been designed and fabricated "in house" to fit a specific enclosure for a designated species or individual. Shift boxes have primarily been used for shifting large elapids that are dangerous to work in an open environment using a hook. However, any venomous species is a candidate for shifting to ensure a safe and controlled procedure.

Shift boxes attached to enclosures need to incorporate the following design elements:

1) Appropriate comfortable size for the snake.
2) Sturdy construction, able to endure dropping and long-term use.
3) Secure method of attachment to the enclosure.
4) Locking sliding door that corresponds to the door on the cage.
5) Large top-opening access door (lockable).
6) Clear top and/or side section to view the snake.
7) Adequate ventilation holes.
8) Sealed surfaces to promote easy cleaning.

Variants on the above design combine a squeeze for restraint. An interior sliding wall (Fig. 12.8) is used to push the snake toward the opening and into the restraint tube. Care is taken to ensure the restraint tube diameter matches the box opening so no gaps exist. Additionally, the tube and the box must be securely attached (usually manually braced) to prevent changes in restraint tube position. Once the snake enters the tube a safe distance it is grabbed and restrained using a normal tube restraint grasp.

Figure 12.9 Shift box/squeeze box. Features include removable squeeze apparatus, slotted end for injections, two capped side ports for tube restraint, and top capped feeding chamber with sliding false floor for protected feeding. Not shown is the removable center divider to create a "U-maze" to facilitate total entry of long snakes. Jacksonville Zoo and Gardens, black mamba exhibit, *Dendroaspis polylepis*. Courtesy of Habitat Systems Limited.

More advanced designs (e.g., by Habitat Systems Limited) combine features to aid in the husbandry and management of venomous snakes (Fig. 12.9). Optional elements include removable squeeze apparatus with a slotted end panel for injections, capped side ports with interchangeable openings of various diameters for tube restraint, enclosed top-feeding chamber with sliding false floor (drops feed rodent into the shift box without directly opening the box), and removable center dividers to create a "U-maze" to facilitate total entry of long snakes. These features increase control while emphasizing safety.

Some boxes incorporate a built-in restraint shield or framed wire mesh panel that can be pushed down for temporary restraint. A common application of this design using a wire mesh top panel is for king cobras (*Ophiophagus hannah*) that frequently retain spectacles. This design is also helpful if treatment requires repeated intramuscular injections.

Shift box design is a function of the intended use (Fig. 12.10). Shift boxes can be used to accomplish tube restraint and anesthesia using the entrance hole of the box. Variations have been described (Bertram & Larsen 2004), but the basic design and function remain the same. When using shift boxes, users must know how all doors operate (especially when removing the box and a second snake is in the cage!) along with corresponding locking and safety features. Some boxes are overdesigned, increasing the opportunity for door to be left open or unsecured. Doors and locks must always be double-checked visually and for movement prior to assessing if a snake is safely secured.

Figure 12.10 Traditional shift box. This simple design enables the snake to shift out of the cage, eliminating direct contact. The snake can then be transferred for anesthesia or other procedures. ourtesy of Habitat Systems Limited.

Unattended boxes that have been removed from the enclosure are placed in larger, secured and labeled containers to alert staff to the presence of a venomous snake.

Restraint or "Squeeze" Box

These boxes are used to restrain the movement of a snake for examination, measurement, and radiography (Quinn & Jones 1974). They consist of a box and a clear shield to press the snake against the bottom of the box for temporary restraint (Fig. 12.11). Most are made of wood, but acrylic boxes have the advantage of allowing the snake to be viewed from all sides, including the ventrum (Krebs et al. 2006).

Figure 12.11 Traditional restraint box for clinical and field applications. Primarily used for injections and measuring. Western diamondback rattlesnake, *Crotalus atrox*.

The size of the snake determines the size of the box; it should enable the animal to lay coiled in a normal position. The open top of the box is fitted with 0.5-cm Plexiglas shield, with a center handle, that can be lowered to press the snake against a thick foam rubber or other soft material pad.

It is important that the shield closely fits the sides of the box to prevent the snake from wedging its head through a gap. The shield is initially lowered using tongs, then secured by hand once safely in place. Holes are drilled into the shield to facilitate injections. Multiple holes are drilled across the shield since the position of the snake is random. Shields made of diamond-mesh expanded sheet metal have also been used (M. Whitney, pers. comm.), but care must be taken to avoid the snake striking and injuring oral areas.

Measurement is accomplished using a dry-erase ink marker to draw a mid-dorsal line equaling the length of the snake. A thin wire is superimposed over the drawn line, then straightened and measured. Map measurers have also been used to trace line lengths.

If a restraint box is to be used for a period of time, holes are drilled through the sides to permit the passage of aluminum rods to hold down the shield (Fowler 1978). If a restraint box is used for radiology, it must have a locking mechanism for the top acrylic shield. Snakes secured in such a fashion should not be left unattended and must be placed in a secured, labeled container.

Restraint Tubes

Manual restraint and immobilization of venomous snakes has been described using a wide variety of techniques for a variety of applications. For many procedures, manipulation of venomous snakes without chemical immobilization is desirable for initial examination, medication, and simple procedures including removal of adhered shed, palpation, blood sampling, and sex determination.

Techniques that employ restraint tools as the primary method of restraint, such as nooses, tongs, strap sticks, bucket restraint (Gillingham et al. 1983), noose tube restraints (King & Duvall 1984), strap boards (Ward & Harrell 1983), and manual restraint following pinning with a snake hook, are to be avoided. While used with some success by professional snake handlers in the venom extraction industry, these methods increase the risk of snakebite for the occasional handler and can injure the snake. Safer methods using clear tubes and shift, restraint, and anesthesia boxes are preferred. These remote-handling methods require more time and equipment, but greatly reduce direct contact with the snake. All procedures should optimize protected contact and effective control, thereby ensuring handler safety.

The standard for safe handling of venomous snakes is the Plexiglas tube restraint (Murphy 1971). This method minimizes the risk to the handler and potential injury to the snake. Clear, hollow tubes are available in a variety of acrylic materials. They can be purchased as individual tubes, usually sold in 2-m lengths, of various diameters (McMaster-Carr). Sets of restraint tubes are also available from some reptile supply companies. Thin-wall, flexible tubes crack easily and therefore are less safe than thicker-walled tubes. Polycarbonate hollow rods and PETG (a copolyester material) with a minimum wall thickness of 0.25 cm are best. These products are more durable and do not break if dropped.

The basic steps for tube restraint are as follows:

1) Choose a tube with an inside diameter that will not allow the snake to turn around (inside diameter less than the length of the snake's head or slightly larger than the snake's girth at mid-body).
2) Using a hook, place the snake on a smooth surface. Small and medium-sized specimens are worked on within a container. This is usually a trashcan or other open-top container large enough to facilitate movement by the handler to manipulate the snake into the tube. Large and more sedentary snakes are worked on the floor or the ground in field conditions. There must be ample open space for handlers to maneuver safely around the snake. Containers are preferred since they limit the range of motion and position of the snake.
3) Use tongs that are longer than the snake's striking range to hold the tube. Grasp the tube in the middle with the tongs in one hand (usually the left hand for a right-handed person) and slowly lower the open end of the tube toward the snake in a manner that will not induce the snake to strike at the tube. Snakes that strike the open end of the tube may incur oral lesions, primarily associated with the mucous membranes that cover the fangs.
4) Using a hook that is longer than the snake's striking range and held above that point, gently touch or hook the animal to manipulate it into the tube (Fig. 12.12). This is a combined maneuver moving the tube and the snake in a fashion that will entice it to enter the tube.

This procedure requires patience! Never hurry and always stay in control of the process.

1) The first goal is to get the snake's head inside the opening of the tube. This should be done quickly to reduce the chance of the snake striking.
2) Sometimes moving the snake backward with the snake hook will encourage it to move forward, entering the tube.

Figure 12.12 Tube restraint. Position of primary handler and snake in tube just prior to restraint. Florida cottonmouth, *Agkistrodon piscivorus*, Central Florida Zoo and Botanical Gardens.

3) Once the snake starts to enter the tube, hold the tube motionless so as not to startle the snake.
4) More active snakes require the tube to be worked down the body following its undulating movements.
5) Once the snake has entered the tube and is at least half way in (the tong grasp point on the tube if the tube is grasped in the middle) and still moving forward, lay the hook down (or hand it to an assistant) and with that hand quickly grasp the snake and the end of the tube at which the snake entered (Fig. 12.13). This secures the snake in the tube and prevents it from backing out. The other hand is used to grasp and support the animal.

Figure 12.13 Tube restraint completed. With large specimens, the primary handler secures the snake and tube while the secondary handler supports and restrains the body. Florida cottonmouth, *Agkistrodon piscivorus conanti*, Central Florida Zoo and Botanical Gardens.

Never overcommit to the grab! If the snake begins to back out of the tube or quickly progresses to the end of the tube, abort the procedure and start over.

1) Once restrained, immediately visually check your grasp. Both the tube and the snake should be held firmly to keep the snake from progressing forward or backward.
2) Make sure there is not an opening between your fingers and the palm of the hand that could allow the snake to withdraw a body coil and withdraw from the tube.
3) With medium to large snakes, the assistant should immediately support and restrain the animal's body once it has been successfully restrained. This permits the primary handler to focus their attention on securing the snake while supporting the tube with their other hand.
4) If a snake has a large girth at mid-body and a relatively small head, a smaller-diameter tube is inserted inside the open end of the tube and over the snake's head to keep it from turning around.

Snakes that are anesthetized require a controlled release from the restraint tube in the following sequence:

1) The primary handler grasps the tube midway with the tongs while maintaining tube restraint with the other hand.
2) The snake and tube are placed in a container and angled vertically. The grip on the snake is released and the hand is withdrawn rapidly from the container (and the snake's striking range).
3) The primary handler and the assistant pick up hooks for further handling.
4) The container is secured and labeled appropriately.

The primary handler and the assistant always review the procedural steps before and during the process to ensure a thorough understanding of roles and expectations.

Many large-bodied pitvipers will attempt to progress up the tube when released. This should be avoided to prevent the snake becoming stuck in the tube. While still maintaining manual restraint, these snakes should be pulled down the tube to a safe point near the end prior to release. When released, many snakes will quickly withdraw from the tube and immediately strike back at the handler. Alternatively, some species (i.e., elapids) will attempt to flee. Handlers need to be prepared to use hooks to keep the snake under control.

Tube restraint can also be accomplished directly from a shift box, facilitated by a squeeze apparatus adapted to the box (Fig. 12.14). The diameter of the restraint tube must match the hole in the shift box.

Tube restraint provides handlers and clinicians with a high degree of control during the examination. The snake is advanced to the end of the tube for cranial and oral

Figure 12.14 Tube restraint directly from a shift box containing a squeeze apparatus. In addition to tube restraint, the body of this 14' king cobra (*Ophiophagus hannah*) is also manually held in the shift box during examination to maintain control of the body. Central Florida Zoo and Botanical Gardens, photo credit Sarah Burke.

examination. Various locations along the snake's body can also be examined. Care is taken to keep a significant portion of the anterior body in the tube. Restraint tubes are also used for administering oral medications and force-feeding (Radcliffe 1975). The major advantage of this technique is that the snake is restrained without grasping the head, and the animal is positioned in a relatively straight line to facilitate examination, medication, tube-feeding, and anesthesia.

A variation of acrylic tube restraint (Mauldin & Engeman 1999) employs wire mesh cable holders as the restraint "tube". While this method can be used with some snakes, it is not recommended for venomous species since they will bite through openings in the mesh, resulting in either envenomation of the handler or oral trauma to the snake.

Restraint Tube Modifications

Clear acrylic restraint tubes can be modified for the needs of the clinician. Tubes can be cut to various lengths to facilitate safe handling (i.e., longer tubes for longer snakes). Tubes can be drilled to create access holes and elongated cutouts made for increased access for minor procedures. Appropriately sized PVC caps, rubber stoppers, or wooden corks can be temporarily or permanently secured at one end to prevent the snake from progressing through the tube.

Care must be taken when any opening is made along the length of the tube to prevent hands and fingers from crossing these openings. Many species are capable of biting and protruding a fang through openings. Bite attempts on the inside of the tube will release venom that will run down the inside of the tube to the hand. Handlers should wear latex gloves to prevent venom contact with the skin, which may lead to envenomation through microcuts. All tubes must be thoroughly washed and disinfected immediately after use.

Anesthesia Boxes

Full clinical examination and surgical procedures require chemical immobilization and anesthesia (see Chapter 12). This is essential when evaluating cranial features such as the nostrils, infra-orbital pits, spectacle and eyes, oral cavity, glottis, and tongue. More general procedures such as blood sampling, examination of the integument, removing adhered shed skin, removal of ectoparasites, cloacal examination and sampling, and palpation may be accomplished by tube restraint. Radiology may be performed on snakes in shift boxes, squeeze boxes (through a fixed acrylic shield), or through bags if the specimen is inactive. If an intended procedure presents a safety concern for personnel, full chemical immobilization is strongly recommended. Some snakes can be induced in restraint tubes with propofol administered into the ventral coccygeal vessels (Chapter 12).

A variety of containers for venomous snakes can be used as inhalant anesthesia boxes. Large clear plastic Rubbermaid® or Sterilite® storage boxes (Fig. 12.15) are available from retail stores. Snakes are placed directly into these boxes only if the lids can be secured to prevent escape. Transparent containers allow observation of the snake during anesthetic induction. A snake contained in a cloth snake bag may be placed inside an anesthesia box. However,

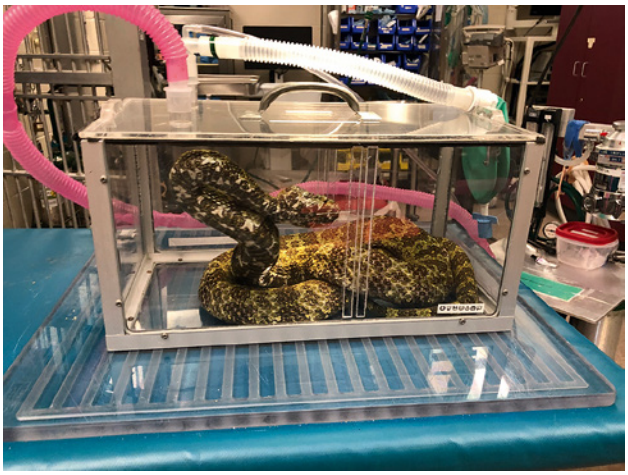

Figure 12.15 Anesthesia box. A clear plastic storage box fitted with an adaptor to receive the corrugated breathing tube from the anesthesia machine. The transparent container facilitates viewing to judge the level of induction. Mangshan pit viper, *Protobothrops mangshanensis*.

judging the anesthetic level will depend on evaluating declining movement in the bag. When testing the movement of a snake inside a bag, always use instruments (forceps, tongs) and never manually palpate the bag.

A snake contained in a shift box or ventilated restraint box can also be placed in an anesthesia box. The anesthesia box, fitted with an adaptor for the breathing system, allows for infusion of the inhalant anesthetic in oxygen from the machine. A shift box may also be enclosed in a plastic bag for administration of inhalation anesthetic through the opening. However, induction is very difficult to evaluate when the snake is enclosed in two containers.

Guidelines to assess whether a snake is safely anesthetized include lack of response to tactile stimulation, inhibition of tongue flicking, and lack of ability to right itself when turned over on its dorsum. Snakes can hold their breath for 15–20 minutes and anesthetic induction can be prolonged. Once anesthetized, a restraint tube is placed over the head and anterior portion of the body as a secondary safety precaution and the snake is then carefully removed from the box. For continued delivery of inhalant anesthetic can be maintained by a cover can be fitted over the open end of the restraint tube, a mask placed directly over the head if removed from a restraint tube, or direct endotracheal intubation whereby a tube is inserted through the snake's glottis and into the trachea (Chapter 12).

Transport

Safe transport and receiving of venomous reptiles require planning and setting up the appropriate equipment in advance. Securing the snake in a cloth bag and placing it in a ventilated locked box is recommended. The cloth bag should be of tight-woven, strong material that allows for good ventilation. Bags are examined for small holes that may be tested by the snake and enlarged, leading to escape. Bags are turned inside out so the seam is on the outside to avoid entanglement in loose threads. Only one animal should be contained in each bag to eliminate defensive striking and facilitate removal. Bags should be long (deep) enough to be easily knotted at the open end and additionally secured with strong tape or plastic cable ties.

To place a snake in a bag, the bag is hung inside an empty container and secured in an open position using clips (clothes pins work well). Tongs are used by an assistant to hold the sides of the bag open. They are then used to close the bag after the snake is guided in by a hook. Commercially available "snake baggers", long-handled rods with an attached and removable bag, increase safety in the bagging process (Bag-Em™, Animal Capture Equipment, Inc.; Snake Bagger®, Midwest Tongs). Never be too anxious to manually close the top of the bag. Most snakes tend to climb upward after being dropped into the bag. Always visually know where the snake is. Use tongs to close and secure the bag, or twist and pull the neck of the bag under the shaft of a secured snake hook prior to knotting.

When knotting, first transfer the bagged snake to a flat surface. Place the shaft of the snake hook across the twisted neck of the bag and pull to secure the snake in the far end of the bag. For additional security, the bag is secured with strong tape or cable ties on either side of the knot. This must be done away from the portion holding the snake. Bags are labeled to identify the snake species with a noticeable "VENOMOUS" notation made on the label. Red labels with the skull and crossbones motive symbolizing poison are most effective. Tongs are used to clamp the bag just under the knot for lifting. Bags should always be carried above the knot and away from the handler's body. Bagged snakes are placed in a suitable container or box while waiting for procedures or transport. Transport boxes containing more than one bagged snake have solid dividers to eliminate the potential for snakes biting each other.

Transport boxes are locked, well ventilated, and kept away from temperature extremes. Boxes are kept out of the sun and transported in air-conditioned vehicles to avoid hyperthermia. Boxes are clearly labeled "CAUTION – VENOMOUS SNAKES" and stored in locked rooms while awaiting transport.

The same level of caution used in bagging the snake must be used during removal from transport containers. Open the transport boxes using the level of caution as if the snake inside had escaped the containment bag. Keep fingers and hands away from openings (use tongs) and be prepared to hook a snake into a holding container. The bag is removed from the container using tongs. Snakes can bite through cloth bags induced by limited visual capability or when the bag is touched. Bites through either bags or screened surfaces can result in significant envenomation. Under these circumstances, a snake's fangs can become momentarily hung up in the bag material, resulting in the expression of large quantities of venom.

Prior to untying the snake bag, place the bag on a flat surface and position the shaft of the snake hook across the neck of the bag below the knot, securing the snake in the end of the bag. All extremities are held safely away from this portion of the bag. Once untied, tongs are used to secure the open bag end. It is then picked up and lowered into a container. The snake is released by picking up the bottom end of the bag with the tongs. Bags with a hemline sewn across the bottom corners of the bag provide an area of material to grab without pinching the snake.

A field transport box (Birkhead et al. 2004) for carrying large numbers of venomous snakes combines both tube restraint and a modified transport container. In this design,

10 polyethylene restraint tubes, capped at both ends, are secured by spacers in a transport container. The advantage of this design is that it allows individual containment of each snake that is positioned for immediate manipulation or restraint.

The International Air Transport Association (IATA) publishes Live Animal Regulations that are adopted by most airline carriers. When shipping airfreight, it is prudent to review these regulations in case airline employees question the design and features of the shipping crate and the methods by which the snakes are contained. IATA requirements (for snakes see Part 8, Container Requirement #44) are presented as examples to be adopted depending on the species and size of the snake. Specific suggestions in the IATA regulations include container rigidity, packing material, size and type of container, specification for snake bags, double-bagging snakes with a transparent mesh inner bag for inspection, wire-covered containers, and an abbreviated listing of venomous snakes and some colubrids that are considered venomous. It is the responsibility of the shipper to ensure materials and methods are appropriate for safe transport. It is rare that an airline employee will ask the shipper to open a container of venomous snakes for inspection. This is not the case for international shipments, which are routinely inspected by wildlife customs agents charged with monitoring species covered under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES).

Venomous Lizard Management

Gila Monsters and Beaded Lizards (Helodermatidae)

Venomous lizards known to produce significant envenomation in humans are restricted to two species, the Gila monster (*Helododerma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*). As studies continue on the evolution of reptilian venom systems (Fry et al. 2006) additional "nonvenomous" lizard taxa will be recognized as having toxin-secreting oral glands. Currently this is restricted to some species of monitor lizards (family Varanidae), especially the desert monitor (Ballard & Antonio 2001).

Helodermatids are large, stout-bodied lizards with large heads, powerful jaws, and short legs adapted to digging. They are easily recognized by their colorful, intricate skin patterns and rounded tuberculate scales, which give them a beaded appearance. Gila monsters average 36 cm as adults while beaded lizards can reach 1 m in total length.

Helodermatids have evolved defensive venom tailored to create significant pain to ward off predators. Bites are extremely painful and can have systemic effects, including a rapid drop in blood pressure that may result in hypotensive shock (Preston 1988). Unlike snakes, the venom glands of helodermids are mandibular and appear as a rounded swelling located midway along the lower jaw. The large triangular-shaped head is the result of well-developed musculature associated with biting and maintaining a vice-like grip. When biting, helodermatids exhibit a pumping action of the jaw musculature while embedding the enlarged, grooved, venom-conducting teeth, located above the venom glands. There are accounts of severe gripping bites resulting in the use of pliers, crow bars, severing of jaw musculature, and decapitation to disengage the lizard from the bitten extremity. Severity of envenomation is a function of the amount of time the lizard is allowed to bite. Envenomation is treated symptomatically as there is no antivenom for helodermatids.

Helodermatids are deceptive, normally exhibiting slow movements and sluggish behavior, but are capable of swift lateral and upward movements of the head and upper body when attempting to bite. Of 21 venomous bites received by zoo workers over a 25-year period (Card & Roberts 1996), four were inflicted by helodermatids. The authors concluded that because helodermatids are generally considered relatively benign captives, this assumption misleads individuals into handling them carelessly. No matter how much their owner professes its tameness, all helodermatids should be handled with the same caution as for venomous snakes.

Manual restraint of helodermatids requires first pinning the head down on a flat surface with a snake hook or pinning bar (Fig. 12.16). Once secured, they are picked up

Figure 12.16 Pre-restraint position for helodermatids. The head should be immobilized prior to manual restraint. Gila monster, *Heloderma suspectum*, Central Florida Zoo and Botanical Gardens.

Figure 12.17 Helodermatids can be manually restrained by securing a firm grip at the base of the head with a forelimb held between the fingers to maintain control of the upper body. Once elevated, the second hand is used to support and hold the body. Gila monster, *Heloderma suspectum*, Central Florida Zoo and Botanical Gardens.

with a firm grip at the base of the head and a forelimb held between the fingers to maintain control of the upper body. Once elevated, the second hand is used to support and hold the body (Fig. 12.17). Locking hemostats (40–60 cm) have also been used to successfully pin helodermatids (Poulin & Ivanyi 2003) by using the interlocking base portion (area between the finger eyelets) as the pinning bar.

Helodermatids can be closely examined using manual restraint. Examination of the oral cavity using a hard rubber speculum has limited use since they will vigorously bite down on any object placed in the mouth.

Helodermatids can be anesthetized by administering an inhalant anesthetic into an induction chamber. Anesthetized helodermatids should again be pinned as described above before removal from the anesthetic chamber. One of the last reflexes to be lost is the defensive bite.

Crocodilians (Crocodiles, Alligators, Caiman, and Gharial)

Darryl Heard

This chapter is dedicated to Dr Gregory Fleming (deceased), a friend, colleague, and the original author of this chapter.

Introduction

Crocodilians are a very old order of reptiles with a great variety of extinct lineages. The living species represent only a small part of this evolutionary diversity, which included aquatic, semi-aquatic, and terrestrial species. The recently recognized 23 living species have increased to 27, and possibly 30, species based on molecular taxonomy (Grigg & Kirschner 2015). These species are distributed over four super families (gharials and gavials, crocodiles, alligators, and caiman).

Crocodilians are popular exhibit animals because of their size and appearance. Furthermore, many species are endangered and conservation programs, in both zoos and in situ, are making increased demands for safe and effective chemical immobilization and anesthesia.

Physiology and Anatomy

The physiology and anatomy of crocodilians is well described by Grigg and Kirschner (2015), and relevant areas for anesthesia are summarized in the following paragraphs.

Crocodilians spend much of their time either basking or with their bodies entirely submerged except for their eyes and nares. Each nostril acts as a waterproof valve that is closed with a muscular flap during submersion and between breaths. Immobilizing drugs can obtund this reflex, allowing water into the respiratory tract (Fleming 1996). The soft palate and gular fold form another respiratory valve. The elongated soft palate presses down against the gular fold, which protrudes from the floor of the pharynx. This seal allows the crocodilian to open its mouth underwater without water entering the internal nares and the glottis. The gular fold may need to be displaced to visualize the glottis for intubation (Fig. 13.1).

Crocodilians possess a pair of well-developed lungs. The primary respiratory muscle groups are the intercostal muscles and two transverse membranes, the postpulmonary and posthepatic membranes, both comprising primary fiberous tissue with a muscular component (Van der Merwe & Kotze 1993). The postpulmonary membrane separates the lungs from the liver. The posthepatic membrane is attached to a sheet of muscle attached at the os pubis. These two membranes act as a "diaphragm". Ventilation is achieved by expanding the intercostal muscles and then membranes pull the liver in a caudal direction to create a negative pressure in the lungs that draws air inward. The glottis is then closed, holding the air in the lungs. When the glottis relaxes air is passively expelled via the elastic recoil of the intercostal muscles and the postpulmonary/posthepatic membranes and lung tissue.

Recent studies have shown alligators, and possibly all crocodilians, have unidirectional airflow through the lungs (Farmer & Sanders 2010; Schachner et al. 2013). The significance of this for respiration and anesthesia is unknown.

Cardiovascular System

Crocodiles are the only reptiles that possess a four-chambered heart. The heart functions like a mammal's, with the exception of anatomical adaptations for an aquatic lifestyle. These include the foramen of Panizza, an opening between the left and right ventricle, the subpulmonary conus in the pulmonary outflow tract of the right ventricle, and the aortic anastomosis, which connects the two aortic arches just posterior to the heart (Axelsson 2001). In addition, crocodilians have a left aorta arising from the right ventricle that allows blood to bypass the lungs.

The foramen of Panizza is a small window located between the intraventricular septum at the confluence of the left and right aortic arches. This opening acts as a pressure valve,

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

allowing blood to flow between the venous and arterial systems, resulting in venous admixture. When the animal is breathing, left ventricular pressure is greater, allowing a small amount of oxygenated blood to flow through the foramen of Panizza into the venous blood supply. When the crocodilian submerges, air held in the lungs restricts blood flow through the pulmonary capillary beds, resulting in pulmonary hypertension, which increases right ventricular and pulmonary arterial pressures. As a result, blood flows from right to left through the foramen of Panizza. Deoxygenated blood is diverted away from the lungs through the left aortic arch to organs that are not sensitive to low levels of oxygen (e.g., the liver and stomach) (Grenard 1991). Oxygenated blood is diverted to oxygen-sensitive organs (i.e., the heart and brain). A combination of blood shunting and anaerobic metabolism may allow an inactive crocodilian to stay submerged for 5–6 hours (Lane 1996).

The right-to-left shunt through the foramen of Panizza has clinical implications during anesthesia when the crocodilian does not have ventilatory support or is apneic. Shunting of blood away from the lungs will delay inhalant anesthetic uptake and removal. This emphasizes the importantance of assisted ventilation and potentially the use of epinephrine in the recovery period (see discussion below).

Renal Portal System

Crocodilians possess a portal system composed of the renal vein arising from the epigastric and external iliac veins. These vessels drain blood from the dorsal body wall, the cloaca, sex organs, and the bladder. Drugs injected into the caudal half of the body, base of the tail, and hind legs may be cleared by the kidneys prior to reaching the systemic circulation. In other reptile species, such as the red-eared slider, studies have shown a significant hepatic first-pass effect following hindlimb drug administration (Holz 1997). A study comparing front leg vs. hind leg injections of buprenorphine in the same species resulted in a 70% decrease in the bioavailability of buprenorphine when injected in the hind end (Kummrow et al. 2008).

Care should also be taken when administering nephrotoxic drugs in the hind legs. When possible, inject anesthetic drugs in the front legs. In some circumstances this may be too dangerous and this author uses the hind legs or tail for intramuscular (IM) injection. Unfortunately, uptake and circulation to the sites of action may be delayed and induction times prolonged.

Physiologic Reference Ranges

Obtaining heart and respiratory rates is very difficult in awake crocodilians. In one study (Huggins et al. 1969), juvenile American alligators (*Alligator mississippiensis*) and smooth-sided caimans (*Caiman sclerops*) were implanted with monitoring equipment and isolated from human contact for 12–20 hours before measuring cardiac and respiratory rates. Normal respiratory and heart rates at 22°C were 0.6 and 11.6 breaths per minute, and 1.6 and 14.2 beats per minute, respectively. Following visual contact with humans, both heart and respiratory rates doubled to 30 beats per minute and 6 breaths per minute (Huggins et al. 1969). Consequently, most captured crocodilians are likely to be tachycardic and tachypneic.

In general, heart and respiratory rates vary inversely with the size of the animal, and not surprisingly are affected by environmental temperatures (Franklin & Seebacher 2003). Prolonged exposure to temperatures above 40°C will cause irreversible cardiac damage. Heart rates as high as 55 beats per minute at 29°C have been recorded in Nile crocodiles caught in traps (Klide & Klein 1973; Loveridge 1979).

Thermoregulation

Crocodilians are poikilothermic, regulating their body temperatures with external environmental heat. They also operate at a preferred optimum body temperature (POBT) similar to mammalian internal body temperatures. For captive crocodilians, a good range for environmental temperatures is 25–35°C (Grigg & Kirschner 2015). Given a selection of temperatures, they are able to select the POBT for their metabolic needs.

Temperatures below and above POBT interfere with digestion and immune function. American alligators take twice as long to digest food at 20°C than at 28°C, while smooth-sided caimans digest food three times faster at

30°C than at 15°C (Coulson & Hernandez 983; Diefenbach 1975). Infection of American alligators kept at 30°C demonstrated the greatest white blood cell response to infection and survival of the infection, while alligators held above the POBT at 35°C succumbed to infection in 3 weeks (Glassman et al. 1981).

Crocodilians under general anesthesia should be kept at temperatures near their POBT or around 29.5°C. Environmental temperatures below POBT decrease metabolism and prolong clearance of parenteral drugs, resulting in delayed recoveries. Induction may also be prolonged because of slowed absorption and circulation times. For example, large Nile crocodiles induced with the neuromuscular blocker gallamine took twice as long to become recumbent at 14°C (40 minutes) than at 26°C (20 minutes) (Fleming 1996). In juvenile saltwater crocodiles, medetomidine (2.5 mg/kg IM) had no effect at 17°C and induction times were inversely proportional to body temperatures above 22°C (Olsson & Phalen 2013b).

Physical Restraint

All crocodilians are capable of inflicting serious damage by ether biting or lashing out with their tails. Since most anesthetic events begin with physical capture and restraint, Chapter 14 is offered as an introduction to techniques that facilitate safe handling in the perianesthetic period. If your anesthetic/restraint team is not familiar with these techniques, they should reach out to other experienced personnel for training and assistance. This should preferably occur before the need for anesthesia.

Successful restraint must be safe for both the handlers and the crocodilian. Reported injuries associated with physical restraint include fractured bones, damaged eyes, and drowning (Walsh 1987). Prolonged struggling will result in marked lactic acidemia, with pH levels dropping to 6.6–6.8 (normal range 7.2 ± 0.2). Like other reptiles, crocodilians take a prolonged period of time to recover from elevations in lactic acid that have been implicated in fatalities post restraint (Olsson & Phalen 2013b). The observation that captured crocodilians may become unconscious and drown if not allowed to rest after prolonged physical restraint may be due to the previously mentioned lactic acidemia (Sedgwick 1986).

Drug Delivery

Since most anesthetic episodes in crocodilians begin with capture and restraint (Chapter 14), it is uncommon for remote injection systems to be used.

Darts

Darting can be used to deliver immobilizing agents. There are several disadvantages, however, to their use: (1) it is difficult to get an accurate shot while the animal is in water; (2) it is difficult to determine if the dart has fully discharged; (3) the osteoderms covering most of the dorsal surfaces of crocodilians may deflect the dart; and (4) once the animal is darted, if unrestrained, it may submerge, become immobilized, and drown. Consequently, darting is more likely to be used in captivity in controlled situations (i.e., a dry enclosure). It is rarely used in the field (Blake 1993; Flammard et al. 1992).

Hand Syringe

The hand syringe has the advantage that it can be accurately placed and the rate of injection can be controlled. The animal, however, must be secured for safe injection. This technique can be used for hand-restrained small animals and for administering reversal agents to larger animals. Both IM and intravenous (IV) routes can be used as described below.

Pole Syringe

The advantage of a pole syringe is that crocodilians can be injected while unrestrained in a shallow pool, net, or snare. The main disadvantage is that the injector must be within 2.5 m of the animal and injection volumes are limited to 10–15 mL. If the anesthetic agent is not administered fast enough the pole syringe and handler may be damaged by the animal.

Injection Sites

The base of the tail just caudal to the hind legs has been common site for IM injections (Jacobson 1984). This area is composed of many layers of muscle with the vertebrae located deep within the muscle, and there is no risk of injecting into any internal organs when using a pole syringe. The main disadvantage is that in obese animals there may be a layer of fat, which if injected could delay drug absorption. Another factor to consider is the possibility of a significant hepatic first-pass effect following hindlimb drug administration (Mosley 2011). When possible, IM injections into the front legs are more effective for drug administration.

IV injections are accomplished by accessing the ventral tail vein (Fig. 13.2) (Wellehan et al. 2004). This site can be used to obtain blood samples, inject IV drugs, or for IV catheter placement. The spinal vein (Myburgh et al. 2014) should not be used for administration of anesthetic drugs.

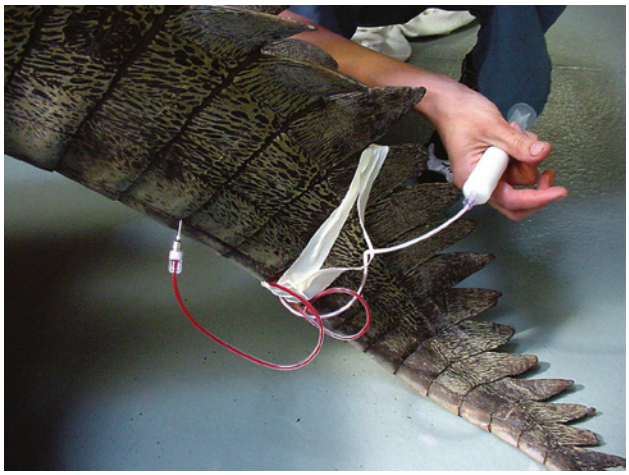

Figure 13.2 Intravenous blood draw via accessing the lateral coccygeal vein. The needle is inserted at a 90° angle at the lateral midline of the tail, just beneath the lateral spinus process of the vertebral body. This same approach may be used to complete intravenous injections of anesthetic drugs such as propofol.

Handling

Once the immobilizing drug has taken effect, it is prudent to use a pole or stick to stimulate the crocodilian a number of times to ensure there is no response. Once this is accomplished, the eyes should be covered with a damp towel and the jaw should be taped shut. Care must be taken to avoid taping the nostrils shut.

The crocodilian can then be rolled onto a stretcher or a large tarp. Care must be taken not to pull and tug on the legs of the animal. Large crocodilians may weigh up to 500 kg and pulling on their legs to move them or lift them may result in fractures or luxations (Blake 1993). To accommodate lifting a crocodilian out of shallow water, 1-m lengths of flat 2-inch commercial crane slinging can be placed under the chest and hind legs. By using the slings to lift, animals can be picked up and moved without pulling on the legs (Fleming 1996).

If the animal is to be intubated, a mouth gag, made of a steel ring, polyvinyl chloride (PVC) pipe, or wood block, should be used to prop open the mouth. Depending on the size of the animal, steel tubing (of varying diameters and widths) can be cut and wrapped with several layers of tape or leather so as not to damage the teeth. A hole in the middle of the gag allows for the passage of anesthetic tubes or endoscopic equipment.

Monitoring

Physiologic monitoring includes the use of a pulse oximeter, Doppler blood flow transducer, electrocardiography (ECG), ultrasound, capnography, and blood gas analysis. As in other reptiles, auscultation for monitoring heart and respiratory function is usually unrewarding. Anesthetic depth is evaluated using the withdrawal reflex of limbs, increasing or decreasing cardiac rates, righting response, and bite and corneal reflexes (Neill 1971; Heaton-Jones et al. 2002).

Electrocardiogram and reference values have been described for the American alligator (Heaton-Jones & King 1994). The ECG leads are attached to 2.5-cm needles passed through the skin. Although pulse oximetry may be used to assess heart rate it does not appear to accurately calculate oxygen saturation in reptiles (Mosley et al. 2004). Crocodilian skin thickness and pigmentation may further hamper measurement with the transmission probe, but a reflectance probe in the cloaca may improve the signal. Blood gases measurement is difficult to interpret because of variables such as temperature, feeding, and sample site (arterial, venous, or a combination of both) influencing the results. Blood lactate levels, however, are usually easy to obtain and measure with small portable monitors.

The Doppler blood flow monitor is a reliable method of obtaining heart rate (Bennett 1996; Neilson 1996). The probe is placed over the heart or a large blood vessel such as the ventral coccygeal, brachial, or femoral artery. Blood flow in the ophthalmic artery may be detected by placing the probe against the globe with the eyelid or third eye lid closed. Alternatively, a dorsally directed probe placed in the cloaca may also detect arterial blood flow. Unfortunately, this technique for prolonged monitoring stimulates evacuation in the cloaca.

Capnography is an important technique for the assessment of the adequacy of ventilation as well as for detection of spontaneous respiration (Fig. 13.3).

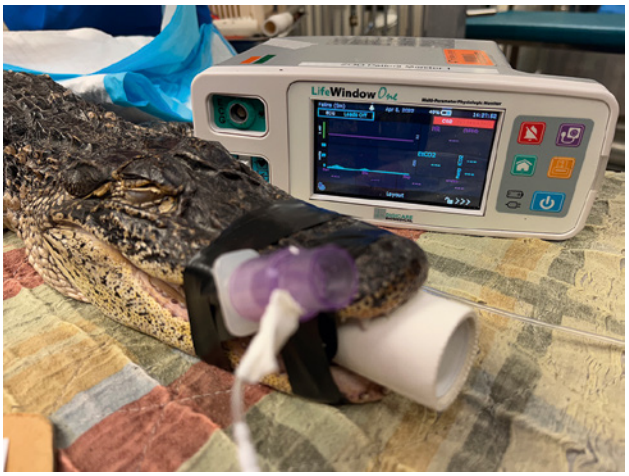

Figure 13.3 Anesthetized American alligator (*Alligator mississippiensis*) recovering from anesthesia. An endotracheal tube is still in place, with an attached in-stream capnograph sensor. Capnography is very useful for assessing the adequacy of ventilation and determining the presence of spontaneous ventilation before extubation. A PVC pipe is in place as a mouth gag.

Analgesia

For a comprehensive discussion of analgesia in animals please see Chapter 2.

As is common in exotic animal medicine, extrapolation of drug doses from similar species is needed to develop effective analgesia. The use of butorphanol as an analgesic in reptiles has been promoted for years based on research completed in birds (Paul–Murphy et al. 1999). Unfortunately, butorphanol in reptilian species (green iguanas and red-eared sliders) even at higher doses only resulted in sedation and no analgesia (Fleming & Robertson 2012; Sladky et al. 2007, 2008; Mosley et al. 2003, 2011). Consequently, this author does not recommend the use of butorphanol except perhaps as part of a multidrug immobilization regimen.

Morphine (0.8 mg/kg) and meperidine (pethidine) (2 mg/kg) in juvenile salt-water crocodiles showed analgesia as measured with thermal antinocioception (Kanui & Hole 1992). In red-eared sliders, morphine (1.5 and 6.5 mg/kg IM) resulted in analgesia, but caused long-lasting respiratory depression at higher doses (Sladky et al. 2007). Using the same methodology in bearded dragons, morphine (10 and 20 mg/kg IM) was analgesic, but the effect was delayed until 8 hours after administration (Sladky et al. 2008). In red-eared sliders, tramadol (5 mg/kg PO every 5 days) induced analgesia via both opioid and nonopioid pathways (Baker et al. 2011).

The use of meloxicam (0.2 mg/kg PO, IM, IV) has been reported in reptiles and IV or PO administration results in the same bio-availability (Hernandez-Divers et al. 2004; Whiteside & Black 2004). The present author has used meloxicam (0.05–0.1 mg/kg PO every 2 days) in medium to large alligators for up to a month.

Sedatives

The author has not used tranquilizers (i.e., phenothiazines) in crocodilians and is unaware of anyone presently using them.

Midazolam is the most commonly used benzodiazepine because it is water-soluble and is compatible when used in multidrug induction regimens. Midazolam (5 mg/kg IM) produced reliable relaxation and sedation for minor procedures in juvenile estuarine crocodiles while reducing indicators of stress (Olsson & Phalen 2013a). The combination of the long-acting zolazepam with tiletamine (Telazol) makes for an effective and safe drug combination for immobilization, although prolonged recoveries are possible.

Diazepam hydrochloride (0.22–0.62 mg/kg) administered 20 minutes prior to succinylcholine resulted in a smoother induction and lower doses of succinylcholine in American alligators (Loveridge & Blake 1972). Heart rates were decreased, respiration was maintained, and recovery for most was within 3 hours.

Reversal of benzodiazepines in mammals with flumazenil has been achieved in dogs at a ratio of 1:13 flumazenil to diazepam, and at 1:20 flumazenil to zolazepam (Lang 1987; Terpin et al. 1978). When using midazolam (5 mg/mL) the present author uses an equal volume of flumazenil (0.1 mg/mL) for convenience. If there are concerns the dose has not worked, an additional dose of the same volume is administered.

Local Analgesics

Due to the issues when using inhalation anesthesia described below, this author has changed to preferentially using parenteral anesthesia combined with either local or regional anesthesia (e.g., brachial, retrobulbar, and mandibular blockade) when applicable (e.g., limb amputation, enucleation). Toxic lidocaine doses have not been established for crocodilians, but extrapolating from mammals this author uses a maximum of 5–10 mg/kg for lidocaine and 1–2 mg/kg for bupivacaine.

A nerve locater can be used to assist in the accurate placement of local anesthetic around nerves (Wellehan 2006). Nerve locators use a pulsatile electric current passed through a needle in contact with the motor nerve (e.g., mandibular nerve) that innervates and thus stimulates an identifiable muscle (e.g., the digastricus muscle). Local anesthetic (e.g., 2% mepivacaine, 1 mg/kg) injected down the needle blocks nerve conduction. This technique has been used to provide analgesia in the mandible of American alligators, dwarf crocodiles (*Osteolaemus tetraspis*) and Yacare caiman (*Caiman yacare*) (Wellehan 2006). A more recent study (Bianchi et al. 2020) describes the use of a lateral approach through the mandibular fenestra (foramen) for nerve blockade in juvenile Nile crocodiles. The present author has used this approach successfully on several large crocodilians.

Muscle Relaxants

Although they have been utilized historically in Africa for the transportation and capture of wild crocodilians (Fleming 1996), the present author sees no need for the use of muscle relaxants given better capture and restraint techniques, and better alternative drugs and drug combinations. Most importantly, muscle relaxants do not provide analgesia for painful procedures in animals that are conscious. For those interested in more information please consult the chapters in previous editions of this book. Drug dosages are summarized in Table 13.1.

Table 13.1 Commonly used perianesthetic drugs in crocodilians.

Drug	Dosage (mg/kg)	Species	Remarks	Reference
Analgesia				
Morphine	0.8 IM	*Crocodylus porosus*		Kanui & Hole (1992)
Meperidine	1–2 IM	*C. porosus*		Kanui & Hole (1992)
Meloxicam	0.1–0.2 IM or PO every 2 days			Whiteside & Black (2004); Wellehan (2006)
Tramadol	5 PO every 5 days			Baker et al. (2011)
Ketoprofen	2 IM every 1–2 days			Tuttle (2006)
Butorphanol	0.1–0.2 IM		May cause sedation but not analgesia Usually combined with other drugs	Sladky et al. (2007, 2008); Fleming (2012) Mosley (2011)
Anesthestics				
Ketamine	11–110 IM		Variable response when used alone	Jacobson (1984); Loveridge & Blake (1972)
Medetomidine	0.13–0.17	Adult *C. porosus* 150–370 kg	Reversed with atipamezole 0.09–0.12 mg/kg IM	Olsson & Phalen (2012a)
Medetomidine	0.5	Juvenile *C. porosus* 2.0–4.8 kg	Reversed with atipamezole 2.5 mg/kg IM for 50 minutes Rapid temperature-dependent induction and recovery at body temperatures above 22°C No induction at 17°C	Olsson & Phalen (2013a)
Ketamine/ Medetomidine	10/0.1 IM			Heaton-Jones et al. (2002); Smith et al. 1998a, b and c
Medetomidine/ Ketamine/ Sevoflurane	0.3/15		Juvenile Nile crocodiles Adequate anesthesia for minimally invasive surgery	Monticelli et al. (2019)
Ketamine/xylazine	7.5–10/1–2 IM			Idowu & Akinrinmade (1986)
Ketamine/ dexmedetomidine/ midazolam	3–5/0.02–0.05/ 0.1–0.3 IM, IV			
Ketamine/ dexmedetomidine/ hydromorphone	3–5/0.02–0.05/ 0.1–0.2 IM, IV			
Alfaxalone	3 IV	Male juvenile *C. porosus* and *C. johnstoni*	Adequate induction at various environmental temperatures, but apnea common	Olsson et al. (2013)
Alfaxalone/ dexmedetomidine/ ketamine	5/0.05/5 IV		22-month-old American alligators Intubation within 10 minutes	Aymen et al. (2021)
Alfaxalone/ Dexmedetomidine/ Midazolam	5/0.05/1 IV		22-month-old American alligators Intubation within 10 minutes All became apneic	Aymen et al. (2021)
Tiletamine/ zolazepam	5–15 IM			Jacobson (1984)
Propofol	Dosage is size dependent: small crocodilians 5–6, large adult crocodilians 1–2 If administered in tail may take up to 15 or more minutes for full effect		Physiologic effects dose and rate dependent with similar effects observed in mammals and birds	

Table 13.1 (Continued)

Drug	Dosage (mg/kg)	Species	Remarks	Reference
Midazolam	0.1–01.5 IM or IV		Usually combined with other drugs Reversed with flumazenil (0.1 mg/mL) equal or twice the volume of midazolam (5 mg/mL) Dosage inversely related to size	Olsson & Phalen (2013a)
Diazepam	0.22–0.62 IM		Poor IM absorption Use has been superceded by midazolam	Loveridge & Blake (1972)
Reversal				
Atipamezole	5 mg/1 mg of medetomidine or 10 mg/1 mg of dexmedetomidine			Heaton-Jones et al. (2002); Smith et al. (1998a–c)
Flumazenil	Equal or twice the volume (0.1 mg/mL) to midazolam (5 mg/mL) IM, IV			
Naltrexone	100 times the dose of potent opioid			Fleming (pers. comm.)
Neostigmine	0.03–0.06 IM	*Crocodylus niloticus*		Jacobson (1984); Flammard et al. (1992); Fleming (1996)
Inhalant anesthetics				
Isoflurane	1–5%		2–3% for maintenance	
Sevoflurane	3–8%		Higher than isoflurane for maintenance	Bertelsen et al. (2005)
Muscle relaxants				
Gallamine *Not recommended on humane grounds*	1–2 IM	*C. niloticus*	**No analgesia!**	Fleming (1996); Jacobson (1984); Lang (1987); Loveridge (1979)
Succinlycholine *Not recommended on humane grounds*	0.33–5 IM		**No analgesia!** Also painful muscle contractions before relaxation that may lead to marked hyperkalemia and lactic acidemia	Blake (1993); Jacobson (1984); Spiegal et al. (1984)

IM, intramuscular; IV, intravenous; PO, oral administration.

Etorphine Hydrochloride

Crocodilians and other reptiles are very resistant to the immobilizing effects of potent opioids. Similar to the comments above about muscle relaxants, this author does not recommend their use.

Effective etorphine dosage varies considerably between and within crocodilian species. For example, American alligators weighing 1.6–3.9 kg required a dose of 1.3–3.1 mg/kg, while larger alligators weighing 39.5–68.0 kg required only 0.03–1.3 mg/kg (Hinsch & Gandal 1969). American alligators administered 0.29–0.51 mg/kg IM were immobilized within 20–25 minutes and were recovered in 60–180 minutes with no reversal drug (Hinsch & Gandel 1969). A 0.11-kg caiman administered the larger dosage of 44 mg/kg was immobilized at 11 minutes and recovered by 40 minutes. Intraperitoneal administration is effective, reducing induction times while having a similar duration of effect as IM administration. However, in Nile crocodiles dosages as high as 8 mg/kg IM were ineffective and only produced pupillary dilatation (Loveridge 1979). Without administration of reversal drugs crocodilians recover within 1–3 hours (Lang 1987). There is no report of using either naloxone or naltrexone to reverse etorphine in crocodilians.

Dissociative Anesthetics

Ketamine Hydrochloride

Ketamine alone has variable effectiveness (Table 13.1). It has been used to anesthetize spectacled caiman (44–50 mg/kg), juvenile American alligators (11–12 mg/kg) (1-hour induction; Beck 1972; Stoskopf 1993), and adult American alligators (45–70 mg/kg, 20-minute induction; Stoskopf 1993). In American alligators (Heaton-Jones 1996; Loveridge 1979) immobilization was only achieved at the higher dosage of 50 mg/kg. Similarly, ketamine alone (18–45 mg/kg) had little effect in Nile crocodiles. Even higher dosages (59–110 mg/kg) caused death in several animals (Loveridge 1979). Consequently, ketamine is usually combined with other drugs to reduce the dosage. This reduces the adverse effects and prolonged recoveries, while still benefiting from its anesthetic effects. There is presently no reversal agent for ketamine and recovery times vary with dose, taking up to several hours.

Tiletamine and Zolazepam

Tiletamine/zolazepam (15 mg/kg IM) in American alligators did not produce complete immobilization (Jacobson 1984). Palpebral reflexes were unaffected, hindlinb withdrawal was slow, and episodes of paddling were noted. Righting reflex was achieved 3 hours post injection, however with higher doses reversal times may be prolonged. In the absence of other alternatives, tiletamine/zolazepam (4–6 mg/kg) alone is the best choice for safe immobilization/sedation in crocodilians. It also has the benefit of being sold as a dry powder in a vial, allowing for variation in concentration. This allows reduction of injection volume when a darting or pole syringe system is used. In a warm environment this author has made up solutions approaching 230 mg/mL (compared with the recommended concentration of 100 mg/mL). To further reduce the volume needed ketamine can be used as a substitute for the diluent.

Partial reversal of tiletamine/zolazepam using flumazenil (1 mg per 20 mg of zolazepam) has been described (Lang 1987). Flumazenil, however, is seldom indicated in partially reversing Telazol because it is expensive, its effects may not last, and it may expose the adverse effects of tiletamine, which may include seizures.

Barbiturates

Barbiturates are not recommended for use in crocodilians except for euthanasia. The first report of pentobarbital in a crocodilian was an oral dose of 200 mg/kg, followed by 15 mg/kg intracoelomic, in a Nile crocodile for removal of a gastric foreign body. It was later demonstrated in this species that 28 mg/kg had an induction time of 2 hours and a recovery of 12 days; 53 mg/kg could cause death (Loveridge 1979). Pentobarbital administered to spectacled caiman at 8.8–15.4 mg/kg IM resulted in induction times of 30–45 minutes and recovery times of 1–5 days.

Alpha-2 Agonists

Xylazine alone has variable to no effect in crocodilians. In Nile crocodiles, a combination of xylazine (1–2 mg/kg IM) followed 30 minutes later by ketamine (20 mg/kg IM) resulted in effective surgical anesthesia for 50 minutes with a 3–4-hour recovery (Idowu & Akinrinmade 1986).

Medetomidine (131–220 μg/kg IM) was first described to provide effective immobilization of American alligators either alone or in combination with ketamine (7.5–10 mg/kg) (Heaton-Jones et al. 2002). As with other anesthetic drugs, juvenile alligators required higher dosages. Mean induction times were 19.6 and 26.6 minutes for juveniles and adults, respectively. Total anesthesia times were 61–220 minutes, with any procedure over 120 minutes requiring supplemental gas anesthesia. Olsson and Phalen (2012a,b) describe the use of medetomidine alone for the sedation/immobilization of both juvenile and large estuarine crocodiles (Table 13.1). Medetomidine (150 μg/kg) resulted in bradycardia and bradypnea (Smith et al. 1998a–c).

Yohimbine hydrochloric acid has a low therapeutic index and is not presently commercially available. Since there is a more effective and reliable alternative (atipamezole), yohimbine is not recommended for use in crocodilians.

The selective alpha-2 adrenergic antagonist atipamezole is an effective reversal drug for medetomidine in crocodilians and other reptiles at five times the dose of medetomidine. It should be only given IM to avoid potential adverse circulatory effects, including hypotension and cardiac asystole. Reversal times vary depending on dose and body temperature, but in the above alligator study this was achieved in 35–37 minutes (Heaton-Jones et al. 2002).

Intravenous Anesthetics

Propofol

Propofol's main disadvantage is that it must be injected intravenously. This author also feels there is an increased risk of morbidity and mortality when it is used in

crocodilians. Recommended dosages are size dependent: small crocodilians receive 5–6 mg/kg while large animals may only require 1–2 mg/kg IV to produce sedation/immobilization. When administered by the recommended IV route (ventral coccygeal vein) induction times may be as long as 15–20 minutes to peak effect.

As with all IV anesthetic drugs, propofol should not be administered into the spinal vein unless it is being used for euthanasia. This is because the spinal vein is in close association with the subdural space and there is great potential for accidental injection directly into the Cerebrospinal fluid.

As with other animals, adverse cardiopulmonary effects are directly related to the rate of administration and dosage. Propofol is also not analgesic and must be combined with analgesics for painful procedures.

Alfaxalone

Olsson et al. (2013) describe the successful use of alfaxalone in juvenile estuarine crocodiles. The benefit of this drug is that it can be given IV or IM. The main disadvantage for its use in adult crocodilians is its low commercial concentration precluding its use as the sole immobilizing agent. The present author uses it at low dosages (0.5 mg/kg IM) and injection volumes for its sedative effects as part of a hand-injected multidrug regimen. The cardiopulmonary effects and need for added analgesia are identical to those for propofol.

Other Injectable Agents

Tricaine methanesulphonate (MS-222) is not recommended for anesthesia of crocodilians. It has been used in juvenile American alligators (88–99 mg/kg IM), producing immobilization in 10 minutes and recovery in 9–10 hours (Brisaben 1966). A higher dosage (150 mg/kg) anesthetized an American alligator for 30 hours (Coulson 1983). It has also been used in spectacled caiman at 110–154 mg/kg IM with no effect (Johnson 1991).

Inhalant Anesthesia

As mentioned above, this author prefers parenteral anesthesia with or without local/regional analgesia for crocodilian anesthesia. In certain circumstances an inhalant (isoflurane) is used to supplement anesthesia. The main reason for using parenteral anesthesia has been faster recoveries, especially when some of the drugs can be reversed. Additionally, in many cases animals anesthetized using these combinations spontaneously breathe during a procedure, although at a sometimes slow respiration rate (1 breath/2–4 minutes).

Since crocodilians are capable of long periods of apnea, mask induction is contraindicated. Consequently, parenteral anesthetics are used for induction to allow safe access for intubation.

Crocodilians have complete tracheal rings and cuffed endotracheal tubes, if over inflated, may cause avascular necrosis of the tracheal mucosa. For endotracheal tube placement first open the mouth by grasping the snout with two hands and flexing the head and neck into a dorsal position. The mandible and maxilla can then be more easily separated and a block of wood or other speculum can be placed. A dog leash placed around the upper and lower jaws may provide greater safe leverage for opening the jaws.

For intubation, a light source (i.e., laryngoscope) is necessary to visualize the glottis. The gular flap will also usually need to be depressed to allow the glottis to be identified. The glottis will be closed unless the animal is exhaling or inhaling. The bevel of the endotracheal tube can be gently used to open the glottis. Application of local anesthetic to the glottis will reduce the response to intubation. It should be noted, however, that glottal paralysis could be prolonged. There is the potential for inhalation of water if the animal is returned to water too soon.

Positive pressure ventilation at a rate of 2–4 breaths per minute is adequate for crocodilians. A capnograph is useful for providing assessment of adequacy of ventilation, as well as the return to complete spontaneous ventilation at the end of a procedure. The end-tidal CO_2 level usually starts at 20 mm. Levels above 30 or below 10 are considered hypercapneic and hypocapneic, respectively. Monitoring chest wall movement is an insensitive guide to spontaneous ventilation compared to capnography.

Once the surgical or painful part of the procedure is completed, ventilation can be switched from oxygen to room air and an ambu bag used to inflate the lungs if necessary. In large crocodilians a double-demand valve (Horne et al. 2001) can be used with pressurized room air (scuba tank) for ventilation.

For crocodilians weighing <5 kg a nonrebreathing system is indicated, with a flow of 300 mL/kg/min. For crocodilians >5 kg, a circle system of 1–2 L/min for maintenance is recommended.

The most commonly used inhalant anesthetics are isoflurane and sevoflurane (Monticelli et al. 2019). Halothane is no longer available. This author usually uses isoflurane, primarily because of its cost compared to sevoflurane. The advantage of sevoflurane for faster recoveries is not clinically significant with careful adjustment of the isoflurane

vaporizer settings during and towards the end of a procedure. This author also occasionally uses nitrous oxide (50–66%) as a carrier gas for its rapid uptake and removal, and additional analgesia (Bertelsen et al. 2005).

A major issue when using inhalant anesthetics in crocodilians is shunting of blood away from the lungs, thereby blocking uptake and removal. In alligators it has been shown that administration of epinephrine at a resuscitation dosage will hasten recovery from isoflurane anesthesia without any apparent adverse effects (Gatson et al. 2017). This may be due to altering the pulmonary shunting, but could also be due in part to increased cardiac output and blood flow. Interestingly, this effect seems to also hasten recovery from parenteral anesthesia. This author routinely uses epinephrine IM during recovery of crocodilians.

Anesthetic Protocols

In formulating an anesthetic protocol (Table 13.1) it is important to factor in the species, medical condition, enclosure, temperature, staffing, and ultimate goal of the immobilization. The importance of capture and restraint has also been emphasized previously and it is recommended that Chapter 14 be used as a beginners' guide to techniques and required equipment.

This author prefers a combination of parenteral drugs for most sizes and ages (Aymen et al. 2021). For example, in medium to large crocodilians I use medetomidine (or dexmedetomidine) (30–70 μg/kg IM) combined with ketamine (3–5 mg/kg IM) and either midazolam (0.2 mg/kg IM) or hydromorphone (0.2 mg/kg IM) (Aymen et al. 2021; Monticelli et al. 2019). This combination is usually administered by hand, even to large crocodilians that are restrained, allowing multiple and occasionally large volume injections in the triceps muscles. Alfaxalone can also be added or substituted for midazolam. Onset of maximum effect may take up to 30–45 minutes.

Alternatively, a combination of zolazepam/tiletamine (Telazol) (4–8 mg/kg IM), as described above, will not be sufficient to reach surgical anesthesia, but should allow safe moderate immobilization sufficient for intubation. For adequate surgical anesthesia the animal may need to be intubated and maintained with 0.5–3% isoflurane in oxygen. To reduce a prolonged recovery the dosage can be reduced to 2–4 mg/kg and combined with medetomidine (or dexmedetomidine) (30–50 μg/kg), which can be reversed with atipamezole at the end of the procedure. When recovery is slow, care should be taken not to immerse the crocodilian in deep water until full recovery.

As discussed previously, propofol and alfaxalone are also appropriate for induction (and perhaps constant rate infusion) in small to medium-sized crocodilians.

Crocodilian Capture and Restraint

Kent A. Vliet and Gen Anderson

Introduction

Anesthesia and chemical immobilization of crocodilians usually requires some form of confinement and physical restraint for safe drug administration and to prevent them seeking refuge in their aquatic environment. Anesthesia and immobilization are discussed in Chapter 13. The following is a description of capture and restraint techniques that work to minimize injury to handlers and animals.

Crocodilians are dangerous; they are capable of injuring, scarring, maiming, and even killing handlers. This is not to imply they are bad, loathsome, or evil. It is simply the result of being large, tremendously powerful, predatory, agile, and adaptable. No-one can safely work with these animals until this is fully comprehended. Furthermore, you must remind yourself of this every time you work with them; complacency is our greatest threat.

There are many safe ways to capture and restrain even very large crocodilians. There are even more incorrect ways. Each capture is different and always has the potential to go wrong. There are many variables that must be taken into account in successfully capturing and restraining a crocodilian.

Ultimately, no amount of detail in this chapter, training, or experience will guarantee no harm to those working with these animals. If you cannot personally accept this liability, you should neither attempt any of the techniques discussed in this chapter nor should you work with crocodilians. Accepting this liability is part of the commitment necessary to work with these magnificent animals.

For larger captive crocodilians, the trend is to reduce contact with the keeper staff by providing shift enclosures and training the animals to use them. This is much preferred over physically capturing and restraining an animal. While the former (shifting) is strongly encouraged, the latter (capture and restraint) will form the body of this chapter. Manual restraint is a necessary tool in professional crocodilian management when maintained under human care for medical purposes, data collection, movement, and changes in social dynamics (Molinaro et al. 2022).

Few publications describe techniques for the safe capture, restraint, and handling of captive crocodilians. Most descriptions are of free-living species, for example the American alligator (*Alligator mississippiensis*) (Chabreck 1963; Jones 1965; Joanen & Perry 1972; Murphy & Fendly 1974; Forster 1991; Jones & Hayes-Odum 1994; Wilkinson 1994), the American crocodile (*Crocodylus acutus*) (Mazzotti & Brandt 1988), the Nile crocodile (*C. niloticus*) (Pooley 1984; Hutton et al. 1987; Kofron 1989), and the saltwater crocodile (*Crocodylus porosus*) (Webb & Messel 1977; Walsh 1987). While useful insights and methods are gleaned from these papers, most describe traps that are of little practical application in the captive environment. Electro-stunning is widely used on commercial farms, particularly with *C. porosus* and *C. niloticus* (Franklin et al. 2003; Sa 2020). This efficient capture technique renders the crocodilian unconscious while minimizing stress to the animal and increasing safety for staff. Electro-stunning is used primarily for commercial slaughter as opposed to zoological purposes.

A detailed list of equipment and techniques used in alligator research is found in McDaniel and Hord (1990). Fowler (1978) makes brief mention of restraint of smaller captive crocodilians. Almandarz (1986) describes physical restraint techniques for reptiles, including crocodilians. The most comprehensive reference is that of Wise (1994). This article contains many pertinent and useful insights that serve as a valuable reference for anyone interested in developing the skills necessary to safely work with these animals. The following discussion builds on and expands the contributions of the above references.

This chapter does not detail all the possible techniques for capture and restraint. The authors have included those they are experienced with, are accustomed to, and

Zoo Animal and Wildlife Immobilization and Anesthesia, Third Edition. Edited by Gary West, Darryl Heard, and Nigel Caulkett.

which they believe provide enhanced safety of staff and while minimizing stress on the animal. The primary author has had the opportunity to capture 24 crocodilian species during several thousand captures over multiple decades, in both captive and free-living situations. Techniques evolve and new, better practices come into use. Others may have different, and even better, methods than those presented here.

Capture Equipment

Crocodilians frequently damage and destroy capture equipment. Consequently, restraint is either an expensive exercise or one develops equipment that is easy and inexpensive to manufacture. The latter allows an adequate supply of equipment to always be available. The standard equipment the authors and staff of the St. Augustine Alligator Farm Zoological Park use for crocodilian capture and handling is described below.

Ropes

Ropes are essential for most captures; they are used to gain a hold on, to restrain, and for the safe release of animals. Several ropes are always available for any capture. The size used depends on the crocodilian to be captured. Smaller animals require smaller diameter ropes, while larger crocodilians necessitate thicker and stronger ropes. Too small a diameter ropes may cinch too tightly on the animal or burn into a keeper's hands during a struggle. Ropes of too great a diameter will not close tightly enough over the neck or jaws, allowing the animal to work itself free.

For adult animal captures, the preferred rope diameter is either 1.6 (5/8) or 1.9 cm (3/4 inches). Ropes have different tensile strengths; the strength must be adequate for the size and mass of the animal to prevent breakage and animal escape. Nylon ropes are generally the strongest, but do not perform as well as the preferred polyester in wet environments. Cotton and sisal work well for many purposes, but rot if not allowed to dry after use or are not stored appropriately. This leads to problems during captures of large animals; the rope may separate under tension, allowing the animal to go free and resulting in the keepers falling back and possibly injuring one another. Woven or braided ropes are less likely to kink or fail than twisted ropes. Many ropes float on the water surface, preventing their placement under the head of a submerged crocodilian. Consequently, ropes should be assessed before purchase for their ability to sink when soaked. The best ropes the authors have used are those designed for arborists. They are soft and pliable yet strong, and they do not tend to "burn" hands when jerked by a crocodilian. At first glance, arborist rope may be cost-prohibitive, but the quality of product and usage capabilities make it worthwhile.

Rope length depends on the intended use. Excessive length makes it difficult to gather and control during hectic moments in captures. Staff may also get tangled up in too much rope. The primary author frequently lassos crocodilians from a distance. For large crocodilians, several people are needed to pull a roped animal from the water or to a position where it can be safely secured. For these purposes, the author uses 8–9 m (25–30 ft) ropes.

Smaller diameter and shorter ropes are ideal for restraint. Ropes of 0.6 (1/4) or 1 cm (3/8 inch) diameter may be used to tie the legs together off the ground. This technique may be implemented to prevent movement and injury, especially of larger individuals, or tie an animal to a ladder or restraint board (Valverde et al. 2021; Buah-Kwofie et al. 2018). Leg restraint must be performed cautiously as it can be risky due to joint damage caused by possible dislocation, unintentional use of a limb as a handle, or too tight bindings. Prolonged restraint using this technique can also lead to muscle damage (exertional rhabdomyolysis) and is not recommended.

Jaw ropes are used to tie the jaws shut or remove the tape from an animal's jaws as it is being released. They are generally small diameter, 0.3 (1/8) to 0.5 cm (3/16 inch), and shorter, 3 (10) to 3.7 m (12 feet), ropes. Cotton clothesline works well for this purpose.

Poles

The primary use of a defensive pole is for the protection of the handler(s). Poles must be of sufficient diameter and heft to maintain a safe distance between the holder and crocodilian during capture, but comfortable for the holder to manage. When charged or lunged at by an overly enthusiastic animal, the pole is used to block the animal's advance.

Poles serve many other purposes. Animals can be discouraged from advancing toward a handler by lightly laying a pole on the soft tissues of its nostrils or against its earflap. Animals can be gently encouraged to move out of the way by touching their hind legs and base of tail, allowing access to a particular animal for capture. In addition, a pole can be used after capture to manipulate and position the animal (e.g., move legs, lift jaws, clamp the jaws shut, etc.) without getting too close.

Defensive poles are generally wooden; if an animal bites them they do not cause significant damage to the teeth. The authors prefer a sturdy, 1½-inch diameter length of solid bamboo or eucalyptus, approximately 1.2 (4) to 1.8 m (6 feet) in length.

Poles greatly increase safety while working in close proximity to crocodilians. However, care must be taken when using them with larger crocodilians. Poles can become dangerous to personnel if grabbed and held in the crocodilian's jaws. When the animal swings its head from side to side, the pole may strike and injure a person. Care must also be taken when recovering a pole from a crocodilian.

A variety of catchpoles are used to grab and hold. They all include a long rod with a cable loop or snare at one end. For larger animals (>2 m) poles are designed so the loop and rope attachment separates from the rod. Commercial catchpoles are used when no other poles are available. They are sturdy and give very good control over the animal. However, even relatively small crocodilians (≥1.5 m) roll or spin violently enough during capture to twist and kink the cable snare, thereby destroying it. Furthermore, during a struggle, the metal rotating cuff adjacent to the snare could push into the animal's head and neck, causing injury. Frequent use of commercial catchpoles is not recommended because of initial purchase cost and the expense and time of repeated repair and maintenance.

Alternatively, it is easy, quick, and very inexpensive to make catchpoles. There are three commonly used simple designs. A "break-away" rope loop can be secured to the end of a pole with electrical tape. Once the rope is placed over the head and neck of the animal, the pole is pulled free and removed from the capture area. Recommended poles for this design are long (3–5 m), 3–4 cm (1½ inches) diameter wooden rods or lightweight aluminum electrical conduits. Swimming pool net poles also can be used; they are lightweight, long, and extensible.

Schedule 40 PVC pipes can also be used to make catchpoles. Snares are made of twisted metal cable and affixed to the end (Fig. 14.1). A metal swivel coupled to an eyebolt through an end cap attaches the snare. The cap is glued onto the end of the PVC pipe (Fig. 14.2). An advantage of this design is that snares of different diameter, or that have become damaged during a capture, can be rapidly exchanged during a capture. A small wire can be attached to the snare base to keep it open until in place on the animal. Surprisingly, jacketed cables with plastic coverings cause more skin damage than exposed metal cables.

The simplest homemade catchpole for animals ≤2–3 m (8–9 feet) in length consists of a ¼-inch polyester, nylon, or cotton rope run through a length of 1-inch PVC pipe (Fig. 14.3). The rope is secured through a hole drilled in the pipe wall close to the end, then run out of the pipe and back in again, to form the loop, and then down the length of the PVC. When the loop is placed around the animal, the rope extending from the back end of the pole is pulled tight and bent back against the pole for added friction. PVC pipes bend and fracture if they are used to lift animals.

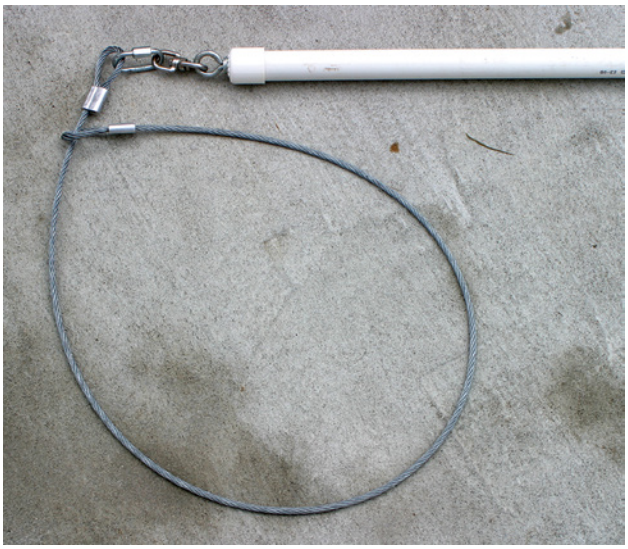

Figure 14.1 A home-made cable snare used for catching small to medium-sized crocodilians. The catchpole is made of PVC piping.

Figure 14.2 A home-made rope snare used for catching small to medium-sized crocodiles. It can also be used as a jaw noose; the rope is placed around the upper and lower jaws and either twisted or the rope pulled at the distal end to tighten. The pole is made of PVC piping.

Once secured with the noose, the handler pulls back in line with the direction of the pipe to pull the animal for positioning and restraint.

The rope catchpole is commonly referred to as a "mouth pole" as it is ideal for safely securing jaws. A shorter version of the loop design works exceedingly well for closing and securing the jaws of captured crocodilians prior to taping or tying. The loop is placed around the maxilla and tightened. Once the jaws are shut, the pole is twisted several times to add more tension to the loop. A person then steps in to quickly secure the jaws.

Figure 14.3 Physical restraint of a small crocodilian (*Crocodylus mindorensis*). Note the electrical tape placed around the jaws and the hand grasping the neck and forelimbs.

Tape

Tape is essential after capture and during restraint; jaws can be safely secured and heavier tapes can be, but are rarely, used to immobilize legs to prevent movement. The most commonly used are silver duct and black PVC electrical tape. Always have a sufficient amount on-hand. PVC electrical tape is preferred as it sticks to itself, not the animal, and has some stretch to ensure proper jaw restraint and handler safety.

Cable Straps

Nylon cable straps or ties (zip-ties) are very useful for securing the jaws of some crocodilians (i.e., narrow-jawed species) before one captures the animal. These come in various lengths and tensile strengths; the largest can resist a force of 100 kg. This temporary method of jaw restraint reduces damage risk during capture and is a useful technique to for slender-snouted species.

Shelf Mats, Rubberized

Shelf mats are made of rubber-coated, woven fabric. They are used as nonskid shelf coverings and are readily purchased. The mats are cut into 5–10-cm (2–4-inch) wide strips to wrap around the snout or the entire head. They are used for this purpose because they do not slip in a wet environment. The crocodile jaws are held shut with a mouth pole or by hand, wrapped with the mat and then taped over. The sponginess of the mat prevents the tape from binding too tightly. Also, the nonslip nature of this material prevents jaw tape from slipping forward and covering the nostrils during transport. Vet wrap is a suitable alternative, but caution must be used to assure the stretchy fabric is not applied too tight. Both methods greatly protect the jaws of slender-snouted species and those with teeth that project outside of the jawbones during manual restraint and transport.

Eye Cloths

The eyes are covered before or after capture with a cloth, towel, or other available fabric such as burlap bag or shirt. This has a calming effect on the animals and likely reduces stress during the capture period. The blinded crocodilian is much less likely to avoid capture and to struggle following capture. Additionally, if the animal does attempt to strike it is undirected and less likely to injure. Eye cloths are safely and gently placed over the eyes using a hook. The cloth is soaked before placement so it will more completely cover the eyes and stay in the proper place on a partially submerged or basking crocodilian.

Eye cloths are secured with a couple of wraps of PVC electrical or duct tape. Crocodilian eyes can be voluntarily withdrawn down into the skull, but some caution must be used when taping the eye cloth. Do not press the eyes too hard or apply too much pressure with the tape. If the eyes are to be covered for an extended period, gauze pads or a folded paper towel are placed over them before taping.

A visual obstruction study on juvenile American alligators by Finger et al. (2018) demonstrated no significant difference in corticosterone levels 30 minutes post capture. Jaws were secured with rubber bands and eyes covered with electrical tape. As crocodilian behavior frequently results in a calmer demeanor after covering eyes with a damp cloth, future research is needed involving other stress indicators to improve crocodilian welfare during capture and restraint.

Hooks

Hooks are absolutely essential tools when working with crocodilians. They facilitate work around the animals by allowing placement of ropes, manipulation of legs, etc. without bringing human appendages within striking range. The authors have used several different hook types. Heavy snake hooks (e.g., python hooks) are sufficiently robust for positioning ropes around a crocodilian's head, lifting legs, lifting the jaws, etc. Hooks are also useful for removing and retrieving ropes during release.

The preferred option is long, very lightweight fiberglass hooks designed for livestock showing. These break fairly easily, but are also inexpensive. They are not substantial enough to manipulate an animal, but are excellent for capture equipment placement and positioning. When

capturing a submerged crocodilian, it is often possible to carefully position a rope loop over and around the head with these hooks without disturbing the animal and causing it to move. Tongs are not recommended as they are often used for feeding crocodilians and may elicit an ill-timed feeding response. Hooks are also handy for retrieving items safely from unsafe locations.

Restraint and Transport Devices

Once captured and the jaws secured, there are many ways to confine or restrain a crocodilian (e.g., bags, buckets, ice chests, shipping crates, ladders, platforms, and cargo nets or marine mammal slings). The restraint technique and equipment selected depends on (1) animal size, (2) duration of confinement, and (3) distance to be transported.

Knives and Other Tools

Cutting implements should always be available during a capture for emergency use. Knives are used to cut tape, frayed rope, etc. Wire cutters are used to cut through cable straps when used on the snouts of some specimens. Not having suitable cutting tools on hand in a timely fashion can result in injury and/or safety concerns for both handlers and animals.

Trauma Kit

If the capture techniques described in this chapter are followed, the risks to personnel are minimized. Depending on the size and species, a bite from a crocodilian can result in minor injuries or severe trauma and death (Savu et al. 2021). The capture team should always be prepared for someone being injured during a crocodilian capture. This includes having a well-stocked trauma kit on hand to provide immediate aid. This kit should include at minimum a pry tool, medical gloves, tourniquet, blood clotting sponge, and scissors (for the removal of clothing and cutting of bandages). A well-stocked trauma kit is not intended to provide proper medical care, but to minimize human blood loss prior to the arrival of paramedics. In the event of limb removal, quick access to a cooler with ice can help preserve the amputated appendage. Wrap with gauze, then place in a plastic bag first before setting on top of ice.

How to Catch a Crocodilian

As described above, crocodilians can be massive, powerful, and often react violently to physical restraint. During capture, the safety of personnel is paramount, followed closely by the welfare of the animals. The techniques favored by the authors restrain the animals completely to limit the possibility of self-injury to the animal and personnel injury. The essential components of successful capture are planning, communication, caution, and knowledge of the animals.

Planning and Preparation

Capture and restraint of small specimens is usually routine and does not necessitate much planning or preparation. This is absolutely not the case when attempting to capture and restrain a larger specimen (i.e., ≥2 m [6 feet] in total length). Preparation includes careful planning, discussion, and oversight. One person (the team or crew leader) is designated the leader and directs everyone else what to do, where to be, etc. Each person's role or roles is discussed and clearly understood before the operation commences.

Many plans, however, are quickly rendered moot if the capture subject is uncooperative. Each capture experience is different; it is not possible to foresee all of the variables likely to be encountered. Flexibility and strategy, the ability to change capture plans in mid-course while still maintaining a safe working environment, are essential. As handlers become more experienced with captures they develop a greater repertoire of techniques to apply to specific situations.

Communication is essential before, during, and after a capture to ensure the safety of the staff and the animal. Each team member must listen for and continue to receive instructions from the team leader throughout the procedure. The team leader must also continually look out for crew safety, make sure staff are in their proper positions, performing their assigned roles, ensure everyone is outside of the strike zone of the animal and escape routes are kept clear at all times.

Environmental Assessment

The first stage of preparation is assessment of the capture environment. If the animal is in a more basic medical enclosure or housed individually, this may be fairly straightforward. However, an animal in a complex habitat full of opportunities (= obstacles) and companions requires more forethought. It is important to answer several questions when assessing the capture environment.

Where are the Escape Routes?

This is perhaps the most important question. More than one route is preferred, but often not available. All team members must be aware of these routes, and they must be left clear at all times during the capture. Personnel must

refrain from blocking escape routes themselves and with extra capture equipment.

What is Physically Possible?

The geography of the enclosure habitat will determine personnel access and the capture techniques used. For example, enclosure structure, landscaping, and furniture such as logs and bridges, can make it difficult to quickly capture a crocodilian (Molinaro et al. 2022).

Is the Animal Trained to Shift?

Many institutions provide adjacent shift areas, similar to those used for mammalian carnivores or large hoofed stock. Crocodilians can be rapidly trained with food to utilize these shifts and to transfer into transport crates. This training facilitates working with these animals and reduces the need for stressful and potentially injurious captures. If a crocodilian does not require a physical examination and or samples to be taken, then a hands-off approach is best for everyone involved.

Will the Animal be Caught in Water or on Land?

The habitat should be assessed to determine whether staging the capture on land or in the water is the best, safest option. In many enclosures, the land surface is insufficient or too crowded with vegetation and furniture to allow a well-coordinated capture. Similarly, some water features make it difficult to gain access to the animal. If the plan is to catch in the water, will the staff be on shore or down in the pool or both?

The characteristics of any water feature must be known to make a proper assessment of its utility in catching an animal. Important variables to know include the total pool area, the water depth, whether the water can be lowered without emptying the pool, the slope of pool sides, and whether staff can easily get out of it.

Land capture requires sufficient space for both the team and the animal, and must allow the staff to stay safely outside the strike zone and out of each other's way. If the animal is on land, the plan should include a contingency for capturing it in the water. Unless caught immediately, crocodilians will seek refuge in water. If either land or water offer ample opportunity for capture, consider choosing to catch in the water. On land, crocodilians feel threatened and cornered. Water is a natural refuge and they often lay more passively, allowing easier placement of the rope and positioning of personnel.

Where will the Animal be Restrained?

In some situations the crocodilian is removed from the enclosure to provide enough space to safely work around the animal. Back areas can be more open due to the needs of maintenance vehicles. In other situations, the jaws are secured while the animal is in the exhibit, then it is removed from the habitat before full restraint or loading into a crate.

Are there Other Animals Present?

Other crocodilians can obstruct access or pose a significant and potentially serious threat to staff and the animal to be captured. If possible, these animals should be shifted out of the way before beginning. Additional staff may be needed to monitor companions; these animals may become involved as the target animal and catch team move about the enclosure. The heightened stress or anxiety in the enclosure associated with the capture may cause the companions to strike out. Care is taken to avoid injury to all animals and staff members involved.

Animal Assessment

Not all techniques are appropriate for all species or size classes. It is required to have natural history knowledge of the animal to be captured; crocodilian species are known for differences in temperament and their capabilities. Saltwater crocodiles (*C. porosus*) and Cuban crocodiles (*C. rhombifer*) are especially dangerous; they may charge and are powerful and agile jumpers. However, this does not imply other species are less dangerous. There are also individual animal differences; some usually mild-mannered species can be unexpectedly belligerent. Ideally, all crocodilians are approached with the same degree of caution. There must be a healthy understanding and respect for the physical abilities of these animals.

Other aspects of the animal's biology, particularly snout morphology, are also considered when preparing for a capture. Slender-snouted species (e.g., *Mecistops cataphractus* and *Gavialis gangeticus*) are more prone to serious snout damage during capture than are species with broader, more robust snouts. As a result, special precautions are necessary in preparing for the capture of these more fragile species. Protecting the jaws prior to capture with cable straps may reduce disfiguring injuries. Conversely, exceptionally robust or broad-snouted species (e.g., the broad-snouted caiman, *Caiman latirostris*) are often difficult to safely secure because there is relatively little purchase area for hands or mouth poles.

The "toothiness" of the animal to be captured should be noted. Protruding teeth cause damage, or even serious injury, when accidentally caught on a hand or arm or forcefully slammed into a team member during a struggle. This danger persists even after the jaws have been secured. Captive crocodilians occasionally have abnormal tooth development resulting in misaligned teeth protruding from the jaws. In some species (e.g., the false gharial, *Tomistoma schlegelii*) the teeth are long, slender, sharp, and naturally

interdigitate, making them very difficult to handle. In these animals it is necessary to wrap the entire jaw line in vet-wrap bandaging tape, a bath towel, rubberized shelf mat, or other material to prevent injury.

Strike Zones

The crocodilian head is its most dangerous part. Many people unfamiliar with these animals believe the tail is the main area to be avoided. While it is true the tail can cause injury, it is the head that has a mouth full of 70–80 teeth and a very high bite force. *C. porosus* has the highest recorded bite force of any extant animal at 3700 psi (Erickson 2013).

The stocky body form and heavily ossified skin of crocodilians limits their flexibility. However, they can and will strike sideways with exceptional speed. In most crocodilians on the ground, the strike zone is defined by the arc of the head swinging from side to side. It is therefore much safer to approach an animal secured by a rope around its neck from the front than the side. Always remember that this is not a steadfast rule when considering the extensive breadth of the current 24 described species. Review the natural history and consider the locomotion capabilities for various crocodilians.

In the process of swinging its large, massive head rapidly to the side, a crocodilian generally swings or slaps with its tail. The tail is solid and strong, and can knock a person off his or her feet or push them toward the jaws. Consequently, catch personnel must also avoid the tail arc.

Roping

Captures generally begin with the securing of a snare or rope noose to the animal. There are two basic variations of this procedure.

Neck Lasso

This technique involves placing the rope over the head and cinching it around the neck. It is usually used for alligator, caiman and heavy-bodied crocodiles. These animals have fairly large jowls at the back of the head behind which the rope loop can take hold. Crocodilian necks are thick, heavily muscled, and usually capable of enduring without injury the forces that occur during struggling. In captivity, where it is often possible to carefully place the rope before closing the loop, some prefer to also hook the noose under one forelimb so it does not cinch tight around the neck. This technique is necessary in very large, heavy specimens that have to be pulled up and over a steep bank or the lip of a pool. This is to prevent too much force being applied to the neck and spine.

Top-jaw Noosing

Top-jaw noosing is used in species with body profiles too slim to allow a neck noose. The rope is caught in the teeth and held firmly. It is of a narrower diameter (≤1.3 cm, 1/2 inch), allowing it to bind more closely around the upper jaw.

A clear advantage of this technique is the greater control of the head, since there is restraint of the snout. However, a major disadvantage is that when the crocodile jerks, twists or shakes, which they do with tremendous force and speed, all of the forces are transmitted through the rope into the hands of the holder. Those who use top-jaw noosing usually secure the jaws with a narrow rope. Two people stand on either side of the head, outside of the strike zone, with the rope stretched between them. This is placed under the lower jaw, and then the ends of the jaw rope are wrapped around one another and exchanged. As the rope is pulled, the jaws are forced together. One person then steps in and holds the knot while the second ties a securing knot. A safer alternative is the use a mouth pole.

Securing the Jaws

Depending in part on the size of the crocodilian, the jaws can be secured with a variety of materials.

Tape

Once the jaws have been closed (by hand in very small specimens or a mouth pole in larger animals), their jaws are usually secured with tape.

Black PVC electrical tape can be used to secure the jaws of crocodilians ≤3 m (10 ft) for short periods of time. It is very quick to apply and sticks well to itself. Most other tapes do not adhere well to crocodilians, especially when wet. During application the tape must be wrapped around the snout and taped to itself to provide a good hold. A general rule is one wrap of electrical tape for each foot (0.3 m) of animal (i.e., for a 5-ft or 1.6-m alligator, wrap the tape five times around the snout). Two rows of tape are applied for large heads.

Do not leave a crocodilian taped for more than a few hours. Electrical tape has a lot of stretch and can be applied with enough force to block the blood flow to the skin. If it remains in place for too long it will cause ischemic skin damage, resulting within a few days in scabbing, sloughing, and scarring.

The author has also used the heavy, bright red tape used for drywall seams. This has excellent adhesive force and a small amount of stretch. However, it does not tear readily, making it necessary to cut it with a knife. The great advantage of this tape is that it is highly visible, making it immediately obvious when an animal has thrown its tape and its jaws are unsecured. This is an added safety measure, especially when transporting several animals at once.

Silver fabric duct tape can be used on larger crocodilians. This also comes in a variety of colors, such as red. It has reasonably good adhesion to itself, but animals otherwise unrestrained are usually able to work it off their jaws within a few hours. A major advantage is it has very little stretch, making it difficult to apply too tightly.

Always create a tab on the top when taping an animal; fold back the end so that it is easy to see and grasp. This facilitates removal of the tape during the release.

Cable Ties

Cable ties (also known as cable straps zip-ties) are frequently used on slender-snouted species (e.g., *Tomistoma*, *Gavialis*, *Crocodylus intermedius*, *C. johnsoni*). There is an increased risk they will damage or even break their snout/lower jaw during capture. This often happens when the animal bites on something in the exhibit and then rolls, applying torsion to the jaws. Securing the jaws shut before a capture reduces the chances of injury. The captures also move more rapidly; staff can restrain the animal in a shorter period of time, further reducing chances of injury and minimizing stress.

To perform the cable strap technique, first make a loop by inserting the tip of the strap through the locking mechanism. Then, drill or punch a small hole through the tip of the strap and thread a string, wire or monofilament line through and tie it. The string and the tip of the cable strap loop are then run through a length of 0.6- (1/4-) to 1.3-cm (1/2-inch) PVC pipe to serve as a catchpole. The loop can be accurately placed over the jaws without touching them. A rapid tug on the string will close the loop and pin the jaws shut, often without disturbing the animal. Alternatively, the cable tie loop is suspended from the string and lowered into a position around the jaws. A swift jerk tightens the strap around the jaws.

This technique is also used with other crocodilian species, but it is more difficult to zip-tie the jaws of broad-snouted species. However, in many species there is a notch or depression in the jaw (e.g., behind an enlarged tooth) into which the cable tie can take hold and tighten down onto the snout.

Caution must be used with these nylon cable ties. Do not trust them; they often are not affixed tightly and can easily slip, releasing the jaws. They also become more brittle with time and prone to breakage; buy new ones before each capture. For a temporary jaw restraint method on slender-snouted species before applying a more secure technique, this method is invaluable.

Other Binds

Less frequently, jaws are bound with rubber bands or heavy cord. Strong, heavy, rubber bands made by cutting tire inner tubes into rings can be used for crocodilians ≤3 m (10 feet) in length.

Eye Coverage

Cover the eyes whenever you restrain a crocodilian. Use an eye cloth or, if the animal is fully restrained, cover the eyes with your hand. During a capture drop an eye cloth in place with a hook. This prevents the animal from seeing your movements, makes it less likely the animal will become unruly, and prevents the animal from directing a strike toward a capture team member. Covering the eyes also keeps the animal quieter and may reduce the stress of the experience for the animal. Though visual obstruction has been proven not to minimize elevated corticosterone levels in juvenile American alligators (Finger et al. 2018), staff observations have confirmed it makes a significant difference in behavior during capture and further research is needed.

Rule #1, Go to the bathroom

There is no delicate way to state this and it seems an odd thing to mention in a discussion of catching crocodiles but, before beginning any major capture operation, make sure each person on the catch team has visited the restroom. These operations can be time-consuming and can be tense for the staff involved. The necessities of bodily functions can arise making a team member uncomfortable and distracted. This can result in actions being rushed or mistakes being made.

Capture and Restraint

Hatchling/Juvenile (Less Than or Equal to 1 m)

Hatchling and small juvenile-sized crocodilians can inflict a painful bite, so caution is still necessary when working with these animals. Biting a keeper is also stressful to the animal and may damage teeth or jaw structures. Also, the animals are small enough that no matter where you grab them, you are never very far from the mouth.

This size of animal is easily grasped by hand. Approach from behind and grab and hold firmly by the neck, over the shoulders, or on the front half of the torso (Fig. 14.3). To reduce the chance of a bite use a hook, a small pole, or any visual barrier such as a broom to push the head away from the hand and block as the animal is picked up. Pillstrom tongs, a standard tool for most herpetologists (Chapter 12), do not work well with crocodilians. The bony armor on the neck and dorsum prevents the tongs from gaining a firm

purchase and the animals can twist, roll, and wrest themselves free. There is also a natural tendency to squeeze the tongs more firmly to prevent this, resulting in injury to the animal.

Once the animal is in hand the jaws must be secured. The animal is held firmly around the neck with one hand, and the other hand is advanced from behind keeping it close to the body. It is placed around the neck and slowly slid forward while gently squeezing. As it moves up onto the head it will slowly close the jaws. The eyes are covered and the head held with this hand. The jaws are then secured shut with tape (even transparent tape will work on this sized animal, a rubber band, or a short length of cotton clothesline) (Fig. 14.3).

Subadults (≤2 m)

Subadult crocodilians or the adults of smaller species (e.g., Chinese alligator, *Alligator sinensis*; African dwarf crocodile, *Osteolaemus tetraspis*; both species of the caiman genus *Paleosuchus*) are perhaps the most difficult size class to capture and handle safely. These animals are large and powerful enough to provide a large struggle, yet still agile and quick enough to turn rapidly and snap.

The tool of choice for these animals is a catchpole made by running a loop of rope through a length of PVC pipe. The loop is placed over the animal's head and around the neck and pulled tight. The rope is bent back against the PVC pipe for added friction. PVC does have some flexion so the animal is not completely controlled. However, the animal can easily be dragged and positioned with this device. Greater control of the animal is achieved if a second person grabs the tip of the tail and pulls the animal. This stretches the animal between the catchpole and the second handler. Maintaining pressure on the tail prevents the animal from twisting or turning to bite. A mouth pole is used to close and secure the jaws. With the animal still controlled by the catchpole, the mouth pole is placed over the snout and the rope pulled tight. It is preferable to stand at the side and slightly behind the animal's head when doing this. The jaws are closed with pressure applied by pulling the rope. When the jaws are completely shut, the mouth pole is twisted several times to add pressure to the jaws. When the jaws are secure and the mouth pole is holding, another crew member steps in and tapes the jaws.

Adult (≥2 m)

Capture and restraint of larger crocodilians is as much a matter of manpower and logistics as it is of proper procedure and safety. A sufficient number of staff is a necessity for a safe and efficient operation. Two people are plenty for a 2-m (6-foot) specimen. Generally, it is best to have at least three or four team members for a 2.5–3-m (8–9-foot) animal. Four or even more people are needed for specimens greater than 3 m (10 feet).

Not to belabor the point, it is ideal when working with these large specimens that they be trained to shift and move into a crate. This provides substantial daily or weekly safety benefits to keeper staff and removes most of the trauma and anxiety of a physical capture. If this is not an option, or if the animal fails to shift when needed, than one may have to proceed with a capture.

As described above, before beginning capture of a large crocodilian make sure ropes that are not frayed or worn and have been soaked are available. Wet ropes not only sink better to position them around an animal, but they do not burn the skin of the animal as dry ropes often will during a struggle.

Catching Adult Crocodilians in Water

If the plan is to catch the crocodilian in the pool the following are some suggestions for techniques to use. If it is possible to lower the water, drop it to a level that just covers the back of the animal (~25 cm [10 inches]). This depth limits the animal's mobility within the water feature while still allowing it to submerge its head. It also provides better visibility of the animal and any obstacles. It is important to keep enough water in the pool for the animal to remain submerged. As long as it can keep its eyes underwater, it is much less likely to become violently defensive.

There are various means of securing an animal in this situation. Most commonly, a rope is placed around the head and neck, and possibly one of the forelimbs. Hooks greatly facilitate safe rope placement and positioning of the noose. Alternatively, a wide lasso is thrown over the head, or a break-away noose or a cable snare catchpole are used to get a line on the animal. If the animal is slender-snouted, or if there are many obstacles in the environment on which the animal might injure itself, the jaws are first secured with a cable strap.

If the team is familiar with the temperament of the animal and it is not reacting violently, it is often possible to manipulate the animal when the water is shallow. Large nets or marine mammal slings may be used to slide under the animal, envelop it, and lift it out of the pool area, greatly reducing the animal's struggles and chances for injury. Animals may also be able to be pushed or herded into a crate or a large-diameter PVC pipe that has been placed in the pool (Saumure et al. 2002).

A common disadvantage of catching in the water is most pools are hard-sided. They are generally constructed of concrete or gunite and readily damage the side of the head of a struggling crocodilian. Attempt to keep the animal

away from the pool sides as it struggles, and move it past these structures as rapidly as possible. Sealed foam rubber gym mats or other shock absorbing materials can be placed against the side of a pool to protect the animal.

Catching Adult Crocodilians on Land

Once the rope is placed on a crocodilian on land there will be a struggle. They are able to generate a tremendous amount of resistance with their short legs forced into the ground. It is best to have sites already identified where one can tie off the rope (fence posts, trees, etc.). Trees must be of sufficient diameter to resist the force of the animal; larger crocodilians will uproot a small tree. Tying off the rope restricts the animal's movements, facilitates repositioning of the handlers to provide further restraint, and, perhaps most importantly, saves energy. Tired or exhausted catch crews are more likely to make mistakes. Successful techniques used for capture of crocodilians on land include the following.

The use of a rope to secure a hold on the animal is most common. Rope lassos can be tossed over the head or the rope is placed with a hook or catchpole. Once the rope is secure, the crocodilian is pulled to the designated work area. The animal is tied to a tree or post. Most carefully prepared capture plans unravel when the crocodilian begins to roll. This tangles ropes, scatters equipment, moves the animal into areas that compromise it or the catch staff, and generally messes up an otherwise well-organized process. Catch leaders must recognize and concede when a plan has been disrupted. Most often it is best to pause momentarily, regroup, reorganize, and then begin again. Once an animal is tied off, it may be possible to cinch a second rope to the tail. Stretch the animal and tie off the second line. This may help prevent the animal from rolling. Once the animal is restrained, a mouth pole is used to close and secure the jaws.

If there is a tree or post within the area, try to pull the animal up to it so that the head is pulled up against the tree. This acts as a stubbing post and can greatly restrict the movement of the head, making it safer to work around the animal.

Most crocodilians, when roped, will pull against the rope in an attempt to escape. A few may be more bold or aggressive and lunge at the staff on the other end of the rope. If this appears to be a possibility, either control the animal by catching it up with a rigid catchpole or place a second rope over the head and stretch the animal.

Mounting

There are situations in which it is necessary to straddle over or "mount" a large crocodilian. With caution, the correct procedure, and experience this is a fairly safe technique. However, the level of security it offers personnel is much less than that of other methods recommended in this chapter (i.e., shifting, working at a distance with hooks and poles, or physical restraint on a backboard). If any of these other methods satisfy the purpose use them instead.

Mounting allows one person to control the animal and its head, take blood or other samples, and facilitates measurement. Once in position on top of the animal the handler is relatively safe. Even with vigorous twists from side to side, the animal should be unable to bite. Care is taken to prevent the animal from rolling. The best technique to prevent this is for other catch crew to keep the tail straight and pull the hindlimbs back and off the ground. Some species (especially caiman) are quite capable of and prone to snapping their heads straight up when a handler leans over them. This is extremely dangerous and can cause serious injury; sit up straight while straddled on the animal.

To attain this position the handler must move into the animal's strike zone, hence the danger of this technique. To do this safely, the animal must be tightly roped and the rope tied securely in front of the head. This prevents the animal from twisting back. The handler moves up along the axis of the animal's body, essentially straight up the tail and the back. Stay as close to the body as possible. If the animal thrashes unexpectedly this will reduce the impact and help maintain your balance. The author finds it useful to nudge the animal with his foot before he proceeds. This tests whether the animal is ready to burst into a struggle. When ready to mount, move forward quickly and deliberately. Place one foot against the base of the tail just behind a hind limb. Move forward rapidly, place the other foot against the other side of the torso at midbody and quickly drop into a seated position on its back, with the knees planted behind the forelimbs of the animal (Fig. 14.4). Cover the eyes with your hand, and keep your

Figure 14.4 Physical restraint of a small to medium-sized crocodilian by straddling the body. Note the covering of the eyes and the noose used to capture the animal.

other hand on the top of the head and snout. Do not let fingers trail off the side of the face as this might elicit a snap to the side.

When ready to dismount make sure the path behind is clear and quickly step back off the animal in the same manner you approached: place your feet against the body and step back along the body axis.

Restraint and Transport

Once the crocodilian is captured and the jaws safely secured, the techniques for safely and efficiently moving it vary. The method of transport depends, obviously, on the size of the specimen and the distance it must be transported. For transport within the institution smaller specimens are simply carried or placed in a bag, pillowcase, duffel bag, bucket, or ice chest. However, even small crocodilians can deliver a painful slap with the tail. This is prevented by placing the tail underneath the arm while holding the animal around the neck and supporting its weight on your arm.

Larger specimens can be heavy, at least unwieldy if not often combative, and difficult to lift and carry. There is a natural tendency to try to lift these specimens by their legs. This can be injurious and must be avoided. The shoulder and hip joints of crocodilians are relatively shallow. It is not difficult to pull a limb out of the joint when lifting its leg. If an animal must be lifted, reach underneath and support it from below the torso and tail. However, crocodilians are not accustomed to being off the ground; they will often struggle, twist, and attempt to roll. The head must always be controlled. Even with the jaws taped shut it is dangerous. Always keep it directed away from others and keep your head away from it.

Ideally, larger crocodilians are either placed into a shipping crate or strapped to a backboard, platform, or aluminum ladder for transport (Fig. 14.5). They must be thoroughly restrained to prevent them from struggling to free themselves and potentially injure themselves or the capture team. Although harsh this has many benefits to the animal as well as to personnel. Some crocodilians will continue to struggle for long periods after capture. This increases their stress and exhausts them. Very large saltwater crocodiles (*C. porosus*) are known to struggle to such an extent that they build up dangerously high levels of lactic acid in their bloodstream (Seymour et al. 1987). This can result in severe acidosis and death. Crocodilians that are completely restrained on a board or platform usually cease to resist. Without the continued struggle there is little chance of the animal seriously compromising itself physiologically.

Restraint can be in the form of nylon cable straps (for smaller specimens), ropes, or cargo straps. The platform can be lifted easily and can be placed on a cart or truck for transport. Straps are placed in several places along the body: over the neck, across the shoulders just behind the forelimbs, across the center of the torso, just in front of

Figures 14.5 Physical restraint of large crocodilians ((a) *Crocodylus novaeguinae,* (b) *niloticus*, and (c) *intermedius*) with restraint board. Cargo straps or plastic seat belts are used to tie the animal to the board. A towel covers the eyes to reduce struggling. Depending on the animal's temperament, even large crocodilians may undergo nonpainful diagnostic procedures, such as this CAT scan, with no to moderate sedation (see Chapter 13). The plastic straps and wood or plastic boards do not interfere with the CAT scan process.

the hindlimbs, on the base of the tail just past the pelvis, and wrapped one or more times across the anterior half of the tail (Fig. 14.5). The head is also secured. If the animal is restrained on an aluminum ladder, it is possible to run the rope through the hollow rungs of the steps to completely secure it to the structure. Cargo straps can be purchased in a variety of widths and strengths. It is best to use those that have a wrenching action to tighten the strap after it is attached.

It is possible to physically restrain even the largest of crocodilians in this manner, assuming the platform and straps are sufficiently strong. However, it can be difficult to release the grip on the buckle of very large cargo straps. A heavy hook is useful for this purpose. For transport to other institutions, crocodilians are generally confined to a shipping crate.

Release Techniques

Releasing an animal that has been captured poses as many safety concerns as the initial capture. One must be concerned not only with the safety of the staff, but also with risks to the animal being released or its enclosure mates.

There is a real possibility the animal may attempt to turn and bite after its jaws have been unbound. Methods should be utilized to put distance between the catch personnel and the animal being released. One such method is the use of a jaw rope. A length of narrow rope is passed underneath the tape or rubber band holding the jaws shut. It is passed from the front to the back so there is no danger of accidentally causing the binds to slip and release the jaws prematurely. The rope is then tied off so that it will grip the binds. With the animal in position, all other restraints are removed, taking care not to trip on or accidentally pull the jaw rope. When all restraints are free and all personnel are well away from the animal, a hard tug on the jaw rope will pull the bindings from the jaws, freeing the animal.

In cases where the animal has been roped around the upper jaw, it will serve as the jaw rope. With the jaws still firmly taped or tied the noose of the top-jaw rope is opened. The length of rope still firmly held in the crocodile's jaws is then used to make several wraps around the snout. This then serves to secure the jaws while the other bindings are removed. When all other restraints are removed and everyone is safely away, the top-jaw rope is unwrapped from the snout. The animal will open its mouth and release the rope.

A rope noose catchpole or mouth pole is ideal for assisting release. The catchpole restrains the animal while the jaw bindings are removed. The pole prevents the animal from moving toward the catch team member holding it. When everyone is safely back from the animal the catchpole is removed.

Immediately after release crocodilians may be highly agitated. If there are other enclosure mates there is a possibility of displaced aggression leading to injury of one or more of the other animals. Before releasing a crocodile make sure it is positioned at a distance from others.

If it is suspected aggression will occur it is possible to release an animal with its jaws still bound and remove the bindings later. Re-tape the jaws and insert a piece of rope or a metal ring under the tape. The rope should float and have a large loop tied in its free end. Once the animals have had sufficient time to calm down after release, a long-handled hook is used to catch the loop in the rope or the metal ring and pull the tape from the jaws.

Cagebirds (Parrots and Perching Birds)

Michelle G. Hawkins and Peter J. Pascoe

Introduction

The anesthesia of caged (and other species) of birds is unique not only from the aspect of anatomy and physiology, but also due to unique requirements for anesthetic equipment, monitoring, and species-specific pharmacology. It is critical to understand the limitations of currently available technologies when dealing with small patients to plan safe anesthetic procedures.

Preanesthetic Evaluation

The medical history and husbandry of the patient is essential for preanesthetic evaluation. History regarding diet, appetite, previous diseases, and drug therapy should always be collected. Examination of the bird's cage and its contents is useful to assess heavy metal exposure and the bird's droppings. The quantity and quality of the droppings will help determine whether the bird has been eating. Changes in the color or consistency of the droppings suggest abnormalities in the gastrointestinal, hepatic, or urinary systems (Doneley et al. 2006).

Allowing time for acclimation to new surroundings will reduce stress and unmask clinical disease. A complete physical examination including respiratory, cardiac, renal, and hepatic function should always be performed and baseline values recorded for comparison during anesthesia. The bird should first be examined closely in its cage, paying particular attention to respiratory rate and effort. The resting respiratory rate is recorded prior to physical restraint for comparison with rates under anesthesia. The quality of respiration is evaluated by ausculting the air sacs ventrally and the lungs dorsally for evidence of harsh airway sounds or evidence of wheezing. The trachea is also ausculted and gently palpated for any abnormalities. The heart is ausculted carefully for murmurs and a baseline heart rate recorded for comparison during anesthesia. Pulse quality is assessed at either the median ulnar or medial metatarsal arteries, evaluating it for symmetry and strength. The body weight is recorded for calculating accurate fluid and medication dosages.

Accurate assessment of renal and hepatic function is difficult during the physical examination. Urine and urates in the droppings are evaluated for quantity and color. Red-tinged urine could be due to hematuria but may be due to dietary colorings. Green or yellow urate discoloration may be biliverdinuria and a sign of hepatic dysfunction (Doneley et al. 2006). Coelomic palpation is performed to assess for organomegaly, which may mechanically compress the air sacs and lungs.

Hydration status is evaluated and recorded, and dehydration corrected, if possible, prior to anesthesia. Compensatory mechanisms are blunted under anesthesia, exacerbating underlying hypotension and poor peripheral perfusion. Hydration assessment includes examination of the moistness of the cloacal and ocular mucous membranes and the elasticity of the skin at the eyelids and over the keel. Sunken eyes and cool extremities also indicate dehydration. The refill time after digital compression of the median ulnar vein should be immediate; venous refill times of >1 second have been suggested to correlate with >7% dehydration (Steinohrt 1999). The packed cell volume (PCV) will often be increased during dehydration. In pigeons that were water deprived for 72 hours, the plasma urea nitrogen increased 6.5–15.3 times, but the uric acid only showed a 1.4–2 times increase (Lumeij 1987). Clinically, however, it appears uric acid does go up with moderate-to-severe dehydration and will resolve with rehydration.

Ideally, a complete blood count and biochemical profile are performed prior to anesthesia. If one hematocrit tube

of blood can be collected, a packed cell volume (PCV), whole-blood smear for estimated white blood cell count and differential blood glucose, and several other biochemistry tests can be obtained. There are several biochemical analysis tabletop systems that require only a very small volume of blood to provide a complete biochemistry profile. Any anemias are characterized as either acute or chronic and regenerative or nonregenerative. Acute anemias are corrected prior to anesthesia as birds may not be able to compensate for lowered levels of oxygen delivery. Transfusion is indicated as in mammals if the PCV is <15–20% and the total solids are <3–3.5 g/dL. However, pet birds often have PCV ≥40% so if the blood loss is acute, the authors may perform a transfusion at a higher PCV. Also, avian total protein values may be much lower than those in mammals (2–3 g/dL). There is a poor correlation between total solids measured by refractometer and protein values measured with the biuret method, making the former an inaccurate criterion for avian transfusion (Lumeij & de Bruijne 1985). The type of surgery to be performed and the potential for blood loss are assessed so a fluid plan can be prepared. PCV may decrease 3–5% during anesthesia due to vascular hemodynamic changes associated with certain anesthetic drugs. Hypoglycemia (<200 mg/dL) is supplemented before anesthesia and glucose concentration monitored. Calcium gluconate is commonly administered in African grey parrots prior to induction to prevent hypocalcemia, a common problem in these species.

The gastrointestinal system has a very rapid transit time compared with most mammals. It is therefore important to carefully consider the nutritional plane of the patient. Prolonged anorexia will lead to a negative energy balance requiring nutritional support in the perianesthetic period. Other indications for additional nutritional support include reduced to absent fecal production and significant reduction in body weight. Nutritional requirements differ between species and classes. To calculate nutritional requirements for the critically ill patient, the basal metabolic rate (BMR) is first calculated: BMR (kcal/day) = K ($BW_{kg}^{0.75}$), K = 78 in nonpasserines and K = 129 in passerines. While these two K-factors provide a basic means of estimating avian BMR, many additional factors have been calculated for specific species. The authors refer the reader to appropriate avian nutritional texts for additional detail (Klasing 1998). The maintenance energy requirements are adjustments to the BMR based on hypermetabolism associated with any disease processes. The most common adjustments are 1.2–1.5 times BMR (range 0.5–2.0 times) (McDonald 2006). The chosen diet depends on the patient's nutritional needs. Foods can be blended to a liquid or commercially available enteral products based on the patient's protein, carbohydrate, and fat requirements can be used. Total parenteral nutrition or partial enteral nutrition is not commonly utilized due to catheter-related complications, poor patient tolerance, and lack of appropriate formulations.

Preanesthetic Supportive Care

Fluid Support

Daily maintenance fluid rates are approximately 40–60 mL/kg/day. This range is based on studies where drinking is the main route of water intake. Birds weighing ≥100 g drink approximately 5–8% of body mass/day. This increases at progressively smaller body masses to drinking rates as high as 50% for birds weighing 10–20 g (Bartholomew & Cade 1963; Skadhauge 1981; Zeigler et al. 1972). Estimation of fluid replacement is based on body weight and dehydration percentage: estimated dehydration (%) × body weight (gm) = fluid deficit (mL). One fourth to half the deficit is given in the first 6–12 hours and the remainder over the following 24 hours (Abou-Madi & Kollias 1992).

Oral fluids are only useful for mild dehydration and are contraindicated in head trauma, gastrointestinal stasis, lateral recumbency, or seizuring. Subcutaneous (SC) fluids are commonly used for maintenance and mild-to-moderate dehydration. However, large volumes may not be absorbed due to the paucity of blood vessels in the subcutis and peripheral vasoconstriction. Volumes of up to 10–15 mL/kg/site can be injected into the inguinal folds, axilla, or dorsum. Overdistension of the SC site can result in compromise of the blood supply and decreased fluid absorption. Before each injection, the administration site is inspected for previous delays in absorption. Only isotonic or nonirritating fluids should be given SC. Dextrose solutions ≥2.5% are not given SC as equilibration between the SC fluids and the extracellular fluid will exacerbate preexisting electrolyte imbalances (Abou-Madi & Kollias 1992; Steinohrt 1999).

Fasting

Preanesthetic fasting duration is determined by species, size, and clinical status, with a goal of reducing regurgitation yet minimizing hypoglycemia (Harrison 1991). Fasting times between 2 and 4 hours have been recommended in medium-sized psittacines, whereas birds ≤100–200 g may not be fasted due to high metabolic rates and easily depleted glycogen stores. However, in broiler chickens and adult Japanese quail fasted for 12 and 48 hours, respectively, blood glucose remained within clinically acceptable ranges

(Lamosova et al. 2004; van der Wal et al. 1999). No studies have been performed evaluating the effect of fasting on psittacines. Scheduling procedures as early in the day as possible reduces fasting times. In species with high metabolic rates, clear fluids high in carbohydrates may be provided to maximize calories while minimizing crop and stomach contents prior to anesthesia. The crop contents may be gently aspirated if anesthesia cannot be delayed.

Equipment

Endotracheal Intubation

The main advantages of tracheal intubation are that it provides a patent airway, reduces dead space, and allows easy application of positive pressure ventilation. The disadvantages are that it can be associated with trauma to the airway, it can significantly increase airway resistance, and the tube can become occluded due to mechanical forces or because of secretions. These factors need to be carefully considered when deciding to intubate a patient. There are a handful of species with notable anatomical variations of the upper respiratory tract. Male ruddy ducks (Chapter 21) and both sexes of emus (Chapter 19) have a tracheal sac-like diverticulum that can be confused for a ruptured trachea (King 1989). In emus, this diverticulum arises as a slit-like opening through incomplete tracheal rings from the ventral surface of the caudal one-fourth of the extrathoracic trachea. The caudal end may extend almost to the sternum (King 1989). This sac allows for the booming call of the emu. In the ruddy duck, a pear-shaped sac opens from the dorsal tracheal wall just caudal to the larynx and extends between the esophagus and trachea (King 1989). This sac is only found in the males and may be involved in the bill-drumming display. In both species, positive pressure ventilation will inflate the sac and some anesthetic gas may be sequestered, potentially affecting anesthetic depth. A bandage can be wrapped around the neck over this area to prevent inflation of the sac. A bullous enlargement of the trachea is found in some species of Anseriformes (King 1989). A median septum is present in the trachea of some penguins (Chapter 21) and petrels. This septum divides the trachea from the bronchial bifurcation cranially for variable distances depending on the species. For example, the median septum of the rockhopper penguin is only 5 mm in length (King 1989), but still may allow for unilateral endobronchial intubation. The median septum of the jackass penguin extends to within 1 cm of the larynx, allowing both unilateral endobronchial intubation and the potential for trauma during intubation (Zeek 1951). However, endotracheal tubes can be modified to allow bilateral intubation in species with median septa.

There is significant variation in tracheal length between species, which has important implications for anatomical dead space. The typical bird trachea is reported to be 2.7 times longer than that of a similarly sized mammal, but because it is approximately 1.3 times wider, the net effect is that resistance to air flow is similar to that in mammals (King 1989). Tracheal dead space volume is approximately four times that of comparably sized mammals (King 1989). In some species (e.g., some swans, cranes, spoonbills, and cassowarys), convoluted loops and coils further increase dead space. Healthy, conscious birds compensate for this larger dead space with a larger tidal volume and lower respiratory frequency than mammals. This results in minute ventilation rates that are about 1.5 to 1.9 times those of mammals (Frappell et al. 2001; Powell & Whittow 2000). However, anesthetic drugs can decrease tidal volume and a greater percentage of minute ventilation can become dead space ventilation (Curro 1998; Ludders 1998; Ludders & Matthews 1996).

An increase in airway resistance is of greatest importance in very small patients since the resistance varies with the fourth power of the radius. For example, decreasing the radius from 5 to 3 mm would increase the resistance 7-fold whereas a decrease from 3 to 1 mm would increase resistance >80 times. Since an increased resistance would require the patient to work harder to breathe, this effect can be minimized by providing positive pressure ventilation.

Despite the above cautions, the authors recommend that for any procedure that requires greater than 10 minutes of anesthesia, intubation should be performed. Many types of endotracheal tubes have been used in birds. Cole, noncuffed, and cuffed tubes have all been used successfully in caged birds (Fig. 15.1). Cole tubes have a narrow tip that is static in diameter for a short distance then increases in diameter. The distal end is advanced into the trachea until the larger diameter abuts against the glottis, creating a seal. However, these tubes tend to plug with secretions easily.

Cuffed endotracheal tubes may be used if the inflation of the cuff is carried out using an accepted method. The most careful approach is to place the tube and then inflate the lung to about 15 cm H_2O and listen for a leak. The cuff is inflated in very small increments until the leak is sealed. Overinflation of the cuff on an endotracheal tube can cause tracheal mucosal epithelial trauma due to lack of expansion of the tracheal rings. However, the avian trachea tapers as it proceeds into the thoracic inlet and a seal is often achieved using a noncuffed tube simply by its contact with the tracheal wall as it is advanced down the trachea. In general, a larger uncuffed tube will fit into the trachea than a cuffed tube because of the space taken up by the cuff. Care should be taken not to jam the tube in too forcefully as that can lead

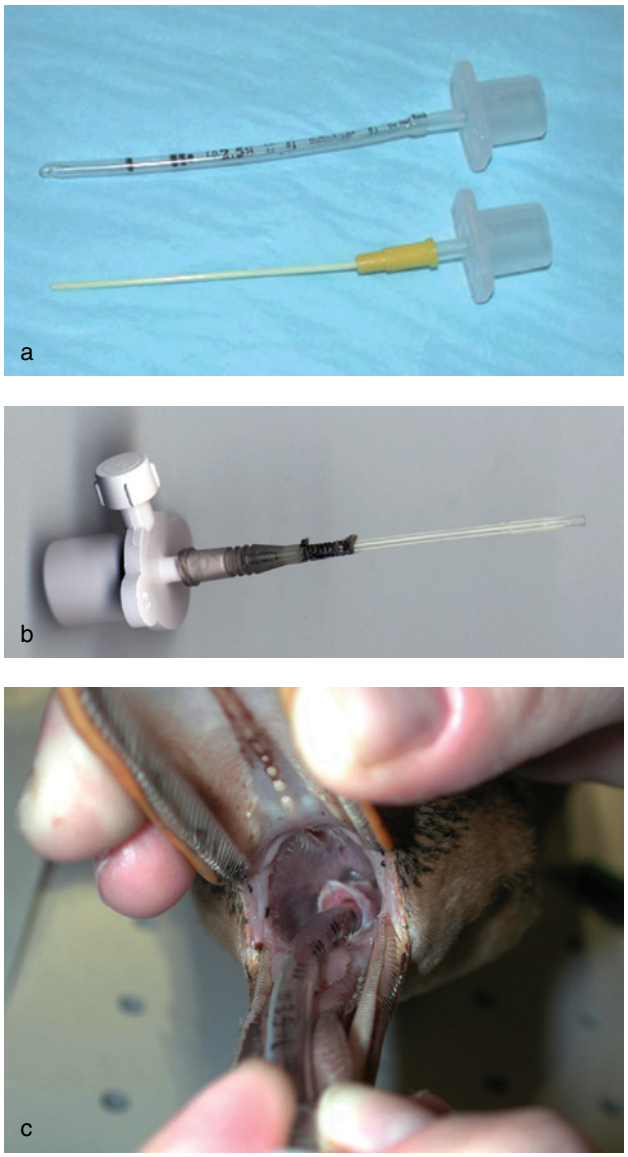

Figure 15.1 Various endotracheal tube types are used in avian clinical practice. Cole, noncuffed, and cuffed tubes have all been used successfully in caged birds (a). Catheters can be modified and used as endotracheal tubes for very small patients (b). Intubation is straightforward as visualization of the glottis is not difficult in most caged birds (c).

to tracheal mucosal damage. The tracheal diameter of many birds is narrower at mid-neck than the glottal diameter. Inflammation of the tracheal epithelium may lead to fibrotic narrowing of the tracheal lumen with complete trans-tracheal membranes (Fig. 15.2). Cuffed tubes without the cuff inflated also have the potential to cause tracheal mucosal damage and inflammation due to the irregularity of the plastic surface of the cuff on the tracheal epithelium. Since this inflammatory process requires time, clinical signs of dyspnea associated with this type of tracheal trauma may not become evident for up to 1 week post intubation. There

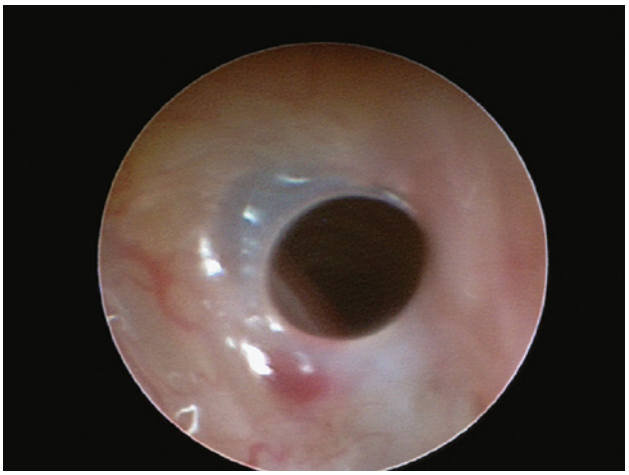

Figure 15.2 Transtracheal membrane occluding approximately 75% of the tracheal lumen in a double yellow-headed Amazon parrot. Note the significant vascularization of the membrane. These membranes have been reported most in birds up to several weeks after intubation with both cuffed and noncuffed endotracheal tubes. Various factors such as overinflation of the cuff, ventilation techniques, and endotracheal tube disinfection protocols have been evaluated but no definitive correlations have been identified to date.

have been a small number of case reports documenting tracheal stenosis or tracheal membrane formation in psittacines post intubation, as well as other species (blue-billed curasow) (de Matos et al. 2006; Evans et al. 2009; Jankowski et al. 2010). These cases have been managed with tracheal anastomosis, with one bird having no respiratory signs for 2 years post resection (Jankowski et al. 2010). Various factors, including ventilation techniques and endotracheal tube disinfection protocols, have been suspected to contribute to this phenomenon and these are factors that are associated with tracheal stenosis in humans (Wain 2009), but no definitive correlation with protocols or procedures has been identified to date.

Although noncuffed tubes are used most, there are several disadvantages to their use. They do not provide a sealed airway, allowing escape of anesthetic gases. This increases the amount of anesthetic gas required and environmental contamination. Also, airway protection from aspiration of secretions or gastrointestinal contents is reduced. This makes it imperative that the oral cavity be clean prior to intubation and monitored throughout the procedure. Elevation of the head and neck may reduce regurgitation of gastrointestinal contents from the crop, proventriculus or ventriculus into the oral cavity. Cuffed tubes have been used in larger avian patients. The cuff is carefully inflated with just enough air to prevent leakage when 10–15 cmH_2O pressure is applied to the breathing circuit (Curro 1998; Ludders & Matthews 1996).

The patient size determines the endotracheal tube size used. The smallest commercial noncuffed tubes have an internal diameter (ID) of 1 mm. However, tubes of <2 mm ID are often highly flexible and kink easily. The smallest diameter cuffed tube is 2.5 mm ID. Very small birds may be intubated with teflon intravenous (IV), red rubber, or urinary catheters. Care is taken to ensure that no sharp edges are present at the end. This is achieved by using a small piece of silicone tubing over the end of the catheter. Ends of catheters can be cut and adapted for use as endotracheal tubes if they are gently filed with an emery board to remove rough edges.

As stated previously, endotracheal tubes with small internal diameters impose significant resistance on gas flow, especially if mucus accumulates. During inhalant anesthesia, copious thick mucus production can occur due to the drying effects of the inspired cold, dry gases. The mucous plug can act as a "flapper" valve allowing air in, but not out. In the authors' experience, humidification of the gases reduces mucus plug formation. Commercially available endotracheal tube humidifiers are available (Humidi-vent Mini Agibeck Product, Hudson RCI, Temecula, CA, USA). Disadvantages of their use include increased dead space and filter plugging with secretions. The use of an endotracheal tube with a Murphy eye, which has both side and end openings, decreases the likelihood of mucus occlusion.

Endotracheal tube obstruction is detected by monitoring the ventilatory pattern. As the airway occludes the expiratory phase duration becomes prolonged (Ludders & Matthews 1996). An anticholinergic (atropine, glycopyrrolate) reduces mucus production and mucus plug formation. However, it also increases mucus viscosity, making it harder to clear secretions from the tube. Some clinicians recommend that the endotracheal tube be removed and replaced after every hour of anesthesia for long procedures.

Extension of the neck, gentle traction on the tongue, and pressure under the mandibular beak will push the glottis forward to aid in endotracheal tube placement. A Q-tip swab is useful to atraumatically pull the tongue forward. Psittacines have a thick, fleshy tongue that makes glottal visualization slightly more difficult. Some birds have very brisk glottal closure reflexes. Intubation in these patients can be facilitated by applying a very small amount of lidocaine to the larynx and waiting 60 seconds. If possible, the tube is secured to the mandibular beak to allow for monitoring the oral cavity during anesthesia. Any portion of the tube extending from the circuit to the glottis is dead space; cutting the tube as close as possible to its entry into the oral cavity will minimize this mechanical dead space.

Inhalant anesthetics can also be administered through a cannula inserted into an air sac for induction and maintenance in birds as small as zebra finches (Fig. 15.3) (Korbel et al. 1993; Korbel 1998a; Mitchell et al. 1999; Nilson

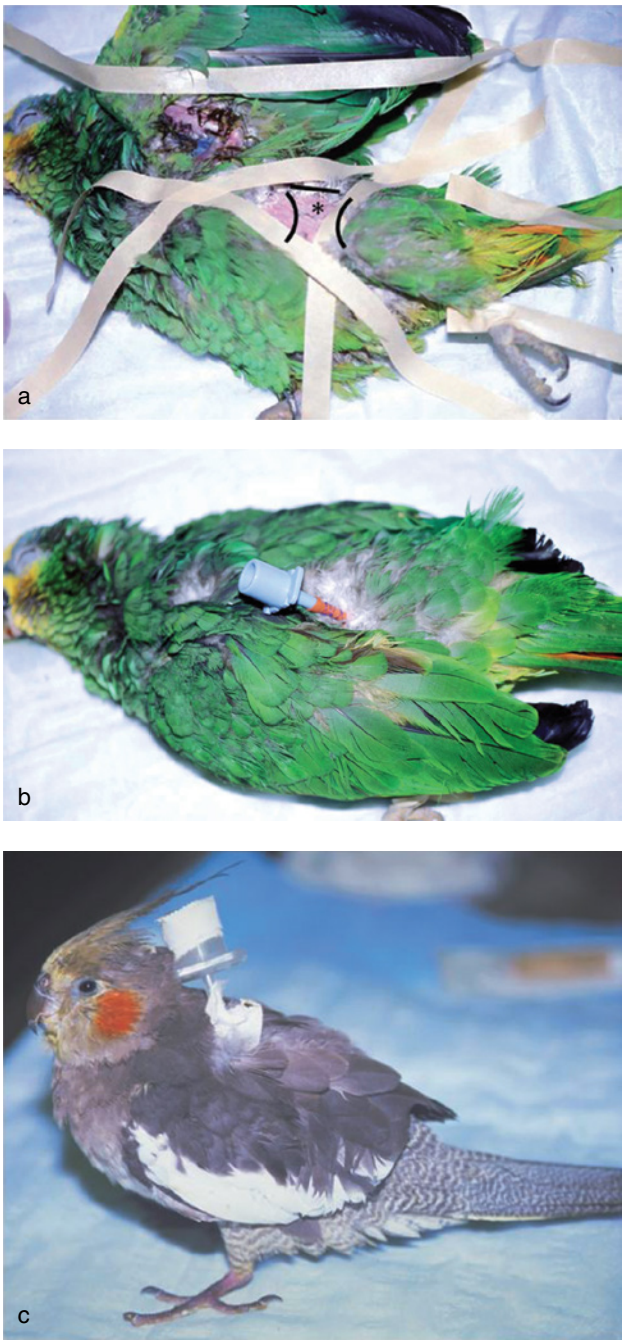

Figure 15.3 Placement of an air sac cannula. Strict asepsis should be observed when placing the cannula. Feathers over the site for cannulation should be gently plucked, contour feathers taped away from the cannula site, and the area should be surgically prepared. The landmarks for air sac cannula placement are caudal to last rib, ventral to the vertebrae, and, in most cases, cranial to hindlimb. The proper site for cannula insertion is marked with * (a). Once the cannula has been surgically placed, it is secured in place with suture (b). A piece of sterile gauze can be used as a filter to minimize contamination of the cannula with particulate matter (c).

et al. 2005; Piiper et al. 1970; Rode et al. 1990; Whittow & Ossorio 1970; Wijnberg et al. 1991). Air sac cannulation provides an airway when upper respiratory tract obstruction is present (e.g., syringeal foreign bodies or granulomas). It is also used for procedures involving the upper airway or cranium (Jaensch et al. 2001; Nilson et al. 2005; Piiper et al. 1970). It is also placed for acute life-threatening obstruction and can be left in place to provide longer-term respiratory support, but not generally for more than 3–5 days without replacing tubes, as inflammatory tissue and cells will accumulate on the tube tip (Korbel et al. 1996; Mitchell et al. 1999).

Materials used for air sac cannulas include sterile endotracheal tubes, large gauge IV catheters (16–18 g), red rubber feeding tubes, and silastic tubing. If the bird is to breathe through the cannula, the tube diameter should be at least equal to the patient's tracheal diameter and short enough to minimize dead space and prevent coelomic soft tissue contusion.

Air sac catheters are usually placed in the left caudal thoracic or abdominal air sac to prevent trauma to the larger right liver lobe. However, catheter placement into the clavicular air sacs has also been reported (Rode et al. 1990; Rosskopf & Woerpel 1990). In sulfur-crested cockatoos (*Cacatua galerita*) caudal thoracic air sac intubation provided stable isoflurane anesthesia without significant respiratory functional changes. Even though caudal thoracic air sac partial pressure of carbon dioxide (PCO_2) decreased to 12.7 ± 7.9 mmHg, spontaneous respiration was still present (Jaensch et al. 2001). Clavicular air sac catheterization was also evaluated but was not successful at either maintaining anesthesia or providing ventilation. In a separate study, clavicular air sac PO_2 and PCO_2 were significantly lower than in the cranial thoracic air sacs, suggesting, at least in sulfur-crested cockatoos, ventilation of this air sac is less than the cranial and caudal thoracic air sacs (Jaensch et al. 2002).

Air sac cannula placement is a relatively simple surgical procedure (Fig. 15.3). For placement into the left caudal thoracic or abdominal air sac, the landmarks are the last rib, the cranial aspect of the femur, and the flexor cruris medialis muscles. Following removal of overlying feathers and aseptic preparation of the skin, a skin incision is made over the desired site. The underlying muscle and air sac membrane are bluntly dissected with a hemostat. The tip of the sterile catheter is grasped with the hemostat and passed into the air sac. The muscle and skin are closed, securing the catheter in place. In an emergency, gas flow and ventilation are provided through an IV catheter placed at the same site and connected to an oxygen source. Care is taken not to advance the catheter needle too far and to limit oxygen flow to prevent hypocapnia. In apneic 1–1.7-kg chickens a flow of 500 mL/min reduced PCO_2 to ≤20 mm Hg (Pascoe, unpub. obs.) so with a small catheter and flow-through ventilation the O_2 flow should probably be <250 mL/kg. Oxygen and anesthetic gases from the cannulated site exit the trachea unless intubated with an occluded endotracheal tube. It is possible to scavenge waste gases by placing a mask or tube over the bird's head and connecting it to an active anesthetic scavenging system.

The most common adverse effects reported with air sac cannulation are apnea, SC emphysema, plugging of the tube, and bacterial contamination with associated coelomitis (Jaensch et al. 2001; Mitchell et al. 1999). Ensure meticulous cleaning/inspection of the tube to prevent plugging. Cleaning is performed with a sterile cotton-tip applicator or Dacron swab. A filter can be designed from small weave gauze (i.e., from the inside of a Hepa-filtered mask) and placed over the end of tube to prevent particulate matter from entering. Although most birds tolerate air sac cannulas, an Elizabethan collar may be required for some. Following cannula removal, the body wall is closed to prevent SC emphysema.

Breathing Systems

Many nonrebreathing systems (e.g., Ayre's T-piece, Mapleson systems, Magill, Jackson-Rees, Norman elbow, and Bain) have and can be used for avian anesthesia. These systems require a relatively high fresh gas flow rate to remove carbon dioxide. These higher flow rates have the added benefit of providing rapid equilibration in inhalant concentration with changes in vaporizer setting. Nonrebreathing systems were traditionally viewed as ideal for small patients because of lower airflow resistance and reduced dead space. Circle systems were believed to have higher airflow resistance because they contain one-way valves and soda lime canisters. However, the primary source of resistance is most likely the endotracheal tube. Studies in infants ≤10 kg (Rasch et al. 1988) and cats (Suter et al. 1989) have shown that resistance was insignificant compared to that produced by the endotracheal tube alone. Circle systems are heavier and bulkier, which predisposes to accidental extubation and difficulty working around the head. For this reason, a nonrebreathing system such as the Bain breathing system is recommended in small birds due to its lightweight design.

Specific flow rates for avian patients have not been defined. As in mammals, 2–3 times minute ventilation appears appropriate when using the T-piece or Norman elbow, but in the Bain circuit a lower flow rate of 150–200 mL/kg/min is effective (Ludders 2001; Ludders & Matthews 1996). The removal of waste gases from the circuit occurs during the pause between expiration and

inspiration. If the respiratory rate is high (shorter pause and therefore more mixing of inspired and expired gases) a higher flow rate is used (e.g., respiration rate >40, increase the flow rate to 300 mL/kg/min). If a capnograph is being used the flow rate can be adjusted to minimize increases in inspired CO_2.

Ventilators

Allometric analyses have been used to predict the effect of body size on respiratory variables associated with gas exchange efficiency between mammals and birds (Frappell et al. 1992, 2001; Maloney & Dawson 1994). A study using 50 avian species found general agreement with the older allometric equations, with some minor differences in coefficients. The variables determined in this study agree with anatomic data and clinical observations, suggesting that irrespective of body size, birds tend to breathe slower and deeper, have lower minute ventilation, and have a greater demand for oxygen when compared with mammals, making the avian respiratory system more highly efficient in terms of oxygen extraction.

Both injectable and inhalant anesthetics cause dose-dependent respiratory depression. Sick or debilitated birds may not be able to accommodate these physiologic changes and require intermittent positive pressure ventilation (IPPV). In mammals, IPPV is associated with reduced cardiac output and hypotension (Steffey & Howland 1977, 1980). In cranes anesthetized with isoflurane, spontaneous ventilation was associated with elevations in arterial partial pressure of carbon dioxide ($PaCO_2$), hypotension, and acidemia compared with controlled ventilation (Ludders et al. 1989). Similarly, there was a significantly reduced $PaCO_2$–to end-tidal carbon dioxide ($PETCO_2$) gradient and no significant difference in mean arterial blood pressure in Hispaniolan Amazon parrots (*Amazona ventralis*) ventilated using IPPV compared to birds breathing spontaneously (Pettifer et al. 2002). It is possible that reduced cardiovascular performance associated with IPPV may not be a concern in birds. However, it is still recommended that cardiovascular variables be monitored closely during IPPV.

Ventilators must cope with the range of tidal volumes in the species of interest. In very small birds this may be ≤1 mL while in a large ostrich it might be ≥2 L. Modern ventilators are usually pneumatic, but control mechanisms may be either pneumatic or electric. If electronically controlled, an auxiliary power source is required if the bird is moved or power fails. The three variables controlled by a ventilator are tidal volume, rate of tidal volume delivery, and respiratory frequency. The method of control varies between ventilators. In volume-limited ventilators tidal volume is set on the machine with the expectation that it will deliver the volume regardless of moderate changes in resistance. Even if the circuit is disconnected the ventilator continues to cycle with no alteration in tidal volume or timing. Some ventilators allow the upper limit for inspired pressure to be set with an alarm. In pressure-limited ventilators the end-inspiratory pressure is set. The ventilator will push gas into the bird until it reaches the set pressure, when the inspiratory phase will terminate and the ventilator allows for passive exhalation. A disconnect or large hole in an air sac is indicated by prolonged inspiration because the preset pressure is not reached. A third method is to set the inspiratory time and achieve different tidal volumes by altering the inspiratory flow rate. This is a form of volume-limited ventilation. The respiratory rate and tidal volume are determined by the gas flow rate. Hence it is necessary to set a faster flow rate for a larger tidal volume. On some ventilators this is set by altering the knob labeled "I:E ratio". This is the inspiratory versus expiratory time and the setting will depend on the number of breaths per minute. If you want inspiration to take 1.5 seconds the I:E ratio would need to be 1:3 for 10 breaths per minute (6 seconds per breath, 1.5 seconds for inspiration:4.5 seconds for expiration) or 1:1 for 20 breaths per minute (3 seconds per breath, 1.5 seconds each for inspiration and expiration). The number of breaths per minute is mostly set by altering a timing device that begins a new inspiration after a set period.

When ventilating birds, it is essential to have a ventilator that can deliver small tidal volumes slowly to give an acceptable inspiratory time. During anesthesia the ventilator should initiate the breath, not the bird, to control the PCO_2. In assisted ventilation mode the bird initiates the breath when its PCO_2 reaches the point set by the central controllers of ventilation in the brain. Since the latter are depressed by anesthetics, assisted ventilation is not likely to decrease PCO_2.

The authors recommend initial inspiratory pressures of 8–10 cmH_2O and rates of 6–10 breaths per minute. Thoracic excursions are assessed as soon as the ventilator is started. The tidal volume is adjusted to achieve an appropriate thoraco-abdominal expansion. The minute volume is lower than in mammals (Frappell et al. 2001) and inspiratory times can be longer. At 6 breaths per minute the I:E ratio could be set to 1:2 to 1:3 (inspiration occurring over 3.3 to 2.5 seconds). During coelomic surgery, when the air sacs have been opened, anesthetic will be pushed by the ventilator into the air being breathed by the surgeons. It is important to avoid or minimize personnel exposure to inhaled agents. In some cases, injectable anesthetics are used if the concerns about using inhalant anesthetics are great.

During positive pressure ventilation, it is possible the direction of gas flow within the lung is reversed. However, the crosscurrent exchange system is not dependent on the

direction of flow and does not significantly affect gas exchange (Ludders et al. 1989; Piiper et al. 1970; Uhart et al. 2020). If a mechanical ventilator is not available, hand ventilation delivered from the reservoir bag provides controlled or assisted ventilation.

Thermal Support

Heat is lost via radiation, evaporation, convection, and conduction. The normal body temperatures of most caged birds range from 39 to 43°C (Dawson & Whittow 2000). Since many birds are small and have a high body-to-surface area ratio they radiate heat rapidly. Once anesthetized, the bird is immobile and relaxed so it will generate less heat from muscle contraction. It is also subject to evaporative loss from the respiratory tract (dry anesthetic gases), skin surfaces (surgical preparations solutions), and open body cavities, conduction of heat via surface contact, and convection of warm gases from around the bird (Wessel et al. 1966). Anesthesia redistributes blood flow and depresses thermoregulatory response, further promoting heat loss. The core body temperature of pigeons with no external heat support dropped ≥8°C in ≤30 minutes of inhalant anesthesia (Harrison et al. 1985). Hypothermia has several adverse physiologic effects. It results in bradypnea and decreased minute ventilation and tidal volume (Moon & Ilkiw 1993). Hypothermia decreases anesthetic requirement and metabolism and will prolong recovery (Ludders & Matthews 1996), therefore monitoring core body temperature and providing thermal support are mandatory to reduce anesthetic morbidity and mortality in the anesthetized and recovering patient.

Body temperature is monitored continuously throughout anesthesia. Prevention of heat loss is essential in the anesthetized patient and supplemental heat sources are used regardless of procedure length. Electronic thermometers and temperature probes provide accurate readings. Cloacal temperatures have been correlated with thoracic esophageal readings, suggesting core temperature may be indirectly monitored (Phalen et al. 1996). However, as cloacal musculature relaxes, peripheral temperature readings are lowered. Esophageal temperature probes provide consistent readings when placed at the level of the heart in the thoracic esophagus. Care is taken to ensure the crop is not damaged during placement and the probe does not back out resulting in incorrect temperature readings.

Since most heat is lost via radiation, the most effective technique to prevent heat loss is to minimize the temperature gradient between the bird and the room. Options include increased room temperature, insulating the patient with clear plastic drapes, and wrapping nonsurgical fields. The surgical time and the amount of time that the body cavities are open are minimized, as are feather plucking and alcohol use for skin preparation. Latex gloves, empty fluid bags or plastic bottles can be filled with water, warmed in a hot water bath or microwave and placed next to the bird. Water bottles are always wrapped in a towel to prevent burns. Circulating warm water blankets insignificantly diminish the rate of heat loss in birds (Phalen et al. 1996; Rembert et al. 2001). Radiant heat lamps are effective at maintaining core body temperature, but the optimal distance between the heat source and the patient differs with patient size, heat lamp strength, and the heat setting (Phalen et al. 1996; Rembert et al. 2001). Forced air warmers (Bair® Hugger) have been thought to be more effective at minimizing hypothermia during anesthesia than other methods (Borms et al. 1994; Machon et al. 1999; Rembert et al. 2001). They are particularly effective when set up to have warm air rising around the patient either by wrapping the patient in the blanket or by using a perforated table. The patient's eyes are well lubricated to prevent corneal ulceration due to drying from the warm dry air. However, one trial showed that an electrical heating method (Hot Dog™, Augustine Medical) was more effective than a forced air warmer (van Zeeland et al. 2012).

Further reductions in heat loss are achieved by warming fluids and reducing respiratory cooling. In pigeons anesthetized for 90 minutes there was no significant difference in heat loss between either a circle system with mechanical ventilator producing heated air, a nonrebreathing system with mechanical ventilator producing nonheated air, and a Bain nonrebreathing circuit (Boedeker et al. 2005). This contrasts with humans, cats, and rabbits in which heated, humidified anesthetic gases reduce or prevent the development of hypothermia (Haskins & Patz 1980; Newton 1975; Shanks 1974; Tausk et al. 1976). In intubated anesthetized ring-necked doves (*Streptopelia risoria*) without thermal support, hypothermia was not lessened by humidification and heating of inspired gases (Phalen et al. 1996). However, in anesthetized pigeons maintained on a facemask, heated inspired gas did minimize hypothermia (Jenkins 1988).

Emergencies

Emergencies during anesthesia should be planned for and anticipated. Many can be averted by careful monitoring of respiratory and heart rates, and body temperature. Emergency equipment (i.e., endotracheal tubes, oxygen, IV catheters and materials for securing them, ventilatory support, and emergency drugs) should always be close by and prepared for use. It is recommended that emergency drug dosages be calculated and 1–2 doses predrawn before

Table 15.1 Emergency drugs used in birds.

Drug	Dosage	Route	Comments
Atropine	0.01–0.02 mg/kg	SC, IM, IV	Most species/preanesthetic
	0.04–0.1 mg/kg	SC, IM, IV, IO, IT	Bradycardia
	0.5 mg/kg	IM, IV, IO, IT	CPR
Glycopyrrolate	0.01–0.02 mg/kg	IM, IV	Slower onset than atropine Most species/preanesthetic
	0.04 mg/kg	IV	Ratites
Epinephrine (1:1000)	0.05–0.5 mg/kg	IM, IV, IO, IT	CPR, bradycardia
Norepinephrine	0.7 µg/kg/min	IV	Increased MAP in Pekin ducks by 11% (Jungbluth et al. 1994)
Dopamine	5 µg/kg/min	IV	Increased MAP in Hispaniolan Amazon parrots by 25% (Schnellbacher et al. 2012)
Dobutamine	5 µg/kg/min	IV	Increased MAP in Hispaniolan Amazon parrots by 17% (Schnellbacher et al. 2012)

CPR, cardiopulmonary resuscitation; IM, intramuscular; IO, intraosseus; IT, intratracheal; IV, intravenous; MAP, mean arterial pressure; SC, subcutaneous.

induction (Table 15.1). Respiratory depression and arrest are treated by turning off the anesthetic and controlling ventilation. Cardiac arrest is usually a result of myocardial hypoxemia and inotropic and chronotropic anesthetic drug effects. Although treatment is often unrewarding (Onuma et al. 2017), administration of epinephrine IV, intratracheal or by intracardiac injection, is recommended. Cardiac massage is nearly impossible due to the heart's anatomical location dorsal to the large bony sternum but should be attempted. Severe bradycardia is treated with atropine, assuming it is due to increased parasympathetic tone. In very small birds, it is possible to see spontaneous ventricular defibrillation as the mass of the heart is small enough that it cannot maintain a fibrillatory pattern.

Hypotension is not a common problem in anesthetized birds but Table 15.1 provides some information on the use of norepinephrine, dopamine, and dobutamine for this purpose (Jungbluth et al. 1994; Schnellbacher et al. 2012). Given that this information is very limited, it is expected that the clinician would use these doses as a starting point and increase/decrease the infusion to achieve the desired outcome.

Anesthesia

Restraint

Correct restraint is essential to minimize patient stress and the time required for anesthetic induction. Stressed birds may die from physical restraint and this risk is magnified in sick or debilitated patients. Appropriate means of physical restraint must be assessed for each patient and appropriate stabilization and supportive care prepared prior to handling. Paper towels, wash cloths, hand towels, large bath towels, or blankets may be used based on the patient size. Hooding calms some species (e.g., raptors and ratites), but care must be taken to ensure adequate air flow. Leather gloves will not protect handlers from the crushing bite of a large parrot. Nets are used to capture birds in larger enclosures or escapees. They should be sized appropriately for the patient to minimize iatrogenic trauma. Once netted, the bird is gently removed to avoid trauma to the wings, legs, or toes. Ear protection for the handler (e.g., cotton balls or ear plugs or noise cancelling headphones) can be used when handling large psittacines (e.g., cockatoos and macaws). Face shields or goggles are used when handling birds likely to inflict ocular damage with the tip of their beaks (e.g., Ciconiiformes).

It is preferable for caged birds to be captured from within their travel cage or hospital enclosure to reduce the chance for injury and reduce stress induced by escape attempts in a room. All perches, toys, and food and water dishes are removed to facilitate capture and minimize trauma, and ambient noise should be reduced. If a patient must be captured from a larger area, this should ideally be done in a small area that is free of windows and doors leading to the outdoors. Alternately, windows can be covered to minimize self-induced trauma if an escape occurs and doors are locked. Some methods to aid capture from a room include placing the bird on the floor or turning off lights as this will often reduce the excitement level of the patient. Regardless of the physical restraint technique employed, care should be taken not to compromise thoracic cage

movement or the ability of the anesthetist to monitor the patient. Movement with the bird in hand should be quiet and calm to reduce fright and stress. The capture is performed expeditiously to minimize stress. If a bird should escape and need to be re-captured or is unduly excited, delay anesthesia until the bird has calmed down.

Once the bird is in hand, a towel is initially placed over the dorsum, then gently wrapped around the wings to restrict flapping and prevent damage to the wings and feathers. Once adequately restrained by the handler, birds are removed from the towel if possible to prevent hyperthermia that can occur subsequent to prolonged restraint. Small birds (e.g., passerines) are restrained with the head between thumb and forefinger, and the body within the palm. Alternatively, in smaller psittacines the head is restrained using a "three-point" technique with the thumb and middle finger supporting the mandible and the index finger on top of the head. Bruising of the face is possible in large macaws and only the minimum pressure necessary to restrict movement is applied. Gentle extension of the bird's neck further limits head movement. Large parrots are strong and will inflict severe wounds if the head and beak are not immediately controlled. Some prefer to encircle the birds neck with their fingers for restraint. A third technique places the thumb under the intermandibular space while the other fingers are placed over the top of the head. This is the author's choice for maintaining full control of the head during restraint. The other hand is placed on the dorsum to secure the wings and legs.

Restriction of the movement of the sternum and thoracic muscles due to overexuberant physical restraint, and dorsal and ventral recumbency are often reported to lead to hypoventilation (Curro 1998; Forbes 1999; Heard 1997; Jaensch et al. 2002; King & Payne 1964; Pettifer et al. 2002) It has been hypothesized that dorsally-recumbent patients have their air sacs and lung openings (ostia) compressed by the internal organs, which may be exacerbated by increasing anesthetic duration (King & Payne 1962, 1964). This hypothesis has led to recommendations to avoid dorsal recumbency in anesthetized birds when possible. Until recently, the only studies of this effect have been in the domestic chicken. The chicken has a very well-developed pectoral musculature that may compress the thorax during respiration in dorsal recumbency more so than lighter-bodied birds. Chickens and other domestic poultry also usually have large amounts of intracoelomic fat that reduces air sac volume. It was shown in a recent evaluation of air sac and lung volume in red-tailed hawks that even birds with significant coelomic fat did not demonstrate a reduction in lung volume, only air sac volume (Malka et al. 2009). Additionally, chickens have a somewhat different gas exchange anatomy that may affect ventilation in dorsal recumbency. While the domestic chicken is not the most appropriate model for flying birds, the recommendation for avoiding dorsal recumbency is also supported by clinical experience (Curro 1998; King & Payne 1964). In a recent study evaluating the effects of positioning on spontaneous ventilation in red-tailed hawks during isoflurane anesthesia, no significant differences were found in minute ventilation, heart or respiratory rates, or arterial blood pressures when birds were placed in either dorsal or lateral recumbency. The PaO_2 was significantly higher in dorsal recumbency (M.G. Hawkins, S.M. Malka, P.J. Pascoe, unpub. data). Any adverse effect of positioning appears to be negated by assisted ventilation.

Preoxygenation

In mammals, the functional residual capacity (FRC) acts to buffer changes in oxygen partial pressures during the respiratory cycle. In the past, it has been suggested that there is little FRC in avian lungs and therefore birds have little mechanism for blunting the effects of apnea on PaO_2 and $PaCO_2$ (McLelland 1989). However, there is a significant reservoir of gas in the air sacs and unidirectional flow of gases through the avian lung may minimize the potential for significant fluctuations in blood gas tensions during short periods of apnea. For example, in chickens, 8 minutes of apnea after breathing 100% oxygen resulted in oxygen blood gas tensions that decreased at a similar rate to that seen in mammals (P.J. Pascoe, unpub. obs.). Having a high concentration gradient (>95% O_2) and small distances to traverse allows for diffusion of oxygen through the lungs as the oxygen is being removed by the blood, accounting for this delayed onset of hypoxia. In a bird breathing room air there is a very small diffusion gradient and because oxygen consumption is higher in birds than mammals any periods of apnea, however brief, must be treated immediately. Normal blood gas values for selected species are presented in Table 15.2. It should be noted that these values are obtained in awake birds on room air. Over a range of 19 species, PaO_2, $PaCO_2$, and pH were noted to average ($\pm$ standard deviation) 91.61($\pm$ 8.5), 31.43 ($\pm$ 4.2), and 7.50 ($\pm$ 0.03), respectively (Powell & Whittow 2000). From these data it is clear birds tend to have $PaCO_2$ tensions that are lower than in many mammals.

The response of birds to hypoxia has been studied in awake animals but not in birds under inhalant anesthesia. Typically, birds do not increase respiratory rate in the early stages of hypoxia but increase minute ventilation by increasing tidal volume (Butler & Taylor 1974). As hypoxia progresses respiratory rate will increase, and oxygen consumption, body temperature, and blood pressure may decrease. Heart rate starts to increase early in hypoxia, but

Table 15.2 Injectable pre-medication/emergency, sedative, tranquilizer, and anesthetic drugs used in birds.

Drug	Dosage (mg/kg)	Route	Indication(s)	Comments	References
Benzodiazepines					
Diazepam	0.2–2.0	IM, IV	Most species Premedication, sedation, anticonvulsant, appetite stimulant	IM administration may cause severe muscle irritation and absorption may be delayed 0.25–0.5 mg/kg has been used as an appetite stimulant and to improve acceptance to novel captive diets for raptors and wild passerines Reversal with flumazenil	Abou-Madi (2001); Samour (2000) Clyde & Paul-Murphy (1994); Suarez (1993) Massey (2003)
	2.5–4.0	PO	Most species/sedation		Ritchie et al. (1994)
	7.3–8.0	IN	Canaries	Dose divided into each nare and given slowly. Dorsal recumbency for ~35 minutes.	Vesal & Eskandari (2006); Vesal & Zare (2006)
Midazolam				In larger macaws the author's have noted regurgitation after doses of >0.3–0.5 mg/kg IM. Water soluble; does not cause muscle irritation with IM use. Reversal with flumazenil	
	0.1–2.0	IM, IV	Most species/ premedication, sedation, appetite stimulant	IM onset 5–15 minutes. Higher dosages may cause profound sedation.	Abou-Madi (2001); Day & Roge (1996)
	2.0–6.0	IM	Quail, sedation	High dosages give greatest sedation without cardiopulmonary effects, but adequate sedation also found with lower dosages, just shorter duration of sedation.	Day & Roge (1996)
	2.0	IM	Canada geese/ sedation	For 15–20 minutes	Valverde et al. (1990)
	2.0	IN	Hispaniolan Amazon parrots	Mild-to-moderate sedation in 3 minutes; reduced vocalizations, struggling and defensive behaviors for 15 minutes; reversed with IN flumazenil	Mans et al. (2012, 2010)
	7.3–8.0	IN	Canaries, ring-necked parakeets	Dose divided into each nare and given slowly. Dorsal recumbency for approx. 17 minutes. Flumazenil reduced time to recovery.	Vesal & Eskandari (2006); Vesal & Zare (2006)
Flumazenil				Benzodiazepine reversal agent	
	0.02–0.10	IM, IV	Most species		Abou-Madi (2001); Day & Roge (1996); Machin & Caulkett (1998a,b)
	0.05	IN	Mallard ducks		Machin & Caulkett (1998b)
	0.13–0.15	IN	Canaries, ring-necked parakeets	Dose divided evenly between nares and given slowly	Vesal & Eskandari (2006); Vesal & Zare (2006)

(*Continued*)

Table 15.2 (Continued)

Drug	Dosage (mg/kg)	Route	Indication(s)	Comments	References
α-2 Adrenergic agonists					
Detomidine	0.3	IM	Rock partridges	Marked sedation/significant decrease in HR, RR, decrease in cloacal temperature, prolonged recoveries (260 ± 18 minutes)	Uzun et al. (2006)
	12	IN	Ring-necked parakeets	Dose divided into each nare and given slowly; sedation <3 minutes but did not allow dorsal recumbency or manipulation; reversal with atipamezole significantly reduced time to recovery	Vesal & Eskandari (2006)
	12–15	IN	Canaries	Dose divided into each nare and given slowly; higher dose prolonged sedation but could not place in dorsal recumbency; prolonged duration of effect (258 ± 2 minutes) but completely reversed with yohimbine IN	Vesal & Zare (2006)
Dexmedetomidine				Use half the recommended dose of medetomidine Reversal with same dose of atipamezole	
	0.025	IM	Common buzzards	Adequate restraint to prevent reaction to handling, but did not allow for intubation. Completely reversed with atipamezole. Mean times to loss of righting reflex = 3.5 ± 1 minutes in common buzzards. No arrhythmias noted on ECG. No excitement or major adverse effects observed in either group.	Santangelo et al. (2009)
	0.075	IM	Common kestrals	Adequate restraint to prevent reaction to handling, but did not allow for intubation. Completely reversed with atipamezole. Mean times to loss of righting reflex = 7 ± 1.2 minutes in common kestrels	Santangelo et al. (2009)
Medetomidine	0.01–0.035	IM	Pigeon, yellow-crowned Amazon	0.08–2 mg/kg IM associated with inadequate sedation. Profound respiratory depression may occur. Much higher dosages appear to be required in some avian species when compared with mammals.	Clyde & Paul-Murphy (1994); Pollock et al. (2001); Sandmeier (2000)
	0.025–0.035	PO	Chickens	Sedation	James et al. (1999)}

Table 15.2 (Continued)

Drug	Dosage (mg/kg)	Route	Indication(s)	Comments	References
Xylazine				Not recommended by itself for tranquilization and seldom used in pet birds due to adverse effects – excitement, convulsions, bradycardia, arrhythmias, bradypnea, hypoxemia, hypercarbia, death when used alone; most useful in ratites	
	1.0–10.0	IM, IV	Most species, tranquilization in combination with ketamine for anesthesia	Adequate sedation often with <4 mg/kg, in smaller psittacines dosages up to 10 mg/kg may be required	Carpenter (2000); Clyde & Paul-Murphy (1994); Huckabee (2000); Ludders, Rode, Mitchell, et al. (1989); Samour (2000)
α-2 Adrenergic antagonists					
Atipamezole				Alpha-2 adrenergic antagonist; 1:1 volume reversal of dexmedetomidine/medetomidine is the general rule; although the same effects would be expected as with medetomidine, there are no data available on the efficacy of atipamezole reversal of dexmedetomidine in birds	
	0.25–0.5	IM	Psittacines, pigeons, raptors, geese	Righting reflex regained 2–10 minutes after administration	Machin & Caulkett (1998b); Pollock et al. (2001); Samour (2000); Santangelo et al. (2009)
	1.3–1.6	IV	Chickens		James et al. (1999)}
	0.18–0.28	IV	Mallard ducks		Machin & Caulkett (1998b)
	6.0	IN	Ring-necked parakeets	Dose divided evenly between nares and given slowly, significantly reduced recumbency time after detomidine administration	Vesal & Eskandari (2006)
Yohimbine	0.1–0.2	IV	Psittacines, raptors, waterfowl, ratites	Reversal for xylazine	Carpenter (2000); Heard (1997); Jensen et al. (1992); Keffen (1993); Raath et al. (1992); Samour (2000)
	1.0	IV	Most species, including psittacines, guinea fowl		Teare (1987)

Ketamine/ midazolam	(K)10–40 + (M)0.2–2.0	SC, IM	Most species, including psittacines		Mandelker (1988); Marx & Roston (1996)
	(K)40–50 + (M)3.65	IN	ring-necked parakeets	Dose divided into each nare and given slowly; onset of action <3 minutes, dorsal recumbency for 71 ± 47 minutes, recovery times reduced with flumazenil IN	Vesal & Eskandari (2006)
	(K) 50 + (M) 2.0	(K)IV, (M) IM	White leghorn cockerels	Midazolam administered 5 minutes before ketamine for typhlectomy; hypoxia, hypercapnia, torticollis, dyspnea, salivation noted; prolonged recovery (92–105 minutes)	Maiti et al. (2006)
Ketamine/ xylazine	(K)25 + (X)3.0 + (D)4.0	K, X, D-IM	Roosters	Use with caution: significant decreases in HR, RR, cloacal temperatures and prolonged recoveries (up to 4 hours)	Mostachio et al. (2008)
	(K)15 + (X)2.5 + (M)0.3	K, X, M-IM	Guinea fowl	Midazolam improved anesthetic quality	Ajadi et al. (2009)
Propofol	2.9–4.7 (induction); 0.4–0.55 (mg/kg/min) (maintenance)	IV	Red-tailed hawks and great horned owls	Minimal blood pressure effects, but ventilation was significantly reduced. Prolonged recoveries with moderate-to-severe excitatory CNS signs may occur in these species with an infusion	Hawkins et al. (2003)
	5.0 (induction); 1.0 (mg/kg/min) (maintenance)	IV	Hispaniolan Amazon parrots	Recovery times (15.4 ± 15.2 minutes) were prolonged when compared with isoflurane; 6/10 birds had agitated recoveries. Light anesthetic plane in 8/10 birds	Langlois et al. (2003)
	5.0 (induction); 0.5 (mg/kg/min) (maintenance)	IV	Wild turkeys		Schumacher et al. (1997)
	8–10 (induction); 1–4 as bolus PRM	IV	Mallard ducks, canvasback ducks		Machin & Caulkett (1998a, 1999)
	8.0 (induction); 0.8–0.9 (mg/kg/min) (maintenance)	IV CRI	Mute swans	Smooth inductions, minimal excitation on recovery	Muller et al. (2011)

D, diazepam; ECG, electrocardiogram; HR, Heart rate; IM, intramuscular; IN, intranasal; IO, intraosseous; IV, intravenous; K, ketamine; M, midazolam; PO, Per OS; RR, respiration rate; SC, subcutaneous; X, xylazine.
Note that these are suggested dosages based on published information and the author's clinical experience. Species and individual variation in response to a given drug can be uncertain so the dosage should be adjusted depending on the clinical response of the animal.

bradycardia ensues during severe hypoxia. This hyperventilation, associated with hypoxia, can decrease $PaCO_2$ but birds can tolerate values <10 mmHg because cerebral blood flow is maintained (Bickler 1992). The responses to hypoxia vary between different species, especially in those adapted to high altitude (Lague et al. 2017).

Preoxygenation is performed whenever possible and when hypoxemia may occur (i.e., upper respiratory obstruction, cardiac, pulmonary or air sac disease). It replaces nitrogen in the respiratory system and can produce an oxygen reservoir 4–5 times normal in the air sacs. The benefits are achieved in ≤1 minute of high inspired oxygen concentration in the healthy bird but may take ≥5 minutes in a bird with compromised respiratory function. Preoxygenation is accomplished with an oxygen cage or an induction chamber in the unrestrained bird, or a facemask in the physically restrained bird. Levels rise more slowly in an unprimed oxygen cage or induction chamber than in a tight-fitting facemask with minimal deadspace. If the bird is allowed to breathe room air the parabronchial oxygen levels can fall precipitously if the bird becomes apneic.

Mask or Chamber Induction

Inhalant anesthesia induction is often performed with either a mask or induction chamber. Before using a mask check the bird is able to breath through its nose when its mouth (beak) is closed. Commercially available veterinary inhalant masks can be used for many species. However, differences in beak anatomy and location of nares require unique masks to be formed from syringe cases, plastic soda bottles, or other materials. The mask is as small as possible, and the entire head of the patient is placed inside the mask. To minimize waste gas release, a seal is developed using a disposable latex glove placed over the mask with a central hole cut for the bird's neck. Although some have suggested that this seal can be used for positive pressure ventilation, it is not recommended by these authors. In addition to increased waste gas release, this technique will introduce gas into the gastrointestinal tract.

Facemask induction in some birds (i.e., waterfowl) is associated with apnea and bradycardia that may last for 3–5 minutes (Ludders & Matthews 1996). This response may even occur from placing a facemask snugly onto the face and beak without inhalant anesthetic. This response is a stress response that appears to be mediated by stimulation of trigeminal nerve receptors in the beak and nares of diving ducks (Butler 1988; Jones et al. 1988; Woakes 1988). Premedication with a benzodiazepine may avert this response. If this response occurs, discontinue inhalation anesthesia, remove the mask, and provide 100% oxygen until bradycardia resolves.

Commercially available induction chambers sized for mice up to small dogs can be utilized for birds as small as hummingbirds. The advantages of these appropriately sized chambers are reduced waste gas and shorter induction times. In stressed birds, the chamber is covered with a towel to darken it. Alternatively, an animal carrier or the front of a hospital cage is sealed with a plastic bag and inhalant anesthetic administered for induction of large or stressed patients. Disadvantages of induction chambers include the inability to auscult the patient, gas pollution when the chamber is opened, and trauma due to flapping during the excitement phase of anesthesia. The latter is reduced by padding the induction chamber and minimizing chamber size to reduce movement. Gas flow rates are adjusted to chamber size to provide an optimum rate of rise of the anesthetic concentration. This might be as low as 0.5 L/min for a 1-L chamber up to 15 L/min for a 60-L chamber. The efficiency of the respiratory system makes high inhalant induction concentrations unnecessary, for example isoflurane vaporizer settings rarely need exceed 3%. The bird is promptly removed after the righting reflex is lost. The final phase of the induction is accomplished using a mask to facilitate monitoring.

Vascular Support

During anesthesia or emergencies IV or intraosseous (IO) fluids are used to provide replacement fluids. Sites for IV catheters include the basilic (ulnar), medial metatarsal, or jugular veins (Fig. 15.4). Small bore over-the-needle catheters (≤24 g) are used. If blood is to be repetitively collected from the catheter, it should be placed in either the jugular (small patients) or a large peripheral vessel. The increased fragility of avian blood vessels, the lack of soft tissue support, and patient temperament make catheter maintenance difficult. The catheter site is gently plucked and aseptically prepared. Catheters are secured with a bandage tape butterfly and sutured with an everting mattress pattern. The catheter site is bandaged for additional security. Complications of long-term, indwelling catheterization include infection and possibly fatal hemorrhage. Jugular catheters require 24-hour monitoring because fatal hemorrhage can occur if the bird pulls or chews on the catheter and damages the vessel.

IO catheterization is used in smaller patients or during cardiovascular collapse (Aguilar et al. 1993; Lamberski & Daniel 1992; Ritchie et al. 1990; Valverde et al. 1993). IO catheter maintenance is easier to achieve due to stability in the medullary cavity. Products that can be utilized include 18–24-gauge, 2–5-cm spinal needles or 18–25-gauge, 2-cm hypodermic needles. The length of the catheter should be long enough to extend a third to a quarter of the length of

Figure 15.4 Sites for intravenous (IV) catheters include the ulnar (basilic) vein (a), medial metatarsal vein (b) or jugular vein. Small bore over-the-needle catheters (24 gauge or smaller) are most often necessary for avian patients.

the medullary cavity. A wire stylet may be necessary with hypodermic needles to reduce the potential for a bone core. The sites most often used include the distal ulna and proximal tibiotarsus. Pneumatic bones (i.e., the humerus and femur) are avoided. Feathers are gently plucked and the site surgically prepared. Wearing gloves, the sterile IO catheter is positioned at the center of the cnemial crest of the tibiotarsus or slightly ventral to the dorsal condyle of the distal ulna and parallel to the bone. The bone is held firmly with one hand while the other applies firm pressure combined with slight rotation (Fig. 15.5). Once the cortex is penetrated, the catheter should advance easily with little resistance. If there is further resistance, the opposite cortex has most likely been penetrated. The cannula is flushed with heparinized saline and should flow easily. Fluids will be seen flowing through the basilic vein when the cannula is correctly placed in the distal ulna. The insertion site is covered with antibiotic ointment and the cannula secured with a bandage tape butterfly at the exit point in the skin and sutured. A bandage can be placed over the cannula site for additional security to prevent trauma or damage to the catheter. Although IO catheters are reported to remain patent for 72 hours without flushing (Ritchie et al. 1990), it is recommended that the catheter be gently flushed with heparinized saline twice daily.

Complications associated with IO catheterization include penetration of both cortices, failure to properly enter the medullary cavity, and extravasation of fluids with associated pain. Extravasation has been observed even with proper catheter placement after 1–2 days of use (Steinohrt 1999). IO catheterization is contraindicated in septic patients and those with metabolic bone disease. Osteomyelitis may occur due to duration or placement of the IO catheter (Steinohrt 1999). Administration of alkaline or hypertonic solutions may also contribute to osteomyelitis and will cause pain and transient microscopic changes in the bone marrow (Lamberski & Daniel 1992; Ritchie et al. 1990). These solutions are therefore diluted prior to administration and the catheter is flushed with heparinized saline after any drug injection.

Crystalloid fluids (e.g., 0.9% NaCl [Baxter, Deerfield, IL, USA], lactated Ringer's [Abbott Laboratories, North Chicago, IL, USA}, Normosol-R [CEVA Laboratories, Overland Park, KS, USA], and Plasmalyte-A [Baxter]) are commonly used for IV volume support, maintenance, and rehydration. Fluids are warmed to body temperature (38–39°C) to minimize hypothermia.

Fluid rates of 3–10 mL/kg/h are recommended for healthy anesthetized patients. This rate is based on studies in human patients. While this is a starting point, it is recognized rates in very small patients may need to be considerably higher, but caution should be exercised to not fluid overload small patients. Each patient is assessed individually for their fluid needs. Fluid boluses of 10–20 mL/kg over 5–7 minutes are well tolerated (Abou-Madi & Kollias 1992). For severe hemorrhage whole-blood transfusion (volume for volume) should be provided. If this is not available, it has been recommended to provide crystalloid fluids at three times the volume of blood loss. However, this recommendation is based on mammals

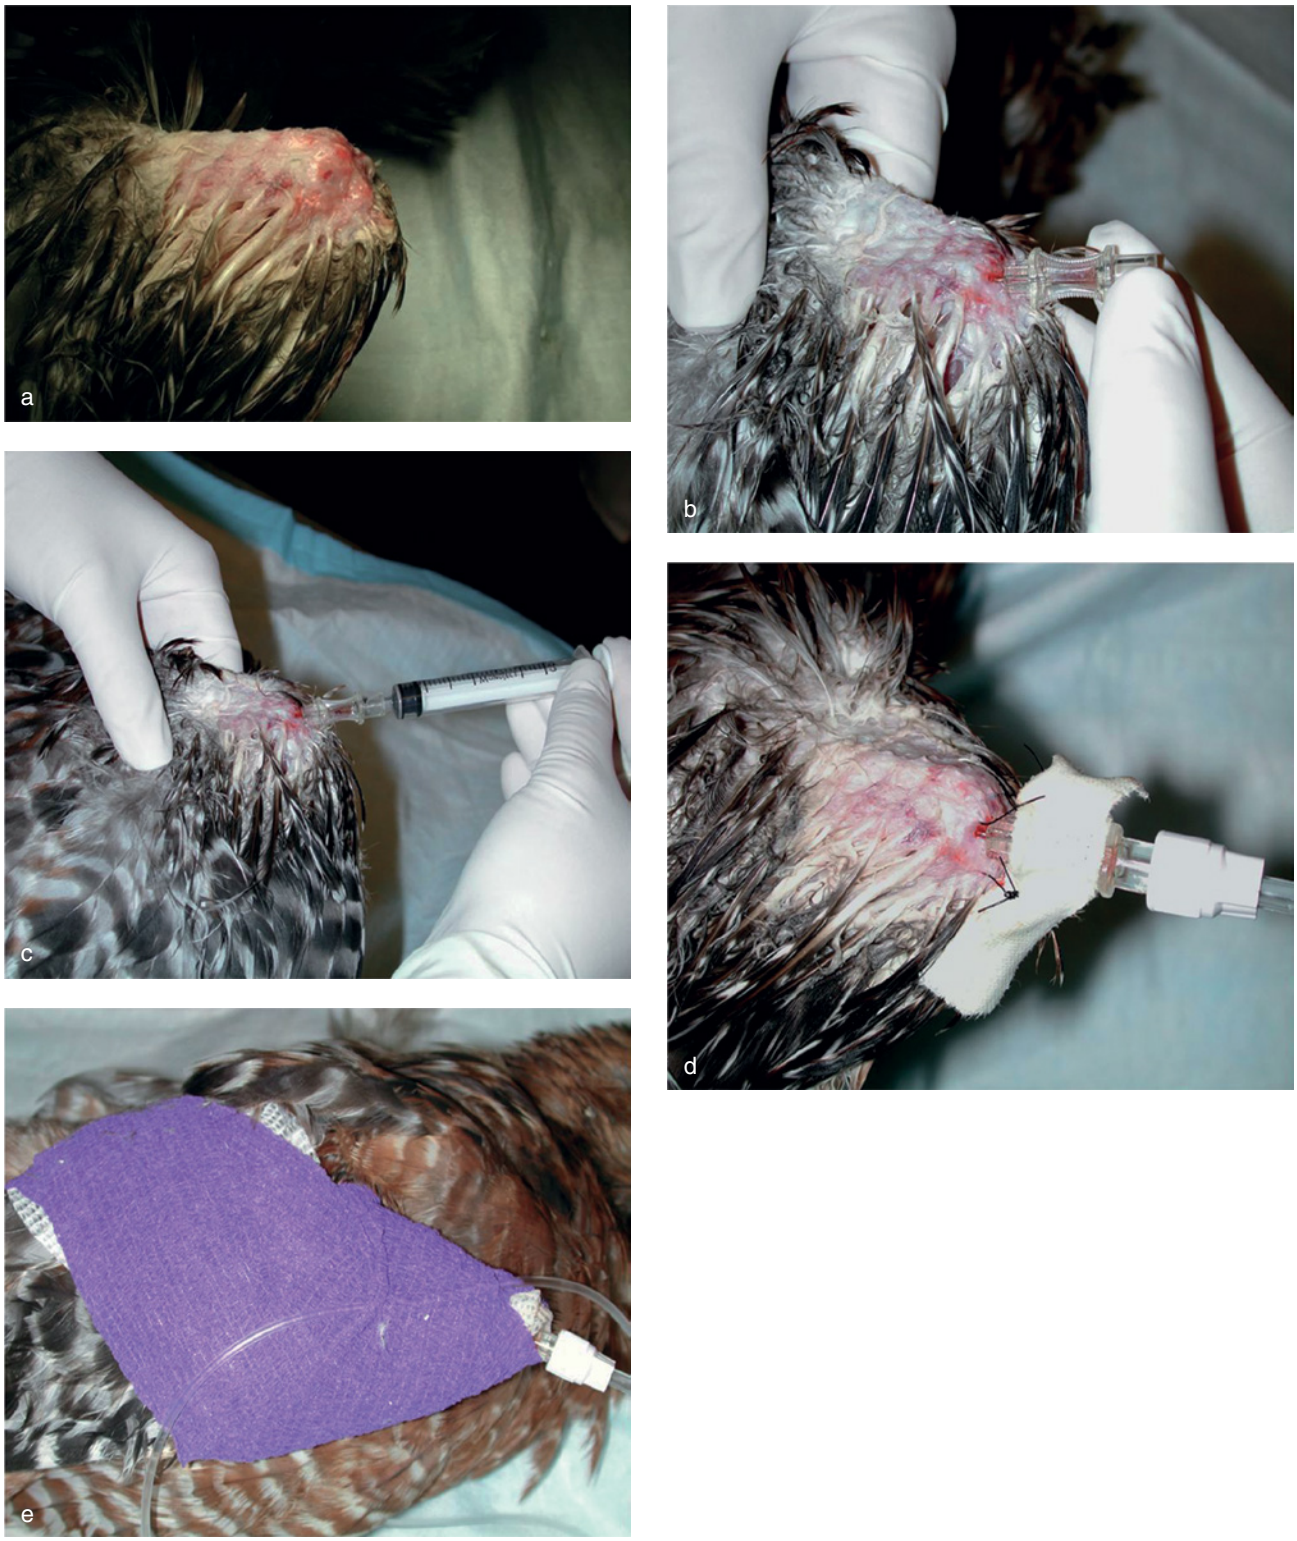

Figure 15.5 Intraosseous (IO) catheter placement in the distal ulna of a bird. Strict asepsis should be observed when placing the catheter. Feathers over the site should be gently plucked and the site should be surgically prepared (a). Wearing sterile gloves, the sterile catheter is positioned slightly ventral to the dorsal condyle of the distal ulna and parallel to the bone (b). The bone is held firmly with one hand while the hand other applies firm pressure combined with slight rotation (c). The cannula should be flushed with heparinized saline and should flow easily (d). The insertion site should be covered with an antibiotic ointment and the cannula should be secured with a bandage tape butterfly at the exit point in the skin and suture (d). A bandage can be placed over the cannula site for additional security and to prevent possible trauma or damage to the catheter (e).

where the interstitial space is twice the vascular volume. In birds, the interstitial space is four times the plasma volume (Skadhauge 1981). Replacement fluid volumes may need to be greater than three times blood loss. Dextrose solutions are added to fluids for treatment of hypoglycemia. Parenteral dextrose use is minimized to prevent compartmental shifts in electrolytes and water leading to hypovolemia (Abou-Madi & Kollias 1992).

Hypertonic fluids (e.g., 7.5% NaCl) are used to expand intravascular volume during resuscitation following acute severe hemorrhage. Hypertonic saline has been evaluated in birds primarily for studying renal sodium excretion and the role of osmotic thirst in the control of normal drinking. In several studies, plasma osmolality increased after bolus infusion (Leary et al. 1998; Yeomans & Savory 1988). The major benefit of hypertonic saline is intravascular volume expansion at a quarter of the volume of isotonic solutions. The mammalian dosage (4 mL/kg) given over 10 minutes is used in birds. However, due to osmotic diuresis and rapid redistribution of sodium cations the intravascular effect is transient (<30 minutes) and additional fluid therapy with a crystalloid or colloid must be used. Hypertonic fluids are contraindicated in dehydration, hypernatremia, and head trauma with intracranial hemorrhage. The sustained use of hypertonic saline is not recommended because hypernatremia and hyperchloremic acidemia, increased bleeding, and exacerbation of underlying cardiac and pulmonary disease due to fluid overload may occur.

Small patient size and species diversity often preclude the use of natural colloids such as homologous or heterologous plasma. The indications for the use of synthetic colloids (e.g., hydroxyethyl starch solutions) are the same as hypertonic saline although the benefits last longer. All are cleared through the kidneys, so they are used with caution in patients with cardiac or renal impairment. They do not provide albumin, thrombocytes, or coagulation factors. Potential adverse effects include anaphylactoid reactions and blood coagulation abnormalities. In critically ill raptors boluses of hetastarch (10–15 mL/kg 6%, every 8 hours) for ≤four treatments) were well tolerated (Stone & Redig 1994). It is suggested that the dose should not exceed ≤20 mL/kg/day.

Reported circulating blood volume percentage based on bodyweight varies considerably (Campbell et al. 1994): 5% in ring-necked pheasants (Campbell et al. 1994), 7.5 ± 1.5% in quail (Takei & Hatakeyma 1987), 16.3–20.3% in the racing pigeon (Campbell et al. 1994), 10.6 ± 2.9% in the galah (Jaensch & Raidal 1998), and 5.4 ± 10.5% and 13.1 ± 2.3% in two strains of chickens (Makinde et al. 1986). Hemorrhage is better tolerated than in mammals. However, when severe (>30% blood volume) or the PCV <20%, whole-blood transfusion is indicated. Heterologous blood cells (e.g., from pigeon or chicken) transfused into parrots last only 12 hours, causing a significant metabolic drain on the recipient as the body utilizes energy to destroy the foreign cells (Finnegan et al. 1997; Sandmeier et al. 1994). The half-lives of homologous and autologous blood transfusions were 8.5 and 9.9 days in conures (*Aratinga* spp.; Degernes & Crosier 1999), 12.5 and 12.2 days in cockatiels (*Nymphicus hollandicus*; Degernes et al. 1999), and 7.1 and 26.8 days in pigeons (Sandmeier et al. 1994), respectively. In pigeons, PCV and total solids were elevated ≥102 hours following homologous transfusion (Finnegan et al. 1997).

The storage of whole blood or blood products has been little studied to date (Morrisey et al. 1997) and transfusions with fresh whole blood are recommended. The anticoagulants citrate phosphate dextrose adenine and acid citrate dextrose are used most at a ratio of 1:9 whole blood:anticoagulant. If given rapidly the citrate can decrease ionized calcium and decrease myocardial contractility. It may be necessary to give calcium gluconate or chloride to the patient to reverse this effect. Donors are screened for infectious diseases. A major/minor crossmatch is performed prior to transfusion. Sixty-six per cent of major crossmatches performed between different species were positive for agglutination or hemolysis whereas between the same species they were all negative (Stauber et al. 1996). Mammalian protocols are presently followed for blood collection and administration. Pediatric blood filters have been evaluated for their ability to cause hemolysis in chicken blood and an 18-μM filter did not cause hemolysis compared to a nonfiltered control (Jankowski & Nevarez 2010).

Standard micro-drip fluid sets used in small animal veterinary practice (60 drops/mL) will not allow appropriate infusion rates in very small patients. Instead, fluid infusion and syringe pumps are used for accurate fluid administration (Fig. 15.6).

Routes of Drug Administration

Drugs can be administered orally in solid or liquid form or even gavaged into the crop. Any drug administered orally in a solid form (tablet or capsule) must be disintegrated and then dissolved before it can be absorbed. Most absorption occurs in the small intestine because of the high surface area and relatively neutral pH. Lipophilic drugs may be able to pass from the intestinal lumen to the blood by simple diffusion but there are enzymes present in the mucosal cells that can metabolize many drugs. These processes and those present in the liver contribute to the first-pass effect where the amount of drug reaching the systemic circulation may be considerably less than the amount absorbed due to intestinal or hepatic breakdown.

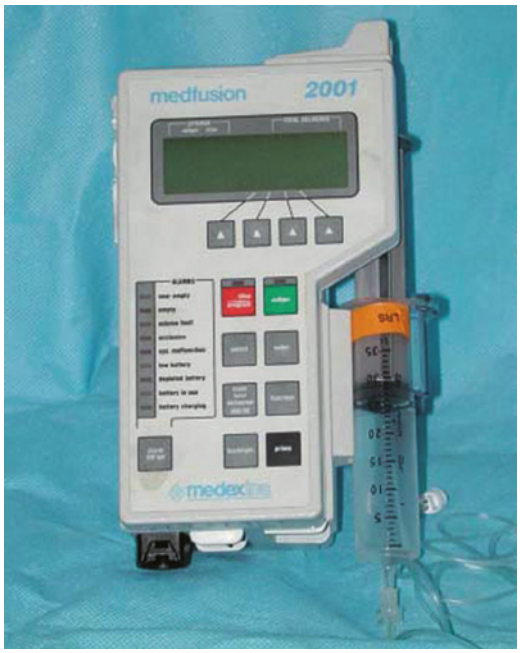

Figure 15.6 To provide accurate infusion rates for small avian patients, fluid infusion pumps and syringe pumps are required.

This can be modified by including another drug that inhibits the specific metabolism of the first drug (e.g., drugs that inhibit cytochrome P450 enzymes). The intestinal mucosa also contains transporters, which can enhance the absorption of a drug, as well as proteins that will eject drugs from the cell back into the lumen. The transporter processes may be saturable such that they limit the uptake of the drug beyond a certain dose and the ejector systems may be overwhelmed by excess drug so that it gets absorbed when it would normally be removed. Inflammatory processes may alter the oral absorption of drugs by damaging the normal barriers. In general, drugs administered orally will take longer to reach peak effect and the dose may need to be altered to account for the bioavailability of that drug.

Oral transmucosal administration is difficult in most birds because it is much more likely that the bird will swallow the drug before it is taken up through the mucosa. However, a study evaluating the oral transmucosal use of pentobarbital for euthanasia in wild birds showed uptake is quite successful (Gardhouse et al. 2021).

Bird skin is much thinner than the skin in mammals and there is often less of a subdermal layer. The most common SC injection site used in birds is in the inguinal area, where there is more redundant skin than elsewhere on the avian body. Do not attempt to use the patagium as a SC site in a flighted bird as this can lead to inflammation and potential contracture of the patagium. There is little redundant skin dorsally and there are anecdotal reports of the needle being advanced too far and intra-spinal cord or pulmonary injection occurring instead. The uptake of a drug from SC administration will depend on its lipid solubility, the osmolality of the solution, and its effects on circulation. A drug like buprenorphine, which is highly lipid soluble, may be absorbed into the SC fat and not be taken up very rapidly. This can be used to advantage to provide a prolonged uptake with buprenorphine when injected subcutaneously in a concentrated form (Simbadol). Diazepam is dissolved in propylene glycol and the solution has a very high osmolality (>9000 mosm/L), making absorption less likely because the solution tends to attract water from the body. Alpha-2 agonists are vasoconstrictors and so SC injection of these drugs reduces uptake by decreasing the blood supply to that area.

Intramuscular (IM) injection tends to provide a more rapid onset than SC because of the greater blood supply, but the same limitations apply regarding osmolality (see above). The most common site used in most birds is the pectoral muscles, but these muscles are much smaller in flightless birds and so care must be taken not to penetrate down to the keel. There is a vascular sinus close to the keel, making it good practice to always inject in the center of the muscle and aspirate before injecting a drug to avoid intravascular injection. The thigh muscles are used in larger birds but concerns have been raised that drugs entering the circulation from this area could be removed by the renal portal system. To date none of the studies that have examined this have shown altered pharmacokinetics compared with pectoral muscle injections (Carvalho et al. 2007).

IO access is used in small birds where IV injections are difficult. Drugs injected by this route will enter the circulation as if they had been injected IV although the onset may be slightly slower (Bakhshi et al. 2019; Valverde et al. 1993). Drugs should not be highly acidic or alkaline because they might damage the bone marrow. This route has been used to maintain anesthesia with propofol (Guimarães et al. 2006).

IV injection is more difficult in birds because the vessels are often very small and it can be difficult to restrain a bird safely and effectively for IV injection. The median ulnar vein (where it crosses the radius and ulna) and the median metatarsal vein are used for injection most commonly during anesthetic events.

Intranasal (IN) administration has been used extensively with the expectation that there will be transmucosal absorption and even transfer into the brain through the cribriform plate. This has been effective with several sedatives and anesthetics, but it is essential that the volume of drug is limited in order not to drown the bird. Drugs that are very acidic (e.g., ketamine) may be quite painful if administered by this route.

To the authors' knowledge, there have not been any studies reporting intracloacal uptake of sedative, analgesic, or anesthetic drugs in birds. Several poultry vaccines have been effectively absorbed via this method (Abaza et al. 2020) whereas poor intracloacal uptake was shown for some anesthetic and sedative drugs in chelonians (Scarabelli & Di Girolamo 2022).

Intraperitoneal (IP) injection has been used in birds in a laboratory setting for several agents. The uptake of drugs from this site can be quite rapid but it is a risky method of administration because of the abdominal air sacs. It is essential when using this method to aspirate before injection to ensure that neither air nor blood are withdrawn.

Preanesthetics

Parasympatholytics

Several authors question the necessity of routine premedication with parasympatholytics in birds. Atropine and glycopyrrolate reduce mucus production and plug formation, but increase viscosity (Ludders & Matthews 1996). Additionally, some practitioners avoid using anticholinergics in birds because they increase heart rate, cardiac work, and myocardial oxygen demand. Therefore, the use of these agents should be weighed against their potential adverse effects as premedications.

Sedatives and Tranquilizers

Sedatives and tranquilizers are used to decrease anxiety and fear during induction, but most tranquilizers lack analgesia. Additionally, most require injection and the handling and restraint may be as much as required for anesthetic induction. The merits of premedication must be weighed against this additional stress in birds.

Benzodiazepines

Diazepam may cause excitement, tachycardia, and tachypnea in birds if given intravenously. Uptake of diazepam from IM or SC injection is erratic but effective by the IN route (Bigham & Zamani Moghaddam 2013; Sadegh 2013; Vesal & Zare 2006). Midazolam (0.2–2.0 mg/kg IM) has been used as a sole sedative for minor, nonpainful procedures (i.e., radiographs) (Valverde et al. 1990). Low doses in this range are most often used for preanesthetic sedation. In pigeons, very high doses of midazolam (14–16 mg/kg IM) induced profound sedation and reduced isoflurane minimum anesthetic concentration (MAC) by approximately a third (Smith et al. 1993; Smith & Muir 1992). IN midazolam (5 mg/kg) caused sedation but not loss of righting reflex (Hornak et al. 2015). The MAC of isoflurane was decreased by 19% and 28% by IM midazolam at 1 and 2 mg/kg, respectively, in Quaker parrots (Zaheer et al. 2020). In quail midazolam (2–6 mg/kg IM) produced chemical restraint and 40–60 minutes of sedation at higher doses (Day & Roge 1996). Sedation with midazolam shortly after capture increased the postsurgical survival of female surf scoters (*Melanitta perspicillata*) surgically implanted with intracoelomic transmitters (Net et al. 2019). A study of 17 psitaccids showed that the combination of midazolam (0.5 mg/kg) and butorphanol (1 mg/kg) decreased the time to intubation with isoflurane, improved the quality of induction, and decreased the required concentration of isoflurane during the procedure by about 30% (Kubiak et al. 2016). In cockatiels midazolam at 3 mg/kg with or without butorphanol induced sedation and the combination was more effective than midazolam alone (Doss et al. 2018).

IN administration of midazolam (0.5 mg/kg) has been used by clinicians to facilitate physical examination, beak trimming, and sample collection in many birds. In ring-necked parakeets (*Psittacus krameri*) midazolam administered intranasally alone or in combination with ketamine produced sedation that allowed dorsal recumbency and adequate sedation for minor procedures (Vesal & Eskandari 2006). In blue-fronted and orange-winged Amazon parrots, IN midazolam (2 mg/kg) resulted in rapid onset (5 minutes) and about 25 minutes of sedation in most birds, but three out of 10 blue-fronted parrots had no sedation (Schaffer et al. 2017). Another group using the same dose of midazolam intranasally in Hispaniolan Amazon parrots found that birds were easier to capture and handle (Mans et al. 2012). In budgerigars (13.2 mg/kg) and finches (13 mg/kg), IN midazolam induced a rapid loss of righting reflex (1–1.3 minutes) and sedation lasting 30–60 minutes (Bigham & Zamani Moghaddam 2013; Sadegh 2013). Sedation duration is significantly reduced after IN flumazenil administration (Mans et al. 2012). The authors recommend titrating the dose to avoid the reversal of the beneficial anxiolysis, sedation, and muscle relaxation.

Midazolam IM did not produce major alterations in cardiopulmonary function in Canada geese (Valverde et al. 1990), quail (Day & Roge 1996), and racing pigeons (Smith et al. 1993; Smith & Muir 1992). Midazolam/ketamine IV produced anesthesia with full recovery in 23 minutes (Machin & Caulkett 1998b). Midazolam reduced mean corticosterone and median lactate concentrations in spectacled eiders (*Somateria fischeri*) by approximately 30%, but blood pH was reduced, likely resulting from sedative-induced respiratory depression. This was easily treated with intubation, mechanical ventilation, and administration of flumazenil. This drug

has been associated with decreased gastrointestinal transit times in cockatiels at 6 mg/kg (Martel et al. 2018), which could result in regurgitation. In pigeons a concentrated formulation of midazolam (50 mg/mL; Zoo-Pharm,Inc. Windsor, CO, USA) resulted in substantially less injection volume when compared with the standard midazolam concentration for IM injection and exhibited the same efficacy, but the study did not evaluate adverse effects such as muscle bruising after injection (Martel et al. 2021).

Alpha-2 Adrenergic Agonists

Xylazine and medetomidine are the most reported alpha-2 adrenergic agonists in birds. However, as the use of dexmedetomidine supplants that of medetomidine, more information on the use of this agent will become available. This drug is the dextro-enantiomer of medetomidine and has twice the potency of the racemic mixture, medetomidine, since levomedetomidine has no action at alpha-2 receptors. To aid dosing for practitioners, dexmedetomidine (0.5 mg/mL) is supplied at half the concentration of medetomidine (1.0 mg/mL) and dosing charts are available for dogs and cats. One study has examined the use of dexmedetomidine in two raptor species at a dose of approximately 25 μg/kg for common buzzards (*Buteo buteo*) and 75 μg/kg for common kestrels (*Falcon tinnunculs*) (Santangelo et al. 2009). The authors noted loss of righting in both species within approximately 8 minutes and sedation was sufficient to allow handling. In the study above, atipamezole was used for reversal at a total dose of 250 μg and provided rapid reversal of sedation. It should be noted atropine was administered in conjunction with dexmedetomidine in this study, which has been reported to cause increases in mean arterial blood pressure, heart rate, and the occurrence of cardiac arrhythmias in dogs and is not recommended for coadministration with dexmedetomidine (Congdon et al. 2011). In pigeons a combination of midazolam (5 mg/kg) and dexmedetomidine (80 μg/kg) administered intranasally produced more profound sedation than midazolam alone but this was accompanied by bradycardia and a decrease in respiratory rate and body temperature (Hornak et al. 2015).

The major advantage of these agents is they can be reversed with atipamezole, yohimbine or tolazoline. Alpha-2 adrenergic agonists can have profound cardiopulmonary effects including respiratory depression, second-degree heart block, bradyarrhythmias, and increased sensitivity to catecholamine-induced cardiac arrhythmias (Altman 1980; Ludders 2001; Ludders & Matthews 1996; Machin & Caulkett 1998a; Maiti et al. 2006; Varner et al. 2004). When used alone at high doses, xylazine is associated with respiratory depression, excitement, and seizure-activity (Ludders 2001; Ludders & Matthews 1996; Machin & Caulkett 1998a; Varner et al. 2004) and is not recommended for sedation. In Pekin ducks xylazine produced significant respiratory depression resulting in hypoxemia and hypercapnia and behavioral changes (i.e., moving, paddling, and picking at their enclosures) that lasted ≤ 45 minutes (Ludders et al. 1989). In mallard ducks xylazine/ketamine/midazolam IV resulted in cyanotic membranes and apnea in three; two died and the surviving animal was reversed with atipamezole (Machin & Caulkett 1998b). Xylazine (10 mg/kg) in rock partridges produced profound sedation only 2–5 minutes post administration and marked hypoventilation, but did not produce a significant decrease in heart rate (Uzun et al. 2006). In roosters undergoing typhlectomy, xylazine (3 mg/kg) induced a loss of righting response in 3–4 minutes. When diazepam (4 mg/kg) and ketamine (25 mg/kg) were given subsequently, significant decreases in heart rate, respiratory rate, and cloacal temperature were observed. A lack of response to painful stimulus was maintained for approximately 1 hour (Mostachio et al. 2008). Xylazine was also evaluated in guinea fowl in combination with ketamine. The addition of midazolam to the combination appeared to improve the duration and quality of analgesic effect (Ajadi et al. 2009).

Much higher dosages of medetomidine appear to be required compared with mammals. In pigeons and yellow-crowned Amazon parrots, medetomidine (2 mg/kg IM) alone did not induce reliable sedation (Sandmeier 2000). Similarly, in pigeons medetomidine (0.2 mg/kg) alone produced only moderate sedation, but significant bradycardia and bradypnea (Pollock et al. 2001). Also in pigeons, a medetomidine (0.2 mg/kg), butorphanol, and ketamine combination produced profound sedation. However, significant bradycardia, bradypnea, and hypothermia were observed (Atalan et al. 2002). Arrhythmias in three out of eight pigeons resolved after atipamezole reversal.

In mallard ducks medetomidine/midazolam/ketamine provided anesthesia and analgesia for 30 minutes' duration when given IV, but not IM (Machin & Caulkett 1998b). Also in ducks, medetomidine/midazolam/ketamine IV produced respiratory depression, apnea, and acidemia; one of 12 died and three required assisted ventilation (Machin & Caulkett 1998a). Very high medetomidine dosages (≤10 mg/kg) in mallard ducks did not increase sedation over 0.2 mg/kg (Machin & Caulkett 1998b). One clinician reported seizures in canvasback ducks with medetomidine IV (N. Caulkett, pers. comm.).

Since medetomidine appears to require combination with other injectable drugs for reliable effect, the advantages of rapid and smooth reversal with atipamezole are negated. Although the mammalian dosage of atipamezole

(five times the medetomidine dose) has been shown to exhibit excellent reversal in some birds (Machin & Caulkett 1998a), a lower ratio (2.5 times) also produces effective reversal (Machin & Caulkett 1998b; Sandmeier 2000). Based on the many adverse effects and disadvantages reported for this class of drugs in birds, it is recommended they be used with great caution. It should also be noted that the doses provided in this chapter for medetomidine can be used at half the value if using dexmedetomidine. A potentially revolutionary peripheral alpha-2 antagonist, vatinoxan, has been studied recently in several mammal species that can reverse the peripheral cardiovascular effects without changing the central sedation (Einwaller et al. 2020; Honkavaara et al. 2020; Pypendop et al. 2019). With the advent of this new peripheral alpha-2 antagonist, new studies in birds using this antagonist directly with dexmedetomidine should be evaluated.

Injectable Anesthetics

There are several situations in which injectable anesthetics are preferable to inhalants. Surgeries involving the beak, mouth, glottis, or trachea are complicated by the presence of an endotracheal tube. Surgery within the coelomic cavity, respiratory system, or pneumatic bones exposes personnel to high levels of inhalant anesthetics. Injectable anesthetics are almost always associated with longer recoveries than inhalants (Mehmannavaz et al. 2015). Also, if it is possible, the injectable drug should be discontinued and replaced with an inhalant as soon as the procedure will allow. Injectable anesthetics are more commonly used in the field due to the ease of transport compared to inhalant anesthetic delivery equipment.

Many injectable drugs are highly variable in their effects between species and individuals (Machin & Caulkett 1998b; Samour et al. 1984). Some of these effects may include poor induction, inadequate muscle relaxation, cardiopulmonary depression, and prolonged or violent recoveries (Langlois et al. 2003; Ludders & Matthews 1996; Samour et al. 1984). Different delivery routes also affect efficacy and dosage. For example, in mallard ducks IM administration of many anesthetics is not effective, suggesting poor drug uptake from the pectoral musculature. Also, no effect was identified when evaluating many drugs given intranasally to mallard ducks (Machin & Caulkett 1998b). Elimination of injectable anesthetics depends on drug distribution, and hepatic and/or renal biotransformation and excretion (Paul-Murphy & Fialkowski 2001). Due to the potential for side effects, patients must be weighed accurately and monitored closely.

Dissociative Anesthetics

Ketamine alone is not recommended due to poor muscle relaxation, myoclonic contractions, opisthotonos, and violent recoveries. It is usually combined with an alpha-2 adrenergic agonist or benzodiazepine or both to improve relaxation and anesthetic depth (Muir 1988). Ketamine may produce convulsions, excitation, and salivation in vultures, but these signs are rarely observed in other species (Muir 1988; Salerno & van Tienhoven 1976). Ketamine/alpha-2 adrenergic and ketamine/benzodiazepine combinations are used for short procedures (i.e., physical examination, minimally painful diagnostics) or induction as part of balanced anesthesia (Boever & Wright 1975; Borzio 1973; Kolias & McLeish 1978a; Ludders, Rode, Mitchell, et al. 1989; Machin & Caulkett 1998b; McGrath et al. 1984; Raffe et al. 1993; Redig & Duke 1976; Vesal & Eskandari 2006).

IM administration of ketamine induces immobilization within 5–10 minutes and lasts for 5–20 minutes, with recovery in 40–100 minutes. These times are dependent on size, dose given, body temperature, and health status (Paul-Murphy & Fialkowski 2001). In mallard ducks midazolam/ketamine IV produced anesthesia with recovery in 23 minutes (Machin & Caulkett 1998b). In another group of ducks ketamine/xylazine (15/5 mg/kg) was compared with ketamine/xylazine/diazepam (KXD; 15/2.5/2.5 mg/kg) administered intramuscularly and the KXD combination produced a more rapid onset and a longer duration of effect (Ahmad et al. 2018). In chickens ketamine (120 mg/kg IM) produced no significant change in respiratory rate, but did induce bradycardia (Salerno & van Tienhoven 1976). As noted above, ketamine (15 mg/kg IM) in combination with xylazine (2.5 mg/kg IM) produced lateral recumbency in 3 minutes that lasted approximately 56 minutes in guinea fowl. The duration of recumbency was significantly longer (91 minutes) with the addition of midazolam (0.3 mg/kg IM) (Ajadi et al. 2009). In ring-necked pheasants a pilot study was used to define doses needed for about 30 minutes of anesthesia. The researchers used 200 μg/kg medetomidine or 3 mg/kg xylazine followed by 80 mg/kg ketamine, 5 minutes later, administered IM (Kaya et al. 2019). The administration of medetomidine was associated with a significant increase in respiratory rate and seven out of 15 birds became apneic following the ketamine injection.

In red-tailed hawks (*Buteo jamaicensis*), ketamine (30 mg/kg IM) produced no significant effect, compared to awake birds, in arterial blood gas or acid-base values, but did produce mild hyperventilation (Kollias & McLeish 1978a). A combination of ketamine (30 mg/kg), xylazine (1 mg/kg), and midazolam (0.2 mg/kg) produced adequate

chemical restraint in eagles (Sadegh et al. 2011). The effects of IO versus IM administration of ketamine were compared in domestic pigeons and both the onset of anesthesia and recovery times were found to be shorter with IO administration. Heart rate decreased significantly in both groups (Kamiloglu et al. 2008).

Propofol

Propofol produces a rapid and smooth anesthetic induction but must be administered intravenously. Because propofol takes about 2 minutes to reach peak effect, the authors suggest a calculated propofol dose be given in quarter increments each administered over 30–60 seconds. This will allow more accurate dosing and minimize apnea and hypotension. In pigeons (Fitzgerald & Cooper 1990) and chickens (Lukasik et al. 1997) propofol had a very narrow margin of safety and respiratory depression. However, at much lower dosages in turkeys (Schumacher et al. 1997) and mallard ducks (Machin & Caulkett 1998a,b) propofol is effective and safe if cardiopulmonary function is monitored and ventilatory support provided. Respiratory depression and significant apnea are common (Hawkins et al. 2003; Langan et al. 2000; Langlois et al. 2003; Machin & Caulkett 2000). In mute swans, propofol provided as a constant rate infusion (CRI) was compared to multiple boluses for short procedures. The overall dose provided by boluses was lower, but the anesthesia was less predictable and the birds were prone to sudden awakening. On recovery, about 50% of the birds in both groups demonstrated a few minutes of excitement. Notably, these birds were maintained on room air, but did not experience a significant change in oxygen saturation (Muller et al. 2011). However, ventilatory support is recommended for any bird anesthetized with propofol, regardless of whether bolus or CRI techniques are utilized. Prolonged recovery, with or without moderate-to-severe central nervous system excitatory signs, has been reported particularly after the use of a CRI (Hawkins et al. 2003; Langan et al. 2000; Langlois et al. 2003). However, one study evaluating its use in the field showed smoother recoveries than with isoflurane anesthesia (Machin & Caulkett 2000). The need for ventilatory support and the potential for excitatory and/or prolonged recoveries limit its use as a sole anesthetic. However, it has been proposed that balanced anesthesia may produce propofol-sparing effects that may reduce these disadvantages (Langlois et al. 2003). In a study in chickens a CRI of propofol was used for an ulnar osteotomy and pinning. Propofol alone was compared with the addition of methadone (6 mg/kg), nalbuphine (12.5 mg/kg), and fentanyl (30 μg/kg loading dose + 0.5 μg/kg/min). The methadone and the nalbuphine resulted in lower infusion rates of propofol (~20% reduction) but the fentanyl did not. The authors did not show that these opioid doses were equivalent. The birds breathed spontaneously and maintained end-tidal CO_2 in the 55–65 mmHg range and recovery to standing was not different between the groups (45–50 minutes) (Santos et al. 2020).

Alfaxalone$_2$

Alfaxalone is a neurosteroid anesthetic that was first developed in the 1970s. At that time, it was licensed for use in animals as a mixture of alfaxalone and alphadolone, mixed in a castor oil base (Saffan®). The latter tended to cause histamine release in many species so the drug was withdrawn from the market. More recently alfaxalone has been dissolved in a cyclodextrin and this base has had very few adverse reactions reported (Alfaxan®). One of the major advantages of alfaxalone over propofol is that it can be administered intramuscularly or even subcutaneously and still have an effect. When administered to mallard ducks IM the bioavailability was 100% and the elimination half-life was around 15 minutes (Kruse et al. 2019). Alfaxalone is a cardiopulmonary depressant but at doses needed for sedation and anesthesia there appears to be minimal depression (Romano et al. 2020). Some investigators have reported transient decreases in heart rate and apnea with higher doses (Baldrey et al. 2014; Balko et al. 2017; Escalante et al. 2018; Romano et al. 2020). Reported doses for small birds (e.g. budgerigars, finches, quaker parrots) are in the range of 20–30 mg/kg, with 10 mg/kg for pigeons, and 2 mg/kg for flamingos (Perrin et al. 2017; Romano et al. 2020; Susanti et al. 2019; Villaverde-Morcillo et al. 2014). The speed of induction and the degree of relaxation have been improved by the addition of other drugs such as midazolam or butorphanol (Perrin et al. 2017). Alfaxalone has been associated with rough recoveries in dogs and cats, and some hyperexcitation during recovery has been reported in birds (Villaverde-Morcillo et al. 2014).

Inhalant Anesthetics

Inhalant anesthetics offer rapid induction and recovery, the ability to rapidly change anesthetic depth, and their use does not require an accurate body weight. Very little of the agent is metabolized, reducing the impact on hepatic and renal function, and recovery is independent of either. Disadvantages include pollution of the work environment and the expense of the anesthetic and associated equipment.

Endogenous catecholamines are released during stress and pain. They can have a significant impact during anesthesia because some inhalant anesthetics sensitize the

myocardium to catecholamine-induced arrhythmias (Aguilar et al. 1995; Greenlees et al. 1990; Joyner et al. 2008; Ludders & Matthews 1996). Clinical observations suggest manipulation of fractured bones, especially the pectoral girdle, causes significant bradycardia and arrhythmias in some patients. However, it is unknown whether this is a vagotonic or baroreceptor effect. Hypercapnia, hypoxemia, and some anesthetics can depress cardiovascular function.

The MAC necessary to prevent purposeful movement in response to a noxious stimulus in 50% of avian patients is used as a measure of inhalant anesthetic potency. MAC for many species is very similar; most birds require approximately the same concentration of inhaled anesthetic for an equivalent amount of stimulation as mammals.

Isoflurane

Isoflurane causes less cardiovascular depression than halothane (Jaensch et al. 1999; Ludders 1992; Ludders et al. 1990; Miller 2005). In mammals, it produces peripheral vasodilation and negative inotropic effects, possibly explaining the dose-dependent hypotension it induces in birds (Goelz et al. 1990; Greenlees et al. 1990; Ludders et al. 1990; Ludders, Rode, & Mitchell, 1989). When isoflurane was compared to sevoflurane and desflurane in red-tailed hawks, isoflurane caused a lower respiratory rate than desflurane. However, $PETCO_2$ did not change and the difference in respiratory rate is unlikely to be clinically significant (Granone et al. 2012). The MAC is 1.32% in chickens, 1.30% in Peking ducks, and 1.34% in sandhill cranes (Ludders et al. 1990; Ludders, Rode, & Mitchell, 1989; Miller 2005). The isoflurane concentration required to produce apnea in ducks was 1.65 × MAC and in cranes was 2 × MAC (Ludders et al. 1990; Ludders, Rode, & Mitchell, 1989). These values are less than those in dogs, cats, and horses (Miller 2005). If surgical anesthesia is achieved in 95% of patients at 1.3 × MAC, isoflurane anesthesia has a low safety margin for apnea.

In addition to cardiopulmonary depression, inhalant anesthetics may cause cardiac arrhythmias. Cardiac arrhythmias have been noted in 35–75% of bald eagles (*Haliaeetus leucocephalus*) anesthetized with isoflurane (Aguilar et al. 1995; Joyner et al. 2008). In both of those studies, second-degree heart block was the most prevalent arrhythmia. In one study, it occurred during induction and recovery in 80% of the cases (Aguilar et al. 1995). Catecholamine release was suspected to be the cause. Cardiac arrhythmias are also commonly detected in other species (Aguilar et al. 1995; Goelz et al. 1990; Korbel et al. 1996), but in the authors' experience arrhythmias are most common in raptors. Cardiac stability is a perceived advantage of isoflurane anesthesia in birds compared with halothane. However, where an electrical fibrillation model was used to investigate myocardial irritant effects of isoflurane and halothane, the former had a lower threshold for electrical fibrillation than halothane (Greenlees et al. 1990). Clinically, arrhythmias appear to be uncommon, but do occasionally occur and warrant vigilant monitoring.

Sevoflurane

Sevoflurane is potentially more useful than isoflurane due to an even lower solubility than isoflurane or halothane. Low solubility allows for faster induction and recovery, as well as more rapid changes in anesthetic depth (Miller 2005; Thurmon et al. 1996). In pigeons, induction and recovery times were more rapid than with isoflurane (Korbel 1998b). This trend was also noted in bald eagles, with faster recovery times compared to isoflurane. A similar number of arrhythmias were noted with each agent (Joyner et al. 2008). In red-tailed hawks, only the time to visual tracking was faster with sevoflurane (and desflurane) compared to isoflurane. Induction time and time to extubation did not vary significantly. All recoveries were noted to be excellent or good (Granone et al. 2012). Sevoflurane administered at 3.5% provided adequate anesthetic plane in crested caracaras (*Caracara plancus*) with significant decreases in respiration rate, arterial blood pressure, cloacal temperature, and blood pH (Escobar et al. 2009). Time to induction and time to recovery were not recorded. Additionally, in several psittacine species recovery times (time to extubation, sternal, and standing) were not significantly different between the two agents, but the birds subjectively appeared less ataxic (Quandt & Greenacre 1999). The time to intubation was longer with sevoflurane (≥4.4 minutes) than isoflurane. However, this was attributed to administration of sevoflurane below the suspected MAC in birds. In Hispaniolan Amazon parrots the time to intubation (38 ± 2 seconds) was rapid with sevoflurane, which was attributed to the higher concentration used during induction. The time to extubation was also rapid (2.3 ± 0.4 minutes) (Klaphake et al. 2006).

In chickens, the MAC of sevoflurane was found to be 2.21% ± 0.32%, which is within the mammalian range (Naganobu et al. 2000), 3.0 ± 0.6% in pigeons, 3.44 ± 0.25% in Amazon parrots, 2.03 ± 0.32% in crested serpent eagles, and 2.9 ± 0.1% in guineafowl (Botman et al. 2016; Chan et al. 2013; Escobar et al. 2012). At this concentration, heart rate did not change significantly and cardiac arrhythmias were not observed up to 2 × MAC (Naganobu et al. 2000). In another study in chickens, hypotension was observed during both spontaneous and controlled ventilation; dose-dependent hypotension was observed only during controlled ventilation (Naganobu et al. 2003). Tachycardia occurred during spontaneous ventilation while the heart

rate remained unchanged during controlled ventilation. However, in Hispaniolan Amazon parrots, bradycardia was observed after 25 minutes using controlled ventilation (Klaphake et al. 2006). Increases in $PaCO_2$ (≤86 mmHg) occurred with increased sevoflurane concentration during spontaneous ventilation. Hypercapnia-induced increases in sympathetic tone were suggested to account for the maintenance of the arterial blood pressures and heart rate in the spontaneously ventilated birds (Naganobu et al. 2003). In both chickens and Hispaniolan Amazon parrots, a significant bradypnea was observed (Klaphake et al. 2006; Naganobu et al. 2003).

Sevoflurane has a less irritating smell than other inhalants. In human pediatric patients it is routinely used for mask induction to prevent struggling due to smell. While the agent cost is higher than isoflurane, many practitioners use sevoflurane for induction then switch to the more cost-effective isoflurane for maintenance.

Anesthetic Adjuncts

In other domestic animals, infusions of other drugs may be used to decrease the dose of inhalant with the expectation of decreasing the cardiovascular and/or respiratory effects of the inhalants. These drugs are often not anesthetics so they have been called adjuncts to anesthesia. Partial IV anesthesia is also used to describe this approach. Opioids, alpha-2 agonists, ketamine, and lidocaine have been investigated in a number of mammals but to date the only studies in birds have involved fentanyl infusions. In red-tailed hawks and Hispaniolan Amazon parrots target concentrations of 8, 16, and 32 ng/mL resulted in similar reductions in the MAC of isoflurane (30–55%) (Pascoe et al. 2018). Based on the data from these studies, a fentanyl infusion rate of 0.3–0.4 μg/kg/min would be required in red-tailed hawks and 5–6 μg/kg/min in Hispaniolan Amazon parrots to achieve about a 50% reduction in MAC. In the red-tailed hawk there was minimal effect on the measured cardiovascular variables (HR, BP) but fentanyl was associated with a decreased HR and BP in Hispaniolan Amazon parrots (Pascoe et al. 2018). The effectiveness of such anesthetic adjuncts needs further evaluation in birds.

Local Anesthesia

There are few studies evaluating local anesthetics in birds. In chickens, successful brachial plexus nerve blocks using lidocaine 2% or levobupivacaine were observed for 30–60 minutes in most birds evaluated (D/Otaviano de Castro Vilan et al. 2006). Another investigator compared local blocks using lidocaine and bupivacaine in chickens and noted a longer duration of sensory blockade in the chickens treated with bupivacaine, but this difference was not statistically significant due to a large amount of variation (Figueiredo et al. 2008). Brachial plexus blocks using ropivacaine (7.5 mg/kg) provided sensory and motor blockade for approximately 2 hours (Cardozo et al. 2009). However, attempts to perform brachial plexus block in mallard ducks with lidocaine and bupivacaine resulted in no consistent alteration in compound nerve action potentials or sensory nerve conduction velocities, suggesting ineffective nerve blockade (Brenner et al. 2010).

Historically it has been stated in the literature that birds may be more sensitive to the toxic effects of local anesthetics than mammals. Toxic effects of lidocaine were reported in birds at lower total doses (2.7–3.3 mg/kg) than in dogs (Hocking et al. 1997), but the authors could not obtain the original work showing this specific range. More recent studies suggest higher doses before toxicity occurs: an effective dose 50 (ED_{50}) of about 6.3 mg/kg was recorded for the onset of a 30% reduction in HR or BP and a massive 29 mg/kg for respiratory arrest in chickens (Brandao et al. 2015; Imani et al. 2013). In a similar study with bupivacaine in chickens the ED_{50} was around 2 mg/kg IV (Imani et al. 2013). Toxic effects are like those reported in mammals and respiratory arrest, seizures, and cardiac arrest have been reported with higher dosages in birds (Ludders 1994). Other adverse effects include depression, drowsiness, muscle tremors, vomiting, hypotension, and arrhythmias as well as CNS signs such as ataxia and nystagmus.

Appropriate lidocaine dosing is difficult in the small avian patient, but toxicity can be prevented by using appropriate concentrations and volumes. This often requires the commercial lidocaine solution (2%, 20 mg/mL) be diluted 1:10 (Ludders 1994). It is unknown whether this dilution allows either appropriate tissue drug levels for analgesia or the expected duration of analgesia to occur (Farley et al. 1994).

Bupivacaine is used conservatively due to concerns that its toxic effects may take longer to resolve. In mammals the maximum recommended dosage of bupivacaine is 2 mg/kg. In mallard ducks (*Anas platyrhynchos*) bupivacaine (2 mg/kg SC) was shorter acting than in mammals (Machin & A., 2001) and showed a faster absorption versus elimination rate. In addition, sequestration and redistribution suggested by increases in plasma concentrations at 6 and 12 hours may delay toxicity. A 1:1 mixture of bupivacaine and dimethyl sulfoxide applied to amputated chicken beaks immediately

after amputation improved feed intake (Glatz et al. 1992). Intra-articular bupivacaine (3 mg in 0.3 mL of saline), was effective for treating arthritic pain in 1.5-kg chickens (Hocking et al. 1997).

EMLA is an acronym for "eutectic mixture of local anesthetic" and is a mixture of 2.5% lidocaine and 2.5% prilocaine for topical use. The depth of penetration of EMLA cream is dependent on the contact time with the skin. In humans, toxicity from EMLA cream is associated with improper administration (i.e., application to large surface areas, prolonged contact time, and application to damaged skin or mucous membranes). Common side effects in humans include skin blanching and local erythema. Less common side effects include methemoglobinemia or neurologic signs, generally when EMLA is applied to a large surface area for a prolonged time. Optimal use in humans requires application and occlusion for 1 hour prior. However, shorter times appear to be effective. There have been no studies evaluating shorter contact times in animals with thin skin, as in birds. The maximum dosage must be calculated prior to administration to prevent toxicity. Systemic uptake may be increased after feather plucking due to skin damage and exposed feather follicles.

For some procedures involving the caudal coelom, a caudal spinal anesthesia technique has been established for chickens (Kazemi-Darabadi et al. 2019). There is no epidural space caudal to the thoracic region of the coelom because there is a general attachment of the vertebral periosteum to the dura mater (Kazemi-Darabadi et al. 2019). In contrast, the arachnoid space is well developed in the synsacral spinal cord (Azcoitia et al. 1987). As a result, epidural injection is not possible in the lumbosacral area of the chickens, but spinal injection can be performed (Kazemi-Darabadi et al. 2019; Khamisabadi et al. 2021). While having delayed onset compared with lidocaine, bupivacaine produced approximately 55 minutes of spinal anesthesia in broiler chickens, much longer than the 18 minutes of spinal anesthesia provided by 2 mg/kg lidocaine (Khamisabadi et al. 2021).

Monitoring

Due to the rapid rate at which birds may decompensate under anesthesia, monitoring is the most important aspect of avian anesthesia. Additionally, many monitors are not built for the small size and rapid heart rate of avian patients and may be more unreliable than in dogs and cats. This means having one person dedicated to consistent, hands-on monitoring and ensuring the anesthetist has a clear view of the patient are critically important.

Cardiovascular

Heart rate is widely variable between individuals and species. Knowledge of expected species values is important, but trends in rate during anesthesia are of more significance. Sudden bradycardia is an indication to decrease anesthetic depth and provide supportive care, such as fluid boluses.

Heart rate and rhythm are monitored by an external or an esophageal stethoscope, electrocardiograph or peripheral pulse rate. Peripheral pulse rates are determined at the brachial, medial metatarsal artery, or carotid artery by direct palpation or with a Doppler ultrasonic probe. The Doppler probe is placed against the palatine artery on the dorsal palate of some species (Fig. 15.7).

ECG limb leads are placed close to the body. Due to the delicate nature of avian skin, the alligator clips are attached to needles or stainless-steel suture passed through the skin, rather than directly attaching to the skin. Heart rate and the presence of an ECG trace are insensitive indicators of anesthetic depth.

Blood pressure may be subjectively assessed by palpating the pulse at the median ulnar or medial metatarsal artery. Changes in pulse pressure and velocity are also reflected in sound.

There is an increasing awareness of the need to monitor blood pressures in avian patients during anesthesia as techniques for monitoring improvement. However, when direct blood pressure measurements are compared across a variety of species in different orders, there are significant differences. This can make it difficult to determine what values are normal for a particular species. There appears to be a trend for Galliformes and pigeons to have lower pressures than Psittaciformes, which also appear to average lower than raptorial species, but this is based on a low number of species. Blood pressure is the result of cardiac output and peripheral vascular resistance. Both are affected by several factors, including autoregulatory control and humoral, hormonal, and neural influences (Smith et al. 2000). Very short-term adjustments are mainly the result of reflex responses within the small arteries and arterioles. Tissue production of metabolic products, including CO_2, H^+, and others, may cause a functional hyperemia in local tissues (Smith et al. 2000). Circulating hormones such as epinephrine, norepinephrine, and angiotensin II also have significant effects on peripheral vascular resistance (Smith et al. 2000). There has not been sufficient research into the differences in these multitude of factors between species to know which is responsible for the differences in resting blood pressures noted clinically. This means that monitoring trends for a particular patient under anesthesia is more important than the actual blood pressure value.

Figure 15.7 In addition to the medial metatarsal artery, peripheral pulse rates can be determined in many birds by placement of a Doppler flow probe over either the brachial artery (a), the carotid artery (b) or over the palatine artery (c) on the dorsal palate of some species of raptors and waterfowl.

Direct arterial pressure monitoring can be performed. The most common sites include the brachial and carotid arteries (Fig. 15.8). The catheters are usually placed percutaneously, but a cut-down procedure is sometimes required to confirm arterial location. Significant arteriospasm may occur in some species. In this author's experience, cutaneous application of a small amount of EMLA 30 minutes prior to percutaneous catheterization reduces arteriospasm. Alternatively, diluted 2.5% lidocaine is applied directly over the artery during a cut-down procedure. Occasionally a profound bradycardia is associated with catheterization of a brachial artery.

Indirect blood pressure monitoring is performed using a Doppler ultrasonic probe to detect arterial flow, a pressure cuff for occlusion, and a sphygmomanometer to measure pressure (Fig. 15.9). Recently, there have been several publications investigating the accuracy and precision of indirect blood pressure (iBP) monitoring in multiple avian species. In Hispaniolan Amazon parrots, iBP measurements obtained with a size 1 neonatal cuff (30–40% of limb diameter) did not provide adequate correlation with direct arterial measurements (Acierno et al. 2008). In red-tailed hawks, iBP measurements were found to more closely approximate MAP measurements over a range of blood pressures and values obtained with a cuff 40–50% of the limb diameter did not differ significantly between wing or leg placement (Zehnder et al. 2009). A study evaluating the precision of multiple iBP measurements in awake psittacines found significant variability between repeated measurements when iBP cuffs were applied multiple times to the same limb (Johnston et al. 2011). Oscillometric devices have demonstrated high failure rates and unreliable measurements in avian patients and are not recommended for iBP monitoring (Acierno et al. 2008; Zehnder et al. 2009). From the studies that have been done, it seems that an appropriately sized cuff and sphygmomanometer can be

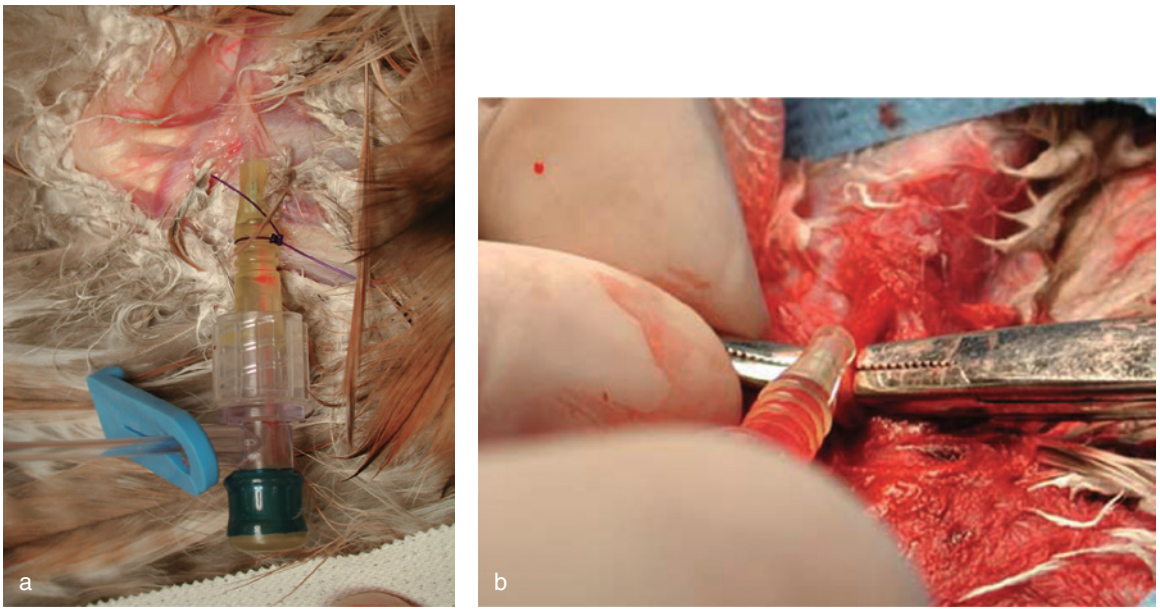

Figure 15.8 Arterial catheterization of the brachial artery in a bird. The brachial (a) and carotid arteries are the most common sites for arterial catheterization in birds. Percutaneous placement is utilized most, but sometimes a surgical cut-down procedure is required to confirm the location of the artery (b).

Figure 15.9 Indirect blood pressure monitoring can be performed using a Doppler ultrasonic probe to detect the arterial flow, a pressure cuff to occlude arterial blood flow and a sphygmomanometer to measure pressures.

used to evaluate trends in iBP during an anesthetic episode, but that repeated sampling that involves different cuff placements (as in different hospital visits) may be unreliable.

Respiratory

Respiratory rate and character should be closely monitored throughout anesthesia as these may be the first indication of problems and are a good sign for early intervention. Ventilation is assessed by observing the frequency and range of sternal motion and reservoir bag movement. Substituting balloons for regular reservoir bags will facilitate visualization of movement in patients with small tidal volumes. However, assessment of adequacy of ventilation by these methods in birds is inaccurate. A sudden change in respiratory pattern involving increased respiratory effort may indicate obstruction of the endotracheal tube, a particular concern in very small patients. Normal ventilation is associated with little to no respiratory tract noise. Whistling, wheezing or harsh sounds may also indicate obstruction. Many birds (e.g., ducks) will normally have an expiratory syringeal noise during IPPV. Apnea ≥10–20 seconds is an indication to decrease anesthetic depth and provide assisted ventilation. The time between respiratory and cardiac arrests may be ≤1–2 minutes. Respiratory monitors that detect gas flow increase mechanical dead space.

End-tidal carbon dioxide ($PETCO_2$) monitoring is used to determine ventilatory efficacy. This can be done using either main-stream or side-stream technology. Main-stream detectors are placed on the end of the endotracheal tube and contain sources of infra-red light and detectors used to measure CO_2 concentration. This means that the displayed waveform is synchronous with the bird's respiration. In birds <5 kg a pediatric adapter should be used with the main-stream adapter to minimize dead space but in small birds (<500 g) this added dead space to the airway is excessive. Side-stream technology draws gas from the airway and passes it through a detector in the monitor so there is always a slight delay between the bird's

breathing and the displayed waveform. This method allows the dead space to be minimized by drawing gas from an endotracheal tube adaptor or from within the airway Ideally the sampling port is located inside the endotracheal tube, but it should not increase airway resistance. Sidestream capnographs draw samples at a rate of 50–200 mL/min. This rate is usually fixed, but some capnographs allow alteration. In small birds even this low flow may exceed minute ventilation so care should be taken to account for this removal of gas by the monitor.

There is relatively good correlation between $PETCO_2$ and $PaCO_2$, with $PETCO_2$ slightly exceeding $PaCO_2$ (Edling et al. 2001; Hawkins et al. 2003; Pettifer et al. 2002). In a study evaluating the accuracy of $PETCO_2$ in multiple raptor species, the authors found that sidestream $PETCO_2$ overestimated $PaCO_2$ at low levels, with the reverse trend at higher levels (Desmarchelier et al. 2007). This can occur in the avian parabronchus, but is impossible in alveolar gas exchange (Powell & Whittow 2000). Carbon dioxide diffusion occurs across the length of the parabronchus, with a higher diffusion rate at the inspiratory end and a lower rate at the expiratory end. Since arterialized blood returning to the heart is a mix of capillary blood draining the entire length of the parabronchus, $PaCO_2$ can be less than $PETCO_2$ in ideal cross-current exchange. With very small tidal volumes there may be enough mixing of expired gas with fresh gas that the capnogram reading is artificially low. One way to check this is to administer a larger breath and to check if the $PETCO_2$ increases: if it does then the ongoing reading is not a true reflection of the $PaCO_2$. The capnogram provides important information regarding trends in $PETCO_2$ (Fig. 15.10) and can also be used to detect changes in dead space. If the inspired CO_2 begins to climb, then this indicates increased dead space. If a nonrebreathing circuit is being used this is most often caused by an inadequate flow of oxygen and is mostly seen when the respiratory rate increases. A flow rate that may have been adequate to remove CO_2 at 20 breaths per minute may not be sufficient at 40 breaths per minute due to a reduction in the time between breaths for gas removal. One further

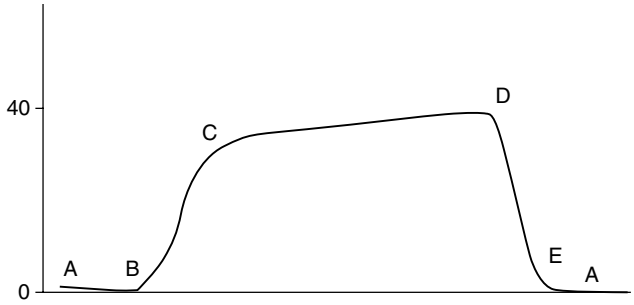

Figure 15.10 Avian capnogram.

complication in birds is that the waveform may suddenly disappear if an air sac is opened because gas is now flowing out of the air sac and not back up the trachea. If an inhalant is being used the surgeons should be notified so that they can potentially close the air sac. If that is not possible then consideration should be given to switching to an injectable technique for anesthesia.

Pulse oximetry has not been validated in birds. The absorption characteristics of oxygenated and deoxygenated avian and human hemoglobin are different, resulting in underestimation of hemoglobin saturation (Schmitt et al. 1998). In pigeons, hemoglobin saturation trends were consistent, but values did not correlate with those derived from blood gas analyses and calculation (Schmitt et al. 1998). A recent study in Andean geese showed an excellent correlation between SaO_2 and SpO_2 but more studies are needed (Ivy et al. 2018). However, these monitors are often used to provide a pulse rate and some monitors have been adapted to count pulses up to 400 breaths per minute.

Anesthetic Depth

The cere, beak, head, cloaca, and digits are used to assess response to pain. Surgical incisions and needle pricks evoke less response under anesthesia than for mammals. Withdrawal reflexes include toe pinch, stimulation of the interdigital tissue, pinching the scaly areas of the skin, cloacal pinch, and feather plucking. Slight corneal and palpebral reflexes are maintained at a surgical plane; their absence may indicate excessively deep anesthesia. In raptors anesthetized with propofol, contour feather plucking did not initiate a response in any bird at any time during the CRI (Hawkins et al. 2003). Rather, toe clamping was a better guide to anesthetic depth.

Glucose

Blood glucose is monitored when possible, particularly during prolonged procedures. In auklets, the values determined by four handheld human glucose monitors were comparable to Chemstrip BG. However, values for all systems were 33% less than those determined by a reference chemistry laboratory (Lieske et al. 2002). Blood storage in heparin was preferable to ethylenediamine tetra-acetic acid. Stored blood glucose values were stable for 4 hours.

Recovery

Recovery complications are usually associated with long anesthetic procedures (≥0.5–1.0 hours). This emphasizes the importance of minimizing anesthetic time. The vaporizer is turned off at the end of the procedure and

circle breathing systems flushed with oxygen. This flushing is unnecessary with a nonrebreathing system. The patient remains connected to the breathing system and oxygen if possible. Signs of recovery include muscle fasciculations, then wing and leg movement. Once beak tone returns, the bird is extubated to prevent severing the endotracheal tube. Once extubated, an anesthetic face mask with or without the rubber diaphragm is placed over the bird's head to continue oxygen supplementation. Most birds are placed loosely in a towel and held upright to minimize self-trauma and regurgitation. Respiration is monitored during towel restraint to ensure adequate sternal movement. Once recovered the bird is placed in a warm, well-oxygenated environment for continued recovery. A quiet dark environment minimizes stress and movement.

Analgesia

Pain Recognition

Pain recognition is critical for providing timely analgesic selection for any species. It requires consideration of age, sex, and species differences, as well as individual behavior and environmental factors. Pain assessment must also account for different types and sources of pain (i.e., acute, chronic, visceral, and somatic). Pain is subjective and the emotional component is difficult to translate because birds lack facial expression and do not share verbal language with humans. In humans pain is what the patient says it is but with birds, people's perceptions of the bird's behavior determines what is recognized as pain.

Behavioral changes associated with pain in birds can be very subtle and obscure but are often the earliest signs of pain detected by owners or animal care staff. Behavioral changes do not manifest uniformly among different species of birds; observers must become familiar with the full range of normal behaviors for the species as well as for the individual. It is important to observe birds' behaviors at appropriate times for each species, for example observing nocturnal species at night. Social species exhibit pain behaviors dependent on the group social dynamics. Predatory species exhibit abnormal behaviors more readily than prey species. Painful behaviors attract unwanted attention from predators, requiring masking to survive. The clinician is viewed as a potential predator. Birds either hide painful or exhibit different behaviors outside their home cage. Without knowing the range of normal behaviors, an observer will find it extremely difficult to detect abnormal behaviors.

Pain can change a bird's social interactions, especially in species with complex social systems. This may be an obvious change, such as perching away from the flock, or might be subtle, such as a reduction in social grooming. When birds are housed as single pets, their social interactions with the owner may be reduced or the bird may permit interactions that it would not otherwise allow. Birds in pain may display guarding behavior to protect a painful area, which may manifest as antisocial behaviors. Some forms of aggression have been linked to painful conditions in birds; anecdotal reports have suggested aggressive behaviors are sometimes reduced or dissipate following treatment of the painful condition.

Feather grooming is an avian behavior that runs the full spectrum of behavioral changes associated with pain, both acute and chronic. Grooming activity may decrease when a bird is in pain, but conversely overgrooming and feather destructive behaviors have been associated with chronic pain, which may include neuropathic pain. In a social species housed within a group, a bird in pain frequently isolates itself from others, it may sleep apart from the rest of the flock, and mutual grooming is often decreased (Le Maho et al. 1992). Increased self-grooming activities or preening other birds can be an intentional distraction.

Birds respond to noxious stimuli with a fight-or-flight response (escape reactions, vocalization, excessive movement) and/or tonic immobility. In domestic chickens (*Gallus gallus domesticus*) removal of feathers caused a progression of behavioral changes from an alert agitated response following the initial removal of feathers to periods of crouching immobility following successive feather removal (Gentle & Hunter 1991). In red-tailed hawks (*Buteo jamaicensis*) hospitalized with recent orthopedic injuries, movement, head motions, and beak clacking were significantly reduced when compared to birds without recent orthopedic injuries (Mazor-Thomas et al. 2014). Studies using chickens with experimentally induced arthritis demonstrated that shifting their attention can reduce painful behaviors (Gentle & Tilston 1999).

Many clinical signs are associated with pain, including change in temperament (either aggressive or passive), restlessness, reduced mobility (Mazor-Thomas et al. 2014) or reluctance to stand or perch, lethargy, hunched appearance, sleep deprivation, tachypnea, and lameness. Reduced food consumption may occur, and bodyweight should be monitored. Animals with abdominal pain can exhibit tensing with a "tucked up" or "hunched" appearance. Birds may either avoid a painful body area or bite/chew it. Decreased or overgrooming (feather-picking) may occur at a painful site. In red-tailed hawks both head movements and beak clacking were decreased in birds thought to be in pain (Mazor-Thomas et al. 2014). Vocalization and writhing occur rarely during acute or severe pain. Owners often describe reduced vocalization in birds with traumatic injuries.

Few physiologic variables are consistent indicators of pain. In chickens during feather plucking, heart rates and respiratory rates were variable, but increased blood pressure was a reliable indicator (Gentle & Tilston 1999). Catecholamines are well-recognized humoral indicators of stress but vary between individuals and species because of differences in adrenal content (Harvey et al. 1984). Corticosterone significantly increases in birds following pain, but it also increases with handling (Heatley et al. 2000). The use of noxious stimuli (primarily thermal) as well as induced pain models (Paul-Murphy et al. 2009a) will allow researchers to evaluate the use of analgesics more objectively in birds.

Pain scales and scoring sheets are increasingly used to assess pain, especially when specifically designed for a given species under well-defined conditions. Using pain scales requires an understanding of both normal and pain-related behaviors for the species and individual. Score-sheet descriptions of behaviors must be refined and terms must be clearly defined to reduce interobserver variability and observer bias. In lieu of species-specific pain score sheets, there is tremendous value in using a generic visual analog pain scale of 1 to 10 to evaluate a bird's pain and the response to treatment and recovery from a painful condition. For example, pigeons following orthopedic surgery were evaluated using a detailed numeric rating scale plus a simple 1 to 10 pain scale, and there was significant correlation between both methods (Desmarchelier et al. 2012a). Effective analgesia is expected to show a marked, easily discernable change in posture or behaviors that will effect a reliable change in the subjective pain score. If no change in pain score occurs, then the drugs, dosage, or frequency of administration should be re-evaluated for that patient. Alternatively, a set of universal questions are used to determine if a patient is in pain:

1) Would the lesion or procedure be painful to any species?
2) Is the lesion or procedure damaging to tissues in any species?
3) Does the patient display any abnormal behavioral responses?

If the answer to any of these questions is yes, then the veterinarian must assume that the patient is in pain and an analgesic plan should be developed.

Approaches to the Treatment of Pain

Surgical incisions and other painful procedures in humans induce prolonged nervous system changes that later contribute to postoperative pain. This noxious stimulus-induced sensitization can be prevented or "pre-empted" by administration of analgesic agents prior to tissue injury. Pre-emptive analgesia with opiates, nonsteroidal anti-inflammatory drugs (NSAIDs), and/or local anesthetics can block sensory noxious stimuli from onward transmission to the CNS, thus reducing the overall potential for inflammation and pain and improving the patient's short- and long-term recovery. Combinations of drugs in a multimodal protocol with opiates, NSAIDs, local anesthetics, and/or other drugs acting at different points in the nociceptive system provide a greater effect and potentially less toxicity than individual drugs given alone, which is especially important in avian species for which few analgesic data are available.

Opioids

Most opioid analgesics are used parenterally because of their overall poor oral bioavailability associated with the first-pass effect. Analgesia is species and intra-species variable at equipotent dosages. Opioids are used for moderate to severe pain, such as traumatic or surgical pain. Opioids reversibly bind to specific receptors in the central and peripheral nervous system. These drugs are categorized as full agonists, partial agonists, mixed agonist/antagonists, or antagonists based on their ability to induce an analgesic response once bound to a specific receptor. The action of opioid drugs on these receptors activates G-proteins, leading to a reduction in transmission of nerve impulses and inhibition of neurotransmitter release (Bovill 1997). Agonist drugs have a linear dose–response curve that may be titrated to reach the desired effect, whereas the agonist/antagonist drugs may reach a ceiling effect after which increasing the dose does not appear to provide additional analgesia. During anesthesia, opioids are used to provide perioperative analgesia that may reduce the concentrations of volatile anesthetics (i.e., gas anesthesia-sparing effects). The most common adverse effects reported with opioids are cardiac and/or respiratory depression. In many cases, these drugs may be reversed with antagonists, which will also terminate analgesia. The application and dosages of several opioid formulations have been scientifically evaluated and clinically applied in birds.

Few studies have been conducted regarding the distribution, quantity, and function of each opioid receptor type in birds, and although marked species variability is assumed, further studies are necessary (Duhamelle et al. 2018). In pigeons, regional distribution of μ, κ, and δ receptors in the forebrain and midbrain were like mammals but the κ and δ receptors were more prominent in the pigeon forebrain and midbrain than μ receptors and 76% of opioid receptors in the forebrain were determined to be κ type (Mansour et al. 1988). However, in 1-day-old chicks

receptor distribution was markedly different, suggesting either age or species effect (Csillag et al. 1990). There were small differences in receptor densities between cockatiels and pigeons but these may not be sufficient to make functional changes (Fousse et al. 2020). In conditioning experiments pigeons were able to differentiate μ from κ receptor agonists. Isoflurane-sparing effects of μ and κ agonists are quite variable in mammals and it is likely that similar variability will be evident in birds (Concannon et al. 1995).

Morphine is a μ-receptor agonist that has been infrequently used in avian medicine because early studies in domestic fowl yielded conflicting results and suggested that very high dosages were required to reduce response to the toe pinch (Schneider 1961) or a noxious electrical stimulation (Bardo & Hughes 1978). In one study, it decreased the response temperature in a thermal threshold test (hyperalgesia) in two breeds but increased it another one (Hughes 1990). A study of adult white leghorns that involved the use of the isoflurane-sparing technique found that increasing doses of morphine (0.1, 1, and 3 mg/kg) caused a significant decrease in the isoflurane MAC (Concannon et al. 1995). An intra-articular injection of 1–3 mg morphine in a domestic fowl arthritis model identified no significant antinociceptive effects, but it is unclear whether synovial fluid pH differences may have affected the activity of the drug (Gentle et al. 1999). The pharmacokinetics of morphine at 2 mg/kg IV also have been evaluated in the domestic chicken (Singh et al. 2010). At this dose, chickens cleared morphine at a higher rate than humans or cats, and plasma morphine analgesic concentrations were like humans for approximately 2 hours. In a recent study evaluating the analgesic efficacy of morphine, lame broiler chickens underwent an obstacle course and latency-to-lie test before injection at 30 minutes and 2 hours after injection, to assess their walking and standing ability (Singh et al. 2017). Following 2 mg/kg IV of morphine, chickens had an increase in time to finish the obstacle course and exhibited sedation which confounded assessment of its analgesic effects. The authors indicated that morphine would likely produce analgesia without sedation at lower doses, which would also require a more frequent administration and warrants further investigation.

Hydromorphone HCl is a μ-opioid receptor agonist with an approximate potency five to seven times that of morphine in humans (Quigley 2003). Hydromorphone shows a dose-responsive thermal antinociceptive effect when administered at 0.1, 0.3, and 0.6 mg/kg IM to American kestrels (*Falco sparverius*) for up to 6 hours (Table 15.3) (Guzman et al. 2013). Severe sedation was detected in four birds when administered 0.6 mg/kg hydromorphone, and when the sedated birds were handled they appeared agitated for a few seconds then resumed sedated behavior. The pharmacokinetics of hydromorphone following IM and IV administration in American kestrels

Table 15.3 Analgesic drug dosages commonly used in birds.

Drug	Dosage (mg/kg)	Route	Frequency	Species	Comments	References
Morphine						
	0.1, 1, and 3	IV	Single	Chickens	15%, 40%, and 52% reductions in the MAC of isoflurane	Concannon et al. (1995)
	2	IV	Single	Chickens	Produced enough sedation that analgesia was not evident	Singh et al. (2017)
Hydromorphone	0.1, 0.3, and 0.6	IM	Single	American kestrels and cockatiels	Increased thermal threshold in kestrels but no effect in cockatiels	Guzman et al. (2013); Guzman et al. (2014c); Houck et al. (2018)
	1 and 2	IM	Single	Amazon parrots	Increased thermal threshold but accompanied by significant agitation	Guzman et al. (2020)
Methadone	6	IM	Single	Chickens	30% decrease in the MAC of isoflurane	Escobar et al. (2021, 2016)

Drug	Dosage (mg/kg)	Route	Frequency	Species	Comments	References
Local anesthetics						
Bupivicaine	1.33, 1.96	IV	Single	Chickens	1.96 mg/kg IV bupivacaine associated with a 50% probability of a clinically relevant change in MAP and HR, whereas 1.33 mg/kg IV bupivacaine is associated with a 1% probability of causing the same effect	DiGeronimo et al. (2017)
	2–8	Peri-neural		Mallard ducks		Brenner et al. (2010)
Lidocaine	1–3	Local		Most species	Incision site infusion	
Ropivicaine	7.5	Peri-neural		Chickens	Successful brachial plexus block in 15 minutes, ~110 minutes of anesthesia	Cardozo et al. (2009)

CRI, continuous rate infusion; HR, heart rate; IM, intramuscular; IV, intravenous; MAC, minimum anesthetic concentration; $PaCO_2$, arterial partial pressure of carbon dioxide; PaO_2, arterial partial pressure of oxygen; PO, per os or orally; q12h, every 12 hrs; q24h, once a day; SC, subcutaneous. Note that these are suggested dosages based on published information and the author's clinical experience. Species and individual variation in response to a given drug can be uncertain so the dosage should be adjusted depending on the clinical response of the animal.

found a high IM bioavailability (75%) and rapid elimination, with a short terminal half-life and a rapid plasma clearance (Guzman et al. 2014b). A similar thermal nociception study in cockatiels (*Nymphicus hollandicus*) that were administered 0.1, 0.3, and 0.6 mg/kg IM hydromorphone and saline treatment showed no significant effect on the thermal threshold, and the highest dosages resulted in only a mild sedative effect (Houck et al. 2018). The thermal antinociceptive effect of hydromorphone was evaluated following IM administration to orange-winged Amazon parrots (*Amazona amazonica*) (Guzman et al. 2020). Hydromorphone at 1 and 2 mg/kg significantly increased thermal foot withdrawal response at 0.5, 1.5, and 3 hours, and 1.5 and 6 hours respectively, compared with the response after saline administration. Significant agitation was observed for 1 and 2 mg/kg hydromorphone doses at 0.5, 1.5, and 3 hours. This kind of agitation in response to an opioid in normal birds may not be present in birds in pain. Other significant adverse effects after administration of 1 and 2 mg/kg hydromorphone included nausea-like behavior, ataxia, and pupillary constriction. One bird regurgitated/vomited after receiving the 2 and 1 mg/kg doses at 0.5 and 1.5 hours, respectively. While hydromorphone at 1 and 2 mg/kg IM appears to have desired analgesic effects, the presence of agitation, nausea-like behavior, and ataxia warrants consideration of lower doses for clinical use in orange-winged Amazon parrots. Plasma hydromorphone concentrations were maintained above 1 ng/mL for 6 hours in six out of seven and eight out of eight orange-winged Amazon parrots receiving 1 mg/kg hydromorphone IV and IM, respectively (Guzman et al. 2020). Hydromorphone hydrochloride had a positive pharmacokinetic profile in this species with high bioavailability and rapid elimination after IM administration, with a short terminal half-life, rapid plasma clearance, and a large volume of distribution (Guzman et al. 2020).

Methadone in small animals acts similarly to morphine regarding its degree of analgesia and duration of action (Plumb 2020). Methadone is a μ-opioid receptor agonist that also is a noncompetitive inhibitor of N-methyl-D-aspartate (NMDA) receptors. Methadone can also reduce re-uptake of norepinephrine and serotonin, which may contribute to its analgesic effects. Due to its additional mechanisms of action, methadone potentially may be more efficacious than other μ agonists (e.g., morphine), particularly for neuropathic or chronic pain (Plumb 2018). Methadone is much more lipid-soluble than morphine and approximately 1–1.5 times as potent. In hens, methadone at a dose of 6 mg/kg IM decreased the isoflurane minimum anesthetic concentrations by 30% at 15 minutes post administration. At this dose, in spontaneously breathing hens, methadone produced mild respiratory acidosis, decreased heart rate, and increased systemic blood

pressure, with occasional cardiac arrhythmias (Escobar et al. 2016). The bioavailability was estimated to be 79% for IM administration (Escobar et al. 2021). Methadone at 6 mg/kg IM in orange-winged Amazon parrots resulted in a significant increase in thermal threshold when compared to saline administration, while lower doses of 1 and 3 mg/kg did not result in a significant effect (D.S.-M. Guzman, pers. comm.). Methadone caused significant agitation and nausea-like behavior when compared to saline administration. The IM mean bioavailability was 85.7% with mean terminal half-lives of 2.35 and 2.29 hours after IV and IM administration, respectively (D.S.-M. Guzman, pers. comm.). While methadone at 6 mg/kg IM appears to have the desired analgesic effects, the presence of agitation, nausea-like behavior, and ataxia warrants consideration of lower doses for clinical use in orange-winged Amazon parrots. Further studies are needed to fully determine the analgesic and adverse effects of methadone in psittacine birds and other avian species.

Fentanyl is a short-acting μ-opioid receptor agonist often administered as a continuous rate infusion or as a transdermal patch. Fentanyl administered at 0.02 mg/kg IM did not affect the withdrawal thresholds to electrical or thermal stimuli of white cockatoos (Hoppes et al. 2003) however, a 10-fold increase in the dosage (0.2 mg/kg) administered subcutaneously did produce an antinociceptive response, but some birds were hyperactive for the first 15–30 minutes after receiving the high dose (Hoppes et al. 2003). Fentanyl had rapid absorption and elimination in cockatoos (*Cacatua* spp.), with a terminal half-life of 1.15 hours (Hoppes et al. 2003). Administered as an IV CRI in red-tailed hawks, fentanyl reduced the minimum anesthetic concentration of isoflurane 31 to 55% in a dose-related manner, without significant effects on heart rate, blood pressure, $PaCO_2$, or PaO_2 (Table 15.3) (Pavez et al. 2011). In a similar study with Hispaniolan Amazon parrots, fentanyl administered as an IV CRI reduced isoflurane MAC similarly to the red-tailed hawks; however, approximately 20 times higher dosing was necessary to achieve the same effects and significant effects were detected in HR and BP, suggesting that while this can also be an effective opioid in these birds, close monitoring is recommended (Hawkins et al. 2018). In several breeds of chickens, the plasma concentrations of fentanyl were evaluated following application of 25 μg/h transdermal fentanyl patches (TFP) (Delaski et al. 2017). The TFPs were in place for 72 hours over the left iliopsoas muscle after plucking the feathers in the region. There was a significant degree of interindividual difference in maximum plasma fentanyl concentrations that was attributed to absorption variability, but all chickens achieved human target plasma concentrations of 0.2–1.2 ng/mL within 2–4 hours and had a rapid decrease in concentrations following patch removal. Based on these findings, fentanyl transdermal patch application for chickens targeted to provide 8–10 μg/kg/h fentanyl resulted in plasma concentrations within the range considered therapeutic in people for 72 hours (Delaski et al. 2017). A transdermal fentanyl solution has been evaluated in Helmeted guineafowl (*Numida meleagris*) (Waugh et al. 2016). The solution was placed on the skin in the interscapular region at 5 mg/kg, which resulted in mean plasma concentrations above those considered analgesic for dogs (0.6 ng/mL) from 4 hours through to at least 7 days with no evidence of adverse effects or change in behavior. Unfortunately, this commercial formulation has been discontinued at the time of writing this chapter. Further studies would be needed to evaluate effective and safe plasma concentrations of fentanyl in birds.

Butorphanol is a mixed κ-opioid receptor agonist and μ-opioid receptor antagonist opioid drug. This opioid has historically been one of the most commonly used opioid analgesics in birds, despite many studies suggesting it requires very frequent dosing. There is some evidence to suggest that butorphanol does not produce dose-related respiratory depression in contrast to μ-receptor agonists. Earlier isoflurane-sparing studies using butorphanol (1 mg/kg) produced an isoflurane-sparing effect in cockatoos and African grey parrots, but not in blue-fronted Amazons (*Amazona aestiva*), indicating species variability either in response to the drug itself or to the dose administered (Curro 1994; Curro et al. 1994). In parakeets, butorphanol (3 and 6 mg/kg) reduced the MAC of sevoflurane 10 and 17%, respectively (Martini et al. 2020). Similarly, in guinea fowl butorphanol (2–4 mg/kg) also reduced sevoflurane MAC by 9 and 21%, respectively (Escobar et al. 2014). When the 4 mg/kg dose of butorphanol was administered rapidly IV there were significant arrhythmias in all birds, significant decreases in heart rates and arterial blood pressures, and one bird died (Escobar et al. 2014). Preoperative butorphanol administration (2 mg/kg IM) did not show significant anesthetic (including time to intubation and extubation) or cardiopulmonary changes in Hispaniolan Amazon parrots anesthetized with sevoflurane (Klaphake et al. 2006). In African grey parrots butorphanol (1–2 mg/kg) showed an increased withdrawal threshold in response to electrical stimuli (Paul-Murphy et al. 1999). In a thermal antinociceptive study in which butorphanol dosages of 3 and 6 mg/kg IM were evaluated in Hispaniolan Amazon parrots, both dosages similarly increased thermal withdrawal thresholds (Sladky et al. 2006). The IV, IM, and PO pharmacokinetics of butorphanol were evaluated in Hispaniolan Amazon parrots (Guzman et al. 2011). Oral administration had very limited bioavailability (5.9%) and is not recommended. The $t_{1/2}$ (half life) of IM and IV administration was very similar at 0.51 and 0.49 hours, respectively. Butorphanol administered at 6 mg/kg IM attained high plasma concentrations which

decreased rapidly over time (Guzman et al. 2011). Based on results in Hispaniolan Amazon parrots, butorphanol tartrate administered at 5 mg/kg IV or IM would have to be administered every 2 and 3 hours, respectively, to achieve target plasma concentrations determined in pharmacodynamic studies (Sladky et al. 2006).

In contrast, American kestrels (Guzman et al. 2014a) administered butorphanol tartrate at 1, 3, and 6 mg/kg IM showed no significant increase in foot withdrawal thermal threshold values and no sedative effects were observed. Instead, hyperesthesia or hyperalgesia and agitation were noted in males receiving 6 mg/kg. Because of these findings, butorphanol is not recommended in this species for pain management until further evidence of its analgesic properties is available. One study evaluating the pharmacokinetics of 0.5 mg/kg butorphanol in red-tailed hawks and great-horned owls (*Bubo virginianus*) found terminal half-lives of 0.93 and 1.78 hours, respectively, when given intravenously, and 0.94 and 1.84 hours, respectively, when given intramuscularly, suggesting the drug requires very frequent dosing in these species (Riggs et al. 2008). Likewise, when a dose of 2 mg/kg butorphanol was administered intravenously to domestic chickens, its terminal half-life was shorter in chickens than in humans, dogs, cattle, rabbits, and owls but longer than in red-tailed hawks (Singh et al. 2011). In a recent study in evaluating the analgesic efficacy of butorphanol, lame broiler chickens underwent an obstacle course and latency-to-lie test before injection at 30 minutes and 2 hours after injection to assess walking and standing ability (Singh et al. 2017). Following 2 mg/kg IV of butorphanol, chickens finished the obstacle course faster after the injection of butorphanol and the authors concluded that it may be analgesic in chickens for up to 2 hours. All these data confirm that frequent dosing of butorphanol is necessary in birds. This may be impractical because of lack of personnel to provide frequent dosing and the stress of frequent handling on the patient. In common peafowl, the pharmacokinetics of butorphanol were assessed after administration via an osmotic pump, a novel delivery method (Clancy et al. 2015). Two osmotic pumps containing 2 mL of butorphanol at a concentration depending on body weight of the bird administering the drug at a rate of 247 μg/kg/h each were surgically implanted in 12 birds and removed 7 days later. The osmotic pumps were 5.1 cm in length and weighed 5.1 g. Plasma butorphanol concentration was measured before implantation SC in the left inguinal region for several hours to days after implantation and 3 and 6 hours after the implant removal. Plasma concentration reached 60 ng/mL after 24 hours in most birds, and in most birds stayed above this threshold for 7 days, then decreased rapidly after implant removal. There was no evidence of sedation or adverse effect. This delivery method holds promise for pain management in large birds with the limitation that it will likely require deep sedation or general anesthesia for implantation and removal. Further research evaluating continuous rate infusions of butorphanol is needed to identify whether this is a good drug for use in balanced anesthesia/analgesia protocols.

Buprenorphine hydrochloride has a slow onset of action with longer duration than other opioid drugs and a unique and complex pharmacological profile. Buprenorphine is thought to act as a partial μ agonist but its κ-receptor activities are less well defined. Several studies suggest that buprenorphine demonstrates κ-receptor agonist effects but other evidence in mammals and pigeons (*Columba livia*) suggests that it also displays some κ-antagonistic activities. Buprenorphine has unusual receptor binding characteristics that appear to be the result of slow drug dissociation from opioid receptors. Buprenorphine at 0.1 mg/kg IM in African grey parrots did not demonstrate any antinociceptive effect when tested by noxious electrical stimulus and pharmacokinetic analysis suggests this dose may not achieve effective plasma concentrations determined for mammals (Paul-Murphy et al. 2004). Pigeons administered 0.25 and 0.5 mg/kg IM buprenorphine had an increased withdrawal threshold from a noxious electrical stimulus for 2 and 5 hours, respectively, suggesting that in different species this drug may have some effect at relatively low doses (Gaggermeier et al. 2003). In American kestrels (Ceulemans et al. 2014), buprenorphine did cause a significant dose-dependent thermal antinociceptive response at 0.1, 0.3, and 0.6 mg/kg IM for 6 hours compared with control treatment. At 0.6 mg/kg, a mild sedative effect was appreciated. The pharmacokinetics of 0.6 mg/kg IM and IV buprenorphine were also evaluated in kestrels and high bioavailability (94.8%) after IM dosing and a longer elimination rate than other opioids were identified (Gustavsen et al. 2014). In a pharmacokinetic study in American kestrels, SC and IM administration of 1.8 mg/kg Buprenorphine SR-LAB™ (Wildlife Pharmaceuticals, Windsor, CO, USA) were both characterized by rapid absorption (Guzman et al. 2017b). Forty-eight hours after administration mean plasma concentrations remained above the target concentration of >1 ng/mL. The elimination half-lives were 13.5 and 11.1 hours, respectively, approximately nine times longer than the half-life of 1.5 hours reported in American kestrels receiving 0.6 mg/kg IM standard buprenorphine (Gustavsen et al. 2014). This difference was expected due to the sustained release properties of this formulation and the higher dose administered than in the prior study. SC hematomas in three of the birds that received Buprenorphine SR-LAB™ SC were attributed to traumatic administration but resolved without intervention. A follow-up study evaluating the thermal antinociceptive effects of this formulation in the

same species concluded that 1.8 mg/kg IM requires administration at least every 24 hours to manage pain but might have a longer duration of action depending on the severity and type of pain, adjunctive therapy, and the individual response (Guzman et al. 2018). In red-tailed hawks (*Buteo jamaicensis*), the pharmacokinetics of two doses of the concentrated formulation of buprenorphine (Simbadol®, Zoetis, Kalamazoo, MI, USA) were evaluated after SC administration (Gleeson et al. 2018). Maximum buprenorphine concentration was achieved at approximately 5 and 15 minutes for the 0.3 and 1.8 mg/kg doses, and plasma concentrations were maintained above 1 ng/mL for at least 24 and 48 hours, respectively. Mean elimination half-lives were 6.23 and 7.84 hours, respectively, for the low and high doses. Adverse effects were not noted in any birds. The use of this concentrated buprenorphine formulation might help reduce stress related to repeated handling and administration of treatments in raptors while providing consistent pain management. An additional benefit is that at the same dose this formulation is more cost-effective than the standard buprenorphine formulation, which is a very important factor for wildlife rehabilitation.

In contrast, studies using cockatiels showed no significant difference in thermal withdrawal threshold using the same dosages of buprenorphine hydrochloride as in the kestrel studies, and no sedative effects were observed at any dosage (Guzman et al. 2018). In orange-winged Amazon parrots, the thermal antinociceptive effects of a concentrated formulation of buprenorphine (Simbadol®) after SC administration was evaluated (D.S.-M. Guzman, pers. comm.). Concentrated buprenorphine at 2 mg/kg resulted in a small but significant increase in thermal threshold when compared to saline, while lower doses of 0.1 and 1 mg/kg did not result in a significant effect. No significant effect of buprenorphine on agitation-sedation score was observed at any of the doses evaluated. These results provide evidence of weak efficacy at lower doses for pain management in this species, like previous findings in the cockatiels, and highlights the differences in efficacy compared with the raptors evaluated. Further studies are needed to fully determine the analgesic and adverse effects of buprenorphine in psittacines and warrants evaluation in other species.

Nalbuphine hydrochloride (HCl) is primarily a κ-receptor agonist and is a partial antagonist at the μ-receptor, like butorphanol. It is used in the treatment of moderate pain in humans and has a relatively lower incidence of respiratory depression that does not appear to be dose dependent. Nalbuphine HCl was rapidly cleared after both IM and IV dosing of 12.5 mg/kg to Hispaniolan Amazon parrots and had excellent bioavailability following IM administration, with little sedation and no adverse effects (Keller et al. 2011). This dosage increased thermal foot withdrawal threshold values in this species for up to 3 hours while higher dosages (25 and 50 mg/kg IM) did not significantly increase thermal foot withdrawal threshold values (Sanchez-Migallon et al. 2010).

Tramadol hydrochloride is an analgesic drug often used in avian medicine due to its ability to be dosed orally. It is a synthetic μ-opioid receptor agonist that appears to have variable efficacy depending on the species. The efficacy is thought to be primarily related to the production of the o-desmethyltramadol metabolite (M1). This metabolite acts centrally over the opioid receptor and is thought to have almost 200 times higher affinity for this receptor than the parent drug. Tramadol also has effects on the κ and δ opioid receptors, as well as inhibiting reuptake of norepinephrine and serotonin (Scott & Perry 2000). The conversion to the M1 metabolite is variable among species, but it is produced in the bird species studied thus far (Black et al. 2010; Kilburn et al. 2014; Souza et al. 2009, 2011, 2012). In humans, less respiratory depression and constipation are seen with tramadol than with μ-agonist opioids, but there are no data on these potential adverse effects in other species.

Pharmacokinetic profiles have been reported for American bald eagles (*Haliaeetus leucocephalus*) (Souza et al. 2009), red-tailed hawks (Souza et al. 2011), African penguins (*Spheniscus demersus*) (Kilburn et al. 2014), Indian peafowl (*Pavo cristatus*) (Black et al. 2010), and Hispaniolan Amazon parrots (Souza et al. 2012), and important differences exist with pharmacokinetic parameters between species. Oral bioavailability of tramadol was higher (98%) for American bald eagles than humans and dogs, suggesting this as a useful route of administration for this species. The terminal half-life of tramadol in bald eagles after oral dosing was two times that reported in dogs, but only half that of humans. Tramadol 11 mg/kg PO achieved concentrations in the human analgesic range for 10 hours in five out of six bald eagles; M1 plasma concentrations reached the human therapeutic range only in two eagles at much earlier time points (Souza et al. 2009).

In red-tailed hawks administered 11 mg/kg PO, analgesic thresholds for humans were maintained for approximately 4 hours with a $t_{1/2}$ of 1.3 (±0.6) (Souza et al. 2011). Based on the pharmacokinetic profile, the recommended dose is 15 mg/kg PO q12h (administer twice a day). In Hispaniolan Amazon parrots, doses of 10 or 20 mg/kg orally did not result in significant antinociception to thermal stimuli and human analgesic thresholds were only reached after dosing with 30 mg/kg orally or 5 mg/kg IV (Guzman et al. 2012). Transient bradycardia was noted after IV administration. In adult peafowl gavaged with 7.5 mg/kg, levels of tramadol remained over the human analgesic threshold

for approximately 1 hour in two out of six birds but M1 metabolite concentrations remained above the human therapeutic threshold for 12–24 hours (Black et al. 2010). This underscores the importance of assaying for pharmacologically active metabolites in these studies. In American kestrels, tramadol at 5 mg/kg PO significantly increased thermal thresholds for 9 hours when compared with baseline thresholds, while 15 and 30 mg/kg PO resulted in fewer antinociceptive effects (Guzman et al. 2014b). In Muscovy ducks (*Cairina moschata domestica*), tramadol at 30 mg/kg PO was effective in improving gait in a temporary arthritis model and assessed by ground-reactive forces measured by a pressure-sensitive walkway system (Bailey et al. 2019). A pharmacokinetic study by the same investigators in the same species following administration of tramadol at 30 mg/kg PO, showed that it has an elimination half-life of 3.95 hours, with a maximum concentration of 780 ng/mL at 1.16 hours (Bailey et al. 2019). In this study, it was also demonstrated that Muscovy ducks readily produce the M1 metabolite and maintain it well above the concentrations that are known to be therapeutic for humans and other avian species. In African penguins (*Spheniscus demersus*) the pharmacokinetic parameters were determined following 10 mg/kg PO administration (Kilburn et al. 2014). The elimination half-life for tramadol was 7.3 hours, which is significantly longer than other species reported. Tramadol and M1 concentrations were determined and were consistent with therapeutic concentrations in humans for 12 hours for tramadol and 36 hours for M1. Based on plasma concentrations alone, the authors concluded that an oral dose of 10 mg/kg of tramadol once daily could be used in this species.

Tapentadol is an analgesic agent that acts as both a μ-opioid receptor agonist and a norepinephrine reuptake inhibitor. It is a common therapeutic agent in human medicine for management of acute and chronic pain and is beginning to be investigated for use in veterinary medicine. The pharmacokinetics of tapentadol were evaluated in Hispaniolan Amazon parrots following a single 30 mg/kg PO of a compounded 5 mg/mL tapentadol suspension (Duvall et al. 2021). Detectable plasma concentrations were identified in only two out of seven birds. The low oral bioavailability and short half-life of this drug in Hispaniolan Amazon parrots suggest that this drug would be of limited clinical use in this species, but further studies are recommended in other avian species to evaluate its analgesic potential.

Non-steroidal Anti-inflammatory Drugs

NSAIDs are used to relieve musculoskeletal and visceral pain, acute pain, and chronic pain such as in osteoarthritis. The pharmacological activity of NSAIDs has been reviewed elsewhere and the mechanism of action is similar when administered to birds (Bergh & Budsberg 2005; Papich 2008). A broad tissue distribution of cyclooxygenase (COX) has been demonstrated in chickens (Mathonnet et al. 2001). The relative expression of COX-1 and COX-2 enzymes varies between species and both enzymes are important in pain and inflammation. The application and dosages of NSAID formulations continues to be scientifically evaluated and clinically applied in birds. The intention of recently developed NSAIDs has been to spare COX-1 and emphasize COX-2 inhibition with the goal of providing analgesia and suppressing inflammation without inhibiting the physiologically important prostaglandins. The common NSAIDs used in avian medicine include meloxicam, carprofen, celecoxib, robenacoxib, and piroxicam, each with a distinct COX-1/COX-2 ratio and differing reports of effectiveness and toxicity in birds.

The most common adverse effects of NSAIDs include effects on the gastrointestinal system, renal system, and coagulation. NSAIDs have been implicated in humans and mammals with an increased risk of myocardial infarction and delays in bone healing (Dajani & Islam 2008; Gerstenfeld et al. 2003), but these effects have not been substantiated to date in birds. It is prudent to remember these adverse effects are often dose dependent and associated with chronic administration. The kidney uses both COX-1 and COX-2 for prostaglandin synthesis and injury occurs when renal prostaglandin synthesis is inhibited. Originally it was hypothesized that the adverse renal effects of NSAIDs were linked primarily to COX-1 inhibition but COX-2 metabolites have been implicated in maintenance of renal blood flow, mediation of renin release, and regulation of sodium excretion. Therefore, in conditions of relative intravascular volume depletion and/or renal hypoperfusion such as dehydration, hemorrhage, hemodynamic compromise, heart failure, and renal disease, interference with COX-2 activity can have significant deleterious effects on renal blood flow and glomerular filtration rate.

The pharmacokinetics of NSAIDs are typically measured from plasma samples but it is important to remember that tissue kinetics may differ significantly, with drugs that have short plasma half-lives being active in the tissue long after the drug has disappeared from the plasma. In mammals this has been evaluated using tissue cages, where it is possible to measure the effect and duration of the NSAID by quantitating the effect on prostaglandins in the tissue. With robenacoxib in cats for example, the mean residence time (MRT) following oral administration was 3.3 hours whereas the MRT in tissue was 24 hours (Pelligand et al. 2012). To the authors knowledge only a single report describes the use of this model in turkeys for evaluation of

sodium salicylate (Cramer et al. 2015) but the researchers did not include plasma concentrations.

Meloxicam is the most widely used anti-inflammatory medication today in avian practice. Meloxicam is a COX-2-selective NSAID that demonstrates COX-1 selectivity at higher doses (Baert & De Backer 2002a, 2003; Castineiras et al. 2021). Meloxicam is currently available in the United States as an oral tablet, oral suspension, and injectable formulation. Single-dose pharmacokinetic studies of meloxicam in chickens (Baert & De Backer 2002a; Souza et al. 2018, 2021), ostriches (*Struthio camelus*; Baert & De Backer 2002a), emus (*Dromaius novaehollandiae*; Baert & De Backer 2002b; Castineiras et al. 2020), mallard ducks (Baert & De Backer 2003), Bilgorajska geese (Sartini et al. 2020), brown pelicans (*Pelecanus occidentalis*; Horgan et al. 2020), turkeys (*Meleagris* spp.; Baert & De Backer 2003), Japanese quail (*Coturnix japonica*; Turk et al. 2021a), Chukar partridge (*Alectoris chukar*; Cetin et al. 2021), pigeons (Baert & De Backer 2003), zebra finches (Miller et al. 2019), ring-necked parakeets *(Psittacula krameria*; Wilson et al. 2004), Hispaniolan Amazon parrots (Molter et al. 2013), African grey parrots (Montesinos et al. 2011), cockatiels (*Nymphicus hollandicus*; Dhondt et al. 2017; Gasthuys et al. 2019), flamingos (*Phoeniconaias minor, Phoeconipterus ruber, Phoeconipterus ruber*; Boonstra et al. 2017; Lindemann et al. 2016; Zordan et al. 2016), African penguins (*Sphenicus demersus*; Morrison et al. 2018), red-tailed hawks and great-horned owls (Lacasse et al. 2013), and multiple vulture species (*Gyps africanus, Gyps coprotheres, Torgos tracheliotos*, and *Neophron pernopterus*; Naidoo et al. 2008) have been published.

Differences in dosage, bioavailability, clearance, and elimination half-lives most likely contribute to the clinical differences seen with the use of this NSAID. For example, the elimination half-life of meloxicam in chickens and pigeons is three times as long as that of ducks, ostriches, and turkeys (Baert & De Backer 2003). Meloxicam in Wyandotte hens had a greater area under the plasma concentration versus time curve, a smaller elimination rate constant, and longer terminal half-life, and the drug persisted longer in their egg yolks compared with white leghorn hens, suggesting the dosing interval of meloxicam administered PO may be every 24 hours as opposed to every 12 hours in white leghorn chickens. Following 1 mg/kg PO administration of meloxicam the elimination half-life and bioavailability of meloxicam in Hispaniolan Amazon parrots were 15.8 ± 8.6 hours and 49–75%, respectively (Molter et al. 2013). However, in African grey parrots following 1 mg/kg meloxicam PO the elimination half-life was twice that of Hispaniolan Amazon parrots, with significantly lower oral bioavailability (38.1% ± 3.6%) (Montesinos et al. 2017). In cockatiels, following 1 mg/kg meloxicam PO of the commercial formulation, it was found to have only 11% oral bioavailability and an elimination half-life of less than 1 hour (Dhondt et al. 2017). The highly variable bioavailability in avian species (Lacasse et al. 2013; Molter et al. 2013; Montesinos et al. 2011) is quite different to that in mammals where it is usually 85% or greater (Dhondt et al. 2017). A possible explanation could be variability in proventricular pH among species (Montesinos et al. 2017). In a multiple-dose pharmacokinetic study performed in African grey parrots evaluating three different dosages (1 mg/kg IM q24h (once a day), 1 mg/kg PO q24h, and 1.6 mg/kg PO q24h) plasma concentrations were maintained at values greater than effective analgesic concentrations described for other avian species and evidence of moderate drug accumulation was found with both IM and PO routes of administration (Montesinos et al. 2019). In white leghorn chickens, dosing of meloxicam 1 mg/kg PO q12h for 5 days resulted in the presence of meloxicam residues in eggs in the yolks and whites after 8 and 3 days, respectively (Souza et al. 2018) whereas Wyandotte chickens administered a single 1 mg/kg dose showed residues at 4 and 9 days, respectively (Souza et al. 2021). Based on these results, a 2-week withdrawal time should be adequate to avoid drug residues in eggs meant for consumption (Souza et al. 2018, 2021). Meloxicam was also identified in two out of three unfertilized eggs of captive bearded vultures after breeding failure, but the implication is unclear (Zorrilla et al. 2018). The large variability in pharmacokinetics between avian species is one of the main issues with analgesic therapy in birds, as cross-species allometric scaling is not reliable and therefore pharmacokinetic/pharmacodynamic analysis is required in every species (Baert & De Backer 2003).

A sustained-release formulation of meloxicam (Meloxicam SR, Wildlife Pharmaceuticals, Windsor, CO, USA) has been evaluated in two species: Hispaniolan Amazon parrots (Guzman et al. 2017a) and American flamingos (Sim & Cox 2018). Based on the results of these studies its use cannot be recommended due to huge pharmacokinetic variability (parrots) and lack of difference from standard meloxicam (flamingos).

There are very few studies evaluating the pharmacodynamics of meloxicam to date. In an experimental trial in lame chickens, meloxicam significantly increased the thermal threshold compared to saline (Hothersall et al. 2014). Administration of meloxicam at 0.5 or 2 mg/kg IM reduced clinical signs associated with experimental systemic inflammation induced by *E. coli* lipopolysaccharide in broiler chickens, but dexamethasone was ultimately preferred by the authors for its clinical effects of reducing the acute inflammation (Nakhaee et al. 2021).

Since higher doses of meloxicam can block COX-1 enzyme activity, this drug has the potential to induce the adverse effects of gastrointestinal, renal, and cardiac toxicity seen in mammals, yet reports of intoxication at doses used in avian practice are minimal. In a number of studies evaluating the adverse effects of meloxicam in budgerigars (*Melopsittacus undulates*, 0.1 mg/kg IM; Pereira & Werther 2007), African grey parrots (0.5 mg/kg IM; Montesinos et al. 2015), zebra finches (1–2 mg/kg PO; Miller et al. 2019), domestic pigeons (2 mg/kg IM; Desmarchelier et al. 2012b), Japanese quail (2 mg/kg IM; Sinclair et al. 2012), American kestrels (*Falco sparverius*, 2–20 mg/kg PO; Summa et al. 2017), and Hispaniolan Amazon parrots (1.6 mg/kg PO; Dijkstra et al. 2015), no significant renal, gastrointestinal, or hemostatic adverse effects were reported at doses in the therapeutic range. However, two out of nine American kestrels had gastric ulceration after a dose of 20 mg/kg (Summa et al. 2017). Plasma and urine N-acetyl-β-D-glucosaminidase activities were significantly increased in African grey parrots at 1.6 mg/kg meloxicam administered PO every 24 hours for 7 days (Montesinos et al. 2019). Elimination half-lives of meloxicam are highly variable, as indicated above, and those species with rapid elimination (Dhondt et al. 2017) are less likely to have adverse effects. Anecdotal reports of visceral gout and gastrointestinal ulceration in brown pelicans, using dosages commonly used in other species, prompted a pharmacokinetic study using a single dose of 0.2 mg/kg PO. The elimination half-life was 36 hours, the highest reported to date in any species, heightening suspicion that adverse effects, including renal toxicity, may be attributed to this (Horgan et al. 2020). The renal effects of NSAIDs have been of particular concern in the Asian vultures (*Gyps bengalensis*, *G. indicus*, and *G. tenuirostris*) (Naidoo et al. 2010; Oaks et al. 2004) but meloxicam may be the exception because of its short elimination half-life (<1 hour) (Swarup et al. 2007). However, recently meloxicam was detected in eggs of captive bearded vultures (*Gypaetus barbatus*) (Zorrilla et al. 2018). Despite meloxicam's large therapeutic range and relative safety compared with other NSAIDs, these new data demonstrate that dose extrapolation is not a suitable method for meloxicam dose determination in avian species. Species-specific pharmacokinetic, efficacy, and toxicity studies are necessary to determine appropriate dosages for different species.

The newer NSAID coxibs celecoxib, mavacoxib, and robenacoxib are COX-2 selective as opposed to meloxicam, which is COX-2 preferential, inhibiting both COX-1 and COX-2. Celecoxib in humans is used for acute pain, osteoarthritis, rheumatoid arthritis, and spondylitis. Its use in veterinary medicine is off-label in the United States: it is not approved for use in any veterinary species. Celecoxib 10 mg/kg PO every 24 hours has been used to reduce inflammation associated with avian ganglioneuritis (Hoppes et al. 2013). A recent study in cockatiels using this dose did not alter the clinical presentation, viral shedding, gross lesions, histopathology, or viral distribution in cockatiels experimentally inoculated with PaBV-2 (Escandon et al. 2019), but the birds were infected with a large viral load inducing severe disease, so it is difficult to determine whether this drug has any efficacy against natural inflammation induced by this disease. Mavacoxib administered orally has a long mean half-life of 15.5 days in dogs, allowing for monthly dosing after two loading doses administered 1 week apart (Lees et al. 2015). Plasma concentrations of 0.4 μg/mL mavacoxib were associated with efficacy in reducing osteoarthritis in dogs (Payne-Johnson et al. 2014).

The single-dose pharmacokinetics and oral bioavailability of celecoxib 10 mg/kg PO and mavacoxib 4 mg/kg PO were evaluated in the cockatiel (Dhondt et al. 2017). Mavacoxib was completely absorbed (bioavailability = 111%) but celecoxib only had a mean oral bioavailability of 56% (Dhondt et al. 2017). Bioavailability of the coxibs is often directly associated with feeding status; the presence of food has been shown to increase absorption of both NSAIDs (Cox et al. 2010). The cockatiels in this study were fed ad libitum. A further study in cockatiels with ad libitum feeding and additional gavage feedings during the study showed that changes in body temperature, mentation, and posture were less pronounced with a single dose of mavacoxib 4 mg/kg PO compared to celecoxib 10 mg/kg at the tested dosages (Gasthuys et al. 2019). This is likely associated with the higher oral bioavailability of mavacoxib in cockatiels compared to celecoxib and meloxicam. Plasma concentrations of 0.4 μg/mL mavacoxib, found to be effective in osteoarthritic dogs (Cox et al. 2011), were maintained for 1000 hours in the cockatiels in the aforementioned studies (Dhondt et al. 2017; Gasthuys et al. 2019) and Caribbean flamingos maintained plasma concentrations >0.4 μg/mL for 120 hours after a single dose of 6 mg/kg (Huckins et al. 2020). Elimination half-lives in cockatiels (135 hours) (Dhondt et al. 2017) and Caribbean flamingos (*Phoenicopterus ruber*) (74.5 hours) (Huckins et al. 2020) were not as long as in dogs but are still much longer than most NSAID elimination half-lives in birds and prompts additional studies to determine dosing regimens (Huckins et al. 2020).

No studies have been published to date on the use of robenacoxib, also a long-acting COX NSAID, but it is being used anecdotally at 2–10 mg/kg IM (Lamb 2019) weekly initially, then monthly in birds with clinical avian bornavirus (Rossi et al. 2018) and West Nile virus. Robenacoxib is available as tablets and in an injectable formulation currently in the United States

The oral bioavailability of carprofen was reported to be 61% in Japanese quail (Turk et al. 2021a). Carprofen given SC improved the locomotion of lame domestic fowl significantly in a dose-dependent manner (McGeowen et al. 1999) and lame birds self-selected food containing carprofen (Danbury et al. 2000). When carprofen was administered at 3–4 mg/kg in drinking water, 15% of birds died on day 10 of treatment so short-term (<7 days) therapy for lameness was recommended (Hadipour et al. 2011). Carprofen administered at 3 mg/kg IM q12h was insufficient to restore weight-bearing in induced arthritis in Hispaniolan Amazon parrots (Paul-Murphy et al. 2009b). The author (M.G.H.) has used this NSAID (1–4 mg/kg PO, SC, and IM q12–24h) short-term (<7 days) in many species. In pigeons, doses of 2, 5, and 10 mg/kg given IM once daily over 7 days resulted in significant increases in alanine aminotransferase and aspartate aminotransferase, and a mild decrease in total protein (primarily globulin) (Zollinger et al. 2011). Additionally, small intestinal vascular congestion was noted grossly and hepatic necrosis, renal congestion, and myodegeneration of the pectoral muscles were noted histologically. These effects were significantly associated with dosing (Zollinger et al. 2011). While not significant, hepatic lipidosis was also noted and the frequency increased with dose. The authors speculate this may be secondary to decreased food consumption noted in pigeons within the highest dosing group (Zollinger et al. 2011).

Even though it is believed that carprofen ingested by Gyps vultures does not pose a toxic risk like diclofenac, there are still concerns about its safety in these birds. A recent pharmacokinetic and toxicokinetic study in white-backed vultures (*Gyps africanus*) of 5 mg/kg administered IV, IM, and PO for the pharmacokinetic study and a subset of birds were administered the dosage found at injection sites in cattle (64 mg/kg) for the toxicology study. Carprofen was well tolerated at 5 mg/kg via all routes of administration, but oral bioavailability was only 42% (Naidoo et al. 2018). One vulture died in the toxicology, study with elevations of uric acid and potassium identified, like toxicity found with diclofenac and ketoprofen in Gyps vultures. The authors suggest that carprofen should not be used in domesticated ungulates in areas where carcasses are accessible or provided to vultures at supplementary feeding sites (Naidoo et al. 2018).

Ketoprofen is commonly used parenterally because of limited oral pharmacokinetic data and difficulty in accurately dosing in small species. In Japanese quail (*Coturnix japonica*) ketoprofen (2 mg/kg PO, IM, IV) showed very low oral (24%) and IM (54%) bioavailability and the shortest half-life reported for any species (Graham et al. 2005). Additional studies are needed to determine whether drug formulation or interspecies physiologic contrasts account for these differences. In mallard ducks ketoprofen (5 mg/kg IM) decreased blood thromboxane B_2 levels for approximately 12 hours (Machin et al. 2001).

Ketoprofen and meloxicam were detected in the eggs of captive-reared bearded vultures (Zorrilla et al. 2018). Two studies evaluating the effects of an extraordinarily high single dose (50 mg/kg IM) of ketoprofen, as a premedication to ketamine and midazolam in pigeons, found no significant clinical differences, biochemistry analytes, or histopathology between the groups (Hajizadeh et al. 2018a,b). Regardless of their findings, the extremely high dosing of this drug should be reviewed in multidose studies and with the utmost caution before considering it for clinical use.

Piroxicam is a nonselective NSAID used for its anti-inflammatory properties and its value as a chemopreventative and antitumor agent. It has a much higher potency against COX-1 than COX-2. In chickens, IM administration of 1–2 mg/kg of piroxicam twice daily for 4 days failed to result in gastrointestinal lesions consistent with toxicity (Awan et al. 2012). Piroxicam has been used in cranes for more than 20 years to treat a variety of conditions including trauma, inflammation, and postoperative pain with minimal observed side effects (Keiper et al. 2017). A pharmacokinetic study in brolga cranes (*Grus rubicunda*) evaluated two single doses of 0.5 and 1 mg/kg PO, finding that daily administration might be appropriate for this species based on plasma concentrations (Keiper et al. 2017).

Scavenging bird species such as vultures and eagles may be exposed to NSAIDs when they feed on livestock carcasses (Green et al. 2016; Sharma et al. 2014). The NSAID diclofenac played the major role in the catastrophic decline in vulture populations on the Indian subcontinent (Swan et al. 2006). Subsequently, other NSAIDs have also been identified as toxic to vultures. Ketoprofen and nimesulfide, a sulfonamide NSAID, caused visceral gout and death in vultures whereas meloxicam and tolfenamic acid (TA) were reported to be safe (Chandramohan et al. 2022; Cuthbert et al. 2016; Galligan et al. 2021, 2022; Naidoo et al. 2010; Nambirajan et al. 2021; Stokstad 2021).

Other NSAIDs must be identified to reduce the use of those toxic to vultures and other scavengers. TA is an NSAID belonging to the fenamates group (Lascelles et al. 2007). This NSAID inhibits both COX-1 and COX-2 receptor activity and exerts potent antitumor activity by both COX-dependent and -independent pathways (Corell 1994). TA was detected in 20% Eurasian griffon vulture (*Gyps fulvus*) nestling samples (Gómez-Ramírez et al. 2020), suggesting it is being used more frequently by veterinarians in the region. A study evaluated the safety of

TA in three *Gyps* species, all of which are susceptible to diclofenac poisoning. Two birds administered 3.5 mg/kg TA PO via gavage died with elevated uric acid levels and severe visceral gout, yet the remainder showed no adverse clinical or biochemical signs at the same or even higher dosages, suggesting the deaths may have been an anomaly due to the high dose used and the high ambient temperatures at the time of the experiment (Chandramohan et al. 2022). TA is likely to be safe to *Gyps* vultures at concentrations encountered by wild birds and could therefore be promoted as a safe alternative to toxic NSAIDs (Chandramohan et al. 2022).

To date only the pharmacokinetics of TA in chukar partridge (Cetin et al. 2021), Japanese quail (Turk et al. 2021a), and geese (*Anser cygnoides*)(Turk et al. 2021b) have been reported. The terminal elimination half-lives ($t_{1/2}\lambda_z$)of TA administered PO in chukar partridges, Japanese quail, and geese were 1.25, 1.95, and 2.31 hours, quite similar to meloxicam (Cetin et al. 2021; Turk et al. 2021b). These short $t_{1/2}\lambda_z$ are important in preventing drug accumulation and delaying toxic effects in repeated administrations in birds (Naidoo et al. 2008). Bioavailability after a 2 mg/kg dose was 88, 78, and 76% for the IM, SC, and oral routes, respectively in geese, and 57% via the oral route in Japanese quail, suggesting good absorption in these species.

Currently there are no specific dosing recommendations for TA in birds, but it is recommended at doses of 2–4 mg/kg in mammals and reptiles (Corum et al. 2019; Tekeli et al. 2020). While the few studies to date are promising, additional studies evaluating clinical efficacy, multidose pharmacokinetics, safety, and residue data of tolfenamic acid should be conducted before widespread use of TA in birds at mammalian doses.

Prostaglandin Receptor Antagonists

Grapiprant is a prostaglandin E2 (PGE_2) receptor antagonist approved for use in dogs in the United States. Grapiprant binds to the E-type prostanoid receptor 4, blocking the sensitization of sensory neurons and stimulation of inflammation, mediated by the PGE_2 receptor. It does not rely on inhibition of COX enzymes and preserves functions associated with COX enzyme pathways. Oral administration of grapiprant at 30 mg/kg to fasted red-tailed hawks achieved plasma concentrations approximately 100 times the canine therapeutic concentrations with no adverse effects identified. It is still unknown whether the dog concentrations are analgesic in birds or toxic in hawks after multidosing (Rodriguez et al. 2021). Grapiprant administered at the same dosage to the same red-tailed hawks with food had significantly lower plasma concentrations compared to when fasted, with delayed absorption and similar half-lives (M.G. Hawkins, pers. comm.). Due to the concern that target plasma concentrations may not be maintained if this dosage is administered every 24 hours versus every 12 hours, multidose modeling simulations showed that the concentrations troughs are still above the target plasma concentrations in dogs for analgesia (M.G. Hawkins, pers. comm.). Further studies to evaluate the pharmacokinetics and pharmacodynamics of multidose grapiprant with food in red-tailed hawks are underway.

Gabapentin

Gabapentin is an analog of the neurotransmitter gaba-aminobutyric acid that binds to voltage-gated calcium channels acting presynaptically to decrease the release of excitatory neurotransmitters, especially glutamate. In humans and animals, it is best used as an adjunct to other analgesics and seems to be most effective for neuropathic pain. Some formulations of gabapentin contain xylitol and these should not be used in birds until further safety evidence is available. The pharmacokinetics of gabapentin have been evaluated in several species. The oral bioavailability was found to be high (>80%) in one species (Hispaniolan Amazon parrots, *Amazona ventralis*) (Baine et al. 2015) and the peak plasma concentration occurs between 0.5 and 2.5 hours (Baine et al. 2015; Browning et al. 2018; Yaw et al. 2015). The terminal elimination half-life has been in the range of 3–5 hours and so gabapentin should be administered two or three times per day to maintain adequate plasma concentrations. In great horned owls (*Bubo virginianus*) following oral administration of 11 mg/kg PO, plasma gabapentin concentrations were maintained above 2 ug/mL for 9.6 hours (Yaw et al. 2015). In Caribbean flamingos (*Phoenicopterus ruber ruber*), gabapentin dosed at 25 mg/kg orally in most Caribbean flamingos maintained plasma concentrations above the therapeutic range established for humans for approximately 12 hours; however, dosages as high as 37 mg/kg orally every 12 hours may be needed in some individuals. Pregabalin is like gabapentin but its use in birds has not been described.

Amantadine

Amantadine is an antiviral medication that increases dopamine in the central nervous system and weakly inhibits the NMDA receptors that contribute to chronic pain (KuKanich 2013). Amantadine is synergistic with NSAIDs, opioids, and gabapentin/pregabalin. In humans,

amantadine has been shown to decrease opioid use in postoperative patients, decrease pain in postherpetic neuralgia, and aid in neuropathic pain (Abd Elmawgood et al. 2015; Bujak-Giżycka et al. 2012). Amantadine administered to dogs at 3–5 mg/kg orally every 24 hours with meloxicam showed significant improvement in management of osteoarthritis pain refractory to meloxicam alone (Lascelles et al. 2008). In orange-winged Amazon parrots, the single- and multiple-dose pharmacokinetic profile was evaluated following 10 mg/kg PO once and 5 mg/kg PO every 24 hours for 7 days (Berg et al. 2020). The heart rate, respiratory rate, behavior, and urofeces were monitored. Mean ± standard deviation maximum plasma concentration, time to maximum plasma concentration, and half-life were 1174 ± 186 ng/mL, 3.75 hours, and 23.2 hours, respectively, for the single-dose study and 1185 ± 270 ng/mL, 3.0 hours, and 21.5 hours, respectively, for the multiple-dose study at steady state. No obvious adverse effects were observed. Based on these results, once-daily administration of amantadine at 5 mg/kg orally in orange-winged Amazon parrots can maintain above-target plasma concentrations with weak accumulation. For long-term administration, especially for other species, it is recommended to check plasma concentrations over time. Further studies evaluating the safety and efficacy of amantadine in orange-winged Amazon parrots and other avian species is warranted. The use of amantadine in chickens, ducks, and turkeys is prohibited in the United States by the Federal Drug Administration.

Cannabidiol

Cannabidiol (CBD) oil is the primary nonpsychoactive cannabinoid derived from the cannabis plant (*Cannabis sativa*). The pharmacokinetics of a CBD oral formulation (50 mg/mL; Canna Companion, Mill Creek, WA, USA) have been evaluated in Hispaniolan Amazon parrots. The highly variable results and short half-life of the drug in Hispaniolan Amazon parrots, even at high doses, suggests that this formulation would have to be administered at least three or four times daily. Evaluation of other formulations and in other species is recommended to further characterize the analgesic potential of CBD in birds.

Balanced or Multimodal Analgesia

Combinations of drugs acting at different points in the nociceptive system are more effective and less toxic than either drug given alone. For example, opioids act centrally to limit nociceptive input whereas NSAIDS act peripherally to decrease inflammation, limiting the nociceptive information that enters the CNS. Synergy has been demonstrated in laboratory animals (Malmberg & Yaksh 1993) and is being tested in the clinical environment.
