International Standard Book Number-13: 978-1-4987-1656-7 (eBook - PDF)

This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the drug companies' printed instructions, and their websites, before administering any of the drugs recommended in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Except as permitted under U.S. Copyright Law, no part of this book may be reprinted, reproduced, transmitted, or utilized in any form by any electronic, mechanical, or other means, now known or hereafter invented, including photocopying, microfilming, and recording, or in any information storage or retrieval system, without written permission from the publishers.

For permission to photocopy or use material electronically from this work, please access www.copyright.com (http://www.copyright.com/) or contact the Copyright Clearance Center, Inc. (CCC), 222 Rosewood Drive, Danvers, MA 01923, 978-750-8400. CCC is a not-for-profit organization that provides licenses and registration for a variety of users. For organizations that have been granted a photocopy license by the CCC, a separate system of payment has been arranged.

Preface

This book has been a long time coming and has taken many hours of sweat and tears to finish. It has been anticipated for several years and has been delayed because of the extensive amount of new and refurbished art work which was required. The book is designed to be a concise, comprehensive and highly graphic presentation of small animal surgery for the practicing veterinarian. It represents the viewpoints and surgical approaches of distinguished leaders in the various surgical fields and is therefore a valuable reference and review of the procedures that the veterinary practitioner is often called upon to perform. I have had innumerable veterinarians call me and say that they use this book daily and could not do the surgery they do without it. I instructed the authors to make each procedure accurate and current. Detailed but clear artwork accompanies each procedure and continues to be an important feature of this book for both students and practitioners. In this day and age the general small animal practitioner is asked to do more and more complicated procedures since many clients cannot afford a specialist. This book makes it possible for them to safely and accurately perform a broader range of procedures, and I have had many veterinarians tell me that they consider this the "bible" and that they could not practice without it. This new edition has been highly anticipated and is finally completed. I must thank each and every author for their hard work, dedication and patience throughout the revision process. My special thanks go to Drs. Waldron and Toombs, consulting soft tissue and orthopedic editors. Their untiring dedication made this book finally become a reality.

M. Joseph Bojrab DVM, MS, PhD.

Dedication

I am dedicating this book to my brother Dr. Donald Charles Bojrab, an outstanding veterinarian in St. Louis MO. Don's not only an excellent small animal practitioner, he is a wonderful human being. He is intelligent, compassionate, unselfish and loving. When our 98 year old mother developed Osteoporosis and was in severe pain for over a year, he flew to Fort Wayne, IN every other week to care for her. At the end he spent 3 months there caring for her before she died, leaving his St. Louis practice on auto pilot. I love him and my sister Darlene dearly.

M. Joseph Bojrab DVM, MS, PhD.

Contributors

Jonathan Abbott, DVM, DACVIM (Cardiology)
Associate Professor
VA-MD Regional College of Veterinary Medicine
Department of Small Animal Clinical Sciences
Blacksburg, VA

Chapter 1

Selection and use of currently available Suture Materials and Needles

Suture Materials and Needles

Daniel D. Smeak

Introduction

Surgeons rely on suture materials to provide critical support of healing tissues during wound repair. A wide variety of suture material types have been developed, each with their own advantages and limitations. The general performance of suture materials is based on their distinct physical properties, handling characteristics, and biological properties. An ideal suture should have acceptable handling characteristics, knot security, and tensile strength. Besides predictable performance, sutures should remain strong enough to prevent disruption of the wound until healing is complete and, ideally, the suture should undergo complete resorption over time. The suture should be sterile, nonallergenic, noncarcinogenic, stable in a contaminated environment, and it should elicit minimal reaction when buried in tissue. In most cases, there are many suture material choices that would be acceptable for wound repair because many have similar general characteristics but are developed by separate manufacturers. However, there is no ideal suture for every procedure, largely because each wound is different and must be considered individually. An otherwise identical wound created in a similar body region may require different suture considerations due to such factors as degree of bacterial contamination, whether there is a local or systemic factor which would delay healing, and even how active the patient may be after surgery. The most critical factors related to the choice of suture include how long the suture is needed to support the wound, and the mechanical and healing properties of the tissue undergoing repair. The surgeon must understand the nature of the suture material, the biological forces in the healing wound, and the interaction of suture and tissues when selecting suture material. This chapter reviews the characteristics of commonly used and newer suture materials, and needles in small animal surgery. Various wound related factors are discussed, which provide the rationale for choosing appropriate suture materials and needles.

Suture Classification and Definitions

Suture materials are classified as absorbable or nonabsorbable, natural or synthetic, monofilament or multifilament, according to their structure and composition (Table 1-1).

Absorbable suture materials undergo degradation and rapid loss of tensile strength within 60 days, whereas nonabsorbable suture materials retain significant strength past 60 days. This definition can be misleading with respect to silk, cotton, linen, and multifilament nylon sutures because these materials are considered nonabsorbable, yet they lose a portion of their tensile strength within 4 to 6 weeks after implantation. Natural materials (chromic gut, silk) are absorbed by enzymatic degradation and phagocytosis, while the newer synthetic sutures are more predictably absorbed through nonenzymatic hydrolysis. In addition, synthetic sutures generally cause less tissue reaction than natural ones. Monofilament sutures are made of a single strand so they resist harboring of bacteria. Multifilament or braided sutures are woven or twisted from many smaller strands. In general, multifilament suture materials are easier to handle than monofilaments. Multifilament sutures (particularly uncoated ones) often create more friction (chatter) as they are passed through tissues when compared to the smoother monofilaments. Excess friction can cause suture-tissue sawing and cutout, especially when suturing friable tissues with a continuous pattern. Multifilament sutures can be capillary, or act as a wick. This quality is undesirable since fluid and bacteria can travel along the suture and contaminate adjacent areas. The chemical composition and coating influence the capillary nature of a suture. For example, coated caprolactam transports nearly twice as much fluid as uncoated polyester of the same suture size. Waxed silk is not capillary, in contrast to the highly capillary nature of uncoated virgin silk. Capillary suture materials are not recommended when sutures could penetrate or become exposed to contaminated or infected areas.

Suture Selection and Use

When choosing a suture material, certain general principles based on the strength of the tissue being closed, the rate of gain in wound strength after closure, and various biological and mechanical suture characteristics should be considered. After considering these factors, the surgeon may have several choices of appropriate suture material that would be acceptable for use in the wound. Selection can then be made on the basis of familiarity with the material, its ease in handling, and other subjective preferences, such as color, or needle selection.

Strength of Tissue

A suture should be at least as strong as the tissue through which it passes. A tissue's ability to hold sutures without tearing depends on its collagen content and on the orientation of collagen fibrils. This explains why ligaments, tendons, fascia, and skin are strongest, muscle is relatively weak, and fat is weakest. Muscle has little suture-holding capability across its fibers and even less in the direction of the fibers. Visceral tissue, in general, ranks between fat and muscle in strength. Bladder and colon are the weakest hollow organs of the body, and stomach and small

intestine are among the strongest. Tissue strength varies within the same organ and with the age and size of the animal.

The choice of suture size is based on the tensile strength of the tissue as well as of the suture material. Catgut and synthetic suture materials are sized according to either United States Pharmacopeia (USP) or metric gauge (Table 1-2). A larger numeric USP value means a larger-diameter suture. Stated numerically, the more zeros (0s) in the number, the smaller the strand. (e.g., 2 polypropylene is larger than 0, and 2-0 is larger than 4-0). The metric gauge is the actual suture diameter expressed in millimeters multiplied by 10. Stainless steel suture can be sized by USP, metric gauge, or Brown and Sharpe wire gauge. Ranges of suture size recommendations for various tissues and surgical applications are provided in Table 1-3. These guidelines are general and are based on currently available literature and my experience. Larger sizes are used in heavier animals, in critical suture lines such as the abdominal fascia, or in tissues closed under excessive tension. The surgeon should strive to use the smallest suture size possible for wound closure since this will result in less tissue trauma, allow smaller knots to be tied, and encourage the surgeon to handle the sutures and tissue more carefully. Oversized sutures can actually weaken the wound through excessive tissue reaction and tissue strangulation. To maintain maximum suture strength once the suture is removed from the packet, certain suture handling rules are suggested (Table 1-4).

Loss of Suture Strength and Gain of Wound Strength

To use absorbable sutures safely, the loss of suture strength should be proportional to the anticipated gain in wound strength. The relative rates of suture strength loss and simultaneous wound strength gain are important to consider. Fascia, tendons, and ligaments heal slowly (50% strength gain in 40-50 days) and are under constant tensile force. For these tissues, nonabsorbable sutures or the prolonged-degrading, synthetic absorbable sutures are indicated. Maxon® and PDS II® sutures can be used whenever an absorbable suture is needed, but these should be considered especially in wounds that are expected to require suture support for more than 3 weeks (such as abdominal wall fascia). Because visceral wounds heal relatively fast, often achieving most of their strength in 21 days, rapid to intermediate-degrading absorbable sutures (Table 1-1) are good choices. Rapidly-degrading synthetic sutures (Caprosyn®, Monocryl®, Vicryl Rapide®) are indicated in rapidly healing tissues such as the mucosal lining of the mouth or urogenital tract where suture removal is not possible or undesirable. The more intermediate-degrading sutures such as (Vicryl®, Dexon®, and Biosyn®) are often chosen to close wounds that are expected to heal within 3 weeks, such as the subcutaneous tissue and muscle. Monofilament nonabsorbable sutures are suggested for skin closure because they induce little foreign body response and skin sutures should remain strong since they are subject to chewing and wear. These sutures also provide long-term stability in procedures involving fascia, tendons, and vascular prostheses. Systemic and local factors affecting wound healing must also be considered before an appropriate suture is selected. For example, catgut in the presence of infection or gastric secretions, or when placed in a catabolic patient can be degraded within days, rendering the wound closure susceptible to dehiscence. When healing is expected to be delayed, prolonged absorbable sutures or nonabsorbable sutures are better choices.

Healing Considerations

Surgeons must consider how the suture alters the biologic processes in a healing wound environment. Regardless of its composition, suture material is a foreign body to tissues in which it is implanted, and to a greater or lesser degree will elicit a foreign body reaction. The amount of reaction depends on the nature of the suture implanted (e.g., surgical gut versus inert, stainless steel), the amount of surface area and coating of the suture, the type and location of tissue closed (intestinal viscera and skin react strongly to silk, whereas fascia reacts minimally to silk), the length of implantation (polyglycolic acid, or Dexon II®, is moderately reactive early but within months is relatively inert), and the technique of suture placement (excessive suture tightening causes tissue strangulation). Excessive suture-induced tissue reaction increases the likelihood of suture-tissue cutout by softening surrounding tissues, increases the risk of infection, and delays the onset of fibroplasia. Sutures causing excessive tissue reaction are contraindicated in areas in which exuberant scar formation can cause a functional problem (e.g., for vascular repair or ureteral anastomosis) or a cosmetic problem (e.g., in skin). The surgeon should strive to inflict the least amount of trauma necessary for the operation, to reduce contamination, and to use sutures that cause the least tissue reaction to avoid excessive inflammation and delayed wound healing. Relatively speaking, it is not the suture material but the surgeon that causes inflammation within a wound, since most reaction is induced during tissue manipulation and the act of suturing.

All suture materials are capable of increasing wound susceptibility to infection. The suture's filamentous nature, capillarity, chemical structure, bioinertness, and ability to adhere to bacteria all play a role in suture related infection. In a classic experiment, a single silk suture reduced the total contaminating dose of Staphylococcus required to induce wound infection 10,000 fold. On the other hand, the byproducts of nylon and polyglycolic acid suture degradation in tissues may have beneficial bactericidal effects. A newer synthetic absorbable suture with an antibacterial coating has been developed specifically for use in contaminated wounds (see discussion under newly developed sutures). In general, sutures that induce the least foreign body reaction in tissues, such as monofilament synthetic absorbable and nonabsorbable sutures, produce the lowest incidence of infection in contaminated wounds. If possible, suture should not be implanted in highly contaminated wounds or wounds with a high risk of infection.

Multifilament nonabsorbable suture materials induce chronic sinus formation more often than absorbable or monofilament sutures. Multifilament nonabsorbable sutures harbor bacteria within the suture interstices, creating an effective barrier to phagocytosis. These sutures should never be used in contaminated wounds. Wound infection also increases the rate of loss of

Table 1-1. Common Sutures and their Salient Characteristics

Classification	Suture Trade Name	Origin	Filament Type	Absorption	Completion of Absorption
Absorbable Rapid					
	Surgical gut suture Chromic gut suture	collagen derived from beef and sheep	multi	(variable) 33% loss - 7 days 67% loss - 28 days	(variable) 60 - 90 days
	Vicryl Rapide (polyglactin 910)	copolymer of lactide and glycolide	multi	50% loss- 5 days 100% loss -14 days	42 days
	Caprosyn (polyglytone 6211)	glycolide, caprolactone, trimethylene carbonate, lactide	mono	50% loss - 7 days 100% loss - 21 days	56 days
	Monocryl (poliglecaprone 25)	copolymer glycolide and epsilon-capro-lactone	mono	40-50% loss - 7 days 100% loss - 21 days	91- 119 days
Absorbable Intermediate					
	Coated Vicryl and Vicryl PlusAntibac-terial (polyglactin 910, triclosan coating-Plus)	copolymer of lactide and glycolide	multi	25% loss -14 days 50% loss - 21 days	56 - 70 days
	Dexon S Dexon II (coated and uncoated polyglycolic acid)	homopolymer of glycolic acid II - polycaprolate coating	multi	35% loss -14 days 65% loss - 21 days	60 - 90 days
	Polysorb (lactomer)	glycolide/lactide copolymer	multi	20% loss -14 days 70% loss - 21 days	56-70 days
	Biosyn (glycomer 631)	glycolide dioxanone trimethylene carbonate	mono	25% loss -14 days 60% loss - 21 days	90-110 days
Absorbable Prolonged					
	PDS II (polydioxanone)	polydioxanene polymer	mono	30% loss -14 days 50% loss - 28 days	180 - 210 days
	Maxon (polyglyconate)	glycolic acid, polytrim-ethylene carbonate	mono	25% loss - 14 days 50% loss - 28 days	180 days

Foreign Body Response	Relative Knot Security	Relative Tensile Strength	Handling Ease	Comments
				Rapidly absorbing sutures should not be used where extended approximation of tissue under stress is required.
moderate	fair	poor	fair	Unpredictable absorption particularly in highly vascular or inflamed tissue, or in presence of gastric secretions.
mild	fair to good	fair	good	Provides about 70% of initial strength of coated Vicryl. Less reactive than gut; indicated for superficial closure of mucous membranes.
mild	good	good	good	Designed to be an attractive alternative to chromic gut. Similar suture characteristics and applications as Monocryl. Excellent choice for bladder closure.
mild	good	good to excellent	good	Minimal tissue drag; handling qualities are very good for monofilaments. Ideal for mucosal suturing and subcutaneous tissue closure.
				General soft tissue approximation; use in visceral tissue where healing is mostly complete in 21 days. Intermediate absorbing suture should not be used where extended approximation of tissue under stress is required.
mild	fair to good	good	good	Plus-Triclosan coating added to provide antibacterial effect. This suture is not to be used close to the eye.
mild	fair to good	good to excellent	good	Smooth coating allows easier knot formation without flaking.
mild	fair to good	good	good	Improvements in braid construction and coating provide better flow through tissue and more knot security.
mild	good	good to excellent	good	Nice handling monofilament absorbable, very strong suture.
				These sutures are indicated when suture strength is needed well beyond 3 weeks; ideal for fascial closure.
mild	fair to good	excellent	good	Excellent general use absorbable material.
mild	fair to good	excellent	good	Similar to PDS II; tends to have more memory and less knot security in larger sizes.

Table 1-1. Common Sutures and their Salient Characteristics (continued)

Classification	Suture Trade Name	Origin	Filament Type	Absorption	Completion of Absorption
Nonabsorbable Monofilament					
	Dermalon Monosof	extruded polyamide filament	mono	—	Slow chemical degradation over years
	Novafil Vascufil (polybutester)	copolymer butylene polytetramethylene	mono	—	—
	Prolene Surgipro II Fluorofil	polymerized polyolefin hydrocarbons	mono	—	—
	Pronova	polyvinylidine polymer	mono	—	—
	Surgical steel suture (steel)	chromium nickel molybdenum alloy	mono	—	—
Nonabsorbable Multifilament					
	Surgilon	polyamide filaments	multi	slow chemical degradation over years	—
	Vetafil Braunamide Supramid	coated polyamide filaments	multi	—	—
	Ticron Surgidac Ethibond excel	polyester fibers (+/- coating)	multi	—	—
	Sofsilk Permabond	silkworm cocoon fibers	multi	30% loss - 14 days 50% loss - 365 days	greater than 720 days

Foreign Body Response	Relative Knot Security	Relative Tensile Strength	Handling Ease	Comments
				Use when long term suture strength is needed. These sutures are more stable in contaminated environments than the multi-filament nonabsorbables; less reactive in tissue.
minimal	fair to poor	good	fair to good	Careful knot tying technique with appropriate number of throws during use is suggested.
minimal	fair to good	good	very good	Soft pliable monofilament suture; excellent for plastic surgery.
minimal	good	good	fair	Greater knot security than many monofila-ments; least thrombogenic. Fluorofil glows under blacklight for easy location.
minimal	good to very good	excellent	good	Good alternative to polypropylene. Better strength and handling; less fraying.
minimal to none	excellent	excellent	poor	Knot ends can cause severe irritation. Tends to fragment and cut into tissue; must secure knots.
				Do not use multifilament nonabsorbable suture in contaminated environments. Use when long term suture strength is needed. Overall better handling than the monofilaments.
minimal	fair	good	good	Should not be used when permanent retention of suture strength is required.
minimal to moderate (if coating breaks)	good	good to excellent	good	Inexpensive suture material often supplied in reels. For external use only.
moderate	fair to poor	excellent	good to excellent	Uncoated sutures have excessive tissue drag. Careful knot tying technique and additional throws may be needed with coated sutures.
moderate	fair to poor	fair	excellent	Best handling multifilament suture.

0.7	3	5	20
0.8	4	6	19
0.9		7	18

To obtain metric gauge, multiply actual size (mm) by 10; for example, USP 0 catgut 0.4 mm in diameter is metric size 4.

strength of suture material. If wound contamination is suspected, synthetic absorbable sutures should be chosen because these sutures are more stable and have predictable absorption rates in contaminated tissue, when compared to chromic catgut. If long-term wound support is required of the suture material, synthetic monofilament nonabsorbables or synthetic (prolonged-degrading) absorbable sutures such as PDS II® or Maxon® are indicated.

The presence of any suture material within the lumen of the biliary or urinary tract can act as a nidus and induce calculus formation or chronic infection. Thus, more rapidly absorbable sutures are recommended in these areas, since they will not persist indefinitely in tissue. Silk and nonabsorbable polyester material, because of their documented calculogenic effects, should never be placed in contact with urine or bile. General guidelines to avoid suture-related complications in surgery are listed in Table 1-5.

Mechanical Properties of Suture and Tissue

The mechanical properties or functions of the suture should be similar to those of the tissue being closed. For example, polybutester (Novafil®), is a suture material that is very pliable and elongates and is most suitable for skin closure because it remains flexible and stretches with movement. More inelastic suture materials, such as those composed of polyester or nylon fibers, are more applicable for anchoring prosthetic materials or

Table 1-3. General Suture Size and Usage Recommendations in Small Animal Surgery

Tissue	Suture Size (USP)	Suture Material: Classes
Skin	3-0 to 4-0	Monofilament nonabsorbable
Subcutaneous tissue	2-0 to 4-0	Absorbable
Fascia	1 to 3-0	Synthetic (prolonged degrading) absorbable, or synthetic nonabsorbable
Muscle	0 to 3-0	Skeletal: synthetic (prolonged degrading) absorbable
		Cardiac: synthetic nonabsorbable
Parenchymal organ	2-0 to 4-0	Intermediate degrading absorbable
Hollow viscus organ	3-0 to 5-0	Monofilament absorbable
Tendon, ligament	0 to 3-0	Monofilament nonabsorbable
Nerve	5-0 to 7-0	Monofilament nonabsorbable
Cornea	8-0 to 10-0	Synthetic absorbable. nonmetallic nonabsorbable
Vascular ligation	0 to 4-0	Small vessels-absorbable; larger vessels- prolonged absorbable or nonabsorbable
Vascular repair	5-0 to 7-0	Monofilament nonabsorbable

for joint imbrication. Similarly, inelastic suture material such as stainless steel should not be used in tissues that stretch or are under constant motion because premature suture-tissue cutout or suture breakage could occur.

Newly Developed Sutures

Newer synthetic sutures have been developed to improve suture strength profiles without negatively affecting suture handling or knot security. The newer synthetic monofilament absorbable sutures are more pliable and better handling. Multifilament sutures may convert a contaminated wound into an infected one, so antibacterial coatings have been developed to inhibit bacterial growth in and around multifilament suture.

Table 1-4. Suture Handling and Storage Rules

1. Protect all sutures from heat and moisture.
2. Never autoclave absorbable sutures.
3. Refrain from soaking absorbable sutures, particularly in hot water.
4. Use strands directly from the packet; avoid excessive handling of suture strands before use.
5. Avoid suture kinking, or crushing suture with instruments.
6. Suture strands with "memory" may be straightened with a gentle tug.
7. Periodically check suture strands for evidence of fraying or defects, particularly when using a continuous suture pattern.

Polyvinylidine *Pronova® (Ethicon)*

This unique synthetic nonabsorbable monofilament suture is made of two polyvinylidine polymers, with a special extrusion process. This produces an optimal balance between suture strength and handling characteristics throughout the range of suture sizes. Pronova® suture sizes, 10-0 through 4-0, are composed of an 80/20 polymer blend, that emphasizes tensile strength without compromising handing in smaller sizes. Pronova® suture sizes, 2-0 through #2, are composed of a 50/50 polymer blend that improves handling in these larger sizes, without compromising tensile strength. This suture will remain secure in critical surgical procedures where life-long strength is desired, particularly in delicate applications where fine sutures are used. Tensile and knot strengths of Pronova® suture meet or exceed those of polypropylene suture in all sizes. The suture has excellent resistance to breakage, fraying, and instrument damage, and has reduced package memory. It is an excellent alternate choice when polypropylene suture is indicated. The suture is best for general soft tissue approximation and ligation including cardiovascular, ophthalmic, and neurologic applications. [Ethicon, Product Information; http://jnjgateway.com/home]

Polyglactin 910 and Triclosan *Coated Vicryl Plus Antibacterial® (Ethicon)*

This synthetic multifilament absorbable suture has an antiseptic coating (Triclosan) that creates a zone of inhibition around the suture site that decreases bacterial colonization of the suture or tissue. The suture performs and handles similarly to Coated Vicryl® suture. Vicryl Plus® is available in suture sizes, 5-0 through 0. It elicits a similar tissue reaction as other synthetic absorbable sutures, and considerably less inflammation than chromic gut sutures, but it should not be used close to the eye (Triclosan may be irritating to the eye). The manufacturer suggests using the suture in procedures that have a higher risk of infection. Few clinical studies have been conducted to substantiate the beneficial effects of this suture.

Glycomer 631 *Biosyn® (Syneture)*

This absorbable monofilament suture is prepared from a synthetic polyester composed of glycolide, dioxanone, and trimethylene carbonate. The advanced extrusion process gives the suture excellent initial strength and knot security and minimal memory. This suture elicits minimal acute inflammatory reaction in tissues. Like other synthetic absorbable sutures, eventual absorption is predictable by means of hydrolysis. Biosyn® sutures are available in sizes #1 through 6-0. The suture maintains 75% strength at two weeks and approximately 40% at three weeks after implantation. Similar to Dexon® and Vicryl®, this suture should not be used where extended approximation of tissue is required.

Table 1-5. General Rules to Avoid Most Suture-Related Complications

1. Avoid multifilament nonabsorbable suture material use in contaminated or infected wounds. Multifilament suture harbors bacteria and may cause persistent sinus formation, or local infection.
2. Avoid nonabsorbable suture exposure within the lumen of hollow organs, such as the urinary bladder or gall bladder, in which calculus formation at a suture nidus is possible.
3. Avoid burying nonabsorbable suture that has been taken from a used open cassette. Consider all suture from an open cassette contaminated.
4. If continued suture strength is important, avoid chromic gut in inflamed or infected tissue, and in wounds with delayed healing (catabolic conditions, radiation wounds, etc). Gut in contact with proteolytic enzymes such as in the stomach lumen or pancreas loses most of its strength within days of implantation.
5. Avoid rapidly absorbable suture material use in critical areas such as tendons or ligaments that are known to heal slowly and are under continual tensile force, or in wounds with delayed healing.
6. Use suture materials that cause less inflammation in wounds that are predisposed to stricture (such as tracheostomies or urethrostomies) or excessive scar formation (such as skin)
7. Avoid capillary/multifilament suture material penetration through known contaminated areas such as the bowel lumen or skin. Bacteria are "wicked" or may be transported to adjacent sterile tissues to form microabscesses around sutures.

Polyglytone 6211 *Caprosyn® (Syneture)*

This absorbable monofilament suture is prepared from a synthetic polyester composed of glycolide, caprolactone, trimethylene carbonate, and lactide. It has very good handling and knot tying characteristics due to its excellent pliability, and has low tissue reactivity. Caprosyn®, similar to Monocryl®, is useful for general subcutaneous tissue closure, urogenital surgery particularly in the urinary bladder, and where the benefits and rapid absorption may play a role in postoperative success.

Suture Knots

A knot consists of a minimum of 2 throws (sometimes termed simple knots). As a knot is created, the material is deformed, and depending on the properties of the material, this deformation may weaken the suture by as much as 50% of its original strength. Therefore, the knot is the weakest part of a suture. The technical performance of the knot is critical to the security of the wound

closure as well as the strength of the stitch. A square knot is least likely to untie or loosen so it is the knot of choice for most suture lines. Depending on how the throws are placed, three different knots can be formed (square knot, granny knot, or a half hitch shown in Figure 1-1). The latter two knots tend to slip and are generally avoided. Square knots are produced by reversing direction on each successive throw while maintaining equal tension on both strands as they are held parallel to the plane of the tissue. Failure to reverse direction of successive throws will result in granny knots. If one strand is pulled under more tension away from the plane of the knot than the other strand, with successive throws, a half hitch (or slip knot) is formed. Sometimes surgeons using monofilament sutures intentionally apply half hitch knots (especially if the wound is under tension) and this allows precise control of intrinsic suture tension. All half hitch knots must be completed with several square knots to prevent loosening. A surgeon's knot is similar to the square knot except one strand is fed through the loop twice on the first throw. The additional pass of suture in the loop produces increased friction. This knot is especially useful when attempting to knot a stitch when tissues are under tension. Multifilament absorbable sutures such as polyglycolic acid or polyglactin 910 may require surgeon's knots when used to close abdominal fascia. This knot is avoided when using gut since the increased friction tends to fray the material and excessively weakens it. Caution should be exercised with using surgeon's knots during vessel ligation, since the bulk of the first throw may not allow complete occlusion of the vessel, and the knot is less reliable than the standard square knot. Surgeon's knots have increased bulk and are asymmetric, so this knot is used only when necessary.

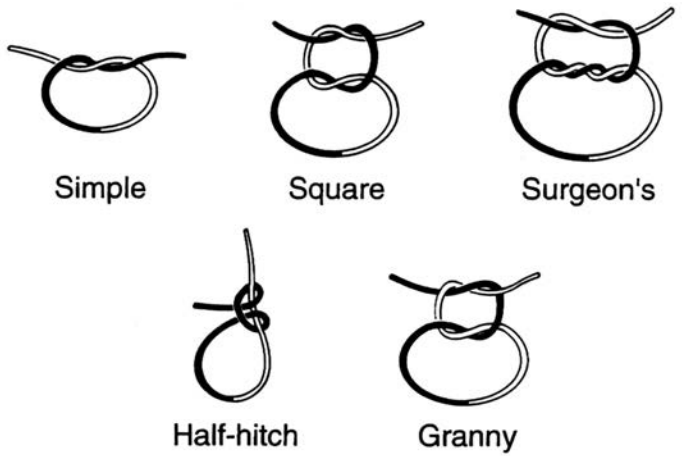

Figure 1-1. Surgical Knots.

Additional factors that influence knot security are the material coefficient, the length of the suture ends (ears), as well as the structural configuration of the knot, mentioned previously. Knots that swell (chromic catgut) or knots formed from stiff suture (ones with memory), require longer knot ears in general. Multifilament sutures possess a higher coefficient of friction, and have better knot-holding properties than the monofilaments in general; however, coating the strands to reduce friction or chatter in tissue also reduces knot security. Three single reversed throws are generally sufficient to secure knots in suture materials with high coefficients of friction and minimal tension. When using monofilament sutures (such as nylon or polydioxanone), or coated multifilament sutures, four or more throws should be applied. In a continuous suture line, the final knot (consisting of a loop and single strand) should have a minimum of 5 throws to be secure. General knot tying rules are included in Table 1-6.

Table 1-6. Knot Tying Principles

1. The primary objective in knot tying is to ensure knot security. The square knot is almost exclusively used since it is the simplest, most secure knot.
2. Use appropriate sized suture to keep the knot as small as possible. Knots in smaller sized material generally are more secure.
3. Avoid friction as the knot throws are tightened. Attempt to tighten throws by pulling in opposite directions, in a horizontal plane, with similar rate and tension.
4. Do not crush or kink suture with surgical instruments while knot tying. Grasp suture only on the end that will be discarded.
5. Avoid excessive intrinsic suture tension to reduce tissue cutting and strangulation.
6. Avoid cutting knot ends too short particularly when using suture with known knot security problems. If ends are left too long, however, irritation from the suture ends may create unwanted tissue inflammation.
7. With instrument ties, hold the needle holder parallel to the wound. Move the needle holder back and forth perpendicular to it.
8. Use a surgeon's knot only when suture tension is such that use of a standard square knot would result in poor tissue apposition. Surgeon's knots take longer to tie and place more suture in the wound than does the square knot. It may not permit proper tension on blood vessel ligations (resulting in partial occlusion) because of the bulk of suture material involved in the first throw.

Suture Needles

Surgical needles are manufactured in a variety of sizes, shapes, and types. Needles are selected to ensure that the tissues being sutured are altered as little as possible by the needle. The needle chosen should allow tissue passage without excessive force and without disruption of tissue architecture. The hole created by the needle should be just large enough to allow passage of the suture material. The needle should be rigid enough to prevent bending, yet flexible enough to bend before breaking.

Regardless of their intended use, all surgical needles have three basic components: the eye (or suture attachment), the body (or shaft), and the point. There are two types of needle eyes commonly used in practice, the economical closed eye (suture is fed through the eye) and swaged (eyeless). Needles permanently connected to suture (swaged needles) produce significantly less tissue trauma and are easier to handle compared to eyed needles; sutures supplied with needles, expectedly, are more expensive.

The bodies or shafts of needles vary in shape and size. The body should be as close as possible to the diameter of the suture material. The cross-sectional configuration of the body may be round, side-flattened rectangular, triangular, or trapezoidal. Some needle bodies are ribbed to prevent rotation and provide better stability of the needle in the jaws of needle holders. Easily accessible tissues such as the skin may be sutured by hand with straight needles but most surgeons prefer curved needles because they are easier to use with instruments. Curved needles are supplied in 1/4, 3/8, 1/2, and 5/8 circle configurations (Figure 1-2). Choice of length, width, and curvature of the needle is dependent on the size and depth of the area to be sutured. Quarter circle needles have limited use, primarily for eye surgery. Three-eighths circle needles are most commonly used in veterinary surgery and are suitable for most superficial wounds. Half circle needles are preferred for deeper wounds and in body cavities. Five-eighths circle needles are applicable for suturing wounds in confined areas such as the oral, nasal, and pelvic cavities.

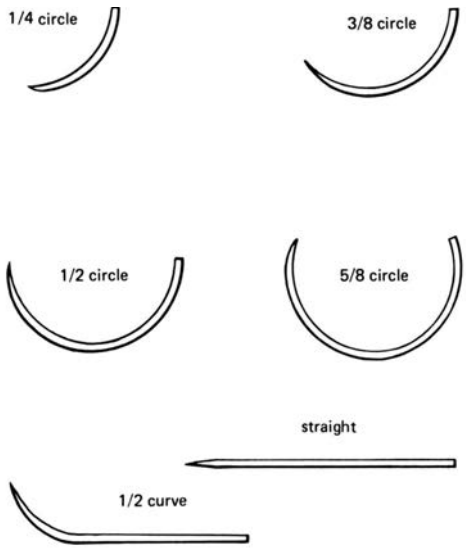

Figure 1-2. Suture Needle Configurations.

The needlepoint extends from the extreme tip of the needle to the maximum cross-section of the body. Three general types of needlepoints include: cutting, tapercut, and taper (or round point) (Figure 1-3). Cutting needles provide edges that will cut through dense connective tissue. They are most suitable for skin, tendon, and fascial closure. Like the conventional cutting needle, the reverse cutting needle has a triangular shaped cross-sectional area; however, rather than possessing a sharp edge on the inner curvature that is weaker and tends to cut tissue as the needle is passed, it has a flat inner curvature with an edge along the outer curvature of the needle point and shaft. Spatula point (side cutting) needles are flat on the top and bottom. They are used primarily in special ophthalmic operations. A tapercut needle combines a cutting point with a round shaft. The cutting point readily penetrates tough tissue but the shaft will not cut through or enlarge the needle hole when inserted. This needle is indicated when ease of penetration is important (vascular grafts, intestine) or when a delicate tissue is sutured to a more dense one (such as urethra to skin closure for a urethrostomy). Taper point or round needles have no edges to cut through tissue. The point pierces and spreads tissue without cutting. They are used for suturing easily penetrated soft tissues such as muscle, viscera, or subcutaneous tissue. Blunt pointed taper needles have a rounded point so they are most useful for suturing friable parenchymal organs such as the liver or kidney. General principles of needle use are list in Table 1-7.

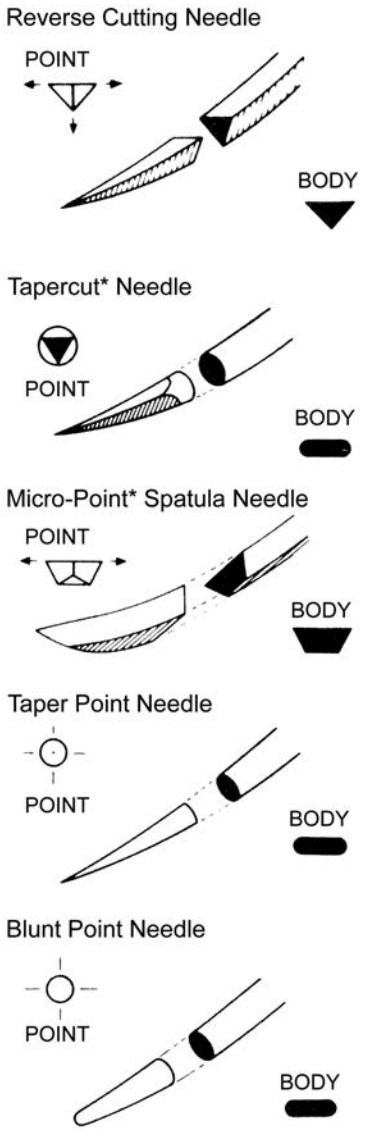

Figure 1-3. Types of Needle Points.

Table 1-7. Principles of Suture Needle Use

1. Swaged needles are less traumatic and always preferred.
2. Curved needles facilitate suturing of deep tissues, and straighter needles are useful in superficial tissues, particularly the skin.
3. For general use, needle holders are used to grasp the needle 1/3 to 1/2 the way down from the suture attachment to the point. Grasp the needle closer to the point if tissue is especially difficult to penetrate.
4. Hold needles in the narrow tips of the jaws of the needle holders.
5. Use taper needles wherever possible; they should not be used if it becomes difficult to pass through tissues.
6. With increasing tissue density, taper-cut or reverse cutting needles are required to penetrate tissue without excessive trauma.
7. Needles should be the smallest size to penetrate the tissue but long enough to penetrate both sides of the incision.
8. Do not grasp the needlepoint with the needle holders or gloved fingers.

Chapter 2

Bandaging and Drainage Techniques

Bandaging Open Wounds

Mark W. Bohling and Steven F. Swaim

Wounds that are large, have extensive tissue damage, and are either contaminated or infected may be managed as open wounds until delayed primary or secondary closure can be performed, or alternatively, may be managed as open wounds throughout the entire healing process. The proper use of bandages and medications helps to provide an optimal environment for development of healthy tissue for wound closure. These techniques also help to provide an environment for rapid progression of contraction and epithelialization of wounds that will heal by second intention.

Bandage Components

A bandage consists of three layers, each of which has distinctive characteristics and functions (Figure 2-1).

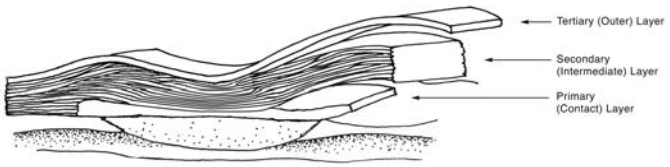

Figure 2-1. The component layers of a bandage. (From Swaim SF, Wilhalf D. The physics, physiology, and chemistry of bandaging open wounds. Compend Contin Educ 1985;7:146.)

Primary (Contact) Layer

The primary (contact) layer of a bandage should be sterile and should remain in close contact with the wound surface whether the animal is resting or moving. This layer should conform to all contours of the wound and, except for moisture retentive dressings (MRD), should allow fluid from draining wounds to pass through to the absorbent, secondary bandage layer. Depending on the wound type and stage of healing, the primary (contact) layer can function in tissue debridement, delivery of medication, removal of wound exudate, or in forming an occlusive seal over the wound. The primary layer is important in providing an environment that promotes healing as opposed to being a layer that just covers a wound. The properties of this layer vary, and it is important to select a dressing material that is appropriate for the current healing stage and to change the dressing type as healing progresses. There are materials that interact with wound tissues to enhance healing rather than to just conceal the wound.

Highly Absorptive Dressings

Gauze dressings are used as an initial dressing on heavily contaminated, infected, and debris-laden wounds. These wounds are in the inflammatory stage of healing. As healing progresses, the primary dressing is changed to one that will promote healing.

Gauze Dressings

Wet-to-dry and dry-to-dry gauze dressings are older techniques used to clean a wound. For wet-to-dry dressings, sterile saline, lactated Ringers solution, or 0.05% chlorhexidine diacetate solution is used to wet the gauze before placing it on a wound with viscous exudate or necrotic material. Exudates are diluted and absorbed into the secondary bandage layer. The fluid evaporates, the bandage dries and adheres to the wound. Bandage removal results in removal of adherent necrotic tissue and debris (Figure 2-2). Because this removal may be painful, moistening the gauze with warm 2% lidocaine may make removal more comfortable for the animal. On cats, warm saline is used to moisten the gauze.

Dry-to-dry gauze bandages are used to clean wounds that have a low viscosity exudate. The gauze is applied dry, and it absorbs the exudate, which evaporates. Removal of the adherent gauze is done as described above with similar results (Figure 2-2).

Gauze dressings have several disadvantages. 1.) Both viable and nonviable tissue are removed with dressing change. 2.) The function of cells and enzymes involved in healing are impaired. 3.) If a gauze is too wet, exogenous bacteria can wick toward the wound, and a wet bandage favors tissue maceration. 4.) Bacteria can be dispersed into the air by a dry gauze at bandage change. 5.) Adherent gauze fibers can remain in a wound to cause inflammation. 6.) Bandage removal can be painful. 7.) Cytokines and growth factors essential for optimal healing are removed with the gauze.

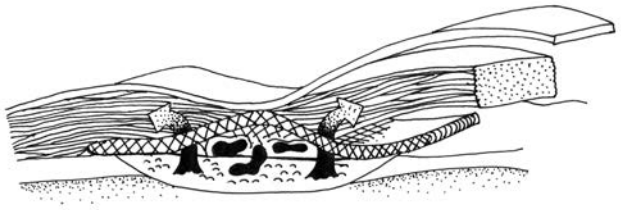

Figure 2-2. With both dry to dry and wet to dry bandages, wound exudate is absorbed into the intermediate bandage layers (arrows). As exudate is absorbed and the bandage dries, necrotic tissue and foreign material adhere to the contact layer. Exudate, necrotic tissue, and foreign material are removed with the bandage. (From Swaim SF, Wilhalf D. The physics, physiology,. and chemistry of bandaging open wounds. Compend Contin Educ Pract Vet 1985;7:146.)

Hypertonic Saline Dressings

These dressings are used in infected or highly necrotic, heavily exudative wounds. They have a 20% sodium chloride content which has the osmotic effect of drawing wound fluid from the tissue to reduce edema and increase circulation. The dressings are changed every one to two days until infection and necrosis are controlled. The dressing desicates both bacteria and tissue. Thus, debridement by these dressings is nonselective in that both healthy and necrotic tissue are removed. Once the wound has reached a moderately exudating granulation tissue stage, a calcium alginate, hydrogel, or foam dressing can be used.

Calcium Alginate Dressings
These are hydrophilic dressings that should be used in moderate to highly exudative wounds, such as would be the case in wounds in the inflammatory stage of healing. They should not be used over exposed bone, muscle, tendons or dry necrotic tissue. They are a felt-like material in a rope or pad form. The calcium alginate of the dressing interacts with wound fluid sodium to create a sodium aliginate gel that maintains a moist wound environment.

The hydrophilic/absorptive nature of the dressing can dehydrate a wound as healing progresses and exudate decreases. If it is left in a wound too long, it dehydrates, hardens, and forms a calcium aliginate eschar which is difficult to remove unless it is rehydrated with saline.

Calcium aliginate dressings are good for the transition from the inflammatory to the repair stage of healing. They enhance autolytic debridement and granulation tissue formation. Two other advantageous properties of the dressing are its hemostatic properties and its ability to entrap bacteria in the gel so they can be lavaged from the wound at dressing change.

Copolymer Starch Dressings
Another type of dressing that can be used in moderate to highly exudative, necrotic infected wounds is a highly absorptive copolymer starch dressing. A hydrocolloid dressing can be placed over the copolymer starch dressing as an occlusive dressing to hold it in place and retain moisture. At dressing change, lavage removes the copolymer from the wound.

The exudate amount in a wound should be observed while using this dressing. As healing progresses, fluid production decreases. If fluid levels get too low, the copolymer adheres to the wound and tissue damage can result when it is removed.

Moisture Retentive Dressings
Moisture retentive dressings (MRDs) provide a warm, moist wound environment that enhances cell proliferation and function during the inflammatory and repair healing stages. The fluid retained over the wound contains the cytokines, growth factors, proteases and protease inhibitors at the proper levels to support healing. In general, a highly absorptive dressing, such as those stated earlier, could be used initially in a wound with considerable necrosis, debris, infection and exudate. Once the wound is relatively clean, then an MRD could be considered.

There are several advantages to MRDs in promoting wound healing (Table 2-1). However, they also have the disadvantages that they can cause softening of periwound skin from retained moisture (maceration) and periwound tissue damage from retained proteolytic enzymes (excoriation).

Polyurethane Foam Dressings
Polyurethane foam dressings are soft, compressible, nonadherent, highly conforming dressings. They are highly absorptive and indicated for use on moderate to highly exudative wounds. The dressings maintain a moist wound environment which enhances autolytic debridement. They promote granulation tissue formation and epithelialization. Thus, the dressings can be used in both the inflammatory and repair stages of healing. An alternative use of the dressing is to saturate it with liquid medication for application on the wound.

Table 2-1. Advantages of Moisture-Retentive Dressings (MRDs)*

- Prevention of wound dessication and excessive whole-body evaporative fluid losses from the wound surface (full-thickness burns and large wounds)
- Maintenance of wound normothermia to improve cellular metabolism
- Provides barrier to urine and other liquids
- Provides barrier to bacteria
- Lower oxygen tension promotes lower pH and enhances collagen synthesis angiogenesis, and leukocyte chemotaxis, and inhibits bacterial growth
- Improved autolytic debridement due to improved leukocyte chemotaxis and retention, and maintenance of wound hydration and normothermia
- Higher concentration of systemically administered antibiotics via improved wound perfusion
- Comfortable for the patient when in place and less uncomfortable to remove compared to adhesive dressings
- Decreased frequency of bandage changes and reduced cost
- Reduced aerosolization of bacteria during bandage changes compared to wet-to-dry bandages
- Decreased scarring

Source: Campbell BG. Dressings, bandages, and splints for wound management in dogs and cats. In: Veterinary Clinics of North America: Small Animal Practice. 36(4): 759-91, 2006. Philadelphia: Saunders.

The stage of healing governs the frequency of changing foam dressings. It can vary between one and seven days, with the longer times time between changes being in the late stages of management when there is less fluid production.

Polyurethane Film Dressings
These film dressings are flexible, transparent, thin semiocclusive (permeable to gas but not water or bacteria) sheets. The transparency allows wound observation, and their adhesive perimeter provides for attachment to periwound skin. Because they are nonabsorptive, they are indicated for wounds with little or no exudate. Thus they are suited for dry necrotic eschars or shallow wounds, such as partial thickness wounds, e.g. abrasions. These dressings could also be used in the late repair stage of healing where there is a small amount of fluid production and a need to retain this to promote epithelialization. Another use is to place the dressings over other contact layers to cause moisture retention and supply a bacteria and waterproof cover.

These film dressings are contraindicated in wounds that are infected and have high exudate levels and wounds with fragile periwound skin. Neither should films be used on wounds with exposed tendon, muscle, bone, or deep burn wounds.

Adherence of the films is poor in areas of skin folds or unshaved hair, and hair growth on periwound skin can push the adhesive

attachment off. However, adherence to periwound skin can be improved with vapor-permeable film spray.

A cloudy white to yellow exudate under the film is just wound surface exudate and should not be confused with infection. The presence of heat, swelling, pain and hyperemia in surrounding tissues would indicate infection.

Hydrogel Dressings
Hydrogels are water-rich gel dressings in the form of a sheet or amorphorus gel. Some of these dressings contain other medications that are beneficial to wound healing, such as acemannan, metronidazole or silver sulfadiazin antimicrobials.

Because of their high water content, the dressings can be used to rehydrate tissues in wounds with an eschar or dry sloughing tissue. A nonadherent semiocclusive dressing or vapor-permeable polyurethane film can be placed over a hydrogel dressing to assure that its moisture is transferred to the tissue and not to the secondary bandage layer. Some hydrogels have an impermeable covering as part of the dressing to serve this purpose. Conversely to wound hydration, some hydrogels can absorb wound fluid and can be used in exudative wounds. These dressings can be used in necrotic wounds to provide a moist environment to enhance autolytic debridement and promote granulation tissue formation.

Hydrogel dressings are generally changed every three days in noninfected wounds, but if the dressing contains an antimicrobial or wound healing stimulant, daily bandage change may be necessary to maintain their activity in the wound. Hydrogel dressings can be changed every four to seven days when they are used to treat abrasions that have minimal exudates. Any hydrogel remaining on the wound at dressing change can be removed with gentle saline lavage.

Hydrocolloid Dressings
These are dressings made of a combination of elastomeric and absorbent components which form a gel when they interact with wound fluid. Some dressings have an outer occlusive polyurethane film. The hydrocolloid adheres to periwound skin while the dressing over the wound interacts with the wound fluid to produce an occlusive gel. This gel may have a yellow purulent appearance and have a mild odor; however, this should not be interpreted as infection it is surface bacterial growth. Infection would be manifested as hyperemia, pain, swelling and heat of the wound and periwound tissues. The gel is more tenacious than just exudate or the gel from hydrogel dressings.

The sheet form of the dressing is the one most frequently used. It provides a thermally insulated moist environment that is impermeable to gas, bacteria and fluid.

These dressings can be used on partial or full thickness wounds with clean or necrotic bases. Such wounds would include pressure wounds, minor burns, abrasions, or graft donor sites. Hydrocolloids can be used in the inflammatory and repair stages of healing. In the inflammatory stage they promote autolytic debridement, and in the repair stage they stimulate granulation tissue, collagen syntheses, and epithelialization. However, wound contraction may be slowed by the dressing adherence to periwound skin.

The dressings should not be used in infected wounds producing large amounts of exudate. The retained exudate can lead to maceration and excoriation of periwound skin.

To apply the dressing, the periwound skin is prepared aseptically. The sheet is cut to a size about two centimeters larger than the wound. The backing is removed from the sheet and it is placed over the wound. The dressing should be changed in about two or three days when it feels like a fluid filled blister over the wound. Change should take place before this fluid leaks from under the dressing edge. Lavage and gentle wiping are used to remove the gel from the wound and periwound skin.

Nonadherent Semiocclusive Dressings
These dressings are porous to allow fluid to move through them into the secondary bandage layer where it can evaporate. However, their absorptive capacity is low, and their porosity can allow exogenous bacteria to wick toward a wound. The dressings are generally used when a wound is in the repair stage of healing.

The dressing can be either an absorbent material encased in a perforated nonadherent covering or a wide mesh gauze impregnated with petrolatum. Although they are classified as nonadherent, these dressings can adhere to a wound. With the petrolatum impregnated gauze, granulation tissue and epithelium can grow into the interstices of the gauze to cause adherence. With the perforated nonadherent dressings exudate can dry in the perforations to adhere the pad to the wound.

Petrolatum impregnated gauze should be used early in the repair stage of healing and should be changed frequently enough to prevent granulation tissue from growing into the mesh openings. Because petrolatum may interfere with epithelialization, its early use may prevent this interference. However, once epithelialization starts, a perforated nonadherent material with absorbent filler should be used.

If the perforated nonadherent material with absorbent filler is used, its purpose is to retain some moisture over the wound to promote epithelialization while allowing excess fluid to be absorbed into the secondary bandage layer (Figure 2-3). This dressing is indicated for superficial wounds that have low to moderate exudate levels. They are often used in the latter part of the repair stage of healing when exudate levels are low. They are a good primary dressing for sutured wounds.

Antimicrobial Dressings
Antimicrobial dressings may contain such agents as iodine, silver, polyhexamethylene biguanide, activated charcoal and antibiotics. Such dressings are indicated to treat infected wounds or wounds at risk for infection. Because these dressings are not moisture retentive, covering them with a polyurethane film dressing may help keep them from drying out.

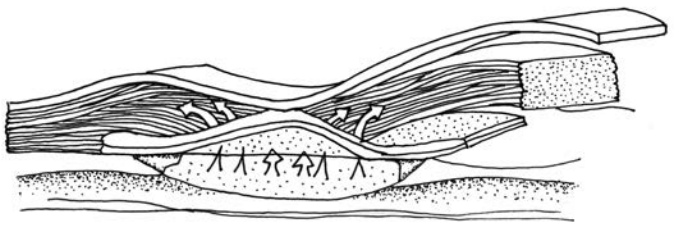

Figure 2-3. With a nonadherent semiocculsive bandage, the primary layer allows absorption of enough excess fluid to prevent tissue maceration (*longer arrows* penetrating the primary layer) but retains sufficient moisture to prevent dehydration and promote healing (*shorter arrows*). (From Swaim SF, Wilhalf D. The physics, physiology, and chemistry of bandaging open wounds. Compend Contin Educ Pract Vet 1985;7:146.)

Iodine dressings contain cadexomer iodine which is released into the wound without a negative effect on wound cells. The dressings are designed to maintain sufficient active iodine levels for about 48 hours.

Dressings with silver ions have a broad antimicrobial activity, which can be effective against otherwise antibiotic resistant organisms, and some mycotic organisms. Various silver-containing dressings are available to include gauze, gauze roll, low adherent, hydrocolloid, hydrogel and alignate dressings.

Polyhexamethylene biguanide (PHMB) is an antiseptic related to chlorhexidine. Gauze sponges and roll gauze have been impregnated with PHMB to provide an antimicrobial dressing (Kerlix® A.M.D., Covidien Co., Mansfield, MA). PHMB is a broad spectrum bactericide, and bacteria do not develop a resistance to it. PHMB-impregnated dressings have prolonged antibacterial activity and thus can prevent wound bacteria from contaminating the environment as well as resisting the penetration of exogenous bacteria into the bandage.

Activated charcoal dressings absorb bacteria and reduce wound odor. They also provide a moist wound environment.

Type I bovine collagen sponges impregnated with gentamicin provide high local levels of antibiotic, but serum levels remain below toxic levels. Such dressings have also been reported to have a hemostatic property.

Extracellular Matrix Bioscaffold Dressings

The extracellular matrix dressings (ECMs) are acellular biodegradable sheets with a three-dimensional ultrastructure. They are derived from porcine small intestinal submucosa (SIS) or porcine urinary bladder submucosa matrix (UBM). The ECMs contain structural proteins, growth factors, cytokines, and their inhibitors. Within two weeks of their presence in a wound there is degradation of the scaffold and the degradation products are chemotactic for repair cells. The repair cells enter the wound as stem cells and they deposit a site-specific matrix. For example, if the dressing is placed in a skin wound, the matrix will be skin/dermis-like. By 30 to 90 days, the bioscaffold is replaced by site-specific tissue.

The ECMs are utilized in a unique way. The wound must be thoroughly debrided, free of topical medications, cleaning agents and exudates. Infection should be eliminated or well-controlled. The ECM sheet is cut to a size slightly larger than the wound. It is rehydrated with saline, tucked under the skin wound edge, and sutured in place. It can be fenestrated if drainage is expected. A nonadhesive or moisture retentive dressing is placed over the ECM. In three to four days, at the first bandage change, all bandage parts are changed except the ECM. It will have a degenerated yellow or brown appearance. A second piece of ECM is placed over the degenerated first piece without removing it and the outer bandage is replaced. The next dressing change is in four to seven days. After two to three ECM applications, no new dressings are added. Usually a granulation tissue bed is present containing a site-specific matrix which will direct the wound healing with tissue like that of the surrounding area. Bandaging of the granulating wound is continued as healing progresses.

Secondary (Intermediate) Layer

Removal of bacteria, exudate, and debris from a wound by wound debridement, lavage, and chemotherapeutics greatly facilitates wound healing. Bandages can assist in this process by absorbing deleterious agents and removing them from a wound. Absorption of serum, blood, exudate, necrotic debris, and bacteria occurs within the secondary bandage layer. If a bandage allows evaporation of fluid (drying), then the exudate becomes concentrated, retarding bacterial growth.

The secondary bandage layer is usually started with a wide-mesh gauze product; (Sof Band® Bulky Bandage, Johnson & Johnson, New Brunswick, NJ; Kerlix® rolls, Covidien, Mansfield, MA) this layer should have a random pattern of fibers to provide maximum capillarity and absorption. It should be applied in a continuous wrapping layers from distal to proximal on the limbs. For the first layer over the primary (contact) layer and the skin of the leg, it is of particular importance to apply the gauze so as to have no wrinkles or folds contacting the skin. Such folds cause pressure spots and make the bandage uncomfortable to the patient, thereby inciting self trauma. This means that it is more important to follow the natural contours of the limb when applying the initial layer, rather than to adhere to a predetermined amount of overlapping of the gauze. Subsequent layers should be applied with approximately 50% overlap. The secondary layer should be applied thickly enough to collect absorbed fluid as well as to pad, protect, and immobilize the wound; besides using roll gauze exclusively, another way to build up the secondary layer is to apply roll cotton or cotton cast padding (Specialist® Cast Padding rolls, Johnson & Johnson, New Brunswick, NJ) over the initial gauze layer to provide additional absorption and padding. Besides its excellent conforming and cushioning properties, cotton cast padding has the further advantage of being relatively safe to apply, as it is difficult to apply it too tightly because it tears under low tension. Cotton cast padding or roll cotton should not be used directly over the primary (contact) layer, as these products could leave lint in the wound.

The frequency of bandage changes depends on the volume of wound discharge and the storage capacity of the absorptive layer. Thus, wounds in the early stages of healing usually produce a

greater volume of exudate and require more frequent bandage changes, though seldom more frequently than twice daily in the authors' experience. One consequence of waiting too long between bandage changes, particularly with contaminated, highly exudative wounds, is that the wet bandage material becomes a culture medium for bacterial growth and perpetuates infection rather than helping to remove it. In addition, if the outer bandage becomes wet ("strike-through"), contamination by exogenous bacteria can occur. Specialized gauze products that have been impregnated with polyhexamethylene biguanide as an antimicrobial (Kerlix® A.M.D., Kendall Co., Mansfield, MA) have been effective in the authors' experience in suppression of bacterial overgrowth in bandages. Even though these antimicrobial dressings have been found effective in preventing exogenous bacteria from contaminating wounds, it is still important to change the bandage before the intermediate layer becomes completely saturated. As healing progresses and wound fluid production decreases, or when an MRD is used, the secondary layer/bandage is changed less often.

Tertiary (Outer) Layer

The tertiary layer of a bandage serves primarily to hold other dressings in place and to immobilize the wounded area, especially when a splint is incorporated in the bandage. Surgical adhesive tape (porous, waterproof, or elastic) is commonly used for veterinary bandaging. Porous tape (Zonas® porous tape, Johnson & Johnson, New Brunswick, NJ; Curity® standard porous tape, Covidien, Mansfield, MA) allows fluid evaporation, thus promoting dryness, but, if the bandage becomes wet from exogenous fluid, surface bacteria can move inward by capillary action and contaminate the wound. Although the antimicrobial dressings help prevent this problem, it is desirable to maintain a dry bandage surface. Waterproof tape can protect a wound from exogenous fluid; however, if it is not properly applied, fluid can still enter the bandage and will be retained. Waterproof tape also tends to create an occlusive bandage that may lead to tissue maceration; therefore, it is primarily indicated for wounds that are not producing large amounts of fluid. Elastic coadhesive wrap (Vetrap® bandaging tape, 3M Co., St. Paul, MN; PetFlex®, Andover Products, Salisbury, MA) provides pressure, conformation, and immobilization. We use porous adhesive tape more often than either waterproof tape or elastic wrap.

If a wound has considerable drainage and absorption is the major function of the bandage, the tertiary layer of the bandage should be placed just tightly enough to hold all layers of the bandage in close contact with each other. An excessively loose bandage, with insufficient contact between the primary and secondary layers, allows fluid to accumulate over the wound, leading to tissue maceration. At the other extreme, if the tertiary layer is applied too tightly, it may compress the intermediate layer and reduce absorption, impede tissue blood supply, and impair wound contraction (Figure 2-4). In addition, overly tight application of bandages on the head and/or neck can lead to occlusion of the pharyngeal area and respiratory embarassment.

The tertiary bandage layer helps to ensure that a limb bandage remains in place. The final piece of adhesive tape is placed half on the bandage and half on the skin to prevent bandage slippage. To help adhere the tape to the skin, a hand is held over the tape for about a minute. The heat from the hand and from the animal's body softens the adhesive on the tape, making it more sticky so as to adhere better to the animal's skin. To help assure adhesion of the tape, a polymeric solution of hexamethyldisiloxane acrylate (Cavilon No Sting Barrier Film, 3M Health Care, St. Paul, MN) may be sprayed on the skin adjacent to the top of the bandage. In addition, when the tape is removed, this solution may be sprayed on the tape to help prevent epidermal stripping. When there are no open draining wounds on the paw, tape stirrups on the paw with incorporation in the bandage also help secure limb bandages.

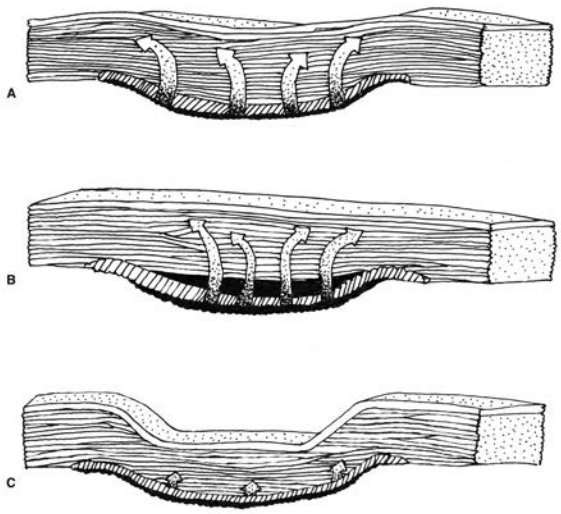

Figure 2-4. Pressure exerted by tertiary bandage layer. **A.** Ideal pressure. All bandage layers are in contact with each other, and the best absorption takes place. **B.** Too loose. All bandage layers are not in contact with each other and the wound; fluid may accumulate. **C.** Too tight. All bandage layers are compressed, resulting in decreased absorption and possibly reduction in tissue blood supply and wound contraction. (From Swaim SF, Wilhalf D. The physics, physiology, and chemistry of bandaging open wounds. Compend Contin Educ Pract Vet 1985;7:146.)

Pressure Bandages

A bandage may be placed to apply therapeutic pressure to an open wound or damaged limb. One indication for pressure bandages is control of minor hemorrhage; however, they must be used with caution and only for a short period of time. Pressure bandages can help to control peripheral edema, and they are more effective in controlling edema from venous or lymphatic stasis than inflammatory edema. Pressure bandages also help to prevent formation of exuberant granulation tissue, to obliterate dead space, and to immobilize fractures and other wounds.

Unless an elastic material is used to apply tension continuously, it is difficult to maintain pressure on a wound surface by using cotton or linen dressings. When cotton and similar materials are applied as a pressure bandage, they generally become compressed in a short time and thus no longer act as a pressure bandage. However, if cotton and linen do not compress sufficiently to relieve the constricting effect of tightly applied adhesive tape, the result may be circulatory embarrassment of the wound and bandaged structure.

A properly applied pressure bandage made with elastic material tends to keep some dynamic pressure on the wound as the patient moves. Even when an elastic material is used for a pressure bandage, excess pressure can impair arterial, venous, and lymphatic flow and can lead to tissue slough as well as nerve impingement. Therefore, the area of the limb distal to a pressure bandage should be carefully inspected for signs of swelling, hypothermia, cyanosis, moisture, loss of sensation, or odor; this duty should be performed at least twice daily by the veterinarian on hospitalized patients or by the client on outpatients. Many limb bandages are applied so as to include the entire foot; therefore the pad surfaces of the two middle digits should be left exposed so that they may be examined. An animal will usually not disturb a comfortable, properly applied bandage; if it licks or chews a pressure bandage, the bandage should be removed and the area should be examined.

Pressure caused by an elastic pressure bandage is governed by five factors: 1) the elasticity of the material used. Higher elasticity equates to more pressure, 2) tension applied at the time of application, 3) width of the tape, i.e., the narrower the tape, the greater the local pressure, and 4) the number and overlap of layers. The pressure produced by these factors is additive. Lastly, pressure is inversely proportional to the circumference of the bandaged body part, i.e., the smaller the circumference, the more pressure is applied, and the greater is the chance of circulatory compromise. Therefore, care should be taken when moving from an area of small circumference to one of larger circumference while bandaging.

For example, when bandaging a limb from distal to proximal, the distal portion of the bandage should be applied with less tension to prevent excessive constriction of this smaller circumference area.

Practice can help assure that elastic tape is applied with the proper tension. As the tape is applied off the roll, it is secured near the bandage with one hand while pulling tape off the roll. Thus, the danger of applying it too tightly is reduced. Another guideline for tape application is to apply it such that the textured pattern of the material is slightly distorted but sill visible. Wraps should overlap one-third to one-half the tape width.

Pressure Relieving Bandages

Bandages may also be configured to relieve pressure on an injured body part. The shape of the bandaged surface has an effect on the amount of pressure exerted on the tissue. The more convex the surface, the greater is the pressure exerted by the dressing on the tissue. Adding more gauze padding over a convex surface makes it even more convex, further increasing pressure. This can be detrimental when treating an open wound over a convex surface. Placing more padding over the wound in an attempt to protect it from pressure has the effect of increasing the pressure and impairing healing. Pressure relieving bandages are indicated for bandaging such areas.

Cast padding material (Specialist Cast Padding, Johnson & Johnson Orthopaedics, Raynham, MA) can be used to make a "donut"-type pad for placement over convex prominences. The principle is to place the hole of the donut over the prominence so the surrounding padding absorbs the pressure, and there is pressure relief over the prominence. Several layers of cast padding are folded on each other; thus, making a pad approximately 3 inches by 3 inches. The pad is folded over on itself and a slit is cut in its center with bandage scissors. After opening the pad, digital tension is used to enlarge the slit to a round opening ("donut" hole). The pad is then placed over the prominence with the hole over the prominence. Secondary and tertiary bandage wraps hold the pad in place (Figure 2-5A-D). These bandages are effective over prominences on the lower limbs, (e.g. lateral/medial malleolus, calcaneal tuberosity, carpal pad). A variant of the "donut" bandage principle has been employed to relieve pressure on the paw pads. This technique uses medium density open-cell foam of a special type used in aircraft seat padding (Confor™ Foam, HiTech Foams, Lincoln NE). Two configurations have proven effective to relieve pressure on a metacarpal or metatarsal pad: an oblong piece of foam is cut to cover the entire palmar or plantar paw surface and a hole is cut in it in the area over the metatarsal or metacarpal wound; the foam is then incorporated into the bandage. For pressure relief over digital pad wounds, a triangular piece of foam is placed directly over the metacarpal or metatarsal pad and incorporated into the bandage, thus helping to elevate the digits and relieve pressure. A metal paw pad cup (cup end of a mason metasplint) can be placed over the bandage with either of these configurations for further help with pressure relief. This type of pressure relieving bandage is indicated for moderate pad wounds on small to medium sized dogs.

Immobilization and extension are important to enhance wound healing over the olecranon. Immobilization allows tissues to heal together and extension prevents elbow flexion to prevent sternal recumbency and thus keeps pressure off of the wound. Several techniques have been used to bandage elbow wounds.

Pipe insulation bandages can be used for wounds over the olecranon. They are made by splitting two pieces of foam rubber pipe insulation lengthwise, cutting a hole large enough to go around the lesion in each piece, and then stacking and taping the pieces together. The cranial aspect of the humeroradial area is well padded with cast padding before taping the pipe insulation bandage in place with the hole over the olecranon. Such padding helps to keep the dog from flexing the joint to position itself in sternal recumbency to place pressure on the olecranon area. It may be difficult to secure the bandage to keep it from slipping distally on the limb, especially on an obese dog that has a short segment of limb proximal to the elbow to which the bandage can be affixed. Affixing the pipe insulation bandage to a body bandage may be necessary to hold the pipe insulation bandage in place: a body bandage is placed just caudal to the forelimbs. A strip of 2 inch adhesive tape is placed, adhesive side down, on this bandage from the dorsal area well down onto the forelimb. The roll of tape is left on the strip. The padding and pipe insulation bandage are placed and taped over the elbow area. The previously placed strip of adhesive tape is twisted 180° at the base of this bandage so the adhesive side faces outward. The tape is then placed adhesive side against the bandage and is taken back onto the body bandage over the animal's dorsum. This forms a "stirrup" to hold the pipe insulation bandage in place (Figure 2-6). No pressure is on the wound, and medications can be applied to

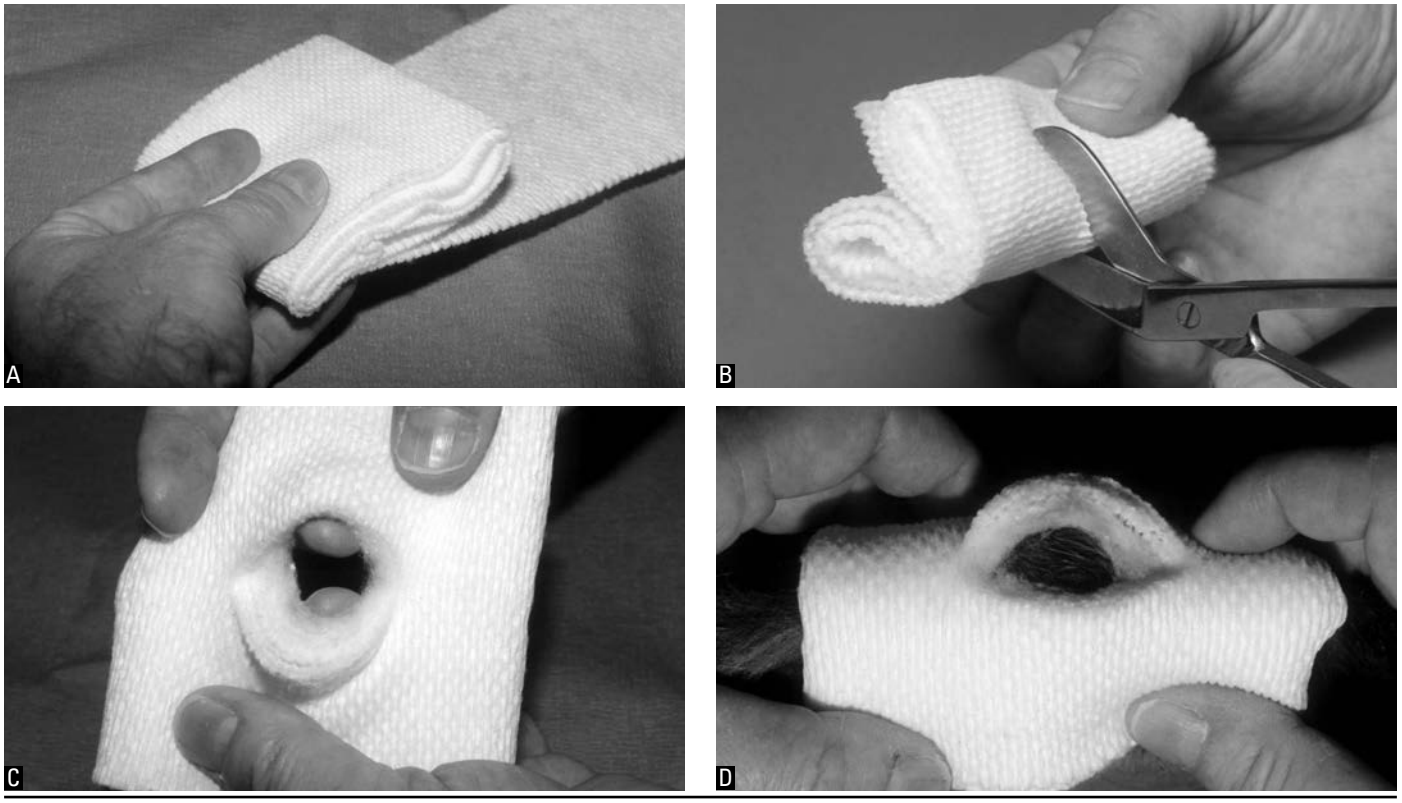

Figure 2-5. A.-D. Donut bandage. **A.** Folding several layers of cast padding to make a pad. **B.** Scissors cutting a slit in folded-over pad. **C.** Fingers enlarging the slit to a round hole. **D.** Pad placed over the calcaneal tuberosity to be held in place with secondary bandage wrap.

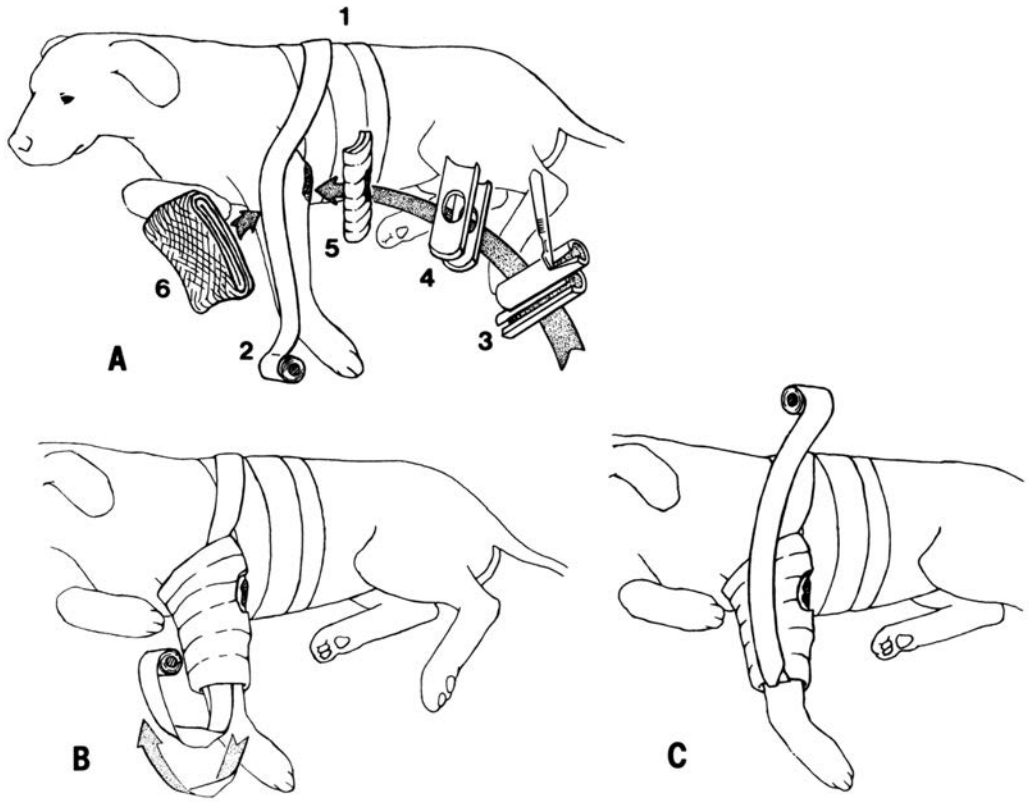

Figure 2-6. A. Steps for putting on a pipe insulation bandage: *1)* place a body bandage behind the front limbs; *2)* transfer tape from the body bandage onto the limb; *3)* split two pieces of pipe insulation; *4)* cut holes in the pipe insulation to go over the elbow ulcer and stack the pipe insulation; *5)* tape the pipe insulations together and place them over the olecranon wound; *6)* put cast padding in front of the elbow area. **B.** Tape the pipe insulation and padding in place. Twist the tape (180°) on the limb (arrow) so the adhesive side is back against the bandage. **C.** Complete the tape stirrup back onto the body bandage.

the wound through the holes in the pipe insulation. The bandage and padding remain in place for several days before adjustment or replacement are necessary. The only daily bandage change necessary is a small amount over the wound.

Splints may also be used on the cranial surface of the forelimb to immobilize the elbow joint in extension and to prevent pressure on wounds over the olecranon. A routine bandage wrap is placed around the elbow; then a section of aluminum splint rod is used to fashion a loop type splint, which is incorporated into the cranial part of the bandage (Figure. 2-7).

The authors have also been able to keep elbows extended and immobilized by placing a body bandage on the dog with extension of the bandage down the length of the leg, i.e., a forelimb spica-type bandage. The leg bandage has some bulk to it. After placing the bandage, fiberglass casting tape (Delta-Lite "S" Fiberglass Casting Tape, Johnson & Johnson, Raynham, MA) is used to create a lateral splint for the limb. The casting tape is layered along the lateral side of the bandage from the level of the paw to over the shoulders. Several layers of tape are used, especially on large dogs. The tape splint is molded by hand to the lateral surface of the bandage until it hardens. When taken away from the bandage, it has the shape of a shepherd's crook or a question mark. This is taped to the lateral side of the bandage, around the limb and over the shoulder area. A hole is cut in the bandage over the olecranon, through which the wound is treated. Usually, the bandage and splint remain in place 5 to 7 days before adjustment or replacement are needed, and the wound is treated daily via the hole with a small bandage covering, following treatment.

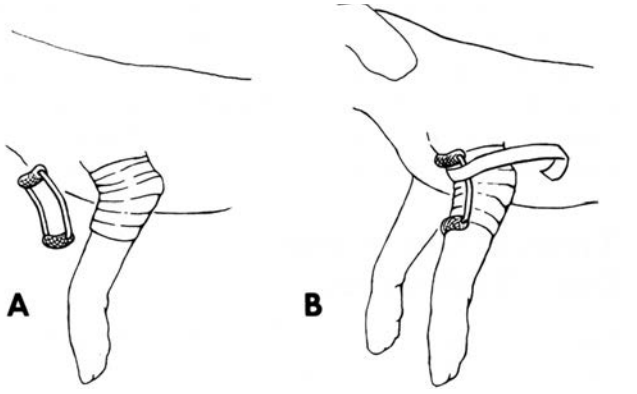

Figure 2-7. Applying an aluminum rod loop type splint in the front of an elbow bandage.

Another application of splints to a special wound healing situation is the use of "clamshell" technique to relieve pressure from the palmar or plantar surface of lacerated pads, pad flaps or pad grafts. This technique is even more effective at relieving pad pressure than the "donut" technique mentioned above and may be particularly indicated for protection of pad surgical sites. After bandaging the foot in a standard padded bandage, (a "donut" of the Confor™ Foam mentioned previously can also be applied over the affected pad or pads), two Mason metasplints are applied, one on the dorsal and the other on the palmar or plantar aspect of the limb with the paw cups facing each other and extending about 2.5 cm beyond the limb. Bandaging tape, applied in a dovetail fashion, secures the splints to the bandage. The metasplints should extend proximally almost to the elbow or to the tarsus. The functional effect is to convert the dog's ambulation to a "tiptoe" gait, like a ballet dancer, thereby relieving pressure from the pads. At the end of the splints, a final layer of duct tape or thick adhesive elastic bandaging material (Elastikon®, Johnson & Johnson, New Brunswick, NJ) helps protect the splints (and owners' flooring!) from abrasion (Figure 2-8).

Figure 2-8. Clamshell bandage splint. A Mason metasplint on the dorsal and plantar surface of a pelvic limb bandage. Paw cups extend beyond the bandage about 2.5 cm and face each other.

The pipe insulation bandage, splint rod loop bandage, and fiberglass splint bandages are also effective in keeping pressure off wounds on the sternum because they prevent elbow flexion and keep the animal out of sternal recumbency. A pressure relief bandage for wounds (i.e., decubital ulcers) over the ischiatic tuberosities is composed of a body bandage with padded aluminum splints taped to either side of the bandage. These splints extend behind the dog and prevent it from attaining a sitting posture to place pressure on the ischiatic area (Figure 2-9).

Mobilization Versus Immobilization

The decision whether a wound should be mobilized or immobilized during healing is often not clear, with advantages and disadvantages to both; wound location and type, and the stage of wound healing are important factors to consider in making the decision.

Maintaining mobility of wounds has been considered to minimize

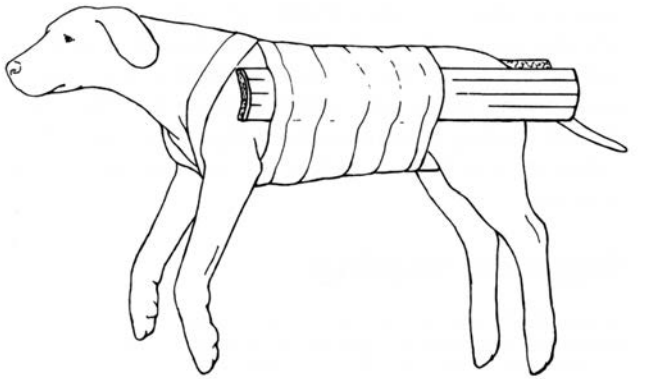

Figure 2-9. Body bandage with a lateral fiberglass splint to keep pressure off the ischiatic area.

negative nitrogen balance of the tissues, to stimulate circulation, to help combat infection, and to allow movement that loosens adhesions. Mobility can also provide massage for better wound drainage and can prevent joint stiffness and osteoporosis.

Other arguments favor wound immobilization to enhance healing. An immobilizing bandage is needed for wounds with underlying orthopedic damage. In addition to providing orthopedic support, wound immobilization may allow better healing over the olecranon, and the calcaneal tuber. Immobilization may also increase tissue resistance to bacterial growth and decrease the probability of infection and its spread by the lymphatics and tissue planes. Other factors favoring immobilization include patient comfort and support of the tissues during collagen synthesis. Wound immobilization also helps to prevent the dislodgment of fragile clots, rupture of new capillaries, and disruption of new fibrin. In addition, immobilization prevents tension on repaired structures (e.g., muscle, tendons, and ligaments).

Pressure bandages help to immobilize wounds; casts and splints also immobilize wounded limbs. Casts should be applied so that swelling can be accommodated as well as controlled. Applying a cast, then splitting the cast longitudinally on both sides, removing and reapplying it (bivalving a cast) allows for swelling and makes dressing changes possible. Application of a half of the cast to the side of the limb opposite the wound can be used for immobilization. Such a half cast can act as a point of counterpressure when a pressure bandage is required. It can be applied so the dressing can be changed without affecting immobilization. Incorporating a Mason metasplint into a bandage placed on a lower limb is an example of this type of immobilization.

Wounds over extensor and flexor surfaces of joints benefit from immobilization during healing. Because flexion of a joint tends to pull wound edges apart on the extensor surface of the joint, immobilization is indicated for such wounds. Large wounds over flexion surfaces of joints can benefit from early reconstructive surgery to help prevent wound contracture leading to deformity and loss of function of the joint. When large wounds over flexion surfaces are to be allowed to heal as open wounds, joint immobilization in extension is particularly important to help prevent contracture deformity. Another specific area where wound immobilization is indicated is the axillary region. As the forelimb moves, shearing and tension forces in this area interfere with wound healing. Reconstructive surgery and immobilization in a Velpeau bandage are needed for wound healing.

Prolonged joint immobilization may lead to cartilage degeneration, pressure wounds, joint stiffness and disuse atriphy. Thus, when bandages are changed, the wound should be cared for and joints should be evaluated for problems.

Wound Drainage Techniques

Mark W. Bohling and Steven F. Swaim

Indications

Although wounds drain best when left open, often they must be closed before they have drained completely. In general, wounds must be drained 1) when an abscess cavity exists, 2) when foreign material or tissue of questionable viability that cannot be excised is present, 3) when massive contamination is inevitable (e.g., wounds in the anal area), and 4) when it is necessary to obliterate dead space to prevent the accumulation of air, blood, serum or exudate, or to permit the egress of air or fluid accumulations from an existing cavity or wound. Specifically, wound drainage in veterinary surgery is used in the management of dog bite wounds with separation of the dermis from underlying tissue, abcessed cat bite wounds, lacerations with loose skin, radical mastectomy and other large excisional wounds, seromas, auricular hematomas, elbow and ischial hygromas, and certain instances of orthopedic trauma such as high energy fractures with extensive soft tissue trauma and swelling.

Types of Drains and Drain Techniques

Materials used for wound drains should be relatively soft, nonreactive, and radiopaque. Flat drains such as Penrose drains are made of soft, thin latex rubber material shaped cylindrically. Tube drains are composed of rubber or plastic tubes or catheters with thicker walls that are not as easily collapsed as flat drains. Multilumen drains are a combination of drain tubes that allow fluid to drain from a wound through one lumen while allowing air or lavage fluids to enter the wound by another lumen.

Drains are classifled as passive or active. Passive drains can be single lumen flat drains, tubular drains, or multilumen drains. These drains function by pressure differentials, overflow, and gravity. Active wound drainage occurs when an external vacuum is applied to the end of a drain tube. Active drains may or may not be open to the atmosphere.

Passive Drains

Flat Drains (Penrose Drains)

Penrose drains are thin walled rubber tubes available from 1/4 to 2 inches in diameter and from 12 to 36 inches in length. The mechanical action of these drains depends on capillary action and gravity because they provide a path of least resistance to the outside. Fenestrating a drain is not advised because drainage is related to surface area and fenestrating the drain reduces the surface area. Penrose drains allow egress of foreign material from the wound. Dead space is obliterated as fluid is drained and normal healing tissue fills the potential space.

Penrose drains are easily sterilized, are readily available, and cause little foreign body reaction. However, the latex causes the earlier formation of a fibrous tract in the tissue, a property that makes it good for draining abscesses because this tract between the abscess cavity and the skin is desirable for better drainage. Because they are soft and flexible, these drains do not exert undue pressure on adjacent blood vessels or other structures.

Single-Exit Drains

Penrose drains can be placed with one end of the drain emerging at the distal aspect of the wound. In preparation for placing such a drain, the hair around the area where the drain will exit should be clipped liberally. The length of drain placed in a wound should be recorded for comparison with the length that is removed. The dorsal end of the drain should be positioned before wound closure, slightly dorsal and lateral to the most dorsal aspect of the wound. The preferred technique for fixing the drain in the dorsal aspect of the wound is to pass a nonabsorbable suture through the skin and the drain and to tie it outside the skin. Only a very small bite is taken in the end of the drain; in the event that the patient removes the drain prematurely, a small suture bite in the drain minimizes the chance that a piece of the proximal portion of the drain will be torn off and remain in the wound. This suture is removed before the drain is removed (Figure 2-10).

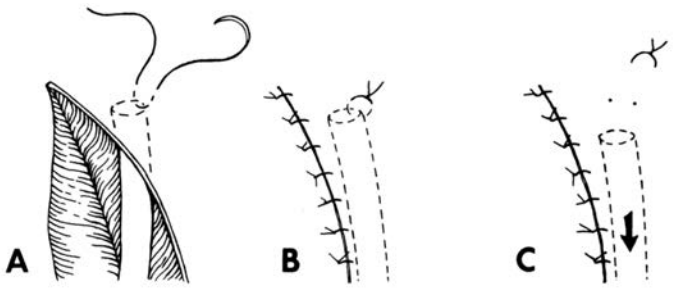

Figure 2-10. Tacking a drain in the proximal aspect of a wound. **A.** The drain is placed off to one side of the wound, and a simple interrupted anchor suture is placed through skin, drain, and skin again. **B.** The wound is closed and the anchor suture is tied. **C.** When the drain is removed, the anchor suture is cut and the drain is pulled out.

When the drain is placed in the wound, it should run as vertically as possible, and placement next to large vessels should be avoided. A drain should never emerge through the end of the suture line; instead, an incision is made in the skin ventral and lateral to the ventral aspect of the wound. A pair of hemostatic forceps can be used to make a tunnel just under the skin for the drain to exit at this incision (Figure 2-11). The exit incision should be large enough to allow drainage around the drain, usually one and one half to two times the width of the drain. A tacking suture placed through the drain and skin where the drain emerges further secures the drain and prevents it from retracting into the wound (Figure 2-12). As the wound is closed, contact between the drain and the skin suture line should be strictly avoided; this can be accomplished by suturing subcutaneous tissue over the drain and by directing the drain so it does not lie under the suture line. Failure to follow this principle invites suture line dehiscence and/or inadvertent incorporation of the drain into the closure. Care should be taken to avoid incorporating the drain into any sutures as they are placed. If the drain is incorporated into a skin suture, it cannot be removed until the skin sutures are removed. If a drain is incorporated into a subcutaneous suture, its removal usually requires at least a partial re-opening of the wound.

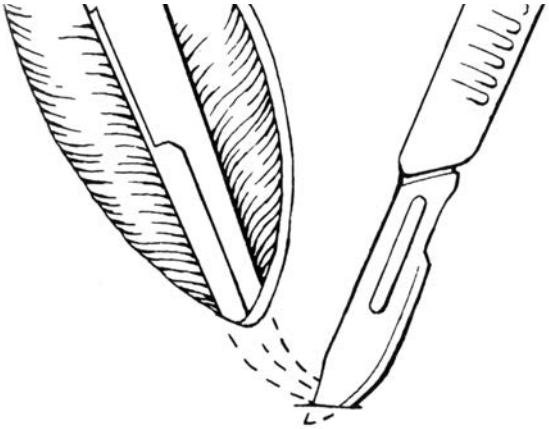

Figure 2-11. Making a subcutaneous tunnel at the distal end of the wound with the tips of forceps. A scapel blade is used to incise the skin over the forceps tips to create a drain emergence site.

To prevent drain incorporation in the suture line, the drain is placed in the wound via the ventral drain hole. The dorsal end of the drain is placed at the appropriate location in the wound. The point at which the drain exits through the ventral drain hole is marked on the drain. The drain is then pulled from the dorsal end of the wound. This pulls the mark on the ventral part of the drain into the wound. The subcutaneous tissue is now apposed over the drain. Every 2 or 3 suture bites, both ends of the drain are grasped, and the drain is pulled back and forth to be sure no suture bite has incorporated the drain. Lack of free drain movement indicates drain incorporation in a suture, and 2 to 3 sutures can be removed and replaced. After all subcutaneous sutures are placed and the drain moves freely, the ventral end is pulled so that the dorsal end is now within the wound, and a deep simple interrupted suture through the skin, drain, and skin again is used to anchor the dorsal end of the drain. The previously placed mark on the drain is again at the level of the ventral drain hole. The skin can now be closed without concern for incorporating the drain because it is protected beneath the subcutaneous tissue. The ventral drain anchor suture is then placed.

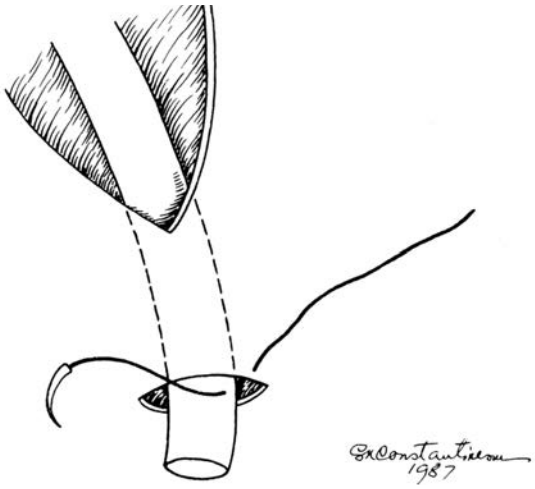

Figure 2-12. Placing and anchoring a drain distally. The drain exits through a hole distal to the wound. The exit hole is large enough to allow drainage around the drain. A simple interrupted nonabsorbable suture is placed through the skin and drain at the drain's exit hole.

When a closed wound (e.g., an unruptured abscess) requires drainage, an instrument with long jaws, such as a Doyen intestinal forceps, can be used to place one end of the drain in the depths of the wound through a stab incision near the dependent aspect of the wound. The tip of the forceps is used as a palpable landmark to pass a simple interrupted suture through the skin, into the drain, and back out through the skin. The suture is tied to anchor the drain in the dorsal aspect of the wound.

Penrose drains can also be used to drain deep wounds; however, care should be taken that an adequate pathway is created from the deep pocket to the skin surface to provide drainage. An open approach is usually made to the deep wound to allow debridement, lavage, culture, and biopsy. Apposition of the tissues overlying the deep pocket is usually sufficient to hold the drain in place. The usual principles of exiting the drain in a position that is dependent to the wound, and not within the primary closure, are followed.

Drains should be covered with sterile absorbent dressings to absorb wound fluid and prevent external contamination. Bandages also help to prevent molestation of the wound by the patient. The bandage should be changed frequently to remove fluid from the wound area. The area around the exit drain should be cleaned at bandage change; antiseptic ointments or creams are sometimes applied to the skin at the drain exit site to protect the skin from irritation from the draining exudate. In these cases, the ointment or cream should not be applied too thickly around the drain exit, or drainage may be obstructed. Inspection of the bandage reveals the nature and amount of drainage, to determine how long a drain should remain in place.

Double-Exit Drains

Penrose drains can also be placed with one end emerging above the dorsal aspect of the wound and the other end emerging below the ventral end of the wound. Simple interrupted sutures are placed through the skin and drain at both points of emergence to prevent the drains from retracting into the wound (Figure 2-13). The use of double exit drains remains somewhat controversial; many surgeons avoid the use of vertically oriented double exit drains, asserting that the double exit holes increase the risk of ascending bacterial infection. However, there is no support for this hypothesis in the scientific data, whether based on experimentation or patient statistics. Double exit drains can be advantageous if the wound is to be flushed with an antibiotic or antiseptic. They are usually used in heavily contaminated or infected wounds. Lavaging the wound from the proximal tube emergence site exposes the wound tract to the solution, although the lavage solution may merely follow the path of least resistance, the drain tract, and not reach the crevices of the wound. Moreover, if pressure is applied to the lavage solution or if the distal drain opening is occluded, the lavage solution can spread wound debris and bacteria into surrounding tissue by hydrostatic pressure.

Another use for double exit drains is when considerable subcutaneous dead space extends up the lateral trunk, across the dorsum, and down the opposite lateral trunk. A drain can be placed from the most dependent area of dead space on one side,

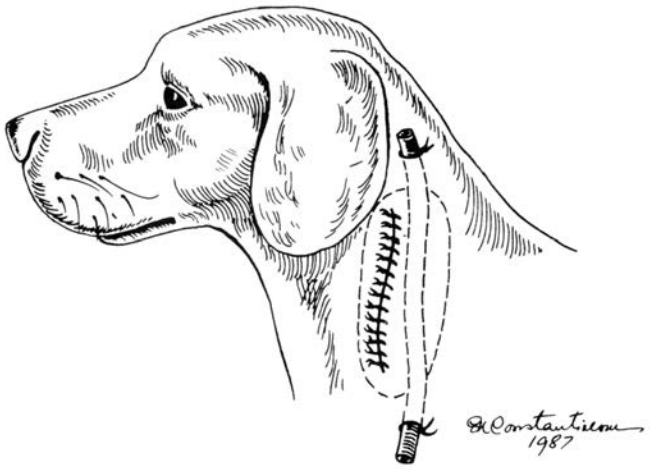

Figure 2-13. A drain can exit at both proximal and distal aspects of a wound. The drain is anchored to the skin at both exit holes. (From Swaim SF. Surgery of traumatized skin: management and reconstruction in the dog and cat. Philadelphia: WB Saunders, 1980:159.)

across the dorsum of the animal to a like area on the opposite side. Thus, the drain passes subcutaneously across the animal's back with an exit on each side to provide drainage.

Tube Drains

Rubber or plastic tubes and catheters of various diameters and designs can be used as tube drains. These cylindrical tubes have a thicker wall than flat drains. They have a single lumen with or without small or large side holes. Additional side holes, if desired, should be cut in an oval and should be no more than one third the diameter of the drain, to prevent kinking and possible tearing of the drain. The basic mechanism of action and the principles of application of tube drains are the same as for flat drains.

Fenestrated tube drains can drain from both inside and outside the lumen, and they can be connected to a suction apparatus for use with a closed collection system. These tubes also allow irrigation through the drain. They are not expensive and they are readily available. Silicone plastic (silastic) tube drains may cause less tissue reaction than rubber tube drains. One disadvantage of tube drains is that their stiffness can cause patient discomfort. These drains may become obstructed by clots and debris, necessitating flushing to clear them.

Active Drains

Open Suction Drains

When a vacuum is applied to one lumen of a multilumen drain, fluid is removed from the wound as air enters the wound through another drain lumen as a sump drain. Although the procedure reduces the drainage time, we do not use it because the increased volume of environmental air drawn into the wound increases the chance of bacterial infection and can be traumatic to the tissues. Bacterial filters can be fitted to the air intake to help decrease contamination.

Closed Suction Drains

Closed suction drainage occurs when suction is applied to a drain tube that has been placed into a wound with no external air venting. This implies not only a single, airtight exit site for the drain, but in addition, an airtight wound (either a natural blind pocket or surgical airtight closure) allowing the creation of a vacuum within the wound. This drainage system facilitates continuous flow and reduces the chance of drainage tube occlusion and the need for wound irrigation. Closed suction drains do not depend on capillary action or gravity. Closed suction drains have the same indications as passive drains; however, they work best when no foreign material or necrotic tissue is present, because these could plug the drain holes.

Numerous commercial portable closed suction drainage systems are available. When incorporated into a bandage, these drains provide portable, continuous, even pressure, and aseptic closed suction drainage. In some of these systems, unless a one way valve device is included, fluid may reflux back into the wound if the animal lies on or puts pressure on the evacuator. The location of the wound, the size of the animal, and the size of the commercial apparatus should be considered when choosing a commercial closed suction system; one model in common use (Jackson-Pratt®, Allegiance, a Cardinal Health company, McGaw Park, IL) employs a clear silastic 100 ml bulb-type reservoir with one-way valve. This is attached to a 25 cm length of 3 x 10 mm, multi-fenestrated drain by a 30" silastic tube. The drain and tube can be trimmed to the desired length, and the suction reservoir can be conveniently stored in a pocket that is constructed in the animal's bandage.

An inexpensive and simple closed suction drainage system can be made using a butterfly scalp needle with its extension tube as the drainage tube, and a 5 or 10 mL evacuated blood collection tube to provide suction. The Luer syringe adapter of the butterfly scalp needle is cut off the tubing and discarded, leaving the needle and attached tubing intact. A scissor is used to cut small (1-2 mm) oval holes into the tubing, extending for a length a little shorter than the length of the wound (Figure 2-14). The fenestrated portion of the tube is inserted through a small puncture wound near the site to be drained. The puncture wound should be the same diameter as the tube. The tubing is secured to the skin with a nonabsorbable pursestring suture. After the wound is closed, the needle on the free end of the tube is inserted into a standard 5 or 10 mL evacuated blood collection tube (Figure 2-15). A light bandage into which the collection tube is incorporated is usually all that is necessary. For large wounds, two drain sets may be necessary.

If the drain is placed under a (non-fenestrated) skin graft, the end of the drain should be placed under the skin at the edge of the graft. A simple interrupted tacking suture is placed through the skin, through the tube, and back out through the skin to anchor the end of the drain. This suture, along with the pursestring suture at the drain exit hole, secures the drain under the graft so it does not move to interfere with graft revascularization (Figure 2-16).

A modification of this closed suction apparatus involves the use of plastic syringes. To prepare the drain tube, the butterfly needle

is removed from the scalp set, leaving the Luer adapter attached to the tubing, and the tubing is fenestrated. (Figure 2-17A). After the tubing has been placed in the wound and the wound has been closed, a plastic syringe is attached to the Luer adapter. The plunger is withdrawn enough to create the desired negative pressure without collapsing the drain tubing, and a 16 or 18 gauge needle is driven crosswise through the syringe plunger just above the syringe barrel to hold the plunger at the desired level within the barrel (Figure 2-17B). Fixation at different levels creates different negative pressures. The size of syringe that is used corresponds to the expected volume of fluid to be drained; a 6 ml syringe can be used when little drainage is anticipated, while a 30 mL syringe can be used when large amounts of fluid are to be removed.

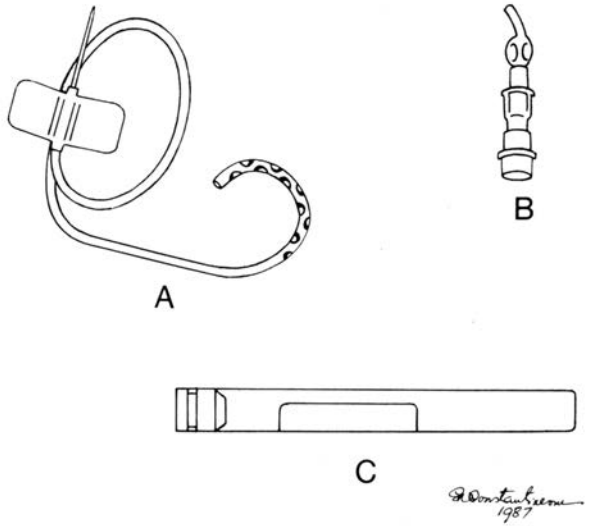

Figure 2-14. Components of a simple closed suction drain. **A.** A 19 gauge butterfly catheter after multiple fenestrations have been made in the tubing. **B.** Luer adapter that was removed from the catheter. **C.** A 10 mL evacuated glass tube.

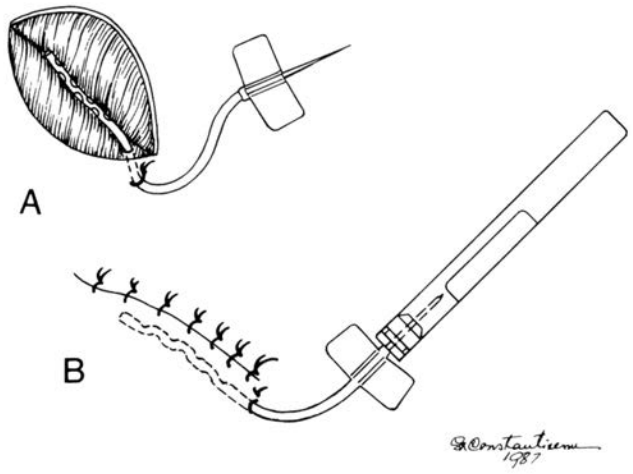

Figure 2-15. Placement of a closed suction drain in a wound. A. The fenestrated portion of the drain is inserted into the wound through a small opening near the distal end of the wound. The tube is secured to the skin with a simple interrupted nonabsorbable suture. B. The wound is closed. The needle on the tube is inserted into a 5 or 10 mL evacuated blood collection tube.

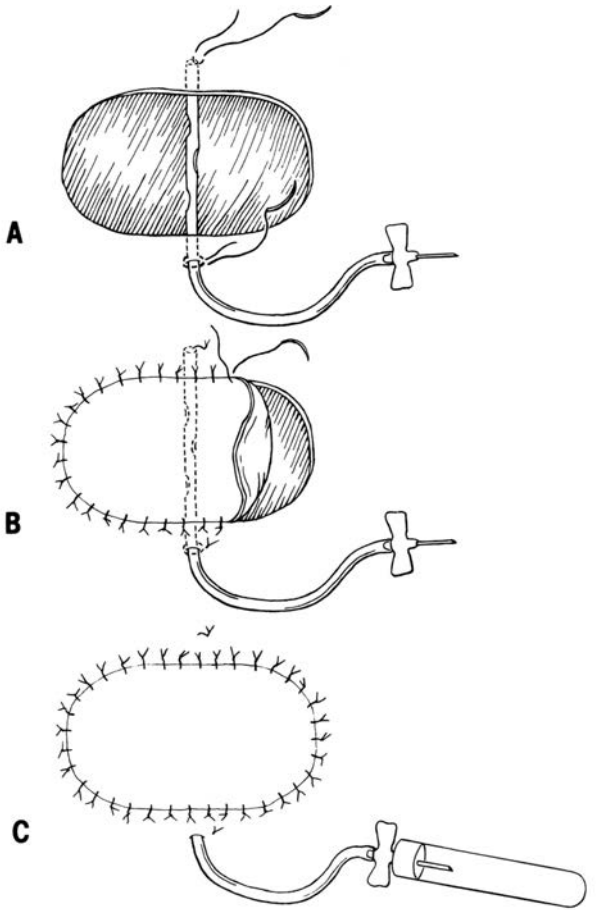

Figure 2-16. Placement of a closed suction drain under a skin graft. **A.** A butterfly catheter with the Luer adapter removed and the tubing fenestrated is placed across the wound bed before the graft is placed. The proximal end is secured with a simple interrupted suture placed through skin, catheter, and skin again. A pursestring suture is used to secure the distal end of the tubing to the skin. **B.** The graft is sutured into place over the drain. **C.** The needle on the catheter is inserted into a 5 or 10 mL evacuated blood collection tube. (From Swaim SF. Skin grafts. Vet Clin North Am Small Anim Pract 1990;20:147.)

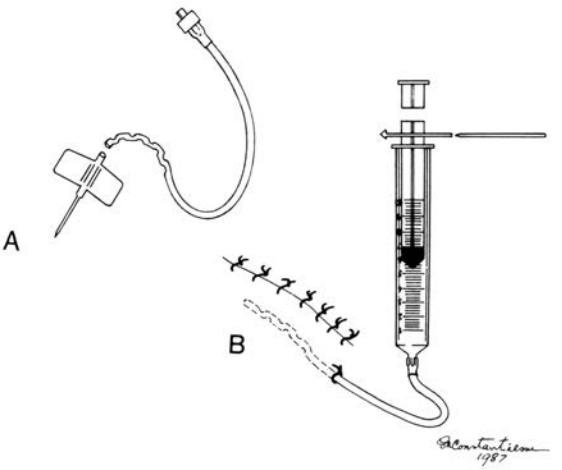

Figure 2-17. Modified closed suction drain. **A.** The butterfly needle is removed from the catheter and the catheter tubing is fenestrated. The Luer adapter is left on the catheter. **B.** A plastic syringe is attached to the Luer adapter of the catheter. A metal pin or hypodermic needle is driven through the plunger just above the barrel after the plunger is withdrawn the desired distance. The end of the plunger can be cut off.

Closed suction drains allow wounds and dressings to be kept dry: they help to prevent bacterial migration through or around the drain; they provide continuous drainage to decrease drainage time; they reduce the need for irrigation; and they have few complications. When used under skin grafts, these drains help to hold the graft in contact with the wound bed, enhancing revascularization and early engraftment. Evacuated blood collection tubes can be changed as often as necessary, and wound fluid can be accurately measured and cytologically examined to assess wound infection.

One disadvantage of closed suction drainage is that high negative pressure can injure the tissue. In addition, although the 10 mL evacuated blood tubes are effective and not cumbersome to incorporate into a bandage, they may need to be changed several times each day in highly productive wounds.

Duration of Drainage

The times for drain removal vary depending on the type of wound drained. A drain should be removed as soon as the need for it no longer exists. The amount and character of drainage fluid are the most important factors in determining when a drain should be removed. In general, it is time to remove the drain when the amount of drainage is significantly decreased (usually by half or more) and is remaining relatively constant from day to day, and the character of drainage fluid becomes less turbid, becoming serous or serosanguinous. Closed suction drains incorporate fluid storage within the system, simplifying evaluation of volume and character. When a passive drain is employed, absorbent bandage material should be placed over the drain to protect the wound and the drain, and to capture the drainage for evaluation of volume and character. To give some specific examples of approximate duration of drainage, a drain placed in a wound to prevent hematoma formation from capillary oozing can be removed within 24 hours. A drain used for an infection, such as an abscess, should be removed in 3 to 5 days or when the infection is controlled. For hygromas and large seromas, the drain may need to remain in place for as long as 10 to 14 days, for severe bite wounds, 4 to 6 days; and for major tumor resection with creation of extensive dead space, 4 days.

Complications and Failures of Drains

Failure to secure a drain to the skin or to protect it from molestation can result in removal of a drain before it has accomplished its purpose, slippage back into the wound, or breaking off in the wound. If strong adhesions form around a drain or if a suture has inadvertently been passed through the drain, the drain may break when being removed, leaving a portion in the wound. Use of drains can cause wound infection because of decreased local tissue resistance and infection ascending around the drain with bacterial proliferation in the area. Proper aseptic technique should always be followed whenever drain management is performed (e.g. emptying the reservoir of a closed suction drain) to minimize the risk of this complication. Drains placed in some areas (e.g., axillary or inguinal areas) may allow air to be sucked into the wound as tissues move. This can result in subcutaneous emphysema. Surgeons should not rely on drains rather than good surgical technique to manage wounds, nor should they give in to the temptation to close and drain areas that would be better left open.

Chapter 3

Electrosurgery and Laser Surgery

Electrosurgical Techniques

Robert B. Parker

Electrosurgical units are probably among the most frequently used and least understood surgical instruments. Little information is available in the veterinary literature concerning basic electronics, proper surgical techniques, and potential hazards. Judicious use of electrosurgery can be of great benefit to the veterinarian in maintaining a bloodless surgical field, but indiscriminate use can create serious complications. The following discussion describes available electrosurgical methods and apparatus and provides a guideline for their proper use.

Electrolysis

Electrolysis implies a unidirectional, direct current flow that produces strong polarity in the anode and cathode (Figure 3-1). The system is of low voltage and amperage. When the electrodes are inserted into the body, hydroxides are produced at the treatment cathode by the following formula:

$$2\,NaCl + 4\,H_2O \longrightarrow \begin{cases} 2\,NAOH + 2\,H_2 \text{ (cathode)} \\ 2\,HCl + O_2 \text{ (anode)} \end{cases}$$

The hydroxides liquefy tissue, yet produce minimal discomfort.

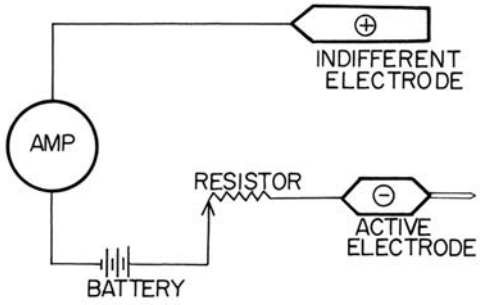

Figure 3-1. Basic circuit diagram for an electrolysis unit.

Electroepilation has been used in ophthalmic surgery for treatment of ectopic cilia or distichiasis. The fine cathode electrode is passed to the base of the cilia, where the current and hydroxides liquefy and destroy the ciliary root.

Electrocautery

The use of cautery to control hemorrhage dates back to ancient times, when a hot iron was used to cauterize wounds. More sophisticated microcautery is now available, but the technique of direct heat application is the same.

Low voltage current is used to heat the treatment electrode, and therefore, electrical energy does not pass through the body (Figure 3-2). The destructive effect is heat coagulation, and the temperature is proportional to the intensity of the current flowing through the resistance of the tip.

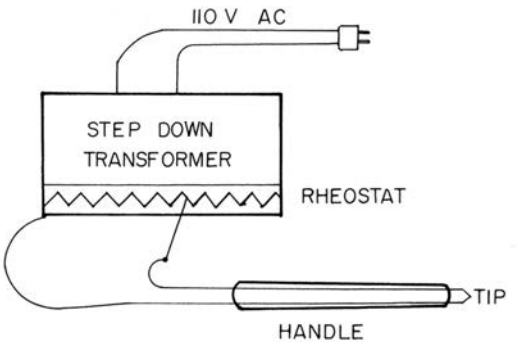

Figure 3-2. Basic circuit diagram for a thermal electrocautery unit.

Advantages of this technique are that 1) the degree of tissue damage is apparent, 2) it coagulates well in a bloody field, and 3) it is inexpensive and simple. The disadvantages are that 1) tissue destruction can be extensive and 2) large lesions are slowly destroyed.

Electrocautery units are generally reserved for minor surgical procedures, such as dewclaw or tail removal in puppies. Disposable electrocautery units, frequently used in ophthalmic surgery, provide fine hemostasis by pinpoint heat application (Figure 3-3).

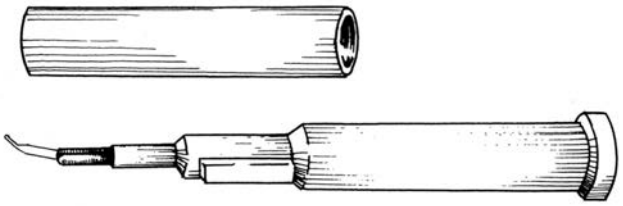

Figure 3-3. Disposable electrocautery unit.

High Frequency Electrosurgery

Most electrosurgical units available today fall into this category. The unit is essentially a radio transmitter that produces an oscillating high frequency electrical field of 500,000 to 100,000,000 hertz (cycles per second). Above 10,000 hertz, current can be passed through the body without pain or muscle contraction. In contrast to electrocautery, the treatment electrode is not hot, but serves to deliver electrical energy at a concentrated area. The electrosurgical effect is determined by 1) the tissue resistance, 2) the mode of application, and 3) the amount and type of current. These factors can be modified to produce the desired surgical response.

Body tissue and fluids have a definite electrical impedance or resistance. Heat is produced by the resistance to current flow as electrical energy is absorbed and converted to thermal energy. Because resistance is inversely proportional to surface area, resistance decreases as the current spreads over the body.

The mode of application can be either uniterminal or biterminal. Biterminal application, used most frequently with cutting or coagulation, implies the use of an indifferent electrode or "ground plate" (Figure 3-4). The indifferent electrode collects

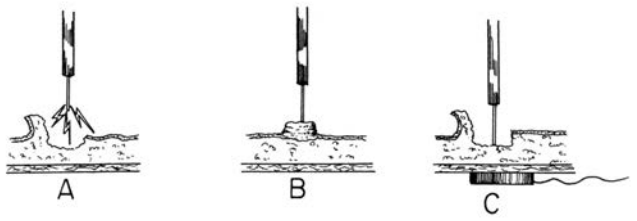

Figure 3-4. Uniterminal techniques, electrofulguration **A.** and electrodesiccation **B.** Biterminal techniques, electrotomy and electrocoagulation **C**.

the current when it has passed through the body and dissipates it over a large surface area to produce a low current density. Because heat production is inversely proportional to the contact area, the large size of the indifferent electrode evenly distributes the heat to prevent burning. The active electrode concentrates the same energy at a small point and produces the surgical effect (Figure 3-5).

With the uniterminal technique, the patient is not incorporated into the electrical circuit. An indifferent electrode is not used and the electrical energy is absorbed by the patient and is radiated into the air. Thus, sparking is produced at the tip and is directly applied to the lesion to cause either fulguration or desiccation (See Figure 3-4).

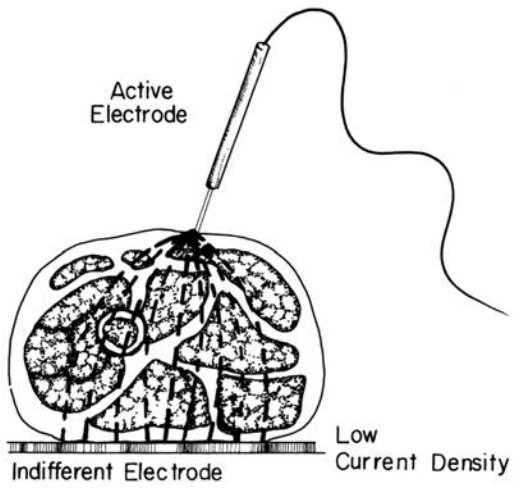

Figure 3-5. High current density at the active electrode and low current density with a properly placed indifferent electrode.

Most modern electrosurgical units provide different waveforms to bring about either cutting or coagulation. An undamped, continuous sine wave makes the most effective cutting current (Figure 3-6). Little hemostasis is achieved with a pure sine wave. In older units, a triode vacuum tube was used to produce the sine wave, but newer solid state units use electronic circuitry to yield a more refined current. A series of damped or interrupted waves achieve coagulation with limited cutting capability (Figure 3-7). Blended currents are possible and produce a combined cutting and coagulation mode (Figure 3-8). The more expensive units are capable of varying the "on-to-off" time to accomplish degrees of cutting versus coagulation.

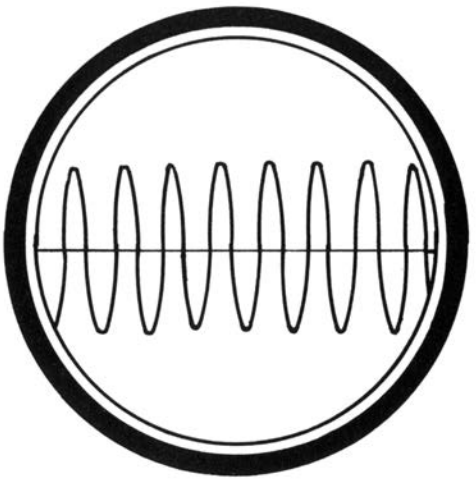

Figure 3-6. Undamped, continuous sine (cutting) waves.

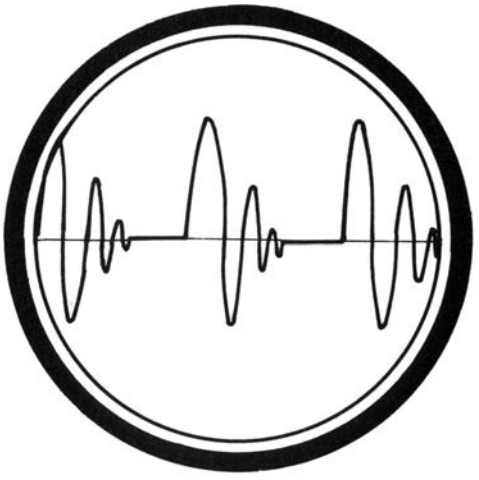

Figure 3-7. Damped (coagulation) waves.

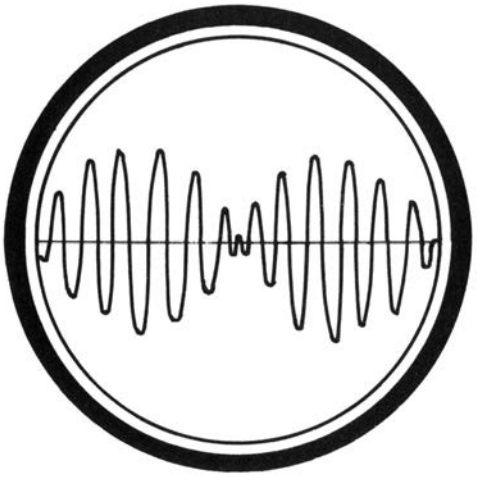

Figure 3-8. Blended (combined cutting and coagulation) waves.

Surgical Techniques

These techniques include electrotomy, electrocoagulation, and electrofulguration and electrodesiccation.

Electrotomy

Electroincision of any tissue causes greater tissue damage than sharp incision; therefore, the veterinarian must weigh the advantages of reduced blood loss and operating time against the disadvantages of increased tissue destruction and healing time. Electroincision of the skin heals primarily, but a definite lag is seen in the ultimate healing of the wound. Healing does occur, however, and maximal breaking strength is achieved.

The primary indications for electroincision of the skin are in patients with clotting disorders or when anticoagulant treatment is anticipated, such as with cardiopulmonary bypass procedures. Because of the initial delay in wound healing, it is recommended that skin sutures remain approximately 2 to 3 days longer with a skin incision made with an electrosurgical unit. The amount of coagulation and necrosis is proportional to the amount of heat produced and its duration of contact. Therefore, it is best to use a smooth, swift stroke when using an electrosurgical scalpel.

The high frequency electrosurgery units such as the Ellman Surgitron (Ellman International, Hewlett, NY) cause no more tissue destruction than traditional cold scalpel surgery if used in the pure cutting mode.

An electrosurgical scalpel has been used to cut virtually every type of tissue; its use in division of muscle or other highly vascular tissue is generally accepted procedure. By using blended currents, muscular tissue can be divided with less blood loss and in less operating time. The small blood vessels traversing muscular tissue can be effectively coagulated without the necessity of using ligatures that are difficult to place unless one includes significant amounts of normal tissue. With electrotomy of muscular tissues, particular attention should be made to large vessels; they can be incompletely coagulated, may retract, and may form a hematoma. If muscle twitching is a problem, one should tense the muscle between one's fingers to facilitate transection.

Although I do not routinely use them, electrosurgical scalpels and loops have been advocated for performing tonsillectomies, uvulectomies, ventriculocordectomies, anal sacculectomies, and skin tumor resections.

Electrocoagulation

The electrosurgical apparatus is extremely useful for coagulation of small bleeding vessels. A damped wave pattern provides the ultimate current for coagulation. Proper technique is required, and the technique of "frying tissue until it pops" is to be avoided. This practice is comparable to mass ligation of a bleeding point, and both lead to unnecessary tissue necrosis.

Vessels less than 1.5 mm in diameter can be sealed by pinpoint electrocoagulation. If larger vessels are coagulated by this method, delayed breakdown and hemorrhage may occur. Because fluids are current conductors, the field must be dry in the area surrounding the bleeding vessel. There are two ways to coagulate a bleeding vessel properly. The first is to apply the activated tip directly onto the vessel. The end point of coagulation is determined by tissue contraction and color change. A more precise method is to occlude the vessel initially with a hemostat or plain tissue thumb forceps. The active electrode is applied directly to the surgical instrument, which carries the current directly to the vessel. Care should be taken to prevent unwanted coagulation by not allowing the instrument to rest on normal tissue when the current is applied.

Electrofulguration and Electrodesiccation

These electrosurgical techniques cause dehydration and superficial destruction by a high-voltage, high-frequency current. These techniques are uniterminal; an indifferent electrode is not used. Electrofulguration damages tissue by electrical energy transmitted through an electrical arc or spark. Electrodesiccation is similar, although the electrode directly touches the lesion (See Figure 3-4). Tissue damage is deeper than with fulguration and may be difficult to control. Electrofulguration of perianal fistulas after a sharp "deroofing" procedure has produced encouraging results. Electrodesiccation has been used for removal of superficial skin lesions.

Precautions

Accidental burns are probably the most frequently observed complication of electrosurgery. It is imperative that an adequate indifferent electrode ("ground plate") be incorporated in the system. Because of its large surface area, the indifferent electrode normally provides a low current density to complete the electrosurgical circuit. If contact between patient and plate is inadequate, however, high density electrical current can easily cause a burn (Figure 3-9). Although the indifferent electrode is designed to be the preferential pathway for the current, a faulty connection between the plate and the unit can result in a burn where the patient touches the metal operating table or the attachment sites of electrical monitoring equipment.

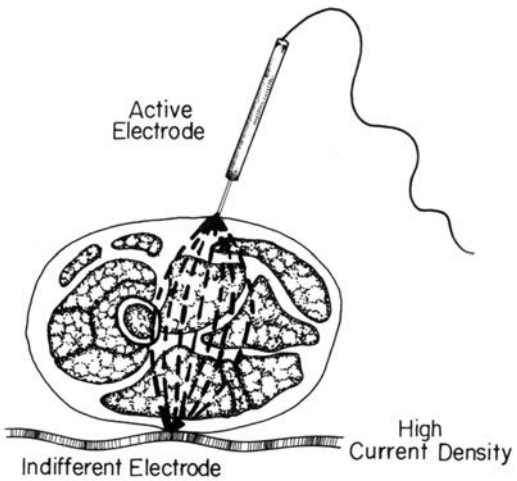

Figure 3-9. High current density produced at the indifferent electrode with improper technique.

More expensive units have a 60 cycle monitoring current flowing through the "ground plate" system. A break in the ground wire or in its ground plate connection interrupts the monitoring current and sounds an alarm. Electrolyte jellies and a large area of contact with the patient are recommended to lower skin resistance and to provide more intimate contact between the skin and the indifferent electrode.

Explosions and fire are potential hazards when inflammable anesthetics, such as ether, chloroform, and cyclopropane, and inflammable skin preparations, such as alcohol, are used.

Electrical channeling occurs when the treatment electrode is used on tissue that has a thin connection to the body. An example is the testicle mobilized out of the scrotum. If electrocoagulation is used, electric energy will be channeled or funneled along the spermatic cord and will cause heat damage.

Cardiac pacemakers are implanted with increasing frequency in veterinary medicine, and the veterinary surgeon should be aware that high frequency electric energy may cause a cardiac arrest by interfering with the operation of the pacemaker.

Electrosurgery–Radiosurgery

A. D. Elkins

Introduction

Electrosurgical units are used to some degree in many veterinary practices. These units are often incorrectly used and in most hospitals under-utilized due to a lack of understanding of proper technique. The use of radiosurgery reduces operative time when used correctly with no delay in healing. The following discussion describes the difference in low frequency, electrosurgery and high frequency (3.8 to 4.0) radiosurgery units and provides a guideline for their proper use.

Radiosurgery is defined as the use of energy created by high frequency alternating current to perform surgical procedures. This is in contrast to electrosurgery in which low frequency (.5 mhz to 3.7 mhz) alternating current is used. The resistance of the tissue to the passage of this current creates heat internally in the tissue resulting in either cutting or coagulation.[1] In radiosurgery, two electrodes (an active electrode and a patient return plate) of greatly different sizes resulting in increased current density at the point of the smaller active electrode are utilized. (Figure 3-10). While the electrode itself remains cold, the highly concentrated high frequency energy creates molecular heat inside each cell. The intercellular water boils and creates a microexplosion, thus incising tissue. The key to successful use of radiosurgery is control of the heat adjacent to the primary incision. By the choice of electrodes and selection and adjustment of the current, the surgeon controls the effect of this energy on the tissues to achieve the desired results. The ideal frequency for radiosugery is 3.8 to 4.0 MHz.[2] This frequency allows for consistent primary healing of skin incisions. When low frequency energy is used to perform a skin incision, the risk of having delayed tissue healing increases due to the build up of lateral heat in the tissue.

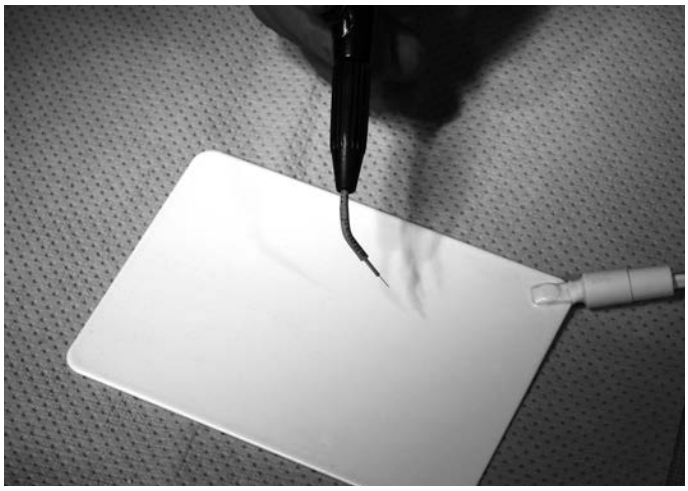

Figure 3-10. Active electrode (wire) and indifferent plate.

A 4.0 mhz radiosurgery incision, unlike a scalpel blade incision, requires no pressure. The results are technique related (these techniques will be discussed later). Most of the factors related to a successful outcome are controlled by the surgeon. The buildup of lateral heat adjacent to an incision should be avoided. The following formula expresses the factors involved in the development of lateral heat.

$$\text{Lateral heat} = \frac{\text{Electrode size x electrode contact time with tissue X intensity of power x waveform}}{\text{Frequency}}$$

The only factor not in the surgeon's control is the output frequency of the equipment used. As can be seen from the above formula, the lower the frequency, the more lateral heat produced.[3]

Radiosurgery can be used for making an incision, excising a mass, obtaining a biopsy or controlling hemorrhage. The majority

of veterinarians who use electrosurgical units use them primarily for hemorrhage control.

Electrocautery

The term electrocautery denotes the use of a hot iron to stop bleeding. The use of cautery to control hemorrhage dates back to the ancient Egyptains.[1] Low voltage current is used to heat an electrode. When this heated electrode is applied to tissue a thermal burn occurs. The destructive effect on tissue is heat coagulation and hemorrhage control. Using electrocautery causes collateral damage to the tissue, resulting in delayed healing, therefore, electrocautery is not the ideal method of hemorrhage control. When describing the use of a radiosurgery unit to stop hemorrhage, the correct term is electrocoagulation. Since there is no heat build-up at the electrode tip this is not cautery. The terms electrocautery and electrocoagulation have been incorrectly used synonymously in the literature.

Electrocoagulation

Electrocoagulation is the use of electrosurgical current to control hemorrhage. Vessels up to 2 mms in diameter can be coagulated with electrosurgery units. Vessels larger than 2 mms should be ligated. Utilizing proper technique by touching an electrode to a vessel in a relatively dry field or to a hemostat which has been applied to the vessel will form a coagulum at the end of a vessel. Excessive heating of the tissue until it snaps or pops should be avoided as this causes increased tissue necrosis. The use of electrocoagulation to control hemorrhage results in better visibility thus allowing the surgeon to be more efficient and reduce operative time. It also reduces the amount of foreign material left in a wound from ligatures. The majority of surgical procedures can benefit from the use of radiosurgical electrocoagulation. It has been said that a poor surgeon is not made better by the use of radiosurgery, only more efficient.

The application of an electrode to an actively bleeding vessel is only successful in controlling hemorrhage if the bleeding is temporarily arrested. This can be accomplished by either direct pressure to the vessel then applying the electrode or clamping a hemostat to the vessel then touching the electrode to the hemostat (Figure 3-11).

When touching the electrode directly to the vessel, a larger electrode, like a ball or blade, is more effective (Figure 3-12). Either of these techniques is effective if the field is relatively dry. This is known as monopolar electrocoagulation. An alternative is the use of biopolar forceps. (Figure 3-13). In using bipolar forceps, one tip acts as the active electrode and the other the indifferent plate. This gives precise pinpoint control of the electrocoagulation effect. It can be used anywhere in the body, but is very useful near delicate and sensitive tissue such as the spinal cord, eye, nerves, or large vessels. Bipolar forceps are very useful for surgery in avian and small exotic species.

Electroincision

An incision with high frequency radiosurgery may replace a scalpel incision in any tissue. This being said, it is imperative to

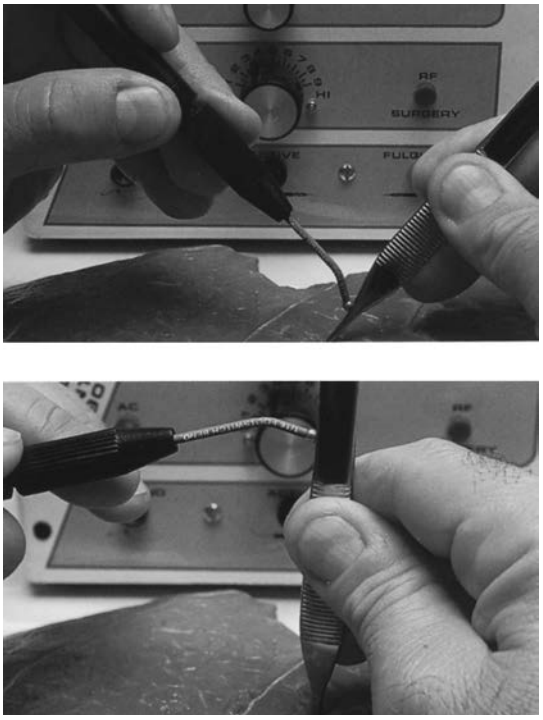

Figure 3-11. Thumb forceps on vessel with electrode applied to thumb forceps.

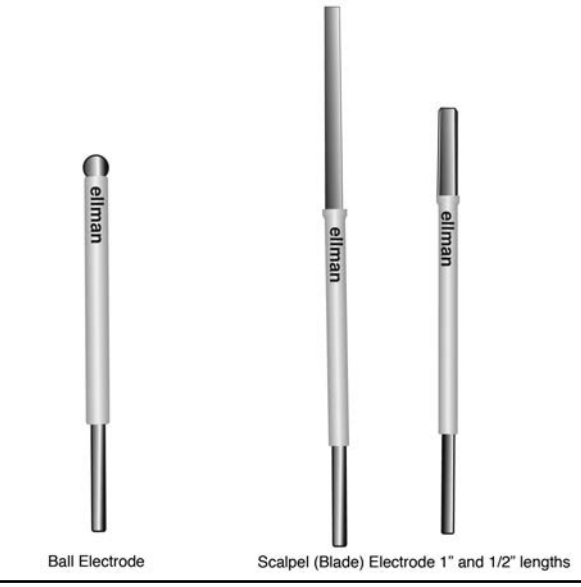

Figure 3-12. Ball electrode and blade electrode used for electrocogulation.

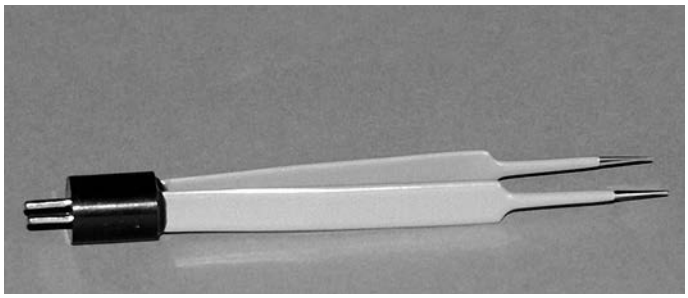

Figure 3-13. Bipolar forces.

use proper technique and a frequency of 3.8 to 4.0 MHz when making skin incisions. A frequency lower than 3.8 to 4.0 MHz risks the buildup of lateral heat in the tissue. This may result in delayed healing and/or dehiscence of the incision.[4]

Four wave forms or current types may be selected when using a high frequency radiosurgery unit. These wave forms are:

A. Fully filtered or continuous wave form is a continuous high frequency waveform that produces a smooth cut (Figure 3-14). It gives a 90% cut and a 10% coagulation effect. It generates the least amount of lateral heat. When this waveform is delivered by a fine wire electrode, it is comparable to a scalpel blade with excellent healing properties[4] (Figure 3-15). A biopsy obtained with this waveform creates a micro-smooth cut with no heat artifact at the edges. This allows an accurate reading by the pathologist on the biopsy specimen. The fully filtered/ continuous waveform should always be used when making skin incisions.

B. Fully rectified waveform is not as smooth as the continuous wave form; thus reducing the efficiency of the cut (Figure 3-16). It does, however, achieve a significant amount of hemostasis. When using a unit with 3.8 to 4.0 output frequency, minimal thermal damage can be expected. This setting produces a 50% cut and 50% coagulation effect. It is ideal for sub-cutaneous tissue incision, dissection or when working in vascular tissue such as the oral cavity.

C. Partially rectified waveform is an intermittent transmission of high frequency waves that increases lateral heat production (Figure 3-17). This is ideal for electrocagulation of small vessels up to 2 mms. It gives 90% coagulation with a 10% cut effect.

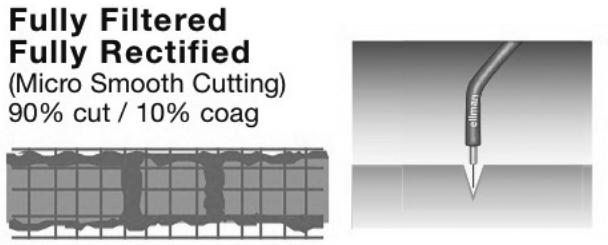

Figure 3-14. Oscilloscope showing fully filtered, 90% cut waveform. Notice the smooth, continuous nature of the waveform

Figure 3-15. Fine Wire electrode.

D. Fulguration is a spark-gap wave form (Figure 3-18). Fulguration rapidly dehydrates or desiccates tissue. This is ideal for areas where the surgeon wants intentional tissue destruction (such as perianal fistula, abscess or draining tracts). This may also be used with a ball electrode to control diffuse, weeping type bleeding. The tissue destruction is self-limiting by the insulating effect of tissue carbonization, therefore only a superficial layer of tissue is damaged.

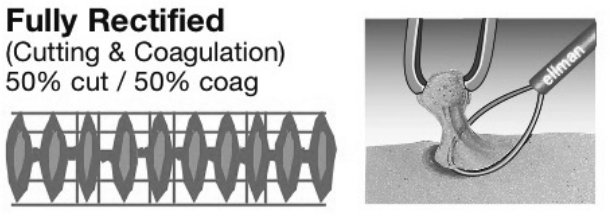

Figure 3-16. Fully recitifed, 50% cut, 50% coagulation waveform on oscilloscope.

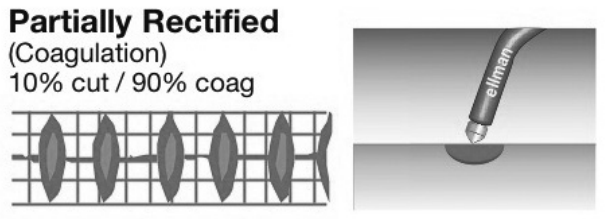

Figure 3-17. Partially recitifed, 90% coagulation/10% cut waveform on oscilloscope.

Figure 3-18. Fulguration waveform on oscilloscope.

Factors to Consider in Selecting Electrosurgery

Tissue selectability is determined by the degree fibers are cut compared with how much they shift as energy is applied.[4] This is important in making incisions around the eye or other mobile skin areas. When incising skin in these areas with a scalpel blade, significant pressure is required and the final incision may not have the desired appearance. This is avoided with radiosurgery in that it is a pressureless cut. Pre-planning the incision by drawing its margins with a skin marker may be helpful.

Multiple studies have been performed comparing high frequency radiosurgery, scalpel and carbon dioxide laser.[5] In one study in human oviduct excision, it was found that radiosurgery produced less lateral heat damage to the surrounding tissue than laser.[5] Although the learning curve with radiosurgery is not steep, poor technique using this method of tissue incision may result in delayed wound healing.

The following points should be considered when utilizing radiosurgery:

A. Use a high frequency (3.8 to 4.0 MHz) unit when making skin incisions. This helps prevent lateral heat damage.
B. Chose the smallest wire electrode available to reduce tissue resistance and heat build-up.
C. Use the full filtered or continuous wave form when making skin incisions.
D. Use the lowest power setting possible without producing drag of the electrode through the tissue. The electrode should pass through tissue effortlessly with minimal sparking or plume production. There should be minimal to no charring of the tissue.
E. Electrode contact time with the tissue is directly proportional to the lateral heat transferred to the tissue. The electrode should be moved rapidly through the tissue. If you have to return to the same area, allow an eight second lag period to occur. This allows heat build-up in the tissue to dissipate.
F. Avoid contact of the electrode with cartilage, bone or enamel. The most sensitive tissue is cartilage due to its high water content. Therefore, when performing a procedure like a feline onychectomy the distal portion of P2 should be avoided.

Precautions

Accidental burns to the patient are the most serious observed complication to electrosurgery.[4] Many electrosurgery units utilize a metal ground plate. If good contact between the ground plate and patient is not present, a burn can be created. The ground plate is designed to be the deferential preferred pathway for current. If a faulty connection exits then a burn can occur.[1] Electrolyte jelly and a large area of contact with the patient are recommended to lower skin resistance and to provide more intimate contact between the skin and the ground plate.[4]

A safer system is the use of an indifferent plate or an antenna plate found with the the Ellman Surgitron or Dual Frequency unit[a] (Figure 3-19). This is a plastic coated plate that requires no conductive gel and does not have to be in contact with the patient. This indifferent plate can be placed under the surgical drape but it should be in close vicinity to the surgical site. This makes the unit more efficient and allows the surgeon to use a lower power setting.

Explosions or fire are potential hazards if using flammable liquids like alcohol. If alcohol is used in the skin preparation for surgery, allow an adequate time for the alcohol to dry.

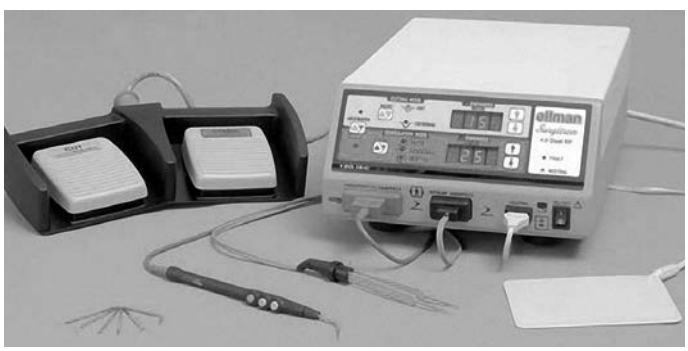

Figure 3-19. 4.0 MzH Dual Frequency radiosurgery unit with indifferent plate.

[a] Ellman International 3333 Royal Avenue, Oceanside, N.Y. 1 1572

In summary, this author has been performing radiosurgery with either an Ellman Surgitron (3.8 mhz) or the newer Dual Frequency (4.0 mhz) Unit for over 30 years. Excellent clinical results can be achieved when high frequency, low temperature radiofrequency devices are used and good radiosurgery principles are followed. The modern radiowave units are affordable, durable and become work horses in surgical practice. Some form of radiosurgery, either for making an incision, excision, dissection or hemostasis is used on each surgery performed.

Lasers in Veterinary Medicine–An Introduction to Surgical Lasers

Kenneth E. Bartels

Introduction

The principles necessary for the concept of laser development were reported as early as the 19th century with Bohr's theory of optical resonance. In 1917, Einstein proposed the concept of stimulated light emission. Finally, in 1960, Theodore Maiman developed the first laser which was a pulsed ruby laser.[1] Since medical use began in the early 1960's, the laser has been considered by many to be "a tool in search of an application." Many of the earlier medical lasers were extremely cumbersome, expensive, and difficult to maintain. However, as biomedical laser technology merged with military and industrial efforts, innovations and improvements in devices and development of new concepts occurred and continue today. Developmental requirements to implement these new technologies include improvements in light delivery systems (robust articulated arms, small diameter wave-guides, and small-diameter optical fibers), compatible laser wavelengths, endoscopic visualization, and more portable, economical, user-friendly biomedical lasers.

Unique Properties of a Laser

Light bulbs and lasers both generate *light,* which is the common name for electromagnetic energy that we can see. The electromagnetic spectrum extends from the very short wavelengths (gamma radiation at 10^{-11} m) to radio waves (10^{-1}). Laser wavelengths fall between the infrared and ultraviolet wavelengths of electromagnetic radiation, which include the

invisible and visible light spectrum. The word **"LASER"** is an acronym that stands for **L**ight **A**mplification by the **S**timulated **E**mission of **R**adiation. An extensive discussion in laser physics is not consistent with this general overview. In simpler terms, as a bow stores energy and releases it to propel an arrow, a laser stores energy in atoms, concentrates it, and then releases it in powerful waves of light energy. This process is called **stimulated emission**. The resulting emission of photons resonates between mirrored ends of a laser resonating cavity. These bouncing photons further excite other atoms in a laser medium. Momentum builds until a highly concentrated beam of light passes through a partially transmissive mirror at one end of the laser resonating cavity.[2]

Like sound through air or water on a lake, light travels in waves. Moreover, the color of light is governed by its frequency and wavelength (distance of one peak to the next). Normal white light is incoherent and includes many wavelengths radiating in all directions. The peaks and valleys of the waves do not coincide. A prism illustrates this as it sorts a white light into individual colors of the rainbow. Laser light does differ from ordinary light much as music does from plain noise. Laser light, in comparison to ordinary light, is **coherent**. Each peak and valley of individual light waves align exactly. If laser light waves could be heard, their sound would resonate with the clarity of a single musical tone. In addition, laser light is of one wavelength (one color), or is **monochromatic**. Finally, laser light is **collimated**, or non-divergent, and directional. Parallel light waves move in unison, reinforcing each other as they travel through space forming a virtual tidal wave of laser energy.

Today's technology allows the manufacture of lasers that produce wavelengths of light extending from ultraviolet to far-infrared wavelengths. Devices range in size from miniaturized diode lasers capable of being passed through the eye of a needle to a free electron laser which covers the entire length of a large building. However, each laser is composed of the same basic components and functions according to the lasing medium stimulated to produce energy emission and light. Please refer to Figure 3-20: Laser Components.

Laser wavelength refers to the physical distance between crests of successive waves in the laser beam, indicated in units of length expressed as nanometers or microns. By definition, 1 nanometer (nm) = 10^{-9} meter, or one-billionth of a meter. One micron (μm) is equal to 10^{-6} meter or 1000 nm. More common medical lasers include ultraviolet (193 nm and 308 nm), visible (532 nm and 630 nm), near-infrared (805 nm, 980 nm, and 1064 nm), mid-infrared (2100 nm), and far-infrared (10,600 nm) wavelength systems. This means that many of the common laser wavelengths used for medical applications (diode/805-980 nm; carbon dioxide/10,600 nm) cannot be seen by the human eye and can be extremely dangerous as far as ocular hazards due to this fact.[2]

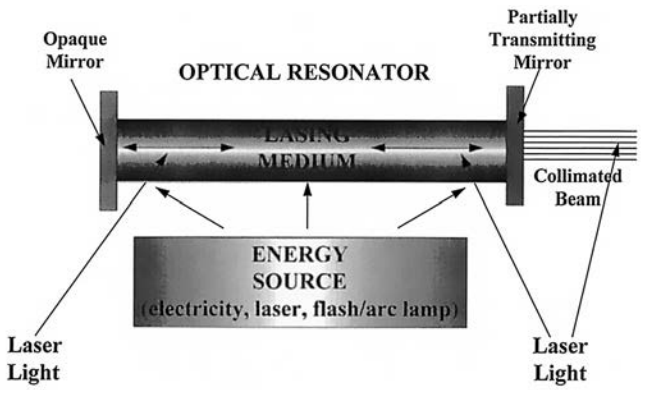

Figure 3-20. Components of a laser.

Types of Laser–Tissue Interaction and Laser Operational Modes

Laser radiation must be converted into another form of energy to produce a therapeutic effect. Laser-tissue interactions are categorized according to whether laser energy is converted into heat (photothermal), chemical energy (photochemical), or acoustic (photomechanical/photodisruptive) energy. Photothermal interactions occur when laser light is absorbed by tissue and converted into thermal energy, which results in a rise in tissue temperature. When far-infrared laser wavelengths (10,600 nm) are used, the water component of tissue plays a predominant role in the absorption of laser energy. Water is heated directly with laser energy, and other molecules may then be indirectly heated via heat conduction. Other tissue components (hemoglobin, melanin, proteins) may also absorb energy at specific mid-infrared wavelengths (805, 980, 1064 nm) and play an important role in the tissue heating process. The absorption of laser energy in any tissue is the sum of the absorptions of each of the tissue components coupled with the absorption coefficient of water. For example, the effective absorption depth or extinction coefficient of CO_2 carbon dioxide laser energy (10,600 nm), which is heavily absorbed by water, is approximately 0.030 mm, but is about 1 to 3 mm for the diode (805/980 nm) or neodymium yttrium aluminum garnet Nd:YAG (1064 nm) lasers, which are less heavily absorbed by water.[3]

Visible laser wavelengths (400 to 700 nm) are poorly absorbed by water and usually rely on blood or other endogenous tissue pigments or exogenous photoactive compounds to absorb laser light and convert them to heat or active photochemical components. Naturally occurring molecules that absorb visible wavelengths include hemoglobin and melanin. Protein molecules, DNA, and RNA absorb ultraviolet wavelengths strongly and usually play a dominant role in converting UV light energy into heat. Figure 3-21 illustrates the water absorption curve, which is an essential component in understanding the concept of laser-tissue interaction.[3]

Pulsed laser energy generated by the dye, holmium, or erbium lasers can be converted into acoustic (photomechanical) energy in the form of a shock wave or a high-pressure wave, which can physically disrupt the targeted structure when combined with a photothermal interaction (laser lithotripsy). Laser light can also be absorbed and converted into chemical energy (photochemical) that can break chemical bonds directly or excite molecules into a biochemically reactive state. Laser wavelength is the critical factor in this process. Short ultraviolet wavelengths (*e.g.,* 193 nm) are needed to maximize chemical bond-breaking processes while minimizing the photothermal process as observed with

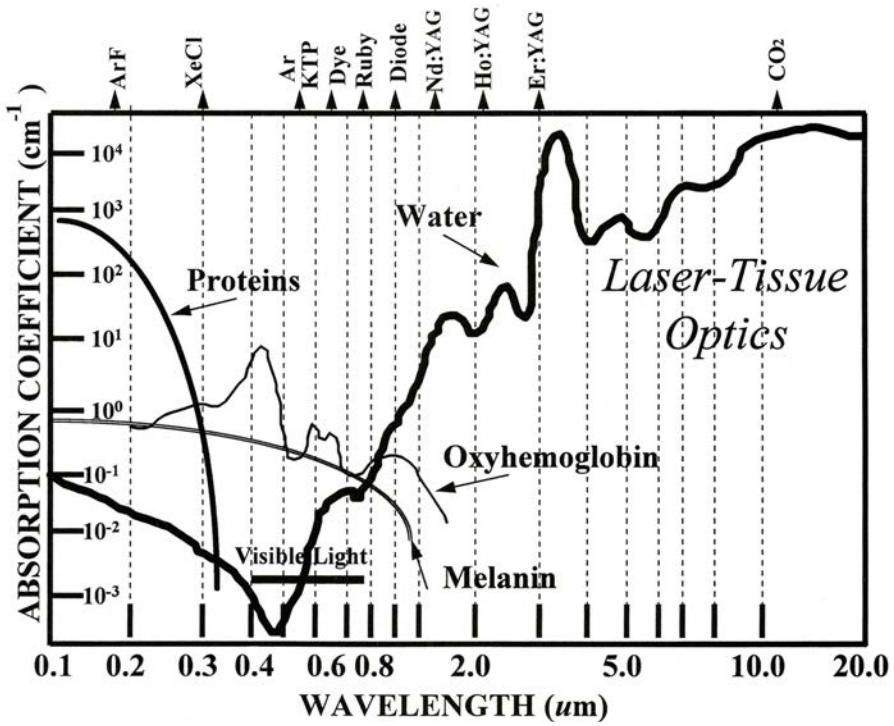

Figure 3-21. Laser tissue optics: water absorption curve. This graph illustrates the varying degrees of absorption of a specific wavelength (color) of light by water compared to absorption in oxyhemoglobin, melanin, and tissue proteins including amino acids, DNA, and RNA. Ar, argon; KTP, potassium titanyl phosphate; XeCl, xenon chloride; YAG, yttrium aluminum garnet.

excimer laser energy commonly used in human ophthalmologic procedures (LASIK).[2,3]

Specific visible wavelengths (630 to 730 nm) can also induce photobiochemical reactions. This type of reaction can be related to photodynamic laser interaction. In general, photodynamic interactions employ light-absorbing molecules (photosensitizers such as hematoporphyrin derivatives) to produce a biochemically reactive form of oxygen (singlet oxygen) in tissue when activated by light of a specific wavelength. Photodynamic interactions are considered to be a special type of photochemical interaction. The therapeutic process is called photodynamic therapy (PDT).[2,4,5]

Biostimulation is a process induced by lower power lasers (5 mW to 12 W/635 to 1064 nm) that may provide pain relief, stimulate wound healing, or alter other biological processes. The entire concept is considered controversial due partly to the fact that all of the physical, biochemical, and physiologic mechanisms are not well understood. Many of the reported results are mostly subjective in nature and are difficult to quantify. However, this therapeutic modality may gain favor as more objective studies are reported.[5,6]

Laser light focused on tissue may be reflected, absorbed, scattered throughout, or transmitted through the tissue. The application of laser energy is very dependent on wavelength, as mentioned previously. It is also essential to say the effect of a laser on tissue is dependent on power. Power is usually expressed in watts. When time is figured into the equation of energy delivery, the term "joule" is used, which is defined as a watt/second. Focal spot size (size of the incident beam of the laser light) results in the concentration of energy within an area, known as "power density" and expressed as watts/cm^2. The advantage of a small spot size is that laser energy is more concentrated and causes less collateral damage, where fewer cells will be affected and destroyed at the margins of an incision. When a rapid, deep incision is required, a small spot size is advantageous in that it will concentrate a high amount of energy into the tissue leading to rapid vaporization. A larger spot size will be less precise and enhance tissue coagulation rather than vaporization. The important term "fluency" takes into account the "time domain" or laser "on time" and is used to describe the total energy delivered to the target tissue in joules/cm^2. Total energy delivered to the tissue target is extremely important when considering a laser beam that is set for a pulsed mode delivery.[2,7]

Biomedical lasers can operate in continuous wave (CW) or pulse mode (single pulse, chopped or repeat, and super-pulse). Laser output in CW mode remains constant, whereas lasers operating in pulse mode deliver short bursts of energy. Manipulating pulse duration and pulse frequency allows the surgeon to adapt laser output to suit a particular clinical application, as well as ensure exquisite control. A laser operating in single pulse mode emits a single, user-defined pulse of energy lasting from a few milliseconds to several seconds. When operating in chopped or gated mode, a laser emits energy at selected pulse duration and frequency. The primary difference between chopped and CW emission is that chopped mode has periodic gaps of zero power in an otherwise CW emission.[2,7]

Superpulse is another temporal mode of CO_2 laser energy delivery that incorporates high peak power in short, high frequency pulses. Lasers operating in a super-pulse mode deliver extremely

high peak power, often 7-10 times higher than the CW maximum power, short pulse duration, and shorter off time than chopped mode. The maximum peak power in super-pulse mode is higher than the maximum CW power by a factor that depends on type of laser and its specific design. The main advantage of using a carbon dioxide laser in superpulse mode is the reduction of carbon formation or a decrease in char.[2,7]

In very simple terms, a volume of tissue cools between rapid pulses of targeted energy, a phenomenon known as thermal relaxation. When laser exposure (pulse duration) is less than thermal relaxation time for the targeted structures, maximal thermal confinement occurs and vaporization (ablation) occurs without damage to non-targeted collateral structures. This concept along with minimal carbon formation on the target tissue surface provides the laser surgeon with exquisite control and precise vaporization not seen with other means of tissue dissection. For surface ablation, use of computerized microprocessors, accessories for some high power carbon dioxide lasers, utilize superpulse laser energy delivery coupled with optomechanical hand-pieces to decrease the "dwell time" a laser beam interacts with the tissue surface. These scanning devices decrease surface carbonization and permit rapid and precise laser vaporization.[3,7,8]

Pulsed laser energy can be converted into photomechanical (photo acoustic) or photothermal energy, depending upon pulse duration, peak power density, and pulse frequency. Photomechanical effects occur when very short (nanosecond – 10^{-9} sec.), high-power laser energy pulses are directed at tissue through a small-diameter optical fiber. The energy plasma-induced shock waves generated at the tip of the optical fiber mechanically disrupts the targeted tissue or calculi. Photomechanical interactions are important in many specialized laser applications, including lithotripsy and ophthalmologic surgery.[9,10]

Photodisruption is a relatively new term used to designate tissue interaction related to effects of ultrafast (femtosecond – 10^{-15} sec.) laser pulses. Laser light is tightly focused to tremendous power density levels (10^{12} W/cm^2) but pulse energies of only 1 uJ. The photomechanical and photothermal side effects are negligible. Tissue is ionized and optically broken down by a process called multiphoton absorption and offers the possibilities to perform very precise surgical operations at the cellular and sub-cellular levels.[9]

The tissue response to the application of photothermal laser energy is a very dynamic process. Changes in the local microcirculation influence the tissue reaction to additional laser energy. When the beam interacts with tissue, the photothermal effect produces a characteristic lesion in living tissue. Initially, hyperthermia and desiccation of tissue and cells occurs and then are followed by coagulation and vaporization. At the impact site, a crater may be formed when tissue has been vaporized from the region. Immediately surrounding the cavity is an area of hyperthermia, cellular coagulation, and eventually, necrosis. This zone is created by the diffusion of laser energy from the point of laser impact. Immediately adjacent to this zone is an area of cellular edema without evidence of alteration in the collagen stroma. The milder thermal injury to the tissue in this region may resolve within 48-72 hours. These phenomena are illustrated in figure 3-22. The generation of smoke, hemorrhage, and char can interfere with the incident laser beam by resulting in scatter, reflection, and absorption of the laser energy and may result in uncontrolled effects on the target tissue or adjacent structures.[3,7,10]

Precise control of hemorrhage and inflammation by photothermal sealing of blood vessels, lymphatic vessels, and incised nerve endings is perceived by most to be distinct advantages of laser surgery. These benefits relate directly to laser tissue interaction depending on wavelength, power, and fluency. However, by inhibiting the early stages of the inflammatory process (lag phase) due to cellular constituents and platelets not being immediately available at the wound site, the healing of laser incisions is minimally delayed. Laser incisions, discounting collateral photothermal effects due to poor surgical technique, gain strength as quickly as incisions made by a steel scalpel and incisional tensile strengths are comparable within 10 to 14 days.[11,12]

Laser vaporization is the process of removing solid tissue by converting it into a gaseous vapor or plume. This is usually in the form of steam or smoke, but laser plume may also contain noxious substances. Therefore, the use of smoke evacuation during laser surgery is deemed essential. Safety issues will be discussed more specifically in a following section. The term "vaporization" is used as a synonym for tissue ablation.

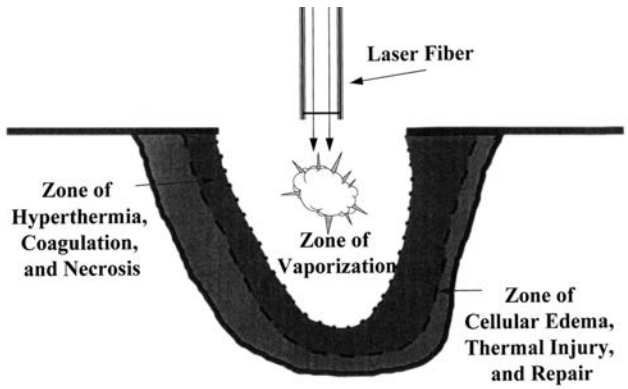

Figure 3-22. Laser tissue interaction. The generalized tissue response to the application of laser energy results in zones of vaporization, necrosis, and reversible thermal injury.

Types of Commonly used Medical Lasers

The development and use of biomedical lasers is considered to be a significant step ahead of mechanical instruments, but falls short of what is needed to be considered as the optimal "light knife" for every surgical situation. Considering differences in laser-tissue interaction, it's still very uncertain whether an "ideal" laser wavelength will ever exist. Discounting future use of free-electron lasers with multi-wavelength variability, acceptance of biomedical use of lasers with a fixed-wavelength has depended more on cost, capability for fiberoptic delivery, portability, flexibility, ease of use, and dependability.[2,4,13]

In medicine today, many different types of biomedical lasers are in use. Each instrument is usually acquired for a specific purpose

in mind, such as dermatologic or endoscopic applications. Overall, the use of laser energy can be an extremely precise and controlled method for tissue removal or cellular destruction. Medical lasers are expensive and require a dedication to proper use and objective evaluation. Lasers in common use today are the carbon dioxide (CO_2), neodymium yttrium aluminum garnet (Nd: YAG), diode, holmium: YAG (Ho: YAG), and dye lasers. The following general descriptions are meant to be used as an overall guide to medical lasers. In no way should it be considered complete. Changes in laser types, wavelength preference, and delivery devices are made on a frequent basis, since they are closely aligned with changes in today's technologic advancements in computer hardware and software.

Carbon Dioxide Laser (CO_2-10,600 nm)

The carbon dioxide laser was one of the first medical lasers used for tissue ablation. At 10,600 nm, the wavelength is ideal for cutting and vaporization because it is highly absorbed by water. It can cut tissue cleanly when the beam is focused onto tissue and can debulk tissue by photovaporization when defocused. Because of the high absorption the 10,600 nm wavelength in water, CO_2 laser energy transmission requires energy delivery through a series of mirrors in an articulated arm or through a semi-rigid waveguide, which makes it awkward for use in an open abdomen or in other localized and confined areas. However, thermal injury from a given amount of energy is relatively superficial (50 to 100 μm in depth).[2] The net surgical result is expressed as "What you see is what you get!" when using the carbon dioxide laser. The learning curve for using a carbon dioxide laser seems to be shorter than with other surgical laser wavelengths (805, 980, 1064 nm) which are optically scattered more in tissue. However, since CO_2 laser delivery systems (articulated arms, hollow waveguides) must be used in a non-contact mode, the tactile appreciation for tissue is lost. This is a disadvantage which can be overcome quite easily with practice. Pertinent engineering specifications for carbon dioxide lasers include the "excitation" mechanism. That is, how the CO_2 gas mixture in the resonating cavity is stimulated to produce 10,600 nm light. Direct current (DC) devices are usually larger machines capable of emitting higher power (> 20 W). Most of these devices use a water cooling mechanism that is either closed or can be connected to a circulating cooling water system. Radiofrequency (RF) excited CO_2 lasers are usually smaller, more robust devices that are either cooled by convection or by an integral cooling fan. RF excited devices usually emit lower power laser energy ($\leq$ 20 W).[10,14]

Nd: YAG Laser (Neodymium Yttrium Aluminum Garnet-1064 nm)

The Nd: YAG or "YAG" laser differs from the CO_2 laser because the wavelength allows transmittance though tissue in addition to surface absorption. High powers up to 100 watts can be delivered through small-core optical fibers that can easily be inserted through the accessory channels of standard GI endoscopes. Since the Nd:YAG laser has less specific absorption by water and hemoglobin than the carbon dioxide laser, the depth of thermal injury can exceed 3 mm in most tissues, which can be useful for coagulation of large volumes of tissue. Fairly rapid tissue vaporization in non-contact mode is possible with a bare non-contact fiber, but collateral thermal injury may be substantial. Power levels approaching at least 50 watts are usually needed for these soft tissue applications.[2]

Continuous wave (CW) Nd: YAG and diode lasers can be used with "hot-tip" delivery systems to perform vaporization and cutting of soft tissue in a contact mode with surgical precision, little collateral thermal injury, and good hemostasis. Hot-tip fibers include sculpted quartz fibers, contact-tipped sapphire fibers, metal-capped fibers, temperature controlled bare fibers, and dual effect fibers. In principle, contact use of fibers for mechanical coaptation of tissue while it is being heated can be advantageous for hemostasis and controlled excision. Use of contact tips for endoscopic application is widely accepted, but some tips are too large to insert through flexible endoscopes.[15,16,17]

Diode Laser (635, 805, 980 nm)

Advancement of semiconductor diode laser development has progressed tremendously in concert with other aspects of medicine described previously. Engineering and commercial specifications have allowed development of devices with wavelengths varying from approximately 635 to 980 nm. Newer technologies may actually allow evolution of diode lasers capable of emitting wavelengths in the mid-infrared range (1.9 to 2.1 μm).[2]

Therapeutic products that employ semiconductor diode lasers were first approved for surgical use in this country in 1989. Diode lasers (1 to 4 watts) are also used for photocoagulation of retinal and other ocular tissues, and have been employed for ophthalmologic applications since approximately 1984.[18] The compact size and high efficiency offer significant ergonomic and economic advantages. High power semiconductor diode lasers appropriate for other surgical applications have been recently introduced for a variety of uses. These lasers currently provide up to 25 to 100 watts at 805 nm or 980 nm, wavelengths that can penetrate deeply into most types of soft tissue, and produce tissue interactions comparable to the Nd: YAG laser (1064 nm).[15] The theoretical difference between use of a diode laser at 805 nm and one emitting a 980 nm wavelength is that a 980 nm device is absorbed to a greater extent by water than is the 805 nm laser, but in actual clinical practice this difference is negligible. Diode lasers can be used with bare-fiber delivery accessories in non-contact mode for deep coagulation, or with hot-tip fibers for precise cutting or vaporization in contact mode. As mentioned, diode lasers can be used for many of the same applications as 1064 nm continuous wave Nd: YAG lasers. However, surgical diode lasers offer considerable advantages compared to Nd: YAG lasers. They are smaller, lighter, require less maintenance, are extremely user-friendly, and can be more economical. Some medical device manufacturers predict prices for diode lasers will eventually drop to the point where they may be competitive with high-end electrosurgical equipment.

Additional applications for diode laser energy have been for chromophore enhanced tissue ablation or coagulation, tissue fusion or laser welding, and photodynamic therapy. The use of sutureless tissue repair employing laser energy has emerged

over the last decade. Tissue welding or fusion has the potential to be one of the most important technical developments in surgery. Used in conjunction with laparoscopic as well as open procedures, laser energy used with biological glue or "solder" reinforcement can provide a higher leakage pressure for vascular and alimentary tract structures than sutures alone. Preliminary investigations involving selective fusion of nerves, urethral tissue, skin, tracheal mucosa, and even bone fragments have also shown promise. Despite a decade of laboratory success in which the superiority of laser tissue welding has been demonstrated, there is still not much clinical use of this technology.[13]

Diode laser (805 nm) induced photothermolysis of tissue selectively stained with indocyanine green (ICG) has shown promise for selective coagulation/vaporization of tumors and contaminated wounds.[4] Diode laser wavelengths of 805 nm have also been reported as being used for tissue welding investigations because applications have been centered around the peak absorption spectrum of indocyanine green (780-820 nm), the selective chromophore used in fibrinogen solder. Laser energy required for tissue fusion is significantly lower (300 mW to 9.6 W/ cm^2) than for incisional/ablative procedures, since minimal thermal changes are required to produce noncovalent bonding between denatured collagen strands and produce the weld.[9] The small, convenient size coupled with reliability and user friendliness has also focused extensive diode laser development for applications in photodynamic therapy, primarily at 635 nm wavelength.[19]

Ho: YAG Laser (Holmium Yttrium Aluminum Garnet-2100 nm)

Clinical holmium lasers have appeared in recent years for arthroscopic surgery, general surgery, laser angioplasty, and thermal sclerostomy. Additional applications have been implemented for laser diskectomy, removal of sessile polyps in the gastrointestinal tract, and otorhinolaryngeal procedures. The main attraction of the holmium laser is its ability to cut and vaporize soft tissue like a carbon dioxide laser, with the added advantage that holmium energy can be delivered through flexible, low OH, quartz optical fibers. Good surgical precision and control can be obtained with a bare optical fiber. Unlike visible wavelength lasers, and again similar to the carbon dioxide laser, photothermal interactions with the holmium laser do not rely on hemoglobin or other pigments for efficient heating of tissue. The water component of tissue is responsible for absorbing holmium laser energy (2100 nm) and converting it to heat. The depth of absorption is quite shallow at approximately 0.3 mm. When cutting or vaporizing tissue, actual zones of thermal injury vary from 0.1 to 1 mm, depending on exposure parameters and the type of tissue. These small thermal necrosis zones provide better surgical precision and adequate hemostasis.[2] Current holmium instruments are flashlamp-pumped systems. The active laser medium consists of a chromium-sensitized yttrium aluminum garnet host crystal doped with holmium and thulium ions. This active medium is referred to as Thulium (Tm), Holmium (Ho), Chromium (Cr): YAG or THC: YAG, and is common to all holmium laser medical devices. Unlike the carbon dioxide laser, higher power holmium lasers cannot operate in a continuous wave mode at room temperature. The relatively low pulse rates (10 to 20 Hz) available from most holmium lasers may be considered as a disadvantage since cutting may be slow or result in jagged tissue edges during incisional applications. In addition, at higher pulse energies ($\geq$ 1 Joule), considerable amounts of acoustical or mechanical energy are generated in tissue. An audible acoustical "pop" may be generated and actually heard during laser application. However, acoustical energy may be considered an advantage when using holmium energy for photodisruptive procedures such as lithotripsy of gallstones or urologic calculi.[20,21,22]

Dye Laser (635 to 700 nm)

Pulsed and continuous wave dye lasers employ an active laser medium that consists of an organic dye dissolved in an appropriate solvent. For the dye laser to work, the dye solution must be re-circulated at high velocity through the laser resonator. Dye lasers are useful for medical applications because they can generate high output powers and pulse energy at wavelengths throughout the visible wavelength spectrum (400 to 700 nm). They are usually pumped by argon lasers, flashlamps, or a frequency-doubled YAG laser. Dye lasers have been used for lithotripsy of biliary and urologic calculi (504 nm-pulsed), activating photosensitizers for photodynamic therapy (635 to 720 nm CW), ophthalmologic operations (805 nm pulsed or CW), and dermatologic applications (577 to 585 nm pulsed) including treatment of birthmarks and removal of tattoos.[2,5,13,20,23]

Laser Delivery Systems

A delivery system refers to the optical hardware needed to transfer energy from the laser to the treatment site. Devices for guiding laser beams to the patient include articulated arms with internal mirrors, hollow waveguides, and optical fibers. Articulated arms and hollow waveguides are used with laser wavelengths (2800 nm to 10,600 nm) that cannot be transmitted through conventional fiber optics due to their light absorption characteristics. Laser energy delivery through an articulated arm has inherent disadvantages due to the size of the arm, durability, and its inability to be used for minimally invasive (endoscopic) procedures. Using carbon dioxide lasers with an articulated arm allows delivery of a precise collimated (Gaussian) focused beam to the incision site. Using a semi-rigid hollow wave-guide provides a non-collimated beam that is multi-model (top-hat) in nature, but still very precise since the laser energy is concentrated and directed through small, aperture delivery tips (0.2 to 1.4 mm diameter) that can be used for precise incisional and ablative applications. Hollow waveguides are advantageous in permitting greater flexibility for performing laser procedures but are not as useful as conventional fiber optic delivery through quartz fibers. Future advances in laser and optical waveguide technologies will include smaller diameter waveguides that can deliver collimated laser energy and be used through endoscopic portals for minimally invasive procedures.[2,16]

The availability of functional and inexpensive optical fibers for laser delivery has played a crucial part in the acceptance of lasers for medical applications. The fibers used in laser medical delivery are made of quartz glass and have diameters ranging from 0.1 to 1 mm. Laser energy is transmitted and reflected along the bends and curves of the fiber until it reaches the tip where it exits.

The ability to transmit visible and near-infrared laser energy, small diameter and flexibility, lower cost, and ruggedness makes quartz optical fibers essential for endoscopic and other minimally invasive applications. Configurations of fiber tips (e.g., flat or cleaved, sculpted orb, chisel) and their ability to transmit energy is a physical science in its own right, but delivery parameters are primarily based on two factors, contact mode of delivery or non-contact mode of delivery. In non-contact mode, a free beam of focused laser energy is delivered to the tissue target surface. The power density and fluency of the laser beam determine the degree of photothermal interaction. Non-contact mode usually increases the surface area covered by laser energy which can decrease the power density and consequently decreases vaporization efficiency unless laser power output is increased. In contact mode, a laser optical fiber tip is brought into direct contact with the tissue target and the resulting photothermal interaction causes carbonization of the tip, which then becomes a focused "hot knife." The chemical structure of certain optical fibers permits transmission of mid-infrared laser energy (Ho: YAG at 2100 nm through a low-OH polyamide fiber) and allows minimally invasive laser surgery through small diameter endoscopes and myelographic needles.[16,24,25]

Laser Safety

Even though sci-fi movies and television portray lasers as "death rays" and "phaser disintegrators," the instrument is probably safer to use than a scalpel or scissors in the hands of a trained operator. However, lasers use by untrained individuals can be dangerous for both the operating team and the patient. Safety standards for medical laser applications have been issued that consider potential hazards and their control measures. The current consensus standard in the United States is through the American National Standards Institute's (ANSI Z136.3) document entitled *Safe Use of Lasers in Health Care* (Available from Laser Institute of America, 13501 Ingenuity Drive, Suite 128, Orlando, FL 32826). Application of surgical lasers in veterinary medicine should adhere to these regulations and guidelines to ensure operator and patient safety. Laser hazards depend on the laser wavelength and power, the environment, and the personnel involved with the laser operation. The laser hazard is defined by a hazard classification (1 to 4). Surgical lasers are almost all classified as Class 4 laser products because they may represent a significant fire or skin hazard and also produce hazardous diffuse reflections. Hazardous diffuse reflections are of concern because the probability of damaging retinal exposure is extreme without proper eye protection.[26,27]

With the biomedical application of lasers, the following safety concerns must be considered:

1. Inhalation of Smoke or Laser Plume

Laser surgery usually creates more smoke than electrosurgical procedures. Reports have mentioned that smoke products from lasers are really no different than those created by electrosurgery, although the quantity is greater. Some studies have actually isolated viable tumors cells from smoke evacuation tubes, so the concept of uncontrolled viral or bacterial vaporization must also be taken into account. Since even sterile smoke can be an irritant, all products of combustion as a result of laser vaporization must be evacuated with a dedicated smoke evacuator. The filters and tubes on these devices require maintenance and periodic replacement, increasing the cost of laser surgical procedures.

2. Laser Induced Combustion

Laser beams can cause fires. The obvious way to prevent laser induced combustion is to make certain the beam is always directed towards the surgery site. In addition, the use of moistened sponges surrounding the surgical site decreases the chance for accidental ignition of drapes, etc., especially when using wavelengths highly absorbed by water, such as the carbon dioxide laser. Polyvinyl chloride endotracheal tubes are especially prone to ignition. An endotracheal tube which is carrying oxygen will literally become an airway blowtorch instantaneously after impact of the laser beam. In airway and oral surgery, the endotracheal tube should be of a type that includes specific laser-safe tubes and less desirably, endotracheal tubes made of red-rubber protected by an application of reflective metal tape.

3. Eye and Skin Burns

Laser energy burns to the eyes or skin on the patient, operator, and assistants are of extreme importance for consideration. Safety glasses or goggles, **specified for each laser wavelength,** must be worn for every laser procedure. Saline moistened surgical sponges or even laser safety eyewear should be considered for protecting patient's eyes. In addition, window barriers, laser safety warning lights, ebonized or a dulled, satin-type finish on surgical instruments to reduce reflection, and laser warning signs on doors are important safety aspects that should not be ignored. The potential for accidental burns and fires usually is related to accidental depression of the footswitch for the laser. All machines are equipped with a standby mode of operation in which the machine is running but laser energy cannot be activated. A major responsibility of the laser nurse or technician is to evaluate the progress of the laser operation and have the machine switched to standby when laser energy is not required. The phrase, "laser on," spoken by the operating laser surgeon and required before the laser is activated, becomes as important as safety glasses, smoke evacuators, or the engineering of the machine itself in fostering safety. A team approach with the surgical laser technician, who basically is in charge of the laser, and the surgeon is essential.

Ignition of methane from the rectum or rumen can also be an exciting occurrence; the gas should first be removed by suction or blocked by tamponade. Vaporization of iodine skin preparations into irritating fumes, ignition of alcohol, or ignition of any pure oxygen environment mentioned previously are also important concerns.

4. Miscellaneous Problems

Other hazards include electrical injury from the high voltage power supply. Laser operation with newer devices is easy since they are extremely user-friendly and reliable, BUT machine maintenance including the purchase of maintenance contracts

may be required to maximize use and minimize safety concerns for mechanical, electrical, and optical failures. This aspect of medical laser usage must be recognized because maintenance contracts and laser repair can both be quite costly.

The use of Biomedical Lasers in Veterinary Medicine

Early reports concerning the use of lasers for medical applications involved animals, either as experimental models or as clinical veterinary patients. In 1968, the removal of a vocal-cord nodule in a dog demonstrated one of the first practical clinical applications of the carbon dioxide laser as a precision surgical instrument.[28] Since that time, use of biomedical lasers has expanded tremendously in both small and large animal surgery. However, to some veterinarians, the laser is still a tool in search of an application. The rising popularity of the surgical laser has been influenced most often by their use in private practice and stems from a blend of its demonstrated precision and control, improved hemostasis, fewer signs of postoperative pain, increased client satisfaction, and affordability. An objective and practical approach to laser surgical procedures in veterinary medicine is essential if the total beneficial potential is to be realized. "Zap and vaporize" techniques coupled with a "burn and learn" philosophy can do potential harm to patient and operator and outweigh any beneficial effect. These concepts have no place in the objective use of lasers in medicine. A concerned effort must be made to evaluate the use of a laser for its potential patient benefit, rather than portraying it as a miracle device of the 21st century that is advertised on an illuminated bill board in front of a hospital. Although the use of biomedical lasers has created an entirely new definition for performing surgery, a surgeon's knowledge of pathophysiology and technical expertise must be the primary factors to determine whether a laser should be used for a particular surgical procedure in lieu of more conventional approaches.[4]

Veterinary Clinical Applications– Small Animal

Many of the early reports involving the use of biomedical lasers concerned endoscopic use of fiber-delivered devices (Nd: YAG laser at 1064 nm) for treatment of laryngeal conditions and pathology of the upper respiratory system in the horse.[17,29,30] Since that time, however, a number of investigators and many practitioners have used carbon dioxide, diode, and Nd: YAG lasers in the treatment of various surgical conditions in small animals.[4,5,18,31-46] Most recently, use of the carbon dioxide laser for both excisional and ablative procedures has become common in many small animal practices. Well informed clients have often requested "laser surgery" due to extensive efforts towards marketing the technology by both veterinarians and laser manufacturers. Often, the procedure of choice for laser surgery has been a feline laser onychectomy.[32] Results that include minimal intra-operative hemorrhage and decreased perception of post-operative pain have been the primary advantages. In addition, elective procedures including laser ovariohysterectomy and orchidectomy have also been promoted for similar reasons. Other applications in general surgery have included conventional soft tissue procedures where precise dissection and control of hemorrhage is important. These procedures have included liver biopsy, resection of hepatic lobes, splenic biopsy, prostatic dissection and ablation, partial nephrectomies and nephrotomies, and excision/resection of a variety of intra abdominal, intrathoracic, cutaneous, and mammary neoplasms.[31] Reports have reviewed clinical uses of laser energy for ablation/palliation of a brain tumor (Nd:YAG), ablation of neoplasms (CO_2, Nd:YAG), and treatment of eosinophilic granulomas (CO_2, Nd:YAG), perianal fistulas (Nd:YAG, CO_2), or acral lick dermatitis (Nd:YAG, CO_2).[33,36,38,42,43,46] Upper airway surgery, especially excision of an elongated soft palate in the dog, is most easily performed using laser energy with minimal post-operative complications.[41]

With advantages of lower morbidity time for some conditions, less perceived signs of pain, and potential treatment regimes for conditions not amenable to conventional surgical/medical procedures, employment of biomedical lasers has not only found use in the clinical small animal setting, but also in the realm of exotic animal and avian practice, where even minimal blood loss can be significant in smaller patients. In addition, clinical use of the holmium:YAG laser for percutaneous prophylactic ablation of intervertebral discs and lithotripsy of urologic calculi in dogs have been reported and show tremendous potential.[24,25,47-49] The use of biomedical lasers for veterinary ophthalmologic applications has been firmly established, although use has not become as common as it is in human medicine. The Q-switched or continuous wave ophthalmic Nd:YAG, argon, and diode lasers have been used as funduscopic photocoagulators in retinopathies, for treatment of lens-induced pupillary opacification, and for transcleral laser cyclodestruction of the ciliary body for glaucoma therapy in dogs. The carbon dioxide laser has also been used for soft tissue periocular and scleral surgical procedures. As experience and interest increases, and lasers become more available to veterinary ophthalmologists, clinical applications will increase as treatment protocols are initiated and proven useful.[18,50]

Photodynamic therapy (PDT) has been used for clinical applications in veterinary medicine by several investigators. A number of initiatives have been reported using PDT for treatment of spontaneously occurring neoplasms in dogs and cats. This exciting treatment modality for selective destruction of neoplasms, employing interaction of a photosensitizer with light in the presence of oxygen, will continue to play a more dominant role in clinical veterinary medicine as protocols are established and new photosensitizing drugs are manufactured and approved for use.[19,51]

Use of biomedical lasers in veterinary orthopedics has been more limited due to a lack of laser devices with appropriate wavelengths for incisional and ablative procedures in bone.[52-54] The horse has been used as a model for biostimulation of articular cartilage and other research applications using the Ho: YAG laser.[21] Practical use of lasers for ablation of bone has not been effective, although laser ablation (CO_2) of methylmethacrylate during removal/revision of total hip prosthesis is possible.[45]

General Surgical Technique in Laser Surgery

The use of surgical lasers can be broadly classified as incisional or ablative surgery. For incisional surgery, a small spot size (0.2

to 0.4 mm) which delivers a high power density is ideal. The main reason surgical lasers are used for incisional surgery is because of the excellent degree of hemostasis obtained. At the tissue interface, blood vessels less than 0.5 mm in diameter can be coagulated and sealed so that use of the surgical laser as a light scalpel is relatively hemostatic in most capillary beds and in the transection of small venules and veins. Lymphatics are also sealed so postoperative edema may be minimized. Subjectively, there seems to be less pain associated with a laser incision and dissection. This observation could be due to the fact that smaller nerves are sealed or even spared at some laser wavelengths.[55] Microorganisms are also destroyed in the process of photothermal ablation, so tissues may be "disinfected" (bacterial numbers reduced by reduction of numbers due to direct vaporization) during laser tissue-interaction.[57,58]

The depth of the incision made by a surgical laser is both a function of the irradiance (power density) and the speed with which the incision is made. With practice, the surgeon can use the laser beam as precisely as the scalpel, with the added advantage of less hemorrhage, and less pain, although objective, published results in veterinary medicine are few.[59,60] Laser incisions tend to be made more slowly than those made with a scalpel, at least initially. The improved hemostasis and incisional control generally makes up for this delay, and in some cases involving highly vascular tissue, a laser incision may actually make it possible to perform laser surgery faster than conventional surgery. Care must be taken not to create excessive collateral photothermal injury (char formation) during the process. Providing tissue counter tension during the incisional procedure aids not only tissue separation, as it does with a scalpel, but also decreases the amount of char formation. A defocused laser beam (holding the handpiece or cleaved optical fiber an appropriate distance from the tissue surface) can be used in some cases to stop bleeding from larger blood vessels that were not sealed by the focused or contact-mode incisional laser beam. Tissue excised with a surgical laser can still be histopathologically evaluated for tumor margins without much difficulty, if proper technique is used that minimizes collateral photothermal damage and the pathologist is informed that a laser was used for the biopsy.[40] As mentioned earlier, healing of laser incisions is minimally delayed due to photothermal collateral tissue interaction.[11,12,61]

Tissue ablation or vaporization is most easily accomplished using a defocused or non-contact, free-beam mode of energy delivery. Defocused beam delivery through an articulated arm or a hollow waveguide can be utilized to ablate tissue efficiently, if carbonization (char formation) is minimized. To accomplish this, optical and mechanical scanners (described previously) are ideal accessories for the carbon dioxide laser. In addition, as char formation occurs, the surgeon should be diligent to remove any buildup of carbonized tissue by using saline moistened gauze sponges to mechanically debride the ablated tissue surface.

Tissue ablation can also be performed using fiberoptic delivery systems in non-contact mode with compatible laser wavelengths (diode – 808/980 nm; Nd:YAG to 1064 nm; Ho:YAG – 2100 nm). Laser power and energy delivery levels must be substantially higher (> 20 W < 100 W) for non-contact, free-beam tissue ablation using fiber optic delivery. It must also be understood that a laser fiber used for contact mode delivery for incisional purposes cannot usually be immediately changed from contact mode to non-contact mode free-beam energy delivery. Since contact mode incisional surgery requires the fiberoptic tip to be carbonized so it can absorb adequate energy to incise tissue, higher energy levels required for non-contact ablation will usually melt the fiberoptic tip. Using a freshly cleaved, a surgeon can go from non-contact, free-beam energy delivery to contact delivery, but cannot go from contact laser surgery to non-contact delivery without re-cleaving the fiber. In the case of sculptured fiber tips (tapered, orb) meant to be used only in contact mode, high power free-beam delivery should be avoided to prevent premature fiber degradation. However, once a sculpted fiber tip is degraded, the fiber can be cleaved and reused in that configuration for both free-beam and contact delivery.

Future Innovations

The use of lasers in medicine is an exciting treatment modality that will continue to produce innovative and new methods for managing diseased tissue. Research focused on basic laser-tissue interaction and selective tissue destruction will become increasingly important. The use of photodynamic therapy (PDT) for treatment of malignant tumors will become an effective part of the veterinary oncologist's armamentarium as more efficacious photosensitizers become available and expanded use of lower cost lasers or even non-laser light sources occurs. Photothermolysis using appropriate chromophores for selective tissue destruction and sterilization/disinfection is currently proving to be efficacious in both the clinical and laboratory settings. Minimally invasive urologic techniques for ablation of bladder, urethral, and prostatic pathologic conditions in small animals will become more common as technologically enhanced and smaller endoscopes are developed, as delivery systems are improved, and as new laser wavelengths are investigated. Laser lithotripsy is now possible using both visible and infrared wavelengths. This technology is currently being used in academic and specialty hospital settings permitting minimally invasive lithotripsy of urinary tract calculi. Tissue fusion/welding of blood vessels, alimentary tract, ureter or urethra, skin, and even bone will become clinically available in the near future. Application of lasers for micromanipulation of gametes and laser energy for improving fertilization and hatching rates during *in vitro* fertilization in domestic animals are close to becoming clinical realities. The use of lasers for soft tissue dental procedures is already feasible and, as investigations continue, use of laser energy for hard tissue dental procedures will be possible.

Low level laser therapy (LLLT), or biostimulation, is now being used commonly in a variety of therapeutic settings in veterinary medicine. The efficacious use of this modality to decrease inflammation and pain, as well as enhance wound healing will continue to be investigated. Well controlled studies are underway using reliable LLLT devices. Positive objective results will provide additional therapeutic option for the practitioner and rehabilitation specialists.[63]

Development of user-friendly, durable, portable, less expensive

laser systems is definitely on the near horizon. Semiconductor laser development from ultraviolet to far infrared wavelengths is feasible. At this point in biomedical laser technology, diode laser development and similar technologies seem to hold the greatest promise. Use of lasers as diagnostic tools and sensors is one of the fastest growing branches of biomedical laser development. Clinical applications involving noninvasive recognition of malignant cells, abnormal tissue, or abnormal metabolites have tremendous potential. Use of available and future laser diagnostic technology could have a significant impact on the veterinary profession if a reasonable cost for equipment can be realized.

Future use of lasers in medicine depends on the active participation of veterinarians in the inception and development of new devices that meet the needs of the entire medical profession. The sensible clinical approach that must be taken every day in the practice of veterinary medicine equips the veterinarian with a unique ability to understand the practical and economic values of biomedical lasers. Veterinary medicine can and should be in the forefront during these exciting times, adding an essential dimension to development of this 21st century technology.

Chapter 4

Oncologic Surgery

The Role of the Surgeon in Veterinary Oncology

Earl F. Calfee, III

Introduction

The discipline of oncology involves the study and treatment of cancer by medical, surgical, and radiologic modes. Surgical therapy may benefit the animal in many cases or be harmful especially if surgery is poorly planned. The expertise of every surgeon's care is related to effort, experience, and the knowledge of individual limitations. The purpose of this chapter is to provide perspective and direction for veterinarians in the decision making process for oncology patients. An important aspect of decision making involves consideration of individual surgical abilities prior to the surgical procedure for animals with cancer.

It is widely recognized that the role of domestic pets in modern society has changed considerably in recent decades. Animals have become a central figure and family member. They are no longer just a "pet" in many households. Concurrently, advances in human and veterinary medicine have made it possible to practice veterinary medicine at a much more sophisticated and intense level than ever before. Significant advances have occurred in many areas of veterinary medicine such as imaging techniques (i.e. nuclear scintigraphy, CT and MRI), to medical therapy (i.e. total parenteral nutrition) surgical procedures (i.e. limb sparing, joint replacement, open-heart surgery, hemipelvectomy).[1-9] The growth of the human-animal bond and advances in veterinary medicine have changed the treatment of oncology patients considerably. The "best practice" of veterinary oncology combines advanced diagnostics, complex surgical procedures and intensive medical therapy. To provide the best or ideal care for the patient and owner, professional collaboration is often necessary between the generalist and specialists in medical, surgical and radiation oncology. At times, a surgeon may act individually in delivering appropriate care especially if a surgical cure is possible. However, in many cases the surgeon is only one piece of the "treatment puzzle".

The most important challenge is to define the disease and develop the most appropriate treatment plan. To best define the disease the surgeon should be able to answer five questions regarding any particular type of tumor. These include:

1. What is the type, stage and grade of cancer to be treated?
2. What are the expected local and systemic biologic activity of this tumor type and stage?
3. Is a cure possible?
4. Is surgery indicated?
5. What adjunctive treatments are available or indicated?[10]

The answers to these questions are often difficult since data regarding specific neoplastic disease is continuously being collected and changes rapidly. Diagnosis of the disease process and consultation with referral specialists is recommended to formulate the most appropriate diagnostic and therapeutic decisions. It is emphasized that the treatment plan for oncology patients, even those with a similar disease, is not necessarily standardized. Each patient must be considered individually and that often requires professional consultation and coordination of efforts.

Diagnostic Approach to Veterinary Oncology Patients

A definitive diagnosis and accurate staging of the disease is essential to provide a logical approach to the work-up and treatment of each patient. Much of the diagnostic approach to patients with neoplastic disease is relatively standardized. Generally, hematologic evaluation (CBC and blood chemistries) is performed to evaluate overall patient health. In some cases, baseline blood work can provide specific prognostic information. An example is the association of increased alkaline phosphatase values with shorter survival times in dogs with appendicular osteosarcoma.[11,12] In addition to hematology, screening for evidence of metastasis is usually performed. This usually involves taking three-view thoracic radiographs. Other methods of evaluation for possible metastasis include lymph node aspiration, abdominal ultrasound, and advanced imaging techniques. Decisions about appropriate imaging modalities for individual cases such as computed tomography (CT), magnetic resonance imagine (MRI) and nuclear scintigraphy should be based on knowledge of specific tumor behavior.

Computed tomography is often used to define the extent of disease in maxillofacial tumors and to evaluate for pulmonary metastasis.[13,14,15] CT has been shown to be more sensitive than radiographs for the evaluation of pulmonary metastasis and intrathoracic lymph node enlargement. MRI has a greater ability than CT to differentiate soft tissue structures and is superior to CT for imaging of central nervous system structures.[16,17]

Nuclear scintigraphy is beneficial for evaluation of metastatic bone lesions. Scintigraphy is especially useful for cases of canine appendicular osteosarcoma where a bone metastasis rate of approximately 8% is reported at the time of diagnosis.[18] Bone metastases are rarely identified based on physical examination or survey radiographs. Scintigraphy is also useful in defining the extent of disease at the primary site for appendicular osteosarcoma prior to limb-spare procedures.[19] Diagnostic techniques that may be used more in the future include sentinel lymph node biopsy based on lymphoscintigraphy mapping, dynamic MRI and metabolic scanning techniques.[20,21,22]

Surgical Biopsy

An accurate differential diagnosis begins with the safe and appropriate collection of tissues for histologic evaluation. Several types of tissue collection methods can be used (i.e. fine needle aspiration, tru-cut, incisional wedge, marginal and

excisional biopsy) and are covered extensively in chapter 5. It is important to consider the consequences of tissue collection techniques because if not performed appropriately a biopsy can diminish the opportunity for a surgical cure during later, more definitive surgery.

One of the more common mistakes occurs while performing marginal tumor excision. There is a tendency to NOT remove as much of the mass and surrounding tissues as possible while performing a resection immediately adjacent to the palpable mass. There is no benefit to "modified marginal resection". The inevitable result is contamination of peripheral and deep tissue structures for locally aggressive tumors. The surrounding tissue contamination with "modified marginal resections" may eliminate the possibility of a clean surgical excision in the future. An incisional biopsy is preferred to a modified marginal resection. For benign tumors a true marginal resection is adequate.

Surgical Therapy

Several tumor types exist where a properly performed surgical procedure alone will provide long term survival times or a cure. Examples include complete surgical excision of grade 1 or 2 soft tissue sarcomas and grade 1 or 2 mast cell tumors, noninvasive canine thyroid carcinomas, canine intramuscular lipomas, canine ceruminous gland carcinomas, canine hepatocellular carcinomas, and feline thymomas.[23-33] With complete surgical excision of the aforementioned neoplasms extended survival times are expected. The term "complete excision" is important in reference to tumor excision. Typical recommendations for complete excision of a tumor are 2 to 3 cm peripheral margins and one deep fascial plane.[27] These recommendations are not appropriate or applicable to all tumor types. In some cases, marginal resection is all that is possible and reliably produces extended survival times. Examples include non-invasive thyroid carcinoma and feline thymoma. In these two examples, local anatomy prevents resection with wide margins, however, experience has shown that marginal resection is adequate and clearly beneficial with these two tumors.[29,33]

The ability to attain a clean surgical margin is primarily dependent on the location of the mass and the ability of the surgeon. Masses located on the distal extremities and the head and neck are surgical challenges because of a lack of redundant peripheral and deep soft tissues and the presence of joints in the extremities. A lack of soft tissue, particularly on the extremities, makes primary closure of excision sites impossible. It is emphasized that complete excision of the mass producing an open wound that must be managed or reconstructed is preferable to incomplete excision of the tumor and complete wound closure. In these cases, complete surgical excision is preferred and open wound management is performed until the formation of healthy granulation tissue occurs. After a healthy granulation bed has formed, free skin grafting can be performed. Alternatively, in some cases, closure can be accomplished through the application of skin flaps or free tissue transfer. Axial pattern flaps (i.e. thoracodorsal, caudal superficial epigastric, reverse saphenous conduit flap, etc) or skin fold flaps are especially useful for reconstruction of large defects.[34,35,36] Skin can also be transferred from distant sites through the use of microvascular free tissue transfer. Most reconstructive techniques are complex and require appropriate planning and surgical expereince prior to the initial surgical procedure.

Clean surgical excisions of masses located over appendicular joints also pose a surgical challenge. This is because of the lack of a single fascial plane over the joint space. This generally makes curative surgical excision of masses over the joint space impossible. The surgeon is then left with radical resection (i.e. amputation) or the combination of conservative (i.e. marginal) surgical excision followed by adjuvant therapies (i.e. external beam radiation).

Other problematic anatomic areas are the axilla, inguen, and perineum. Surgical wounds in the axilla and inguen are predisposed to complications. Healing is difficult because of high motion, dead space and the tendency for seroma formation. The perineum is a challenge because of its proximity to the anus. Prior to definitive surgery on masses in any of these regions careful consideration must be given to the potential detrimental effects of incomplete tumor excision. It is often advisable to consider consultation with a board certified surgeon prior to performing any surgical procedure for these cases. Incisional biopsy to obtain a definitive histologic diagnosis is almost always required in these anatomic regions.

Surgery as Part of Multimodality Therapy

In some cases of neoplastic disease, surgery as a single mode of therapy may provide short-term benefits, but additional modes of therapy can significantly extend disease free intervals or prolong life. Animals that have incomplete surgical removal of masses such as mast cell tumors or tumors located adjacent to appendicular joint spaces may benefit from radiation therapy. Two additional examples where multimodal therapy is of significant benefit are canine appendicular osteosarcoma and feline vaccine associated sarcoma. Canine appendicular osteosarcoma has been extensively studied and is known to have high metastatic potential. Early in the study of this disease, radical surgery (i.e. amputation) alone was shown to have no significant benefit on survival times and be a purely palliative procedure.[38] The benefits of chemotherapy combined with surgery have been demonstrated in several studies with an extension of survival times from a median of four months to a median of 11 to 12 months.[39,40,41,42]

Feline vaccine associated sarcomas benefit from a multimodal approach. This tumor has a relatively low metastatic (approximately 20% at time of the initial diagnosis) rate but has very aggressive local behavior. Conservative surgical excision (marginal resection) is futile. In many cases because of location (i.e. intrascapular) radical surgery is not possible, therefore a combination of surgery and radiation therapy is utilized. The combination of surgery and radiation therapy has been shown to increase survival times to approximately 2 years.[43,44,45,46]

In many animals with neoplastic disease, the benefits of adjuvant therapies have not been demonstrated. Canine anal sac apocrine gland adenocarcinoma, grade 3 soft tissue sarcoma and feline

oral squamous cell carcinoma are examples of tumors with aggressive behavior where adjuvant therapy has not been studied or shown to be beneficial. In some situations (i.e. grade 3 soft tissue sarcoma and apocrine gland ACA) appropriate studies do not exist to adequately evaluate the benefit of adjuvant therapies.[47,48,49] In other diseases such as feline oral squamous cell carcinoma, the benefits of adjuvant therapy have been more extensively evaluated and no survival benefit has been attained with aggressive adjuvant therapy in addition to surgery.[50]

Conclusion

The treatment of cancer is a constantly changing process. The veterinary surgeon can influence treatment of the patient with cancer either positively or in some cases negatively. The consequences of any tissue collection must be considered prior to biopsy or excisional surgery. Initial diagnostics, tissue sample collection, and in some cases definitive surgical procedures may be performed by general practitioners following appropriate principles. To provide the best care for the cancer patient, knowledge of the current literature and early communication with appropriate specialists in oncology is recommended.

Editor's Note: Adjunctive therapy of anal sac apocrine gland adenocarcinoma with chemotherapy following surgery has increased median survival times in dogs. Radiation has also proved valuable in some cases. An oncologist should be consulted.

Chapter 5

Tumor Biopsy Principles and Techniques

Nicole Ehrhart, Stephen J. Withrow and Susan M. LaRue

The diagnosis of neoplastic and other pathologic conditions in animals depends on the procurement of an accurate biopsy specimen. Without an appropriate histologic diagnosis, it is impossible to plan appropriate therapy. Histopathologic results aid the clinician in providing an accurate prognosis and thereby guide the owner in the selection of various treatment options.

The ideal biopsy should procure enough tissue for specific pathologic diagnoses without jeopardizing the patient's well being or the surgeon's ability to achieve local tumor control. Many biopsy techniques can be used on any given mass. The procedure used is determined by 1) the clinician's goals for the patient (i.e., diagnosis with no treatment versus diagnosis with treatment); 2) the skill and preference of the clinician; 3) the anatomic site of the mass; and 4) the general health status of the patient.[1] Cytologic preparations obtained by fine needle aspirate are often helpful in guiding the selection of the optimal biopsy technique.

General Considerations

Biopsies can be obtained before the initiation of definitive therapy (pretreatment biopsy) or histologic specimens may be evaluated after the mass is removed in its entirety. In most situations, pretreatment biopsy is the optimum route of action because it provides a diagnosis before the institution of invasive or aggressive therapeutics.

Pretreatment biopsy is warranted when the type of treatment would be significantly altered by knowing the tumor type. For example, if an animal presents with a mediastinal mass, the distinction between a thymoma (responsive to surgery) and lymphoma (responsive to chemotherapy) would be important to make before instituting treatment.

If the *extent* of treatment would be altered by knowing the tumor type, pretreatment biopsy should be performed. Certain cancer types (e.g., mast cell tumors and soft tissue sarcomas) have high local recurrence rates and therefore require removal with wider margins than benign or lower grade malignant tumors. Many studies in both animals and human patients have shown that the best chance for surgical cure is to remove the lesion completely the first time. Clinicians who are tempted to "peel out" or "shell out" a lesion without knowing the histologic diagnosis are playing a dangerous game that may leave microscopic disease in the patient. If the lesion is malignant and incompletely excised, it will often grow back more quickly and invasively than the initial mass, thus potentially compromising further attempts at treatment.

Pretreatment biopsy should be considered when the tumor is in a difficult location for surgical reconstruction, such as a distal extremity, tail, or head and neck, or when the procedure could carry significant morbidity (e.g., maxillectomy or hemipelvectomy).

Finally, pretreatment biopsy is warranted when knowledge of the diagnosis would change the owner's willingness to treat the disease. An owner may be more willing to allow the veterinary surgeon to perform a thoracic wall resection for a low grade soft tissue sarcoma (slow to metastasize) than for a high-grade osteosarcoma (metastasizes quickly).

In two situations, pretreatment biopsy is *not* indicated. The first is when knowledge of the tumor type would not change the surgical therapy. Examples of this are a splenectomy for a localized splenic mass or a lung lobectomy for a solitary lung mass. The second situation is when the biopsy procedure is as dangerous or as difficult as the definitive treatment (brain biopsy). In these cases, biopsy information is obtained after surgical removal of the lesion.

Soft Tissue Biopsy

Needle Core Biopsy

The most common use of the needle core biopsy is for externally palpable masses. This procedure can be done on an outpatient basis with local anesthesia and sedation. The method uses various types of needle core instruments (Tru-Cut [Tru-Cut biopsy needle, Travenol Laboratories, Inc., Deerfield, IL 60015] or A.B.C. Needles [A.B.C. Needles, Monoject, St. Louis, MO 63310]) to obtain a piece of tissue 1 to 2 mm in width and l to 1.5 cm long. The most commonly used size is a 14 gauge diameter needle; however, these needles are available in 16 and 18 gauge sizes as well. Any mass larger than 1 cm in diameter can be sampled using this instrument. These instruments can also be used for deep tissues, such as kidney, liver, and prostate, in a closed method or an open method at the time of surgery. Despite the small sample size, the pathologist is usually able to discern tissue architecture and tumor type. With experience, the clinician can usually tell whether representative samples have been obtained. Fibrous and necrotic tumors may not yield diagnostic tissue cores. If the clinician believes that representative samples have not been obtained, an incisional biopsy is indicated.

The area to undergo biopsy is clipped and prepared as for minor surgery. Sensation in overlying skin and muscle can be blocked using a local anesthetic along the area that the needle will penetrate. The mass is fixed in place with one hand, and a 1-mm stab incision is made in the overlying skin. The needle biopsy instrument is introduced through the stab incision, and several needle cores are removed from different sites in the tumor through the same skin hole (Figure 5-1). The tissue is then removed from the trough of the instrument with a hypodermic needle and is placed in formalin. Samples can be gently rolled on a glass slide for a cytologic preparation before fixation if desired. Skin sutures are usually not required. The biopsy tract, including the stab incision, should be removed at the time of definitive surgery.

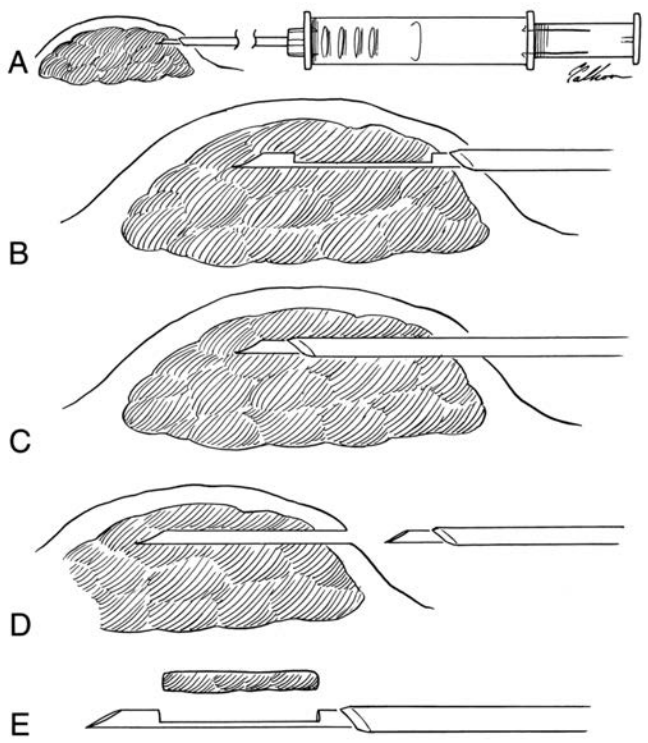

Figure 5-1. Needle core biopsy technique. **A.** A stab incision is made, and the instrument is inserted through the tumor capsule with the outer sleeve closed over the inner cannula. **B.** The outer sleeve is held fixed while the inner cannula is thrust forward into the tumor. **C.** The outer sleeve is pushed forward to slice off the specimen, which is protruding into the trough. **D.** The instrument is removed closed. **E.** The inner cannula is exposed, revealing the tissue specimen in the trough. (Modified from Withrow SJ, MacEwen EC. Small animal clinical oncology. 2nd ed. Philadelphia: WB Saunders, 1996.)

Punch Biopsy

Another simple biopsy technique is the punch biopsy method (Figure 5-2). This technique uses Baker's biopsy punch (Baker Cummons, Key Pharmaceuticals, Inc., Miami, FL 33169) instrument to obtain the specimen. The skin is prepared for minor surgery, and the overlying skin is anesthetized with a local anesthetic. Baker's punch is applied to the mass in a manner that will yield a composite of normal and abnormal tissue. Pressure is applied as the instrument is twisted. The specimen is grasped and lifted with forceps while the operator uses scissors or a scalpel blade to cut the base. Care should be taken to not deform the tissue. Impression smears can be made for cytologic evaluation before placement in formalin. Multiple specimens may be taken from a single mass. A single skin suture per biopsy site is usually sufficient to close the defect and to control hemorrhage.

Incisional Biopsy

Incisional biopsy (Figure 5-3) is used when neither cytologic examination nor needle core biopsy yields a diagnosis. As mentioned, incisional biopsy is preferred for ulcerated or necrotic tissue because core biopsy rarely yields a diagnosis. Tumors are often poorly innervated, and as long as overlying skin is anesthetized, a wedge of tissue can often be removed without general anesthesia. Externally located tumors that are ulcerated

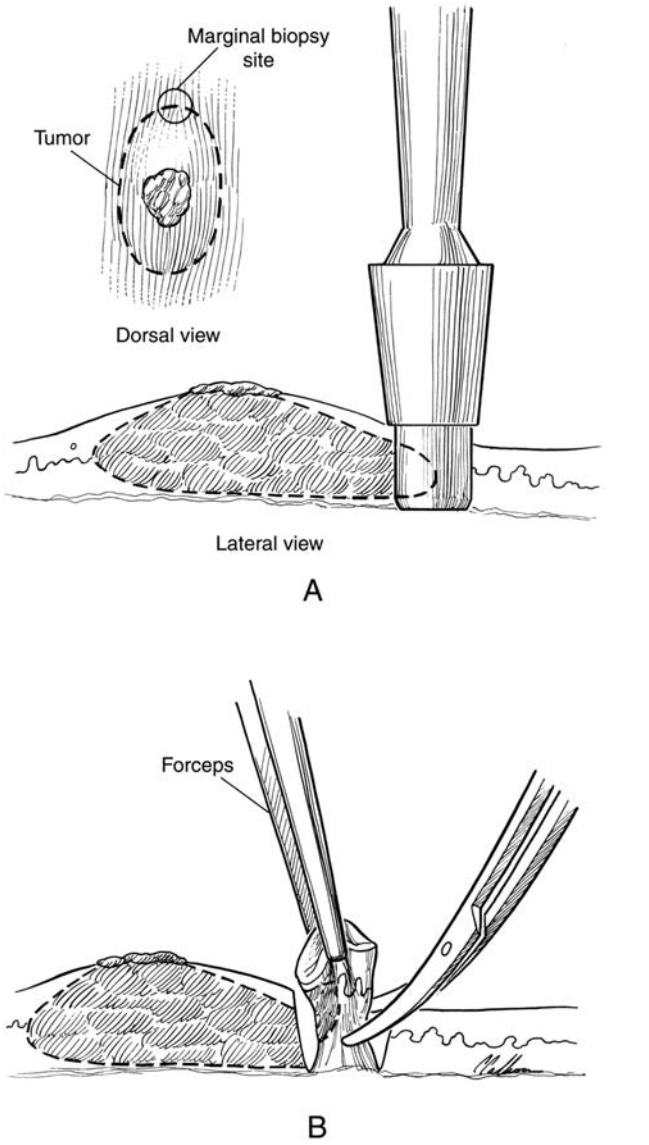

Figure 5-2. Punch biopsy technique. **A.** Baker's punch biopsy instrument is applied directly to the mass, and downward pressure is exerted while the instrument is twisted. When the metal end is buried up to the plastic hub, the instrument is removed. **B.** Forceps are used to lift the biopsy specimen gently, and scissors are used to cut the base.

may undergo biopsy without even the use of local anesthetics. The goal is to obtain a composite biopsy of abnormal tissue and adjacent normal tissue without compromising subsequent resection. The incisional biopsy tract always must be removed with a tumor at curative resection. Thus, the surgeon must not open uninvolved tissue planes that can become contaminated with tumor cells. In general, any normal tissue that the scalpel or surgical instruments have touched during an incisional biopsy is considered contaminated with tumor cells and is at risk for eventual tumor growth.

Excisional Biopsy

Excisional biopsy (See Figure 5-3) can be both diagnostic and therapeutic. Excisional biopsy is best used when the treatment would not be altered by knowledge of the tumor type. Benign skin tumors and small malignant dermal lesions located in an area where reexcision (2 to 3 cm margins in all directions including deep) can be reasonably obtained are also amenable to excisional biopsy. All other masses should undergo biopsy before the curative surgical procedure. Additional uses of excisional biopsy are for solitary lung, splenic, and retained testicular masses.

Endoscopic Biopsy

Endoscopic biopsy is used most commonly in the gastrointestinal, respiratory, and urogenital systems. It is convenient, safe, and cost effective; however, it has several limitations. Visualization may be inadequate, resulting in nonrepresentative biopsy samples. Full-thickness biopsy specimens are often impossible to acquire in these organs, and therefore, inflamed tissue or normal tissue overlying a tumor may undergo biopsy, not the tumor itself. A histopathologic diagnosis of inflammation in an animal suspected of having neoplasia should be interpreted with caution.

Laparoscopy and Thoracoscopic Biopsy

These techniques are best used when all staging and diagnostic procedures suggest inoperable and diffuse disease or when precise staging is indicated and an open procedure is not desired. Laparoscopic and thoracoscopic biopsy can yield important information regarding the extent of disease. Its disadvantages are that it can take as long as an exploratory laparotomy, it requires general anesthesia, and it does not give the clinician visualization as clear as that attained during open exploratory. In most cases, it cannot provide for excision. This procedure also carries some risk of hemorrhage and leakage of fluid from hollow organs and tumors. Animals staged by whatever means as having resectable disease are often best served by open exploratory laparotomy or thoracotomy, whereby resection with curative intent can be performed.[1]

Image-Guided Biopsy

The use of fluoroscopy, computed tomography, and ultrasonography has greatly expanded the clinician's ability to stage and diagnose neoplasia. Image guided biopsy may result in the avoidance of more invasive diagnostic procedures. A disadvantage of image-guided biopsy is that the technique requires specialized equipment and training. Biopsy in a closed space with limited visualization of the lesion carries some risk. As with laparoscopy and thoracoscopy, image guided biopsy is best done when the clinician is fairly certain that an excisional attempt would be unsuccessful or when pretreatment biopsy results would change the owners' willingness to pursue more aggressive medical or surgical therapy.

Tissue Procurement and Fixation Guidelines

The concept that performing a biopsy releases tumor cells and leads to early metastasis and decreased survival has proved false. Although biopsy procedures do release tumor cells into the circulation, neoplastic cells are constantly shed into vessels and lymphatics on a day to day basis.[1] No evidence in either human patients or animals indicates that a properly performed biopsy leads to a decrease in survival or early metastases. On the other

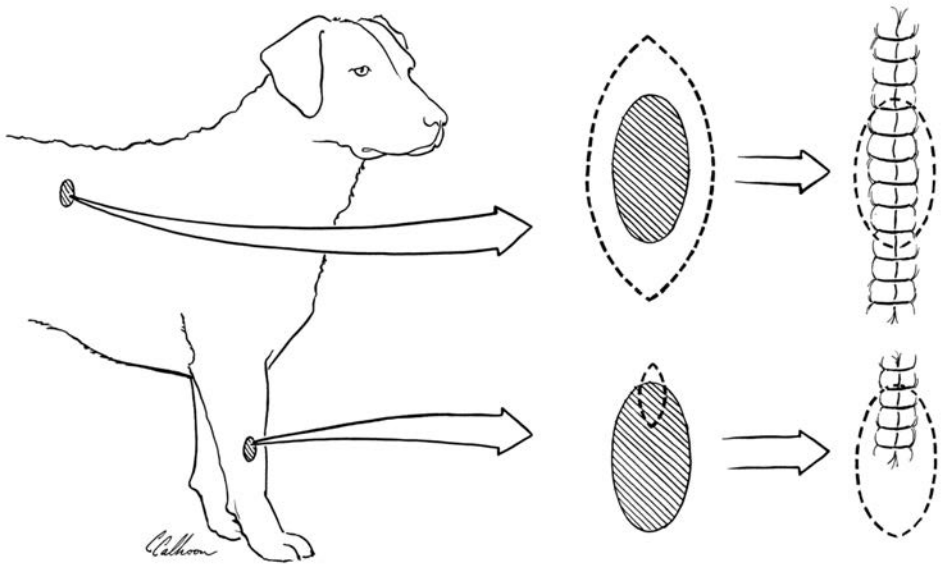

Figure 5-3. Excisional (top) and incisional (bottom) biopsy. The location of the top tumor would be amenable to wide excisional margins with an option to pursue a re-resection if needed. The location of the bottom tumor is less amenable to wide excisional margins. Attempts to excise this tumor with close margins may leave residual disease in this patient and may compromise the optimum surgical course of treatment. The bottom tumor should undergo biopsy before resection with curative intent. The axis of the biopsy incision is parallel to the long axis of the leg. (Modified from Withrow Sj, MacEwen EC. Small Animal clinical oncology. 2nd ed. Philadelphia: WB Saunders, 1996.)

hand, a poorly planned or improperly executed biopsy can result in significant alterations in the optimum treatment plan.

Biopsies should be planned so the tract may subsequently be removed with the entire mass. The ideal circumstance is when the biopsy is performed by the surgeon who will eventually perform the curative intent procedure. Biopsies performed within a body cavity (either open or closed) should be done so tumor cells are not "spilled" into the cavity. This precaution prevents seeding of peritoneal or pleural cavities. The sample size of the specimen affects the accuracy of the diagnosis. Because tumors are not homogenous and often contain areas of necrosis and inflammation, larger samples or multiple samples from different areas in a mass are more likely to yield a diagnosis. The smaller the sample, the less representative it is of the whole tumor. Thus, if needle core biopsy specimens are obtained, several samples should be submitted. Biopsies should not be obtained with electrocautery because this technique will disturb and deform the tissue architecture. Likewise, the clinician should take care not to deform the sample with forceps, suction, or other handling methods. Cautery can be used after blade removal of a specimen to control hemostasis if necessary.

The junction of normal and abnormal tissue is frequently the best area for sampling. This aids the histopathologist in comparing normal and abnormal tissue architecture. It is important to plan the incision so the normal tissue incised during the biopsy can easily be removed and is not necessary for reconstruction of the surgical defect. (The exception to the tissue junction rule is bone biopsies, discussed later in this chapter.) Biopsies performed on the legs or the tail should be done using an incision parallel to the long axis of the structure. This technique aids in resection of the biopsy scar if needed.

Excisional specimens submitted for biopsy should be evaluated for surgical margins. The surgeon should mark any areas of question or submit a margin from the patient in a separate container. It is good practice to mark all excisional margins routinely with ink. The pathologist samples tissue from several areas of the specimen. If tumor cells extend to the inked margin microscopically, the excision should be considered incomplete ("dirty"). Lateral and deep margins of an excised mass can be painted with India ink and allowed to dry before placement in formalin. Commercially available colored inks can be used to denote different sites on the tumor if desired (Davidson Marking System, Bloomington, MN).

Ultimately, the surgeon has the responsibility to communicate to the pathologist what is expected when evaluating margins on an excisional sample. Of course, incisional biopsies, needle core biopsies, and punch biopsies have incomplete margins by definition. Pathologists may not know whether the sample is intended to be excisional and do not always evaluate margins unless asked. Good communication between the pathologist and the clinician is vital to the care of the patient. Waiting until recurrence of the tumor to reoperate on a known malignancy that has been incompletely resected is a disservice to the client and the animal. Incomplete surgical resection of malignant disease is best dealt with early so further surgery or adjuvant therapy can be instituted immediately.

Tissues should be fixed in 10% neutral buffered formalin in a ratio of I part specimen to 10 parts fixative. Proper fixation is vital for accurate pathologic diagnosis. Tissue thicker than 1 cm does not fix deeply. Large masses can be sliced like a bread loaf, leaving one edge intact to allow for orientation. Alternatively, representative samples from the tumors can be sent while the larger portion of tumor is saved in formalin and further sections submitted if the pathologic diagnosis is in question. It is possible, especially in some large splenic masses, for only a

small portion of the mass to be neoplastic and for the rest to consist of hematoma, necrosis, or fluid. This possibility emphasizes the need to submit several representative samples or, when possible, the entire mass. Tissue that is prefixed over 2 to 3 days in formalin can be mailed with a tissue - to - formalin ratio of 1:1.

For the pathologist to provide the most accurate diagnosis, each sample must be accompanied by a complete history. Whenever the histopathologic diagnosis does not concur with the history, clinical signs, or clinician's impression, a call to the pathologist is warranted. In some cases, a small but vital piece of information left out of the patient's history can drastically change the pathologist's impressions. Pathology is a combination of art and science, and diagnoses are only as accurate as the information provided by the clinician.

A veterinary trained pathologist is always preferable to a pathologist trained in human disease. Although similarities exist across species lines, there are enough histologic differences to result in interpretive errors.

Frozen Sections

Frozen sections are becoming more common in the perioperative setting in veterinary medicine. This process provides a rapid means to a diagnosis at the time of surgery, as well as information on adequacy of tumor resection and the presence or absence of metastases. Although the use of this technique in veterinary medicine is limited to those institutions with specialized personnel and equipment, it is of potentially great value to the surgeon. Accuracy rates are high (93%) when results are compared with those from traditional paraffin embedded tissues.[2]

Bone Biopsy

Bone biopsy is essential in the diagnosis of proliferative and lytic bone lesions. Results of a bone biopsy often determine the course of treatment and may drastically change proposed operative intervention. As with all biopsies, the clinician must plan the biopsy with the intended curative treatment in mind. The most common instruments used for bone biopsies are the Michelle trephine (Michelle trephine, Kirschner Co., Timonium, MD) and the Jamshidi type bone marrow biopsy needle (Jamshidi bone marrow/aspirate needle, American Pharmaseal, Valencia, CA 91335; Bone marrow biopsy needle, Sherwood Medical, St. Louis, MO 63130). When used properly, both instruments provide a suitable sample with minimal complications. The small size of the Jamshidi biopsy needle cannula is advantageous in that it requires a smaller skin approach (1-mm stab incision) and leaves a small diameter bone defect, making biopsy related fractures less likely than with a trephine. Trauma to soft tissue structures and hemorrhage are minimal with the Jamshidi method.

Jamshidi needles are available in single use and reusable models.[3] The reusable model is "self sharpening" and steam sterilizable. In our experience, the single use model may be reused 10 to 15 times after gas sterilization. Jamshidi type needles are available in various sizes, but the 8 and 11 gauge needles (4 inches long), are most commonly used. A Jamshidi-type needle features a pointed stylet that facilitates passage through the soft tissues (Figure 5-4). The stylet is secured by a screw on cap. The tip of the cannula is tapered, allowing the specimen to be locked into the cannula. This tapering eliminates the rocking motion necessary to break off and retrieve a tissue specimen when using a trephine. A small probe is also provided to assist in removing the specimen from the needle. The specimen must be pushed out the handle because damage and compression distortion of the specimen will occur if it is pushed out the tapered cannula tip.

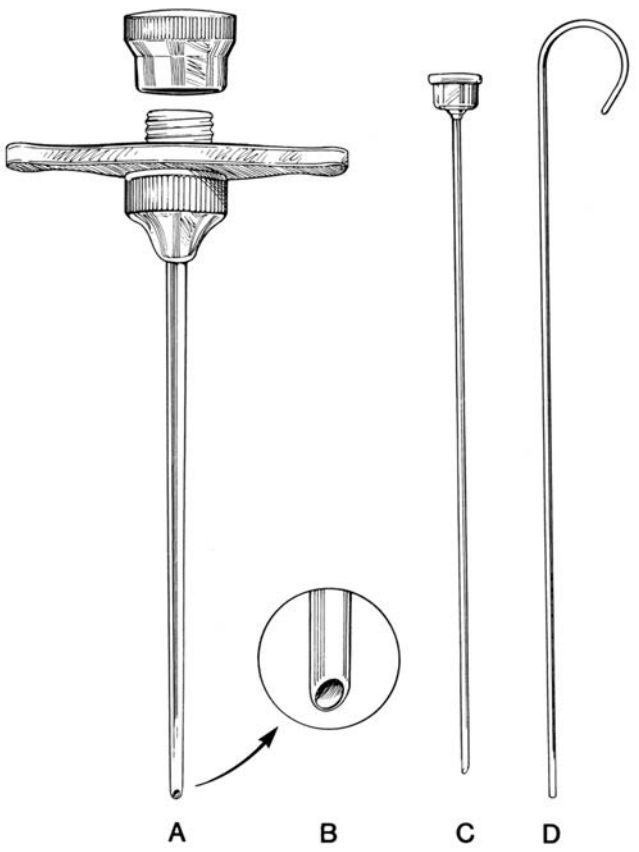

Figure 5-4. Jamshidi type biopsy device. **A.** Cannula and screw on cap. **B.** Tapered point to "lock in" the biopsy specimen. **C.** Pointed stylet to advance the cannula through soft tissue structures. **D.** Probe to expel the specimen out of the cannula base. (From Powers BE, LaRue SM, Withrow SJ, et al. Jamshidi needle biopsy for diagnosis of bone lesions in small animals. J Am Vet Med Assoc [in press].)

Indications and Preoperative Considerations

Bone biopsies are most often performed to confirm the presence of a neoplasm suspected on radiographic and clinical evaluation. Primary malignant tumors of bone in dogs include osteosarcoma, chondrosarcoma, fibrosarcoma, and hemangiosarcoma. Plasma cells, myeloma, and other round cell tumors can also originate from bone. Metastatic spread to bone from other primary tumors must also be considered. Metastasis to bone can occur with almost any type of tumor. The clinical and radiographic signs of primary and metastatic bone tumors can be similar; they include lameness of the affected limb, a warm swelling that is sensitive when palpated, and lytic and proliferative changes, which are apparent on radiographs. Other conditions that can

mimic bone tumors include fungal and bacterial osteomyelitis. Dogs with fungal infection have generally traveled in fungus-endemic areas. Dogs with bacterial osteomyelitis usually have intermittent drainage from the lesion and a history of penetrating trauma or previous surgery.

Although history, clinical signs, and radiographic changes can aid in making a presumptive diagnosis, the definitive diagnosis of bone lesions can be obtained only through histologic evaluation of a tissue specimen. Radiographic evaluation before biopsy should include two different views (craniocaudal and lateral) of the lesion. As previously mentioned, biopsies are traditionally obtained at the junction of tumor and normal tissue. However, in bone, the center of neoplastic lesions is most likely to yield diagnostic material.[4] Bones surrounding almost any insult, including trauma, infection, and tumor, can become reactive. Although biopsy specimens obtained at the center of bone tumors often contain considerable necrotic tissue, tumor identification is not impeded.[4] Inadequate sampling may result in a report of reactive bone. In these cases, the clinician should consider rebiopsy, especially if the diagnosis of reactive bone does not fit the clinical picture. The center of the lesion can be measured on the radiograph with reference to a nearby landmark, generally the adjacent joint. The radiograph should be in view and a sterile ruler available at the time of biopsy.

The skin incision and route of the biopsy needle should be made with subsequent surgical procedures in mind (i.e., limb sparing operations). Questions of preferred location of biopsy are best directed to the referral institution that would perform the definitive surgery. In any case, a joint should never be entered and dissection through the planes or neurovascular bundles should be avoided. If evidence points toward primary bone tumor and if the clients are interested in pursuing limb sparing surgery, referral for biopsy may be the best alternative. General anesthesia is usually necessary for bone biopsy. Selection of the anesthetic regimen depends on the general condition of the animal, on personal preference, and on experience. Because many of these patients are geriatric, complete blood count, serum biochemistry, and urinalysis are indicated. In some cases, particularly in animals with a lytic lesion, heavy sedation and local anesthesia may suffice.

Surgical Technique

The surgical site should be aseptically prepared and routinely draped. Adhesive drapes covering the biopsy site offer excellent protection allowing palpation and manipulation of the limb. A 1 - to - 2 mm stab incision in the skin is made at the desired location. The Jamshidi cannula, with the stylet locked in place, is gently pushed through the soft tissue structures. When bone is reached, the location of the cannuta should be evaluated using the radiographs as reference (Figure 5-5). The cannula can be shifted to a different location if desired. The stylet is removed. With a gentle twisting motion and the application of firm pressure, the cortex is penetrated. The cannula is advanced through the medullary cavity, taking care to avoid penetrating the opposite cortex (Figure 5-6). After the instrument is removed, the specimen is pushed from the tip out through the base of the cannula with the probe, not with the stylet (Figure 5-7). The procedure is repeated, following the soft tissue tract previously established. The instrument can be angled in different positions after reaching the bone. Two or three specimens should be obtained. If the center of the lesion is so soft that a core of tissue cannot be obtained, the cannula should be directed toward the peripheral aspect of the lesion. Hemostasis is generally not a problem with this technique; however, if bleeding occurs, direct pressure is sufficient to control it. The Jamshidi instrument bends if excessive pressure is applied.

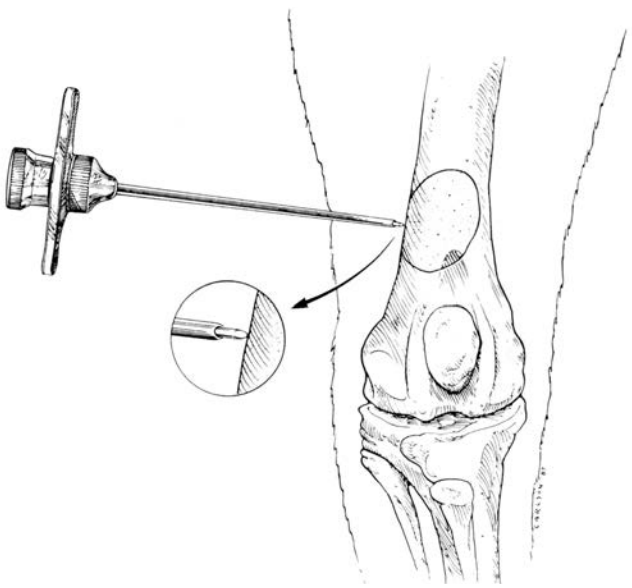

Figure 5-5. With the stylet locked in place, the cannula is advanced through soft tissue structures until bone is reached. The cannula should point toward the center of the tumor.

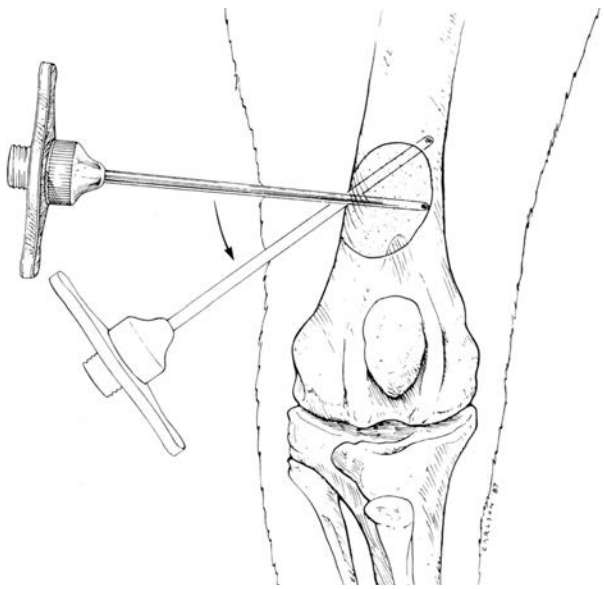

Figure 5-6. After the stylet has been removed, using a twisting motion and applying gentle pressure the cortex is penetrated. The cannula is advanced until the opposite cortex is reached and then is withdrawn. The procedure is repeated with the cannula pointed toward the periphery of the lesions.

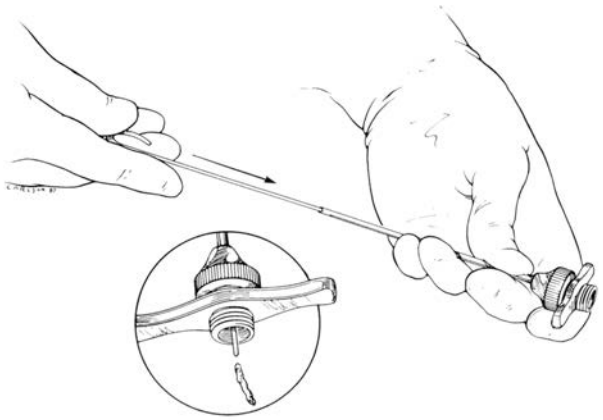

Figure 5-7. The probe is inserted into the tip of the cannula, and the specimen is expelled through the cannula base (inset).

Damage to the cannula and stylet can occur during biopsy of normal cortical bone or of an extremely proliferative and organized bony lesion. If the cannula cannot be inserted, its position should be reevaluated to ensure that the cannula is not on adjacent normal bone. If the position appears correct, a trephine may be indicated to obtain an adequate sample. A skin suture may be placed after the procedure. For biopsies of the lower extremities, a soft wrap may be applied.

Biopsy specimens should be placed in a 10% neutral buffered formalin solution as soon as possible to prevent desiccation. Specimens can also be placed in culture medium if desired. Samples should be sent to a pathologist and laboratory experienced in evaluating and processing bone specimens.

Nasal Biopsy

A nasal biopsy requires that the animal be anesthetized, with an endotracheal tube inserted. The cuff of the endotracheal tube should be inflated and checked periodically to prevent aspiration of blood during the procedure. Several procedures have been used to procure nasal biopsies. In our experience, the easiest and most successful procedure in dogs is the use of a rigid plastic tube, such as the outer sleeve of a Sovereign catheter (Sovereign indwelling catheter, Monoject, Division of Sherwood Medical, St. Louis, MO) or spinal needle.[5] The actual catheter portion is discarded, and the metal stylet is cut off at the hub using bandage scissors. The catheter sleeve is slid over the remaining hub, and a 12-mL syringe is attached. The location of the tumor is visualized on radiographs, and the plastic sleeve is measured from the medial canthus of the eye to the tip of the nose. The sleeve can be marked or cut off so the clinician does not introduce the biopsy device further than this distance. This technique prevents disruption of the cribriform plate and invasion of the brain. The tube is introduced past the wing of the nostril using gentle pressure. It is then reamed in and out of the tumor repeatedly while suction is applied to the syringe. Hemorrhage is common but usually self limiting and should not deter the clinician from being aggressive. The device is withdrawn from the nose, and the syringe is removed and filled with air. The specimen is then forced out by flushing the air through the tube using the syringe. Samples should be placed on a gauze sponge to allow blood to drain away. Tumor tissue is usually white to tan, although it may be hemorrhagic and mucoid. All tissues are placed in 10% buffered formalin for evaluation. Smaller pieces can be placed on filter paper before placement in formalin to preserve architecture.

In cats, smaller dogs, and brachiocephalic breeds, a curette can be used followed by flushing the nose with saline. Care is taken to properly inflate the endotracheal tube cuff to prevent aspiration. The instrument should not be introduced further than the distance from the tip of the nose to the medial canthus. It is helpful to mark the instrument with a piece of tape at this distance. Sponges should be placed above the soft palate and at the external nares to catch bits of tissue. The curette is then introduced into the nasal cavity and a scooping action is used to dislodge tumor fragments. Cool saline is used to flush out specimen pieces using a pulsing action. All tissue is submitted for histopathologic evaluation.

Mild hemorrhage is noted for several hours after the biopsy. Sneezing after the biopsy can aggravate this hemorrhage. Patients should undergo recovery in a quiet area with supervision and should be kept for several hours or overnight after anesthetic recovery. These techniques are safe, they have minimal morbidity when compared to open biopsies, and they yield excellent specimens.[5]

Interpretation of Results

The biopsy should be reviewed with respect to other data concerning the patient, such as clinical signs, history, and physical examination. A clinician should expect to receive the following information in a biopsy report: a determination of neoplasia versus no neoplasia; a diagnosis of benign versus malignant; a histologic type; grade of tumor if applicable; and margins if excisional. Interpretive errors can occur at any level of diagnosis. An estimated 10% of biopsy results may have some clinically significant inaccuracy. If the biopsy result is inconclusive or is inconsistent with the clinical findings, one of several actions should be taken. At the very least, the pathologist should be called and the concern expressed. This exchange should be looked on as welcome and helpful for both parties, not as an affront to the pathologist's expertise. In many cases, added information may lead to resectioning of the available paraffin tissue block, use of special stains for certain tumors, or a second opinion. Rebiopsy is also a possibility if the tumor is still present in the patient.

A properly performed biopsy and interpretation are the most important steps in the management of the cancer patient. The decision to submit a tissue specimen for histopathologic examination should not be left to the owner. If necessary, the charge for submission and interpretation of the biopsy should be included in the surgery fee. Mass excision without interpretation is no longer considered the standard of care. Because of increasing legal concerns, much more is at stake than the satisfaction of medical curiosity.

Chapter 6

Supplemental Oxygen Delivery and Feeding Tube Techniques

Nasal, Nasopharyngeal, Nasotracheal, Nasoesophageal, Nasogastric, and Nasoenteric Tubes: Insertion and Use

Dennis T. Crowe and Jennifer J. Devey

Indwelling tubes that enter the nose and stop in the ventral nasal meatus (nasal), pharynx (nasopharyngeal), or trachea (nasotracheal) are effective for the delivery of supplemental oxygen (O_2). Those that continue on through the ventral nasal meatus and pharynx and stop in the caudal thoracic esophagus (nasoesophageal [NEO]) are useful for the delivery of fluids and nutritional supplements or for the aspiration of air and fluids to provide decompression of the esophagus in conditions causing megaesophagus. Tubes that continue on into the stomach and either stop there (nasogastric [NG]) or continue into the duodenum or jejunum (nasoenteric [NET]) are useful for delivery of fluids and nutrients or for removal of accumulated air and fluids. All these tubes are placed initially into the nasal passage and are passed into the ventral meatus using the same technique. The type of tube selected depends on its intended use. Placement of each of the types of tube is simple to perform. In rare instances, placement under fluoroscopic guidance may be required (i.e., placing an NG tube past an esophageal stricture or placing an NET tube). After insertion, all indwelling tubes are generally well tolerated by most patients, even patients that are completely alert. On occasion, an Elizabethan collar is recommended to prevent the patient from dislodging the tube. Sedation is not necessary in most patients. The nose generally accommodates up to three to four types of tubes at the same time. When more than one type of tube is placed in the nose, the tubes must be labeled appropriately to avoid complications.

Oxygen Administration

Nasal Tubes

Indications

Supplemental oxygen (O_2) should be provided as a first line of treatment to dogs and cats in shock (septic, traumatic, cardiogenic) and cardiac failure and those with respiratory compromise. This supplementation is also a useful treatment in postoperative critically ill patients during the anesthetic recovery period and in anemic animals.

The use of O_2 cages has been helpful in providing an O_2-enriched atmosphere for animals. However, these cages are expensive, and available sizes often cannot house large to giant breed dogs adequately. They also are inefficient to operate because a considerable amount of O_2 is dissipated into the room each time

the door is opened. Furthermore, once a patient is placed into an O_2 cage, careful evaluation, continued monitoring, and treatment are difficult in the "forced" isolation that this form of O_2 therapy requires. Much time is also required to generate the higher levels of O_2 recommended in patients placed in O_2 cages. The law of displacement dictates the time required. The cubic volume of commercial O_2 cages varies from 300 to 500 L. If O_2 is provided at a flow rate of 20 L/minute into the cage, and no leakage occurs, it will take a minimum of 12 minutes to achieve the O_2 concentration of near 100% that is recommended in patients suffering from life-threatening conditions. O_2 cages are also inefficient at providing sustained concentrations of O_2 higher than 50% because of unavoidable leaks. In investigations with one O_2 cage, the O_2 concentration could not be held above 40%.

Other available means of providing supplemental O_2 therapy include the use of face masks, O_2 hoods, bilateral human nasal cannulas, and transtracheal catheters. Difficulties with the use of a mask in nervous and apprehensive animals are all too familiar. O_2 hoods are well tolerated and provide up to 80% O_2 concentrations, but access to the face is restricted, and the animal is unable to drink or eat (Figure 6-1). These collars can, however, be used in conjunction with nasal catheters or short nasal cannulas to increase tracheal O_2 concentration.

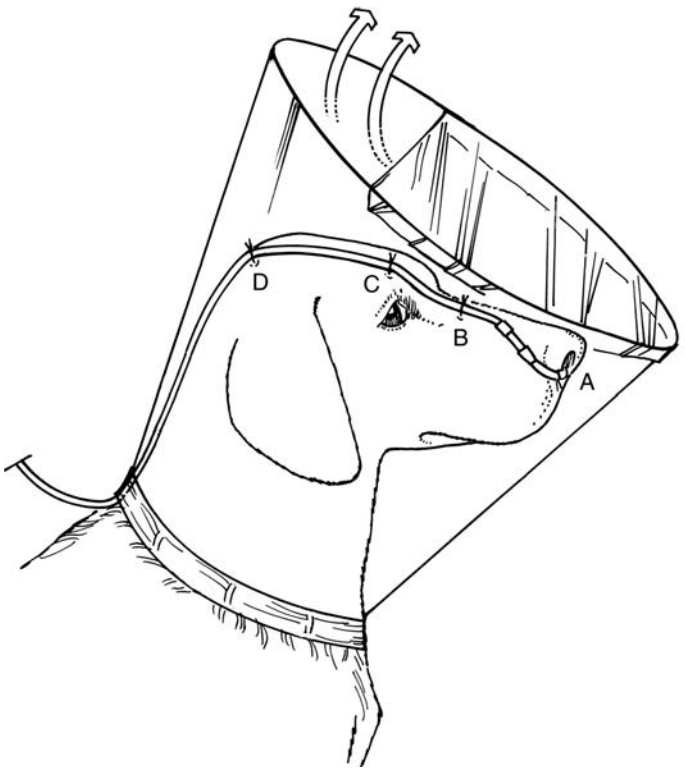

Figure 6-1. Detailed drawing showing suture at: the base of the nose in the skin, then going around the tube and tied tightly **A.** the mid dorsal region of the nose in the skin, then going around the tube and tied tightly **B.** eye level on the dorsum of the head in the skin, then going around the tube and tied tightly **C.** ear level on the dorsum of the head in the skin, then going around the tube and tied tightly **D.** The tube is then brought behind the neck and is secured with a section of tape around the neck (inset). A section of oxygen tubing or intravenous administration tubing is used to connect the tube to the oxygen source with a regulator. For animals that are extremely active, a section of tape can also be placed around the chest and the tube secured to this tape.

Short human nasal cannulas are inserted into the nares and are secured around the neck using a drawstring. These devices are well tolerated, but they frequently dislodge if the patient is active. Complications with transtracheal catheters have been reported. Nasal O_2 administration is an efficient and effective means of providing high inhalational concentrations of O_2 (up to 85 to 95%). *The deeper the placement of the end of the tube in the respiratory tract, the more efficient the device is in elevating the concentration of O_2.* Nasal tubes are not as effective as nasopharyngeal tubes in raising the inhaled tracheal O_2 concentration. The highest concentrations of O_2 are achieved with the use of nasotracheal tubes.

Insertion Technique

The animal's head is held gently restrained upward, and 1 mL of 2% lidocaine (dogs) (Animal Health Associates, Kansas City, MO) or 5 drops of 0.5% proparacaine ophthalmic Solution (dogs and cats) (Ophthaine, ER Squibb & Sons, Princeton, NJ) are administered into either nostril. The right nostril generally is preferred for right handed operators and the left nostril for left handed operators. The local anesthetic solution is allowed to run down the nasal passage. This procedure is repeated after 10 to 20 seconds. After another short waiting period to allow for desensitization, the tip of the selected catheter is lubricated on its outer surface with a commercial water soluble lubricant (Xylocaine Jelly 2%, Astra Pharmaceutical Products, Inc., Worcester MA). The catheter can be a 3.5- to 8-French red rubber (Sovereign, Sherwood Medical Products, St. Louis, MO) or polyvinyl chloride (Cook Critical Care, Bloomington, IN) tube, or for extremely small patients, a long flexible 17-gauge polyethylene intravenous catheter. The addition of small side holes helps to disperse the stream of O_2 more evenly within the nasal passage; however, these holes are not usually required.

For nasal O_2 tube placement, the tube is premeasured alongside the patient's face so the tube's tip, after placement, extends into the nasal cavity to the level of the first or second premolar. This facilitates flow through the ventral nasal meatus. This tube can be measured alongside the animal's teeth or by measuring from the tip of the nose to the medial canthus of the eye. After premeasuring, the tube is introduced into the nasal orifice while the patient's head is held firmly. Cats have a straight nasal passage, and the tubes generally pass easily. In the dog, pushing the tip of the nose upward allows the tube to be passed more easily into the ventral meatus. The tip is directed ventromedially (Figure 6-2). In the cat, the tube can be simply inserted straight in most cases. After this initial introduction, the tip, in both the dog and the cat, is directed ventromedially until the desired length has been inserted (Figure 6-3). Most animals object to the initial passage of the tube by sneezing and trying to shake their heads, but then they remain quiet after tube passage has been completed. If an animal objects to the insertion of the tube, slight sedation is recommended using low doses of intravenous neuroleptanalgesia (e.g., butorphanol [Torbugesic], 0.1 to 0.4 mg/kg, and diazepam [Valium], 0.05 to 0.2 mg/kg, or acepromazine .02 to .04 mg/kg).

After insertion to the level required, the tube is fixed to the skin using 3-0 or 2-0 silk suture with a swaged-on cutting needle. The

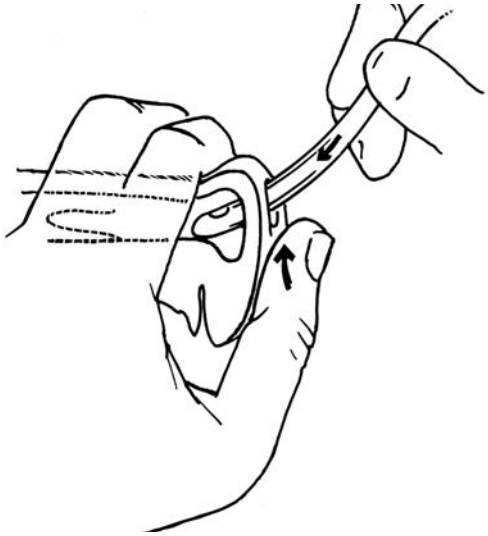

Figure 6-2. Parasagittal section showing insertion of a nasal tube through the nares. Note the ventral protuberance at the base of the nostril and the ventral direction of the tube after it passes over the small ventral protuberance. (Modified from Crowe DT. Clinical use of an indwelling nasogastric tube for enteral nutrition and fluid therapy in the dog and cat. J Am Anim Hosp Assoc 1986;22:675-678.)

most critical area requiring initial fixation is the first 0.5 cm after the tube exits from the nostril. This suture is usually *preplaced* to facilitate securing the tube immediately after it is placed. Several sutures are used to secure the tube (Figure 6-4). Each suture is placed through the skin in a "quick pass" fashion without hair clipping, aseptic preparation, or local anesthesia. After a loose simple interrupted suture is tied, the ends are wrapped around the tube and are tied again. An alternative fixation method is to apply a few drops of cyanoacrylate glue to the tube and tufts of hair on the nose and along the face, or skin staples can be used to secure the tube. Elizabethan collars are only required in patients objecting to the tube.

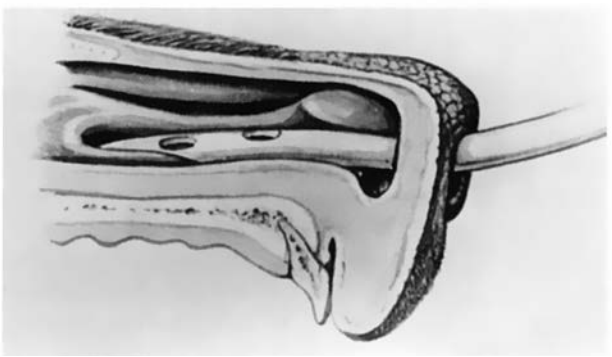

Figure 6-3. Parasagittal section showing completion of the insertion of a nasal tube to be used for oxygen delivery. The tube stops in the ventral nasal meatus just before the level of the maxillary turbinate. (From Crowe DT. Clinical use of an indwelling nasogastric tube for enteral nutrition and fluid therapy in the dog and cat. J Am Anim Hosp Assoc 1986;22:675-678.)

Oxygen Delivery Protocol

Tubing for O_2 administration (Tomac, American Hospital Supply Corp., Chicago) or an intravenous administration set is connected to the external end of the tube. The other end, in turn, is attached to the O_2 source with a standard O_2 flow meter. If O_2 supplementation for more than 24 hours is anticipated, use of a commercial humidification chamber is recommended. Alternatively, a homemade humidifier can be fashioned using a crated intravenous fluid infusion bottle. The O_2 source is attached to the vent hole, and O_2 is bubbled through warm water. Additional tubing, as necessary, is used between the patient and the humidifying unit to allow the animal freedom to move without fear of tube disconnection. The homemade humidification chamber full of water must not tip over, because this would result in rapid delivery of water into the patient's nasal passage.

For patients being resuscitated, flow rates that generate at least 60 to 80% O_2 concentrations are recommended. In patients that have hemodynamic and pulmonary stability, flow rates are decreased 50% to provide approximately 40% inspired O_2. The flow rate to provide 60 to 80% O_2 concentrations is approximately 50 mL/kg body weight per minute in small dogs and cats and approximately 100 mL/kg body weight per minute in large dogs when delivering O_2 using properly placed nasal catheters. A proportionally greater amount probably is required in large breed dogs because of a concomitant increased amount of anatomic dead space in larger animals.

After O_2 administration is begun, the patient should be observed carefully to determine the response to therapy and to identify adverse effects, which are rare. Clinical signs such as decreased anxiety and decreased respiratory rate and effort indicate an improvement in response to the O_2. Pulse oximetry can also be used to assess oxygenation. O_2 supplementation is indicated whenever O_2 saturation is below 92%. Accurate measurements are, however, sometimes difficult to obtain in the awake patient because of probe placement difficulties. In the critically ill patient, arterial blood gases should be monitored whenever possible. Partial O_2 pressures considered sufficient should be at least 60 to 65 mm Hg. If hypercapnia exists (PCO_2 greater than 50 mm Hg), mechanical ventilation rather than simple O_2 supplementation should be performed. Provided sufficient volume exchange is taking place to prevent hypercapnia, the O_2 flow rate can be increased to provide greater inspiratory O_2 concentrations if no favorable clinical response is observed or arterial PO_2 values remain below 65 mm Hg. Permissible flow rates and the corresponding O_2 percentages in the inspired air are given in Table 6-1. If after increasing the flow rates arterial O_2 values do not increase above 70 mm Hg, intermittent positive pressure ventilation (IPPV) with positive end-expiratory pressure should be instituted. If the patient's work of breathing does not improve with the high concentration of O_2, then control of breathing with IPPV should be provided. *The use of mechanical ventilation in these patients is important; otherwise, ventilatory failure and death will ensue.*

Complications

Complications with the use of nasal O_2 administration are uncommon. O_2 is dry and cool; therefore, prolonged use (more

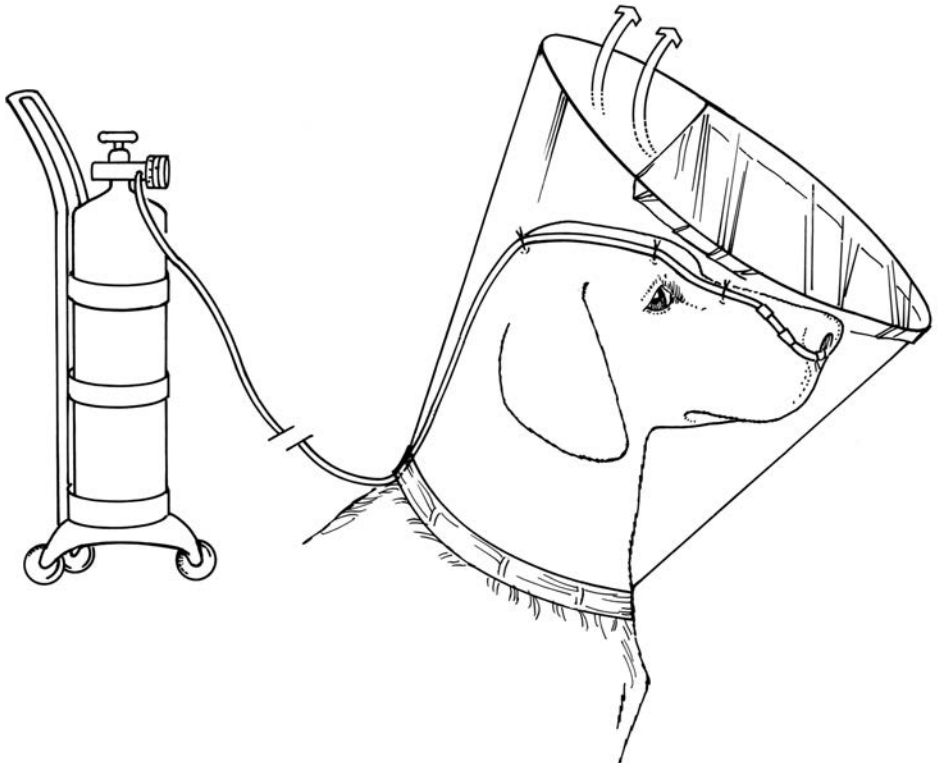

Figure 6-4. Nasal oxygen tube in place and fixated with a skin suture close to the external nares. The tube is also secured with other skin sutures. The tube could also be secured ventral to the eye and ear. Elizabethan collars with clear plastic wrap over the front can be used to increase oxygen concentrations if required. This "Crowe collar" can also be used independently to provide a rapid means of increasing inspired oxygen levels. (Modified from Fitzpatrick RK, Crowe DT. Nasal oxygen administration in dogs and cats: experimental and clinical investigation. J Am Anim Hosp Assoc 1986;22:293-297.)

than 3 to 5 days) may cause rhinitis and sinusitis. When these complications do occur, they usually are mild and become evident as a persistent serous nasal discharge. The discharge usually clears within several days after the nasal tube is removed. The use of nasal O_2 in patients with nasal bone fractures may lead to subcutaneous emphysema. If blood is present in the nose, nasal O_2 administration is not recommended because bubble formation and foam may interfere with air exchange. In these patients, nasotracheal or transtracheal O_2 is recommended.

Tube dislodgment is an infrequent complication if the catheter is placed in the nose for a sufficient distance and if fixation of the tube is performed correctly. Persistent sneezing and continued irritation are rare and necessitate the use of repeated local anesthetic instillation, an Elizabethan collar, or light intravenous chemical sedation (e.g., oxymorphone at 0.02 mg/kg or diazepam at 0.1 mg/kg). Mild epistaxis caused by misdirection of the tube into the maxillary or ethmoid turbinates during placement may occur, but in our experience this occurs rarely and is not severe enough to warrant discontinuation of a tube's insertion or use.

Contraindications

Patients with severe tracheobronchial froth or fluid accumulation, as observed in animals with severe pulmonary edema, should receive nasotracheal or transtracheal O_2 rather than nasal O_2. Nasal tubes should be avoided in those patients with severe epistaxis or mucopurulent nasal discharge, suspicion of maxillary or cranial vault fracture after head injury, or head injury or any condition in which elevation of intracranial pressures

secondary to sneezing or struggling is contraindicated. Ineffective ventilation requiring other primary care (intubation and positive-pressure ventilation) is also a contraindication to the placement of nasal O_2 tubes.

Nasopharyngeal Tubes

Nasopharyngeal tubes allow delivery of O_2 into the nasopharynx. This method can provide high concentrations of O_2 and, if flows are high enough, some level of continuous positive airway pressure (CPAP). CPAP is even more effective if bilateral nasopharyngeal tubes are placed. As the patient exhales, it exhales against some force created by the flow of the O_2 in a caudal laryngeal direction. The goal is to create an increase in the patient's functional residual volume. This can be done with CPAP.

A nasopharyngeal tube is placed in a fashion similar to that of a nasal catheter, but the lubricated tip of the tube is continued through the ventral meatus past the maxillary turbinate. The tube is held alongside the face and neck and is premeasured from the external naris to just proximal to the larynx. In dogs, some resistance may be encountered at the maxillary turbinate region because of a narrowing of the ventral meatus in a dorsoventral direction. If the tube cannot be passed farther than the level of the eyes in dogs or cats, the tube is assumed to be in the dorsal meatus with its tip in the ethmoid turbinate. The tube must be withdrawn and redirected ventrally if this occurs. After the tip is past the maxillary turbinate in the ventral meatus, resistance to the tube's passage decreases, and the tube can be passed into the nasal pharynx and pharyngeal isthmus. The ideal location is just dorsal to the rima glottis (Figure 6-5).

High O_2 flow rates (greater than 200 mL/kg per minute) should be administered carefully when providing O_2 through nasopharyngeal tubes. Rarely, gastric distension occurs if flow rates are exceedingly high (greater than 200 mL/kg per minute) or if the nasopharyngeal catheter migrates into the esophagus. Bradycardia, believed to be vagally mediated, can also occur.

Nasotracheal Tubes

Nasotracheal tubes provide an effective means of providing O_2 to the patient that has laryngeal palsy or a collapsing cervical trachea. These catheters also generate some degree of CPAP when high flow rates are used. Patient tolerance is usually good, with little coughing. In animals that do not tolerate the tubes, mild sedation may be required.

Before placement of a nasotracheal tube, the tube should be premeasured such that the tip will rest at the level of the tracheal bifurcation or fifth intercostal space. A 3.5- to 8-French feeding tube is generally used. The tube is placed in a fashion similar to that of a nasopharyngeal catheter. The tube is passed blindly into the trachea through the larynx by hyperextending the patient's head and neck and advancing the tube (Figure 6-6). If coughing is noted, another 0.33 mL of local anesthetic is infused through the tubing, with the tubing in the mid distal pharynx. Once the membranes around the larynx are anesthetized, the tube is advanced as inhalation occurs. If the tube does not pass after several attempts, a short-acting neuroleptoanalgesic can be

administered to the patient, and the tube can be placed by direct visualization using a laryngoscope and something to grasp the tip of the tube and direct it through the rima glottis into the trachea.

The position of the tube should be confirmed with a radiograph or by aspiration using a 60-mL syringe. If the tube is in the trachea, air should continue to be aspirated easily. If the catheter is in the esophagus, air may be initially aspirated, but it should stop.

The nasotracheal tube is used in a fashion similar to that of nasal and nasopharyngeal tubes. For nasotracheal catheters, flow rates are decreased by 50% from those recommended for nasal O_2 tubes to provide equivalent O_2 concentrations. Humidification of the O_2 is essential with the use of nasotracheal tubes, to prevent mucosal drying and dysfunction of the mucociliary apparatus, which can lead to an inability to clear secretions and possible pneumonia. Infusion of saline through the nasotracheal tube can be used to help loosen secretions in patients with dysfunction of the mucociliary apparatus or pneumonia.

Tubes for Gastrointestinal Access

Indications

NEO, NG, and NET tubes can be used for decompression and feeding. Smaller bore NEO, NG, and NET tubes are useful for the administration of water, electrolytes, and liquid enteral support diets. Because dehydration and protein–energy malnutrition frequently are encountered in seriously ill or injured animals, the use of these indwelling tubes for rehydration and nutritional support often is a key component in successful overall patient management. Contraindications to use of NEO or NG fluid and nutritional therapy support include persistent vomiting and high gastric residual volumes. The presence of stupor or coma is a relative contraindication to NEO and NG feeding, particularly if bolus feeding is provided. If slow, continuous-rate infusions result in minimal residual volumes, then the risk of regurgitation and aspiration is low enough that NEO or NG feeding can be used.

Decompression of a dilated esophagus, stomach, or intestinal tract can be accomplished by use of large-bore single lumen or double-lumen (sump) NEO, NG, or NET tubes. Decompression of the esophagus alleviates some of the risk of aspiration in the patient with megaesophagus and actively decreases the stretch in the skeletal muscle that results in dilatation. In the stuporous or comatose patient, or in the patient receiving mechanical ventilation, active decompression helps to prevent aspiration. In the patient having difficulty ventilating, decompression of the stomach improves ventilation because of reduced impedance to diaphragmatic excursions. This is particularly helpful in cats and small dogs because they breathe primarily using the diaphragm. Clinically, NG decompression has been helpful in the temporary management of gastric dilation–volvulus syndrome when the gastric distension has been due primarily to air and fluid. Decompression of the stomach after abdominal surgery helps to decrease the time to return to normal gastric motility. After placement, the NG tube is periodically aspirated (e.g., once every 1 to 2 hours). The tube is left in place until bowel sounds return or the patient is believed to be out of danger of postoperative redistension. Antral dilation

is a strong stimulus for vomiting. The use of NG tubes decreases the incidence of vomiting in the patient with gastrointestinal or pancreatic disease and is especially useful in the patient with canine parvovirus infection.

Tube Selection and Insertion

The techniques for inserting an NEO, NG, or NET tube for decompression or feeding are the same. Polyvinyl chloride (Argyle nasogastric feeding tube, Sherwood Medical Products), polyurethane (Cook Critical Care), or red rubber tubes from 3.5 French (cats and small dogs) to 12 French (medium to large dogs) are used. Specially designed tubes that are weighted on their proximal ends with either tungsten or mercury are useful to ensure that the tube will stay in the stomach lumen (Travasorb dualport feeding tube, Baxter Health Care Corp., Deerfield, IL). The smaller the tube, the more difficult it is to use for decompression. A nylon stylet that accompanies commercial polyurethane tubes provides added stiffness necessary for insertion. With smaller polyvinyl chloride tubes, a woven angiographic wire stylet (Wire guide, Cook Critical) is used to provide added stiffness. One or two milliliters of vegetable or mineral oil is injected into the lumen of a tube to facilitate ease of insertion and withdrawal of the woven wire through the lumen.

After selection of the tube and placement of the stylet, the length necessary to reach the distal thoracic esophagus (NEO) or the stomach (NG) is determined by measuring alongside the patient's neck and body from the tip of the nose to the eighth or ninth rib for NEO tubes or to the thirteenth rib for NG tubes (Figure 6-7). For NET tubes, length is added to ensure that the tip of the proximal end of the tube will reach the area of the bowel lumen selected. Most often, the tube for enteral feeding is a nasoduodenal tube with a tip that ends near the pelvic flexure of the duodenum. The tube in these cases is premeasured to extend from the nose to the wing of the ilium (See Figure 6-7).

The lubricated tip of the tube is introduced into the patient's nostril in the same manner as described for nasopharyngeal tubes. After the tip is past the maxillary turbinate in the ventral meatus, resistance to the tube's passage decreases, and the tube can be passed into the nasal pharynx and pharyngeal isthmus. At this point, the patient's head must be kept in a neutral position, with the neck gently flexed to facilitate passage of the tube into the esophagus (Figure 6-8). If the neck is hyperextended, the tube may enter the larynx and trachea. With continued advancement of the tube, the patient is often observed to swallow several times. Once the tip of the tube has been advanced into the caudal thoracic esophagus (NEO tube) or into the proximal portion of the stomach (NG tube), the lubricated stylet is withdrawn. The

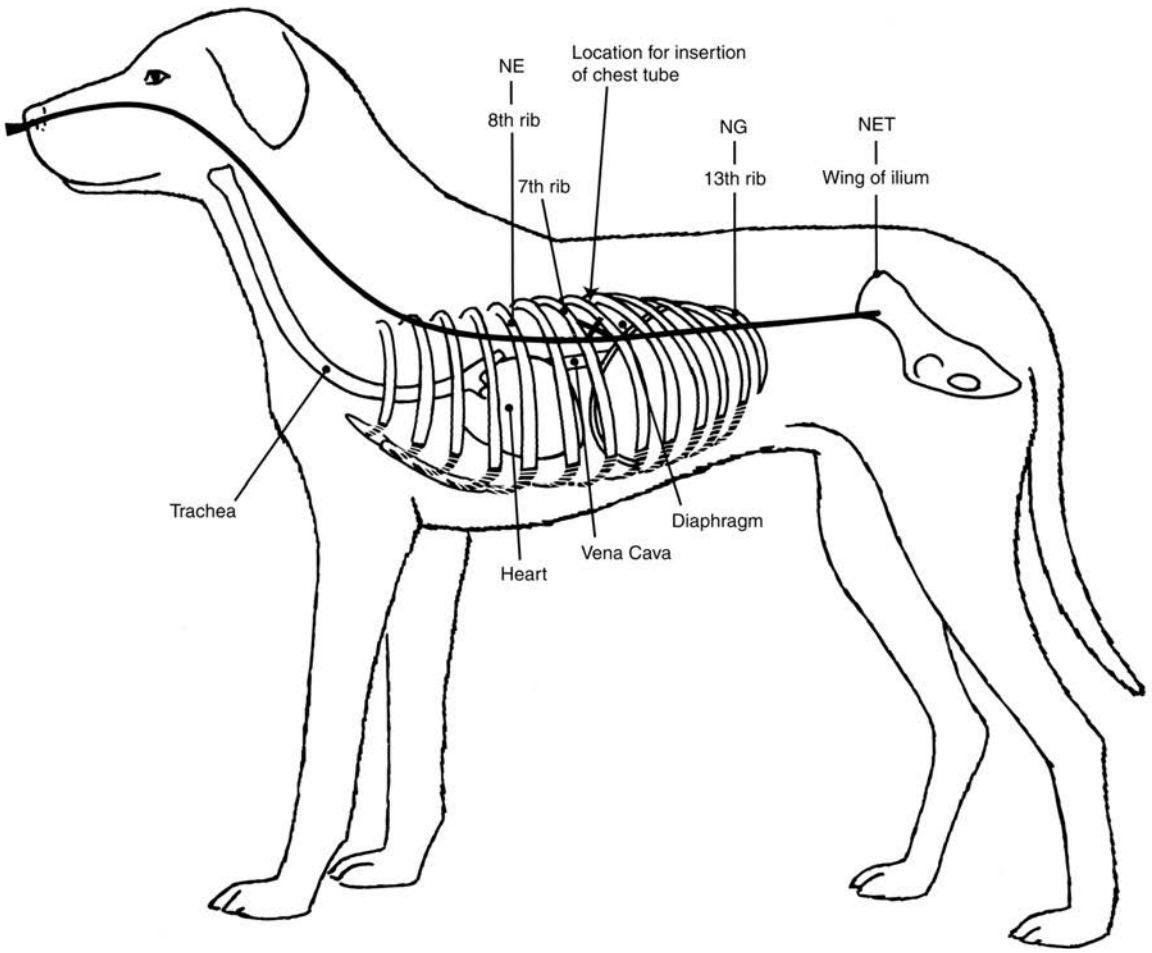

Figure 6-7. Drawing depicting landmarks used to premeasure the various feeding or decompression tubes. The tube should be premeasured from the tip of the nose of the animal to the eighth rib for nasoesophageal (*NE*) tubes, to the thirteenth rib for nasogastric (*NG*) tubes, and at least to the wing of the ilium for nasoenteric (*NET*) tubes.

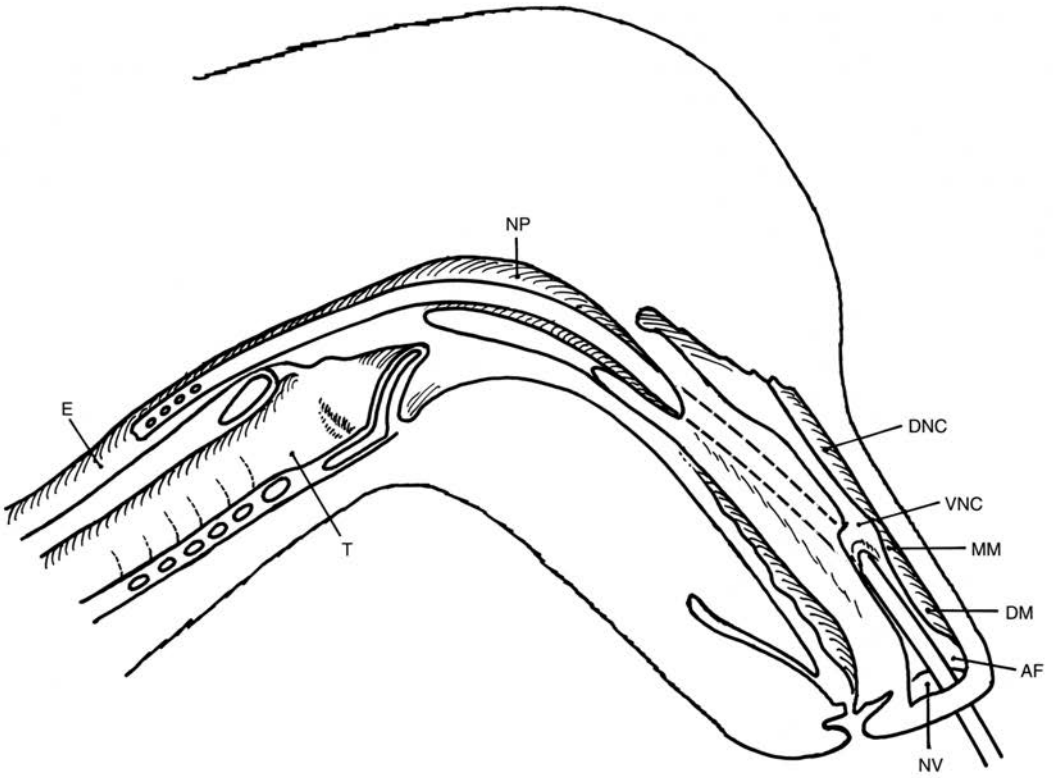

Figure 6-8. Parasagittal section showing the insertion of a nasogastric tube through the nasal passage and into the esophagus. The head is bent to help the tube follow the dorsum of the wall of the pharynx and then course dorsally into the esophagus. Structures identified include the nasal vestibule (*NV*), cartilaginous septum (*CS*), dorsal meatus (*DM*), middle meatus (*MM*), ventral nasal concha (*VNC*), dorsal nasal concha (*DNC*), alar fold (*AF*), nasopharynx (*NP*), esophagus (*E*), and trachea (*T*). (Modified from Crowe DT. Clinical use of an indwelling nasogastric tube for enteral nutrition and fluid therapy in the dog and cat. J Am Anim Hosp Assoc 1986;22:675-678.)

use of a stylet also helps to facilitate the passage of the tube into the stomach through the cardia.

Air is injected into the tube while auscultation of the left chest wall and left paralumbar fossa is performed; the presence of gargling sounds during this procedure indicates that the tube is in the distal esophagus or stomach, respectively. In most cases, a lack of coughing during injection of 5 to 10 mL of sterile saline down the tube indicates that the tube is not in the trachea. However, the result of this test may vary with the individual animal, and the position of all tubes should be radiographically confirmed if they are to be used for infusion of fluids or liquid diets.

Special tubes or manipulations are required for placement of NET tubes into the duodenum or jejunum. The tube can be guided by peristaltic action into the duodenum, but this is often difficult to accomplish. The tubes can be guided through the pylorus using endoscopy or fluoroscopy. NET tubes have been most successfully placed at the time of abdominal surgery by the surgeon guiding the tip of the tube, which is palpated and guided through the stomach and intestine into the portion of the bowel intended. Weighted tungsten or mercury tubes have been used to help in guiding tubes through the stomach into the intestine (Travasorb dualport feeding tube, Baxter Health Care Corp.). The weighted tip also may help to ensure that the tube will stay in the bowel lumen and not curl or kick back into the stomach. Passage of the tube into the small intestine through the action of peristalsis has been unreliable, particularly in sick patients with at least some degree of gastroparesis. Metoclopramide, 0.4 mg/kg per day intravenously, has been used to help stimulate gastric motility to facilitate the tube's passage into the duodenum.

Once the tip of the tube has been placed in the desired location, the tube is secured with several sutures placed at the base of the nostril and around the tube, or with glue as described previously for nasal O_2 tubes. If the tube demonstrates a tendency to back out of the nose, 1 to 2 cm of coated copper wire (18 gauge telephone wire) can be used to support the bend in the tube as it exits from the nose. On occasion, the tube may back out of the intestine, or the dog or cat may vomit the tubes into the mouth. In this case, the tube must be removed. A narrow gauge flexible wire can sometimes be left in the tube to help prevent tube migration. Specially designed catheters are also available that allow the delivery of nutrients while the wire is left inside the catheter lumen.

The remaining length of the tube or an attached extension tube (intravenous administration extension set) is secured to the top of the patient's head or the side of the face. An Elizabethan collar can be applied if necessary. The end of the tube is capped to prevent air from entering the gastrointestinal tract by diaphragmatic movement until its use is required.

Protocol for Using Tubes for Decompression

A 60-mL syringe is attached to the end of the tube, and aspiration is done as often as required to keep a slight amount of negative

pressure on the hollow viscus aspirated. For prevention of recurrence of gastric dilation or for decompression of the small intestine, aspiration generally is performed every 1 to 2 hours until a negative pressure is reached each time. If the fluid aspirated is viscous, dilution with sterile water or saline may be required. The tube should be flushed with a small amount of saline or water each time the tube is used, and then the tube should be capped. Holding the column of water in the tube helps to prevent clogging. Maintenance of decompression usually is required only for 24 to 48 hours because most intestinal ileus or gastroparesis is resolved by then.

The efficiency of gastrointestinal decompression achievable with a simple single lumen tube (Argyle stomach tube (Levine Type), Sherwood Medical Products) and intermittent aspiration with a syringe can be improved by the use of a double lumen sump tube (Salem sump tube, Sherwood Medical Products) with continuous 20- to 30-mm Hg suction or intermittent mechanical 80- to 90-mm Hg suction. This type of suction requires the use of specially designed equipment. Automatic intermittent suction, for example, is often best performed with the use of a thermotic drainage pump that is electronically driven (Thermotic drainage pump, GOMCO, Allied Healthcare Inc., Buffalo, NY). Fortunately, in most clinical patients, this type of special equipment is not necessary, and simple intermittent syringe decompression is sufficient.

Protocol for Using Tubes for Feeding

For the administration of fluids and liquid enteral diets, a syringe is used for slow bolus delivery. Slow bolus delivery of fluids and liquid enteral diets can be done safely through NEO and NG tubes in animals that are conscious. However, bolus feeding is not recommended in unconscious or semiconscious patients because of the higher risk of pulmonary aspiration. Bolus feeding should not be done through an NET tube initially because of the high occurrence of vomiting and diarrhea, which can be caused by the acute overload of hyperosmolar nutrients in the small intestine. Drip infusion is the preferred method of the delivery in these circumstances. A pediatric intravenous fluid administration set and bottle are used for the delivery of enteral diets. The use of an enteral or intravenous infusion pump or a syringe facilitates the delivery of these enteral liquid diets.

Initially, an electrolyte and glucose mixture is administered at a rate of 0.25 to 0.5 mL/kg per hour. This rate can be used in all patients including those that have had gastrointestinal surgery; however, it may be too fast for those patients that have undergone massive bowel resections or have pancreatitis. In such patients, the initial rate infused should be no greater than 0.1 to 0.2 mL/kg per hour. The drip rate is steadily increased until caloric requirements are met. Rates higher than 4 mL/kg per hour are usually associated with severe, osmotically induced diarrhea; therefore, the maximum rate usually used for constant rate infusions is 2.0 to 3.0 mL/kg per hour.

Many monomeric and polymeric liquid diets are available for tube feeding. Monomeric or elemental diets are composed of amino acids (Vivonex, Sandoz Nutrition, Minneapolis MN; Alitraq, Ross Laboratories, Columbus, OH) or dipeptides and tripeptides (Peptamen, Clintec Nutrition Co., Deerfield, IL) and require no digestion before absorption. The amino acid–based diets tend to be hyperosmotic and may require dilution initially to a 50% concentration. They usually are more expensive than polymeric diets, but they may be useful in patients with decreased digestive ability. The dipeptide- and tripeptide- based diets tend to be isosmolar and can generally be given initially at full strength concentration. Polymeric diets (Impact, Sandoz Nutrition; Jevity, Ross Laboratories) are made of complex carbohydrates and proteins and require digestion before absorption, but they are usually isosmotic unless they are flavored. Special polymeric diets designed specifically for cats and dogs (CliniCare and RenalCare, Pet Ag Inc., Hampshire, IL) have been developed and have been clinically effective in providing nutritional support to critically ill or injured dogs and cats. Polymeric diets are usually administered either full strength if plasma proteins are normal and anorexia has not been present for longer than 3 days. If plasma protein levels are below normal or anorexia has been present for longer than 3 days the diets should be initially diluted to a 50% concentration with water. The monomeric diets may require dilution to 25% concentration for initial administration. After the rate of administration is stabilized at 2 to 3 mL/kg per hour and the diet is found to be tolerable (no abdominal pain, vomiting, or diarrhea), the concentration of the diet can be gradually increased.

Complications

Complications with feeding and decompression tubes are primarily associated with tube migration, especially dislodgment. Dislodgment is usually caused by vomiting or by the animal's pawing at the tube or rubbing its face.

When concern exists about the location of the tip of the tube, a radiograph should be taken to ensure that the location is correct. Disaster can occur if a tube is displaced into the trachea and food is administered.

Esophagostomy Tube Placement and Use for Feeding and Decompression

Dennis T. Crowe and Jennifer J. Devey

Esophagostomy tubes provide a simple and effective means of administering fluid and nutritional support to the small animal patient. The tubes can also be used for esophageal or gastric decompression.[1] Esophagostomy tubes can be rapidly placed (generally within 5 minutes) and require minimal surgical equipment (a scalpel blade, a pair of curved forceps, and nonabsorbable suture material). Simple red rubber feeding tubes are most frequently used. Patients have been fed for up to 2 years using these tubes. No cases of esophageal stricture or permanent esophagocutaneous fistula have been observed.

Indications

Esophagostomy tubes are indicated whenever nutritional support is required and the stomach is functional but the patient is unwilling or unable to ingest food or water. Esophagostomy tubes can also be used to keep the stomach and esophagus decompressed because aspiration of these tubes helps to prevent air or fluid from accumulating. This may be useful in the management of patients with megaesophagus or those that have undergone surgical correction of gastric dilatation–volvulus.

Esophagostomy tubes were developed and first used in clinical veterinary medicine by Crowe.[2] They were developed and used to avoid the airway difficulties associated with pharyngostomy tubes (Figure 6-9).[3] With pharyngostomy tubes, a portion of the tube can interfere with laryngeal function, even after careful placement using modified techniques. The surgical approach for placement of the esophagostomy tube is simpler than that of the pharyngostomy tube, with less likelihood of damage to vital vascular and neurologic structures. Percutaneous gastrostomy tubes require special feeding tubes and because of penetration of the stomach and peritoneal cavity, the risk of leakage and subsequent development of peritonitis always exists. From our experience, the patient does not need to be subjected to these risks, and, whenever possible, an esophagostomy tube should be selected over a gastrostomy tube. Most conditions for which clinicians use percutaneous gastrostomy tubes for feeding can be also managed with esophagostomy tubes. Esophagostomy tubes can be used in patients that have had esophageal surgery; however, care should be taken to ensure that a smaller bore flexible feeding tube is used and that the end of the tube is not rubbing against a wound site or surgical incision.

Contraindications

In general, esophagostomy tubes should not be used for feeding or decompression if the patient 1) is vomiting, 2) has cervical or thoracic esophageal disease that will be worsened by the placement of a tube passing through the affected area, and 3) has

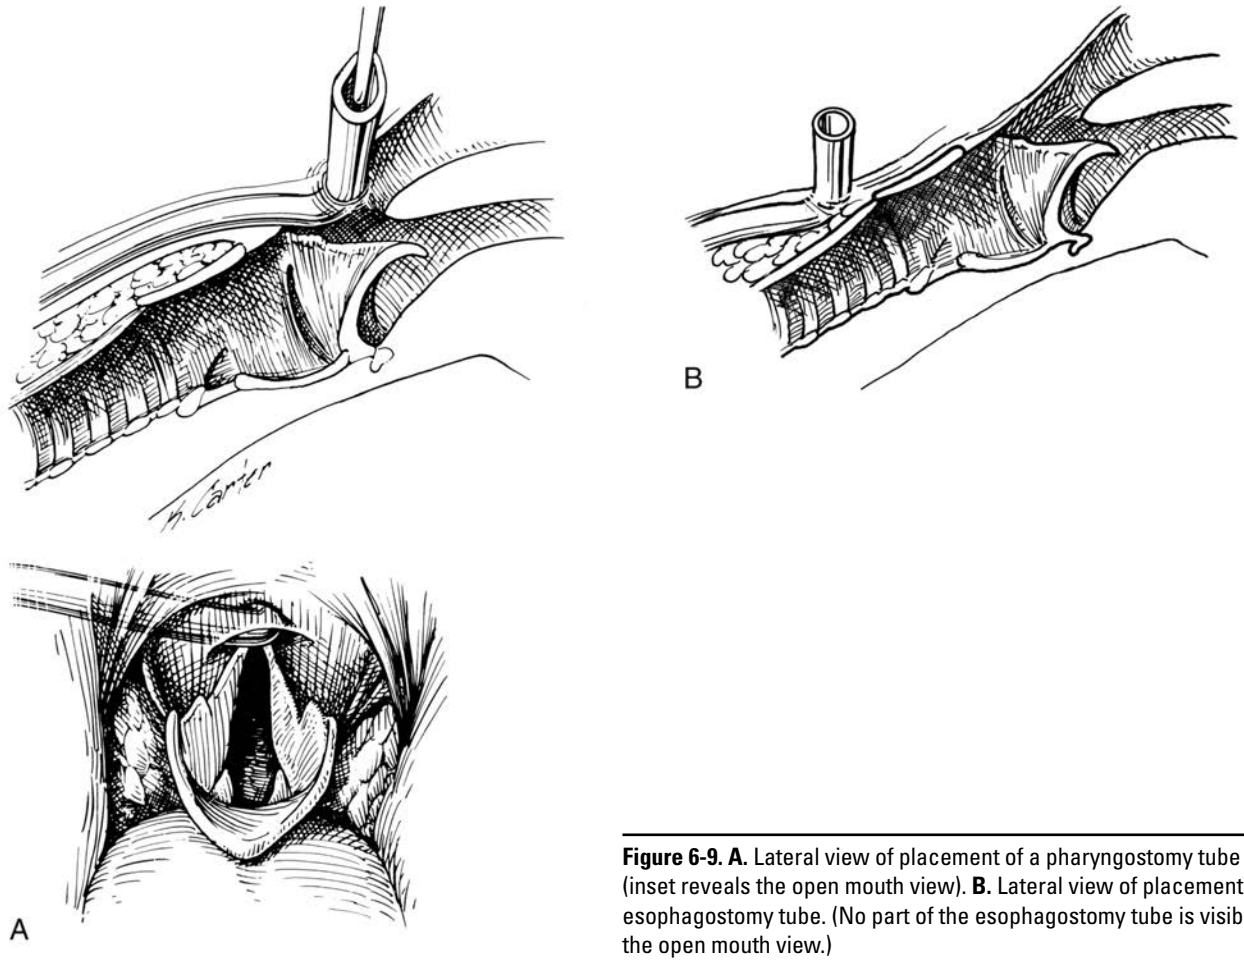

Figure 6-9. A. Lateral view of placement of a pharyngostomy tube (inset reveals the open mouth view). **B.** Lateral view of placement of an esophagostomy tube. (No part of the esophagostomy tube is visible in the open mouth view.)

an infection involving the cervical region close to the tube exit site. Because placement of esophagostomy tubes requires light general anesthesia, the risks of anesthesia should be weighed against the benefits of the placement of esophagostomy tubes in critically ill animals.

Tube Selection

The type and length of tube selected depends on the intended use of the tube. Esophagostomy tubes used for feeding or for esophageal decompression (i.e., for long term management of megaesophagus) should end in the distal thoracic esophagus. Tubes that pass through the lower esophageal sphincter increase the risk of gastroesophageal reflux in some patients. For gastric decompression or feeding, whenever the esophagus needs to be bypassed, an esophagogastric tube is placed with the tip of the tube resting in the midfundic region of the stomach. An esophagoenteral tube can also be placed at the time of abdominal surgery if the stomach needs to be bypassed. The proximal end of the tube should be shortened as required, so only sufficient tubing protrudes from the skin to permit attachment to a syringe for feeding or decompression. Excessive tube length protruding from the skin may be annoying to the animal and may catch on objects.

Esophagostomy tubes used for feeding or decompression should be flexible and in general of as large a bore as possible. This provides less chance for kinking and occlusion. The actual size of each tube selected depends on the size of the animal and on the intended purpose for the tube (Table 6-2). Generally, no tube smaller than 10 French should be used for decompression or if a canned or gruel diet is to be used for feeding. For small cats and dogs, a 10- to 12 French tube is used. For medium sized dogs, a 12- to 18 French tube is used, and for large to giant breed dogs, an 18- to 30 French tube is inserted. When using the tube only for the delivery of liquids, smaller-diameter tubes can be used. Tubes should be flexible yet stiff enough to resist kinking. Commonly, tubes made of red rubber (Sovereign, Sherwood Medical Products, St. Louis, MO), polyvinyl chloride (Argyle feeding catheter, Sherwood Medical Products; Cook Critical Care, Bloomington, IN), polyurethane (Cook Critical Care), Teflon (Cook Critical Care), and silicone (Baxter Health Care Corp., Deerfield, IN) are used. Tubes made of polyurethane or silicone resist the hardening caused by gastric fluids and are recommended if one anticipates that the tube will be used for longer than 1 week. Commercially available tubes frequently require the addition of three to five side holes. These holes can be made carefully using curved scissors. The diameter of the holes should not exceed approximately 20% of the tube's circumference.

Table 6-2. Guidelines for Esophagostomy Tube Size Selection*

	Decompression	Feeding	
Body Weight (kg)	Gastric or Esophageal	Gruel	Liquids Only
< 1	8-10	10	3.5-6
1-3	10	10	6
3-5	10-12	10-12	6
5-10	12-18	12-18	8
10-20	14-20	14-20	8
20-30	20-26	20-26	10
30-40	26-28	26-28	10
> 40	28-30	28-30	12

*** All tube sizes are in French.**

Surgical Technique

Tube Esophagostomy

Light general anesthesia is induced and is maintained throughout the procedure. The airway is protected with a cuffed endotracheal tube. The entire lateral cervical region from the ventral midline to near the dorsal midline is clipped and is aseptically prepared for surgery. Usually, the left side is chosen; however, both sides can be used. The procedure is illustrated in Figure 6-10. Curved forceps are inserted into the pharynx and then into the proximal cervical esophagus. Curved Kelly forceps are recommended for use in cats and small dogs. In larger dogs, longer curved Carmalt, Mixter, or Schnidt forceps are recommended. The tips of the forceps are turned laterally, and pressure is applied in an outward direction, thereby tenting up the tissues so the tips can be seen and palpated (Figure 6-10A). A small skin incision (just large enough to accommodate the tube) is made over the tips of the forceps using a scalpel blade, and the tips of the forceps are bluntly forced to the outside (Figure 6-10B). In larger animals, as continued pressure is applied, the scalpel blade is used to cut through the thicker esophagus and to allow passage of the forceps.

The selected tube is premeasured and marked using the landmarks listed in Table 6-3. Esophagostomy tubes are usually measured to the level of the xiphoid or ninth intercostal space. Esophagogastrostomy tubes are measured to the thirteenth rib.

The tip of the tube is grasped by the forceps (Figure 6-10C) and is pulled into the esophagus and out through the mouth (Figure 6-10D). The aboral tip of the tube is turned around and is redirected into the esophagus. The tube is then pushed into the esophagus with the aid of the forceps (Figure 6-10E) By retracting the external end of the tube 2 to 4 cm, the tube is felt to "straighten," and then it passes more easily. The tube is then passed to the premeasured mark. The oropharynx is visually examined to confirm location of the tube in the esophagus. Ideally, the location of the tip should be confirmed with a lateral radiograph in patients with megaesophagus, esophageal stricture, or any other unusual condition involving the esophagus.

An alternative method of confirming appropriate location of the tube in the distal esophagus involves passing the tube into the stomach. Placement is checked by infusing 30 mL or more of air (using a syringe) and ausculting for bubbles over the stomach region. Once bubbles are heard, the tube is retracted to locate the tip in the distal esophagus. If bubbles are not ausculted in the desired location, a chest radiograph should always be taken to confirm appropriate location.

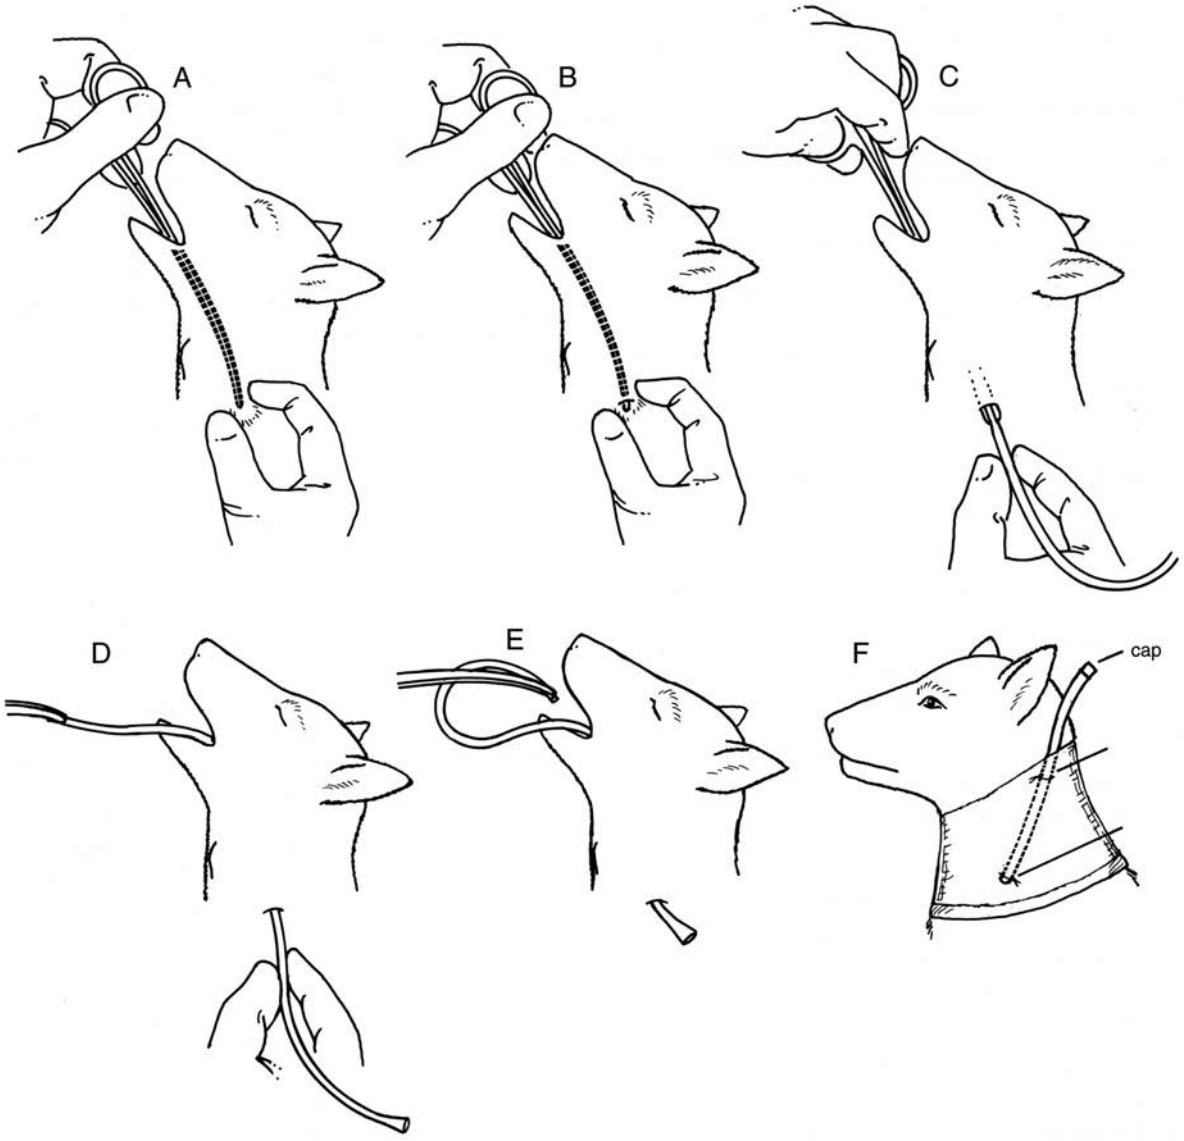

Figure 6-10. Drawing illustrating placement of a large bore esophagostomy tube using curved hemostats. **A**. The hemostats are inserted into the oral cavity, oropharynx, and proximal esophagus; then the tips are pushed laterally. **B.** A skin incision is made, and the tips of the hemostats are pushed through the wall of the esophagus and the subcutaneous tissues. **C.** The flexible feeding tube is grasped with the tips of the hemostats. **D.** The tube is pulled out through the mouth with the hemostats. **E.** The tube's tip is regrasped with the hemostats and is guided down the pharynx and esophagus. **F.** The tube is pulled gently to straighten the curve in the tube, and after it is advanced so the tip is in the midthoracic esophagus, it is anchored with a suture that enters the fascia and periosteum around the wing of the atlas.

The tube is secured to the periosteum of the wing of the atlas or deep fascia using nonabsorbable suture (Figure 6-10F). The suture is secured to the tube by using several wraps of the suture around the tube. The tube should also be secured to the skin where the tube exits. Care should be taken not to tighten the suture to the point that it binds the skin to the tube because this may cause irritation and necrosis.

Percutaneous Esophagostomy Tube Placement

An alternative technique for placement of smaller-bore esophagostomy tubes that are only used for administration of water and other liquids involves percutaneous insertion of a long 10- to 14-gauge venous catheter (Intracath, Becton Dickinson, Sandy, UT) into the esophagus.[4] This "needle" esophagostomy tube can be inserted under sedation without passage of an endotracheal tube. Curved Kelly forceps are passed into the pharynx and proximal esophagus similar to the procedure described for surgical esophagostomy tube placement. The tips of the forceps are then turned outward and are opened slightly so they can be palpated. The needle is inserted through the skin into the target location between the tips of the forceps. Once a popping sensation is felt, indicating puncture of the esophagus, the catheter, with the stylet backed out slightly, can be passed through the needle and down to the premeasured location in the distal third of the esophagus. The catheter is sutured to the cervical fascia and skin in a manner similar to that described for surgical esophagostomy tubes. Sterile saline is then injected through the catheter to ensure good fluid flow. If one has any question about the location of the catheter, a lateral radiograph should be taken.

Table 6-3. Premeasured Landmarks Where Distal End of Tube Should Reach

Type of Tube	Landmark
Esophagoesophagostomy for decompression	Slightly caudal to point of maximum intensity of heart tones (ninth ICS)
Esophagoesophagostomy for feeding	Point of maximum intensity of heart tones (6th ICS)
Esophagogastrostomy for decompression	Thirteenth rib corresponding to midgastric region
Esophagogastrostomy for feeding	Thirteenth rib corresponding to midgastric region
Esophagoenterostomy for feeding	Wing of ilium (or whatever is necessary for surgeon manipulating the tube)

ICS, intercostal space.

Bandaging

A 4x4 gauze dressing containing chlorhexidine, povidone–iodine, or triple antibiotic ointment is placed over the tube's exit site in the skin, and a light circumferential wrap is placed. The end of the tube should be capped to prevent spontaneous air or fluid movement through the tube. Commercial feeding tubes are supplied with caps. For most noncommercial tubes, the cap to a hypodermic needle makes a tight fit and easily can be removed.

Care of the Tube

A "trap door" is made in the bandage to allow inspection, cleaning, and 4x4 gauze dressing changes (Figure 6-11). The ostomy site should be inspected on a daily basis for the first 5 days after insertion, then every other day for 10 days, then every 3 days thereafter. The ostomy site should be cleaned of exudate with a dilute bactericidal solution suitable for using on wounds or a 50:50 mixture of 3% hydrogen peroxide and sterile saline.

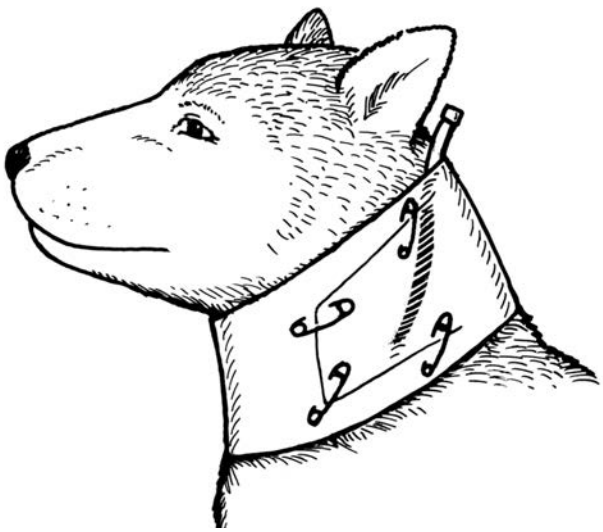

Figure 6-11. Drawing illustrating the cervical dressing covering the esophagostomy tube. A trap door over the tube's exit site at the skin is made and is held closed with four safety pins when it is not needed.

Triple antibiotic ointment is then applied, and the 4x4 gauze dressing is replaced.

Procedure for Administration of Fluids and Liquids

Fluids (crystalloids, oral rehydrating solutions, water) and liquid diets can be infused as a constant rate infusion using an administration set and pump similar to that used for intravenous crystalloids. Rates should be set at 1 mL/kg per hour initially. The infusion can be gradually increased by 1 mL/kg per hour until the desired infusion rate is achieved. The infusion rate should not exceed 6 mL/kg per hour.

Fluids, liquid medications, and liquid diets can also be infused slowly using a syringe. The esophagostomy tube should be flushed with water (5 to 60 mL, depending on the size of the tube and patient) after every bolus feeding or every 6 hours in patients fed by constant rate infusions.

Procedure for Administration of Gruel Diets

Gruel diets should be blenderized to ensure that no large particles that may cause an obstruction are infused. If one has any doubt about whether the gruel is liquid enough to pass through the tube, the gruel should be infused through a tube of equivalent diameter first. Boluses should be limited to less than 5 mL/kg initially. Rates can be slowly increased based on patient tolerance. The feeding should be stopped if one sees evidence of salivation, regurgitation, or vomiting or if the animal appears nauseated or uncomfortable. Boluses should not be larger than 25 mL/kg at one time. A bolus should not be given rapidly, and extremely hot or cold materials should not be infused. Immediately after the conclusion of the bolus feeding, the tube should be flushed with water. This helps to prevent the gruel from remaining in the tube where, over time, it may become inspissated and cause an obstruction. A plastic shield or plastic wrap should be used to cover the bandage when infusions are administered to prevent soiling of the dressing.

Procedure for Use for Decompression

Esophagostomy tubes ending in the esophagus can be used to keep the esophagus decompressed in the patient that has poor esophageal motility. Patients with chronic megaesophagus, persistent right aortic arch, or acute megaesophagus are at increased risk for pulmonary aspiration and may benefit from esophageal decompression.[2] Decompression is performed by aspirating the tube periodically until all the retained air, fluid, and other material is removed. Esophagostomy tubes ending in the esophagus or stomach can also be used to prevent the recurrence of gastric dilatation in patients recovering from surgery to correct gastric dilatation–volvulus. Studies in human patients have shown that, by preventing passage of air into the stomach, patients return to full oral feeding much more rapidly.[5] This finding is assumed, but not proved, to be true in dogs and cats. The tube can be hand suctioned as frequently as needed or connected to a continuous suction device (GOMCO, Allied Healthcare, Buffalo, NY). If viscous or tenacious fluids are suctioned, small volumes

of saline or water should be infused into the tube to prevent tube obstruction. An esophagogastric tube can be used for gastric decompression. If gastric secretions are tenacious, saline can be infused initially to break up the secretions before aspiration.

Removal of the Tube

As opposed to gastrostomy tubes, which must remain in place at least several days before removal to allow for a good seal to form between the stomach and the abdominal wall, esophagostomy tubes can be safely removed the same day they are placed. The dressing and the sutures are removed while the tube is held in place. The tube is then occluded and pulled out. The ostomy site should be cleaned, bactericidal ointment should be applied, and a light bandage should be placed around the patient's neck. The bandage should be removed in 24 hours and the wound inspected. If the ostomy site has not sealed yet, the bandage should be replaced. In patients requiring a new bandage, changes are done every 1 to 2 days until the ostomy site has sealed. This generally takes only a few days.

Long Term Feeding

On occasion, animals require the use of an esophagostomy feeding tube for weeks or months. A fistula usually develops after a few weeks. If the feeding tube needs to be replaced, it is generally a simple procedure because the old tube is removed and a new one is directly fed into the fistula. This usually only requires a local anesthetic block for suture placement. Once these tubes are no longer needed, they are removed as described previously. The fistula closes quickly (within a maximum of a few days), but it may take a week or more to completely heal.

Complications

Most complications relate to skin irritation and inflammation. These problems usually can be prevented by ensuring that the skin sutures are not placed too tightly and that the skin is not pinched or folded during suture placement. If the tube is not secured to the periosteum or deep fascia, the tube will retract and move as the animal moves around, leading to possible inadvertent tube removal and significant skin irritation. If mild dermatitis is present, it will usually resolve with time and regular wound cleaning. On occasion, the dermatitis may not resolve until the tube is removed.

By pushing the forceps out in a lateral direction, the esophagus is approximated to the skin. If this maneuver is not performed adequately, the surgeon risks lacerating the external jugular vein as well as creating additional tissue trauma. This complication is rare when proper technique is used. Bleeding from a lacerated jugular vein has occurred in one known patient; this bleeding was controlled easily and definitively using direct pressure.

In extremely debilitated animals, care must be taken to adhere closely to the technique described. Serious complications can result, with dissection of the tube alongside the esophagus, if the tube is not brought out into the patient's mouth after grasping of the tip of the tube with the forceps. Because the surrounding soft tissues are more easily penetrated, the tube can then course alongside the esophagus instead of in the esophageal lumen. Because the clinician may not be aware of this situation, the tube must be brought out into the patient's mouth before being passed back into the esophagus.

Comments

The use of esophagostomy tubes for both feeding and decompression is both a practical and a life saving procedure. More than 500 of these tubes are estimated to have been used to feed dogs and cats since 1988, with beneficial results. The technique has also been used in other mammalian species including the rat, ferret, and monkey. Esophagostomy tubes can also be used effectively in the nutritional support of birds. When comparing the technique with percutaneous gastrostomy tube placement, the use of esophagostomy tubes is less costly, requires no special equipment or special tubes, takes less operative and anesthetic time, is easier to perform, and is associated with fewer complications. No threat of peritonitis exists, and the tube can be removed safely at any time.

Use of Jejunostomy and Enterostomy Tubes

Chad M. Devitt and Howard B. Seim III

Metabolic support has become an integral part of surgical critical care in veterinary medicine.[1] Jejunostomy or enterostomy tubes are methods of nutritional supplementation in patients after abdominal surgery. Small animal patients undergoing abdominal surgical procedures are often compromised and are likely in need of nutritional support.

Nutritional support is indicated in patients that are unable to meet nutritional demands by oral consumption of food. Malnutrition can be defined by one or more of the following criteria: anorexia for longer than 5 days, weight loss of more than 10% body weight, increased nutrient loss (i.e., vomiting, diarrhea, protein-losing nephropathy), low albumin, and increased nutrient demands (i.e., surgical stress, sepsis, cancer, chronic infections).

A basic premise "if the gut works, use it" may seem an oversimplification of the benefits of providing nutritional support by physiologic routes (i.e., the gastrointestinal tract versus parenteral administration). In general, the more orad nutrients are placed in the gastrointestinal tract, the better patients are able to assimilate complex diets into essential nutrients. Conversely, bypassing a functional segment of the gastrointestinal tract (i.e., stomach) results in necessary alteration of the dietary composition to accommodate for the loss of the portion of gastrointestinal tract.

General Considerations

Whenever a surgeon enters the abdominal cavity, one question should be answered: Could this patient benefit from a feeding tube? Surgically placed feeding tubes carry little additional operative risk, are economical, and are simple to place and manage; therefore, they pose little risk to the patient while providing a large potential benefit. Special equipment is not required for placement of enteral feeding tubes. The tubes used are 3.5- to 5 French infant feeding tubes at least 36 inches in length. If intestinal surgery is performed, the catheter is placed aboral to the site of surgery. Appropriate diets include commercially available polymeric and monomeric diets. The preferred mode of administration is by slow, continuous rate infusion; however, small frequent boluses can suffice.

Indications

Placement of an enterostomy feeding tube may be indicated in any patient undergoing an abdominal operation. The major criteria are a functional small intestine and the need for nutritional support.[2,3] Choosing the appropriate method and determining the need for nutritional support are based on applying the least invasive technique that carries the greatest likelihood of success with the least amount of morbidity.

Feeding through an enterostomy tube has induced pancreatic secretion and therefore was previously contraindicated in patients with pancreatitis.[4,5] Acute pancreatitis induces a hypermetabolic state with increased caloric and nitrogen demands and at the same time renders the gastrointestinal tract unable to meet these increased needs.[4,5] Because the exocrine function of the pancreas is stimulated by the vagus nerve and by release of gastrointestinal hormones in response to food, one can reasonably expect that if the diet is administered into the jejunum, thereby bypassing the cephalic, gastric, and duodenal source of pancreatic stimulation, no significant increase will occur in the exocrine activity of the pancreas.[6] Patients with pancreatitis experience modulation of bacterial flora within the intestinal tract and increased bacterial translocation, and they suffer from a negative energy balance. Early alimentation through an enterostomy tube in human patients with pancreatitis results in improved immune status and fewer complications.[4,6,7] A jejunostomy tube may allow aggressive nutritional support at an earlier time in the postoperative period. Although these issues are controversial, enteral nutrition is considered an integral part of aggressive treatment of acute pancreatitis in human patients.[4,6,7]

Contraindications

The major contraindication to the use of a jejunostomy tube is any disorder causing a nonfunctional gastrointestinal tract (i.e., ileus or neoplastic obstruction of the intestine).[2,3]

Operative Technique

From a midline laparotomy incision, a segment of proximal jejunum that is easily approximated to the ventrolateral body wall is isolated. The direction of ingesta flow (orad to aborad) is determined by tracing the bowel segment from a known anatomic landmark (i.e., stomach or duodenum). A 2- to 3 cm longitudinal seromuscular incision is made in the antimesenteric border of the isolated segment of jejunum. At the aboral end of the seromuscular incision, a stab incision is made through the submucosa and mucosa into the lumen of the jejunum (Figure 6-12A). A 5 French Argyle feeding tube (Sherwood Medical Products, St. Louis, MO) is directed through the stab incision aborally into the lumen of the jejunum. Approximately 20 cm of feeding tube is threaded aborally into the small intestine (Figure 6-12B). The seromuscular incision is closed with 3-0 or 4-0 monofilament synthetic absorbable suture in an interrupted Cushing pattern (Figure 6-12C). The surgeon should close this incision in such a manner that the feeding tube is buried in the submucosa of the incision, effectively creating a submucosal tunnel (Figure 6-12, *inset*). The remaining catheter is exteriorized through a small stab incision in the ventrolateral body wall. Care is taken to select a site that will not result in excessive tension or radial directional changes of the bowel. The enterostomy site is sutured to the peritoneal surface of the adjacent body wall (Figure 6-13). Care is taken to create a watertight jejunopexy on all sides of the enterostomy. The catheter is secured to the skin of the adjacent body wall with a Chinese finger trap friction suture. Abdominal wall closure is routine. A protective bandage is placed on the patient after the procedure, and an Elizabethan collar is used to prevent premature removal of the jejunostomy tube.

Diet Selection, Dose, and Administration

The ideal enteral diet formulation is isotonic, has a caloric density of 1 kcal/mL, a protein content of 4.0 g/100 kcal (16% of total calories), and approximately 30% of calories as fat. Commercially available diets designed for humans are the best diets for small animal patients. Liquid enteral diets can be categorized as polymeric diets or monomeric diets. Polymeric diets contain large molecular weight proteins, carbohydrates, and fats. They require normal intestinal digestion. Most are relatively isotonic, contain about 1 kcal/mL, and are readily available. Monomeric diets are composed of crystalline amino acids as the protein source, glucose and oligosaccharides as the carbohydrate source, and safflower oil as the essential fatty acid source. They are hyperosmolar and expensive. A summary of polymeric and monomeric diets is included in Table 6-4.

For patients with impaired digestive or absorptive function (pancreatitis, enteritis, hepatic disease) or suspected food allergy, a commercial polymeric, enteral liquid diet may be indicated. Patients should be closely monitored for formula intolerance. Jevity (Ross Laboratories, Columbus, OH) is the initial

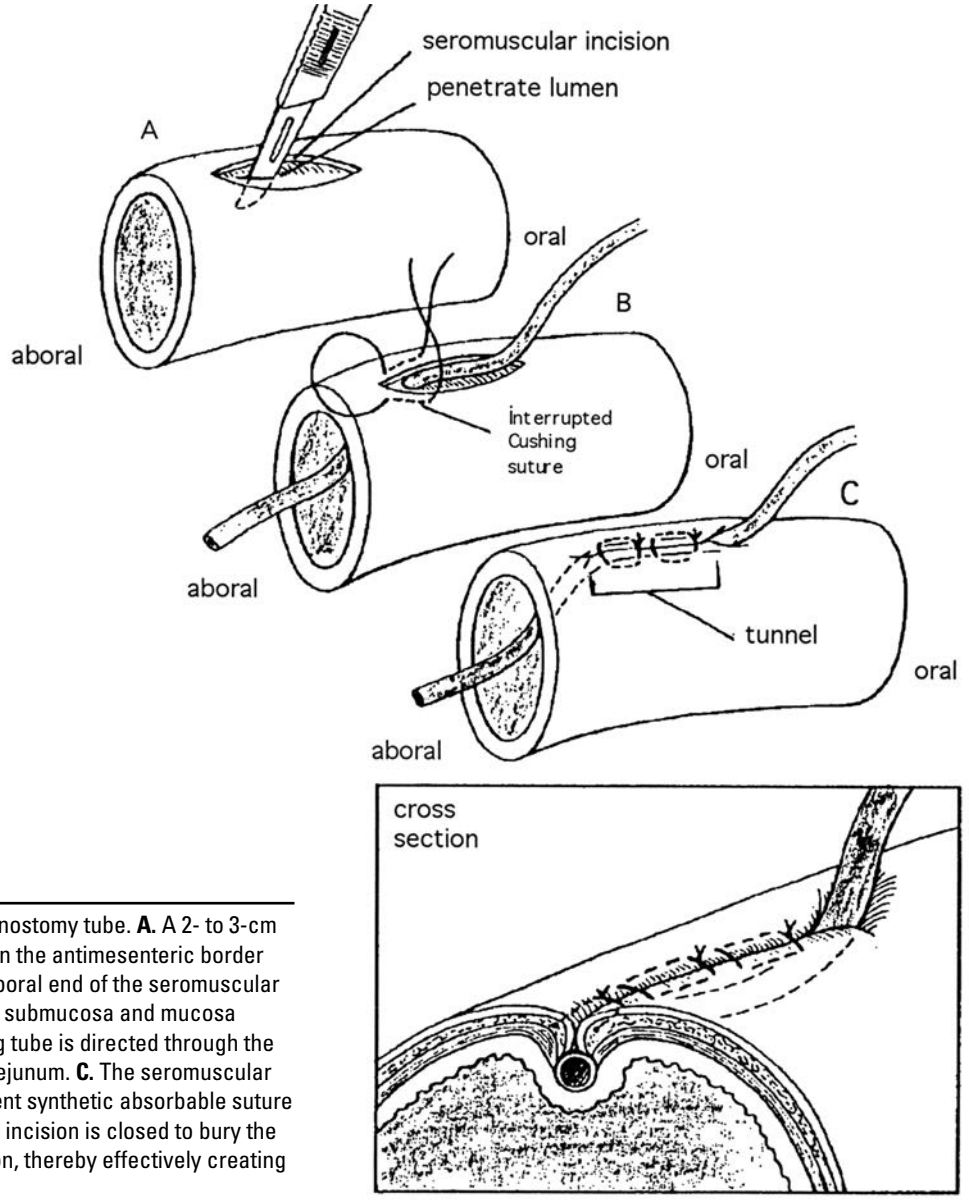

Figure 6-12. Steps in the placement of a jejunostomy tube. **A.** A 2- to 3-cm longitudinal seromuscular incision is made in the antimesenteric border of the isolated segment of jejunum. At the aboral end of the seromuscular incision, a stab incision is made through the submucosa and mucosa into the lumen of the jejunum. **B.** The feeding tube is directed through the stab incision aborally into the lumen of the jejunum. **C.** The seromuscular incision is closed with 3-0 or 4-0 monofilament synthetic absorbable suture in an interrupted Cushing pattern. **Inset.** The incision is closed to bury the feeding tube in the submucosa of the incision, thereby effectively creating a submucosal tunnel.

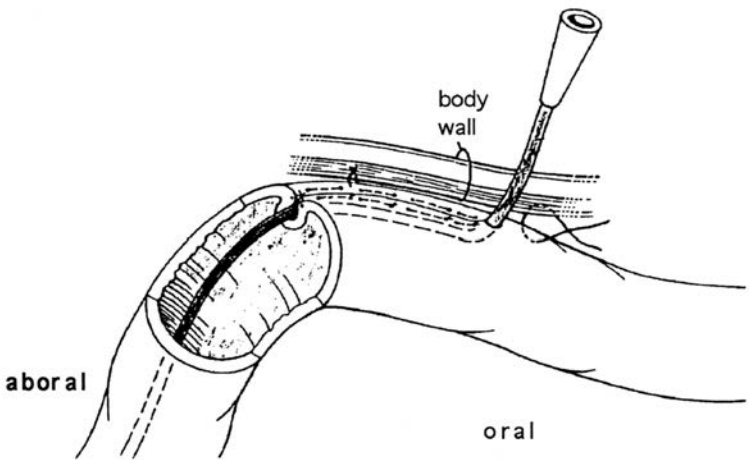

Figure 6-13. The remaining catheter is exteriorized through a small stab incision in the ventrolateral body wall. Care is taken to select a site that will not result in excessive tension or radial directional changes of the bowel. The enterostomy site is sutured to the peritoneal surface of the adjacent body wall. The catheter is secured to the skin of the adjacent body wall with a Chinese finger trap friction suture. Abdominal wall closure is routine. A protective bandage is placed on the patient after the surgical procedure, and an Elizabethan collar is used to prevent premature removal of the jejunostomy tube.

Table 6-4. Commercially Available Polymeric and Monomeric Diets and Their Composition

Diet	Calorie content (kcal/mL)	Protein (g/100 kcal)	Protein (g/mL)	Fat g/100 kcal	Osmolality (mOsm/kg)
Polymeric					
Jevity	1.06	4.20	0.045	3.48	310
Osmolite HN	1.06	4.44	0.047	3.68	310
Impact	1.00	5.50	0.055	2.80	375
Clincare feline	0.92	7.0	0.064	4.60	368
Clincare canine	0.99	5.0	0.050	6.10	340
Monomeric					
Vivonex HN	1.00	4.60	0.042	0.90	810
Vital HN	1.00	4.17	.046	1.08	460

formula of choice, owing to the potential benefits of its fiber content. If the patient becomes intolerant to Jevity, Osmolite HN (Ross Laboratories) should be used. The protein sources of many human products may not provide adequate arginine and sulfur-containing amino acids for cats, and additional protein supplementation is required for long term use.

Monomeric diets are indicated for patients with exocrine pancreatic insufficiency, short bowel syndrome, or inflammatory bowel disease or when polymeric diets are not tolerated. Monomeric diets promote maximal nutrient absorption and minimal digestive and absorptive work. In addition, monomeric diets are less stimulatory for exocrine pancreatic secretion and may have a role in nutritional support of pancreatitis patients.[8] To match the caloric density of polymeric formulas, their osmolality must be two to three times higher, a feature that can create disorders of gut motility or fluid balance. Their cost is about seven times more per calorie compared with polymeric formulas. In most cases, a polymeric diet may be tried first, owing to the decreased cost, ease of preparation, and physiologic benefits to enterocyte function.

To determine the dosage of diet to feed, one must first calculate the basal energy requirement (BER, resting energy requirement) based on body weight. The BER is calculated from the following formulas for dogs weighing less than 2 kg:

$$BER\ (kcal/day) = 70(wt_{kg}0.75)$$

The following formula is used for dogs weighing more than 2 kg:

$$BER\ (kcal/day) = 30(wt_{kg}) + 70$$

After determination of the BER, additional factors can be multiplied depending on the condition of the animal:

$$ER\ (kcal/day) = BER\ X\ 1.25\ to\ 1.5$$

Protein supplementation should be considered in patients with significant negative nitrogen balance. Commercially available polymeric and monomeric enteral diets are designed for human patients and have significantly lower protein levels. ProMod (Ross Laboratories) is a readily available protein supplement and contains approximately 75% high quality protein (5 g/6.6 g scoop). The guideline for dietary protein requirements in dogs is 5 to 7.5 g/100 kcal, the guideline for cats is 6 to 9 g/100 kcal. Patients with renal or hepatic insufficiency should be reduced to less than 3 g/100 kcal in dogs and less than 4 g/100 kcal in cats.

Feeding can begin immediately in patients with good peristalsis noted at surgery, a secure jejunopexy, and an adequate submucosal tunnel of the feeding tube. However, if uncertainty exists, waiting 18 to 24 hours after placement allows a fibrin seal to form at the jejunostomy site and gut motility to normalize. The calculated volume of diet is gradually administered over 4 days (Table 6-5). These are only guidelines, however, and each patient requires a feeding regimen tailored to fit individual needs.

Table 6-5. Recommended Enterostomy Feeding Schedule

Day	Fraction of Calculated Volume*	Dosing Interval
> 1	1/4	qid
2	1/2	qid
3	3/4	qid
4	full dose	qid

*** Calculated dose is diluted to the full volume with tap water**

Complications

Complications of jejunostomy tubes include leakage of intestinal contents or diet and are rare; however, they can be devastating.[2,3] Therefore, critical placement and monitoring of the tubes in the early postoperative period are imperative. Peritonitis can result from leakage of intestinal contents from the jejunostomy site or from tube displacement into the peritoneal cavity. Clinical signs of peritonitis include vomiting, tachycardia, pyrexia, and abdominal pain. Patients in which a leak is suspected should be evaluated and treated immediately, because progression of clinical signs can be rapid.

Abdominal discomfort, nausea, vomiting, and diarrhea can occur if the diet is infused too rapidly, if a large dose is given, or if the formula is not tolerated by the patient. Decreasing the amount, rate, or concentration of diet infused may alleviate these problems. If gastrointestinal upset persists, one should consider changing the diet or method of nutritional support.

Metabolic complications can occur and include transient hyperglycemia as a result of the insulin resistance present in many critically ill patients. Occasionally, these patients require additional insulin supplementation. Hypophosphatemia has been reported to develop subsequent to enteral alimentation in severely debilitated cats.[9] Complications associated with hypophosphatemia include hemolytic anemia and neurologic signs. Investigators have hypothesized that cats in a state of chronic malnutrition have phosphorus depletion despite normal serum phosphorus levels. The institution of enteral alimentation stimulates insulin secretion and cellular uptake of phosphorus and glucose for glycolysis. Phosphorylation of adenosine diphosphate to adenosine triphosphate results in further phosphorus depletion and severe hypophosphatemia. This condition is referred to as the refeeding phenomenon in humans and was first described in World War II victims. One should begin feeding cautiously in debilitated, hypophosphatemic patients.

Chapter 7

Minimally Invasive Surgery

Endosurgery

James E. Bailey and Lynetta J. Freeman

Minimally invasive surgery (MIS) includes surgical techniques that are designed to minimize the invasiveness of the anatomic approach while maintaining or improving surgical precision and efficiency. Endoscopic surgery (endosurgery) involves performing a minimally invasive surgical procedure with visualization provided by an endoscope. Laparoscopic and thoracoscopic surgery include endoscopic approaches to the abdominal and thoracic cavities, respectively. The purpose of this chapter is to introduce the fundamentals of endosurgery to surgeons untrained in these techniques and to encourage the adept surgeon to do more.

Advantages and Disadvantages

Every veterinary surgeon is charged to restore biologic form and function. Of equal importance is the veterinary surgeon's management of pain associated with the procedure. Advantages of the endosurgical techniques include reduced incision size, decreased closure times, minimal scar formation, and improved visualization of the surgical site. Evidence of a more rapid return to work and better cosmetic appearance in human patients does not necessarily apply to veterinary patients although attempts to compare postoperative activity levels of animals undergoing minimally invasive surgery have demonstrated that dogs undergoing laparoscopic ovariectomy with minimally invasive techniques recover more quickly than those undergoing open surgery.[1] The improved visualization provided by MIS is dramatic and is an invaluable teaching tool. Although moderate cost savings have been demonstrated when endosurgery is chosen in human medicine, the same issues do not apply to veterinary medicine. In fact, the initial investment for equipment purchase is considerable and the extra supplies needed for each case add to the cost of each procedure. These disadvantages, along with the greater learning curve, with its associated complications, often deter veterinarians from attempting MIS procedures. So why should veterinary surgeons consider endosurgical methods as an alternative, let alone a principal choice? The veterinary surgeon's innate hunger for precision and technical skill may be enough to answer this question. Minimally invasive surgery is a state of mind–a creed. Furthermore, as the pioneer endosurgeon Nadeau pointed out in 1925, "How often is not the surgeon or the diagnostician confronted with a case in which the difficulties of reaching a decision urge the desire to get a glimpse of the body interior!"[2] Still more important is the issue of pain management. The surgical entry wound with endosurgery is considerably smaller than with traditional surgical approaches. A surgical entry wound often causes greater associated morbidity and pain than the internal operation itself. The simple reduction in entry wound size of endosurgery has led to reduced postoperative pain, reduced requirements for narcotic analgesics, fewer

respiratory difficulties, reduced adhesion formation, earlier ambulation and return to feeding, and rapid return to self-sufficiency. The veterinary surgeon should investigate all means of pain management for their patients.

Indications and Contraindications

If the surgeon is proficient in performing minimally invasive surgery, endosurgery is simply an alternative approach to a surgical problem. The indication for a specific surgical procedure is no different from an open approach, except that with MIS there may be less postoperative pain, faster recovery time, and decreased wound infection rates and adhesion formation. The reduction in postoperative morbidity and enhanced visualization obtained with endosurgery may be relatively greater for animals with a very thick body wall. The primary contraindication for endosurgery is the anticipated failure to provide an adequate optical cavity. Significant adhesions, thoracic or abdominal effusion, or very large space-occupying masses are relative contraindications for an endoscopic approach. The presence of a diaphragmatic hernia is another relative contraindication. If a defect is present in the diaphragm, pneumothorax or pneumomediastinum may develop when abdominal insufflation is used to establish an optical cavity.

Safety and Efficacy

The veterinary surgeon should have a thorough understanding of each specific surgical therapeutic technique, including associated complications and contraindications. Those same complications and contraindications also apply to the endosurgical approach. Because the number of possible endosurgical procedures is almost endless, no purpose exists in listing all associated complications here. However, a few complications are specific to endosurgical approaches. Although the incidence of these complications is extremely low, some may be lethal and understanding such complications is mandatory. Client consent should be obtained for procedure conversion and the animal should always be surgically prepared for conversion to an open technique.

The anesthesiologist or anesthetist should be prepared for the unique aspect of anesthesia in the endosurgical patient. Several complications are associated with patient positioning and the use of insufflation gases in laparoscopy. Trendelenburg positioning (head-down tilt) and pneumoperitoneum (abdominal gas insufflation) increases the risks of gastrointestinal reflux and acid aspiration. Proper fasting, endotracheal intubation with a cuffed tube, and prompt attention to reflux are necessary. Abdominal distension produced by gas insufflation used in laparoscopy can trigger vasovagal reflexes, decrease venous return and cardiac output leading to hypotension. With compression of the diaphragm, there can be ventilation-perfusion mismatch and decreased vital capacity, functional residual capacity, and compliance. Positioning (head-up or head-down) contributes to this cardiopulmonary insult. Ventilatory support is mandatory in most cases. Thoracoscopic techniques provide additional challenges to the anesthesiologist in providing proper anesthesia and ventilation while establishing a working space within the thorax. In most cases, the space is established by decreasing the tidal volume of both lungs or by ventilating only one lung without insufflation of the thorax. An intimate knowledge of one-lung ventilation techniques is necessary for advanced thoracoscopic techniques. Anesthetic considerations for endosurgery are reviewed in the literature.[3]

Troubleshooting

Equipment failure that cannot be resolved during MIS will dictate conversion of the procedure to an open approach. Since veterinarians are generally directly responsible for hospital equipment and maintenance, a review of common equipment disorders is presented. An interruption or incompatibility of any one of these components will cause procedural delay. Hospital personnel need to be trained to set up, trouble-shoot, and solve issues efficiently. If inadequate light is encountered, the surgeon should ensure that the system has been white balanced prior to use, that the light source is taken off stand-by, and that the light guide cables are of sufficient diameter and compatible with the light source. A 5 mm scope will deliver less light than a 10 mm scope. In general, a smaller laparoscope needs to be positioned closer to a structure for the image to appear as bright as when using a larger scope from further away. When the camera image fails to appear on the monitor, it is usually caused by incorrect output to input connections. The output of the camera should be connected to the input of the monitor. If a video recorder is used, it is typically inserted between the output of the camera and the input of the monitor to ensure that the highest quality image is recorded.

Gas insufflation is used during endosurgery to create a viewing cavity, or to lift the body wall, thereby producing a protective distance between the viscera and instruments being inserted into the cavity. Automatic insufflators are used to regulate the body cavity gas pressure to a pre-set value, usually 8 to 15 mm Hg. When pressures exceed 20 to 25 mm Hg, there can be significant cardiopulmonary embarrassment. Carbon dioxide is the most commonly used gas for insufflation because it is cheap, it is most soluble (perhaps reducing the likelihood of gas embolus), it is rapidly resorbed and eliminated by the lungs, and it does not support combustion when electrocautery is used. However, CO_2 may cause irritation to the body cavity through formation of carbonic acid on visceral surfaces and is absorbed into the blood, possibly leading to hypercarbia, stimulation of the sympathetic nervous system, vasodilation, hypertension, tachycardia and other arrhythmias. Surgeons should try to use the lowest pressure that enables sufficient visualization. If inadequate insufflation of the abdominal cavity occurs, the gas supply to the insufflator, the pressure and flow settings on the insufflator, and tubing attachment at the trocar and at the insufflator should be checked. Further, all trocars should be examined for open stopcocks or inadequate seals.

The surgeon must be attentive to the introduction and position of their surgical instruments within body cavities at all times. Each instrument should be monitored by camera as it is introduced into the body cavity and followed to the target organ, keeping the tip of the instrument centered on the monitor. The surgeon should never coagulate or cut unless clear visualization of the target tissue is obtained. Most injuries to viscera (spleen, stomach, bowel, ureters, and lung) are due to blind placement of insuf-

flation needles and trocars. Splenic injuries caused by Veress needle placement are usually self-limiting. Large vessel injury can occur as well, causing severe bleeding, or worse, venous air embolism through entrainment of insufflation gases. Diagnosis and treatment of air embolism requires cooperation between the surgeon and anesthesiologist. Monitoring for a precipitous drop in end-tidal CO_2 can be invaluable in these cases.

Equipment Needed

Light, Optics, Video: The multicomponent surgical video system

The standard video tower has a light source, light guide cable, rigid operating telescope, video camera, one or two video monitors, and often, a video recorder. For laparoscopy, a high-flow insufflator, CO_2 tank, yoke for the gas supply, and tubing are also used. The purpose of the system is to provide live, full color images of the interior of the body, as well as capture and storage of images for review.

General Considerations

Image quality is the foremost consideration. The video system component with the lowest resolution capabilities defines the resolution for the entire system. The final image is affected by a number of variables, including camera design, signal format, video processor, monitor capabilities, and user settings. The controls should be easy to identify and activate, providing easily interpretable feedback. Some degree of automation will further simplify use. Compatibility with existing equipment and hospital sterilization methods is important. Prior experience with the manufacturer is also invaluable.

Light Source

Purpose: Supplies light to surgical site via the endoscope.

Recommendations: Xenon or advance LED lamp with a minimum 500 hour lamp life and backup lamp. Lamp standby mode and bulb-life meter. Auto-illumination.

Explanation: Adequate illumination of the endosurgical field is essential to safely completing the procedure. Light transmitted from the tip of the endoscope must reflect off anatomic structures and be picked up by the lens system of the endoscope. Light emitted into the body cavity reduces in intensity by the square of the distance traveled. Changing focal points changes reflected light intensity. Such changes demand an adjustable or automatic light source output control. Automatic brightness control helps maintain a constant image brightness regardless of the target distance. Usually xenon, or more recently advanced LED light sources, are used over halogen or metal halide bulbs. Although these modern external light sources may operate at very high temperatures, little of this heat ever reaches the patient. However, if a xenon light source is used, burns and fires induced by excessive heat production at the interface between the fiberoptic light cable and the rigid operating endoscope are still quite possible. For this reason, the light source should not be left turned on when the fiberoptic cable is detached from the rigid operating endoscope. Auto-illumination, low-intensity default settings and lamp standby mode can help minimize this risk.

Fiberoptic Light Cable

Purpose: Carries light to surgical endoscope.

Recommendations: Secure connections and connector compatibility with multiple manufacturers (universal clamp). Adequate size, durable and flexible construction.

Explanation: The development of fiberoptics in the 1960s made it possible to present intense light to the endosurgical field without burning the patient. An incoherent bundle of glass fibers, 10 to 25 μm in diameter, connects the light source to the rigid surgical endoscope. Fiberoptic bundles fan around the inner core lens system of the endoscope, carrying light to the surgical field. Due to air-to-glass interface at connecting points and fiber mismatching, only approximately one-quarter of the original light is transmitted, making bright light sources necessary. Secure connections are necessary to prevent cable disconnections and burns. Durable, flexible construction is necessary to limit light fiber fracture and subsequent loss of delivered light.

Surgical Endoscope (Laparoscope)

Purpose: Directs light into surgical site and directs reflected light back to camera head.

Recommendations: Hopkins rod-lens system. Autoclave compatible. Compatible with all common light sources, light cables and video processors.

Explanation: Reflected light, incident with the operating endoscope, is captured by a lens system. The diameter of the standard lens system ranges from 1 to 5.5 mm, with the large lens providing better resolution. Laparoscopes vary in their depth of focus, magnification, color differentiation, brightness and resolution, as well as their angle of vision and field of view. Superior light capture is accomplished with the now commonplace Hopkins glass rod-lens system, and high quality lens systems. Laparoscopes also vary in their sensitivity to reuse and sterilization methods.

Video Camera

Purpose: Generates an electrical signal from reflected light captured

Recommendations: Three-CCD (3-chip) cameras will generally provide superior image quality and color differentiation. Auto-white balance. Camera zoom control. Camera head with integrated, easy to use, imaging controls. Universal optical coupler will attach to a variety of surgical endoscopes.

Explanation: Light captured by the rigid operating endoscope can be viewed directly or with greater ease and resolution using a miniature video camera, also called a charge-coupled device (CCD). The CCD or "chip" is a photosensitive silicone sensor composed of thousands of photoelectric picture elements

(pixels). Quality cameras use from one to three CCD chips. A single chip camera uses color-filter overlays or rotating filter wheels to produce color separation. Three chip cameras use a prism to separate the incoming light into the additive primary colors of red, blue and green (RBG), with each chip dedicated to one color, thus producing superior color reproduction. However, light sensitivity is more important than color separation. A high-quality single-chip camera can outperform some three-chip systems. Still–in general–three chip systems offer better color reproduction and image quality than single chip systems. The camera head can also have controls for light source control, image zoom and peripherals like a video recorder.

Camera resolution is based on the number of pixels available (called the "native resolution") and is generally less than that of the video processor. Resolution is compromised in cameras with less than 400 horizontal rows of pixels. One-chip cameras typically generate signals with a maximum of 400 to 500 lines of horizontal resolution, whereas three-chip cameras can create signals with 700 or more. The camera is often the limiting factor for the overall resolution.

An optical coupler is used to attach the camera to a surgical endoscope. Video endoscopes have the camera situated at the tip of endoscope (so-called chip-on-the-tip configuration), but are less commonly used for laparoscopic surgery at this time.

Video Processor (Camera Control Unit or CCU)

Purpose: Translates the signal from the camera head into video signal and routes the video signal to the video monitor.

Recommendations: Variety of video format outputs (composite, S-video, RBG). Digital output for high definition systems (DVI). Matching outputs to display and camera inputs. Brightness and color controls.

Explanation: The overall resolution is affected by the method of communicating the image. The standard one-wire, composite video signal is simple and familiar. Component video signals (two-wire Y/C or S-video, and three-wire RBG) reproduce more monochrome and color image detail. High definition (HD) systems are becoming standardized at this time. To be considered HD, the system should have a 16:9 picture aspect ratio and either 720 horizontal progressive scan lines (720p), 1080 horizontal interlaced scan lines (1080i) or 1080 horizontal progressive scan lines (1080p) digital output formats. Progressive scan shows fewer artifacts with rapid movement, but interlaced is equally effective in laparoscopy. Since video processors cannot provide greater resolution than offered by the video camera, the CCD pixel arrays will also have to be larger or the resolution will not improve. The video processor will need to be paired with a flat-panel liquid crystal display (LCD) with a similar aspect ratio, horizontal lines and input formats. The monitor resolution should reflect the resolution of the camera or image quality may be lost. In general, the field is rapidly moving towards HD systems at this time.

Video Monitor

Purpose: Displays the live image

Recommendations: HD flat panel LCD with a number of video format inputs (composite, S-video, RBG, and DVI). Consider using more than one LCD for alternate viewing. Horizontal lines of resolution or pixel density, as well as video inputs to match video processor outputs.

Explanation: A flat panel LCD will be necessary for HD video processor output. However, flat panel screens are also light weight and easy to mount even when used with a lower resolution input. Flat panel screens of various types have essentially replaced the traditional cathode ray tube monitor.

The US standard, NTSC (National Television System Committee) format has 525 horizontal scan lines, 4:3 picture aspect ratio and runs 30 fields or frames per second (fps). Many surgical monitors in use today have at least 550 to 700 horizontal lines of resolution, a 13-inch diagonal screen, and are medical grade to limit chassis electrical current leakage. However, the introduction of flat panel fixed-pixel array monitors has changed the game. Resolution of these flat panel monitors is determined simply by the physical number of columns and rows of pixels creating the display. The monitor must be compatible with the method of communicating the image from the camera (composite, S-video, RBG or digital), but then uses a digital video processor with memory array, called a scaling engine, to match the incoming image format. Again, the image resolution will be no better than the input from the camera regardless of the flat panel pixel density. The digital signal can be communicated through a standard Bayonet Neill-Concelman (BNC) connector using serial digital interface (SDI) or high-definition serial digital interface (HD-SDI). However, the industry has moved to digital communication via Digital Visual Interface (DVI). DVI is also compatible with High-Definition Multimedia Interface (HDMI) with no signal loss using DVI-to-HDMI adapter.

Video Image Capture

Purpose: Document and archive procedures, teaching

Recommendations: Large hard-drive with DVD archiving and input/output for additional storage attachment (eg. Universal Serial Bus - USB). Digital capture device for instantaneous and continuous capture. Capture resolution should match image resolution for equivalent replay (with alternative setting available).

Explanation: Picture archiving and communication systems (PACS) are computer-based systems that can store and retrieve images in digital format from several different diagnostic imaging modalities including endoscopic surgery. Digital-image storage does help organize storage of large volumes of images (such as radiographs) and video, however communication with a PACS is likely unnecessary for the average endosurgeon. Temporary storage to a large hard-drive and subsequent download to a DVD for storage will usually suffice, with the understanding that the average DVD lifespan is limited by the quality of the materials and manufacturing methods, as well as the storage and handling.

However, in general, manufacturers performing non-standardized accelerated age testing claim life spans ranging from 30 to 100 years for high quality DVD-R and DVD+R discs and up to 30 years for DVD-RW, DVD+RW and DVD-RAM. Alternatively, additional portable hard-drives may be connected to the primary hard-drive for archive download (if connectivity provided). HD image capture will require larger storage space.

Trends and the Future

Natural orifice "scarless" surgery is being evaluated for surgical access to organs deep inside the body, without external incisions in the abdominal wall. Operating room automation systems designed to control multiple operating-room devices using a single, common interface are available. Three-dimensional endoscopic surgical techniques have developed more slowly with concerns regarding surgeon's perception of depth and scaling. Telepresence including telemedical training and telerobotic endoscopic surgery are well established. Telerobotic systems like the da Vinci robotic surgical system (Intuitive Surgical, Inc., Sunnyvale, CA, USA) are being used in more and more human community hospitals with more and more surgery going "robotic". Small, wireless robots about 3 inches in length have been developed which when inserted into a body cavity can be controlled wirelessly by the physician to perform biopsy, drug delivery, and control of hemorrhage.

Endosurgical Instrumentation

Basic veterinary endosurgical hand-held instrumentation has not changed dramatically since it was introduced in the late 1990s. Endoscopic clip appliers, surgical staplers, and automatic suturing devices were introduced between 1990 and 2000 and are continuing to be refined for use in human surgery. Endoscopic clips have greatly facilitated endosurgical procedures and provide secure hemostasis and sealing of viscus structures. Multiple clip appliers enable rapid and repeated application of clips. These clips are used to occlude blood vessels and other small, hollow structures. They are useful in controlling acute bleeding; however, secure ligation is only accomplished with complete skeletonization of the vessel. Endosurgical stapling devices place six rows of linear staples that provide closure and hemostasis, and incision between the middle rows of staples. Staple leg length varies according to anticipated tissue thickness. Newer staplers have staggered staple heights with the outer rows forming larger staples and the inner rows forming smaller tighter staples. Cartridges are available in 30, 45, and 60 mm lengths.

Although monopolar and bipolar electrocautery have been used extensively in MIS, recent major advances have been made in methods for achieving hemostasis and cutting of tissue. The Harmonic Scalpel uses ultrasonic energy to coagulate and cut tissue, reducing lateral thermal injury and has an advantage because no electrical current passes through the patient's body. The vibrating blade creates cavitation in the tissue which opens up planes of dissection that are not initially apparent. Dissection is facilitated by appropriate tissue tension. Water vapor generated during coagulation must be vented to ensure a clear surgical field. The LIGASURE bipolar sealing device, like the Harmonic Scalpel, can be used for dissection without precise skeletonization of vessels. The tissue to be coagulated and cut is grasped in the jaws of the instrument and current is applied while the tissue impedance is monitored by the instrument. When current flow drops below threshold, an audible alarm sounds to signal complete hemostasis and an internal knife can then be activated to cut the tissue. The LIGASURE is capable of effectively ligating vessels up to 7 mm in diameter. The Ethicon ENSEAL device also uses bipolar energy to simultaneously cut and seal tissue up to 7 mm in diameter. A unique polymer temperature control feature is provided within the jaws of the device to precisely heat tissue to 100 C and limit the lateral thermal spread outside the electrode area. Care should be taken to close the device prior to withdrawal from the trocar to prevent damage to insulation of the wires to the electrodes. The insulation of all monopolar devices should be inspected to ensure that it is intact, as burns may occur where a defect in insulation contacts tissues.

Endoscopic Suturing

The cost of materials for endoscopic suturing is less than for clips, staplers, and energy devices, but manual suturing is more time-consuming. A description of all aspects of laparoscopic suturing is beyond the scope of this chapter and the reader is referred to recent publications[4,5] and the following illustrations of extracorporeal ligation with Roeder knot, ligation with a pre-tied loop ligature, such as ENDOLOOP, and classic intracorporeal instrument knot tying.

Extracorporeal Knot Tying

Equipment

Pretied endoknot or long suture (endosuture) (at least 48 cm)
Knot Pusher
One endoscopic needleholder and one endoscopic grasping forceps
Endoscopic scissors

Technique

This technique is defined as throws created outside of the body under direct vision which are then transferred to the body cavity by a knot pusher. This technique, unlike the pre-tied loop ligature, can be used on skeletonized structures, and does not require a free end. The structure to be ligated is identified and isolated. The free end of a 48 cm suture is grasped with a needle driver and passed into the body cavity through a cannula. The ligature is passed around the structure with assistance of a second grasping forceps entering the body from another port. The ligature is then transferred to the original needle driver and pulled out through the cannula. The remainder of the ligature is fed into the cannula while the surgeon simultaneously pulls the free end of the ligature from the body cavity. The grasping forceps is used to prevent pulling and sawing to the tissue being ligated. The free ends of the ligature are tied in a Roeder knot (Figure 7-1A-F). The knot is then transferred to the body cavity with a knot pusher.

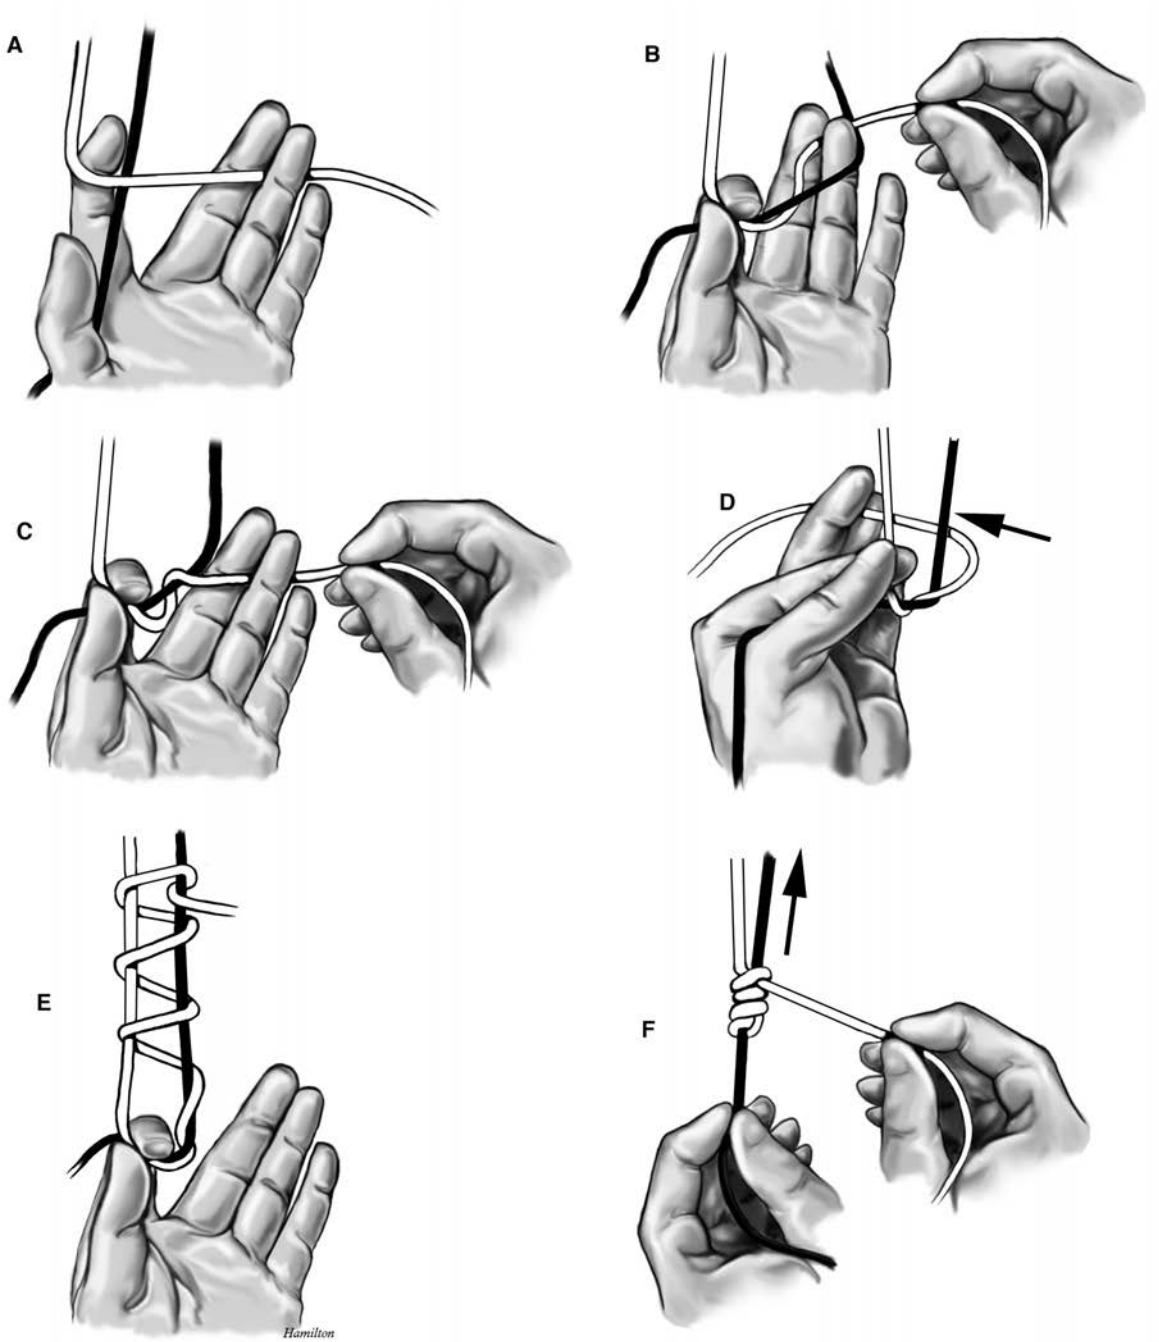

Figure 7-1. Extracorporeal Knot Tying. **A-C.** Produce a simple or surgeon's throw. **D-E.** Wrap the free end three times around both limbs of the loop. Then wrap the free end around the black limb once or twice. **F.** Tighten by pulling on the free end and advancing the knot with a knot pusher.

Pre-tied Loop (ENDOLOOP) Ligatures

Equipment

Pretied loop ligature (ENDOLOOP or SURGITIE)
One endoscopic needleholder and one endoscopic grasping forceps
Endoscopic scissors

Technique

Pretied loop ligatures are commercially available as ENDOLOOP or SURGITIE ligatures and require a free pedicle for proper use. The pre-tied loop ligature is passed through one port and a grasping forceps is passed through a second port. The grasper is passed through the loop to grasp and elevate the structure to be ligated. The knot is placed at the level of the intended ligation, and the loop is slowly closed with a knot pusher. The commercially available products have a nylon cannula with a conical tip that serves as the knot pusher. The cannula is scored near a red tab. After the grasper is positioned through the loop the tab is broken from the cannula at the score point. The tab is held with one hand while the cannula is advanced with the other. (Figures 7-2A-F) Endoscopic scissors are used to cut the suture tail (Figures 7-2G-I).

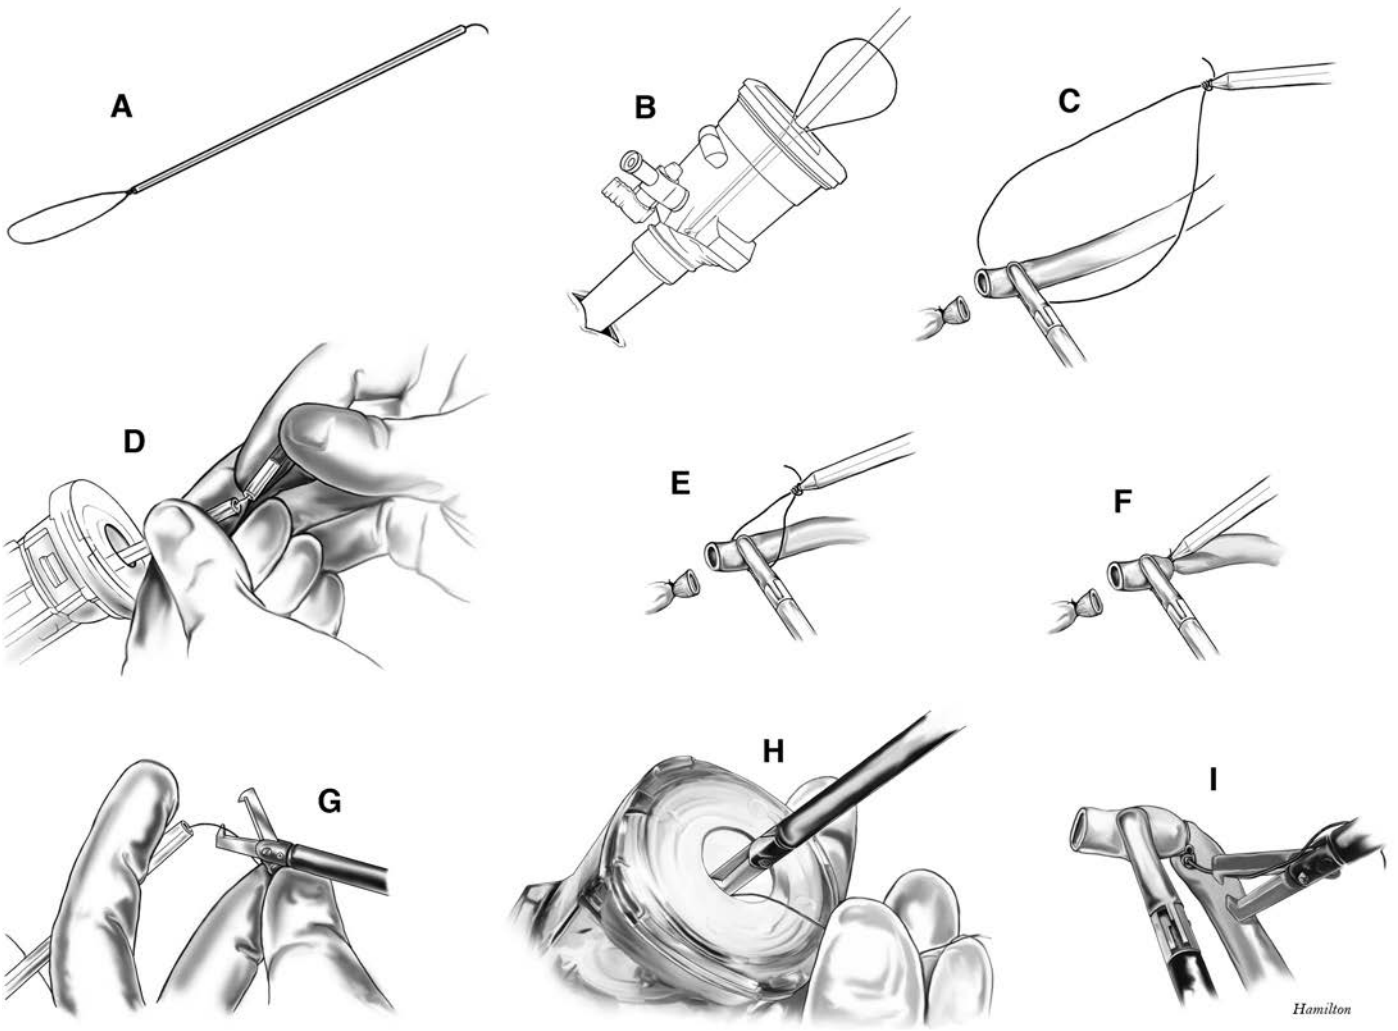

Figure 7-2. A. Pre-tied loop ligature. **B.** The loop folds backwards during insertion through the trocar. Using a trocar with clear housing allows visualization of the loop during insertion to ensure that it is not caught in the flapper valve mechanism of the trocar. **C.** The loop is introduced into the body cavity and a second grasping forceps elevates the desired tissue through the loop. The grasping forceps are passed to an assistant who holds the tissue firmly. **D.** Outside the trocar, the break point of the plastic cannula is identified by the red tab. The red tab is held with one hand while the plastic cannula is advanced with the other. **E.** As the cannula is advanced the knot is pushed distally, causing the loop to become smaller. **F.** The knot is positioned at the desired location and the cannula is firmly advanced while holding the suture taught to tighten the loop. **G.** The suture is cut and the tab is removed. The plastic cannula is removed. **H.** Laparoscopic scissors are introduced beside the suture. This maneuver avoids the need to place a third trocar for introduction of scissors. **I.** With the suture guiding the scissors, the suture is cut.

Intracorporeal Instrument Knot Tying

Equipment

Short ligature (10 to 15 cm) with a curved or half-curved (ski) needle
Two endoscopic needleholders or one needleholder and one grasping forceps
Endoscopic scissors

Technique

Endoscopic knot tying is an advanced technique that requires practice in an endoscopic training box for the surgeon to become proficient before attempting to perform the technqique on a patient. Proper suture placement requires proper trocar-cannula placement. The surgeon places two working cannulas and one cannula for the laparoscope. Ideally, the cannulas will be positioned in baseball diamond configuration with the laparoscope positioned at home plate, pointing towards the monitor. The two working ports are positioned at first and third base, with the incision at second base. The incision should be oriented nearly parallel to the shaft of the active needle holder. One simple intracorporeal suture technique is illustrated in (Figure 7-3A-H).

Intracorporeal Suturing

Equipment

ENDOSTITCH Suturing Device with ENDOSTITCH suture material available in sizes 0 to 4-0 (absorbable, silk, nylon, and polyester)
10 mm trocar

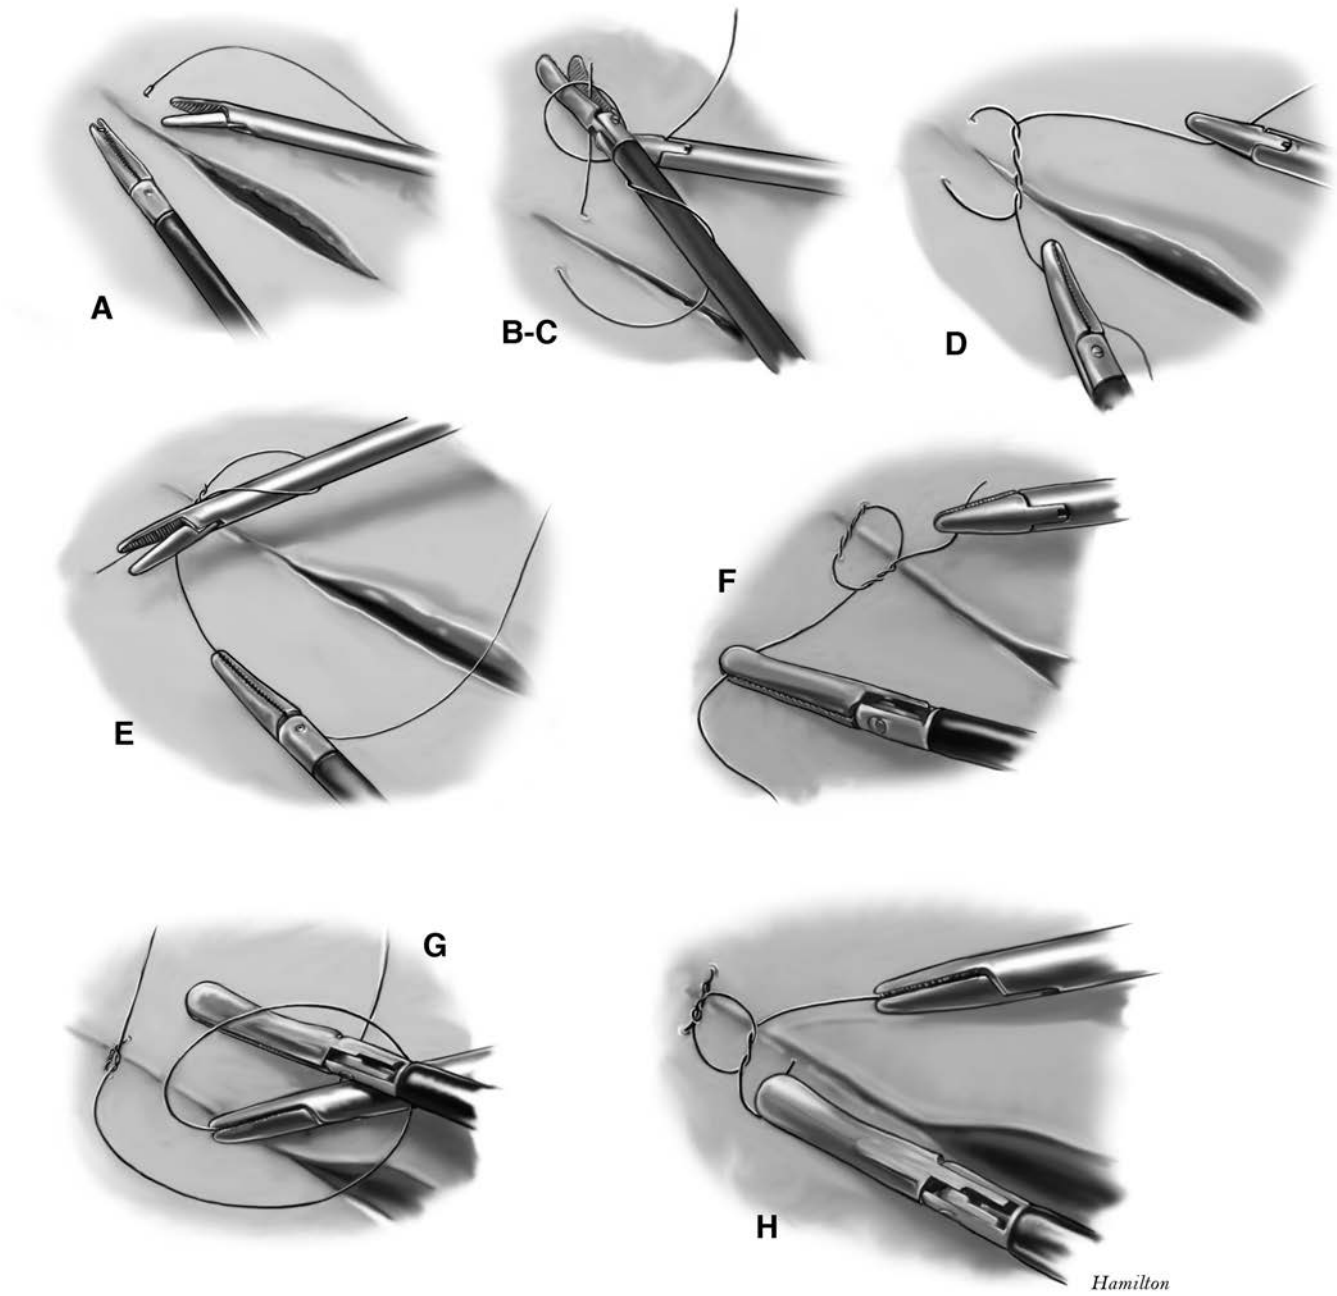

Figure 7-3. Intracorporeal Knot Tying. **A.** For optimal suturing, the incision is oriented at a 30 degree angle to the scope. The needle holder is held in the dominant (right) hand. Grasping forceps are used with the other hand. The needle is driven through tissue as pressure is applied to the tissue with grasping forceps. **B.** The needle tip is grasped and removed. A large C loop is made as the suture attached to the needle is brought to the right side of the incision. The suture is then wrapped about the grasping forceps, once for a simple throw and twice for a surgeon's throw. **C.** The suture tail is grasped with grasping forceps and brought through the loop. **D.** Even tension is applied to both the grasping forceps and the needle holder to complete the first throw of a square knot. **E.** A reverse C loop is then created with the grasping forceps holding the long end of suture. The needle holder is placed ventral to the free end of suture and the grasping forceps is used to wrap a single loop around the needle holder. The free end of suture is grasped and pulled through the loop. **F.** The square knot is tightened by moving the needle holder to the right and applying even tension with the needle holder and grasping forceps. **G.** A large C loop is made with the needle holder and the suture is wrapped around the grasping forceps. The free end of suture is grasped and pulled through the loop. **H.** The throw is tightened with even tension applied to the grasping forceps and needle holders.

Technique

The suture material is swaged to the center of a needle, oriented in a T-fashion. Each end of the needle is loaded into the jaws of the ENDOSTITCH suturing device. The needle can be toggled from one jaw to the other by flipping a switch on the suturing device handle. The needle is loaded on one side, the jaws of the device are closed on tissue, and the switch is flipped to transfer the needle to the other jaw of the instrument. Thus, the needle is held securely and passed through tissue easily, without the difficulty of loading the needle into the needle holder each time. After the tissue is apposed, it is possible to tie a knot by passing the needle around the suture material to create a loop and then passing the needle through the loop. Alternatively, barbed sutures, such as the V-LOC suture (Covidien) or STRATAFIX (Ethicon) can be utilized to avoid the need to tie an intracorporeal knot.

Laparoscopic Endosurgical Procedures

Patient Positioning

Equipment

Tilt table or other means of tilting the animal by elevating the head or feet and rotating the animal side to side

Technique

The animal may be placed in several different positions, depending on the procedure. In general, the laparoscope should be inserted to face the monitor with the target tissue placed between the trocar insertion site and the monitor. Usually, the target tissue will be elevated for optimal visualization. For procedures involving the cranial abdomen or thorax, position the monitor at the head of the table and elevate the head. For procedures involving the caudal abdomen or thorax, position the monitor at the foot of the table and elevate the tail. For ovariectomy procedures, the animal will need to be rotated to the right and to the left to identify the left and right ovaries, respectively.

Access

Equipment

Veress needle or Hasson trocar (blunt trocar with olive plug)

Technique

There are two methods used to create access to the abdominal cavity. A closed approach uses a Veress needle to insufflate CO_2 to create a space for primary trocar insertion. The body wall is grasped and lifted while the Veress needle is passed in the direction predicted to be devoid of viscera. Proper needle placement is confirmed by aspiration and hanging-drop techniques. The body cavity is insufflated with gas, and the needle is removed. The skin incision is made roughly equal to the diameter of the trocar being inserted, and the primary sharp trocar is then blindly placed in a similar fashion to the needle. In the dog, when the Veress needle is inserted at the umbilicus, it is not uncommon to injure the spleen. For this reason, many veterinarians use the open approach to gain entry to the abdominal cavity. The open approach, also known as the Hasson technique, uses a blunt trocar with an olive plug or a screw tipped trocar inserted under direct visualization. The skin incision is made and a midline incision is made through the linea alba. Sutures are placed on each side of the fascia and, after the trocar is inserted, are tied to the olive plug of the trocar (Figure 7-4A-F). Optical trocars, such as the OPTIVIEW, have a central channel for the laparoscope that allows continuous visualization of each tissue layer during insertion. They are used both with and without insufflation of the abdominal cavity. After the primary port is inserted, insufflation of the abdominal cavity with CO_2 is performed to provide a viewing cavity in which to work. Additional ports are placed as needed for each procedure.

Laparoscopic Liver, Intestinal and Pancreatic Biopsy Procedures

Indications

If abdominal exploratory and organ biopsy can be obtained with MIS, this method is preferred over other techniques. Laparoscopic liver biopsy enables the surgeon to obtain more tissue that is needed for heavy metal analysis than what can be obtained with ultrasound directed fine needle aspirates or ultrasound guided core biopsy procedures. Full thickness intestinal biopsy is preferred over obtaining endoscopic biopsy samples for accurate diagnosis of diseases of the intestinal tract. Finally, laparoscopy permits examination of internal organs and visual confirmation of hemostasis without the invasiveness of open surgery.

Equipment

5 mm trocars
5 mm blunt probe
5 mm endoscopic grasping forceps
5 mm endoscopic cup biopsy forceps
Hemostatic agent such as ENDO-AVITENE, SURGICEL, GELFOAM, or collagen sponge
Introducer sleeve and plastic push rod from a pre-tied loop ligature system (SURGITIE)

Technique

Liver Biopsy. When laparoscopic liver biopsy is the only technique being performed, positioning the animal in left lateral recumbency allows more of the liver surface to be exposed through the right lateral mid-abdominal approach. In addition, this position improves visualization because the falciform ligament moves out of the field. However, performing laparoscopic exploration is more difficult, so animals are usually positioned in dorsal recumbency if both techniques are to be performed.

If ascites is present, the open technique for primary port placement should be used to allow suctioning of the ascitic fluid before port placement. Pneumoperitoneum is created, the laparoscope is inserted, and the abdomen is inspected. The liver is inspected and any lesions are identified. A second 5 mm port is then placed in the right or left cranial abdominal quadrant, corresponding to the site of the lesion. A blunt probe is used to palpate and elevate each of the liver lobes prior to biopsy. Any remaining ascitic fluid is aspirated.

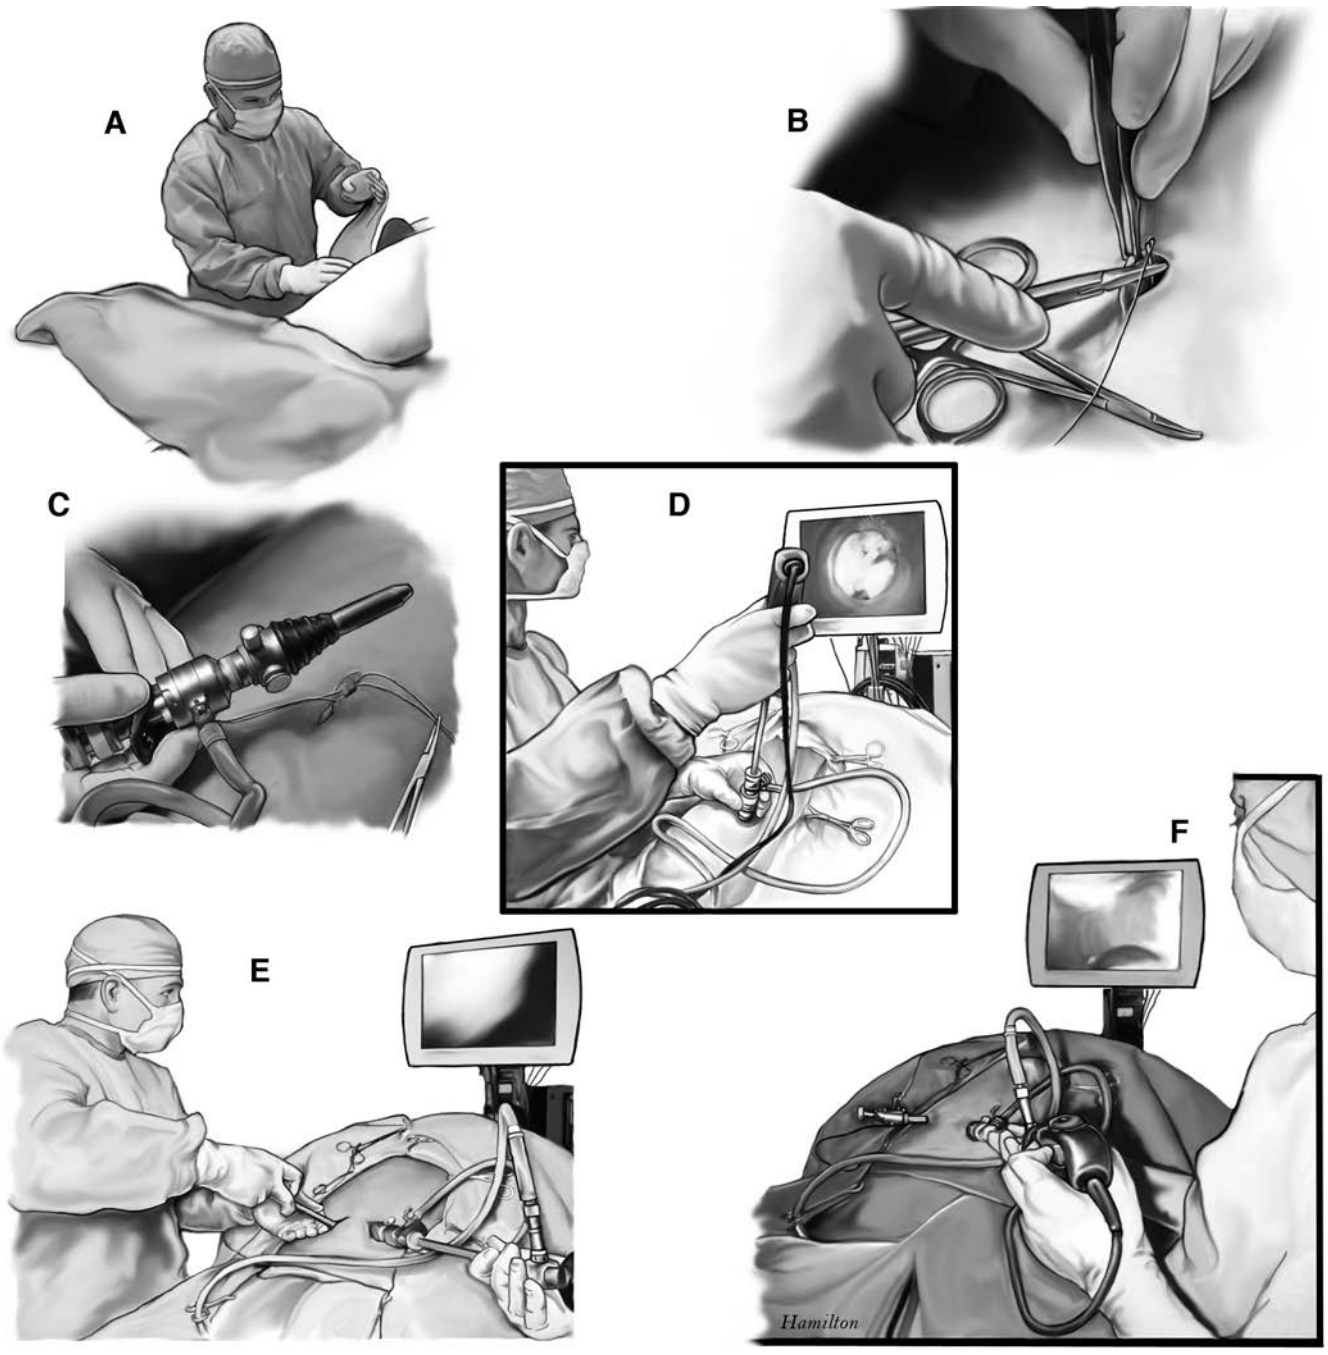

Figure 7-4. Laparoscopic Access. **A.** The abdomen is aseptically prepared for abdominal surgery with wide draping to facilitate ovarian suspension when laparoscopic ovariectomy is being performed. **B.** A small incision is made on midline near the umbilicus. The incision is extended into the abdominal cavity through the peritoneum. Two stay sutures are placed through the abdominal fascia. **C.** A reusable Hasson trocar has an olive plug that features a blunt obturator and tying posts to secure the sutures placed in the abdominal fascia. **D.** After the primary port is placed, the abdomen is insufflated with CO_2 to 12 mm Hg and the laparoscope is introduced. **E.** The working port is placed with direct visualization of its insertion provided by the laparoscope. **F.** A second port is placed in the cranial right abdominal quadrant to facilitate procedures in the cranial abdomen such as liver biopsy or laparoscopic-assisted gastropexy.

Liver biopsy is usually associated with minimal bleeding; however, placing small sections of Gelfoam into the abdominal cavity near the anticipated biopsy site assists in controlling bleeding if it does occur.[6] The Gelfoam sections are back-loaded into the introducer sleeve of the SURGITIE (pre-tied loop ligature) system, introduced through the trocar, and pushed into the abdominal cavity with the plastic rod. If generalized liver disease is present, marginal biopsy samples are obtained from the edge of the liver lobe (Figure 7-5A-C). The 5 mm biopsy forceps are passed through the port, opened, and positioned on tissue. Pressure is held for approximately 30 seconds and then the forceps are rocked or twisted until the tissue is detached. The Gelfoam samples are then nudged into the defect with the forceps to assist in hemostasis. A minimum of five samples are taken: one or two for histology, one for culture, and three to five for heavy metal analysis. If a discrete lesion is identified, the biopsy cup forceps can be used to obtain a sample as just described, or a needle aspirate or core biopsy can be performed

under direct visualization. For these biopsies, the needle is inserted through the abdominal wall, directly above and perpendicular to the lesion. Under direct observation, the needle is inserted into the core of the lesion and the syringe is aspirated or the barrel of a core biopsy needle is advanced to obtain the specimen. Suspending ventilation during this step helps avoid tearing the hepatic capsule. Aspirates of the gallbladder can be obtained using a spinal needle. To minimize bile leakage, the needle is introduced through hepatic parenchyma before entering the gallbladder.

Laparoscopic Intestinal and Pancreatic Biopsy. To reduce operative time and the potential for abdominal spillage, intestinal biopsy procedures begin with laparoscopic exploration for assessment of the liver and biliary tract and pancreatic biopsy. The procedure is then converted to a mini-laparotomy for obtaining multiple biopsy samples of the intestinal tract.

The initial 5 mm port is placed on midline just caudal to the umbilicus. A second 5 mm port is placed in the cranial right quadrant for insertion of biopsy and grasping forceps. Following liver biopsy and aspiration of the gallbladder, the biliary tree is examined. If there is dilation of the common bile duct and cystic duct, the region where the biliary and pancreatic secretions enter the duodenum must be seen. Visualization is obtained by elevating the duodenum and retracting it medially and caudally. If white, plaque-like discoloration of the pancreas is seen, a biopsy of that area should be obtained, as this can be an early sign of pancreatic adenocarcinoma. Biopsy samples can be obtained with the 5 mm cup forceps. Bleeding is minimal. The remainder of the left and right lobes of the pancreas can be visualized by applying traction to the duodenum and elevating

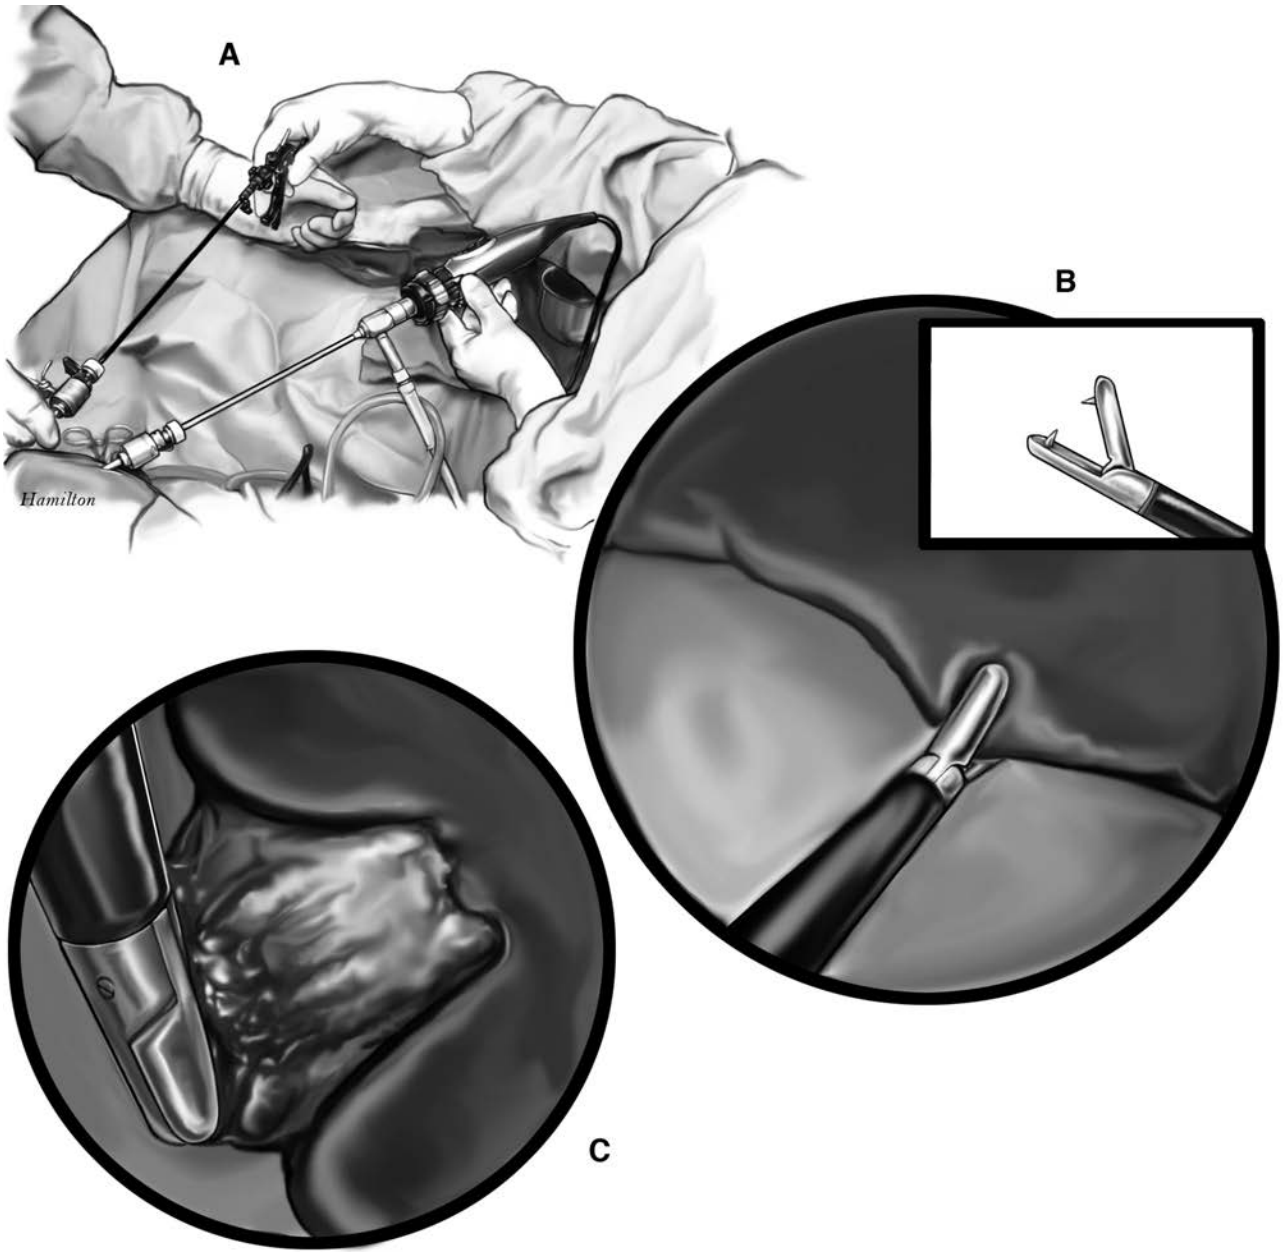

Figure 7-5. A. Laparoscopic Liver Biopsy. A 5 mm laparoscope is placed through the port at the umbilicus. Biopsy forceps are inserted through left lateral 5 mm port. **B.** Laparoscopic toothed biopsy forceps are used to obtain a sample from the liver margin. **C.** Gelfoam is placed in the biopsy site to assist with hemostasis.

the greater curvature of the stomach. To examine the bowel laparoscopically, a third port is placed for insertion of another pair of grasping forceps and a "hand-over-hand" technique is used to trace the bowel.

Usually, it is easier and quicker to visually examine the colon laparoscopically and then convert to a mini-laparotomy. To do so, the trocars are removed and the midline incision is extended cranially and caudally along the linea for a total length of ~ 5 cm. A loop of intestine is grasped and traced orally and aborally to completely examine and palpate the small intestine, mesentery, and mesenteric lymph nodes. Only a portion of the intestine is exposed and the remainder is returned to the abdominal cavity as the exploration proceeds. The entire intestinal tract is examined and full thickness biopsy samples of the stomach duodenum, jejunum, and ileum are obtained. The stomach may be difficult to expose, and if needed, the incision can be extended cranially.

Prior to closure, the abdomen should be inspected to ensure hemostasis. If the animal is hypotensive during surgery, bleeding can occur when the abdominal pressure is reduced and blood pressure returns to normal. If there is concern for active bleeding or contamination from the biopsy procedure, abdominal lavage and inspection should be performed prior to closure. The midline incision and trocar sites are closed in layers.

Laparoscopic Ovariectomy, Ovariohysterectomy

Indications

This procedure is indicated for elective sterilization or retrieval of ovarian remnants left from an incomplete ovariectomy. Studies have demonstrated that there is no increase in complications, such as weight gain, stump pyometra, urethral sphincter incompetence or uterine neoplasia associated with ovariectomy versus ovariohysterectomy. However, it is wise to be specific in discharge instructions for clients as to the procedure being performed to avoid potential future misunderstanding if the animal is seen by another veterinarian. Recently, randomized studies demonstrated that dogs undergoing laparoscopic ovariohysterectomy required less postoperative analgesia than those undergoing an open procedure.[7,12] Another study demonstrated less decrease in postoperative activity levels with laparoscopic approaches in small dogs, compared to open surgery.[1]

Equipment for dogs > 25 kg

10 mm blunt-tip trocar-cannula (with reducing cap to be compatible with 5 mm laparoscope)
5 mm sharp trocar-cannula
5 mm grasping forceps
Laparoscopic spay hook or large curved needle
5 mm LIGASURE device, ENSEAL or Harmonic scalpel

As a general guideline, in cats and very small dogs a 2.7 mm rigid scope is used; for dogs < 25 kg, a 5.0 mm laparoscope is used, and for dogs > 25 kg, a 10 mm laparoscope is used. The size dictates the size of the Hasson trocar, which is placed on midline, just caudal to the umbilicus.

Technique

The abdomen is insufflated to 12 mm Hg and the abdomen is explored. A second 5 mm port is placed on midline about halfway between the umbilicus and pubis. The grasping forceps are inserted and the animal is rotated to the right to expose the left uterine horn and ovary. Grasping forceps are used to grasp the proper ovarian ligament and elevate the ovary to a convenient location on the body wall (Figure 7-6A-F). The location must be inside the sterile field, hence a wide surgical clip and preparation are needed. A laparoscopic spay hook is inserted through the body wall and the ovary is draped over the hook as it is rotated to engage the tip in the body wall. If a needle and suture are used, the needle is rotated and removed from the body and forceps are attached to the suture and used to elevate the ovary and body wall. For secure and rapid hemostasis, an energy system such as the LIGASURE or Harmonic Scalpel is used. The jaws of the device are positioned across tissue, energy is applied, and the tissue is cut. The ovarian pedicle and suspensory ligament are cut first, followed by transection of the fallopian tube and proper ovarian ligament or the proximal portion of the uterine horn. Hemostasis is complete and the ovary is left suspended to the abdominal wall. The energy device is removed and the laparoscope is transferred to the caudal port. Grasping forceps are inserted through the subumbilical port to grasp the ovary as the needle or spay hook is released. The tissue is then removed with the trocar by detaching the sutures from the olive plug. Following inspection to ensure that the entire ovary was removed, the trocar is replaced and the procedure is repeated on the right side. Following final inspection to ensure hemostasis, the insufflation is relieved, and port sites are closed in 2 layers. A 5% lidocaine patch is applied to the skin around the port sites and postoperative analgesia is provided with nonsteroidal anti-inflammatory medication and injectable opioid pain medication.

Complications are rare, and the most common are inflammation of the port sites. Iatrogenic trauma to the spleen or other abdominal organs during insertion and removal of laparoscopic equipment, electrocautery injury to surrounding tissue, and subcutaneous emphysema may occur. Usually these complications are self-limiting and are treated conservatively with no serious consequence.

A laparoscopic ovariohysterectomy can be performed using a similar approach; however, with only one working port, it can be difficult to mobilize the ovary and keep it retracted to gain access to the broad ligament. If so, one can place an additional port so that caudo-medial retraction can be provided while the energy modality is used to coagulate and divide the broad ligament to the level of the uterine arteries and uterine bifurcation. Once both broad ligaments are transected, the uterine body is coagulated and cut or ligated. If the uterine body is small, the LIGASURE, ENSEAL, or Harmonic Scalpel can be used to coagulate and cut it. If very large, the uterine body may need to be ligated. The caudal midline trocar is removed and the incision enlarged so that the uterine body is exteriorized. An extracorporeal ligature can then be used to ligate the uterine body in the same fashion as in open surgery (technically performing a laparoscopic-assisted ovariohysterectomy). Another alternative is to use a pre-tied loop suture. The pre-tied loop is introduced and the ovaries and uterine horns are passed through it such that

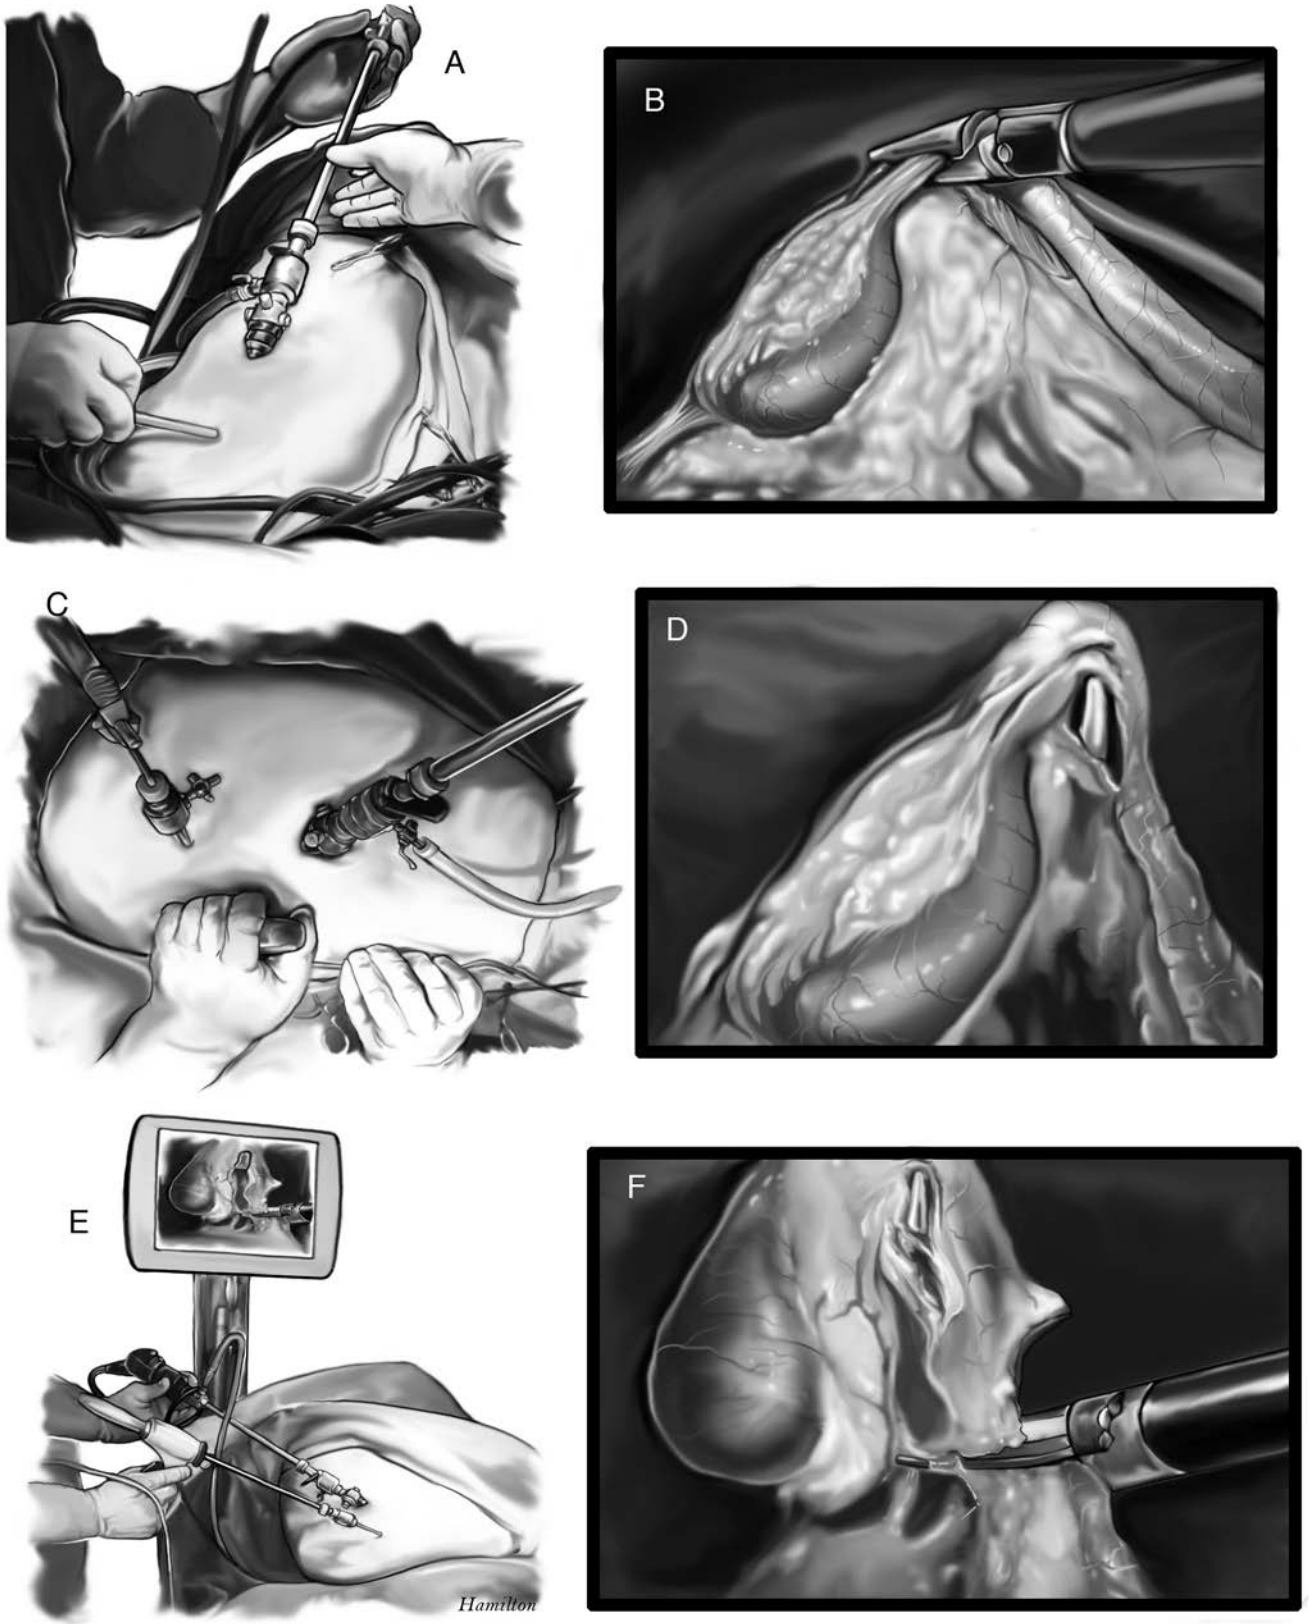

Figure 7-6. Laparoscopic Ovariectomy. **A.** A second 5 mm port is placed on midline midway between the umbilicus and pubis. **B.** The proper ligament of the left ovary is grasped and elevated to the body wall. **C.** External view showing the animal rotated to the right and the spay hook being introduced into the abdomen. **D.** The spay hook is introduced percutaneously and the proper ligament is draped over the hook and secured. **E.** External view showing the harmonic scalpel being used through the caudal midline port. Monitors are positioned at the head and foot of the table and the surgeon is observing the procedure on the monitor at the end of the table. **F.** The harmonic scalpel is used to transect the suspensory ligament, ovarian pedicle, and proximal portion of the uterine horn and the round ligament of the left ovary.

the loop can be positioned on the uterine body. A nylon cannula is broken and advanced to tighten the loop, taking care to avoid incorporation of other structures into it. When the loop is tight, the suture tail is cut with laparoscopic scissors. The uterus is then transected and removed from the sub-umbilical port.

If the tissue is suspected to be malignant or infected, a specimen retrieval bag can be utilized to protect the body wall from contamination. The bag is introduced through one of the ports, tissue is placed in it and the mouth of the bag is closed for withdrawal from the body. Final inspection is performed and the port sites are closed routinely.

Cryptorchid Castration

Indication

This procedure is indicated for animals that have intra-abdominal retained testicles, which are susceptible to torsion and neoplasia. A laparoscopic or laparoscopic-assisted technique can be performed, depending on available equipment. If an energy modality such as LIGASURE, ENSEAL, or Harmonic Scalpel is available, the laparoscopic approach is performed. If not, the laparoscopic-assisted technique is easiest and quickest.

Equipment

10 mm blunt-tip trocar-cannula (with reducing cap to be compatible with 5 mm laparoscope)
5 mm sharp trocar-cannula
5 mm grasping forceps
Laparoscopic spay hook or large curved needle
5 mm LIGASURE device, ENSEAL or Harmonic scalpel

Technique

With both techniques, the animal is positioned in dorsal recumbency and prepared for abdominal surgery. Following the guidelines described earlier, a Hasson port is placed on midline caudal to the umbilicus. The abdomen is insufflated and inspection is performed. Once the testis is identified, a second 5 mm or 10 mm port is placed under direct visualization in the caudal abdominal quadrant on the side opposite the location of the testicle if performing a totally laparoscopic procedure (Figure 7-7A-D). If the laparoscopic assisted technique will be utilized, the port is placed on the same side as the retained testicle. If both testicles are retained, they can usually be retrieved through the same port with the laparoscopic technique. The port is ideally placed just lateral to the lateral edge of the rectus abdominis muscle, taking care to avoid the caudal deep epigastric vessels.

If the laparoscopic assisted technique is used, the testicle is identified and elevated to the body wall. The trocar is removed and the testicle is exteriorized. It may be necessary to enlarge the incision, depending on the size of the laparoscopic port. Similar to open surgery, ligation of the gubernaculums, pampiniform plexus, and spermatic cord is performed. If both testicles are retained, it may be necessary to place a second working port in the opposite caudal abdominal quadrant for removal of the second testicle. Following final inspection to ensure hemostasis, the port sites are closed routinely.

When the 2-port laparoscopic technique is used for a totally laparoscopic procedure, the testicle is lifted suspended from the abdominal wall with a percutaneous suture, similar to the technique used for ovarian suspension in the laparoscopic ovariectomy. The LIGASURE, ENSEAL, or Harmonic Scalpel are used across the gubernaculums, pampiniform plexus, and spermatic cord. Alternatively, clips or sutures can be used. Once ligation and transection are complete, the testicle is removed. If a 10 mm port is placed on midline, the testicle can be removed from that port by transferring the laparoscope to the caudal port. Following final inspection, the port sites are closed routinely.

Gastropexy

Indications

Prophylactic gastropexy is performed to prevent gastric volvulus in large breeds of dogs that may be predisposed to developing gastric dilatation-volvulus syndrome. The procedure can be combined with laparoscopic ovariectomy in female dogs or castration in male dogs. In females, the laparoscopic-assisted procedure is performed; in males, an endoscopic-assisted procedure using a flexible endoscope avoids the need to use laparoscopic equipment. The technique is an incisional gastropexy procedure performed by suturing the seromuscular layer of the stomach to the internal fascia and transverse abdominis muscle at a site selected approximately 3 cm caudal to the costal margin on the right side. Biomechanical studies and clinical experience suggests that the resultant gastropexy adhesion is strong and reliable.[8]

Equipment

Laparoscopy equipment for the laparoscopic-assisted approach
10 mm blunt-tip trocar-cannula (with reducing cap to be compatible with 5 mm laparoscope)
10 mm sharp trocar-cannula
10 mm endoscopic Babcock forceps
Flexible endoscope for the endoscopic-assisted approach
76-mm long needle with size-2 polypropylene suture

Technique

Laparoscopic Approach. Following general anesthesia and positioning in dorsal recumbency, the abdomen is prepared for abdominal surgery. The monitor is placed at the animal's head and the surgeon stands on the animal's right side. A 10 mm Hasson port placed on midline, just caudal to the umbilicus serves as the camera port. The abdomen is insufflated to 12 mm Hg and inspected. Particular attention is paid to the location of the stomach, omentum, and spleen. The pylorus is identified beneath the right medial liver lobe and gallbladder. A second 10 mm port is placed 3 to 5 cm caudal to the ribs on the right side at the lateral edge of the rectus abdominis muscle. Babock forceps are introducted to elevate the liver lobes and fully expose the ventral aspect of the stomach (Figure 7-8A-H). Using the aperture of the Babcock forceps as a measuring tool, a site is selected in the antral region of the stomach approximately 5 cm orad to the pylorus and midway between the greater and lesser curvatures of the stomach. The gastric wall is grasped firmly and elevated to the body wall as the trocar cannula is withdrawn.

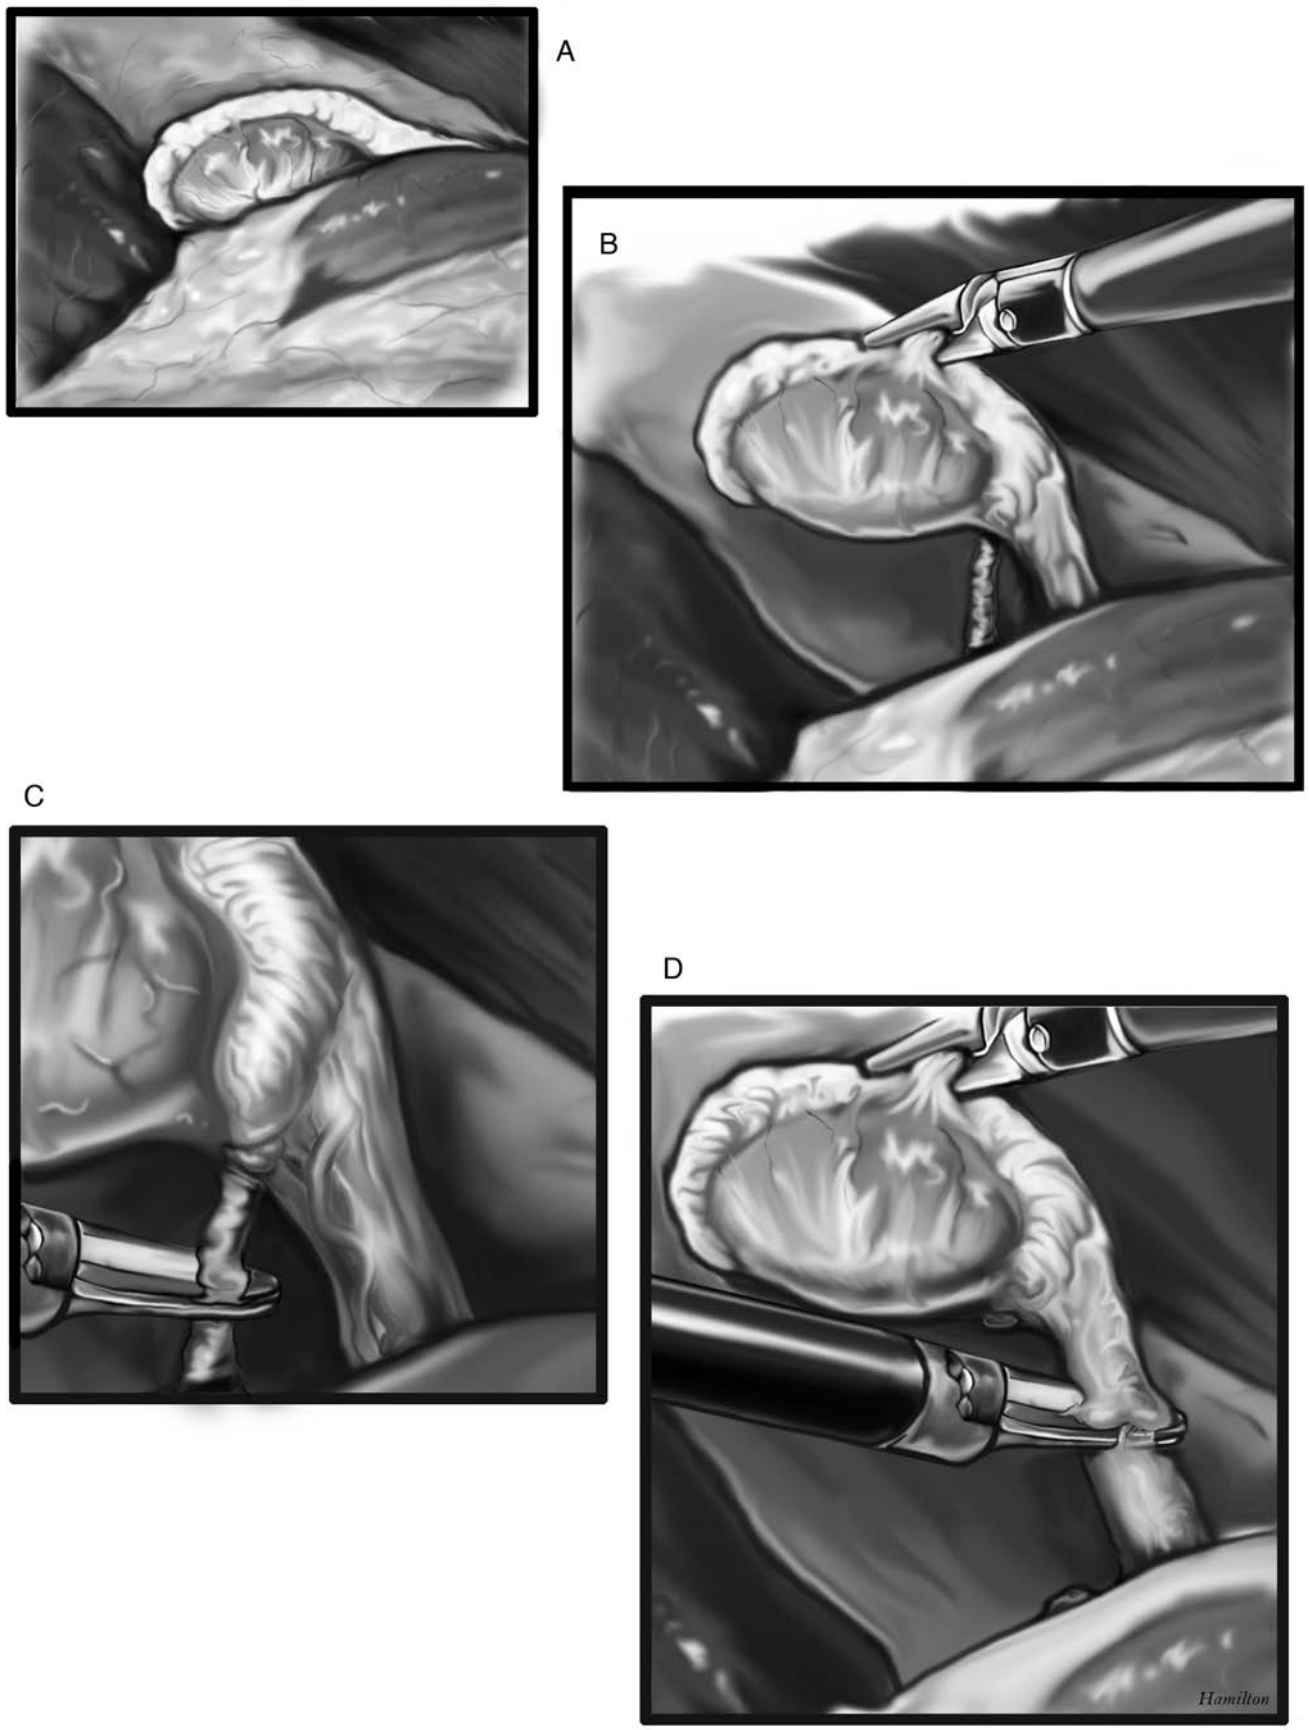

Figure 7-7. Laparoscopic Cryptorchid Castration. **A.** The retained testicle is identified on the right side, lateral to the urinary bladder (arrow). **B.** In this case, a port was placed in the right cranial quadrant to enable a gastropexy procedure. Grasping forceps are used to elevate the testicle. **C.** The vas deferens and pampiniformplexus are identified as the testicle is elevated. **D.** The harmonic scalpel is used for obtaining hemostasis and transection of the vascular structures. The testicle was then removed when the right cranial quadrant incision was enlarged prior to the gastropexy procedure.

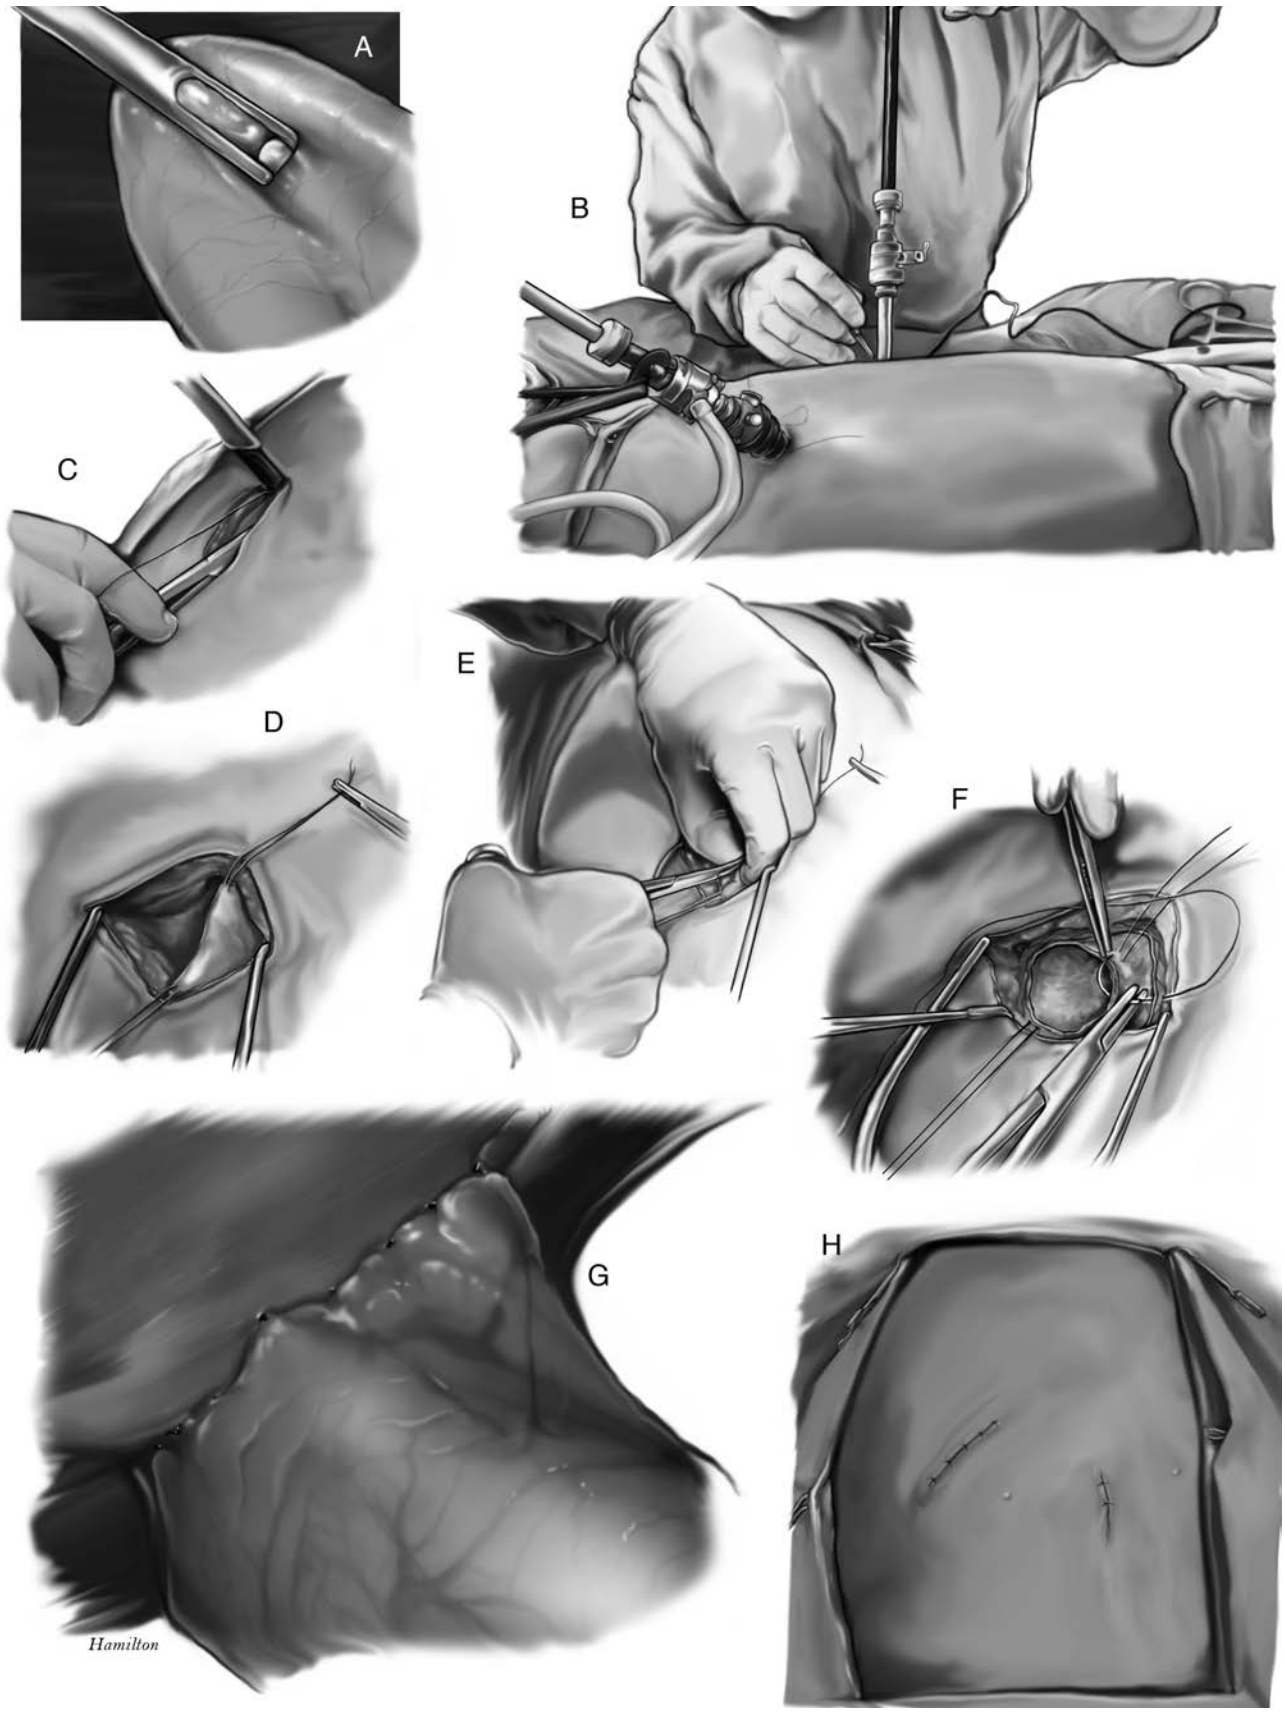

Figure 7-8. Laparoscopic-Assisted Gastropexy. **A.** The stomach is elevated to the base of the trocar with Babcock forceps. **B.** The skin and body wall incision is enlarged with a scalpel blade. **C.** With the forceps elevating the stomach, two stay sutures are placed about 5 cm apart in the gastric wall. **D.** A Gelpi retractor assists in providing clear visualization of the gastric surface. **E.** A seromuscular incision is made in the stomach wall. Pinching the surface of the stomach causes the mucosa to slip away, making the incision less likely to penetrate the mucosa. **F.** The seromuscular layer of the stomach is then sutured to the abdominal wall with a continuous pattern of absorbable sutures. **G.** Final inspection of the gastropexy site prior to closure. **H.** External view of the two incisions for laparoscopic-assisted gastropexy.

When the Babock forceps reach the abdominal wall, the skin and abdominal fascial incisions are extended to ~ 5 to 6 cm with a scalpel blade under laparoscopic visualization. Pneumoperitoneum is lost as the incision is extended and the insufflation gas is turned off. Bleeding is minor. Two stay sutures are placed in the gastric wall about 5 cm apart and the Babcock forceps are removed. Two Gelpi retractors or the Lone Star Veterinary Retractor system with multiple elastic stays can be helpful to aid in exposure and identification of the layers of the abdominal wall. The seromuscular layer of the stomach is then sutured to the abdominal wall with size 2-0 absorbable suture. The external fascia, subcutaneous tissue, and skin are closed routinely. Following inspection of the gastropexy site to ensure that there is no twisting of the gastric wall, the abdomen is desufflated, the umbilical port is removed, and the fascia, subcutaneous tissue and skin are closed. An alternative, totally laparoscopic, approach is direct laparoscopic suturing of the gastric seromuscular incision to an incision in the peritoneum and transversus abdominis muscle with traditional needleholders, barbed sutures, or using the ENDOSTITCH device.[9]

Endoscopic Approach. A flexible endoscope is passed to inspect and dilate the stomach with air. The animal is tilted to the left approximately 30 degrees to allow the distended stomach to be in contact with the right lateral body wall caudal to the costal margin. With gastric distention, identification of the pylorus, and indention from forceps applied to the body wall, the correct site for gastropexy is identified.[10] A large needle is passed percutaneously under direct vision with the endoscope into the stomach and back out through the abdominal wall. A second suture is placed under direct vision from the endoscope 4 to 5 cm from the first suture. Externally, an incision is made through the skin and abdominal wall between the 2 sutures. The gastric surface is identified and a 3 to 5 cm seromuscular gastric incision is made, avoiding the mucosa. Similar to the laparoscopic assisted gastropexy, the seromuscular layer of the stomach is sutured to the body wall and closure proceeds as described previously. The stay sutures are removed and final endoscopic inspection is performed. The surgeon should be alerted to the possibility of trapping of omentum or abdominal contents between the gastric and abdominal wall so careful identification and palpation should be performed prior to placing the percutaneous sutures.

Laparoscopic-assisted Cystoscopy

Indications

This procedure is performed when the surgeon desires to minimize the approach to bladder biopsy (Figure 7-9A-E) or management of urinary calculi that are too large or too numerous for other less invasive treatment modalities.[11] Most often, the procedure is performed in male dogs because stones are more easily retrieved from the urethra in female dogs. The benefit of this procedure is that the incisions are very small and there is less likelihood of urine contamination of the abdomen. Preoperative patient management practices and preparation are similar to open cystotomy.

Equipment

30 degree rigid cystoscope, 1.9 mm for small dogs and cats, 2.7 mm for most other dogs
Saline irrigation fluids with pressure bag and ingress/egress tubing
Stone Basket, compatible with insertion through the working channel of the cystoscope
Arthroscopy or alligator forceps
2 trocars, either 5 mm or 10 mm, depending on the laparoscope size
5 and/or 10 mm Babcock grasping forceps
5 mm disposable screw tipped trocar (optional)

Technique

The initial port is placed on midline near the umbilicus for insertion of the laparoscope. Following insufflation and inspection of the abdomen, a second 5 mm or 10 mm port is placed to exteriorize the bladder. In females, it is placed on midline; in males, the second port is placed lateral to the prepuce at the lateral edge of the rectus abdominis muscle. Through the second port, grasping forceps are introduced to grasp the apex of the bladder and elevate it to the body wall as the trocar is removed. Usually, a 10 mm incision is sufficient unless a very large stone is being removed, but a 5 mm port will need to be enlarged. Stay sutures are placed in the bladder wall and a stab incision is made into the bladder with a #11 scalpel blade. The bladder wall can be sutured to the skin to prevent abdominal contamination during the procedure or a 5 mm disposable screw tipped trocar can be positioned if repeated insertions of the cystoscope are anticipated. The insufflator is turned off and the laparoscope is disconnected from the camera and light guide cable. The camera and light cable, along with the ingress and egress fluid lines, are then attached to the cystoscope. The cystoscope is inserted into the bladder, the fluids are turned on, and thorough visual inspection of the bladder is performed. In male dogs, it can be helpful to pass a urinary catheter to assist in occluding the urethral lumen so that stones do not lodge in the urethra during cystoscopy. At the end of the procedure, the urethra can be flushed with the catheter to ensure that all stones are retrieved. A flexible endoscope can also be used to inspect and/or retrieve urethral calculi.

One of several methods may be used for stone retrieval, depending on the size and number of cystoliths present. The wire stone basket is efficient for removal of large numbers of small calculi that stick together with blood clot. The basket is passed through the working channel of the cystoscope and, under direct vision, passed past the calculi and opened. As the basket is closed, the stones are brought to the end of the cystoscope and the cystoscope is removed from the bladder to deliver the stones. If calculi are too large for the stone basket, they can be retrieved with forceps inserted beside the cystoscope. Numerous small calculi can be removed by using a suction device in the bladder and flushing the urethral catheter. At the end of the procedure, the urethral catheter is withdrawn and the cystoscope is positioned in the trigone region of the bladder. The urethral catheter is simultaneously flushed and passed, and any remaining stones are seen as they are flushed back into the bladder. Bladder polyps or biopsy can be performed with either cystoscopic technique using a biopsy forceps or externally, if full-thickness resection is needed.

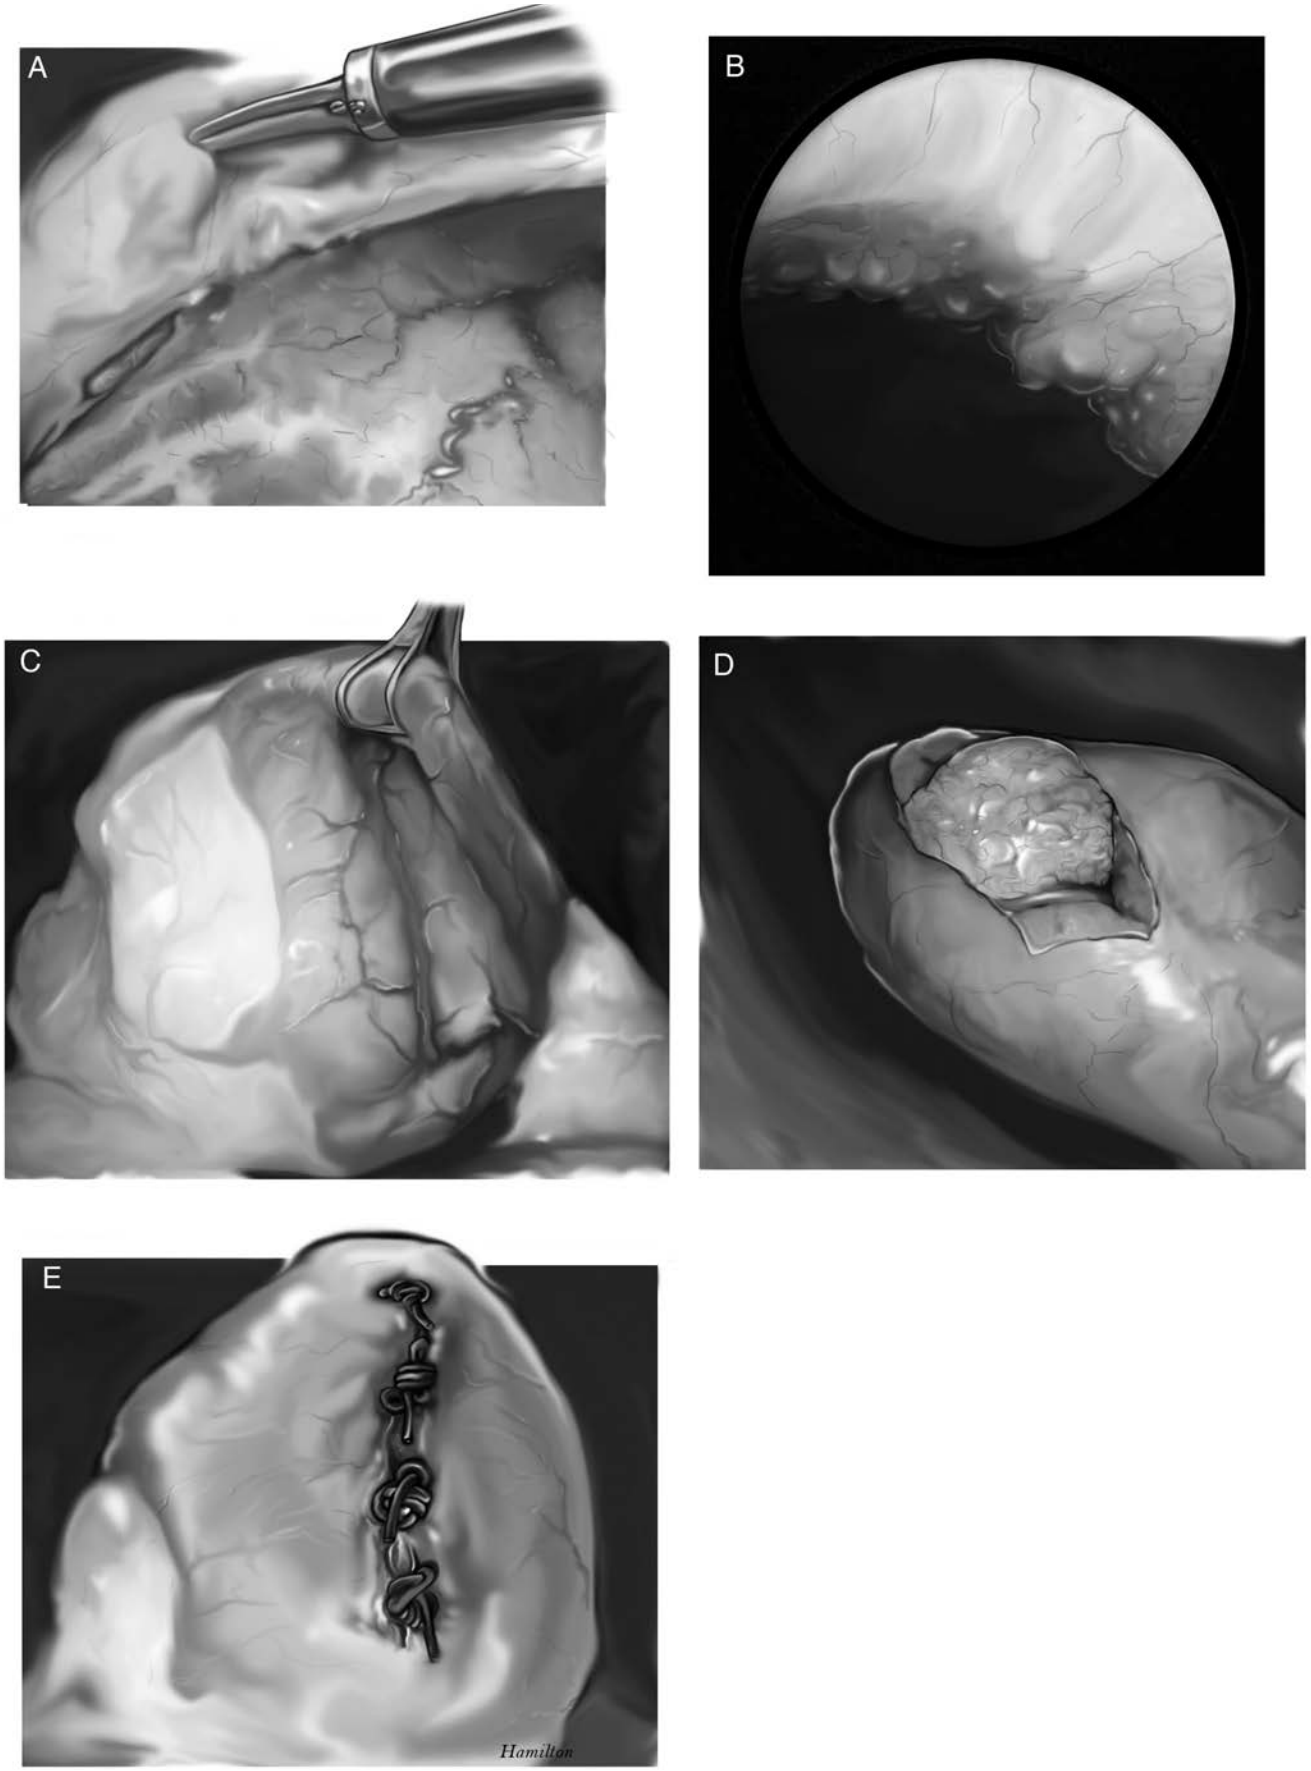

Figure 7-9. Laparoscopic Assisted Cystotomy. **A.** Visual inspection of the urinary bladder revealed scarring on the surface in this case of transitional cell carcinoma. **B.** Cystoscopyrevealed an irregular mucosal surface in the region of the trigone. **C.** Babcock forceps are being used to elevate the bladder to the abdominal wall. **D.** External view of the cystotomy showing bulging of the tissue from inside the bladder. **E.** Laparoscopic view of the bladder closure with simple interrupted sutures.

The cystotomy is then closed and the bladder is returned to the abdominal cavity. The caudal incision is closed, the laparoscope is re-attached to the camera and light guide cable, and the abdomen is re-insufflated. Following final inspection, the camera port is removed, the CO_2 is allowed to escape and the port site is closed routinely. Although always a concern, seeding of the abdominal wall with tumor cells following biopsy of transitional cell carcinoma has not occurred.

Thoracoscopy

Eric Monnet

Introduction

Thoracoscopy is a minimally invasive technique for viewing the internal structures of the thoracic cavity. The procedure uses a rigid telescope placed through a portal positioned in the thoracic wall in order to examine the contents of the pleural cavity. Once the telescope is in place, either biopsy forceps or an assortment of surgical instruments can be introduced into the thoracic cavity through adjacent portals in the thorax to perform various diagnostic or surgical procedures.

The minimal invasiveness of the procedure, the rapid patient recovery, and diagnostic accuracy make thoracoscopy an ideal technique for selected cases over more invasive procedures. Small animal thoracoscopy has not only developed into a diagnostic tool but more recently has progressed to become a means for performing minimally invasive surgical procedures.[1-4]

Despite the advent of newer laboratory tests, imaging techniques and ultrasound directed fine needle biopsy or aspiration, thoracoscopy remains a valuable tool when appropriately applied in a diagnostic plan. Thoracoscopy may also provide accurate and definitive diagnostic and staging information that would otherwise only be obtained through a surgical thoracotomy.[5-6]

Indications and Contraindications

The most common indication for thoracoscopy is to examine and biopsy thoracic organs or masses. Thoracoscopy is also a means of performing various surgical procedures. Thoracoscopy may not completely replace an exploratory thoracotomy but can provide a minimally invasive means of accomplishing a number of diagnostic and surgical procedures in small animals.

Diagnostic thoracoscopy is commonly used as a method for obtaining pleural biopsy, lung biopsy, cranial mediastinal and lymph node biopsy. Common surgical techniques currently being performed in small animals include partial pericardectomy or pericardial window, patent ductus arteriosus, lung lobectomy, resection of cranial mediastinal mass, correction of vascular ring anomalies, thoracic duct ligation, and debridement for the treatment of pyothorax. The advantages of surgical thoracoscopy over conventional open surgical exploratory thoracotomy include improved patient recovery because of smaller surgical sites, lower postoperative morbidity with lower infection rates and decreased postoperative pain.

Thoracoscopic Equipment

The basic equipment required for diagnostic thoracoscopy includes a telescope, corresponding trocar–cannula units, light source, and various forceps and ancillary instruments.[7-9] The telescope most commonly used by the author is a 5 mm diameter 0° field of view telescope for routine diagnostic thoracoscopy. The 0° designation means that the telescope views the visual field directly in front of the telescope. Angled viewing scopes, the most common being a 30° telescope, views in a 30° downward direction. The angled telescopes enable the operator to look over the top of organs and view in small areas which is very useful during thoracoscopy to look at hilar lymph nodes, around the base of the heart, the hilus of lungs during lobectomy, and the mediastinum.

The telescope is attached to a light source using a light guided cable. A Xenon light source with a high intensity is considered to give the truest colors of abdominal organs and is recommended. A high intensity light source provides enough light for deep chested dogs. The telescope is also attached to an endoscopic video camera which allows the image to be viewed on a monitor.

Open or closed cannulas can be used to perform thoracoscopy. With closed cannulas, a controlled pneumothorax can be induced and a ventilator is not required. With open cannulas, a ventilator is required because the pleural space is open to the environment. Open cannulas are recommended to perform thoracoscopy because they eliminate the risk of tension pneumothorax especially when advanced surgical procedures are performed. The open cannulas can be either soft or hard. Soft cannulas are less traumatic to the intercostal artery and nerve, and can be cut to a desired length therefore they do not protrude excessively into the thoracic cavity. Rigid cannulas are required for a transdiaphragmatic sub-xiphoid approach. Rigid cannulas protect the telescope better when an intercostal approach is performed. Ribs are very rigid and it is easy to bend or even break a scope if there is no cannula to move the ribs with. Closed or open cannulas are placed over a blunt trocar into the thoracic cavity. Cannulas exist in a wide variety of diameters. Diameter of the cannulas is determined by the instruments that will be used during the procedure. For example, the stapling equipment used for lung lobectomy comes in a 12 mm diameter. Therefore, a 12 mm cannula will have to be placed for the introducation of the stapling equipment. Thoracoscopy can be performed without cannulas. However, this technique increases the risk of damaging the intercostal nerve and artery. This approach is reserved for small size animals since cannulas take up excessive space in their thoracic cavity.

During diagnostic thoracoscopy, a number of accessory instruments are essential.[6,8,9] A palpation probe is required to move and palpate the thoracic organs. Most palpation probes have centimeter markings so one can estimate the relative size of organs or lesions. The palpation probe can also be used to apply pressure on a biopsy site that is bleeding excessively. Biopsy forceps are used for biopsy of lymph nodes, and pleura.

Surgical thoracoscopy often requires a vast array of instruments designed for specific indications. Common instruments include grasping forceps, scissors, aspiration tubes and clip applicators. Certain specialized instruments such as stapling devices are generally 10 to 12 mm in diameter. Many of the surgical instruments also have capabilities for monopolar electrosurgery at their distal tip. Retractors are very important during thoracoscopy because they allow retraction of lungs. With retractors, lung lobes can be removed without using one-lung ventilation.

Approaches

Since ribs are supporting the thoracic wall, the chest wall cannot be distended to create a working space. Different options are available to increase working space. First, lung tidal volume can be decreased on the ventilator and the frequency of ventilation increased. This will reduce the volume of the lungs without reducing ventilation. This will expand the surgical field enough to be able to perform diagnostic thoracoscopy. Second, one-lung ventilation can be instituted to completely collapse the lung on one side of the thoracic cavity.[10,11] One-lung ventilation induces a right to left shunt that results in desaturation of oxygen in arterial blood. To further assist patient ventilation, it is recommended to use positive end expiratory pressure since it does not reduce cardiac output but maintains open alveoli in the dependent ventilated lung. One-lung ventilation is mostly used with an intercostal approach when a lung lobectomy is performed. Different techniques have been described to achieve one-lung ventilation in dogs. Selective bronchial intubation with a long small diameter endotracheal tube can be used.[12] This technique works most effectively for selective ventilation of the left lung. Since the bronchus of the right cranial lung lobe is so cranial, it is difficult to perform selective intubation of the right lung. A double-lumen endotracheal tube can be used to intubate the left and right lung lobes. This approach allows one branch of the tube to be occluded so that the other lung can be selectively ventilated. Again, because of bronchial anatomy this technique is not very efficient in dogs. Introduction of an endobronchial occluder is commonly used in dogs to induce one-lung ventilation.[10,11,13] The occluder is advanced either through or along the endotracheal tube and is positioned under bronchoscopic guidance. After placement of the occluder in the desired position, the balloon at the end of the occluder is inflated to occlude the bronchi. It is important to induce one-lung ventilation with this technique, after the dog has been positioned for surgery. Manipulation of the patient can easily dislodge the ballon and cause complete occlusion of the trachea. When one-lung ventilation is used it is critical that a capnograph is used to monitor carbon dioxide production and patency of the airway. Third, carbon dioxide insufflation can be used to collapse the lung lobes.[14] This technique creates a pneumothorax and the amount of pressure in the pleural space will control the degree of the pneumothorax. This technique is not currently used in veterinary medicine. It can induce severe atelectasis and severe desaturation of oxygen in the arterial blood. This technique has been used to visualize specific areas of the pleural space.

Thoracoscopy can be performed using either a trans-diaphragmatic or an intercostal approach.[7,12,15] The trans-diaphragmatic approach allows visualization of both hemi-thoraces. A long axis view of the thorax is then obtained. This is the approach of choice for exploration of the thoracic cavity and biopsy. An intercostal approach is indicated for surgical thoracoscopy because it allows very good visualization of specific structures in the affected hemithorax.

Transdiaphragmatic Sub-xiphoid Approach

The patient is positioned in a dorsal recumbent position. First, a screw-in cannula is inserted from a sub-xiphoid position in a cranial direction. Before insertion of the screw in cannula, a small skin incision is performed caudal to the xiphoid. The cannula is screwed into the thoracic cavity under thoracoscopic visualization. After penetration of the thoracic cavity by the cannula, the thoracoscope is advanced into the thoracic cavity. After intial exploration of the thoracic cavity, two other cannulas are placed under thoracoscopic visualization to allow utilization of instruments. These cannulas are placed in intercostal spaces according to the location of the lesions, which require exploration or treatment. Cannulas need to be placed as ventral as possible to allow maximum mobility of the instruments. Metzenbaum scissors with electrocautery and grasping forceps are used to incise the mediastinum. This will allow exploration of both hemithoraces. A 0° telescope is used for initial exploration.

Intercostal Approach

Postioning of the patient is very important during an intercostal approach since it uses gravity to move lungs and heart within the thoracic cavity. Patients can be placed in ventral recumbency for exploration of the thoracic duct or in an oblique position to be able to visualize the hilus of the lungs during lung lobectomy.

During an intercostal approach, all the cannulas are placed in intercostal spaces in a triangular fashion around the organ or the lesion to be explored. Cannulas can be introduced from the third to the ninth intercostal space. The cannula used for the introduction of the telescope is usually placed as far as possible from the organ or the lesions to be biopsied or resected. After incising the skin with a #10 blade, a mosquito forceps is used to bluntly dissect through the intercostal space. The thoracoscopic cannula is then bluntly introduced into the intercostal space, and into the pleural space. Cannulas can be introduced at any level from dorsal to ventral in the intercostal space.

Surgical Procedures Performed with Thoracoscopy

Pericardial Window and Subtotal Pericardectomy

Creation of a window in the pericardium establishes permanent drainage for patients with pericardial effusion.[16-18] This procedure is performed effectively with minimally invasive technique and reduces operative trauma and postoperative pain. Indications for permanent pericardial drainage include neoplastic effusions, hemorrhage from neoplastic masses, inflammatory disease, and idiopathic effusion. This procedure prevents cardiac tamponade in the future by allowing drainage of pericardial fluid into the pleural space.

Approach

To create a pericardial window the patient is placed in dorsal recumbency and a para-xiphoid telescope portal is established.[12,15,16,19] There are two options for placing operative portals. The first places both portals on the right side and the second places one portal on the right side and one on the left side. Each has advantages and disadvantages with the choice between the two related mostly to surgeon preference. The first option places operative portals in the right 6th or 7th intercostal space and in the right 9th or 10th intercostal space. The second option places portals in the left and right 9th and 10th intercostal spaces. All portals are placed ventral to the costochondral junction in the area of the lateral margin of the transverse thoracic muscles. As an alternative, an intercostal approach can also be performed. The patient is placed in left lateral recumbency, and the camera portal is placed in the right ventral third of the 6th or 7th intercostal space. Two instrument portals are then placed in the right 4th intercostal and the 8th intercostal spaces. This approach allows a better visualization of the right atrial appendage and aortic root for diagnosis of neoplastic disease. A pericardial window will then be created on the right side of the pericardium. The phrenic nerve has to be indentified and avoided prior to incising the pericardium.

Surgical Technique

The surgeon stands on the right side of the patient for the paraxiphoid approach and on either side of the patient for the intercostal technique. The telescope operator stands at the foot of the patient or across the patient from the surgeon. Obliquing the patient slightly to the left (10° to 15°) can facilitate visualization and manipulation when both portals are placed on the right side. With all portals in place, the first step of the procedure is to incise the ventral mediastinum to move it from the visual and surgical field. Scissors are used to cut the mediastunum with electrosurgical assistance for control of bleeding. Inadequate control of bleeding from the mediastinal vessels interferes with the procedure by allowing blood to drip onto the telescope and obscure visualization. It is recommended to explore the cranial mediastinum for lymph node enlargement and biopsy. Biopsy of the medistinal lymph node may reveal the diagnosis of mesothelioma of the pericardium that might not be diagnosed on the pericardial window tissue submitted for biopsy.

A site is selected for the pericardial window on the cranial surface of the heart. When a pneumothorax is established and the patient is in dorsal recumbency, the apex of the heart falls dorsally presenting the cranial surface of the heart to the surgeon. Grasping forceps with teeth are used to pick up a fold of pericardium and Metzenbaum scissors are used to cut into this elevated fold of tissue for intitial penetration of the pericardium. This technique minimizes the potential for cardiac damage. The graspers are then repositioned to pick up a margin of the initial pericardial incision. Any excess pericardial fluid that has not been previously evacuated and that interferes with visualization is removed with suction. The pericardial incision is extended to remove a patch of pericardium taking care not to damage the phrenic nerves, heart, lungs or great vessels. There is no objective data to define how much pericardium to remove. The portion removed needs to be large enough to prevent closure of the defect by the healing process and small enough to preclude herniation of the heart though the window. A four centimeter by four centimeter portion of tissue is an acceptable size. The removed patch is extracted from the chest through one of the operative portals and is inspected for size and to define pathology. Samples are submitted for histopathology, and if indicated, for cultures.

Any residual pericardial and pleural fuid is removed with suction and the cavities are irrigated with saline. Operative portal cannulas are removed and the portals closed in layers to achieve an airtight closure. A thoracostomy drain is placed in a routine fashion through the chest wall. Placement of the tube can be controlled by visualization with the thoracoscope.

Partial Lung Lobectomy

Lung biopsy for chronic lung disease, excision of lung masses, lung abscesses, emphysematous bullae, or any other localized disease process in the peripheral portions of the lung lobes can be performed quickly and effectively with minimally invasive technique. Partial lung lobectomy can also be performed for diagnostic biopsy of generalized lung disease.

Approach

Portal placement for partial lung lobectomy is dictated by the location of the lung to be removed. Dorsal recumbency and the para-xiphoid telescope portal allows examination of both sides of the chest for cases where the side of the pathology cannot be determined preoperatively with radiographs or other diagnostic techniques. Lateral recumbency provides greater unilateral access and is the preferred position. The telescope and operative portals are inserted using appropriate triangulation to access the involved lung lobe lesion.

Surgical Technique

For small peripheral lesions and for lung biopsies the loop ligature technique can used.[12,15] The top of the lobe to be removed is positioned through a pretied loop ligature (Endoloop), which is tightened. The ligated portion of the lung is transected and removed. This technique is quick, easy, and safe. Larger or more central lesions require an endoscopic stapling device (Endo GIA) for occlusion and transaction of the portion of the lobe to be removed. When performing partial lung lobectomy with an endoscopic stapler the telescope and operative portals are placed, and the lung lobe lesion is defined and retracted or elevated as needed. The endoscopic stapler is placed through an additional portal to provide optimal alignment for application of the stapler. Following transection of the lung lobe the excised portion is removed from the chest by enlarging one of the portals to allow passage of the tissue. An endoscopic tissue pouch (Endopouch) can be used to facilitate tissue removal. The transected lung margin is observed for air leakage or bleeding with the telescope before exiting the chest. A thoracostomy drain is placed at a site away from all portals, operative and telescope cannulas are removed, and the portals are closed.

Lung Lobectomy

Complete lung lobectomy can be performed in dogs with minimally invasive technique.[15] It is the author's impression that lung lobes with small masses and that are away from the hilus of the lung can be removed with minimally invasive surgery. Large pulmonary masses impair visualization of the hilus of the lung and make manipulation of the affected lung lobe difficult.

Approach

Lateral recumbency with intercostal portal placement is the preferred technique for complete lung lobectomy. One-lung ventilation is recommended to increase the amount of space available in the thoracic cavity for manipulating the instruments and the lung mass. A telescope portal and two operative portals are placed with triangulation and the hilus of the lung lobe to be removed is prepared with sharp dissection.

Surigical Technique

For caudal lung lobes, the pulmonary ligament is incised to free the lung lobe from the diaphragm for manipulation into position for placement of the endoscopic stapling device. Individual structures of the hilus are not isolated for minimally invasive lung lobectomy and are separated from surrounding structures only enough to place the stapling device. A 45 mm to 65 mm long stapling cartridge with 3.5 mm staples is placed across the hilus of the lobe to be removed through its own additional portal that is placed ventrally and caudally at a location to allow the stapler to be placed perpendicular to the bronchus and blood vessels. The stapling cartridge must be long enough to include the entire hilus to be stapled. The resected lung lobe is removed from the thorax through a small intercostal thoracotomy. Enlarged hilar lymph nodes can be biopsied or removed with minimally invasive technique. If a lymph node is to be dissected and removed for biopsy, sharp and blunt dissection are used for lymph node removal with electrosurgical assistance and hemoclip application for hemostasis. An endoscopic tissue retrieval pouch facilitates removal of the lung lobe and decreases the potential of seeding neoplastic cells or infection to the chest wall. Prior to removal of the telescope the hilus is observed for air leakage or bleeding. A chest drain is placed at a site away from all portals, the operative and telescope cannulas are removed, and the portals are closed.

Thoracic Duct Ligation

Management of chylothorax by thoracic duct occlusion is possible with minimally invasive technique.[3] Magnification produced by the telescope and video system greatly enhances visualization of the thoracic ducts and instrumentation designed for minimally invasive surgery facilitates manipulation of structures deep in the chest. Occlusion can be achieved with vascular clips specifically designed for minimally invasive surgery (Endoclips).

Approach

Intercostal portals are placed with the patient in sternal recumbency. Intercostal portals are placed in the left chest wall with the patient in right lateral recumbency for cats. The telescope portal is placed in the seventh intercostal space at the dorso–ventral midpoint of the intercostal space. Operative portals are placed midway between the telescope portal and the dorsal end of the ribs in the sixth and ninth intercostal spaces.

Surgical Technique

The pleura is dissected to expose the thoracic ducts and multiple clips are applied to all visible branches of the duct. Injection of the popliteal lymph node or the cysterna chyli with methylene blue is recommended to improve visualization of the thoracic duct.

Peristent Right Aortic Arch Ligation

Minimally invasive transection of the ligamentum arteriosum in cases with persistent right aortic arch (PRAA) has been shown to be an effective alternative to the open surgical approach.[2,22]

Approach

To perform minimally invasive PRAA correction the patient is placed in right lateral recumbency, the telescope portal is placed in the left 4th or 5th intercostal space at the costochodral junction, and operative portals are placed in the 3rd and 6th or 7th intercostal space at the level of the costochondral junction and at the dorsal end of the 5th intercostal space.

Surgical Technique

A retractor is placed in the 6th or 7th intercostal portal to retract the cranial lung lobe caudally. A stomach tube is placed in the esophagus to improve visulazation of the ligamentum arteriosum. A palpation probe is used to further localize the ligamentum arteriosum. The ligamentum arteriosum is dissected with sharp and blunt dissection to isolate it from the pleura and esophagus. Endoscopic 5mm vascular clips are placed on the isolated ligamentum arteriosum and it is transected between the clips. An ultrasound dissector can be used to seal the edges of the ductus arteriosus and transect it. Any remaining fibers are dissected and divided and the esophagus is dilated by passage of a balloon dilation catheter or esophageal bougies. A chest tube is placed and the portals are closed. Postoperative dietary management is the same as for open surgical PRAA correction.

Mediastinal and Pleural Mass Excision

Selected neoplastic, (thymoma) and inflammatory masses can be removed effectively with minimally invasive technique.[15] Masses that are inoperable with minimally invasive technique can be evaluated for open surgical excision or biopsied and staged for appropriate non-surgical treatment. Patient position and portal placement are defined by location of the mass. Cranial mediastinal masses are visualized most effectively in dorsal recumbency with a para-xiphoid telescope portal. Operative portals can be placed with both portals on one side or with bilateral portals. Intercostal space selection for the operative portals again depends on the location and size of the cranial mediastinal mass. Portals are placed as ventrally in the appropriate intercostal spaces as possible without traumatizing the internal thoracic artery. Masses are dissected with sharp and blunt dissection as indicated with ligatures, vascular clip, and electrosurgical assistance for hemostasis.

Thoracoscopy is in its infancy in veterinary medicine and surgery. The major advantage of thoracoscopy seems to be the reduced morbidity and pain when compared to thoracotomy.

Small Animal Arthroscopy

Kurt S. Schultz

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Introduction

Arthroscopy is the technique of endoscopic examination of a joint. The use of arthroscopy is growing rapidly in small animal orthopedic practice for several reasons. Arthroscopy is significantly less invasive than a traditional arthrotomy and both veterinarians and pet owners are seeking to minimize pain associated with surgical trauma. The excellent visualization provided by arthroscopy has led to the discovery of new joint diseases and for certain diseases such as ligamentous instability of the shoulder or medial compartmental disease of the elbow it may be the only practical method of diagnosis. Arthroscopy provides increased magnification and visualization of joint structures and this may be its greatest advantage over traditional surgical techniques.

Magnification has provided new understanding of the development of osteoarthritis in small animals. For example, it is now known that osteoarthritis of the canine elbow affects the medial compartment much more severely than the lateral compartment (medial compartment disease). Arthroscopy has also demonstrated that osteoarthritic lesions may occur in sites identical to that of osteochondritis dissecans (OCD) in the shoulder or stifle without diagnostic radiographic findings. Finally, arthroscopy has the ability to diagnose and grade osteoarthritis much earlier and with greater accuracy than radiography in virtually all joints (Table 7-1).

Other advantages of arthroscopy include the ability to perform procedures that are not possible with arthrotomy. The use of radiofrequency therapy for joint stabilization is only possible through arthroscopy. Topical osteoarthritis treatment using microfracture or abrasion techniques can be performed more precisely with arthroscopy due to the magnification that arthroscopy provides. A contributing factor to the increased use of arthroscopy in small animals has been the development of smaller but high quality instrumentation. Arthroscopes of 1.9 to 2.7 mm in diameter are routinely used in small animals and in the near future diagnostic arthroscopes as small as 1.1 mm in diameter will be available for outpatient diagnosis and follow up procedures (second look arthroscopy). Client demand has also stimulated the increased use of arthroscopy. Many pet owners are knowledgeable regarding arthroscopy and understand the benefits of minimally invasive surgical technique. The ability to provide arthroscopy in small animals allows veterinarians to provide advanced orthopedic diagnosis and therapy. Although increased expense is associated with arthroscopy, I have found most clients willing to incur the increased cost due to the previously mentioned advantages of the procedure (Table 7-2).

Arthroscopy presents challenges but has few disadvantages. Arthroscopic equipment is expensive and requires specialized care and handling. The cost for an arthroscopy system varies considerably with equipment selected. In addition, becoming proficient in arthroscopy both diagnostically and therapeutically can be difficult and requires considerable time. The skills involved in arthroscopy are considerably different from those of traditional surgery although some principles remain the same. Continuing education courses are available for training in small animal arthroscopy and veterinarians interested in becoming proficient are encouraged to gain experience in the teaching laboratory. Iatrogenic damage to the joint and the equipment is common during the learning process. Initially, performing an arthroscopic procedure will require more time than traditional surgery but with increasing experience arthroscopic procedures become faster than open surgery. Arthroscopy seems likely to become the standard of care for many diagnostic and therapeutic procedures involving the joints of companion animals.

Basic Terminology

Arthroscopy is the technique of endoscopy of a joint. **Instrumentation** refers to the insertion of an arthroscope or other instruments into the joint. **Triangulation** refers to successful visualization of the hand instruments through the arthroscope in a manner that is conducive to performing biopsies or therapeutic procedures within the joint. All equipment inserted into the joint is done through **portals** or holes established through the skin and soft tissues. **Cannulas** are metal tubes that maintain the portals and protect the instruments during the procedure. Arthroscopes are always used through specifically designed cannulas. Other instruments and fluid outflow devices may be used with or without cannulas. Fluid flowing into the joint is referred to as **in-flow or ingress** while fluid flowing out of the joint is referred to as **out-flow or egress**. Portals are defined by their use. The arthroscope is inserted through a scope or camera portal and power and hand tools are inserted through an instrument portal. Repeat arthroscopic examination of a joint that has been previously scoped is referred to as **second-look arthroscopy**.

Instrumentation Arthroscopes differ in diameter (1.9, 2.3, 2.7 mm and larger), length (short, long) and angle. Arthroscopes in common use in small animal arthroscopy include any of the diameters and lengths described and most scopes have a 30° angle. The diameter designates the telescope diameter alone and does not include the diameter of the arthroscope cannula, which is necessary for use. The selection of diameter is based on the size of the joint and surgeon preference with larger scopes providing more rigidity and greater field of view and smaller scopes causing less iatrogenic damage and having greater mobility.

Table 7-1. Common Diagnoses with Arthroscopy

Shoulder	Elbow	Carpus	Hip	Knee	Tarsus
OCD	FCP	osteoarthritis	osteoarthritis	OCD	OCD
Osteoarthritis	OCD	Chip fractures	Labral tearing and avulsion	Cruciate disease	Chip fractures
Biceps disease	UAP		Tearing of the ligament of the femoral head	osteoarthritis	
Medial collateral tearing	Osteoarthritis of the medial compartment				
Lateral collateral tearing					

Table 7-2. Common Arthroscopic Procedures

Shoulder	Elbow	Carpus	Hip	Knee	Tarsus
Fragment removal – OCD	Fragment removal – OCD, FCP	Fragment removal – chip fractures	Osteoarthritis assessment	Fragment removal – OCD	Fragment removal OCD
Osteoarthritis treatment – microfracture, abrasion	Osteoarthritis treatment – microfracture, abrasion	Osteoarthritis treatment – microfracture, abrasion		Osteoarthritis treatment – microfracture, abrasion	Osteoarthritis treatment – microfracture, abrasion
Biceps tenotomy				Meniscal treatment	
Soft tissue shrinkage for instability				Cruciate excision	

The camera head attaches to the arthroscope eyepiece. Cameras are digital and available as 1 or 3 chip and must be used with a specific camera box that processes the image for the video monitor. For general use, 1-chip cameras provide excellent resolution and recording capabilities and 3 chip cameras are only necessary for video or still image work that is to be published. Medical grade video monitors are recommended to provide a bright, clear, and accurate image. Most new light sources use xenon lamps, which provide increased light intensity and higher color temperature than halogen and therefore provide higher visual clarity and truer color. Xenon light sources are more expensive than halogen but are recommended for superior image quality.

Fluid flow during arthroscopy helps maintain joint distention, aids in clearing blood and other debris from the joint, and decreases the risk of joint contamination. Fluid may be delivered to the joint by gravity or from an arthroscopic pump. The use of lactated ringers solution as lavage fluid is preferred over saline as the former is thought to be less destructive to articular cartilage. Fluid outflow is provided by either a disposable needle or a specific outflow cannula.

The majority of arthroscopic therapy is performed with hand instrumentation. Both hand instruments and power tools are inserted into the joint through an instrument portal that may be used with or without a cannula. Hand instruments include probes, knives, curettes, and forceps. The most commonly used probes are right angled and may have calibration marks for measurement of lesions. Numerous styles of knives and curettes are available for manipulations of soft tissue. The most common forceps used in small animal arthroscopy are graspers for removal of hard or soft tissues and biters for debridement of soft tissues.

Power instruments are not necessary for basic small animal arthroscopy but increase the surgeon's efficiency and capabilities. The most common power instrument used is a shaver. These motorized hand tools have numerous tip designs including burrs, sharp cutters, and aggressive cutters. Additional power instruments include electrocautery and radiofrequency. Electrocautery tips specific for use in arthroscopy are available for some electrocautery generators. Alternatively, cautery may be performed by use of a radiofrequency unit. These units, which are available in both bipolar, and monopolar designs have also been advocated for soft tissue ablation and collagen shrinkage.

Arthroscopy of the Shoulder

Knowledge of diseases of the shoulder and their treatment has grown recently due to increased experience with shoulder ultrasound, arthroscopy, and MRI of the shoulder. The differential diagnosis for shoulder diseases has been expanded, as have the potential methods of treatment. Arthroscopy of the canine shoulder should be performed with a 2.7 mm arthroscope. A cranio-lateral or caudo-lateral arthroscope portal is generally used (Figure 7-10). Recently described portals include a medial portal using an in to out technique. Arthroscopy on the shoulder requires less equipment than other joints but can be the most difficult to instrument for beginning arthroscopists. The shoulder is also the least forgiving when mistakes in technique lead to substantial fluid leakage. Regardless, complications associated with arthroscopy of the shoulder are uncommon.

Thorough examination of the shoulder joint with the arthroscope includes assessment of the cartilage of the humeral head and glenoid cavity, evaluation of the origin of the biceps tendon and the remainder of the proximal tendon, evaluation of the subscapularis tendon, and evaluation of the medial glenohumeral ligaments. Lesions of the cartilage of the shoulder joint include OCD, focal or localized osteoarthritis, and generalized osteoarthritis. OCD is the most commonly treated disease of the shoulder joint. Arthroscopic treatment of OCD is usually rapid and highly successful. Although similar clinical results can be obtained

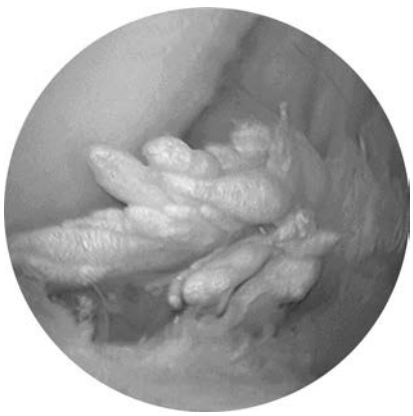

Figure 7-10. Arthroscopy of the canine shoulder with a 2.7 mm arthroscope and a craniolateral or caudo-lateral arthroscopic portal.

with arthrotomy, arthroscopy can aid in retrieving fragments that have migrated and allows easier inspection of the entire lesion. Focal osteoarthritis can occur in a site identical to that of OCD. The specific cause of the lesion is unknown and it may not be apparent on radiographs. Treatment may include topical arthroscopic techniques such as microfracture or abrasion arthroplasty although the primary treatement is medical. Generalized osteoarthritis may be identified with or without other injuries to the shoulder such as tearing of the biceps tendon or collateral ligaments.

Diseases of the biceps tendon are easily diagnosed with arthroscopy since it provides outstanding visualization of this structure. Tendon tears and synovitis are readily apparent. Tears can be rapidly treated by tenotomy through a cranial portal but synovitis should not be treated with tenotomy since it may be an indication of other joint disease.

Arthroscopy has demonstrated that many dogs suffer from damage to the supportive structures of the shoulder including the medial and lateral collateral ligaments and the subscapularis tendon. Other supportive structures with the exception of the biceps tendon cannot be visualized through an arthroscope. If damage to these structures is identified they may be treated by arthrotomy and ligament reconstruction or through arthroscopy by the use or radiofrequency that shrinks collagen thereby eliminating instability.

Arthroscopy of the Elbow

Elbow dysplasia is the most common cause of forelimb lameness in dogs. The ability to diagnose and treat this widespread disease has improved through the use of arthroscopy. The single greatest lesson learned from elbow arthroscopy is "for a forelimb lameness of unknown origin, arthroscopy of the elbow should be part of the diagnostic plan." Justification for this philosophy is the high prevalence of elbow osteoarthritis found during arthroscopic examination in spite of normal radiographic findings.

The two primary indications for elbow arthroscopy are for diagnosis of suspected elbow joint disease and for treatment of elbow dysplasia. It is well recognized that osteoarthritis and fragmented coronoid process (FCP) can be present with minimal radiographic changes (Figure 7-11). Correct diagnosis of these cases may be impossible without arthroscopic examination due to minor radiographic changes. Arthroscopic examination permits thorough exploration of the joint with a minimally invasive technique and enables increased visualization of all important regions of the joint. Fragmentation of the medial coronoid process is easily visible with arthroscopy as is cartilage damage.

Once disease of the elbow joint is confirmed, arthroscopy permits treatment of most of these diseases with methods that may be more effective and are less invasive than arthrotomy. Arthroscopy permits rapid and easy removal of loose fragments due to OCD or FCP. Areas of cartilage damage may be treated with topical management such as microfracture or abrasion arthroplasty. These two techniques produce bleeding at the site of cartilage disease which encourages the formation of fibrocartilage.

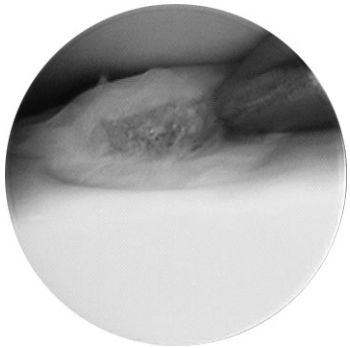

Figure 7-11. A fragmented coronoid process on arthroscopic examination.

Abrasion arthroplasty is performed with a hand burr or preferentially a power shaver burr. A thin layer of subchondral bone over the area of the lesion is removed until bleeding is observed in the area of cartilage loss. Microfracture is performed with an appropriately angled micropick. The pick is placed against the surface of the diseased cartilage or subchondral bone and then impacted to create microfractures into the bone marrow. These cracks allow bleeding into the diseased area, the formation of a clot, and subsequent fibrocartilage formation. Although the efficacy of these procedures is controversial, they are recommended in the management of elbow arthritis.

Less commonly, elbow arthroscopy has been used to treat humeral condylar fractures and ununited anconeal process. In both cases, arthroscopy is used primarily to visualize joint surfaces and assure congruency during screw insertion for stabilization of the condylar fracture or ununited anconeal process. Arthroscopy is also useful for diagnosis of incomplete fusion of the humeral condyle which is difficult to diagnose radiographically.

Arthroscopy of the Carpus

Arthroscopy of the carpus is uncommonly performed as there are few clinical applications. Diseases diagnosed and treated with arthroscopy have included joint infection, chip fracture removal, and cartilage assessment in association with osteoarthritis.

Arthroscopy of the Hip

The technique of arthroscopy of the canine hip was described in the early 1990's but its use has been limited until recently. The ability to visualize the, articular cartilage, femoral capital ligament, and acetabular labrum by arthroscopy allows accurate grading of intrarticular disease. Grading of hip disease has been employed primarily in clinical research involving the use of triple pelvic osteotomy (TPO) used for treatment of juvenile hip dysplasia. Other potential clincial applications include evaluation of fractures of the femoral head and septic arthritis of the hip. Arthroscopy of the hip is potentially simpler than in other joints such as the shoulder, elbow, and stifle.The coxofemoral joint is easily entered and complete examination of the joint can be achieved quickly. Special instrumentation is not necessary for arthroscopy of the hip joint although long versions of arthroscopes (2.7 mm, 30E, long) and hand instruments are needed.

Arthroscopy of the Stifle

Arthroscopy of the stifle provides a minimally invasive method for evaluation of all structures of the stifle joint. Stifle arthroscopy is a rapid and minimally invasive method for the treatment of OCD. For the experienced arthroscopist, an OCD lesion can be quickly removed through a very small incision. The cartilage lesion may then be treated with abrasion arthroplasty or microfracture to encourage cartilage healing. Arthroscopy is also commonly used in the diagnosis and management of cruciate disease and meniscal injury (Figure 7-12). In cases where early cruciate ligament injury has occurred, diagnosis may be difficult due to the lack of palpable instability or other obvious clinical changes. Arthroscopy provides excellent visualization of the cruciate ligament and meniscus. Small tears in the meniscus are more easily seen and treated through an arthroscope than by arthrotomy. The use of arthroscopy in the management of known cruciate injury eliminates the need to incise the joint capsule which is thought by some surgeons to be the primary cause of pain following conventional arthrotomy.

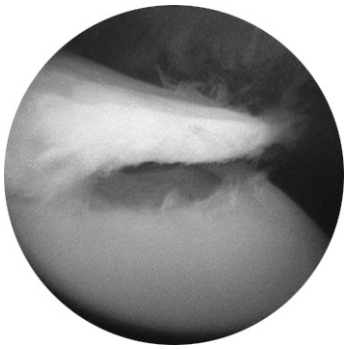

Figure 7-12. Arthroscopic appearance of cruciate disease and meniscal injury.

The stifle joint is often difficult to visualize for inexperienced arthroscopists because there are numerous cavities within the joint and the fat pad and synovium can obscure anatomic structures. I remove a portion of the fat pad with either a power shaver or radiofrequency probe to enhance visualization of the joint. Once the fat pad has been ablated there should be a clear view of the cruciate ligaments, femoral condyles, patella, trochlear groove, long digital extensor tendon, and the medial and lateral meniscus. Arthroscopy of the stifle is also used for treatment of articular fractures and techniques are being developed for the mangement of patella luxation.

Placement of a large cannulas in the stifle joint for fluid lavage and the use of shavers for synovectomy are useful techniques employed in treating septic stifle joints. These techniques are easily mastered with experience in arthroscopy.

Arthroscopy of the Tarsus

Arthroscopy of the hock is regarded as difficult. Entry into joints with significant effusion is generally easy but entry into joints with minimal effusion is much more difficult. Hock arthroscopy is primarily used for treatment of OCD and evaluation of cartilage damage.

Chapter 8

Microvascular Surgical Instrumentation and Application

Otto I. Lanz and Daniel A. Degner

Introduction

Microvascular surgery in veterinary medicine is indicated for free tissue transfer such as skin and muscular flaps and in kidney transplantation. Microvascular instrumentation development began in the 1930s and progressed further in 1952 with the creation of the Microsurgical Instrumentation Research Association.[1] Thanks to the work of Acland, Buncke, Tamai, and others, many instruments have been designed specifically for varying microsurgical needs. This wide variety of microvascular instruments includes both basic and sophisticated instrumentation that is necessary for correct tissue handling during surgery.[1,2]

Microsurgical instruments have fine tips like ophthalmic instruments, but they differ in that they are a more standard length, whereas ophthalmic instruments are generally shorter than conventional surgical instrumentation. Plastic and reconstructive surgery usually involves a superficial operative field and the average length of the instruments is 14 to 16 cm.[2] The majority of instruments are spring loaded to reduce cramping of the hand muscles during long procedures that can lead to shaking and tremors. The handles are generally rounded to facilitate maneuvering the instruments in the fingers and allowing them to be rolled in the fingers, as necessary for suture placement and tissue manipulation. Many microsurgical instruments are grooved near the head to make them conform to the notch created between the surgeons' thumb and index finger. This groove allows the instrument to rest in the notch without being actively held, to minimize muscle fatigue from grasping the instrument, which can result in tremors. Additionally, many instruments are counterbalanced with a weight at the head of the instrument to minimize finger fatigue caused by prolonged gripping of the instrument (Figure 8-1).

Instruments for microvascular surgery are generally made of stainless steel with the tips of the instruments containing chromium to increase their strength. Some surgeons advocate the use of titanium instruments, which are lighter, stronger, and more importantly have antimagnetic properties that prevent the fine microneedles used in suturing from sticking to the instrument. Microsurgery is performed with the surgeon in a sitting position to minimize fatigue and muscle tremors. The surgeons' antebrachium rests on the table, with the heels of the hands resting comfortably on the table as well. The instruments are held as one holds a pen or pencil, with most operative maneuvers carried out by the fingers while the wrists remain motionless on the table.

Figure 8-1. These microsurgical tying forceps are of standard length with miniaturized tips, rounded shanks; this instrument is contoured to fit in the notch between the base of the thumb and the index figure and is counterbalanced.

This chapter describes instrumentation and suture materials that are most commonly used when performing veterinary microsurgery. In addition, descriptions of free skin transfer, free muscle tissue transfer and their indications are presented.

Jeweler's Forceps

Jeweler's forceps consist of two flat, narrow legs connected at the head that narrow to form the jaws of the instruments.[1-3] The contact surface at the tips is referred to as the bit and the distance between the jaws is approximately 8 mm. Jeweler's forceps are numbered according to the width of the bit and legs and their overall shape. Five basic jeweler's forceps are used in microvascular surgery: Nos, 2,3,4,5, and 7 (Figure 8-2A,B,C). The No. 2 forceps have the largest contact surface and are advocated for use as needle holders. The No. 3 forceps are used for testing vessel patency. The Nos. 4 and 5 forceps are useful for delicate tissue handling; the No. 4 forceps have a slightly larger bit. The No. 7 forceps have the unique feature of having curved tips, which are useful to access obstructed areas or to prepare small vessels for anastomosis (Figure 8-2C).

Special care must be taken to avoid bending the tips of jeweler's forceps. The tips should be examined under a microscope before the beginning of a surgical procedure to assess the alignment of the tips because bent tips may catch on adventitia, tear vessel walls, and inhibit proper handling of the microneedle. The tips of some jeweler's forceps are pointed or rough, leading to tissue or vessel damage and inadvertent cutting of suture material. For these reasons, it is recommended to gently file the tips of jeweler's forceps with an emery board or Arkansas stone before their first use.

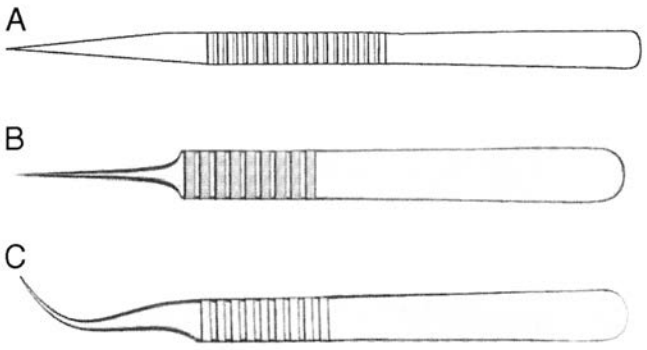

Figure 8-2. Jeweler's forceps are available in different sizes and configurations. **A.** No. 3 jeweler's forceps are used to test the patency of small vessels by occluding the flow with the forceps and allowing the vessel to refill after the forceps are removed. **B.** No. 5 jeweler's forceps have fine, delicate tips for microsurgical applications. **C**. No. 7 jeweler's forceps have a curve enabling the surgeon to gain access to remote areas of the surgical field.

Jeweler's forceps are inexpensive and have a wide range of styles and usefulness during microvascular surgery; however, they do not have round handles, are not counterbalanced, and are of short length. In contrast, microvascular forceps are available in a variety of styles and designs but are considerably more expensive than jeweler's forceps. Microvascular DeBakey forceps, microring tipped forceps, and a variety of curved or straight microforceps are available. These forceps are appropriate in length, have round handles, and are counterbalanced.

Needle Holders

Number 2 jeweler's forceps are used as needle holders for their simplicity, ease of knot tying, lack of concern about entrapment of the suture material in the lock mechanism, and low cost. The major disadvantage of jeweler's forceps is that the needle is not held securely and may slip at an inopportune moment. Additionally these forceps do not have rounded handles, lack a grooved head, and are not counterbalanced. Rounded shanks are particularly important in needle holders because passage of the microneedle through the vessel wall requires that the instrument be rolled in the fingers.

The three basic parts of the needle holder are the jaws, the lock, and the shank. The jaws are usually flat and not grooved. Generally, curved needle holders are used because they have less of a tendency to obstruct the surgeon's view of the operating field. Ratchetless needle holders are used exclusively in microsurgery because of the delicate nature of the microneedles. Additionally, the locking and unlocking of the ratchet causes motion in the tips that can damage the vessel.

Scissors

Microvascular scissors are among the more expensive instruments in the microvascular surgical pack. They should have rounded shanks, be spring loaded, and have fine, delicate tips. They are used for delicate dissection, for cutting suture, and for trimming adventitia during vessel preparation.

Scissors are composed of blades, lock, and shanks. The blade tips are pointed or slightly rounded, and the blades are only sharp along their inner surface. The blades may be straight, curved, or angled at 45°. The shanks are spring loaded so the blades are open at rest, and when the shanks are compressed, they come together with a cutting action. These instruments are used for blunt dissection by closing the blades, inserting them into the fascial plane, and allowing the spring action to open the blades within the tissue plane. Scissors must be thoroughly cleaned, well protected when not in use, and their sharpness constantly maintained.

Vessel Dilators

Vessel dilators are modified jeweler's forceps with a narrower, smoother, nontapering tip (Figure 8-3). The tips of this instrument are inserted into the vessel lumen and are opened slightly to dilate the vessel gently as part of vessel preparation. Dilators may also be used as a counterpressor when suturing vessels. They should be inspected under high magnification to ensure alignment of the tips. The tips must be smooth and unbent to prevent injury to the vascular intima when they are inserted into the vessel lumen.

Microvascular Clamps

Microvascular clamps are used to occlude the vessel and prevent intraoperative hemorrhage. These clamps must be atraumatic yet have adequate closing pressure to prevent hemorrhage from the vessel. The blades should be flat to disperse the pressure evenly across the vessel, and they should have a rough surface to hold the vessel securely. Clamps should be easy to apply with finger pressure or applicator forceps (Figure 8-4). Most clamps are small enough to fit in the operative field but large enough to be easily manipulated. Clamps are available in various sizes with varying closing pressure to accommodate variation in vessel size. The closing pressure of the clamps should be less than 30 gm/mm to avoid endothelial damage. The surfaces of the clamps are usually dull, to minimize light reflection.

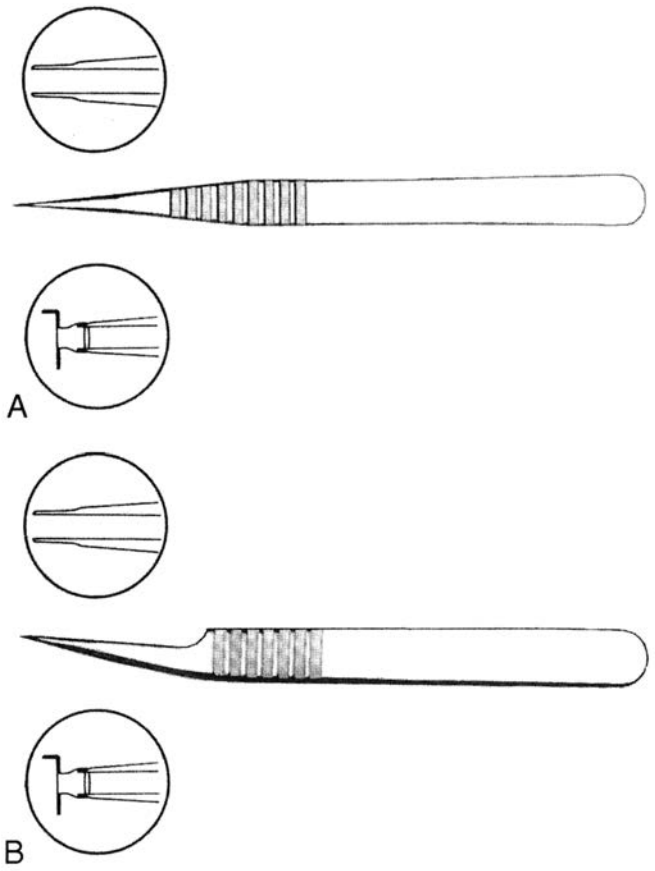

Figure 8-3. Vessel dilators have smooth, nontapered tips that are inserted into the vessel lumen and are opened gently to dilate the vessel. **A.** No. 3 jeweler's forceps modified for use as a vessel dilator. **B.** Another vessel dilator with angled tips.

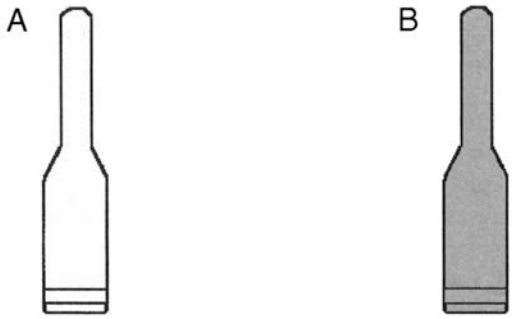

Figure 8-4A and **B**. Vessel clamps are precisely manufactured to provide adequate pressure to occlude blood flow without damaging the vessel.

The approximating clamp facilitates retraction and reapproximation of vessels for suturing. The purpose of the approximator clamps is to decrease the amount of tension between two vessels being anastomosed, thereby allowing for atraumatic vascular anastomosis. An approximating clamp is composed of two microvascular clamps joined by a connecting bar. The clamps may be movable along the connecting bar to allow for the distance between vessels to be adjusted (Figure 8-5) or fixed in position to the connecting bar, a position requiring that the clamps be placed at the appropriate distance along the vessels because the interclamp distance cannot be adjusted. The entire clamp should fit in the operating field, yet be large enough to be easily maneuvered and turned over for suturing both sides of the vessels. The Acland framed nonmovable approximator clamps have two cleats on the frame that facilitate vessel anastomosis, especially when a surgical assistant is not available (Figure 8-6). Because they are expensive microvascular instruments, extreme care should be taken when cleaning and storing microvascular clamps and approximator clamps to prevent damaging them.

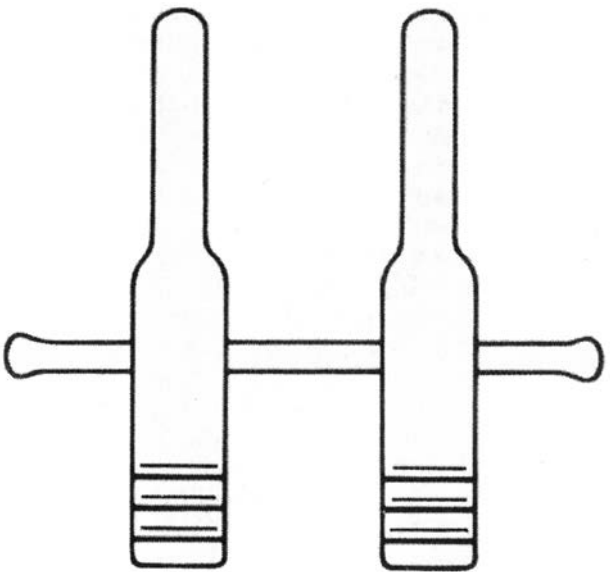

Figure 8-5. This vessel approximator clamp consists of two vessel clamps that are movable along the bar. Vessels to be anastomosed are placed one in each clamp; then the distance between the vessel ends can be adjusted.

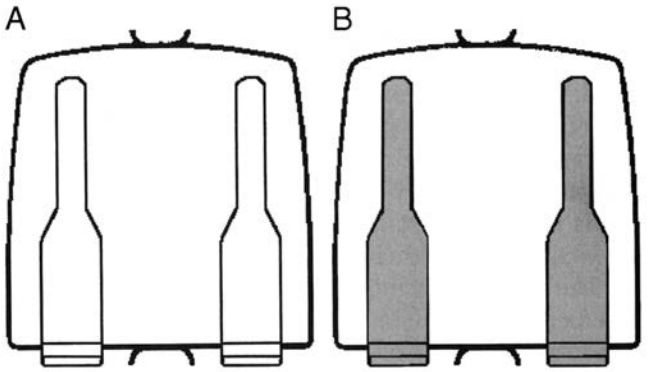

Figure 8-6A and **B**. Another vessel approximator clamp in which the clamps do not move along the bar. With this type of clamp, the vessels must be positioned precisely to allow the ends of the vessels to be sutured because the distance between them cannot be adjusted.

Coagulators

Hemostasis is essential for creating a clear field for microvascular surgery. Because of the magnification required to perform surgery, even small amounts of blood can obscure the operating field making surgery virtually impossible. Unipolar coagulators damage surrounding tissue because the current passes from the cautery tip, through surrounding tissues, into the patient, and out to the ground plate. This dissipation of current and associated heat generation can damage the parent vessel of interest. Bipolar cautery has the advantage that both current and heat are only produced in the small space between the tips of the coagulating forceps. This restricts the amount of tissue damage, yet it provides for accurate hemostasis. A thin layer of sterile petrolatum applied to the tips of bipolar cautery forceps helps to prevent charred tissue from adhering to the tips of the forceps. If bipolar coagulation is not available, jeweler's forceps can serve as cautery forceps. Although this application is monopolar, it is more precise and minimizes the amount of lateral heat and damage to adjacent tissues compared with the standard cautery pencil.

The amount of cautery used in microsurgery should be kept to a minimum, to avoid damage to vessels or other important structures that may be in the vicinity of the operating field. For vessels larger than 1.5 mm in diameter, hemostatic clips are effective in achieving hemostasis without damaging adjacent structures. Clips are used judiciously because too many hemostatic clips can interfere with the surgical procedure.

Suction

Vacuum suction is an optional tool in microvascular surgery. If mechanical suction is used, care must be taken to avoid contact with vessels or nerves. Endothelial damage from suction can lead to complete thrombosis of the vessel and surgical failure. Standard suction tips are generally too large for microsurgical application. A 20-gauge catheter may be connected to appropriately sized Silastic tubing and connected to the suction unit to create a fine tipped suction device. A small fenestration created in the Silastic tubing allows the surgeon some control over the strength of the vacuum. The surgeons' finger is placed over the hole to occlude the fenestration partially or completely, thereby adjusting the amount of suction at the catheter tip. This control over the strength of suction aids in minimizing vascular injury. Sterile applicators can also be used for fluid absorption, but care must be taken to avoid damaging vessels or nerves.

Irrigators

Irrigation of the wound is essential in microvascular surgery to decrease the amount of desiccation caused by the intense light source of the operating microscope. Irrigation is also used to remove clots and to float the vessel edges apart. Standard irrigation syringes are too bulky and flood the microsurgical field. A simple irrigator can be made for microsurgery using a 10-ml syringe attached to a 20-gauge needle or catheter using either saline or heparinized saline. Irrigation is applied in a gentle stream. The catheter tip is not inserted into the vessel, to avoid damaging the vascular endothelium.

The Bishop-Harmon anterior chamber irrigator is used extensively in ophthalmic surgery and is applicable to microvascular surgery. Many cannulas are available and the advantage of this system is that it is easier to operate and to control the flow of the fluid with the small bulb than with a syringe.

Background Material

When performing microvascular surgery, a background is used to set the vessels out from surrounding structures. Background material is placed behind the structures of interest to improve their visualization through the operating microscope. Various colors are advocated to maximize visualization of the structures of interest. Use of dark colors, such as green or blue, enhances visualization of the artery and the vein, as well as the suture material. Background materials are commercially available, but a rectangular section of a balloon can be sterilized and used as an inexpensive background.

Counterpressor

Counterpressors are used to avoid suturing the opposite wall of a vessel during a vessel anastomosis. When the surgeon passes the needle through the vessel wall, counterpressure must be applied, or the wall is pushed away. The counterpressor provides resistance for passing the microneedle. The instrument must be sturdy, small enough to fit in a vessel, and easily maneuverable. The counterpressor has either a circular or a double-pronged tip, so the microneedle can be passed through the circle or between the tips. A counterpressor can be constructed by twisting 34-gauge wire onto itself, creating a tiny loop at the end. The free end is connected to a disposable tuberculin syringe or a metal bar to serve as a handle.

Maintenance of Instruments

Microvascular instruments are delicate and easily damaged. Extreme care is exercised when cleaning and storing instruments. After use, instruments are soaked in warm water containing a commercially available enzymatic cleaner, rinsed in distilled water, and air dried. Ultrasonic instrument cleaners offer the best way of cleaning microinstruments. Care should be taken when instruments are dried with a cloth, because

the delicate tips of the microinstruments bend easily. After the instruments are thoroughly cleaned and dried, tipped instruments should be covered with rubber tubing to protect them from bending. Because of the amount of electrical instrumentation in the operating room, microinstruments become magnetized, causing the microneedle to become attracted to clamps and other instruments during surgery. This problem is prevented by subjecting the instruments to a demagnetizer coil before packing and autoclaving takes place.

Storage boxes should contain specially shaped, trough like receptacles made of foam to prevent damage to instruments. Instruments must not be stored where they are in direct contact with metal or other instruments. Gas is the preferred method of sterilizing micoinstruments because steam damages the instruments over time.[1-3]

Microvascular Suture

The creation of microsuture enabled surgeons to anastomose vessels with a diameter of 1.0 to 2.0 mm. The microvascular needle consists of a point, blade, and body, and swage. The needle may be straight or curved, and the curve may be one-half, three-eights, one-fourth circle, or progressive. A 3-4 mm length needle is used most commonly. The diameter of the needle is important because it is directly related to the amount of trauma the needle inflicts on the vessel. Most microneedles contain a tapered point, which is the least traumatic to tissue. Currently, flat needles are used almost exclusively because the flat needle is more secure in the needle holder than a round needle, which can roll between the microneedle holder jaws. The needle may be made from carbon steel, stainless steel, or other metal alloys, with carbon steel being the strongest and least malleable.

Nylon is the most commonly used suture material in microvascular surgery.[1,2] It is smooth; allowing it to glide easily through tissue, and it has a high tensile strength while causing minimal tissue reaction. The major disadvantage of nylon is that additional throws may be needed to ensure knot security. The most commonly used suture in microvascular surgery is 10-0 nylon on a tapered needle.[4]

Vessel Preparation and Anastomosis

In veterinary medicine the long-term patency of microsurgically anastomosed vessels in the dog is approximately 93 to 95%.[5-7] Performing a microsurgical anastomosis of an artery or a vein has three steps: 1) vessel preparation; 2) vessel anastomosis; and 3) evaluation of vessel patency.

Vessel Preparation

Vessel preparation is one of the most critical steps in performing a microvascular anastomosis. Vessel preparation includes proper alignment of the vessel in the approximator clamp, vessel irrigation, trimming the adventitia from the end of the vessel, and vessel dilation. The ends of the vessels must be properly oriented in the approximator clamp to ensure that the vessels are not twisted following completion of the anastomosis (Figure 8-7). Blood should be flushed from the vessel lumen flushed, using

Figure 8-7. Vessel ends placed in an approximator clamp.

heparinized saline delivered with a #22 angiocath. This procedure prevents blood located at the ends of the vessels from developing into a thrombus (Figure 8-8). To prepare the vessels, 2-3 mm of adventitia is removed from the end of each vessel. Adventitia is removed with jeweler's forceps or microsurgical forceps and microscissors under 10-16x magnification. Once the adventitia is draped over the vessel end, a small hole is made in the adventitia with microsurgical scissors, and one blade of the scissors is placed into this hole (Figure 8-9). The scissor blade is moved adjacent to the attachment of the adventia on the vessel, and the adventitia is excised around the circumference of the vessel wall. This prevents adventitia from being caught in the lumen during anastomoses. The framed approximator clamp is then applied, bringing the two ends of the vessels close enough so that there is little tension during the anastomosis. It is important to remember that the clamps will be flipped after the near side of the anastomosis is complete. Vessel spasm can be reversed with topical lidocaine or gentle dilation. Vessel dilation results in temporary paralysis of the smooth muscle in the vessel, thereby preventing vasospasm at the anastomotic site (Figure 8-10). Dilating the vessel also helps to increase the overall diameter of the lumen and helps delineate the near and far wall of the vessel.

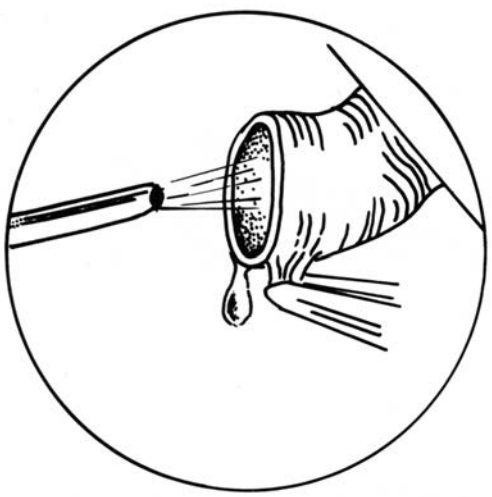

Figure 8-8. Irrigation of vessel ends to remove intraluminal blood.

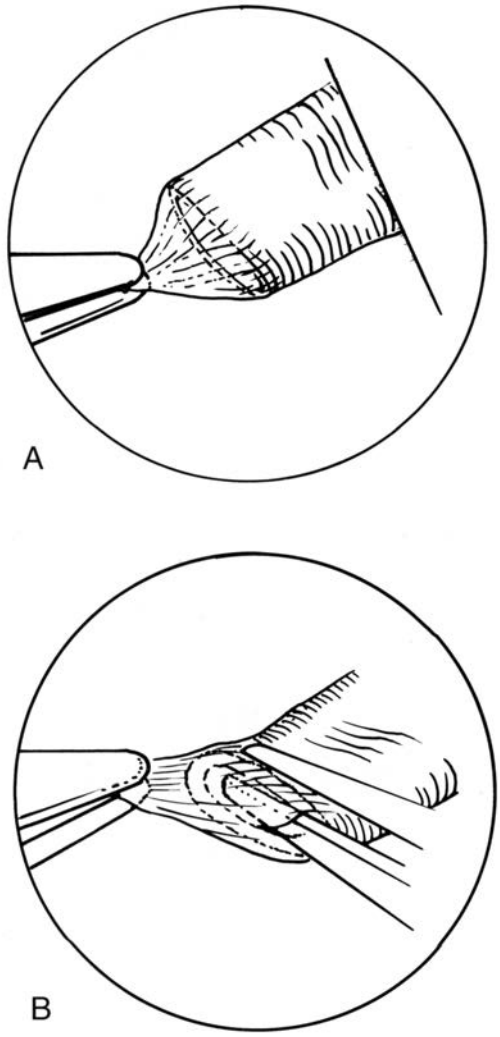

Figure 8-9. A. The adventitial skirt is drawn over the vessel end with a pair of forceps. **B.** The adventitia is then excised.

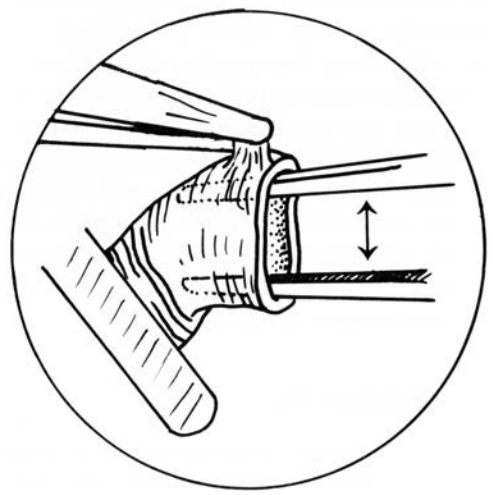

Figure 8-10. Vessel dilation is performed to prevent vasospasms and to improve definition of the vessel lumen.

Preparation of veins is technically much more difficult than arteries due to the relative thinness of the venous wall. Special care must be taken when removing the adventitia of a vein because inadvertent damage to the tunica media may result, thus weakening the vessel. Irrigating the end of a vein with a 22-gauge catheter will help in identifying the lumen of the vessel and the adventitia. Thin-walled veins may be prepared by submerging the vessel in a pool of saline to improve visualization of the vessel lumen.[3]

End-to-End Vessel Anastomosis

The end-to-end vascular anastomosis is usually performed by using a full thickness simple interrupted pattern with 10-0 nylon on a 100 µm flat-bodied needle. The ends of the vessels are aligned in the approximator clamp to create a 1 to 2 mm gap between the vessel ends. A background may be placed behind the approximating clamps to improve visualization of the vessels and suture material. The needle is grasped using a two-handed technique by grasping the suture with one hand and the needle with the other. The needle is held just beyond its midpoint, 1-2 mm back from the end of the needle holder. Three guide sutures are placed 120° apart, two on the near vessel wall, and one in the far vessel wall (Figure 8-11). The suture tags are left long to help manipulate the vessels with minimal trauma during the anastomosis procedure. It is imperative that the guide sutures be accurately placed, as sutures not exactly 120° will result in twisting at the anastomotic site. With the guides in place, equal numbers of interrupted sutures are placed between each guide suture. Counterpressure may be applied adjacent to the intended exit site of the needle to aid in passage of the needle through the vessel wall (Figure 8-12). Enough sutures are placed so that there is no anastomotic leak. Usually a total of 9 sutures are necessary for the average size artery. Needle placement must be accurate and symmetric. The needle entry point should be twice the thickness of the vessel wall away from the edge and symmetrical entry should be taken on the opposite edge. Uneven placement leads to vessels overlapping and thrombus formation. Needle placement should utilize a two-handed action under 20x to 30x magnification. The needle lumen is cannulated with micro-forceps or in larger vessels the adventitia is grasped to provide

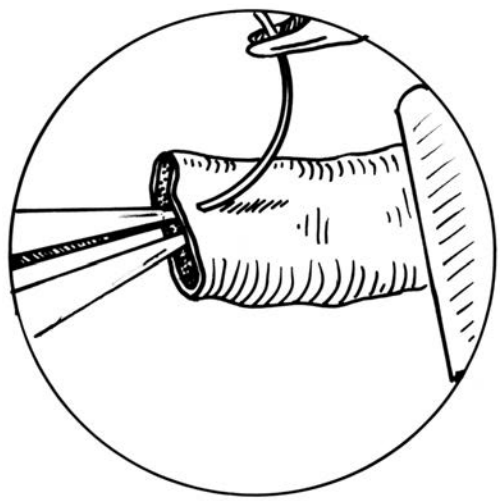

Figure 8-11. Atraumatic manipulation of the vessel wall is performed by inserting the tips of a pair of forceps into the vessel lumen.

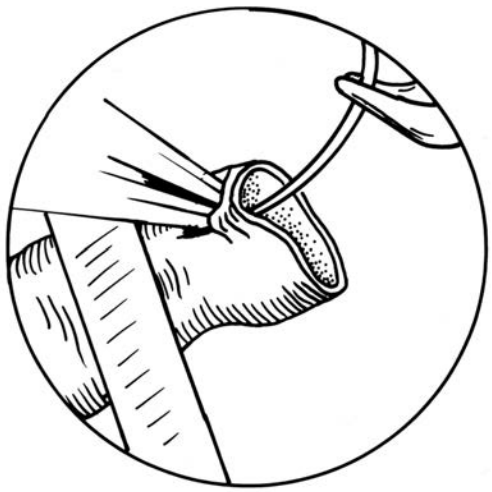

Figure 8-12. Counterpressure is applied adjacent to the site of exit of the needle to facilitate passage of the needle through the vessel wall.

counter pressure as the needle is advanced through the vessel wall. After the needle penetrates the wall, the needle is pulled along its arch. A two-pass technique is used, unless the vessel edges are approximated. Tying the suture correctly also impacts on the likelihood of vascular patency. Knots need to lie flat and the proper amount of tension must be applied each time. Excessive tension damages the vascular intima while inadequate tension hampers proper vessel approximation. Surgeon's knots are thrown first, followed by a simple square knot. After the near vessel wall is sutured, the clamp is flipped, and the process is repeated on the far vessel wall. Veins are anastomosed in a similar fashion but extreme care must be taken since the walls of veins are delicate and easily torn by suture material. A continuous suture pattern provides the same accuracy and versatility as a simple interrupted suture pattern[8-10] and is significantly faster and associated with less anastomotic leakage.[9] However, a continuous pattern significantly narrows the vessel lumen. As a result, a continuous suture pattern should be avoided in arteries with a vessel diameter greater than 0.7 mm in diameter and in veins with a diameter greater than 1.0 mm in diameter.[9] The main application of the continuous suture pattern is for end to side anastomoses performed on large arteries and veins.

Release and removal of the microvascular clamps should be completed in the same order each time. Once both anastomoses are completed the anastomoses are irrigated with a 1% lidocaine solution and the clamp release is started. The arterial clamp is released first, then the venous clamp. This eliminates misinterpreting venous backflow for adequate arterial inflow. Some leakage may occur at the anastomosis, and usually stops with direct pressure. Continued bleeding will occasionally occur and requires additional suture placement.

End-to-Side Anastomosis

Careful placement of sutures can accommodate disparities in vessel luminal diameters of up to 2:1.[11] The technique involves placing interrupted sutures farther apart on the larger vessel. When vessel diameter differences of 2:1 or 3:1 occur, beveling or spatulation of the vessel with the smaller luminal diameter is advisable.[3,12] When beveling an edge, the oblique cut should not be more than 30° in order to avoid turbulence. Spatulation is performed by creating a longitudinal incision in the cut end of the smaller vessel. When vessel discrepancy exceeds 3:1, end to side anastomosis is required.

End-to-side anastomosis is performed when there is a large vessel diameter mismatch. In order to minimize turbulent flow at the anastomosis site, the angle between the donor and recipient vessel should be as small as possible. Angles less than 60° are preferred. The angle of anastomosis can be decreased by spatulating or beveling the vessel with the smaller diameter. To prepare the recipient vessel, an approximator is placed on the isolated side of the recipient vessel and the adventitia is removed from the proposed arteriotomy site. A properly sized arteriotomy forcep is placed on the recipient vessel and a Dennis blade is used to gently cut the portion of artery held by the arteriotomy forcep or a stay suture technique can be used to create the arteriotomy (Figure 8-13). A single clamp is placed on the donor vessel and the adventitia is removed. Intraluminal blood from both the donor and recipient vessel is flushed with heparinized saline to prevent thrombus formation. Unlike the end to end technique, there are only two guide sutures, each placed 180° apart. The intervening sutures are placed as usual using a continuous or interrupted suture pattern.

Evaluation of Patency

Patency of a vascular anastomosis can be tested in a variety of ways. Venous patency is easily assessed when the vessel is translucent. Direct observation of expansive arterial pulsation is a reliable indicator of patency, whereas longitudinal pulsation usually signifies partial or complete obstruction. In free tissue transfer, examination of the arterial bed of the transplanted tissue flap for pulsation and evaluation of the cut surface of the flap for capillary bleeding can document arterial patency.

The chance of vessel thrombosis is greatest at the site of anastomosis 15 to 20 minutes following completion of the anastomosis. It is therefore advisable to observe the anastomosis and test vessel patency during this period of time. If partial obstruction occurs, gently squeezing the vessel with forceps, or massaging the vessel may break up the thrombus. A complete thrombosis necessitates resection of the damaged area, and repeating the anastomosis. Vascular thrombosis is most commonly due to technical error in suture placement, or the use of a vessel with a damaged intima. Venous rather than arterial thrombosis is the most common cause of flap failure. The thinner venous wall makes the anastomosis more fragile, more compressible, and more likely to twist and kink. After the first 20 minutes, postoperative days 1-3 are also critical for anastomotic patency. In most cases, a flap that is viable at day 5, will likely survive.

Anastomotic Devices

Anastomotic coupling devices may be used in place of hand suturing for microvascular anastomosis. Anastomotic devices reduce anastomotic time by 50%-75%, and have patency rates similar to hand suture techniques.[13,14] The device performs well on thin-walled vessels of similar size, but can cause vessel intimal

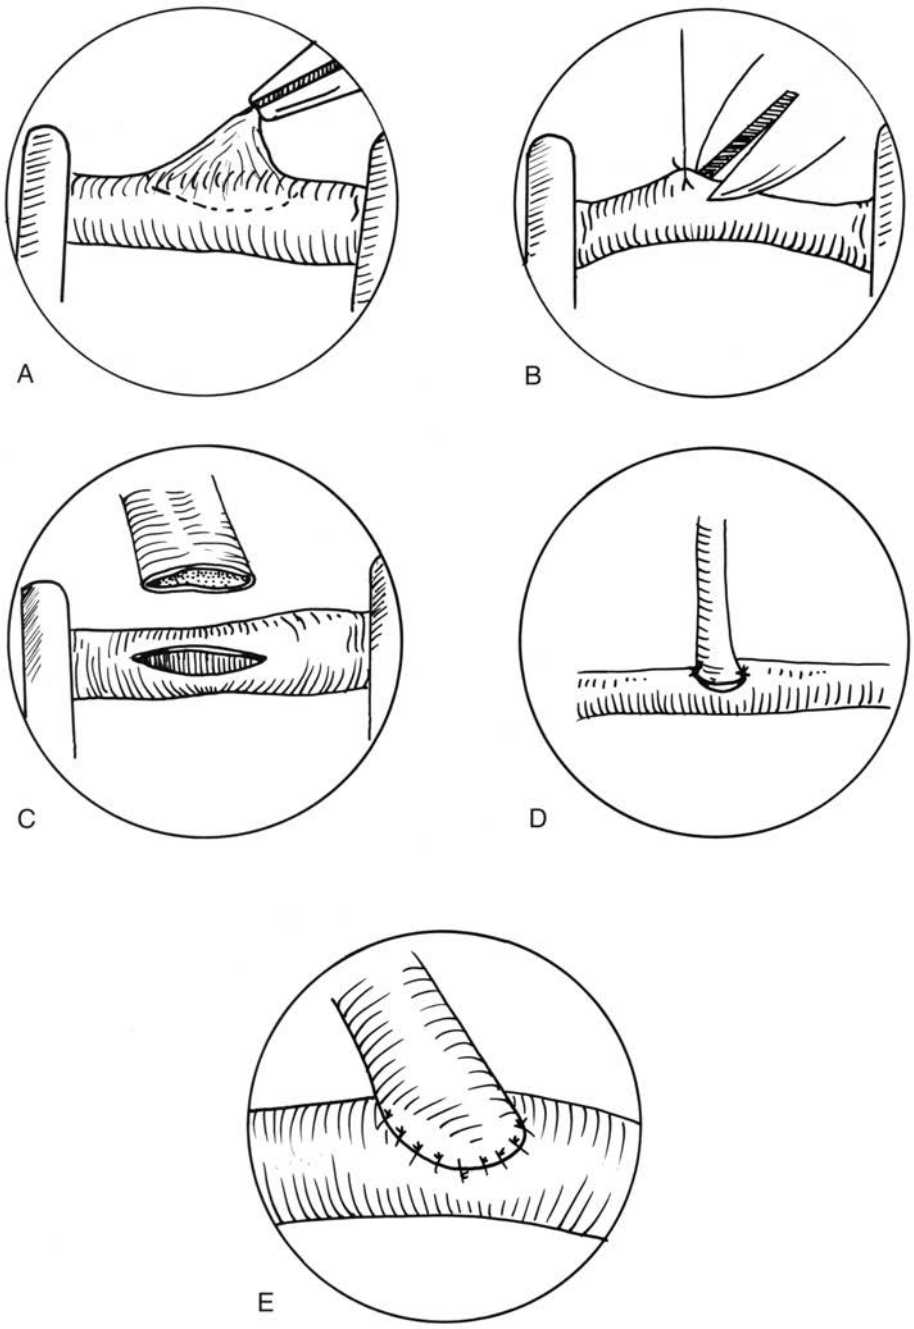

Figure 8-13. End-to-side anastomosis. **A.** The adventitia is removed from the vessel. **B.** A stay suture is placed in the wall of the vessel, and the arteriotomy is performed. **C.** The diameter of the arteriotomy site should approximate the diameter of the "end" vessel. **D.** The first two sutures are placed 180° apart to position the vessels for the anastomosis. **E.** The sutures are placed perpendicular to the anastomotic line in a radiating fashion.

damage on thick-walled arteries. Because of the increased risk of technical errors associated with performing a suture microvascular venous anastomosis a coupling device is routinely used and recommended when performing the venous anastomosis. Some familiarity with the device is necessary for success, but the technique can be quickly learned. The coupling device consists of a pair of polyethylene rings with six small pins on one side of each ring. The anastomosis is performed by pulling the end of the vessel through the ring and impaling the wall of the vessel over the six pins. The other end of the vessel is also impaled on the pins of the second ring, and the two rings are precisely joined together with an anastomotic instrument. This device provides a secure anastomosis with intima-to-intima contact which in turn improves patency and reduces the chance of thrombosis (Figure 8-14). A second major advantage to using a coupling device is shortened overall procedure time which decreases the overall ischemia time of tissue when compared to hand suturing.[13-15] Anastomotic couplers come in sizes of 1.0 mm, 1.5 mm, 2.0 mm, 2.5 mm, and 3.0 mm diameter.

Free Skin Flaps

Microvascular free skin flaps can be used to reconstruct wounds in almost any location on the body. Some of the described axial pattern skin flaps can be used for this purpose.[16] The requirements for an axial pattern tissue flap to be used as a free flap include a

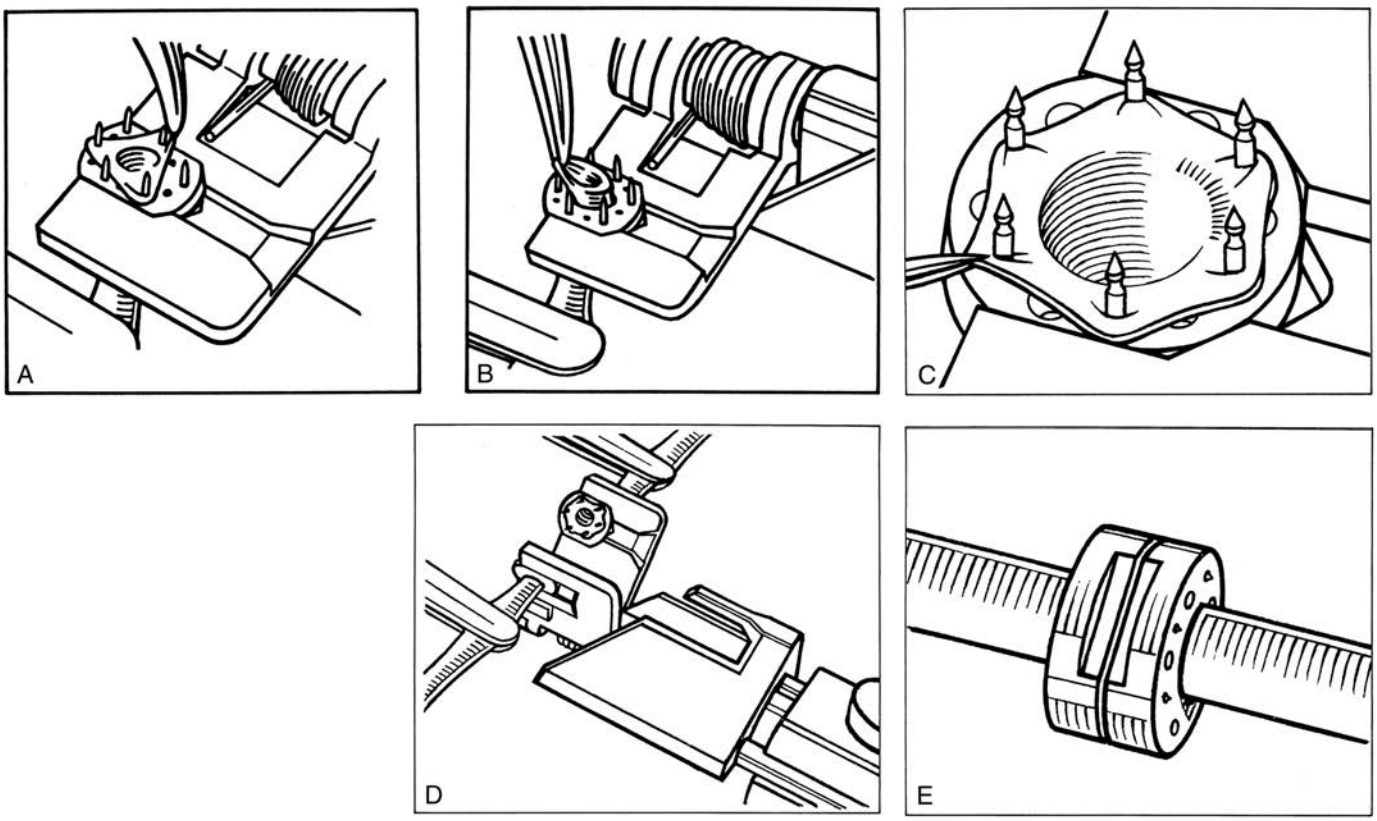

Figure 8-14. Anastomotic coupling devices can be used to anastomose vessels instead of hand suturing. **A-C.** The vessel is drawn through the lumen of the anastomotic ring device, and the vessel wall is implanted on alternate pins of the ring. **D** and **E.** The ends of the vessels are approximated by precisely mating the anastomotic rings together with the anastomotic instrument.

1 mm pedicle vessel diameter and a 2 to 4 cm vascular pedicle length. Generally, the longer the vascular pedicle, the easier it is to perform the vascular anastomosis. As a result, the omocervical, thoracodorsal, deep circumflex iliac, caudal superficial epigastric, and the medial saphenous fasciocutaneous flaps could be used in free tissue transfer. The skin flaps that are most commonly used for this purpose are the medial saphenous fasciocutaneous and omocervical cutaneous free flaps.[5-7,17-21]

Blood Supply Patterns

The skin has two sources of blood supply. In dogs and cats the predominant blood supply is from direct cutaneous arteries. These arteries typically perfuse a very large section of skin. Over the torso they exit the body wall and lie in the well-developed panniculus carnosus muscle known as the cutaneous trunci muscle. In other areas of the body where the panniculus is absent (extremities), the cutaneous arteries run in the subcutaneous fascial layer.[22]

The direct cutaneous artery divides into a network of branches, similar to a tree trunk and its numerous branches. All of the tissues that are supplied by this single artery are called the primary angiosome. Other angiosomes called secondary angiosomes are connected to the primary angiosome by choke vessels (Figure 8-15). The skin within the primary angiosome will consistently survive; likewise a large portion of the secondary angiosome usually will survive. Extending the flap into the tertiary angiosome leads to inconsistent survival.[22] Since vessels cannot be visualized on the surface of the skin either mapping of the vasculature with Doppler or the use of deep anatomic landmarks are used to define the angiosome of a skin flap. One precautionary note is that the skin of dogs and cats is loose over the torso and may shift during positioning of the patient on the operating table; this will shift the angiosome relative to deep anatomical landmarks. In order to correct for this problem, the skin should be grasped, pulled upward, and then allowed to relax back in position. This should reposition the skin relative to deep anatomical landmarks.

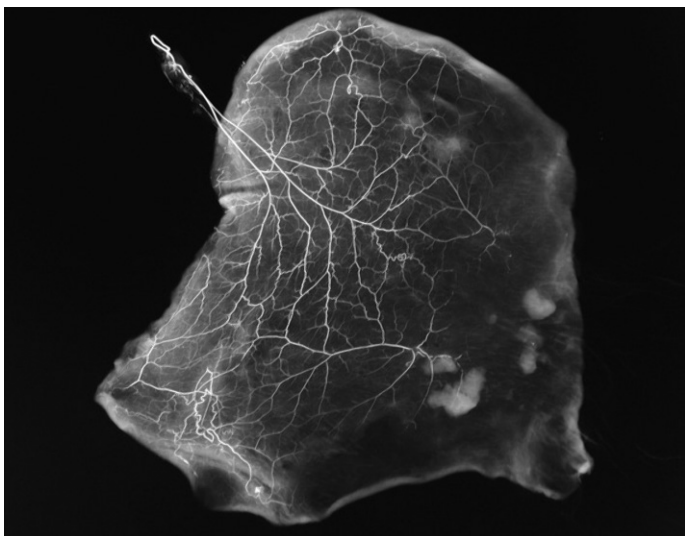

Figure 8-15. Angiogram of a deep circumflex iliac flap from a cat demonstrating a primary (1), secondary (2) and tertiary (3) angiosome.

Another useful technique to identify the angiosome when elevating a skin flap is to use a transillumination technique. As the skin is dissected off the underlying muscle, it is elevated and illuminated with an operating lamp on the epithelial side of the flap and inspected from the subcutaneous side. The vessels can be easily visualized through the skin. Use of this technique will aid in preventing damage to the perforatoring vessels of the skin.

Omocervical Free Skin Flap[7,18-21]

The flap tends to have a substantial amount of subcutaneous fat associated with the skin. As a result, it is best suited for wounds located at the level of or proximal to the stifle; it can also be used for wounds in the forelimb that are located at the level of or proximal to the antebrachial region. If the dog is very lean, the flap likewise will be very thin and can be used in any location on the body. The flap has a thick coat of hair which makes it suitable for reconstruction of a highly visible region.

Flap Designs

- Simple skin flap
- Myocutaneous - skin flap and the cervical portion of the trapezius muscle
- Osteomyocutaneous - skin flap, the cervical portion of the trapezius muscle, and the spine of the scapula

Blood Supply

The blood supply of the omocervical free skin flap arises from the cutaneous branch of the superficial cervical artery and vein. These vessels penetrate the fascia between the omotransversarius and the cervical portion of the trapezius muscles. The superficial cervical artery and vein have 7 named branches, most of which supply the adjacent muscles. The prescapular lymph nodes are intimately associated with the vessels as they traverse medial to the aforementioned muscles. This is in the region of the cranial shoulder depression, which is easily palpated cranial to the scapula. In a large breed dog, the vascular pedicle of the flap is about 5 cm long and the diameters of the artery and vein are about 1.5 mm and 4 to 5 mm, respectively. The vein is very thin walled which can make it more challenging to work with during microvascular anastomosis to a recipient vein. One should be aware that the vascular pedicle does not always course under the omotransversarius, but may travel superficial to it (Figure 8-16). This variant was reported in 1 dog and described in another 2 dogs.[17]

Anatomic Boundaries

The cutaneous anatomical boundaries of the angiosome of the superficial cervical artery include the wing of the atlas cranially, dorsal midline, spine of the scapula caudally, and the acromion of the scapula ventrally. The axis of the cutaneous vessels is oriented in a caudoventral to craniodorsal direction, therefore the outline of the flap should be oriented in this direction (Figure 8-17).

Procedure

The cervical region in some dogs can be laden with fat. This makes the dissection of this flap very difficult. In order to prevent damage to the vascular supply during the dissection of the flap,

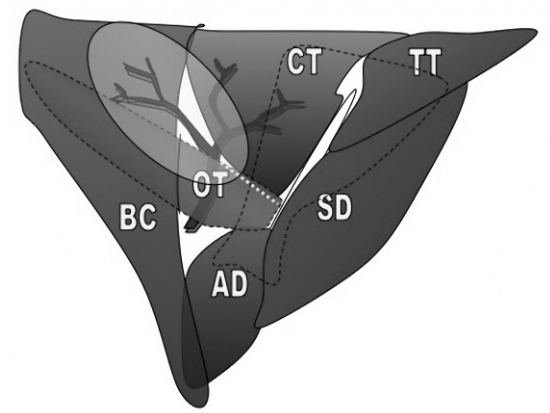

Figure 8-16. Lateral view of left shoulder. Take note of the typical pathway (left figure) of the superficial cervical vessels (deep to omotransversarius) versus the anomalous (right figure) path of the vessels (superficial to the omotransversarius muscle). Abbreviation key: *CT*=cervical part of trapezius muscle; *TT*= thoracic part of trapezius muscle; *SD*=spinous head of deltoid muscle; *OT*=omotransersarius muscle; *BC*=brachiocephalicus muscle; *AD*=acromial head of deltoid muscle.

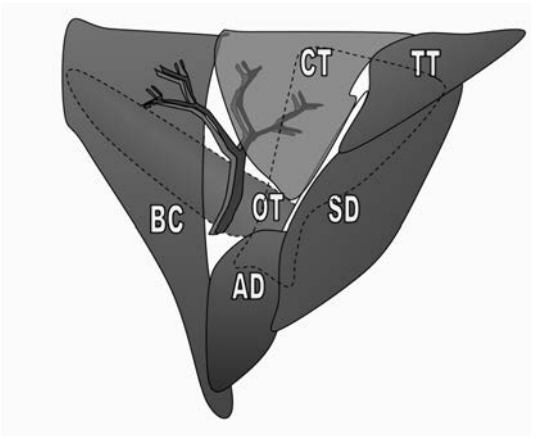

Figure 8-17. Lateral view of left shoulder depicting the location of the omocervical free flap. Abbreviation key: *CT*=cervical part of trapezius muscle; *TT*= thoracic part of trapezius muscle; *SD*=spinous head of deltoid muscle; *OT*=omotransversarius muscle; *BC*=brachiocephalicus muscle; *AD*=acromial head of deltoid muscle.

the underlying fat should be elevated with the skin. After the skin has been incised around the entire circumference of the proposed flap, the caudal border of the flap is dissected until the intermuscular septum between the cervical portion of the trapezius and the omocervical muscle is identified. The dissection then continues along the dorsal border in a ventral direction.

The fascia between the cranial border of the cervical part of the trapezius and omotransversarius is incised to the level of the acromion, which exposes the superficial cervical artery and vein. The cutaneous branches are visualized and the remaining portion of the skin flap is dissected free from the muscles. The muscular branches of the superficial cervical vessels are ligated and divided. The fat surrounding the vessels is carefully removed (skeletonized) in order to decrease pedicle bulk of the pedicle.

Careful removal of adventitia at the proposed site of vein transection when it is distended with blood can make this

process more easily performed, than after the vessel has been transected and deflated. After the vessels have been isolated as far down the pedicle as possible, they are occluded with microvascular clamps, ligated distal to the clamps, and transected.

The wound is closed in layers in order to minimize dead space. It is advisable to place a closed suction drain in the wound for 3 to 5 days, as seroma formation is a common complication in this highly mobile region. The recipient site is protected with a soft padded bandage. The bandage is changed daily as abundant serosanquinous discharge is expected.

The flap is transferred to the recipient wound. Care is taken to ensure that the vascular pedicle is not twisted. The skin flap is then tacked in place with a few sutures in order to ensure proper orientation of the hair (if possible) and vascular pedicle. Microvascular anastomosis of the artery and vein of the flap to recipient vessels is performed.

Medial Saphenous Fasciocutaneous Free Flap[5,6]

Uses

This flap is relatively thin therefore it is useful for reconstruction of wounds located on the distal extremities and face. The flap is somewhat sparsely haired in some dogs and the client must be informed about the potential for less hair at the recipient site.

Flap Designs

- Simple skin flap
- Myocutaneous - skin flap and the distal half of the caudal head of the sartorius
- Osteomyocutaneous - skin flap and distal half of the caudal head of sartorius and medial tibial cortex
- Osteocutaneous - skin flap and medial tibial cortex

Blood Supply

The blood supply to this flap comes from the saphenous artery and medial saphenous vein (Figure 8-18). Proximally, these vessels lie under the caudal aspect of the caudal head of the sartorius, then enter the superficial fascia at the level of the distal femur.

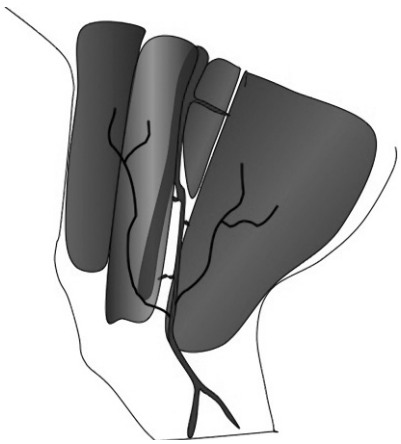

Figure 8-18. Medial view of vessels of the right hindlimb. Take note of the two muscular branches that penetrate the caudal head of the sartorius and one branch that enters the cranial aspect of the gracilis.

There are two cutaneous perforators that perfuse the medial saphenous fasciocutaneous flap: a cranial branch and a caudal branch (Figure 8-19). Cadavaric studies have confirmed that the skin on the entire medial aspect of the femorotibial region from the level of the inguinal ligament to the distal tibia is perfused by segmental fascial perforators of the saphenous artery. Two muscular branches are found proximal to the cutaneous branches: one to the distal gracilis muscle and the other to the distal sartorius muscle. The distal 1/2 of the caudal head of the sartorius is consistently perfused by the saphenous artery. The gracilis muscle is not well perfused by the saphenous vessels, as its dominant blood supply is based on the proximal caudal femoral artery and vein.

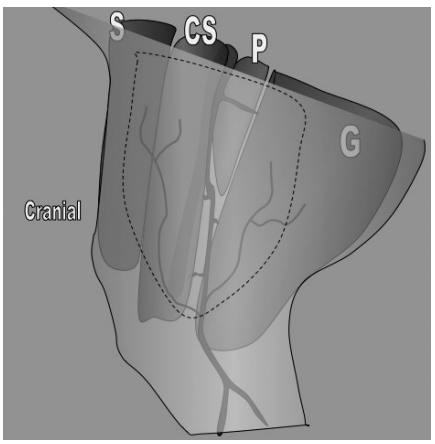

Figure 8-19. Medial view of right thigh. Take note of the two cutaneous perforators that perfuse the medial saphenous fasciocutaneous free flap. Abbreviation key: *Cr*=cutaneous perforator of the medial saphenous flap; *Ca*=caudal perforator of the medial saphenous flap; *S*=cranial head of sartorius muscle; *CS*=caudal head of sartorius muscle; *P*=pectineus muscle; *G*=gracilis muscle.

Anatomic Boundaries

The medial saphenous fasciocutaneous free flap generally is based on the proximal two cutaneous branches. If a smaller flap is needed, it can be based on either the cranial or caudal cutaneous branch. The most proximal cutaneous branch supplies the caudal half of the flap and the second cutaneous branch supplies the cranial half of the flap. There may be some variation of the location where the first two cutaneous branches originate off the medial saphenous vessels, thus care must be taken when elevating the flap. The flap generally is centered over the thigh region with the proximal most aspect of the flap being at the junction of the thigh and abdomen. The flap should not be centered over the stifle as this may increase the risk for incisional dehiscence.

Procedure

The proximal, cranial and caudal borders of the flap are incised and the flap is elevated. A transillumination technique is used to identify the cutaneous perforators of the flap. The distal border of the flap should be incised last, as the cutaneous vessels may extend off the parent vessels in a more distal location than expected. Next, the saphenous artery and medial saphenous vein distal to the cutaneous perforators are isolated, ligated and divided. The saphenous vessels are dissected from their fascial

attachments between the gracilis and the sartorius muscles. The gracilis muscular branch of the saphenous vessels is ligated and divided. Two muscular branches of the saphenous vessels entering the caudal head of the sartorius muscle are ligated and divided. The pedicle is then completely isolated to the level of the femoral vessels.

The vessels are ligated at the level of the femoral vessels, occluded with microvascular clamps just distal to this region, and sharply divided. The medial saphenous nerve, which is sacrificed at the time of the vessel dissection, is injected with bupivacaine (Figure 8-20). The donor site is closed in two layers: subcutaneous fascia and the skin. A drain is usually not placed in the donor site.

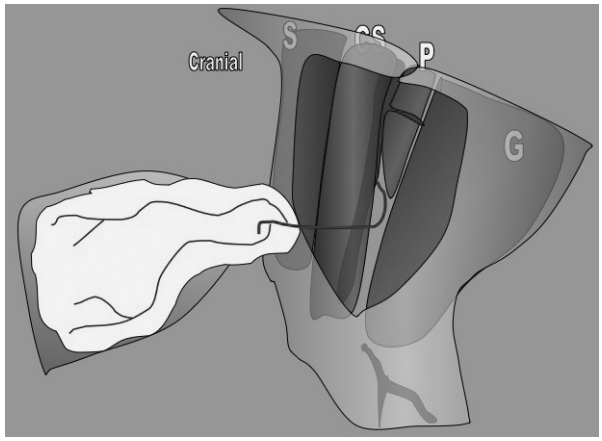

Figure 8-20. Medial view of right thigh. The saphenous artery and medial saphenous vein have been ligated and divided distal to the cutaneous perforators of the medial saphenous fasciocutaneous flap. Abbreviation key: *S*=cranial head of sartorius muscle; *CS*=caudal head of sartorius muscle; *P*=pectineus muscle; *G*=gracilis muscle.

A number of precautions should be taken in order to decrease the risk of donor site wound dehiscence:

- The maximum width of the flap should not be greater then 6 cm in a large breed dog; if the flap needs to be wider, harvest a much longer flap as the length of the flap will translate into greater flap width.
- Attempt to keep the location of the flap as proximal as possible.
- Flex and extend the stifle to determine the isometric points of tension and temporarily appose the skin edges with towel clamps at the time of wound closure.
- Close the fascia that is attached to the underlying skin edges with a simple interrupted pattern and close the skin with an interrupted intradermal pattern.
- Protect donor site with a modified Robert-Jones bandage for 10 days after surgery.

Table 8-1 summarizes important differences between the medial saphenous fasciocutaneous and omocervical free flaps.

Free Muscle Flaps

Muscle flaps have a number of characteristics which make them ideal for reconstructive surgery. A muscle flap will revascularize a wound bed rapidly and improve the delivery of antibiotics, antibodies, and components of cell mediated immunity to the area. Oxygen tension in the wound bed is increased which inhibits anaerobic infection and promotes healing. A muscle flap can prevent, and potentially help to eliminate osteomyelitis in open fractures. In humans, open tibial fracture osteomyelitis has almost been eliminated as a postoperative complication, with the use of free muscle transfer. Muscle flaps provide a healthy, well vascularized surface for immediate free skin grafting. Muscle flaps conform well to any shape wound bed and they will atrophy to 40% of their original thickness within two months after surgery.

Table 8-1. Free Flap Charactaristics

Flap	Medial saphenous free flap	Omocervical free flap
Thickness of flap	Thin	Thick
Appearance in wound bed	Conforms well	Bulges due to fat
Hair orientation	Good match to distal extremity, at times flap will have incorrect hair orientation	Poor match to distal extremity
Coat thickness	Frequently thinner than native coat of distal limb	Frequently thicker and longer than native coat of distal limb
Muscle within angiosome	Caudal head of sartorius	Cervical part of trapezius
Bone within angiosome	Medial tibial cortex - will survive based on periosteal blood supply	Spine of scapula has questionable survivability
Vascular pedicle length	7 to 10 cm	4 to 5 cm
Vein of pedicle	Thick and easy to work with	Thin and more challenging to work with
Vessel diameters	Adequate for anastomosis	Adequate for anastomosis
Identification of vascular pedicle	Easy	More difficult
Ease of flap elevation	Easy	More difficult
Size of flap	Limited width	Less limitation

The advantage of using a muscle flap over a free skin flap is that the angiosome is contained within the specific muscle; therefore there is no "guess work" as to the location of the blood supply. If the skin is shifted or skewed off important deep landmarks, the flap may not be within the primary angiosome.

Selection of the appropriate muscle for wound reconstruction is important in the preoperative planning. A muscle that is expendable with little functional or cosmetic detriment to donor site function should be used. The muscle should fit the size and shape of the wound. The rectus abdominis muscle is ideal for distal extremity wounds. Due to its length, the blood supply of the rectus can be anastomosed to recipient vessels that are well outside the zone of the wound. The cervical part of the trapezius is also acceptable for distal limb extremity. Its vascular leash is relatively long, however, if trauma to the extremity is extensive and recipient vessel integrity is questionable, it should not be considered as a first choice. The latissiumus dorsi myocutaneous flap is useful for very large wounds that require bulk, but is infrequently used in veterinary medicine in free tissue transfer.

All muscle flaps need a cutaneous covering. There are two options: free skin grafting or creation of a composite flap (myocutaneous). One of the primary disadvantages of using a myocutaneous flap to reconstruct a wound on the distal extremity is that the resultant flap tends to be rather bulky, thus it is cosmetically less acceptable. If the patient gains a significant amount of weight, the flap usually will become bulkier due to deposition of adipose tissue. The second disadvantage of a myocutaneous flap based on the perforator system in dogs is that survival of the skin portion is inconsistent. The survival of the skin pedicle when developed on the axial pattern blood supply is consistent. Skin grafting over the muscle flap is more successful in veterinary patients.

Trapezius Free Muscle Flap[23,24]

Uses

The cervical portion of the trapezius can be used for reconstruction of distal extremity and facial wounds. It is a fairly sizeable muscle flap and can therefore be used to reconstruct moderately large wounds. The muscle may be harvested with the omocervical skin flap to form a myocutaneous flap. This composite myocutaneous flap, however, tends to be very bulky when used for reconstruction of distal extremity wounds.

Blood Supply

The cervical portion of the trapezius muscle is a relatively thin and broad muscle with the superficial cervical artery and vein serving as the dominant pedicle. This muscle is useful for reconstruction of distal extremity and facial wounds.

The cervical part of the trapezius muscle has a type II blood supply. The dominant pedicle consists of the superficial cervical artery and vein which enters the cranial aspect of the muscle. The blood supply within the muscle can be visualized on the under side of the muscle. The vascular pedicle is about 5 cm long and the artery and vein diameters are approximately 1.5 mm and 4 to 5 mm, respectively. Numerous side branches arising from the superficial cervical artery and vein enter the omotransversarius, deltoid, supraspinatus and brachiocephalicus muscles and need to be ligated and divided during the dissection. The pedicle has a relatively thick cuff of fat that can be safely removed in order to skeletonize the vascular pedicles.

Procedure

A skin incision is made 5 cm cranial and parallel to the full length of the spine of the scapula. Next the fascial attachment between the cervical trapezius muscle and the omotransversarius muscle is incised with a pair of scissors (Figure 8-21).

The omotransversarius is retracted ventrally to expose the superficial cervical artery and vein (Figure 8-22). Branches of the superficial cervical artery and vein extending into the omotransversarius, acromial deltoid, supraspinatus and the brachiocephalicus muscles are ligated and divided to free the pedicle. If a skin paddle is not included in the flap design, the direct cutaneous artery and vein are ligated and divided. At this

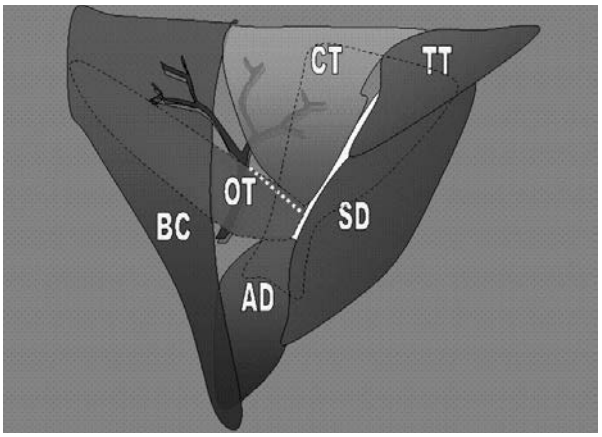

Figure 8-21. Lateral view of the left shoulder region. The dashed line indicates the initial incision that is made between the omotransversarius and the cervical part of the trapezius. Abbreviation key: *CT*=cervical part of trapezius muscle; *TT*= thoracic part of trapezius muscle; *SD*=spinous head of deltoid muscle; *OT*=omotransversarius muscle; *BC*=brachiocephalicus muscle; *AD*=acromial head of deltoid muscle.

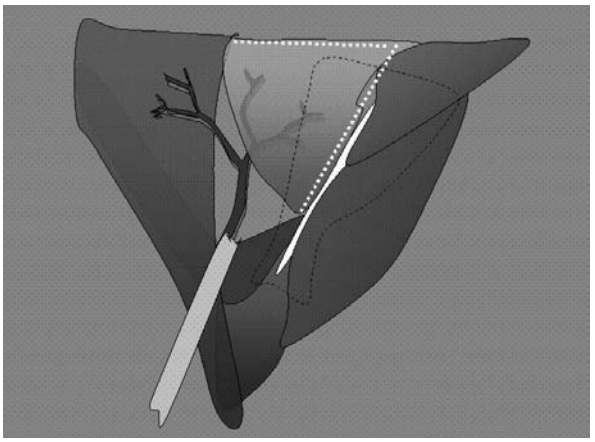

Figure 8-22. Lateral view of the left shoulder region. The omotransversarius muscle is retraced ventrally to expose the superficial cervical artery and vein. The dashed line demonstrates the incision in the origin and insertion of the cervical part of the trapezius muscle.

point the fat and prescapular lymph nodes can be removed from the pedicle using very gentle dissection and ligation of any side branches. The attachment of the trapezius muscle to the dorsal spinous processes and the spine of the scapula are incised. The trapezius muscle is flipped over which will expose the blood supply from the superficial cervical artery and vein (Figure 8-23).

A prominent dorsal venous extension from the superficial vein, beyond the branch that enters the trapezius, is ligated and divided. At this point the entire trapezius should be completely free other than being attached to its vascular pedicle.

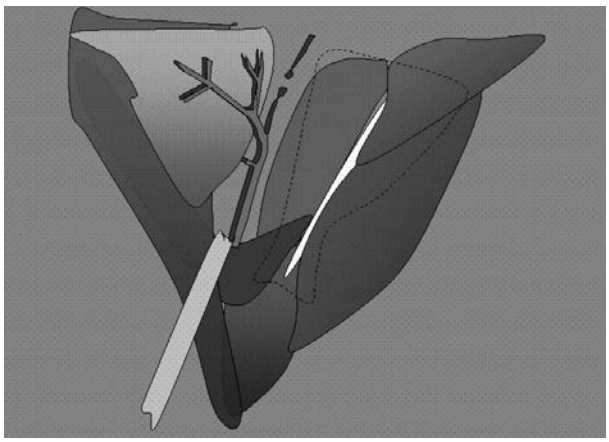

Figure 8-23. Lateral view of the left shoulder region. Following detachment of the origin and insertion of the muscle, the flap is flipped over to expose the blood supply entering the flap.

Rectus Abdominis Free Muscle Flap[25,26]

Uses

The rectus abdominis muscle is very useful for distal extremity, facial, and intraoral reconstruction. Because the flap is long, it can be revascularized to recipient vessels that are distant to the primary wound bed.

Blood Supply

The rectus abdominis muscle is thin and flat and extends from the first rib to the brim of the pelvis. The abdominal portion of the rectus abdominis can be used as a free flap. The muscle has multiple tendinous intersections located along its length. The rectus muscle has a type 3 blood supply. The blood supply to the rectus abdominis is from three sources: the cranial epigastric, caudal epigastric, and segmental lateral perforator arteries and veins. The caudal epigastric vessels join the caudal superficial epigastric vessels from the mammary chain to form the pudendoepigastric vessels. In some dogs the pudendoepigastric vessels are absent, leaving the caudal superficial epigastric and the caudal epigastric vessels to originate directly from the deep femoral artery and the external iliac vein.

The caudal two-thirds of the abdominal part of the muscle is perfused by the caudal epigastric artery and vein. The primary angiosome based on the caudal vascular pedicle extends approximately to the third tendinous intersection. Based on the fact that the caudal pedicle is perfusing a much larger portion of the muscle, a free rectus muscle flap should be based on this set of vessels.

The caudal epigastric artery and vein enter the caudolateral aspect of the rectus abdominis muscle near the inguinal ring. The pedicle is about 2 to 3 cm long, and the artery and vein diameters are 1 mm and 2.5 mm, respectively; by harvesting the pudendal artery and vein, the diameters of the vessels are greatly increased.

Surgical Procedure

A ventral midline skin incision is made from the xiphoid process to the cranial border of the pubis. In male dogs a parapreputial incision is made. The initial skin incision is deepened to the level of the linea alba. Subcutaneous tissues are then dissected off the superficial rectus sheath.

The superficial rectus sheath is incised starting at the external inguinal ring and extended cranially over mid portion of the muscle. The muscle is dissected out of its sheath with a combination of blunt and sharp dissection. Dorsally, the deep rectus sheath, which is less adherent to the muscle is bluntly dissected. Perforators entering the lateral aspect of the muscle are ligated and divided. The flap is transected at the cranial border and is reflected caudally.

The caudal epigastric artery and vein are ligated just proximal to the caudal superficial epigastric vessels and divided. The superficial rectus sheath is closed with 0 PDS in a simple continuous suture pattern. Subcutaneous tissues and skin are closed routinely.

Table 8-2 summarizes important characteristics of the trapezius and the rectus abdominis muscle flaps.

Chapter 9

Pain Management in the Surgical Patient

Pain Management in the Small Animal Patient

Stephanie H. Berry and Richard V. Broadstone

In spite of increased emphasis on pain management in small animals recently, veterinarians can be reluctant to administer appropriate analgesic agents to their patients. This reluctance appears to be based on the perception that pain free animals may damage surgical repairs, exhibit undesirable side effects from analgesic drugs, or that analgesic drugs may mask clinical signs of disease. It is known that untreated pain can produce detrimental physiologic effects that adversely affect the response to therapy. Transmission of painful stimuli to the central nervous system results in a marked neuroendocrine stress response. Increased levels of circulating catecholamines and catabolic hormones can lead to decreased immune system function, impaired wound healing, hypercoagulability, increased myocardial oxygen consumption, gastrointestinal stasis, and decreased pulmonary function.[1] By designing and implementing appropriate analgesic protocols, veterinarians can decrease the neuroendocrine stress response and improve the postoperative recovery of surgical patients.

The Pain Pathway

In simple form, the pain pathway consists of three neurons. Specialized free nerve endings, or nociceptors, transduce mechanical, chemical, or thermal stimuli from the environment into electrical signals. These electrical signals are then transmitted by afferent sensory fibers to the dorsal horn of the spinal cord where modulation of the painful stimulus can occur. The signal ascends the spinal cord, and is then projected to the cerebral cortex where perception of pain occurs.[2]

Untreated pain can result in sensitization of both the central nervous system and peripheral receptor sites. Tissue damage and inflammation at the site of injury cause release of chemical mediators such as Substance P, prostaglandins, leukotrienes, and bradykinin. These mediators excite and increase the sensitivity of peripheral nociceptors to painful stimuli.[3] The mechanism of central sensitization is complex and occurs at the level of the spinal cord and brain. Glutamate, appears to be the primary mediator and activator of *N*-methyl-D-aspartate (NMDA) receptors, which results in an increased responsiveness of spinal neurons to stimuli.[4]

The exact mechanisms responsible for the generation and maintenance of pain in animals are still being investigated. It is clear, however, that modulation and inhibition of painful stimuli serves to avoid or decrease the adverse consequences of the neuroendocrine response to untreated pain.

Recognition and Assessment of Pain

Recognition of pain in the small animal patient can be difficult. Several scoring systems have been developed or adapted from human medicine and general guidelines for recognizing painful behaviors in animals have been published. Traditionally, methods for scoring the intensity of pain in animals have included the visual analogue scale (VAS), the simple descriptive scale (SDS), and the numerical rating scale (NRS).[5] However, a gold standard for pain recognition and assessment has not been established in veterinary medicine.

The *visual analogue scale* consists of a 10 cm line with the ends relating to extremes of pain intensity. The left end of the line is labeled as "no pain" while the right end of the line is labeled as "worst pain possible for this procedure". An observer places a mark on this line that best corresponds with the intensity of the animal's pain. The distance from the left end of the line to the intersecting mark is then measured and this number is the VAS pain score. The VAS has been used in several clinical studies to assess pain and although the VAS is easy to use, it does have limitations.[6-8] First, this technique simply assigns a number to a subjective judgment, making the assessment one-dimensional. Significant observer variability has also been demonstrated, even when trained individuals view the same animal at the same time.[8] These limitations must be recognized when using the VAS as a basis for designing analgesic protocols.

The *simple descriptive scale* is the most basic method for assessing pain in animals. The scale consists of four to five degrees of severity such as no pain, mild, moderate, and severe pain. An observer assigns the patient to a category based on their observations of that patient. The SDS is a broad classification and does not allow for small changes in pain response to be identified.[5]

Holton et al have shown that physiologic factors such as heart rate, respiratory rate, and pupil size are not useful indicators of pain in hospitalized dogs, however other investigators have shown that a combination of several physiologic and behavioral parameters considered together can be useful in assessing pain.[9,10] The *numerical rating scale,* combines both physiologic and behavioral categories with numeric scores assigned to each category. The scores are then summed to yield an overall pain score and used as the basis for analgesic therapy (Table 9-1).

Recognizing Painful Behaviors

Characteristic changes in behavior have been associated with pain in both dogs and cats. It is important to observe the animal's posture, temperament, locomotion, and vocalization for changes that may indicate untreated pain. In dogs, postural changes such as holding the tail between the legs, arching of the back, or drooping of the head have been associated with untreated pain. Additionally, a reluctance to move, nonweight-bearing lameness, attacking, biting, barking, and whimpering are also behaviors that have been associated with pain.[11] Cats exhibit more subtle behavioral changes associated with pain such as escaping or avoidance, hiding, squinting of the eyes, reluctance to move, hissing or lack of interest in food or grooming.[12] Assessments of

Table 9-1. An Example of a Numerical Rating Scale for Assessment of Analgesia.

Numerical scores are given in each category. The values are then summed to yield a total pain score. Treatment is based on the total pain score. Modified from Hellyer & Gaynor (1990).

Observation	Score	Description
Heart Rate	0	0-15%increase from baseline
	1	16-30% increase from baseline
	2	31-45% increase from baseline
Respiratory Rate	0	0-15% increase from baseline
	1	16-30% increase from baseline
	2	31-45% increase from baseline
Vocalization	0	No vocalization
	1	Vocalization that responds to a calm voice
	2	Vocalization that does not respond to a calm voice
Interactive Behavior	0	Normal
	1	Not interactive when approached, looks at affected limb
	2	Not interactive when approached, not mobile, vocalizes when affected limb touched
	3	Aggressive when approached, extremely restless
Lameness	0	No lameness evident
	1	Lameness evident in affected limb
	2	Moderate lameness evident in affected limb, patient occasionally only toe-touches
	3	Patient will not bear weight on affected limb
Range of Motion	0	0-20% decrease from baseline
	1	21-40% decrease from baseline
	2	41-60% decrease from baseline
	3	Patient will not tolerate movement
Tolerance to pressure	0	0-20% decrease from baseline
	1	21-40% decrease from baseline
	2	41-60% decrease from baseline
	3	Patient will not tolerate touching of affected limb
	Total Score (0-18)	

animals for pain should occur frequently, at regular intervals, and be documented in the medical record. Especially important times for assessment are if there is onset of new pain, when previously identified pain changes in frequency or pattern, or when there has been a major therapeutic intervention. Changes in the analgesic plan should be made in response to these assessments.

The Analgesic Plan

Proactive planning and design of analgesic protocols should be performed for all small animals undergoing surgery. These plans should be individualized and should consider such factors as the type of surgery or procedure to be performed, the expected severity of pain, any underlying medical conditions, the risk/benefit ratio of available analgesic techniques, and any previous clinical experiences with the animal. After considering these factors, a complete history should be gathered from the owner and a plan including preoperative, intraoperative, and postoperative analgesics should be constructed. Once the plan is enacted, the animal's pain level and behavior should be assessed frequently and refinements in the treatment protocol should be made.

Preemptive and Multimodal Plans

Preemptive analgesia refers to the practice of administering analgesics to a patient before a painful stimulus occurs such as surgery. The preemptive administration of analgesics has been shown to decrease the intensity and duration of postoperative pain.[13] Additionally, preemptive analgesics have been shown to decrease both peripheral and central nervous system sensitization.[14,15] It is important to remember, however, that administration of analgesic drugs preemptively will not eliminate postoperative pain, but can reduce the severity and duration of that pain.

A simplified explanation of the pain pathway is described here however, it is important to recognize that clinical pain is the result of signals transmitted along a multitude of pathways throughout the peripheral and central nervous systems. These pathways involve many mechanisms and neurotransmitters so, it is unlikely that a single analgesic agent or technique will alleviate all pain. Construction of a multimodal analgesic plan that uses drugs of different classes, each acting at different sites along the pain pathway (e.g. NSAIDS, opioids, local anesthetics), will result in more effective pain relief. Additionally, the co-administration of drugs in various classes has additive or synergistic effects and individual drug doses can often be reduced.

Analgesic Drugs

The drugs commonly used to treat perioperative pain in companion animals consist of nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, alpha-2 agonists, local anesthetics, and adjunctive medications.

NSAIDs

These are commonly used in the canine and less frequently in the cat for analgesia (Table 9-2). These drugs are used to treat pain in a variety of cases ranging from acute surgical pain to chronic pain. Analgesia, anti-inflammatory, and antipyretic effects are brought about by inhibition of the cyclooxygenase (COX) enzymes resulting in a decrease in the release of prostanoids and prostaglandin.[16] It is known that NSAIDs act at the tissue injury site and there is evidence that NSAIDs also produce analgesia at the level of the central nervous system.[17] NSAIDs are well absorbed after oral administration, or when given parenterally.[18] Most are metabolized in the liver and the metabolites are then excreted in the urine and feces.[19] NSAIDs are effective, relatively inexpensive, and long lasting analgesics, however side effects may occur. Gastrointestinal irritation ranging from mild gastritis and vomiting to intestinal ulceration, hemorrhage and death have been reported.[20] Nephrotoxicity can also occur after NSAID administration due to decreases in renal blood flow.[21] Hepatotoxicity has been reported (with Labrador Retrievers over represented) and is generally believed to be idiosyncratic.[22] Serious complications have been associated with the use in dogs of NSAIDs intended for humans. NSAIDs should not be used in animals with existing renal or hepatic insufficiency, gastric ulceration, dehydration, hypotension, shock, or coagulopathies. Additionally, NSAIDs should not be administered concurrently with other nephrotoxic drugs, corticosteroids, or other NSAIDs. Careful monitoring for gastrointestinal, renal, or hepatic toxicity is required when using NSAIDs, especially in animal's at high risk. Renal and hepatic function should be evaluated before instituting NSAID therapy in dogs at risk for complications and during chronic NSAID therapy.

Opioids

Opioids are the most consistently effective drugs used for the treatment of moderate to severe pain (Table 9-3). This class of drugs produces analgesia by acting on opioid receptors without the loss of proprioception or consciousness. Three opioid receptors (mu, kappa, and delta) have been identified and are found in varying numbers within the brain, dorsal horn of the spinal cord, and the periphery.[23,24] Activation of opioid receptors results in inhibition of adenylate cyclase, a decrease in the opening of voltage-sensitive calcium channels, inhibition of the release of excitatory neurotransmitters, and activation of potassium channels resulting in membrane hyperpolarization.[25] The overall effect of opioid receptor activation is a decrease in neurotransmission.[26]

Opioid analgesics are classified by their receptor selectivity and may be active at one or more receptors. Mu agonists include morphine, oxymorphone, hydromorphone, fentanyl, and meperidine. These agonists induce a maximal response, and can produce increasing levels of analgesia with increasing dosages. This is in contrast to the partial mu agonist, buprenorphine, which binds tightly to the mu receptor but does not induce a maximal response.[27] Butorphanol has agonist activity at the kappa receptor and antagonist activity at the mu receptor.[28] Increasing doses of butorphanol are associated with a ceiling effect, such that no improvement of analgesia occurs with increasing doses.

In addition to producing analgesia, the opioids also affect other organ systems. Opioid administration can result in respiratory depression due to a decrease in the respiratory center's response

Table 9-2. Nonsteroidal Anti-inflammatory Drugs used in the Treatment of Peri-operative Pain.

Drug	Dosage	Frequency	Notes
Carprofen	Dog: 4.4 mg/kg IV, SQ, IM 2.2 mg/kg PO	Once at induction Every 12 hours	Acute hepatoxicity reported, does not appear to affect platelet function
	Cat: 4.0 mg/kg SQ, IV (67)	Once at induction	
Deracoxib	Dog: 3-4 mg/kg PO	Every 24 hours	COX – 2 inhibition, GI upset can occur
Etodolac	Dog: 10-15 mg/kg PO	Every 24 hours	Enterohepatic circulation maintains serum concentrations for extended period
Ketoprofen	Dog: 2.0 mg/kg IV, IM, SQ, PO 1.0 mg/kg IV, IM, SQ, PO	Once Every 24 hours	Preoperative administration can result in hemorrhage due to antithromboxane activity, not recommended for more than five days, renal damage reported
	Cat: 2.0 mg/kg SQ 1.0 mg/kg PO	Once Every 24 hours	
Meloxicam	Dog: 0.2 mg/kg IV, SQ 0.1 mg/kg IV, SQ, PO	Once Every 24 hours	
	Cat: 0.2 mg/kg SQ 0.05 mg/kg PO	Once Every 24 hours for 3-4 days	
Firocoxib	Dog: 5 mg/kg PO	Every 24 hours	Use of doses more than 5 mg/kg in puppies less than 7 months of age can result in severe adverse reactions, including death.
Tepoxalin	Dog: 10 - 20 mg/kg PO 10 mg/kg PO	Once Every 24 hours	Preoperative administration is not recommended
Ketorolac	Dog: 0.5 mg/kg IV, IM	Every 12 hours for 1 to 2 treatments	1 to 2 treatments only to reduce risk of gastric ulceration
Acetaminophen	Dog: 10 - 15 mg/kg PO	Every 8 hours	Can be combined with opioid for synergistic effect
	Cats: **Do not administer to cats**		**Do not administer to cats.**
Aspirin	Dog: 10 - 25 mg/kg PO	Every 12 hours	Ulcers and renal damage at higher doses
	Cat: 1 - 25 mg/kg PO[67]	Every 72 hours	
Tolfenamic acid	Dog: 4.0 mg/kg IM, SQ, PO	Every 24 hours	Give for four days, then off for three days
	Cat: 4.0 mg/kg SQ, PO[67]	Every 24 hours	Use for 3 days in cats
Piroxicam (Feldene)	Dog: 0.3 mg/kg PO	Every 48 hours	Use with gastroprotectant
Robenacoxib (Onsior)	Dog: 2 mg/kg SQ 1 mg/kg PO	Once perioperatively Every 24 hours	

Table 9-3. Opioids used in the Treatment of Peri-operative Pain.

Drug	Dosage	Duration	Notes
Morphine	Dog: 0.1-0.5 mg/kg IV 0.5-1.0 mg/kg IM, SC Cat: 0.05-0.1 mg/kg IV 0.1-0.2 mg/kg IM, SC	1 hour 3-5 hours 1 hour 3-4 hours	Dysphoria in cats with higher doses. Histamine release when given IV rapidly.
Morphine (Oral)	Dog: 0.5-4.0 mg/kg PO Cat: 0.25-1.0 mg/kg PO	4 hours; 8-12 hours if sustained release 4 hours	
Hydromorphone	Dog: 0.05-0.1 mg/kg IV 0.1-0.2 mg/kg IM, SC Cat: 0.05-0.1 mg/kg IV 0.1-0.2 mg/kg IM, SC	1 hour 3-4 hours 1 hour 3-4 hours	Associated with occasional hyperthermia in cats, no histamine release, less vomiting
Oxymorphone	Dog: 0.05-0.1 mg/kg IV, IM, SC Cat: 0.05-0.1 mg/kg IV, IM, SC	4 hours 4 hours	Less vomiting.
Fentanyl	Dog: 2-10 mcg/kg IM, SC Cat: 1-5 mcg/kg IM, SC	0.5 hour 0.5 hour	
Meperidine	Dog: 3-5 mg/kg IM, SC Cat: 3-5 mg/kg IM, SC	1-2 hours 1-2 hours	Significant histamine release if given IV.
Buprenorphine	Dog: 10-20 mcg/kg IV, IM, SC Cat: 10-20 mcg/kg IV, IM, SC, Buccal	6-8 hours 6-8 hours	Onset of action may be 30 minutes or more.
Butorphanol	Dog: 0.2-0.4 mg/kg IV, IM, SC Cat: 0.2-0.4 mg/kg IV, IM, SC	1 hour 1 hour	Only use for minor pain
Butorphanol (Oral)	Dog: 1.0-4.0 mg/kg PO Cat: 0.5-2.0 mg/kg PO	1-4 hours 1-4 hours	
Methadone	Dog: 0.3-1 mg/kg SC, IM, IV (slowly) Cat: 0.1-0.5 IV, IM	1-4 hours 1-4 hours	
Remifentanil	Dog: 4-10 mcg/kg/hr Can be increased to 20-60 mcg/kg/hr intraoperatively Cat: 15-60 mcg/kg/hr		Should be used as a constant rate infusion
Opioid Antagonist Naloxone	Dog: 0.01 mg/kg IV 0.04 mg/kg IM Cat: Same as dog	20-40 minutes 40-70 minutes	Animal should be observed for renarcotization or resedation due to short duration of action.

to increasing levels of CO_2.[29] The respiratory rate and rhythm may also be altered. Some animals pant due to the drug's effect on the thermoregulatory system. Respiratory depression is often cited as a reason for withholding opioid therapy but is rarely of clinical significance when proper dosing regimens are used.

The cardiovascular system may be affected by opioid administration. Bradycardia may result from inhibition of sympathetic tone to the heart.[30] Opioid induced bradycardia is not life threatening and usually does not require treatment. Opioids have little effect on cardiac contractility. Some opioids, particularly morphine and meperidine, can produce hypotension due to histamine release.[31,32] The degree of histamine release appears to be related to the overall dose and rate of administration, therefore small doses administered slowly should minimize this potential problem.

The propulsive activity of the gastrointestinal tract is decreased after opioid administration, which may result in constipation. Smooth muscle and sphincter tone tend to be increased, but intestinal peristalsis is decreased.[33] Vomiting may occur after direct stimulation of the chemoreceptor trigger zone.[34] Tone of the biliary sphincter is increased, which will increase biliary pressure. Contraction of the smooth muscle of the pancreatic ducts can increase plasma concentrations of lipase and amylase.

Alterations in mood and locomotion have been documented after opioid administration. Paradoxic excitement or dysphoria is possible in any species, although it appears that cats are more susceptible especially if excessive doses are given.[37] Opioid induced dysphoria may be treated with sedatives such as acepromazine, or in severe cases an opioid antagonist such as naloxone. Antagonism of opioids should be performed cautiously in animals experiencing pain since the analgesic effect of the opioid will be reversed.

Opioids can produce additive or synergistic effects when used in combination with other analgesics such as NSAIDs, alpha-2 agonists, and local anesthetics. Commonly, the dosage of each drug can be reduced, thereby potentially reducing the severity of adverse effects of each class of drugs.

Local Anesthetics

Local anesthetic drugs are tertiary amines connected to an aromatic ring by either an ester (procaine, tetracaine) or amide (lidocaine, mepivacaine, bupivacaine, ropivacaine) linkage (Table 9-4).[18] Local anesthetics bind to voltage gated sodium channels within nerve membranes, preventing the influx of sodium ions.[38] This prevents the conduction and propagation of nerve impulses and can produce complete analgesia. Local anesthetics with an ester linkage are hydrolyzed by pseudocholinesterases, while those with an amide linkage are metabolized by the liver.[18]

The use of local anesthetic drugs is relatively safe when administered correctly. However, if local anesthetic is injected intravenously or used in excessive doses, central nervous system and cardiotoxicty may occur. In the central nervous system, toxicity manifests as sedation, nausea, ataxia, nystagmus, and tremors, which can progress to convulsions, unconsciousness, coma, and eventually respiratory arrest.[39] Blockade of sodium channels within the myocardium will depress the electrical conduction pathways and the mechanical function of the heart. This can result in sinus bradycardia and sinus arrest.[40,41] The peripheral vasculature can also be affected by the administration of local anesthetics resulting in peripheral vasodilation and hypotension.[42] Finally, local anesthetics can cause direct damage to the tissues injected, allergic reactions, and methemoglobinemia.[43,44]

Local anesthetics when used epidurally in conjunction with opioids will produce a more profound and longer lasting analgesia than either drug used individually.[45] The use of local anesthetics also reduces the inhaled anesthetic requirements of animals thus reducing the dose dependant effects of inhaled anesthetics on the cardiopulmonary system.[46] Specific analgesic techniques using local anesthetic drugs are discussed later in this chapter.

Alpha-2 agonists

Alpha-2 receptor agonists (Table 9-5) bind to both pre and postsynaptic receptors throughout the central nervous system. Activation of these receptors results in neuronal hyperpolarization and a decrease in sympathetic nervous system activity.[47] Alpha-2 receptors are closely located to structures involved in pain processing and activation is thought to interfere with sensory transmission and reduce the release of pain related neurotransmitters resulting in analgesia, sedation, and muscle relaxation.[48]

Alpha-2 agonists have profound effects on the cardiovascular system, commonly producing bradycardia and/or bradyarrhythmias, as well as decreases in contractile force, stroke volume, and cardiac output. After administration, blood pressure will transiently increase followed by a decrease in blood pressure from baseline values.[49]

Administration of Alpha-2 agonists will results in a dose dependent decrease in respiratory rate and tidal volume, which can result in significant respiratory acidosis and hypoxemia in some animals. Marked relaxation of the muscles of the upper airway also occurs; therefore, patency of the upper airway should be ensured and monitored.[50]

Vomiting and retching can occur after administration of an alpha-2 agonist, especially in cats.[51] Gastrointestinal motility is decreased[52] and urine output will increase.[53] Hypoinsulinemia resulting in a transient hyperglycemia has also been reported in dogs after alpha-2 agonist administration.[54]

The usefulness of alpha-2 agonists as sole analgesic agents is limited by their short duration of action and dose dependant cardiopulmonary depression. However, alpha-2 agonists, when given in conjunction with other analgesics such as opioids, are extremely effective analgesic agents. Patient selection should be considered carefully and the use of alpha-2 agonists should be limited to animals without significant systemic disease or dysfunction. It is important to recognize that the sedative effects of alpha-2 agonists persist for a longer period of time than the analgesic effects.[55] Therefore, adequate analgesia cannot be assumed based only on behavioral evaluation of the patient.

Table 9-4. Local Anesthetics used in the Treatment of Peri-operative Pain.

Drug	Dosage	Onset	Duration	Notes
Lidocaine	Dog: ≤ 6 mg/kg Cat: ≤ 3 mg/kg	10 minutes	60-120 minutes	Effective topically, can be used intravenously
Mepivacaine	Dog: ≤ 6 mg/kg Cat: ≤ 3 mg/kg	5 minutes	90-180 minutes	Less tissue irritation Not effective topically
Bupivacaine	Dog: 2 mg/kg Cat: 1 mg/kg	20 minutes	240-360 minutes	Not effective topically Selective sensory blockade with limited motor blockade, selectively cardiotoxic
Etidocaine	Dog: 3 mg/kg	5 minutes	180-300 minutes	Not effective topically Preferential motor blockade, cardiotoxicity similar to bupivacaine.
Ropivicaine	Dog: 2 mg/kg	5 minutes	180-300 minutes	Less cardiotoxic than bupivacaine
EMLA cream		Apply topically 60 minutes before procedure. Cover with occlusive dressing	1-2 hours following removal of cream	1:1 mixture of lidocaine and prilocaine; do not apply to damaged or broken skin, middle ear, or ocular structures; Prevent licking and/or oral ingestion

Table 9-5. Alpha-2 agonists used in the Treatment of Peri-operative Pain.

Drug	Dosage	Duration	Notes
Xylazine	Dog: 0.1-0.5 mg/kg IM, IV Cat: 0.1-0.5 mg/kg IM, IV	0.5-1.0 hour 0.5-1.0 hour	Sedation, bradycardia Vomiting (esp. in cats)
Dexmedetomidine	Dog: 0.5 mcg/kg IV 5-15 mcg/kg IM Cat: 5- 20 mcg/kg IM	2-3 hours 2-3 hours	
Romifidine 0.5-1.5 hour	Dog: 10-20 mcg/kg IV, IM Cat: 20-40 mcg/kg IV, IM	0.5-1.5 hour 0.5-1.5 hour	
Alpha-2 Antagonist: Atipamezole	Dog: 0.05-0.2 mg/kg IV,IM Or 2-5 times dexmedetomidine dose Cat: 0.05-0.2 mg/kg IV,IM Or 2-5 times the dexmedetomidine dose	1-3 hour	IV administration usually reserved for emergencies; can cause excitement, delirium, and vomiting

Analgesic Adjuncts

There are other classes of drugs that are not regarded as analgesics but may be helpful in the treatment of refractory pain states (Table 9-6). These drugs may enhance analgesia produced by traditional analgesic drugs by interacting with receptors within the pain pathway or altering nerve conduction pathways in pain modulating systems. It should be noted that while the drugs discussed here can play an important role in treating pain, especially in cases of refractory pain states, most produce little to no analgesia when used by themselves. They should be used in conjunction with known analgesics such as opioids.

Nociceptor activation and bombardment of the dorsal horn of the spinal cord leads to activation of N-methyl-D-aspartate (NMDA) receptors, which are thought to play a role in central sensitization. Ketamine is an N-methyl-D-aspartate (NMDA) receptor antagonist and is thought to produce analgesia and limit hyperalgesic states.[56] It appears that ketamine is most effective when administered preemptively and its short duration of action suggests that administration via a constant rate infusion is beneficial.[57] When administered as a constant rate infusion in dogs undergoing forelimb amputation, ketamine significantly reduced postoperative pain scores and increased animal activity three days postoperatively.[58] Analgesic doses of ketamine are considerably lower than those used to produce anesthesia, but potential side effects include sympathetic stimulation of the cardiovascular system, respiratory depression, and stimulation of the central nervous system.

Amantadine is another NMDA receptor antagonist that has been used in humans for the treatment of neuropathic pain and in patients with opioid tolerance. The pharmacology of amantidine has not been well established in dogs and cats and behavioral effects can be seen at high doses.

The anticonvulsant, gabapentin, has been used in humans with chronic pain syndromes.[60] The exact mechanism of action is unclear, although gabapentin is known to bind to receptors within the brain and may enhance the action of gamma-aminobutyric acid (GABA).[61] There are no controlled studies involving the use of gabapentin to treat pain in dogs and cats however there are anecdotal reports of its use in animals.[62] It appears that gabapentin may work synergistically with other drugs in producing analgesia and may inhibit the development of hyperalgesia due to injury. Gabapentin is metabolized by the liver and excreted by the kidneys. Side effects reported in humans include sleepiness, fatigue, and weight gain with long term administration.[61]

Tramadol is a centrally acting analgesic that has a low affinity for mu opioid receptors and is less potent than morphine.[63] Tramadol inhibits norepinephrine uptake and facilitates serotonin release, which contributes to its analgesic effects.[64] It has been shown

Table 9-6. Other Agents used in the Treatment of Perioperative Pain.

Drug Class	Drug	Dosage	Duration
NMDA Antagonist	Ketamine	Dog: 2 mg/kg IV, IM Cat: 2 mg/kg IV, IM	20 minutes 20 minutes
NMDA Antagonist	Amantidine	Dog: 3-5 mg/kg PO Cat: 3-5 mg/kg PO	24 hours 24 hours
Anticonvulsant	Gabapentin	Dog: 1.25-10mg/kg PO Cat: 1.25-10 mg/kg PO	24 hours 24 hours
Other	Tramadol	Dog: 5 mg/kg PO 2-4 mg/kg IV Cat: 1-2 mg/kg IV	6 hours 6 hours Unknown
Glucocorticoid	Prednisolone	Dog: 0.25-0.5 mg/kg PO Cat: 0.25-0.5 mg/kg PO	24-48 hours 24-48 hours
Tricyclic antidepressant	Amitriptyline	Dog: 1.0mg/kg PO Cat: 0.5-1.0 mg/kg PO	12-24 hours 12-24 hours
Phenothiazine	Acepromazine	Dog: 0.02-0.1 mg/kg IV, IM, SC Cat: 0.02-0.1 mg/kg IV, IM, SC	2-6 hours
Benzodiazepine	Diazepam	Dog: 0.1-0.5 mg/kg IV, IM Cat: 0.1-0.5 mg/kg IV, IM	1-3 hours 2-4 hours

that tramadol can be used safely to control pain after ovariohysterectomy and other soft tissue procedures in dogs.[65] Tramadol is metabolized by the liver and side effects include nausea and vomiting and prolonged administration can result in constipation or diarrhea.[66]

Although glucocorticoids are not analgesic drugs, their use as potent anti-inflammatory agents may contribute to treating pain associated with inflammatory conditions such as otitis externa and osteoarthritis.[68] Glucocorticoids inhibit and reduce inflammation by inhibiting phospholipase A_2 and by stabilizing cellular membranes.[68] Potential side effects of long-term glucocorticoid therapy include iatrogenic Cushing's disease, while abrupt termination of glucocorticoid administration may lead to an Addisonian crisis. Glucocorticoids also affect the gastrointestinal mucosa, which may lead to ulceration and perforation.[69] Immunosuppression and delayed wound healing may occur especially when higher doses are administered.

Tricyclic antidepressants can also play a role in pain management. Amitriptyline works in the central nervous system to block the reuptake of serotonin and norepinephrine.[70] Amitriptyline has been shown in humans to be beneficial in the treatment of neuropathic and chronic pain states by enhancing the actions of opioids.[71] There are no controlled studies using Amitryptilline in veterinary patients however it is thought that the tricyclic antidepressants would have similar analgesic effects in animals.

Finally, sedatives such as acepromazine and diazepam may be useful in potentiating or prolonging the effects of analgesic agents. If these sedatives are used, careful evaluation of the patient must continue as the central nervous system depression and sedation may mask signs of untreated pain.

Multimodal Analgesic Techniques

Systemic analgesic agents are often combined with local or regional anesthetic techniques to produce a balanced analgesic protocol that may maximize analgesic efficacy.

Local Anesthetic Techniques

Local anesthetic agents block transmission in all nerve fibers and are ideally suited for preemptive administration (Table 9-7). Local nerve block techniques are relatively easy to perform and have few complications. The benefits of performing these techniques include a significant reduction in inhaled anesthetic requirements and reduction in postoperative pain. Some of the techniques can be performed on conscious animals however most local techniques are easier to perform on sedated or anesthetized patients. The clinician should base their choice of which local anesthetic agent to use for a procedure on how quickly the local anesthetic is needed to work, the route of administration, and the expected duration of pain (Figure 9-1).

Topical local anesthetics can be used to desensitize cutaneous areas for minor, relatively noninvasive procedures. EMLA cream can be applied to the skin overlying a vessel before venepuncture, while 2% lidocaine jelly can be used to desensitize mucosal surfaces such as the urethra before catheterization.[72] If local anesthetics are used on mucosal surfaces, doses should be calculated carefully, as these drugs are readily absorbed into the systemic circulation.

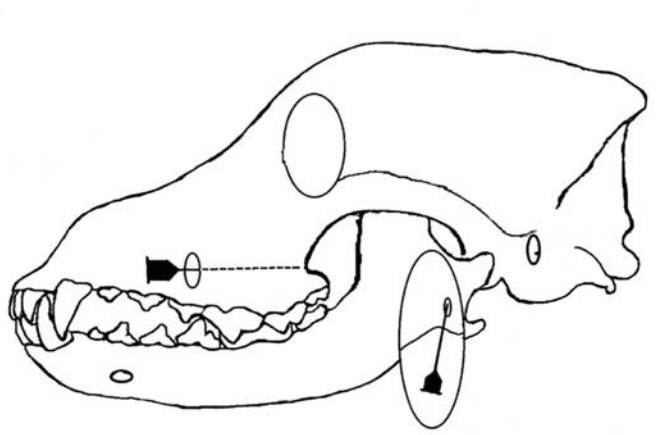

Figure 9-1. Lateral view of a dog's skull demonstrating needle placement for maxillary and mandibular alveolar nerve blocks. The mandibular foramen (oval inset) is on the medial side of the right mandible.

Most commonly, local anesthetics are infused around surgical sites allowing for procedures such as skin mass excision and repair of lacerations to be performed without general anesthesia although sedation is often required. After aseptically preparing the surgical site, local anesthetic should be infiltrated into all of the effected tissue planes. The needle is inserted into the skin and the plunger aspirated to prevent accidental intravenous injection. Total doses should be calculated carefully to avoid toxicity. If infiltration of lidocaine is being performed in a conscious patient, the lidocaine can be mixed with sodium bicarbonate (0.1 ml of 1mEq/ml $NaHCO_3$ to 0.9 ml of 2% lidocaine) to reduce the discomfort felt by the animal on injection. Infiltration of local anesthetic into more invasive surgical sites can be continued over a period of time by using a fenestrated catheter attached to a reservoir. The catheter is placed in the surgical site and the reservoir is filled with local anesthetic. The reservoir can then be set to slowly deliver the local anesthetic to the surgical site over a period of days.

Local anesthetic infiltration into a surgical incision site either before the incision is made or just prior to closure is an effective analgesic technique. Infiltration of local anesthetic along the muscle of the abdominal wall of a celiotomy incision helps to control abdominal wall pain. If the block is performed before closure, a sterile syringe, needle, and local anesthetic agent are delivered to the surgeon aseptically. The musculature and subcutaneous tissues along both sides of the incision are then injected uniformly and wound closure proceeds normally.

Animals recovering from thoracotomy may benefit from blocking the intercostal nerves prior to incisional closure and/or the instillation of local anesthetics into the pleural space.[74] If the patient has a thoracostomy tube, a local anesthetic such as 0.5% bupivacaine can be administered through the tube (1.5 mg/kg in the dog, flushing the tube with saline after administration). The animal is positioned to allow the local anesthetic solution to bathe the

incision site (incision side down) for 10 to 20 minutes after instillation. If the animal does not have a thoracostomy tube in place, the local anesthetic can be instilled by aseptically placing an over the needle catheter into the pleural space. Complications of this procedure include infection and pneumothorax.[75]

Local anesthetics can also be infused into the peritoneal cavity using a similar technique. An over the needle catheter is aseptically placed into the abdomen at the level of the umbilicus. A mixture of local anesthetic and saline (total volume 10-20 mls) is then instilled. This technique may be helpful for those patients suffering from abdominal pain. Doses are calculated carefully, remembering that local anesthetic drug uptake will occur rapidly, particularly if the peritoneum is inflamed.[76]

Epidural Technique

Analgesia and/or anesthesia caudal to the diaphragm can be achieved with an epidural injection (Figure 9-2). The technique is relatively easy to perform and does not require specialized equipment. Injections are performed with the patient chemically restrained or anesthetized because the patient must remain still during the procedure. The hanging drop technique is described below. The animal is placed in sternal recumbency with the hind limbs extending cranially.The hair overlying the lumbosacral space is clipped and the skin is aseptically prepared. Sterile gloves are worn and the lumbosacral space is identified by placing the thumb and middle finger of the non-dominant hand on the cranial edges of the wings of the ilia. The index finger of the same hand then palpates the spinal process of the seventh lumbar vertebrae. The lumbosacral space is identified as a depression caudal to the spinous process. An appropriately sized spinal needle (20-22 gauge) is then introduced on midline at an angle that is perpendicular to the skin. Once the needle has passed through the skin, the stylet is removed and a small amount of sterile saline is placed into the hub of the needle. The needle is then slowly advanced through the overlying tissues until it passes through the ligamentum flavum. Commonly, a distinctive pop is felt and the saline in the hub of the needle is drawn into the space. If the needle encounters bone before puncturing the ligamentum flavum, it is withdrawn slightly and redirected. After the needle is directed into the epidural space, the hub of the needle is observed for the presence of blood or cerebral spinal fluid. If neither is present, the epidural injection is preformed. If blood is present, the needle is withdrawn and the process repeated. If cerebral spinal fluid is flowing from the needle, a decision to inject the analgesic into the subarachnoid space must be made. If it is decided to proceed with the injection, the dose of the analgesic must be reduced by at least 50%.[77] After injection, the needle is completely withdrawn. If injecting a local anesthetic epidurally, the animal is placed with the affected side down for a period of 5 to 10 minutes.

Epidural injections can also be performed in lateral recumbency. The procedure is the same, with the area over the lumbosacral space clipped and aseptically prepared. The anatomic landmarks are identified, and the spinal needle is advanced through the skin. In this position, however, the stylet remains in place until the needle is thought to have penetrated the ligamentum flavum. Once the needle is in the epidural space, the stylet is removed and the hub of the needle is observed for blood or cerebrospinal fluid.

A test injection of a small amount of air can be performed to confirm the needle placement. If the needle is correctly placed, there should be little to no resistance to injection of air.[78] The injection of drug is performed, the needle is withdrawn and the animal is placed with the affected area down if local anesthetic drug is administered. It should be noted that, in cats, the spinal cord usually ends at the first sacral vertebra making it more likely to puncture the dura during needle placement and obtain cerebrospinal fluid during epidural injection.[77]

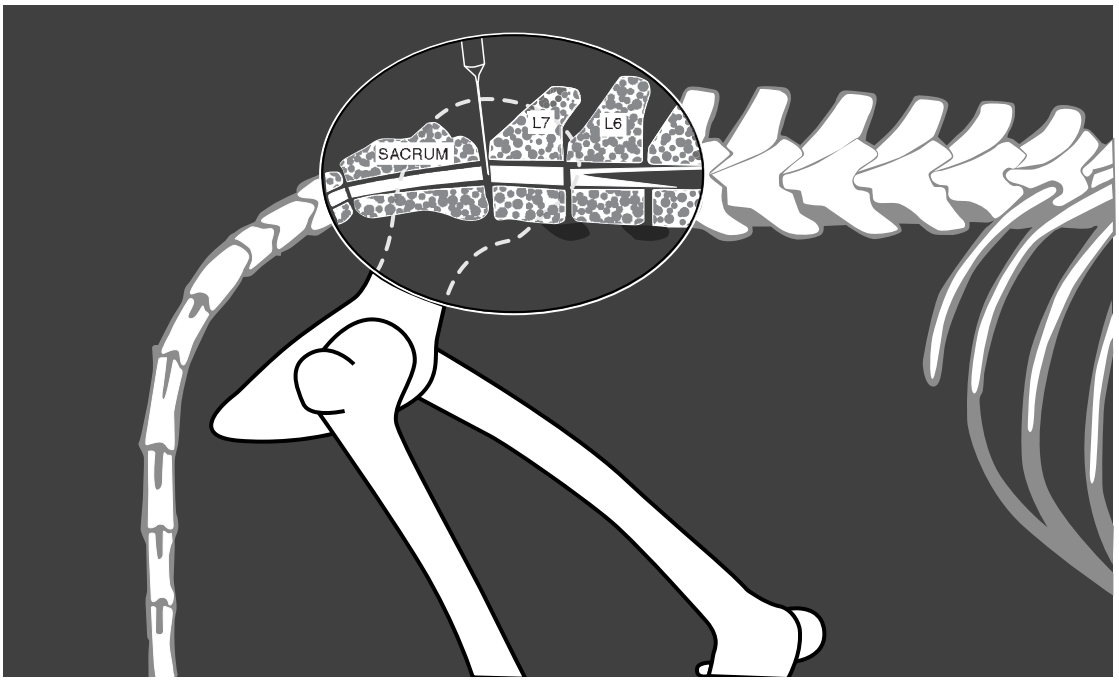

Figure 9-2. Lumbosacral epidural injection.

Table 9-7. Selected Local Anesthetic Techniques

Block	Area Desensitized	Materials
Infraorbital nerve block[91]	Bone, soft tissue, and teeth rostral to maxillary first molar including hard and soft palate on side injected	Tuberculin syringe; 27 or 25 gauge, 3/4 to 1 inch needle Dog: 0.1 to 0.5 ml of 0.5% bupivacaine Cat: 0.1 to 0.3 ml of 0.5% bupivacaine
Mandibular nerve block[91]	Bone, teeth, soft tissue, and tongue on infiltrated side	Tuberculin syringe; 27 or 25 gauge, 3/4 to 1 inch needle Dog: 0.1 to 0.5 ml of 0.5% bupivacaine Cat: 0.1 to 0.3 ml of bupivacaine
Mental nerve block[91]	Bone, teeth, and soft tissue rostral to the second premolar on the injected side	Tuberculin syringe; 27 or 25 gauge, 3/4 to 1 inch needle Dog: 0.1 to 0.5 ml of 0.5% bupivacaine Cat: 0.1 to 0.3 ml of 0.5% bupivacaine
Auriculotemporal and great auricular nerve blocks[92]	External and internal ear	Syringe; 22 gauge, 1 inch needle
Radial, Ulnar, Median, and Musculocutaneous nerve block (RUMM)[93]	Anesthesia distal to the elbow joint	Two 20 or 22 gauge 1 inch needles Syringe
Radial, Ulnar, and Median nerve block (RUM)[93]	Anesthesia to distal forelimb	Three 22 or 25 gauge, 3/4 to 1 inch needles Syringe
Intravenous Regional (IVRA) Analgesia/Anesthesia[94]	Anesthesia of limb distal to tourniquet	Tourniquet, Esmarch bandage, intravenous catheter, syringe, 20 gauge 1 inch needle
Intercostal nerve block[94]	Tissues of thorax on side injected	22 gauge 1 inch needle Syringe
Intraarticular[94]	Joint infused	22 - 25 gauge, 3/4 to 1 inch needle Syringe

Technique	Notes
Palpate infraorbital foramen dorsal to upper third premolar. Needle can be advanced into the foramen in larger dogs.	Complications include damage to nerve and soft tissue (rare), Cardiotoxicity due to inadvertent intravenous administration of bupivacaine. Calculate doses carefully. Aspirate before injection.
Palpate mandibular foramen intraorally–lingual surface of mandible, 2/3 of distance from last molar to angular process of the mandible. Insert needle intraorally near foramen.	Complications include damage to nerve and soft tissue (rare). Cardiotoxicity due to inadvertent intravenous administration of bupivacaine. Calculate doses carefully. Aspirate before injection.
Dog: Palpate the middle mental foramen. Insert needle into the submucosa in a rostral to caudal direction. Injection should be ventral to the rostral root of second premolar. Cat: Place needle in submucosa caudal and ventral to lower canine	Complications include damage to nerve and soft tissue (rare), Cardiotoxicity due to inadvertent intravenous administration of bupivacaine. Calculate doses carefully. Aspirate before injection.
Auriculotemporal nerve is located caudal and dorsal to masseter muscle and rostral to the ventral ear canal. Great auricular nerve is ventral to wing of atlas and caudal to vertical ear canal.	Preoperative performance of block may reduce inhalant requirements during total ear canal ablation and may improve recovery postoperatively
Palpate the lateral aspect o the epicondyle of the humerus. Move proximally and palpate the radial nerve between the brachialis and triceps muscles. Palpate the medial aspect of the epicondyle of the humerus. Move proximally and palpate the median, ulnar, and musculocutaneous nerves between the triceps and biceps muscles. The brachial artery is adjacent to these nerves and can be felt pulsating.	Useful for patients with radial, ulnar, and/or metacarpal fractures. Due to proximity of the nerves to the brachial artery and vein, syringes must be aspirated before injection.
Three injection sites: 1. Medial to the accessory carpal pad 2. Lateral and slightly proximal to accessory carpal pad 3. Dorso-medial aspect of proximal carpus	Useful for cats undergoing onychectomy. Calculate dose of local anesthetic carefully.
Place intravenous catheter in accessible vein. Desanguinate the limb with Esmarch bandage. Place tourniquet immediately proximal to bandage. Remove Esmarch bandage. Inject lidocaine through intravenous catheter. Slowly remove tourniquet within 90 minutes.	**Do not use bupivacaine due to cardiotoxicity when given IV.** Ischemic injury can occur to limb if tourniquet is not released within 90 minutes.
Percutaneous injection: Aseptically prepare skin over intercostal nerves. Introduce needle caudal to each rib near the intervertebral foramen. Advance needle to rib, then withdraw slightly into the tissues caudal to rib. Aspirate, then inject. Intraoperative injection: Nerves can be identified and injected from the pleural side of thorax.	Due to overlapping innervation, at least three consecutive intercostal nerves must be blocked. Commonly, at least two intercostal nerves cranial and caudal to the affected area are blocked, in addition to the site of incision. If performed percutaneously, complications include pnuemothorax, intrathoracic injection, and pulmonary laceration
Anatomic landmarks depend on joint being injected. Aseptically prepare skin over joint. Place needle into joint space. Remove joint fluid if needed. Inject enough local anesthetic to result in slight distension in the joint capsule	Can use local anesthetics and/or morphine. Complications include infection if not performed aseptically.

If repeated injections or continuous administration of epidural analgesics is desired, placement of an epidural catheter should be considered. A Tuohy or Hustead needle is required to place an epidural catheter. These needles have a curve at the tip that aid in directing the catheter cranially when placed into the epidural space. There are a variety of epidural catheters available that are characterized by their size and material used to construct the catheter. Epidural catheters made of nylon or those with a wire spiral within the wall of the catheter are resistant to kinking, while others have a wire guide in the lumen of the catheter and are more flexible. Polyamide catheters are softer, more flexible and kink more easily.[77] Prior to beginning the procedure, the clinician measures the animal to determine how much of the catheter needs to be inserted, making sure to account for the length of the Tuohy needle used for catheter placement. For a hind limb procedure, the catheter may only need to be inserted to the level of the fifth or sixth lumbar vertebrae, abdominal procedures require the catheter to be advanced to the second or third lumbar vertebrae, while for a thoracotomy the catheter should be advanced to the fifth or sixth thoracic vertebrae.

The animal is clipped and prepped using the anatomic landmarks for a epidural injection. A keyhole drape is placed over the lumbosacral space and the landmarks are palpated with sterile gloved hands. A small stab incision is made in the skin overlying the lumbosacral space using a sterile #11 blade to facilitate the passing of the Tuohy needle. The Tuohy needle is placed into the stab incision, and advanced through the overlying tissues until the ligamentum flavum is penetrated. Needle placement in the epidural space can be confirmed with a test injection of a small amount of air. The epidural catheter is then passed through the needle to the desired spinal segment. If the catheter has been advanced beyond the end of the Tuohy needle, no attempt should be made to withdraw it through the needle, as the catheter may be sheered off by the sharp edge of the needle. Once the catheter is in place, the wire stylet is removed if present, and an adapter is attached to the end of the catheter. A bacterial filter and injection cap primed with saline or analgesic are then connected to the catheter. The catheter should then be secured to skin at its exit site. A radiograph can be taken to confirm the placement of the catheter. Additionally, catheter placement can be guided by fluoroscopy, if available. If cleanliness and sterility are maintained, epidural catheters can remain in place for days to weeks.[79]

Complications of both single epidural injection and epidural catheter placement include infection, cranial spread of local anesthetic resulting in motor blockade of respiratory muscles, hypotension when using local anesthetics, and urine retention. Muscle spasms of the rear legs, pruritis, epidural hemorrhage, and spinal cord or nerve root trauma have also occurred. Contraindications for epidural injection include pyoderma at the site of injection, coagulopathy, and sepsis.[77] Drugs commonly used in epidural injections and infusions are listed in Table 9-8. *It is emphasized that preservative free formulations of these drugs should be used for epidural injection.*

Transdermal Analgesic Administration

Transdermal administration of analgesics allows for delivery and maintenance of sustained concentrations of a drug avoiding the peaks and troughs associated with intermittent parenteral administration. Fentanyl and lidocaine are available in transdermal formulations and their use has been investigated in veterinary clinical patients.[80-81]

Table 9-8. Drugs used for Epidural Injections

Drug	Dose	Duration
Morphine	0.1 mg/kg	20-60 minute onset
	0.0125 mg/kg/hour for constant rate infusion	16-24 hour duration
Buprenorphine	5-10 mcg/kg	45-60 minute onset
	1.25 mcg/kg/hour for constant rate infusion	8-12 hour duration
		May result in less urine retention
2.0% Lidocaine	4 mg/kg	5 minute onset
		45-90 minute duration
0.5% Bupivacaine	1 mg/kg	20 minute onset
		120-360 minute duration
0.125% Bupivacaine	0.1-0.2 mg/kg/hour for constant rate infusion	Note: Lower concentration may lessen degree of motor blockade
2.0 % Mepivacaine	4 mg/kg	5 minute onset
		60-90 minute duration
0.5% Ropivacaine	1 mg/kg	15 minute onset
		90-420 minute duration
Morphine and Bupivacaine	0.1 mg/kg of morphine and 1mg/kg of bupivacaine.	20 minute onset
	6 ml maximum volume	12-24 hour duration

To apply a fentanyl patch, the hair of the animal is clipped and any gross debris is removed from the surface of the skin with water or saline. Alcohol should not be used as it will alter the lipids present on the epidermis, which will affect drug absorption. Once the area is completely dry, the patch is placed firmly onto the skin and held in place for one to two minutes. The patch should be placed in an area that will minimize patient removal and/or possible oral ingestion, as overdose may occur. Commonly, patches are placed on the dorsum of the neck or lateral thorax. A light bandage can then be placed over the patch. Transdermal patches should not be placed in direct contact with heating pads, as increases in cutaneous blood flow will increase drug absorption.[82]

Fentanyl patches are available in 25, 50, 75, and 100 mcg/hour concentrations. Clinicians should select a patch that will deliver a dose of 3-5 mcg/kg/hour in their patient. Once the patch has been placed, steady-state plasma concentrations are obtained in 18 to 24 hours in the dog while in the cat, 6 to 12 hours is required for steady plasma concentrations to be reached. Parenteral administration of opioids should be provided to animals when indicated to provide analgesia during the lag time until effective plasma concentrations are reached. The patch is designed to deliver fentanyl over a period of 72 hours, but they may be effective for longer periods. Studies have shown that there is significant inter and intra-individual variation in plasma fentanyl concentrations after patch application.[83] For this reason, patients should be carefully monitored for signs of pain and/or side effects.

Complications associated with the use of fentanyl patches include respiratory depression, sedation, inadequate analgesia, skin irritation, failure of the patch to adhere to the skin, and human abuse. In cats, mydriasis, agitation, and dysphoria may be observed.[83] If significant respiratory depression is observed, the patch should be removed and an opioid antagonist administered. Once a patch is removed, plasma levels decrease over a period of twelve hours. Patches should be disposed of carefully in the same manner as other controlled substances.

Lidocaine patches have been approved for use in humans for the treatment of peripheral neuropathies such as post-herpetic neuralgia and have generated interest in both human and veterinary pain management.[84] It is thought that application of a lidocaine patch produces local tissue concentrations that are high enough to produce local analgesia, without complete sensory block, for periods up to 24 hours.[85] The lidocaine patch is a 10 by 14 cm patch that contains 700 mg of 5% lidocaine. In human studies, once the patch is applied, up to 35 mg of lidocaine is absorbed topically, producing analgesia within 30 minutes,[85] with a half-life of 6-8 hours.[86] The amount of lidocaine absorbed is directly proportional to the area of skin that is covered and the length of time the patch is in contact with the area.[85] In contrast to transdermal fentanyl, transdermally administered lidocaine has a very slow rate of systemic absorption, which makes systemic lidocaine toxicity unlikely.[85] The pharmacokinetics of the lidocaine patch in dogs and cats are similar to those observed in human studies, showing significant tissue levels at the site of patch application, with peak plasma concentrations taking 10-36 hours to be achieved due to slow systemic absorption.[87,88]

To apply a lidocaine patch, the hair over the area should be clipped and the skin cleaned if needed. It is believed that the lidocaine patch acts by local nervous tissue penetration and not systemically like the fentanyl patch, thus the lidocaine patch must be placed close to or directly over the painful area. Unlike the fentanyl patch, the lidocaine patch can be cut to fit the patient or site of application without altering drug delivery. In surgical patients, the patch can be cut to the length of the incision and cut pieces should be placed on either side of the incision. Unused, cut portions of the patch can be saved for use at a later time. Seemingly, lidocaine patches can be left in place for three to five days with minimal side effects.[88] Side effects of lidocaine patches in humans include skin irritation erythema, hives, and edema associated with the lidocaine patch. These complications typically resolved within hours of patch removal.[89] In dogs, skin irritation/inflammation has been noted after patches have been in place for 72 hours.[88] Although systemic toxicity is unlikely, animals should be monitored for signs of overdose that include bradycardia, hypotension, facial twitching, and seizures.

Fentanyl and lidocaine patches are useful as analgesic adjuncts but should not be used as the sole method of providing analgesia to animals with moderate to severe pain.

Constant Rate Drug Infusions (CRI)

Constant rate drug infusions administered intravenously through an indwelling catheter are used to manage pain effectively while limiting the peaks and troughs of intermittent analgesic administration. This technique has been found to be particularly effective in animals whose pain has been refractory to intermittent administration of analgesics. Typically, a loading dose of the analgesic is administered parenterally followed by a constant rate infusion of the analgesic. Analgesics may be delivered using a syringe pump, or added to the patient's maintenance fluids. An example of the calculations used for constant rate infusions can be found in Table 9-9. Opioids, local anesthetics, and analgesic adjunct drugs have been used in constant rate infusions to treat pain in animals. Appropriate doses for these drugs are found in Table 9-10.

Table 9-9. Calculations for constant Rate Infusions.

You are presented with a 15 kg dog. You would like to start a lidocaine constant rate infusion.

1. Calculate loading dose
   - 15 kg x 2 mg/kg = 30 mg or 1.5 ml of 2% lidocaine. Administer over 20 minutes
2. Calculate maintenance fluid rate
   - (15 kg x 60 ml/kg/24 hours)/24 hours = 37.5 ml/hour
   - Assuming that you have a 1 L bag of fluids, this bag will last for 26.6 hours
3. Calculate how much lidocaine you will need
   - 50 mcg/kg/min = 3mg/kg/hour
   - 3mg/kg/hour x 15kg x 26.6 hours=1197 mg or 59.85 mls of 2% lidocaine
4. Prepare the fluid for administration by first removing 59.85 mls from the fluid bag. Then add the lidocaine to achieve the exact concentration desired.

Table 9-10. Drugs used as constant Rate Infusions for the treatment of Peri-operative Pain.

Drug	Dosage	Notes
Morphine	Dog: Loading dose: 0.1-0.25 mg/kg IV (slowly) CRI: 0.1-0.5 mg/kg/hour IV Cat: Loading dose: 0.05-0.1 mg/kg IV (slowly) CRI: 0.05-0.2 mg/kg/hour IV	Histamine release occurs even at low doses,[31] 48% reduction in isoflurane requirement of dogs[95] Morphine is commonly combined with lidocaine or lidocaine and ketamine (MLK). MLK caused a 45% reduction in the isoflurane requirement of dogs
Fentanyl	Dog: Loading dose: 2-5 mcg/kg IV CRI: 2-5 mcg/kg/hour IV for analgesia CRI: 10-45 mcg/kg/hour IV for surgical analgesia Cat: Loading dose: 1-3 mcg/kg IV CRI: 1-4 mcg/kg/hour IV for analgesia CRI: 10-30 mcg/kg/hour IV for surgical analgesia	54-66% reduction in isoflurane requirement of dogs
Butorphanol	Dog: Loading dose: 0.2 mg/kg IV CRI: 0.1-0.2 mg/kg/hour IV Cat: Loading dose: 0.2 mg/kg IV CRI: 0.1-0.2 mg/kg/hour IV	
Ketamine	Dog: Loading dose: 0.5-2.0 mg/kg IV CRI: 0.5 mg/kg/hour IV during surgery CRI: 0.1 mg/kg/hour IV postoperatively Cat: Loading dose: 0.5 mg/kg IV CRI: 0.1-0.5 mg/kg/hour IV	25% reduction in isoflurane requirement of dogs[95]
Lidocaine	Dog: Loading dose: 2 mg/kg IV CRI: 50-100 mcg/kg/min IV Cat: Loading dose: 0.5-1.0 mg/kg IV CRI: 10 mcg/kg/min IV	19% reduction in isoflurane requirement of dogs[46]
Dexmedetomidine	Dog: Loading dose: 0.5 mcg/kg IV CRI: 0.5-1.5 mcg/kg/hour IV	Significant cardiopulmonary changes occur even with microdoses[49]

Analgesic Protocols

The clinician should be familiar with various analgesic drugs and drug delivery techniques available for administration of these agents. Use of combinations of drugs and techniques in a well-planned multimodal and balanced analgesic protocol will provide the safest and most effective clinical control of pain. The analgesic regimens described for the canine in Table 9-11 are examples of multimodal analgesic plans. All analgesic protocols should be designed to meet a specific patient's needs and potentially modified in response to regular and frequent pain assessments.

Table 9-11. Examples of Analgesic Protocols

Procedure	Preoperative analgesics	Intraoperative analgesics	Postoperative analgesics
Canine exploratory laparotomy for small intestinal resection and anastomosis	• 0.5 mg/kg morphine IM-20 minutes before anesthetic induction	• Additional 0.25 mg/kg morphine IV as needed • 2 mg/kg lidocaine IV over 20 minutes followed by 50 mcg/kg/min as constant rate infusion	• 0.5 mg/kg morphine IM every 4 hours for first 24 hours • Continue lidocaine CRI for first 24 hours
Lateral thoracotomy	• 0.1 mg/kg oxymorphone IM-20 minutes before anesthetic induction	• Morphine (0.1 mg/kg/hr) and lidocaine (50 mg/kg/hr) constant rate infusion • Intercostal nerve blocks with 1 mg/kg of bupivacaine prior to closure	• Continue morphine and lidocaine CRI for 24 hours • 0.5 mg/kg morphine IM if needed for rescue analgesia • Instill 1 mg/kg of bupivacaine (diluted with saline to volume of 10-20 ml) into the thorax via thoracostomy tube every 6 hours
Total ear canal ablation	• 0.1 mg/kg oxymorphone IM-20 minutes before anesthetic induction	• Auriculotemporal and great auricular nerve blocks with 2 mg/kg bupivacaine during sterile prep • 5 mcg/kg fentanyl loading dose IV followed by 5 mcg/kg/hour constant rate infusion	• Continue fentanyl constant rate infusion for first 24 hours • 4 mg/kg carprofen SC at recovery
Radius/Ulna fracture repair	• 0.1 mg/kg hydromorphone IM-20 minutes before anesthetic induction	• RUMM block with 2 mg/kg bupivacaine during surgical prep • 0.05 mg/kg hydromorphone IV as needed	• 0.1 mg/kg hydromorphone IM every 4 hours for first 24 hours • 2 mg/kg ketoprofen SC at recovery
Dorsal hemilaminectomy	• 0.5 mg/kg morphine IM-20 minutes before anesthetic induction	• 0.25 mg/kg morphine IV as needed • 0.1 mg/kg preservative free morphine placed on the spinal cord • Incisional block with 2 mg/kg bupivacaine prior to closure	• 0.5 mg/kg morphine IM every 4 hours • If pain is not easily controlled, consider an IV morphine (5 mcg/kg/min), lidocaine (50 mcg/kg/min), ketamine (2 mcg/kg/min) constant rate infusion
Stifle arthroscopy	• 0.5 mg/kg morphine IM-20 minutes before anesthetic induction	• Epidural injection with 0.1 mg/kg preservative free morphine • Intra-articular injection with 2 mg/kg bupivacaine	• 0.5 mg/kg morphine IM every 4 hours • 4 mg/kg carprofen SC at recovery

Section B

Nervous System and Organs of Special Sense

Chapter 10

Nervous System

Peripheral Nerve Sheath Tumors

Daniel Brehm

Introduction

Tumors of the peripheral nervous system represent approximately 27% of all canine nervous system tumors.[1] These tumors most commonly affect the spinal nerve roots in the caudal cervical and cranial thoracic region and the nerves of the brachial plexus.[2] A variety of terms has been used to refer to tumors of the peripheral nervous system, including schwannoma, neurilemoma, neurinoma, neurofibroma, and neurofibrosarcoma.[2] The term Peripheral Nerve Sheath Tumor (PNST) (sometimes also referred to as Malignant PNST) is currently used to refer to these tumors based on their presumptive common cell of origin, the Schwann cell, and similar biologic behavior.[2] Some pathologists also use the term PNST as synonymous with or closely related to the tumor hemangiopericytoma and place it within the category of soft tissue sarcoma, again based on a presumptive similar cell of origin.[3] Hemangiopericytomas are generally found in the skin and subcutaneous tissues–frequently on the limbs-and are characterized by a locally aggressive, but usually systemically passive biological behavior. Although the histiogenesis of PNST involving the spinal nerve roots and plexus nerves and those found in the skin and subcutaneous tissues may be similar, the clinical signs associated with them are very different. The predominant focus of this chapter will be on peripheral nerve sheath tumors which affect the major spinal and cranial peripheral nerves, plexus nerves, and nerve roots.

Peripheral nerve sheath tumors are characterized as being locally aggressive, invasive neoplasms with a very low metastatic potential.[2] Many sites affected by PNST have been described, including the nerves of the lumbosacral plexus, the sciatic nerve, the thoracic ventral spinal nerve roots, and the trigeminal and vagus nerves.[2,4-8] These tumors are difficult to treat because of their invasive nature and frequent proximity to the spinal cord. One of the most common complications of treatment is tumor recurrence.[2] Peripheral nerve sheath tumors are uncommon in cats, although there are reports of these tumors causing spinal cord compression at the mid thoracic and thoracolumbar vertebrae.[9]

Histology / Biologic Activity

Peripheral nerve sheath tumors are histologically heterogeneous, comprising cells which are either spindle or oval to round in shape and arranged in interlacing bundles to[10,11] sheets and cords of pleomorphic cells.[2] Divergent differentiation is seen, with tumors described with fibrous, chondroid, osteoid, myxoid, and squamous and glandular[9,11,12] epithelioid components.[2] Malignant cellular criteria are typically present,[9,10] including anaplasia, multinucleation, high mitotic index, and necrosis.[2] Immunohistochemically, most PNST are positive for vimentin and S-100, and negative[10,12,13] for alpha-smooth muscle actin.[9] The gross characteristics of PNST vary depending on location. Those involving the spinal and plexus nerves often appear as firm, white-grey, fusiform or bulbous thickenings[9] (Figure 10-1). The masses are typically locally aggressive, extending proximally and distally along the nerve with poor circumscription.[2,7,9,14] The tumor may involve one or multiple nerves within the plexus and can extend through the vertebral foramen into the spinal canal. These tumors do not typically invade the soft tissues surrounding the nerves, but they can invade the spinal cord after extension into the spinal canal.[3]

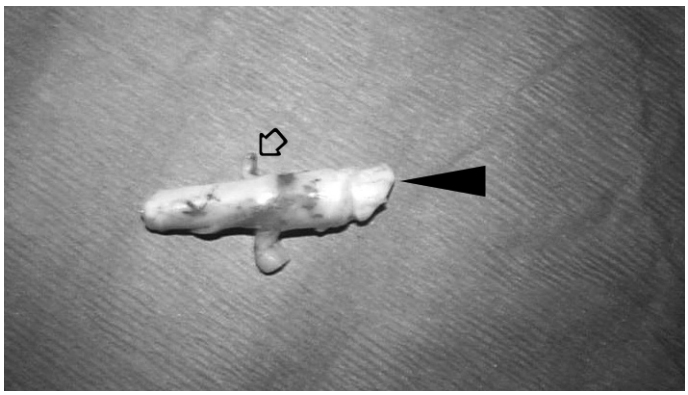

Figure 10-1. Postoperative resected section of a brachial plexus nerve containing a peripheral nerve sheath tumor. The nerve is markedly enlarged due to the tumor (closed arrow). The open arrow points to a normal size nerve within the plexus adjacent to the tumor.

Clinical Signs

The presenting signs of PNST depend upon the location of the neoplasm and the degree of involvement of the affected nerve tissue. Signs will differ depending on whether the tumor affects a single peripheral nerve, multiple nerves within a plexus, nerve roots, or the spinal cord. Peripheral nerve sheath tumors are usually slow growing, so clinical signs are often present over a period of weeks to months or longer.[2,7,15] Peripheral nerve sheath tumors most commonly affect the nerves of the brachial plexus and the spinal nerve roots in the caudal cervical and cranial thoracic spine.[2,9,14-16] The most common presenting sign of tumors in this location is a chronic, progressive, unilateral forelimb lameness, seen in approximately 78% of cases in one study.[2] The lameness often has an insidious onset with an

unknown cause. The lameness is usually initially weight bearing, but tends to progress to a non weight bearing status over time. Many dogs react painfully to manipulation of the limb and to deep axillary palpation, although the exact painful site is difficult to discern. A palpable mass is present in only approximately 37% of cases.[2] Moderate to severe muscle atrophy of the affected limb is commonly seen, occurring in approximately 93% of cases in one study.[2] Paresis and neurological deficits of the affected limb may be seen as the tumor compromises nerve function. Additional signs, including paraparesis, loss of the cutaneous trunci reflex, and ipsilateral Horner's syndrome can be seen if the tumor extends through the intervertebral foramen to involve the spinal cord. Signs of spinal cord involvement may develop after a period of forelimb lameness, concurrent with the lameness, or as an initial finding depending on the site of origin of the tumor.[9]

Peripheral nerve sheath tumors in other locations manifest with different presenting signs. A smaller population of PNST affects the nerves of the lumbosacral plexus.[2,4] These tumors present with a unilateral hind limb lameness which can progress to unilateral or bilateral hind limb paresis if the tumor invades the spinal canal. Peripheral nerve sheath tumors have been described specifically affecting the sciatic nerve and presented with signs of a hind limb lameness and associated sciatic nerve deficits.[5] Rectal examination of these dogs revealed a palpable intrapelvic mass not visible on survey radiographs. Peripheral nerve sheath tumors have also been reported to affect the trigeminal nerve.[7] The main presenting sign of these tumors was unilateral atrophy of the temporalis and masseter muscles, seen in all ten described dogs. One case report described a dog presenting with chronic vomiting, coughing, and signs of respiratory distress and with clinical findings of Horner's syndrome, ipsilateral laryngeal hemiplegia, and a ventral cervical mass identified via ultrasonography.[8] At necropsy, a PNST was identified affecting the vagosympathetic trunk. An intrathoracic PNST has been described in a dog which presented for a persistent, productive cough and regurgitation.[6] This tumor was believed to originate from the ventral thoracic spinal nerve roots.

The differential diagnoses for the most common presenting sign of PNST is any musculoskeletal disorder which produces a forelimb lameness. Many affected dogs have some degree of concurrent elbow or shoulder joint disease which can make definitive diagnosis of the PNST initially difficult. Because there is often a painful reaction on manipulation of the shoulder region, shoulder-area soft tissue injuries, such as biceps tendon or infraspinatus or supraspinatus muscle injuries, may be presumed to be the causative problem.[17] Although chronic musculoskeletal injuries can be associated with muscle atrophy, the atrophy seen with PNST tends to be more severe. Peripheral nerve sheath tumors also must be differentiated from other spinal nerve diseases, such as nerve root disease secondary to intervertebral disc compression.

Diagnostics

Survey radiographs may provide useful information in the workup of PNST. It is useful to characterize orthopaedic disease and to help rule out primary bone diseases such as proximal humeral or vertebral osteosarcoma. The most common described radiographic abnormality with PNST is widening of an intervertebral foramen when tumors extend into the vertebral canal.[18] Survey radiographs are generally of limited use in the diagnosis of PNST because only a small percentage of cases demonstrate detectable abnormalities.

Myelography is a more useful radiographic diagnostic tool and is essential in cases in which there is suspicion of tumor extension to the vertebral canal (Figure 10-2). In one study, approximately 95% of cases with nerve root involvement had abnormal myelograms.[2] Myelography also accurately identified the lack of macroscopic vertebral canal or nerve root involvement in 9 of 10 cases in which the PNST was located within the brachial plexus. A normal myelogram does not rule out PNST nor does it fully rule out involvement of the nerve roots, but it can be very useful to better plan the surgical approach or approaches needed for treatment.[2]

Advanced imaging techniques including computed tomography (CT) and magnetic resonance imaging (MR) have become valuable tools in the diagnosis of PNST. These imaging modalities have greater diagnostic sensitivity than conventional radiography and can provide important pre-treatment information on tumor localization and the degree of tumor extension.[4,5,7,14,15,17] Computed tomography was used to identify masses of the brachial plexus in 24 dogs in one study.[15] Twenty of the 24 cases (83%) demonstrated either uniform or heterogenous contrast enhancement. Tumors as small as one cm in diameter were identified; however, it should be noted not all masses identified on CT are associated with neuronal structures. Magnetic resonance imaging has been used in the diagnosis of PNST's of the radial nerve, trigeminal nerve, and in an intrathoracic location.[6,7,14] The majority of the

lesions were isointense on T1-weighted images and either isointense or hyperintense on T2-weighted images (Figure 10-3). All of the lesions demonstrated contrast enhancement. MR is becoming the preferred advanced diagnostic test due to its superior resolution of the tumor boundary and the absence of beam-hardening artifacts.[7]

Electromyography (EMG) is a useful tool in assisting with the diagnosis of PNST. Because of the destructive nature of PNST, the electrical conductivity through affected nerves is frequently altered. A primary goal of EMG, used in conjunction with other diagnostic tests, is to differentiate between muscle atrophy due to denervation and muscle atrophy due to disuse.[18] In the clinical setting, this applies to differentiation between muscle atrophy seen with nerve disease and that seen with orthopaedic disease.[2,7,14] It is not specific for PNST since other types of nerve injury (such as brachial plexus avulsion injuries) can produce EMG changes.[19] When used in cases of PNST, EMG can help determine the extent and severity of the nerve damage caused by the tumor, in effect helping to localize the tumor.[19] In one study, all twenty nine dogs in which EMG was performed demonstrated abnormal, spontaneous electrical activity in muscles of the tumor-affected limb.[2] In a separate study, EMG studies were used to confirm the diagnosis of sciatic nerve tumors in two dogs.[5] Changes seen on EMG studies include fibrillation potentials, positive sharp waves, and bizarre high frequency discharges.[7,19]

Surgical Treatment

The goals of treatment of PNST include eradication of the tumor, relief of pain associated with the tumor, and stabilization of neurological dysfunction caused by the tumor. The primary mode of therapy of PNST is aggressive surgical resection of all affected nerve tissue.[2] The tumor may be approached peripherally if it is located outside of the spinal canal, via a laminectomy if it involves the spinal canal, or from both approaches if the tumor involves both canal and peripheral locations. If the tumor has resulted in severe neurological dysfunction of an affected forelimb, or if resection of the tumor will significantly compromise forelimb function, amputation of the limb may be necessary with resection of the tumor. The basic principle of tumor removal is to resect all affected nerve tissue with a wide margin of grossly normal nerve proximal and distal to the mass. This frequently requires resection of multiple nerve branches due to the highly invasive nature of the tumor. Incomplete excision is common despite aggressive surgical treatment because of the difficulty of discerning normal from abnormal nerve tissue during surgery.[2] All resected tissue should be submitted for histopathology with proximal and distal edges marked with ink to assist the pathologist in assessing completeness of excision.

Surgical Approaches to the Brachial Plexus

The main and usually best approach to the brachial plexus is the craniolateral approach.[20] This provides a wide exposure to the plexus nerves and allows exploration and treatment of the peripheral nerves to the level of the spinal canal. Full exploration of the caudal plexus nerve roots requires transection of the scalenus muscle and cranial rotation of the first rib following an osteotomy near the costochondral junction. The craniomedial approach to the plexus provides better exposure of the peripheral nerves distal to the plexus.[19,20] This approach, though, provides limited access to the proximal portions of the plexus nerves, and it typically involves more muscle dissection than the craniolateral approach.[20] Both approaches can be easily modified into a forequarter amputation if the degree of tumor resection will result in a dysfunctional limb.

Craniolateral Approach[20]

The dog is placed in lateral recumbency with the affected limb, shoulder area, and caudal neck prepared for aseptic surgery. A skin incision is made at the cranial border of the mid scapula and extending distal to the greater tubercle of the humerus. The omotransversarius muscle is transected over the cranial edge of the scapula. Dissection continues ventrally dorsolateral to the cleidobrachialis muscle. The omotransversarius and cleidobrachialis muscles are elevated cranially and cranioventrally, respectively and the scapula is elevated caudally to expose the brachial plexus. The plexus nerves are better defined after separation from the loose subscapular connective tissue. The scalenus muscle may need to be transected to expose the seventh and eighth cervical and first thoracic ventral nerve branches. The first rib can be osteotomized just proximal to the costochondral junction and rotated cranially and laterally to further expose the first and second thoracic ventral nerve roots if these need to be treated as well. This will require ligation of the first intercostal artery and vein and transection of the first intercostal space musculature.

Craniomedial Approach[19]

The dog is placed in lateral recumbency, with the affected limb retracted caudally. An incision is made from the caudal aspect of the jugular furrow, medial to the greater tubercle of the humerus, and to the axilla. An incision is made at the medial edge of the cleidobrachialis muscle. The cranial edge of the superficial pectoralis muscle is transected near to its insertion on the humerus. The plexus is exposed by lateral retraction of the limb and blunt dissection around the nerves.

Surgical Approach to the Lumbosacral Plexus

The lumbosacral plexus is a comparatively uncommon site for PNST. In one study, only eight of the 51 cases had tumors affecting either the lumbosacral nerve roots or the sciatic nerve.[2] Clinical signs associated with tumors affecting the lumbosacral plexus nerve roots include hind limb lameness and hind limb paresis or paraparesis.[2,5] Tumors in this area may be more difficult to locally resect because of the limited access to the lumbosacral nerve trunk. A lumbosacral nerve sheath tumor was completely excised in one study via a hemipelvectomy.[4]

Approach to the Lumbosacral Nerve Trunk[21]

The patient is positioned in ventral recumbency. A dorsal skin incision is made from the craniodorsal iliac spine caudally to the ischiatic spine. The gluteal fascia and underlying superficial gluteal muscle are incised and the sacrospinalis muscle fibers are separated over the dorsal iliac spine and body. The middle gluteal muscle is incised along the dorsal aspect of the ilial wing and body. Blunt intrapelvic dissection following retraction of the middle gluteal and sacrospinalis muscles exposes the lumbosacral nerve trunk.

Laminectomy

A laminectomy is needed in cases in which the PNST extends from a peripheral location into the spinal canal or when the tumor originates at the nerve roots within the canal.[2,12] A hemilaminectomy is usually performed to allow exposure of the nerve roots and the ventrolateral aspect of the spinal cord. The laminectomy may need to be made over several intervertebral spaces if the tumor involves multiple nerves. After exposure of the spinal cord and nerve root, a durotomy is performed to allow transection of the nerve root at the level of the cord. The nerve root is then dissected out from the surrounding epaxial musculature as far as possible. Unless all of the tumor-affected nerve tissue can be removed, a second surgery to remove the diseased tissue from a peripheral approach is necessary. It is more typical, though, that the laminectomy is performed subsequent to a peripheral approach to remove tumor tissue extending into the spinal canal.

Adjuvant Therapy

Chemotherapy and radiation therapy are of questionable benefit in the treatment of PNSTs affecting the major nerves of the brachial and lumbosacral plexes. There is minimal data describing the efficacy of adjuvant therapies for PNST in these locations. The majority of information relative to radiation therapy efficacy refers to the peripherally located, soft tissue sarcoma categorization of nerve sheath tumors (hemangiopericytomas). Radiation therapy as an adjunct to incomplete surgical excision of canine soft tissue sarcomas resulted in a reported disease free interval of 1082 days with a survival rate of 76% at five years.[22] If PNSTs affecting the plexus nerves have a biological response similar to those placed in the soft tissue sarcoma category, then adjuvant radiation therapy could be considered an appropriate part of the management of these tumors. The major problem with plexus-located tumors is their proximity to the spinal cord. A recurrent tumor, or a tumor which continues to grow despite radiation therapy will have more profound clinical consequences than those tumors located distally on a limb or on the dog's trunk, and this will likely lead to shorter disease free intervals and survival times.[2] At this time, without further data specific to PNSTs affecting the major plexus nerves, radiation therapy can only be considered as a reasonable, but not proved adjunct to surgery.

Prognosis

The prognosis of PNST is generally guarded to poor.[2] The highly infiltrative nature of PNST and the difficulty of identifying the true extent of the tumor make complete surgical excision difficult to achieve. The proximity of many of these tumors to the spinal canal also limits complete excision. Prognosis has been linked to tumor location. In one study, tumors were divided into three anatomical groups: tumors distal to the brachial or lumbosacral plexus (Peripheral Group), tumors involving nerves within the plexus (Plexus Group), and tumors involving the vertebral canal (Root Group).[2] The median survival time of dogs in the Root Group was five months. The median survival time of the Plexus group was 12 months. Although there was no statistical difference, the trend was for dogs in the Plexus Group to survive longer than dogs in the Root Group. This survival difference is a reflection of the proximity of the tumor to the spinal cord in the Root Group and the profound clinical effects tumors in this location can have on the patient. Over 82% of all dogs in this study followed to death or at least three months following diagnosis had either recurrence of clinical signs or an unaltered, progressive worsening of presenting clinical signs. Most of the dogs either died directly from or were euthanized due to the effects of the tumor. In the study describing trigeminal nerve sheath tumors, only three of the ten dogs were treated surgically.[7] One of these cases was alive without disease progression 27 months after surgery, one was alive four months after surgery, and one was euthanized from progressive disease five months after surgery. Survival times of the non-treated cases ranged from five to 21 months.

Conclusion

Peripheral nerve sheath tumors are aggressive tumors which can be difficult to definitively diagnose and successfully treat. Tumor recurrence, or unabated progression of presenting clinical signs are the most common complications of treatment. The hallmark signs of PSNT, which should be an impetus to pursue further diagnostics, are a chronic, progressive forelimb lameness and marked muscle atrophy. The treatment of choice for these tumors is aggressive surgical excision, which may require peripheral excision of the mass, limb amputation, laminectomy, or a combination of these procedures. The efficacy of adjuvant therapies is not clear at this time. The best approach to these tumors will likely be early and aggressive intervention, using diagnostics such as electromyography and MR imaging sooner rather than later in the diagnostic workup, to hopefully identify the tumor before it has had opportunity to invade multiple nerves or the spinal canal. Because of the aggressive nature of these tumors, the overall prognosis of PNST still has to be considered guarded to poor.

Peripheral Nerve Biopsy

John H. Rossmeisl Jr.

Peripheral nerve biopsies are routinely performed in veterinary practice and are essential in some cases, along with complete clinical and electrophysiologic examinations, for accurate diagnosis of neurologic disease. General indications for peripheral nerve biopsy include neurologic deficits referable to an anatomic area innervated by the nerve, clinical signs consistent with flaccid paresis or paralysis, hyporeflexia to areflexia, neurogenic muscular atrophy, and sensory deficits of the innervated area. Evaluation of an appropriately collected nerve biopsy may also provide prognostic information, and rarely, a specific etiology for the observed clinical signs.[1]

Selection of Biopsy Sites

Although it is possible to biopsy virtually any nerve, whether it be of a mixed, motor, or purely sensory variety, several criteria are used to guide selection of a specific peripheral nerve for biopsy. A priority is that the clinical neurologic examination has provided evidence that the selected nerve is affected by the neuropathy. When possible, clinical evidence of specific nerve involvement is further confirmed by electrophysiologic examination such as nerve conduction studies. Nerves selected for biopsy should be easily identifiable, relatively consistent in their neuroanatomic location, able to be protected from entrapment and recurrent trauma, and accessible with minimal patient morbidity.[1] In addition, ideally the nerve should have published normal, quantitative electrophysiologic and morphometric data available for comparative study, and innervate a skeletal muscle that is amenable to biopsy for which normal data is available.[1-3]

In cases where generalized clinical neurologic disease is present, biopsy of the mixed function common peroneal nerve will usually provide a representative specimen. The common peroneal nerve is a preferred biopsy site as many generalized peripheral neuropathies preferentially affect the pelvic limbs prior to the thoracic limbs and normal morphometric and electrophysiologic data for the common peroneal nerve exists for both cats and dogs.[1,3] The common peroneal nerve is also easily visualized as it courses over the lateral head of the gastrocnemius muscle. The flat structure and readily identifiable fascicles make the nerve especially amenable to biopsy. In the pelvic limb, the tibial nerve is a frequently biopsied nerve, as is the ulnar nerve in the thoracic limb. The purely sensory caudal cutaneous antebrachial nerve and caudal cutaneous sural nerve are the most commonly sampled thoracic and pelvic limb nerves in cases in which sensory neuropathy is suspected.

Peripheral Nerve Biopsy Techniques

Peripheral nerve biopsy is usually performed under general anesthesia. There are two basic techniques used to obtain peripheral nerve biopsies, nerve transection and the fascicular biopsy technique. The fascicular biopsy technique is preferred over nerve transection since fascicular biopsy allows for the structural and functional preservation of the majority of the remaining nerve, and thus is associated with minimal or

transient clinical morbidity. Specialized equipment is generally not needed, but operating loupes to improve the surgeon's visualization of the operative field are valuable. The fascicular biopsy technique will be described here through an approach to the common peroneal nerve. Detailed descriptions of the surgical approaches to several other peripheral nerves have been published elsewhere.[1,2]

The animal is placed in lateral recumbency, and an area extending from the distal third of the femur to the proximal third of the tibia is prepared for aseptic surgery. The common peroneal nerve can be palpated percutaneously as it courses on the lateral aspect of the stifle just caudal to the proximal tibia and fibula. A 5- to 7-cm oblique skin incision extending from just caudal to the lateral femoral condyle to the proximal fibula will expose the underlying fascia of the biceps femoris muscle, through which the target nerve can be palpated (Figure 10-4). The biceps femoris fascia is elevated and a 5-cm fascial incision made which will allow visualization of the underlying common peroneal nerve as it courses over the lateral head of the gastrocnemius muscle (Figure 10-4- inset). Perineural fat and fascia should be carefully and bluntly dissected off of the visible portion of the nerve. The caudal 1/3 of the proximal end of the exposed nerve is isolated using a ligature of 5-0 or 6-0 silk suture. Gentle traction placed on the proximal ligature allows for the longitudinal division using ophthalmic scissors of a 2- to 4-cm long distal fascicular biopsy specimen. Fascicular biopsy specimens should not exceed 30% of the diameter of the parent nerve from which they are harvested. In the event that the underlying disease process or inherent structure of the nerve complicates visualization of individual nerve fascicles, the exposed nerve segment can be atraumatically spread over a sterile tongue depressor or scalpel handle, which can aid identification of fascicles (Figure 10-5). The biceps femoris fascia is closed with absorbable suture, and the skin closed routinely. Application of an external protective dressing is usually not necessary. Although it was originally reported that neuromas occur frequently following fascicular biopsy, more recent clinical experiences with large numbers of patients suggest that biopsy-related complications are rare.[2,3] In the case of peroneal nerve biopsy, the most commonly reported complication consists of transient proprioceptive deficits and knuckling of the pes, both of which usually resolve within 5 days of the procedure.

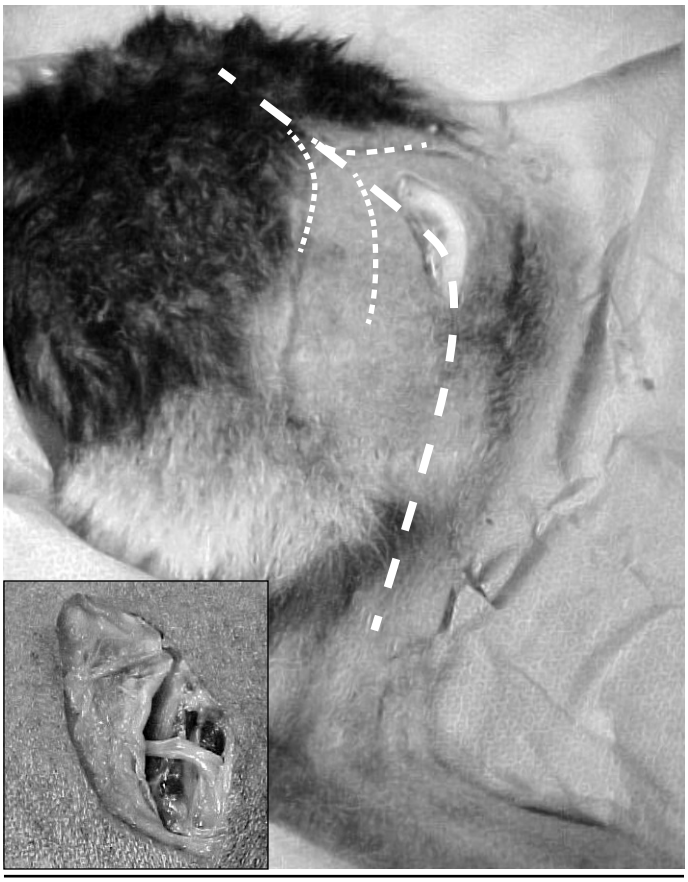

Figure 10-4. Fascicular biopsy of the common peroneal nerve is initiated by making a 5- to 7-cm slightly oblique skin incision extending from just caudal to the lateral femoral condyle to the proximal fibula. The common peroneal nerve (dashed lines) can be percutaneously palpated beneath the fascia of the biceps femoris muscle as it courses on the lateral aspect of the stifle just caudal to the proximal tibia and fibula. Performance of a 5-cm fascial incision will allow for visualization of the underlying common peroneal nerve as it courses over the lateral head of the gastrocnemius muscle (Figure 10-4 inset).

Processing of Nerve Biopsy Specimens

Nerve biopsies require special handling to avoid artifact formation while in fixative. In order to prevent significant contracture of the biopsy sample, several techniques have been described to maintain the length of the nerve biopsy prior to fixation. These techniques include pinning the nerve at both ends to a section of tongue depressor with 25 to 27 gauge hypodermic needles or securing the nerve to a length of the stem of a standard wooden cotton tipped applicator by placing a circumferential suture of

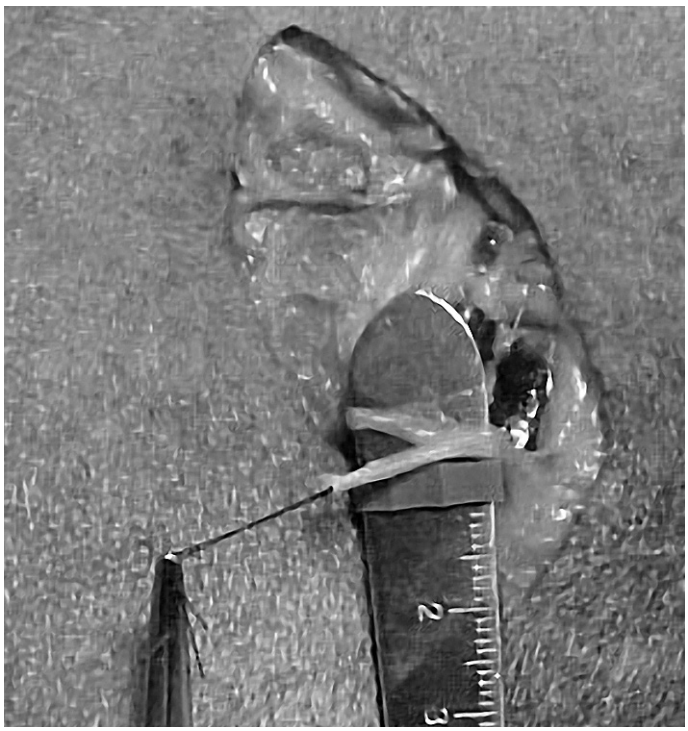

Figure 10-5. Minimal traction placed on the proximal silk ligature allows for the excision of a 2 to 4-cm long distal fascicular biopsy specimen. Gentle spreading of the isolated nerve over a scalpel handle facilitates identification of individual nerve fascicles.

5-0 or 6-0 silk at either end of the biopsy. The nerve may also be suspended directly in the fixative using a stainless steel weight attached to the free end of the original silk suture that was placed in the proximal portion of the nerve during the biopsy procedure.

Ideally, the specialized laboratory that will be receiving and processing the nerve sample should be contacted prior to performance of the biopsy so that laboratory requests for specific fixatives can be followed. Nerve biopsy specimens are preferably fixed in both 2.5% glutaraldehyde and 10% formalin.[1] If biochemical or specific immunohistochemical studies are desired, snap-freezing of unfixed nerve tissue may be required. Formalin-fixed specimens are embedded in plastic and routinely stained with hematoxylin and eosin, Luxol fast blue, or Gomori trichome stains and evaluated with light microscopy for evidence of axonal degeneration, overt demyelination, or inflammatory or neoplastic cellular infiltrates. Fixation of samples in glutaraldehyde allows for preparation of semithin and ultrathin sections for more detailed light microscopic and ultrastructural examinations, respectively. Quantitative morphometric analysis of myelinated and unmyelinated axonal numbers and diameters and nerve fiber densities may be performed so that disorders of myelin may be identified. Glutaraldehyde fixation also allows for examination of single teased fiber preparations. Evaluation of teased fiber specimens is especially useful for identification of disorders of myelinated fibers. The technique allows for the quantitative assessment of the lengths and morphology of successive myelin internodes in a single nerve fiber. This procedure permits characterization of specific demyelinating processes such as segmental and paranodal demyelination, as well as remyelination.[4] In addition, information regarding current nerve fiber degeneration can be obtained from examination of teased fiber specimens.

Chapter 11

Muscle Biopsy

Skeletal Muscle Biopsy Techniques

John H. Rossmeisl, Jr.,

The diagnostic approach to a patient with suspected neuromuscular disease begins with a thorough history and complete neurologic examination, which will often yield information regarding the component of the motor unit affected. Performance of electrodiagnostic tests in patients with neuromuscular disease often provides important information pertaining to the specific localization and extent of the disease within the motor unit, however it is necessary in some cases to perform skeletal muscle biopsy, often in conjunction with peripheral nerve biopsy. Morphologic evaluation of biopsy specimens will confirm clinical and electrophysiologic findings and is required to diagnose and classify the underlying disease responsible for the clinical signs.

General clinical indications for muscle biopsy include generalized or focal muscle weakness, stiffness, contracture, atrophy, myalgia, or hypertrophy.[1,2] Less commonly encountered clinical abnormalities that are suggestive of underlying motor unit disease include muscle fasciculations, rippling, myokymia, and myotonia. Identification of biochemical alterations such as an elevated serum creatine kinase concentration, lactic acidemia, or myoglobinuria, in any animal with clinical signs compatible with myopathic disease is also an indication to perform muscle biopsy. It is recommended that at least two muscle samples from distant locations, such as the thoracic and pelvic limbs, be examined when attempting to confirm the presence of a generalized neuromuscular disorder.[1,2]

Selection of Biopsy Sites

Several criteria should be considered prior to selection of the specific biopsy site. Primarily, there should be historical, clinical, and, ideally, electromyographic (EMG) evidence that the specific muscle is affected by the underlying disease.[2] Chronically affected, severely atrophied muscles are poor candidates for biopsy, as meaningful interpretation of biopsies sampled from such sites is often impeded by significant replacement of myofibers with adipose and fibrous tissues.[1] Muscles should also be evaluated for any previous disease, trauma, intramuscular injections, or surgery that could result in morphologic artifacts in the biopsy specimen. It is noteworthy that needle EMG evaluation can also induce focal muscle necrosis in areas of needle insertion.[1] Subsequently, when performing an EMG examination of a patient with a suspected generalized neuromuscular disease, it is preferred to electrophysiologically evaluate one side of the patient's body, and then utilize the results of the EMG examination to obtain biopsy samples from affected muscles on the contralateral side.[1,2]

The muscle selected for biopsy should be readily accessible and easily identified through a minimally invasive surgical approach; be able to be sampled with minimal resulting morbidity to the native muscle or surrounding soft-tissues; and ideally have previously published normative data regarding myofiber size, type, and distribution available for comparison.[1,2] Thoracic limb muscles commonly selected for biopsy include the distal thirds of the medial or long heads of the triceps brachii, or proximal portion of the superficial digital flexor. In the pelvic limb, the distal third of the biceps femoris or vastus lateralis, and proximal third of the lateral head of the gastrocnemius or cranial tibial muscles are frequently sampled. Reference data for both the dog and cat are available for each of these muscles.[1] If disease of the muscles of mastication is suspected, the temporalis muscle is the preferred biopsy site.

Additional factors to consider prior to selecting a biopsy site is the suspected localization of the disease within the motor unit, which is based on the differential diagnoses formulated following completion of the clinical examination. Biopsy of specific muscles or certain regions within a muscle may be required to provide the highest diagnostic yield. For example, when ultrastructural, immunohistochemical, or in vitro electrophysiological examination of the motor end plate is required, as would be necessary to confirm a diagnosis of congenital or seronegative, acquired myasthenia gravis, it is recommended that biopsy of a muscle, such as external intercostals, anconeus, or similar muscle that has high concentration of end plates and is able to be harvested intact from origin to insertion be performed.[1] In these circumstances, it is generally advised to discuss the proposed site and method of processing of muscle biopsy specimens with the laboratory or pathologist that will be charged with interpreting the biopsy before the procedure to facilitate collection of a diagnostic sample.

In situations where the specific location of the disease within the motor unit is unable to be determined following clinical examination and adjunctive electrophysiologic testing is unavailable, it is prudent to consider sampling anatomic sites that are amenable to simultaneous biopsy of muscle and peripheral nerve through a single surgical approach.[2] In the pelvic limb, the biceps femoris and lateral head of the gastrocnemius muscles, as well as the common peroneal nerve are all accessible through a single incision placed over the caudolateral aspect of the distal femur and proximal tibia. In the thoracic limb, performance of an oblique incision extending from the medial humeral condyle to the point of the olecranon provides satisfactory exposure to the distal third of the medial head of the triceps and superficial digital flexor muscle, as well as the ulnar nerve at the level of the elbow.

Skeletal Muscle Biopsy Procedures

Two muscle biopsy techniques have been described, the open and percutaneous needle-biopsy procedures.[1,3,4] The percutaneous method offers the advantages of not requiring general anesthesia for completion, being minimally invasive, and has been shown to be capable of providing diagnostic quality samples in dogs using readily available, inexpensive, commercial biopsy needles (Perfectum 11-gauge needle, Popper and Sons, Inc., New Hyde Park, NY) with minimal morbidity.[3,4] The primary limitations of the percutaneous procedure are the small sample size of tissue obtained using this method, and inability to prevent contraction of myofibers after sampling.[1,4]

Although open muscle biopsy procedures can also be performed using local anesthetics, general anesthesia is usually indicated to facilitate completion of electrodiagnostic testing that often precedes performance of open muscle biopsy. If local anesthesia is considered for open biopsy, care must be taken not to infiltrate the anesthetic agent deep into the muscle that has been selected for biopsy.[2] Open muscle biopsy is readily performed with basic surgical instrumentation.

The skin overlying the biopsy site should undergo routine aseptic preparation, regardless of the type of biopsy procedure performed. When using the open technique, the skin and any superficial fascia are incised, carefully dissected, and retracted to facilitate visualization of the myofiber orientation of the muscle selected for biopsy. Manipulation of the muscle biopsy site with forceps should be avoided. Following identification of the intended biopsy site, there are three similar methods by which biopsies intended for routine histochemical analysis can be harvested: the stay suture procedure, the muscle clamp method, and the free hand technique. It is not necessary to maintain biopsy specimens that will be subjected to routine analyses in a stretched position.[1,4]

To harvest the muscle biopsy using the stay suture procedure, a 0.5 cm diameter, 2 cm long strip of muscle is created by placement of two stay sutures. The stay sutures should be placed perpendicular to the longitudinal orientation of the myofibers, and be tied loosely so as not to excessively constrict the myofibers. After the stay sutures are in place, two 2 cm long incisions are made parallel to the direction of the myofibers and extending just beyond the proximal stay suture immediately distal to the other stay suture in order to further isolate the muscle (Figure 11-1). The two stay sutures can be used to manipulate the biopsy specimen atraumatically during the remainder of the procedure.

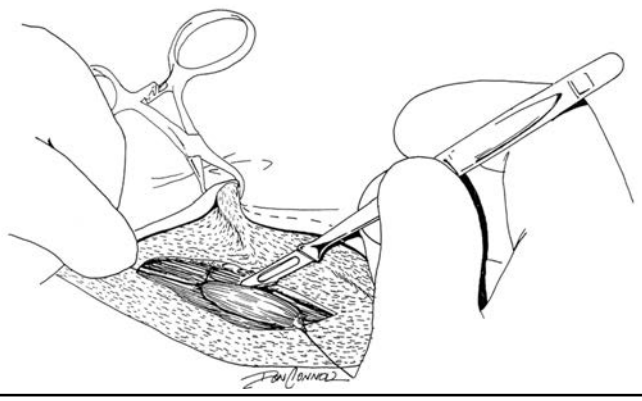

Figure 11-1. Following placement of the two stay sutures at both ends of the desired biopsy site, incisions are made along each side of the biopsy specimen in a direction parallel to the long axis of the myofibers.

While holding the proximal stay suture, the isolated segment of muscle is undermined using a scalpel blade or sharp dissection scissors (Figure 11-2), with a desired final biopsy thickness of approximately 0.5 cm. Complete separation of the biopsy specimen from the native muscle belly is achieved by cutting of the ends of the biopsy sample proximal and distal to the stay sutures (Figure 11-3), in a fashion that permits removal of both stay sutures with the biopsy specimen.

When using a commercial clamp system (Price muscle biopsy clamp, V. Mueller Instrument, Chicago, IL) to perform open muscle biopsy, a cylinder of muscle is created by first making two 2 cm long incisions parallel to the direction of the myofibers, with the intent of separating an approximately 0.5 cm diameter segment of muscle between the two incisions. The muscle clamp system is then applied to the ends of the incised segment of muscle (Figure 11-4). Using the handle of the muscle clamp to manipulate the biopsy specimen, the isolated muscle cylinder within the clamp is undermined and collected in a manner identical to that described for the stay suture technique.

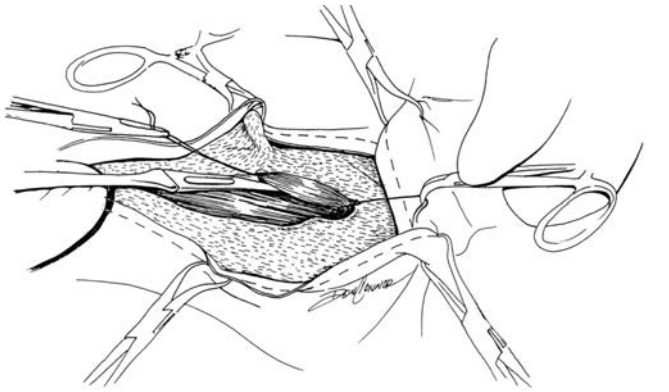

Figure 11-2. After completion of the two parallel incisions, the biopsy specimen is undermined by sharp dissection with a scalpel blade.

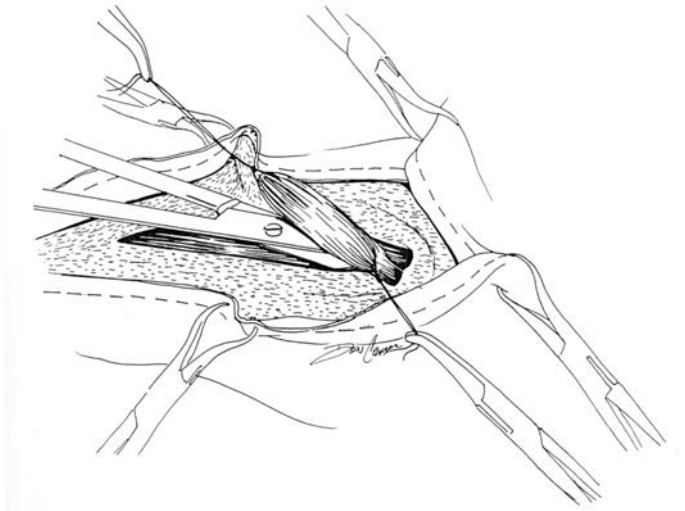

Figure 11-3. Once the muscle has been completely undermined, the biopsy sample is separated from the native muscle belly by cutting the myofibers adjacent to the sutures with sharp scissors or a scalpel blade in a fashion that allows for removal of both stay sutures with the biopsy specimen.

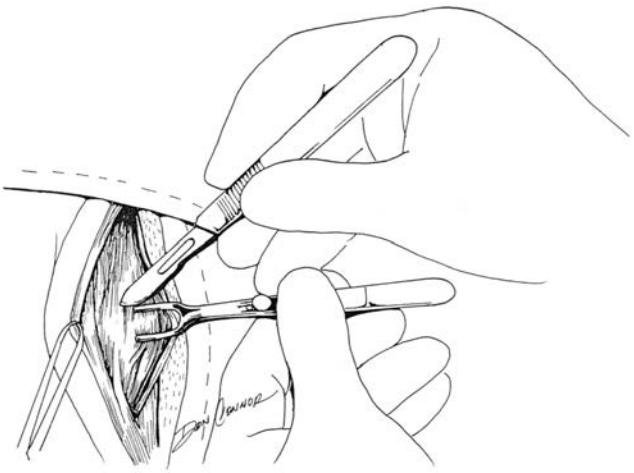

Figure 11-4. An alternative technique to the stay suture method of open biopsy involves placing a commercial muscle clamp system on the muscle after parallel incisions have been made adjacent to the desired specimen.

The procedure for the free hand, open biopsy is similar to that described for the stay suture and muscle clamp methods. The primary difference with the free hand technique is that instead of utilizing a stay suture or muscle clamp to manipulate the muscle specimen during procurement of the biopsy, the proximal end of the biopsy specimen is minimally but directly handled with microsurgical forceps. Following completion of the biopsy procedure, the end of muscle specimen that was manipulated with the forceps is trimmed using a sharp, fresh scalpel blade to remove any artifacts caused by direct handling of the muscle.[2]

If an open muscle biopsy procedure is planned, it is important to consider the potential need to obtain samples for electron microscopic evaluation. These samples are ideally collected first with minimal manipulation of the myofibers. A muscle biopsy clamp system should be considered if muscle is being harvested for ultrastructural evaluation, as these clamps prevent both handling artifacts and myofiber contracture after excision and immersion in fixative.[1] Alternatively, if a muscle biopsy clamp is not available, a 0.25 to 0.5 cm in diameter, 1.5 cm long cylinder of muscle can be created by performing a modification of the previously described stay suture technique. In order to maintain the muscle in a stretched position during completion of the biopsy, the isolated cylinder of muscle is secured to a 2 cm length of small diameter wooden dowel using the long ends of the stay sutures, prior to undermining and complete separation of the biopsy specimen. Biopsy samples destined for ultrastructural evaluation are typically fixed in glutaraldehyde, and muscle biopsy clamps applied to these samples can be removed without compromising sample quality after 24 hours of fixation.[1] Following collection of the biopsy for electron microscopic analysis, additional biopsies for routine histochemical examinations can be obtained from adjacent myofibers.

The degree of hemorrhage associated with muscle biopsy procedures is usually minimal, and can often be controlled with digital pressure after harvesting the biopsy. Suture ligation may be required if a larger intramuscular vessel is encountered. The use of electrocautery should be avoided until all muscle

biopsy samples have been obtained. Closure of the superficial muscular fascia and subcutaneous tissues is performed with an absorbable suture, and the skin is closed with sutures or staples. Application of external wound dressings following open muscle biopsy is rarely necessary. Complications associated with both the open and percutaneous muscle biopsy techniques are uncommon, but can include hematoma formation, wound dehiscence, and infection.[1,3]

Processing of Muscle Biopsy Specimens

Most freshly harvested muscle biopsy specimens are transported without delay to specialized diagnostic laboratories for processing.[2] Therefore, prior to obtaining the muscle biopsies, it is crucial to contact the individual laboratory to which the samples are being sent to obtain specific instructions regarding recommended handling of harvested tissue, and to coordinate timely shipping and receiving of tissue samples. The histochemical and cytochemical characteristics of freshly collected muscle biopsy specimens can be acceptably preserved for approximately 30 hours if biopsy specimens are placed on gauze pads lightly moistened with physiologic saline, subsequently sealed in an airtight container, and maintained at 4° C until processing occurs.[2] This method allows for appropriately handled and packaged samples to be safely transported overnight to the diagnostic laboratory.

Once harvested, proper processing of muscle biopsy specimens is necessary to prevent introduction of processing artifacts and prevent loss of metabolic substrates and tissue enzymes. Immersion of muscle biopsy specimens in formalin provides limited diagnostic information, but may allow for morphologic characterization of any cellular infiltrates present in the sample. The method of obtaining and preserving muscle in glutaraldehyde for ultrastructural analysis has been previously described and reviewed.[1,2] Routine histochemical analysis of muscle is ideally performed on biopsy specimens that are processed by fresh freezing using the gum tragacanth-isopentene-liquid nitrogen method.[1,3] Uncontrolled freezing of muscle biopsy specimens can result in massive artifact formation that can completely compromise the diagnostic quality of the sample.

Muscle biopsies are readily obtained, and when properly performed and processed, are capable of providing essential information regarding a specific etiology for, the underlying disease process occurring within the muscle. The normal morphologic and histochemical characteristics of skeletal muscle using a standard battery of stains have been reviewed extensively elsewhere.[1,2] Even in cases in which a specific etiological diagnosis is not obtained from the biopsy, certain pathologic abnormalities that can be identified in muscle biopsy samples often provide insight into the basic underlying mechanism of the disease. For example, visualization of any of the following changes in a biopsy specimen are consistent with denervation of the muscle, and thus are coined neuropathic lesions: angular myofiber atrophy, small grouped myofiber atrophy, fiber type grouping, pyknotic nuclear clumping, or large grouped myofiber atrophy.[1,2] Primary myopathies are usually divided into inflammatory and non-inflammatory types based on the presence or absence of inflammatory cell infiltrates in representative biopsy specimens, respectively. Morphologically, there are a variety of non-specific findings in muscle biopsies that are suggestive of myopathic disease. These include myofiber splitting, degeneration or regeneration, necrosis and phagocytosis, internalized nuclei, and vacuolization.[1,2] Increased amounts of fibrous or adipose tissues within muscle biopsy specimens can be a feature of both primary myopathic and neuropathic muscular disease.

Chapter 12

Eye

Surgery of the Eyelids

J. Phillip Pickett

Anatomy

The eyelids function to maintain the health of the ocular surface. The eyelid muscles enable the lids to close over the ocular surface which helps distribute the pre-corneal tear film and protect the corneal and conjunctival surfaces from injury. Tactile cilia (lashes) sense approaching objects before they contact the globe, thus initiating the protective blink response. Glandular tissues secrete portions of the pre-corneal tear film (tarsal or Meibomian glands secrete the oily portion of the pre-corneal tear film and goblet cells of the conjunctiva secrete the mucinous portion of the pre-corneal tear film).

Important anatomic structures of the eyelids are illustrated in Figures 12-1A, B. The outermost surface of the eyelids is covered by relatively loose, haired skin in the dog and cat. Dogs usually have only upper eyelashes or cilia originating from the eyelid margin while cats do not have true eyelashes. On the lower eyelid, beneath the lid margin and parallel to the lid margin is a 1-2 mm wide zone of hairless skin. This nonhaired-haired demarcation is a surgical surgical landmark for entropion correction surgeries. Beneath the skin near the lid margins run the muscle fibers of the orbicularis oculi muscles. These muscle fibers (innervated by the palpebral branch of the facial nerve) run parallel to the lid margin and are responsible for eyelid closure. The upper eyelid has four muscles innervated by the occulomotor, facial, and sympathetic nerves that actively elevate the upper eyelid. Sensation to the eyelids is provided by the ophthalmic and maxillary branches of the trigeminal nerve. At the medial canthus, the medial palpebral ligament retracts the canthus medially; at the lateral canthus, the retractor anguli ligament/muscle retracts the lateral canthus laterally. Defects in the aforementioned liagamentous supportive structures may result in entropion and ectropion. Deep to the eyelid skin and orbicularis oculi muscles lies the connective tissue tarsal plate which contains the tarsal (Meibomian) glands. These glands are alligned perpendicular to the lid margin and there are approximately 30-40 per lid in dogs and cats. The gland openings may be seen with magnification along the lid margins. The tarsal plates are not as rigid in dogs and cats as in man, and their flaccidity may contribute to ectropion and entropion in some canine breeds. The innermost layer of the eyelids is the palpebral conjunctiva. This conjunctiva is firmly adherent to the tarsal plate area of the eyelids, but is loosely attached to the underlying eyelid stroma in the palpebral fornices.

Near the eyelid margins on the upper and lower lids, approximately 1-3 mm lateral to the medial canthus, are the openings (punctum) of the nasolacrimal duct system. These punctum lay at the medial most aspect of the cartilaginous tarsal plate and are just inside the eyelid margin on the palpebral conjunctival surfaces. The palpebral surface of the third eyelid conjunctiva at the medial canthus has a raised haired structure; the lacrimal caruncle.

Surgical Procedures

Temporary tarsorrhaphy

Temporary partial or complete closure of the palpebral fissure can be used to protect the globe following proptosis, extra- or intra-ocular surgery, or under conditions where the cornea may be overly exposed (e.g. palpebral nerve paralysis). If the temporary tarsorrhaphy is to be left in place for more than 48 hours, stents should be placed between the suture material and the eyelid skin to prevent the sutures pulling through the eyelid or cutting into the skin (Figures 12-2A, B). Pieces of sterilized "postal" rubber bands or a similar latex or silicon material make excellent stents for this purpose. If the tarsorrhaphy is to be maintained for more that 3-6

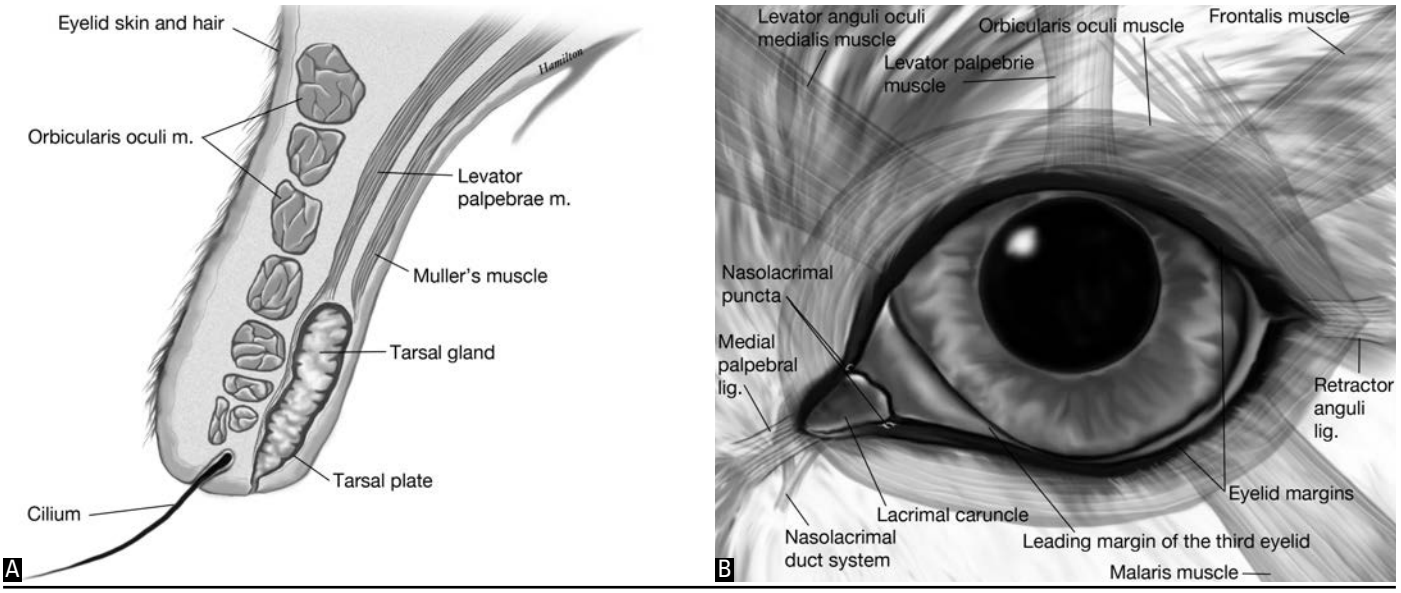

Figure 12-1. Applied eyelid anatomy. **A.** Cross section of canine upper eyelid. **B.** Frontal view of superficial and deep structures of the eyelid.

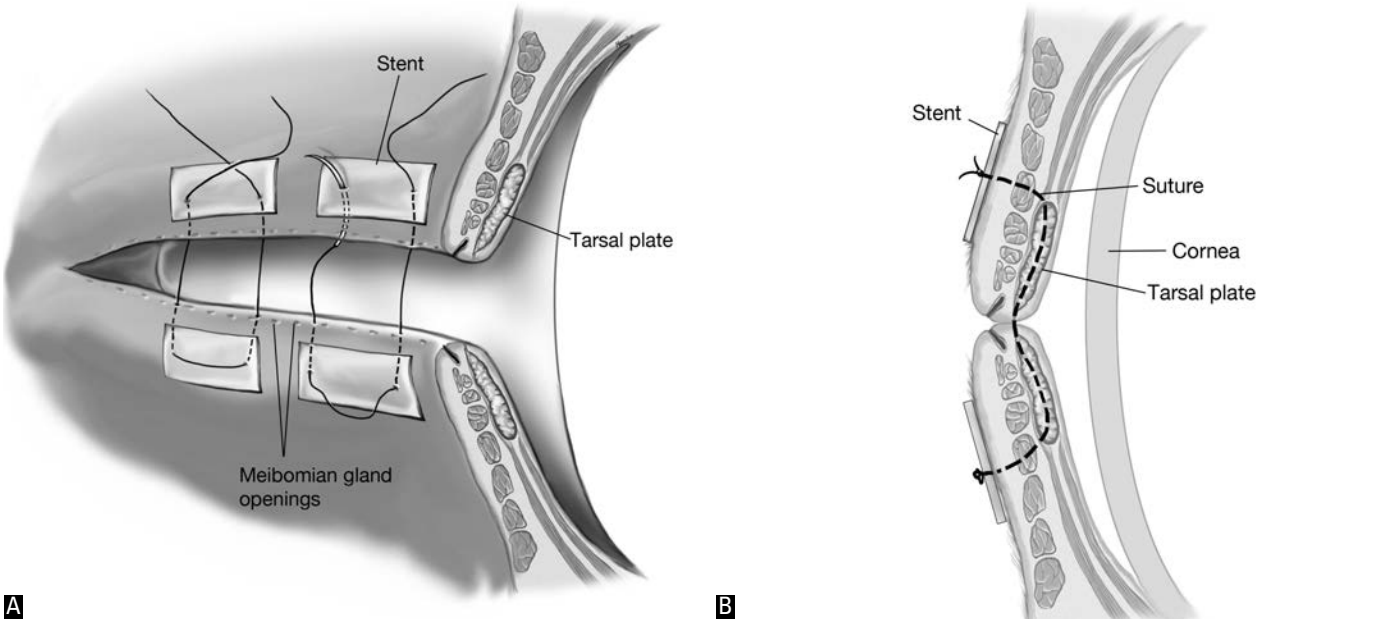

Figure 12-2. Proper placement of temporary tarsorrhaphy sutures over stents. **A.** Frontal view of placed tarsorrhaphy suture over a stent and details of placement of suture through eyelid and stent. **B.** Cross section of tarsorrhaphy suture placement over stent.

days, non-reactive suture such as monofilament or braided nylon is preferred to more reactive suture such as silk. Fine suture (5-0 to 6-0) with a small cutting needle allows proper placement of the suture. The needle should be passed first through the 4 mm x 6 mm stent and then through the eyelid skin 3-6 mm from the eyelid margin. By passing the needle into the tarsal plate, the needle should exit the eyelid margin at the level of the Meibomian gland openings. The needle should then be passed into the opposite lid margin at the Meibomian gland openings through the tarsal plate, and then out through the eyelid skin approximately 3-6 mm from the lid margin. The needle should then be passed through the stent material away from the lid, and then passed back through the stent material towards the lid. The needle is then passed through skin, tarsal plate, and Meibomian gland openings as previously described, across and through the opposite lid, and finally through the first piece of stent material so that the needle exits the same side of the stent material where the original suture bite took place. When finished, the completed suture pattern resembles a horizontal mattress pattern through eyelids and stents. Meticulous exit and entry of the needle at the Meibomian gland openings will result in excellent eyelid margin apposition with little to no risk of suture abrading the corneal surface. The suture should be tied tightly so that post-operative loosening and corneal abrasion by the suture may not occur.

Eyelid Laceration Repair

Full thickness eyelid lacerations that occur perpendicular to the eyelid margin are commonly seen secondary to fight wounds and other sharp trauma. Proper closure will result in a functional eyelid and a cosmetically acceptable palpebral fissure. The technique for eyelid laceration closure described may also be used to remove a full thickness eyelid tumor or to shorten an eyelid margin for correction of ectropion.

The skin, stroma, and conjunctiva of the eyelids are extremely vascular, and minimal debridement of damaged tissue following an eyelid laceration is recommended. Following surgical preparation of the skin and conjunctival surfaces with povidine iodine solution diluted with saline (10% povidine iodine solution diluted with saline to 1% final iodine concentration) and saline rinse, debridement of the wound with a scalpel blade is performed until the skin edge begins to hemorrhage. Closure of eyelid lacerations is performed with fine, absorbable suture (6-0 Vicryl) so as to appose the edges of the lacerated tarsal plate (Figure 12-3A-E). The first bite of the needle should enter the tarsal plate away from the lid margin and exit the tarsal plate close to the lid margin edge of the tarsal plate (Figure 12-3B). The needle is then passed to the opposite side of the wound and into the tarsal plate in the area closest to the lid margin to exit the tarsal plate away from the lid margin. If performed properly, the suture pattern approximates a horizontal mattress pattern with no suture passing through the palpebral conjunctiva (therefore there will be no possibility of suture rubbing the cornea) with the knot being tied and buried within the eyelid stroma away from the eyelid margin. A simple continuous pattern trailing away from the eyelid margin completes closure of the palpebral tarsal plate/conjunctiva with the final knot being buried within the eyelid stroma (Figure 12-3C). It is important to place suture bites so that no suture is passing through the palpebral conjunctiva that could abrade the corneal surface. A fine, braided, synthetic absorbable suture is preferred over larger, monofilament, and/or catgut suture material, especially in thin-lidded dogs and cats. If the eyelid stroma is excessively swollen, or the patient is a large dog, additional simple interrupted sutures to close the more external orbicularis oculi muscle are indicated. Skin closure must be meticulous at the eyelid margin so as to result in a smooth, anatomic eyelid margin. Three suture patterns have been described to appose the eyelid margin skin. I prefer to use a simple horizontal mattress pattern (Figure 12-3D) using fine (4-0 to 6-0) nonabsorbable (silk or nylon) braided suture followed by simple interrupted skin sutures. A cruciate or "figure of eight" suture (Figure 12-3E) involving the lid margin followed by simple

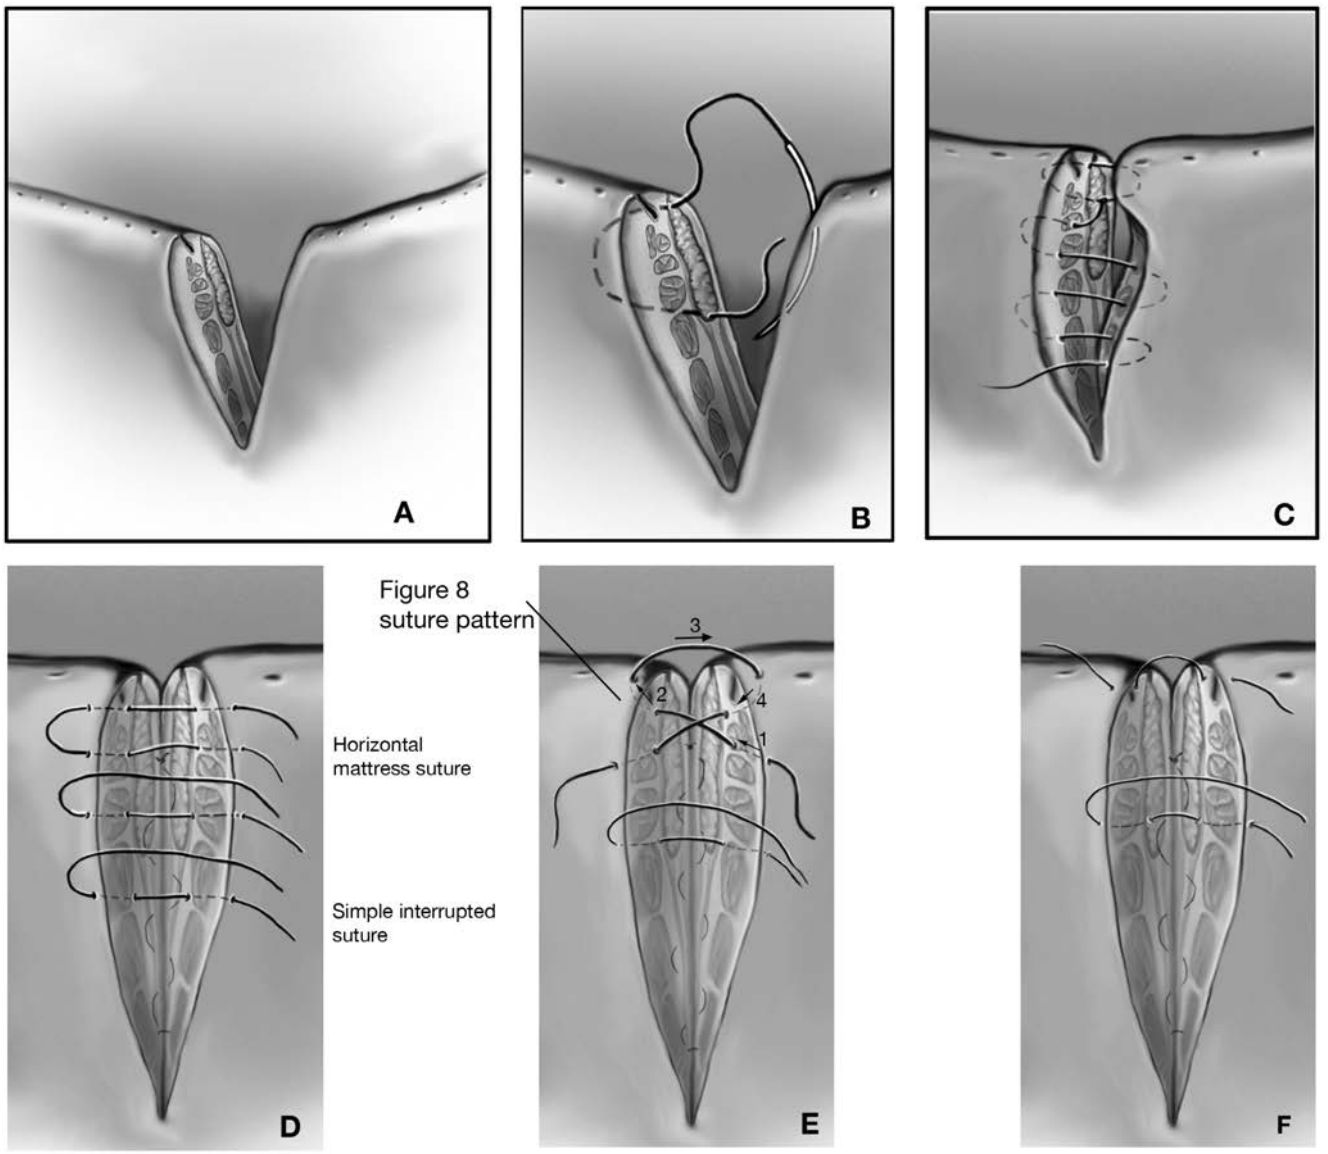

Figure 12-3. Full thickness eyelid laceration repair. **A.** Frontal/cross sectional view of full thickness eyelid laceration. **B.** Proper placement of fine, synthetic, absorbable suture in the tarsal plate to close the tarsal plate/lid stroma. **C.** The buried suture is tied so the knot is buried within the eyelid stroma and cannot abrade the corneal surface. A continuous pattern within the eyelid stroma finishes closure of the deep lid layers. It is important that the suture does not pass through the palpebral conjunctiva, either during the running stitch pattern or when the final knot is tied. **D.** Use of a horizontal mattress suture to close the eyelid margin followed by simple interrupted suture to close skin/orbicularis layer. The suture tags of the first suture may be left long and incorporated into the subsequent simple interrupted suture to prevent suture tag abrasion of the corneal surface. **E.** Use of a figure of eight or cruciate pattern to oppose the lid margin without suture tag abrasion of the cornea. **F.** Use of a simple interrupted suture to close eyelid margin. The suture should be placed very close to the lid margin, the tags left long, and the tags tied back from the corneal surface in the subsequent simple interrupted skin sutures.

interrupted skin sutures also results in excellent closure. A well placed simple interrupted suture at the lid margin (Figure 12-3F) with the suture tags being tied back by subsequent simple interrupted sutures can result in excellent anatomic closure as well, but it is important to tie the suture tags in a manner that does not allow the suture tags or the knot to come in contact with and abrade the corneal surface. If eyelid closure is precarious due to tissue friability and/or swelling, temporary tarsorrhaphy sutures, one on either side of the wound closure, can help immobilize the lids and "splint" the lid until healing is complete and sutures are removed 10 days post-operatively.

Full Thickness Eyelid Wedge Resection for Correction of Ectropion

Ectropion is eversion of the lower eyelid margin resulting in spillage of tears onto the face (epiphora) and excessive exposure of the palpebral and bulbar conjunctiva and cornea. Ectropion is usually seen in those canine breeds with heavy facial skin, excessively long palpebral fissures, and/or lax tarsal plates (e.g. hounds, giant breeds, and sporting breeds). A simple technique for "tightening" lower lid ectropion involves a full thickness wedge resection of the lid to shorten the lid margin (Figure 12-4 A-E) with closure of the wound being similar to that described for eyelid laceration repair.

A smooth eyelid margin to help stabilize the precorneal tear film meniscus is desirable, so the wedge resection to shorten the lid margin is performed laterally (Figure 12-4B). There should be some tarsal plate left on each side of the wedge to allow for closure of the wound in two layers. The initial incision is made using a scalpel with a Jaeger lid plate inserted into the cul-de-sac to stabilize the eyelid (Figure 12-4B). The incisions should be made perpendicular to the eyelid margin (parallel to each other) to the level of the edge of the tarsal plate and then taper to a point that ends in the deepest recess of the cul-de-sac (Figure 12-4C). The incisions may also be made using a Metzenbaum scissor, with the shape of the excised wedge being the same as that described for scalpel excision using a lid plate. It is important that the initial incisions from the lid margin through the length of the tarsal plate be parallel to each other so that upon closure, there will be a straight, non-indented eyelid margin. Closure of the wound is in 2 (or 3) layers as for an eyelid laceration (Figures 12-4 D and E).

Eyelid Tumor Resection

Eyelid margin tumors are commonly seen in dogs. Meibomian

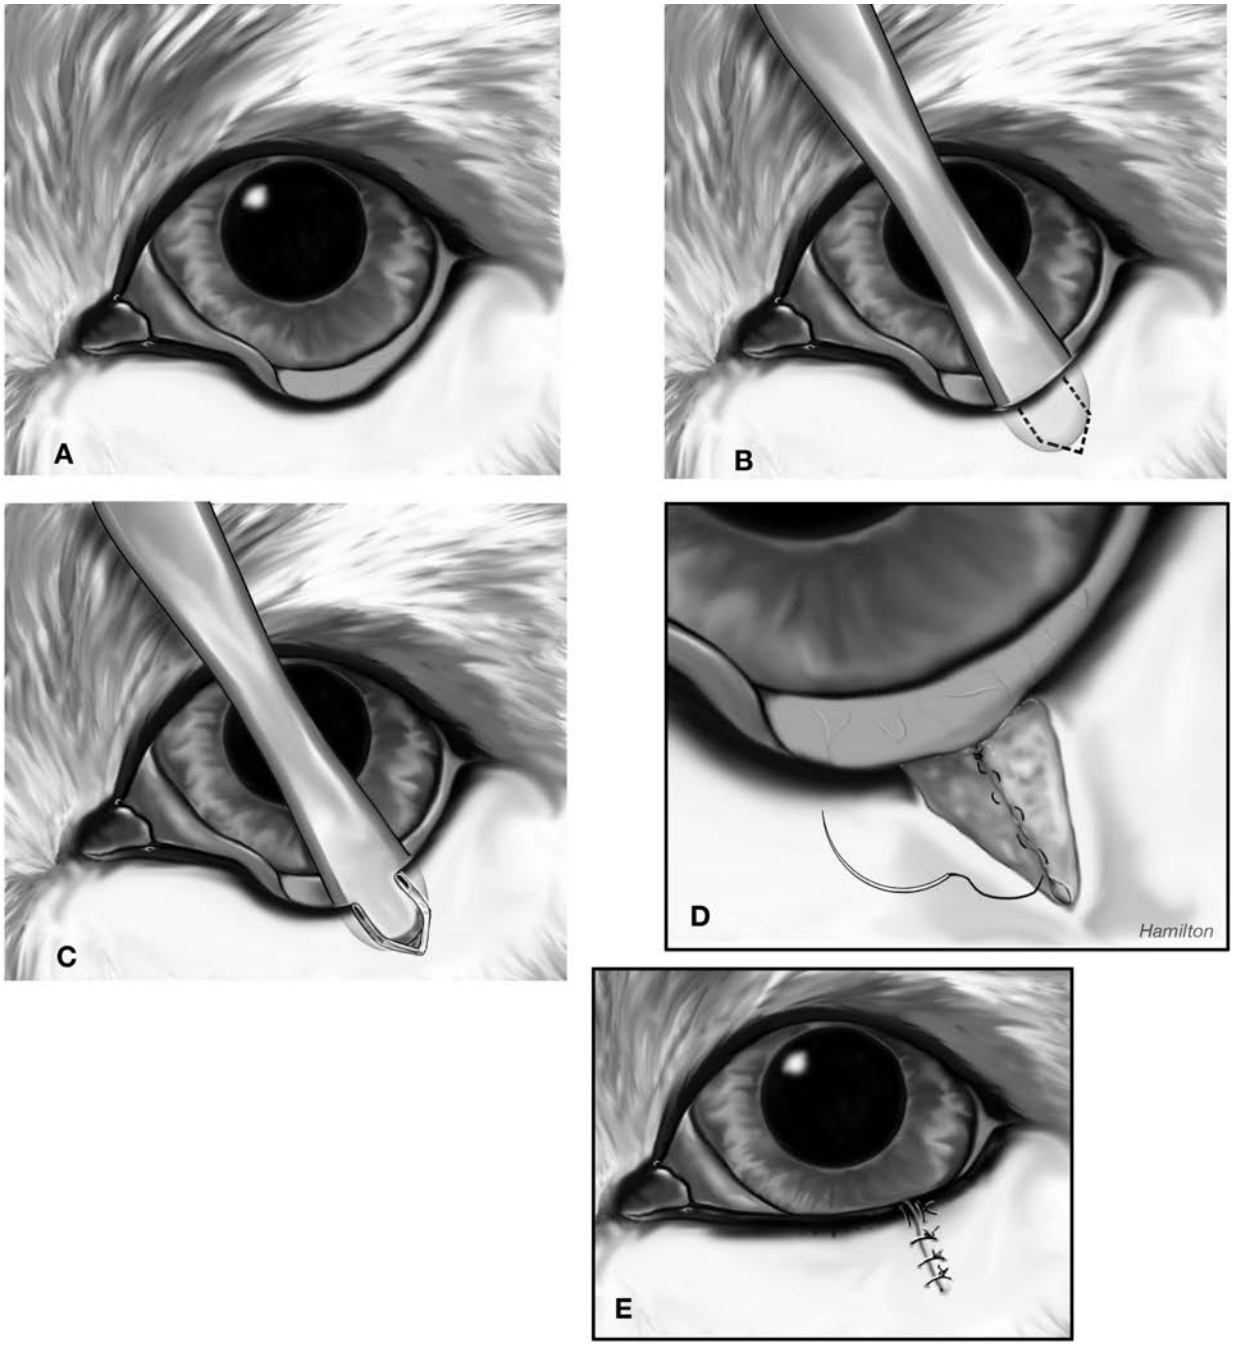

Figure 12-4. Full thickness eyelid resection to correct simple ectropion. **A.** Lower lid ectropion with exposure of ventral bulbar conjunctiva and cornea as well as lower lid conjunctiva. **B.** Use of Jaeger lid plate to excise full thickness wedge of eyelid. The excision should be made laterally so as to maintain a smooth eyelid margin. The initial cuts from the eyelid margin should be parallel through the tarsal plate and then taper to the depth of the cul-de-sac. **C.** With full thickness wedge removed, surgeon should be able to visualize the edges of the cut tarsal plate. **D.** Closure of deep eyelid tissue in same manner as described for eyelid laceration repair. **E.** Skin closure in the same manner as for eyelid laceration repair.

gland adenomas, mast cell tumors, papillomas, melanomas, and squamous cell carcinomas may occur in the lid. In cats, eyelid neoplasia is uncommon and most tumors are malignant. A full thickness wedge resection as described for ectropion correction and a two-layer closure as described for eyelid laceration is used to remove most eyelid tumors.

Depending on the species (cats have tight lid margins compared to dogs with more lax margins) and breed (hounds and sporting breeds have more lax lids than do toy breeds such as miniature poodles), approximately 1/4 to 1/3 of an eyelid may be removed and closed in the manner listed above for ectropion correction. It is important to excise the eyelid with incisons through the tarsal plate area being made parallel to each other and perpendicular to the lid margin to maintain a smooth, anatomic lid margin after healing.

If more than one-third of the lid margin is excised to obtain tumor free margins, closure may be complicated by inadequate surrounding tissue. This may result in excessive lid margin tension and poor lid function. A lateral canthotomy incision may enhance lid closure by allowing eyelid tissue to slide medially and be advanced to close the defect (Figure 12-5A-C). Following excision of the eyelid mass, a Metzenbaum scissor is used to

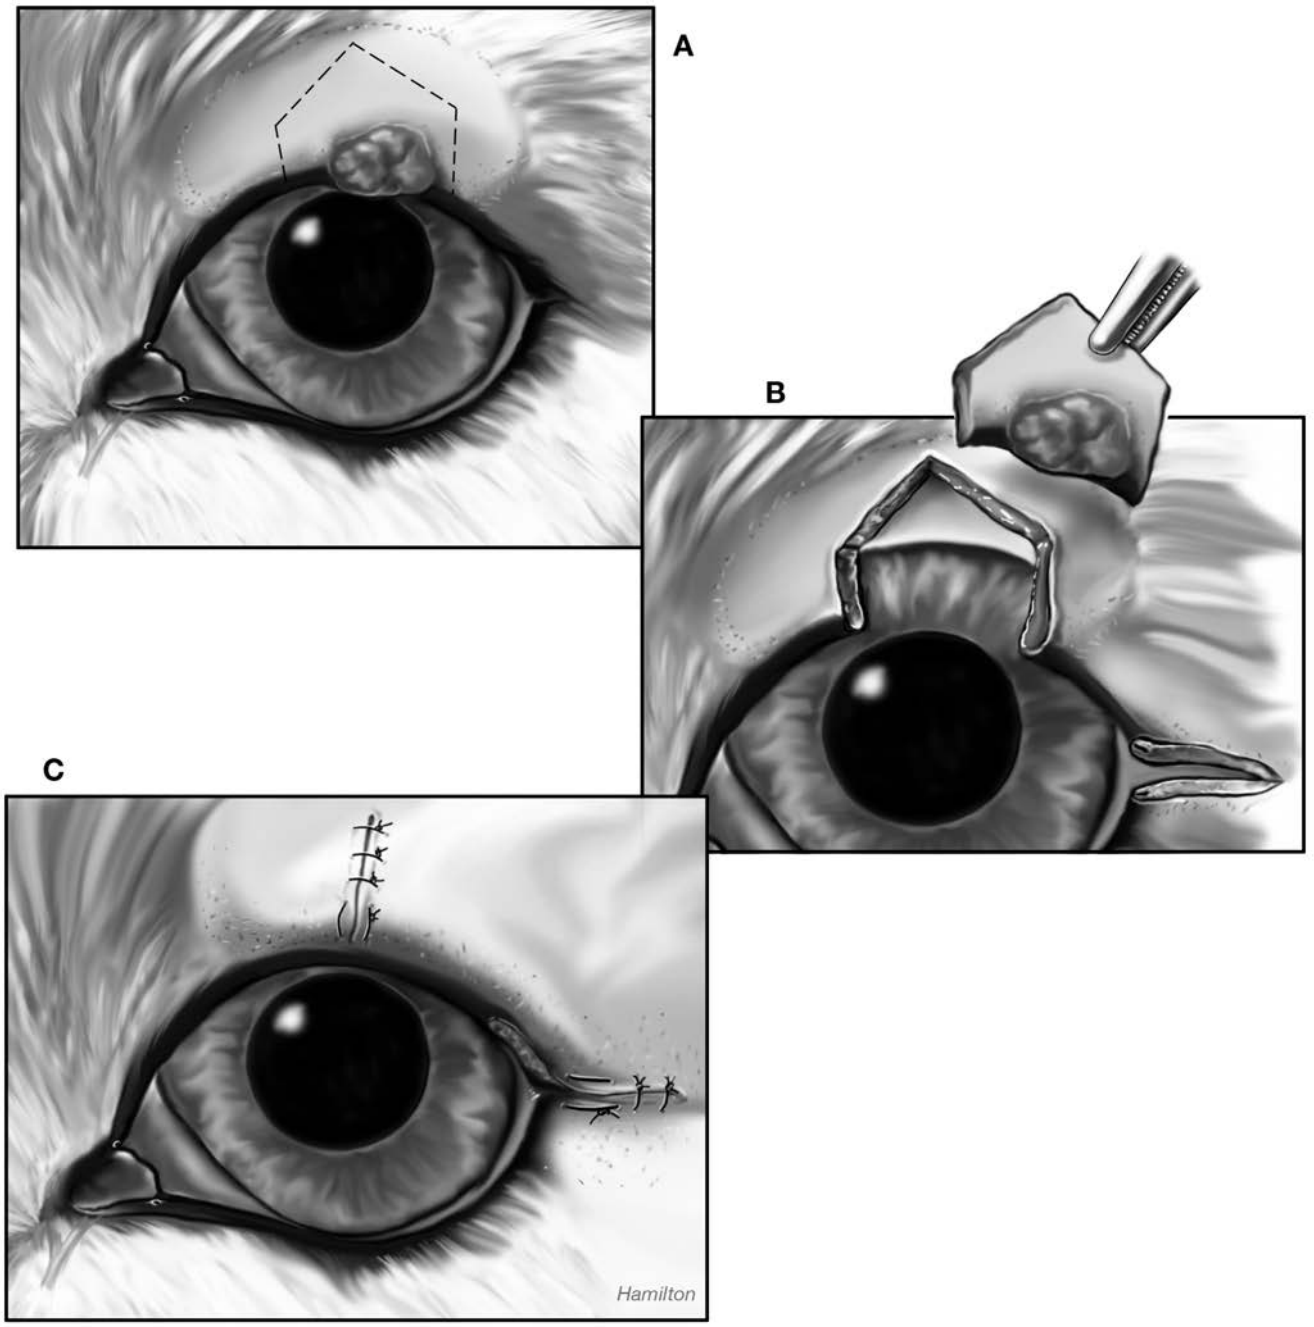

Figure 12-5. Wedge excision for removal of eyelid mass. **A.** Excision of 1/3 or more of eyelid margin to remove an eyelid mass. **B.** Lateral canthotomy is performed from canthus to the depth of the cul-de-sac with a Metzenbaum scissor taking care not to sever the orbital ligament. **C.** The eyelid margin wound is first closed in two layers. The lateral canthotomy is closed as it lies in two layers. This will result in a wound edge of the lateral canthotomy becoming the new eyelid margin. This is allowed to heal be second intention.

cut full thickness from the lateral canthus to the depths of the cul-de-sac laterally being cautious so as to not cut the lateral orbital ligament. This incision (Figure 12-5B) yields less lateral tension, which allows for a more effective two-layer closure of the lid wound. Closure of the lateral canthotomy using the two layer technique leaves a small wound margin at the lateral canthotomy incision to heal by second intention (figure 12-5C).

If one-half or more of the eyelid margin must be excised for tumor excison, a semicircular sliding skin flap is constructed to close the resulting defect. Following excision of the lid mass and a releasing lateral canthotomy (Figure 12-6A), the semicircular skin flap is constructed by making a curved skin incision extending laterally from the end of the lateral canthotomy extending approximately 1.5-2.5 times the width of the void to be filled (Figure 12-6B). Excision of a Burow's triangle of skin at the lateral terminus of the semicircular flap incision will minimize focal terminal distortion upon closure of the wound. The surgeon should use caution in making the skin incision and during undermining of the flap to not damage the superficial temporal artery located subcutaneously lateral to the lateral canthus. A two layer closure of the lid mass excision wound is followed by buried absorbable sutures placed to reduce dead space beneath the skin flap. The skin flap incision is closed in two layers up to the edge of the new lateral canthus. The newly formed eyelid margin created by the skin flap is left to heal by second intention. Complications may include trichiasis from facial hair, a flaccid lower eyelid that permits epiphora, or a flaccid upper eyelid (ptosis) due to excision of the levator palpebrae muscle in the original excision.

Entropion

Entropion is defined as inward turning/inversion of the eyelid(s). The condition is commonly seen in dogs and occasionally in cats resulting in frictional irritation of the conjunctival and corneal surfaces by eyelashes and/or facial hairs of the lid. This frictional

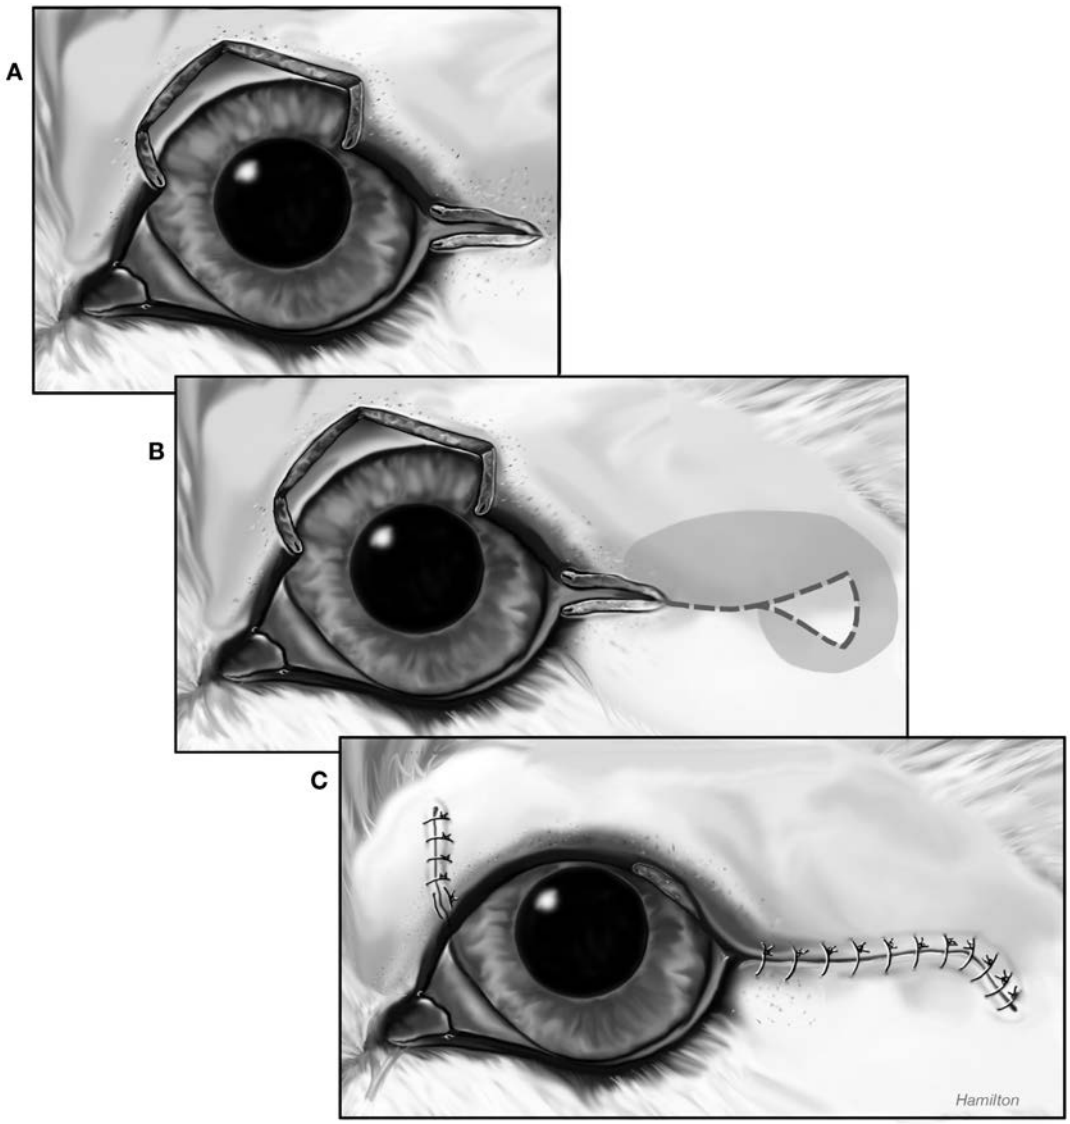

Figure 12-6. Wedge resection of a large eyelid mass with use of a semicircular flap to fill in eyelid margin void. **A.** Excision of 1/2 or more of eyelid margin to remove an eyelid mass in conjunction with lateral canthotomy. **B.** Dotted line indicates the semicircular graft cut and Burow's triangle. Cross-hatching indicates skin to be undermined to allow sliding of the graft. **C.** Eyelid margin excision site is first closed in two layers. Buried absorbable sutures reduce dead space under semicircular graft. Semicircular graft is closed up to the point of lateral canthus in two layers. The semicircular flap makes the new lateral aspect of the upper eyelid; the new eyelid margin is allowed to heal by second intention.

irritation is painful and may lead to corneal ulceration, corneal neovascularization and deposition of pigment on the corneal surface (pigmentary keratitis). In severe cases, vision loss from corneal scarring and opacification, corneal perforation, and loss of the globe from deep corneal ulceration are possible.

In cats, lower lid entropion may be seen in brachycephalic breeds (e.g. Persians and Himalayans) as a conformational defect due to the shortened face. Spastic entropion occurs when an ocular irritant causes severe blepharospasm that leads to rolling in of the eyelid margin. Since the frictional irritation of the facial hairs on the corneal surface causes more pain, spastic entropion becomes a cycle of pain, blepharospasm, and corneal irritation with continued pain and blepharospasm. Spastic entropion may be seen in young cats (< 6 months of age) of the brachycepahlic breeds and in adult cats with corneal pain due to infectious (e.g. feline herpes virus-1) or irritation induced keratitis conditions.

In dogs, spastic entropion is seen in young puppies of breeds (e.g. Shar Peis, Chow Chows, and others) with excessive facial skin and laxity of eyelid structures such as the retractor anguli muscle or ligament. In some puppies, when neonatal ankyloblepharon resolves and the eyelids open at 2 weeks of age, the eyelid margins begin to roll inward due to heavy facial skin and eyelid laxity. In adult dogs, spastic entropion may be seen in animals that have a painful ocular condition leading to excessive blepharospasm similar to that described for cats.

Lower eyelid entropion in dogs is commonly seen in younger dogs (less than one year of age) due to deep-set globes and conformational defects of the eyelids and facial structures. Lower eyelid entropion may also have a spastic component which should be considered when surgically correcting the defect.

Upper eyelid entropion occurs in those heavy faced breeds (e.g. bloodhounds, Shar Peis, Chow Chows, mastiffs, and others) where the extreme weight of the forehead skin and upper lids and a lack of connective tissue structures leads to the upper eyelid margins rolling over onto the ocular surface with the upper eyelashes abrading the corneal surface. Upper eyelid entropion usually has a major spastic component similar to that caused by lower eyelid entropion.

Lateral canthal entropion occurs mostly in heavy faced breeds (e.g. Shar Peis, Chow Chows, mastiffs, St. Bernards, Bernese mountain dogs, English bulldogs, and others) where there is also laxity of the retractor anguli ligament/muscle. This allows the lateral canthal structures to roll inward causing frictional irritation to the cornea and conjunctiva. A spastic component may be seen in cases of lateral canthal entropion. In those breeds (St. Bernard, mastiffs, Bernese mountain dogs, Newfoundlands, and others) with excessively long palpebral fissures (macropalpebral fissure) and lax tarsal plates, a combination of lateral canthal entropion and lower lid ectropion with an upward "notching" of the upper eyelid margin is seen.

Medial canthal entropion is seen primarily in brachycephalic breeds (pugs, Shi Tzus, Lhasa Apsos, and others). The brachycephalic conformation results in the medial palpebral ligament being too tight causing the medial aspect of the upper and lower eyelids to roll inward. Frictional irritation to the corneal surface by the medial canthal hairs and lashes leads to medial corneal neovascularization and subsequent pigment migration (pigmentary keratitis). This form of entropion seldom appears to be painful to the patient and usually does not have a spastic component similar to other forms of entropion.

Temporary Everting Suture Technique for Treatment of Spastic Entropion

Temporarily everting the eyelid margins is an effective method of disrupting the cycle of frictional irritation, pain, and blepharospasm caused by spastic entropion. This technique should always be used in young animals prior to more permanent skin removal entropion repair. It is difficult to evaluate how much tissue needs to be removed in the young patient with entropion, and overzealous tissue removal may result in eyelid scarring and/or ectropion in later life. Likewise, in an adult animal with no history of previous entropion, the practitioner should identify the underlying source of pain, treat that condition, and temporarily evert the eyelids for pain relief rather than performing permanent entropion corrective surgery. A simple technique to evaluate for spastic entropion is to apply a drop of topical anesthetic (0.5% proparacaine) to determine if blepharospasm abates. If topical anesthetic use relaxes the blepharospasm and resulting entropion, a temporary everting technique maintained for 7-10 days may result in resolution of the entropion without tissue excision. *Topical anesthetic is applied as a diagnostic test only and is contraindicated as therapy for spastic entropion.* Topical anesthetics are epithelial toxic, and by deadening the ocular surface to pain and sensation, further damage to the corneal surface may occur.

Periocular hair is shaved and the skin is prepared with dilute povidine iodine and saline. Multiple everting sutures of either a braided or monofilament synthetic (polypropylene or nylon) suture material are placed in the skin. Either vertical mattress (Figures 12-7A-D) or horizontal mattress (Figure 12-7E) sutures are used. I prefer multiple small (5-0 or 6-0) sutures versus fewer larger (2-0 or 3-0) sutures. In young patients, thin, friable skin may not hold a larger suture, and if the suture pulls through the skin, entropion resumes, and a noticeable scar may be present from the resulting defect. Suture placement depends on how much entropion is present. If only the lower lid is involved, only everting sutures involving the lower lid are used. It is not uncommon in Shar Peis, Chow Chows, and bulldogs for entropion to affect the upper and lower lids and lateral canthus (Figure 12-7F), thus everting sutures are placed in all 3 areas (Figure 12-7G). For the vertical mattress suture technique, the first bite into the skin should be very close to the outside edge of the lid margin and the needle directed away from the lid margin. The second bite should be further away from the lid margin so that when the knot is tied with appropriate tension, the eyelid margin is everted from the ocular surface. The suture tag closest to the globe should be cut close to the knot so as to not abrade the cornea while sutures are present. The suture tag directed away from the lid margin should be long to allow for suture removal in 7-10 days. For the horizontal mattress technique, the first bite

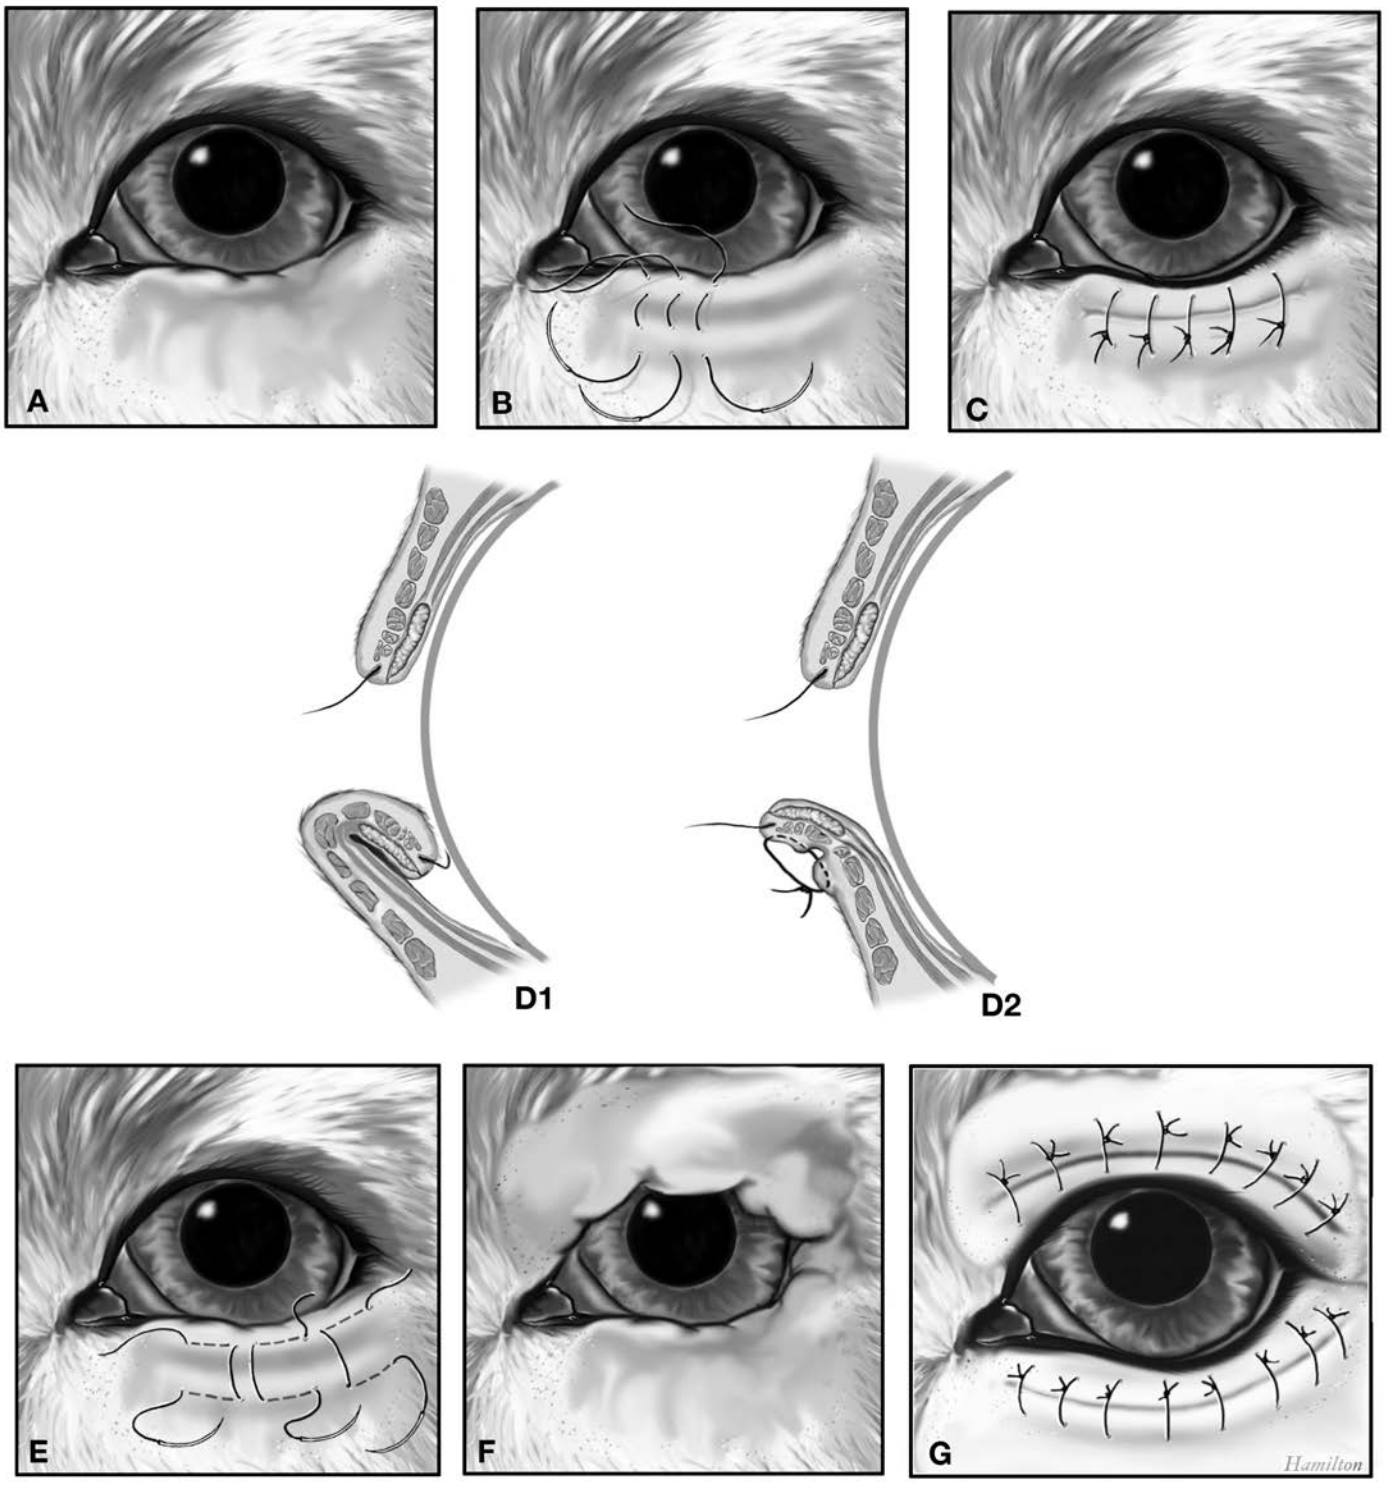

Figure 12-7. Temporary everting suture correction of spastic entropion. **A.** Lower eyelid entropion commonly seen with spastic entropion. **B.** Placement of multiple fine, synthetic vertical mattress sutures to evert the spastic entropion. Sutures may be placed and tied in sequence, or, in very small animals, all sutures may be pre-placed and then tied. **C.** Finished product using vertical mattress temporary everting sutures. Note how the suture tags closest to the lid margin are cut very short and the suture tags away from the lid margin are left long to aid in suture removal. **D.** Cross sectional view of spastic entropion and after temporary everting suture placement. Note that the lid margin is overly everted. This is preferred to prevent the patient from spasming eyelids and causing frictional irritation of the cornea by the sutures. **E.** Placement of horizontal mattress sutures for temporary eversion of lid margins. **F.** Upper, lower, and lateral canthal spastic entropion commonly seen in Shar Pei and Chow Chow puppies. **G.** Suture placement/final product for treatment of upper, lower, and lateral canthal spastic entropion.

should be close to the lid margin and the exit site of the needle equally close to the lid margin. The second bite will be further from the lid margin with the needle path being parallel to the first needle tract/lid margin. After tying the suture, the knot is rotated away from the lid margin and suture tags are cut to avoid corneal irritation. Prevention of post-operative self-trauma (or trauma by the bitch if puppies are still nursing) is important. If the cornea is ulcerated, symptomatic care with topical antibiotic ointment with or without use of atropine for cycloplegia and pain relief is indicated. Sutures should be left in as long as possible (7-10 days) to reduce blepharospasm and recurrence of entropion.

Modified Hotz-Celsus Technique for Correction of Simple Entropion

The simplest technique for correction of lower or upper lid entropion is a modification of the Hotz-Celsus technique used in man. Skin is excised and wound edges are sutured in a manner that everts the entropic area of the lid margin (Figure 12-8A-D). Prior to surgery, it is important to estimate how much tissue must be removed to correct the entropion without causing ectropion. This determination is made based on experience, but there are techniques and surgical landmarks that will aid the surgeon. Prior to patient sedation, a drop of topical anesthetic is placed in the affected eye and the patient placed on an elevated table for examination. The surgeon should examine the patient with magnification without touching the face or periocular structures. This will assist the surgeon in accurately estimating the amount of tissue to be excised. After anesthetic induction, hair removal, and disinfection of the surgical site, the patient is placed in lateral recumbency for surgery. A Jaeger lid plate is placed to tense the eyelid and an incision is made with a scalpel. The saline moistened Jaeger lid plate is placed in the cul-de-sac and an assistant tenses the eyelid by lifting the lid with the lid

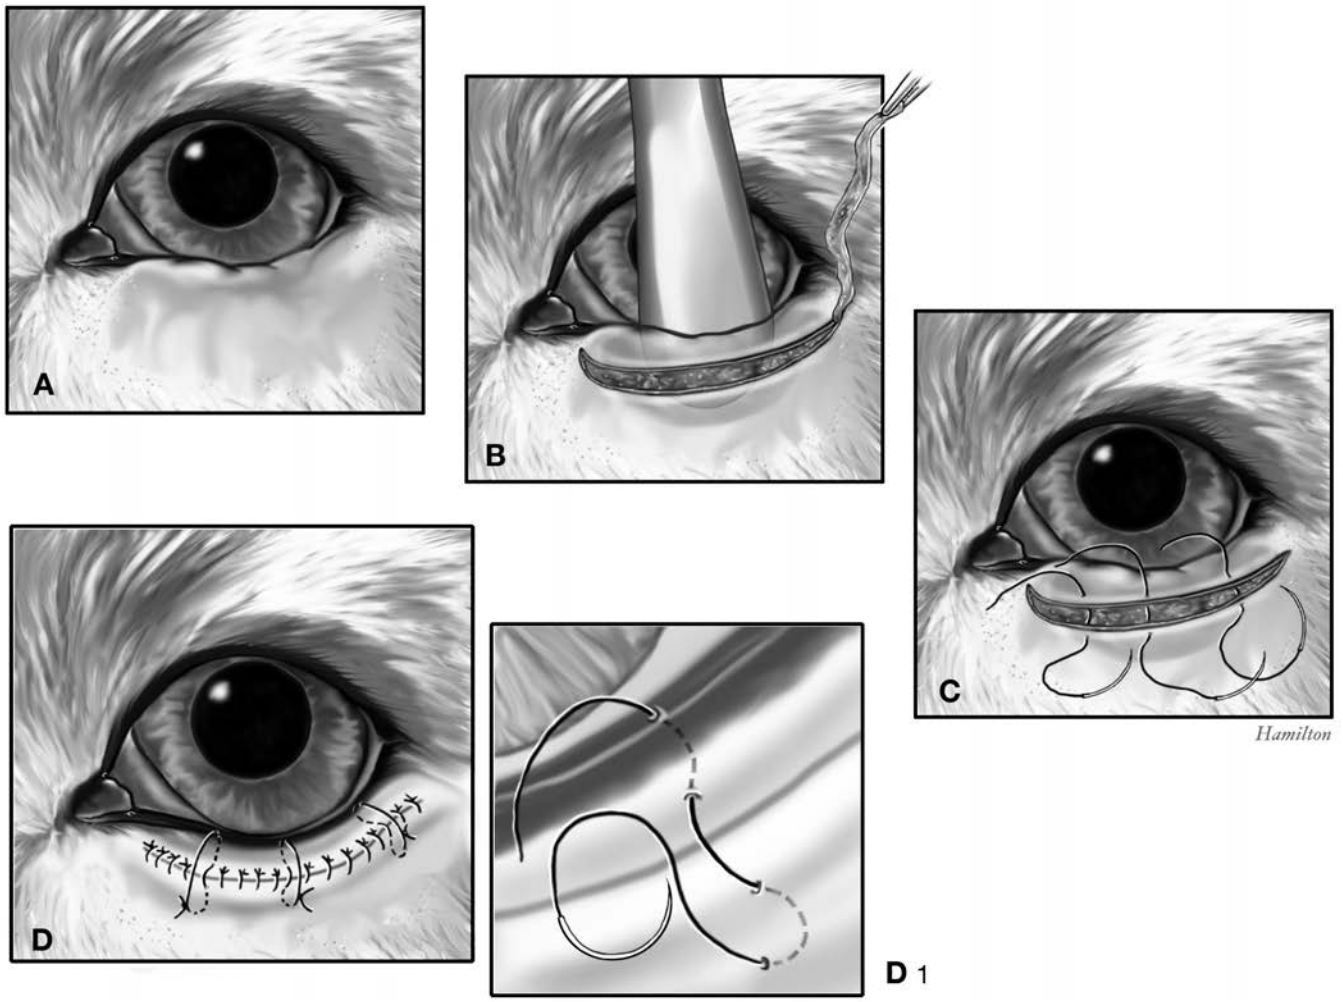

Figure 12-8. Modification of simple Hotz-Celsus procedure for entropion correction. **A.** Lower lid entropion. **B.** With the Jaeger lid plate in position, a smooth tapering skin incision can be made with a scalpel (bold dashed lines). The stippled area represents the area of the lid that was entropic. **C.** After excision of the skin, the Jaeger lid plate is removed and the skin is closed without tension. The first suture (1) is placed to halve the incision line. The next two sutures (2 and 3) are placed so as to quarter the incision line. **D.** depending on size of suture being used, sutures are placed 2-4 mm apart. Note that suture tags closest to the globe are cut short, those directed away from the globe are left long to enhance removal at a later date. Everting vertical mattress sutures are shown (**A, B,** and **C**) in this illustration. These are placed in those dogs with a severe spastic component to their entropion to prevent post-operative spasming with suture tag abrasion of the corneal surface. To accomplish this pattern (see inset), the first pass of the suture is across the wound (1) as with the other simple interrupted sutures to close the wound, and the second pass is through the skin away from the incision (2). When tied, these vertical mattress sutures evert the lid margins just like the everting sutures described above under spastic entropion correction.

plate (Figure 12-8 B). The surgeon uses thumb and index finger placed at the medial and lateral aspects of the area to be incised to tense the tissue for a smoother incision. The incision closest to the lid margin should be made at the level where the eyelid hair begins (lower eyelid) or about 1-2 mm away from the upper eyelashes (upper eyelid). The first incision should be made far enough from the lid margin to allow placement of sutures that will not abrade the cornea during healing. The surgical incisions and resulting wound should only be skin thickness, and no attempt should be made to remove orbicularis oculi muscle or tarsal plate structures. The second incision should be made distal to the initial incision at the point of greatest entropion and join the ends of the first incision in a smooth tapering fashion. The amount of tissue to remove is determined in the preoperative examination prior to sedation and by looking for a line of hair loss or skin discoloration due to the entropion. After the skin incisions, the skin is removed with the scalpel or a fine scissors. Following excision of tissue, the Jaeger lid plate should be removed and the skin sutured as it lies without tension (Figure 12-8C). The first nonabsorbable suture (4-0 or 5-0 monofilament or braided nylon or polypropylene) skin suture should approximately halve the wound defect. The next two sutures should be placed to divide the suture line into quarters. Since the second incision is in the form of an arc, it is longer than the initial skin incision that is parallel to and close to the lid margin. By utilizing a simple interrupted closure, bunching or "dog-ears" of one end of the suture line with a continuous suture pattern is prevented. The fine sutures should be placed close together (2-4 mm apart, depending on the size of the patient and suture size) and the suture tags closest to the eye should be cut close to the knot with the tags away from the eye being left longer. In animals with excessive preoperative blepharospasm and a spastic component to the entropion, intermittent vertical mattress sutures may be placed along the suture line to "overcorrect" the entropion until the skin sutures are removed at 10-14 days post-surgery (Figure 12-8D). In some cases, I "overcorrect" dogs of certain breeds (Chow Chow and Shar Peis) with vertical mattress sutures to prevent post-operative spasming with resulting suture contact of the corneal surface. Post-operative therapy consists of prevention of self-trauma, topical antibiotic ointment for treatment of corneal ulcers, systemic antibiotics, and non-steroidal anti-inflammatory drugs for pain.

"Arrowhead" Technique for Correction of Lateral Canthal Entropion

In those breeds with lateral canthal entropion but a normal length palpebral fissure (e.g. Shar Peis and Chow Chows), a modification of the Hotz-Celsus procedure (termed the "arrowhead" technique) may be used to evert the lateral canthal eyelid skin (Figure 12-9A-D). The Jaeger lid plate is used to tense the tissue, allowing smooth incision of the eyelid skin with a scalpel. The lid plate is placed in the lateral cul-de-sac and tensed upward by an assistant, simultaneously the surgeon tenses the lateral canthal tissue with the thumb and index finger on the upper and lower lids. The initial skin incisions should be approximately 2 mm from the lid margin along the upper and lower lids. Beginning about 6 mm from the lateral canthus, the skin incisions start to diverge from the lid margin and meet 5 mm lateral to the lateral canthus. (Figure 12-9B). This provides the surgeon additional tissue for closeing the resulting defect. The second incision begins at the medial-most extent of the first incision and gradually diverges from the first incisions. The point of intersection of the incisions lateral to the lateral canthus is dependent on how much eversion of the lateral canthus is necessary. In patients with minimal loose facial skin, closure of the "arrowhead" shaped skin incision may be adequate to correct the lateral entropion. In most dogs undergoing this procedure, however, a prosthetic lateral canthal ligament must be constructed to retract the lateral canthus and correct the defect. Prior to closure of the skin, blunt dissection is performed to undermine the skin over the lateral orbital ligament. Either a 4-0 monofilament nonabsorbable (nylon or polypropylene) or polydioxanone suture is used to first take a bite in the lateral most tip of the tarsal plate followed by passage of the suture through the periosteum over the orbital ligament. The surgeon may use two sutures (Figure 12-9C, upper) or a more complex placement of one suture (Figure 12-9C, lower) to pull the lateral canthus laterally and anchor it to the orbital ligament. Skin closure should begin at the lateral-most "point" of the "arrowhead" followed by a suture of the upper and then lower lid as for the traditional Hotz-Celsus technique (Figure 12-9D). In those dogs with upper, lower, and lateral canthal entropion, a skin incision of approximately 270° around the eyelid circumference (Figure 12-9E) may be made to result in correction of all abnormalities with one surgery. Temporary everting sutures as described for the Hotz-Celsus entropion correction are highly recommended in these patients. In patients with a macropalpebral fissure, this "arrowhead" correction technique corrects the entropion, but the ultimate exaggerated lateral placement of the lateral canthus may be cosmetically unacceptable, so the more complex lateral canthal reconstructive surgery described by Bigelbach is indicated.

Modification of Bigelbach's Combined Tarsorrhaphy-canthoplasty Technique for Repair of Lateral Canthal Entropion and Lower Lid Ectropion

In those dogs where a combination of macropalpebral fissure and lateral retractor anguli ligament laxity results in lateral canthal entropion and lower eyelid ectropion (e.g. St. Bernards, mastiffs, Newfoundlands, and similar breeds), a technique to shorten the palpebral fissure and retract the lateral canthus has been described (Figure 12-10A-G).

First, the amount of eyelid to be excised must be determined. From 20 to 30% of the lateral-most upper and lower lids may be removed and still retain normal function and an acceptable cosmetic appearance. The upper and lower eyelid margins are notched with a scissor or scalpel an equal distance from the lateral canthus (Figure 12-10B). The distance from these notches to the lateral canthus (D) is measured. Extending from the lateral canthus, sweeping upward and downward from the lateral canthus and following the general curvature of the eyelids, two skin incisions are made with a scalpel (Figure 12-10C). These incisions are two times D in length. The tips of the two curved incisions are connected by a vertical skin incision, and

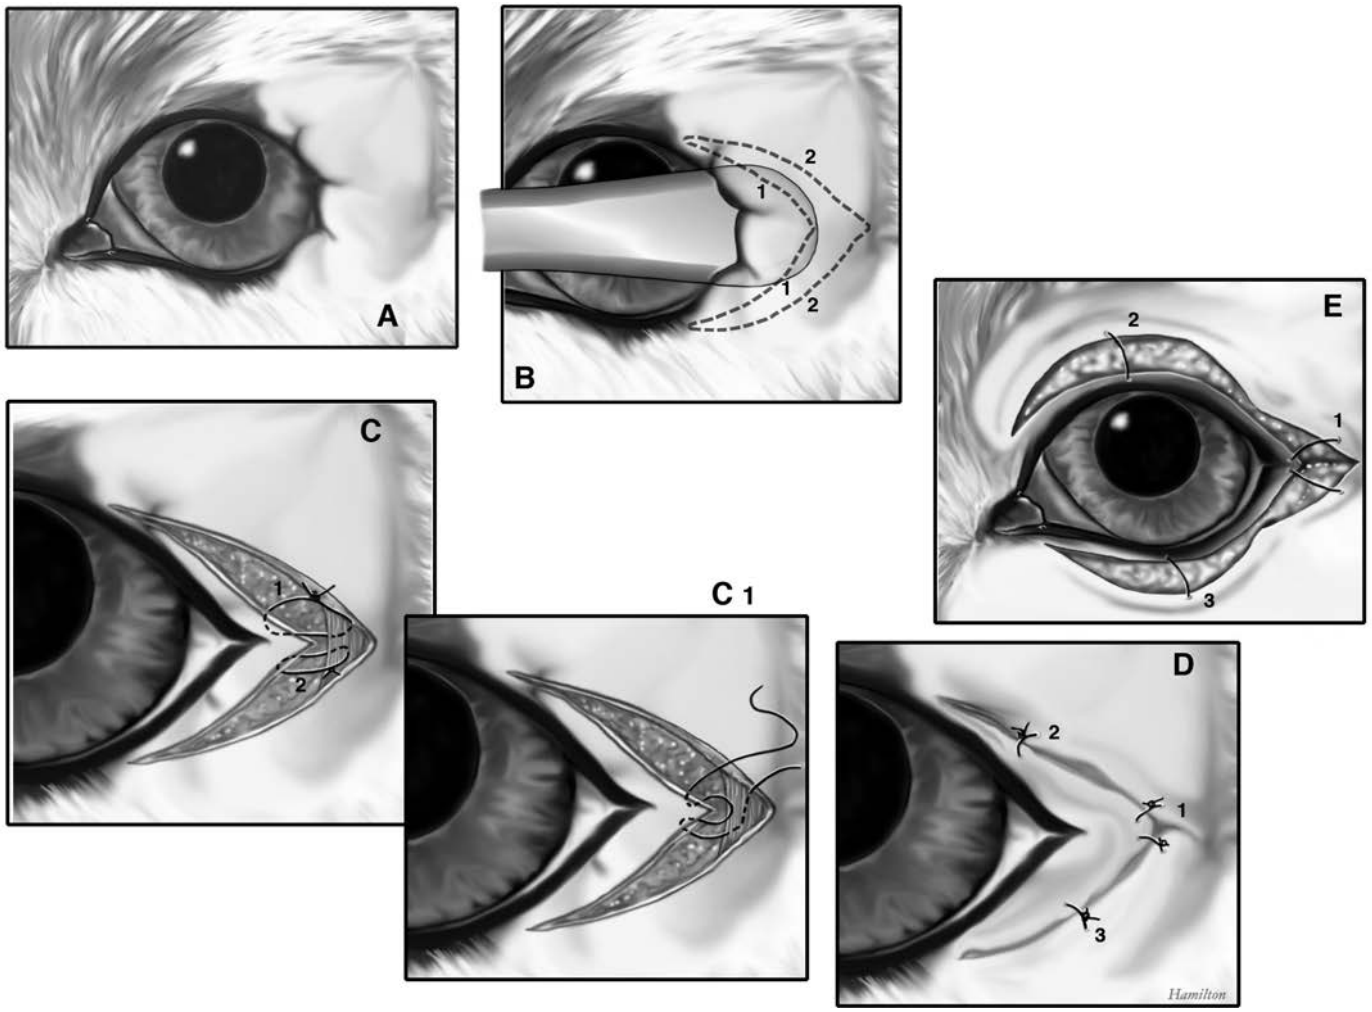

Figure 12-9. "Arrowhead" technique for correction of lateral canthal entropion. **A.** Lateral canthal entropion. **B.** Placement of Jaeger lid plate to tense tissue. Scalpel is used to incise skin as depicted by dashed lines. The incisions (1) 2 mm from the lid margins are made first. Approximately 5 mm from the lateral canthus, the incisions gradually diverge so that where the two initial incisions meet is approximately 5 mm lateral to the lateral canthus. The second incisions (2) diverge from the medial-most tips of the first incisions and meet lateral to the lateral canthus. This outlined skin is excised with a scalpel or small scissors. **C.** In loose skinned dogs, a prosthetic lateral canthal ligament is constructed prior to skin closure. Two sutures (1 and 2, upper diagram) of 4-0 monofilament absorbable or nonabsorbable material are placed to retract the lateral tarsal plates towards the orbital ligament. One continuous suture (lower diagram) may be used instead of two. **D.** Skin closure of the "arrowhead" begins with closure of the lateral-most aspect (sutures labeled 1) followed by closure of the middle of the upper lid incision (2), then the lower lid (3). The remainder of the suture line is then filled in with simple interrupted nonabsorbable sutures like was the case with the Hotz-Celsus procedure described above. **E.** For those patients with complex upper lid, lower lid, and lateral canthal entropion, a continuous upper lid, lower lid, and lateral canthal skin incision may be made. The lateral canthus is closed first (1), followed by closure of the middle of the upper and lower lid incisions (2 and 3). The remainder of the skin closure is as described above.

full thickness lid incisions are made from the original notches to the tips of the sweeping skin incisions using either a scissor or a Jaeger lid plate and a scalpel (figure 12-10D). The skin of the incision triangle is removed with scissor or scalpel, and the full thickness eyelid triangles from the upper and lower lids are removed with scissors (Figure 12-10E). The tarsal plate edges and ends of the severed orbicularis muscle of the upper and lower lids are tacked to the lateral orbital ligament with absorbable suture (5-0 Vicryl or 4-0 PDS) in the same manner as described for the "arrowhead" lateral canthal entropion repair (Figure 12-10E). The upper and lower eyelid stroma is sutured to the subcuticular fascia of the face in a buried, continuous pattern with the same absorbable suture (Figure 12-10F). The skin is closed to align the lateral canthus with the center of the vertical connecting incision (Figure 12-10G) using a single horizontal mattress suture of 4-0 braided nylon or silk. The remainder of the skin incision is closed with simple interrupted sutures.

Medial Canthoplasty to Correct Medial Entropion and to Shorten the Palpebral Fissure (Roberts and Jensen "pocket-flap" Technique).

Reconstruction of the medial canthus in brachycephalic breeds of dogs may correct medial entropion and reduce frictional irritation to the cornea that causes pigmentary keratitis. In addition, the shortening of the palpebral fissure reduces exposure of the cornea, enhances total closure of the lids during blinking and during sleep, reduces frictional irritation from nasal fold trichiasis, and may help to prevent proptosis in predisposed exophthalmic dogs.

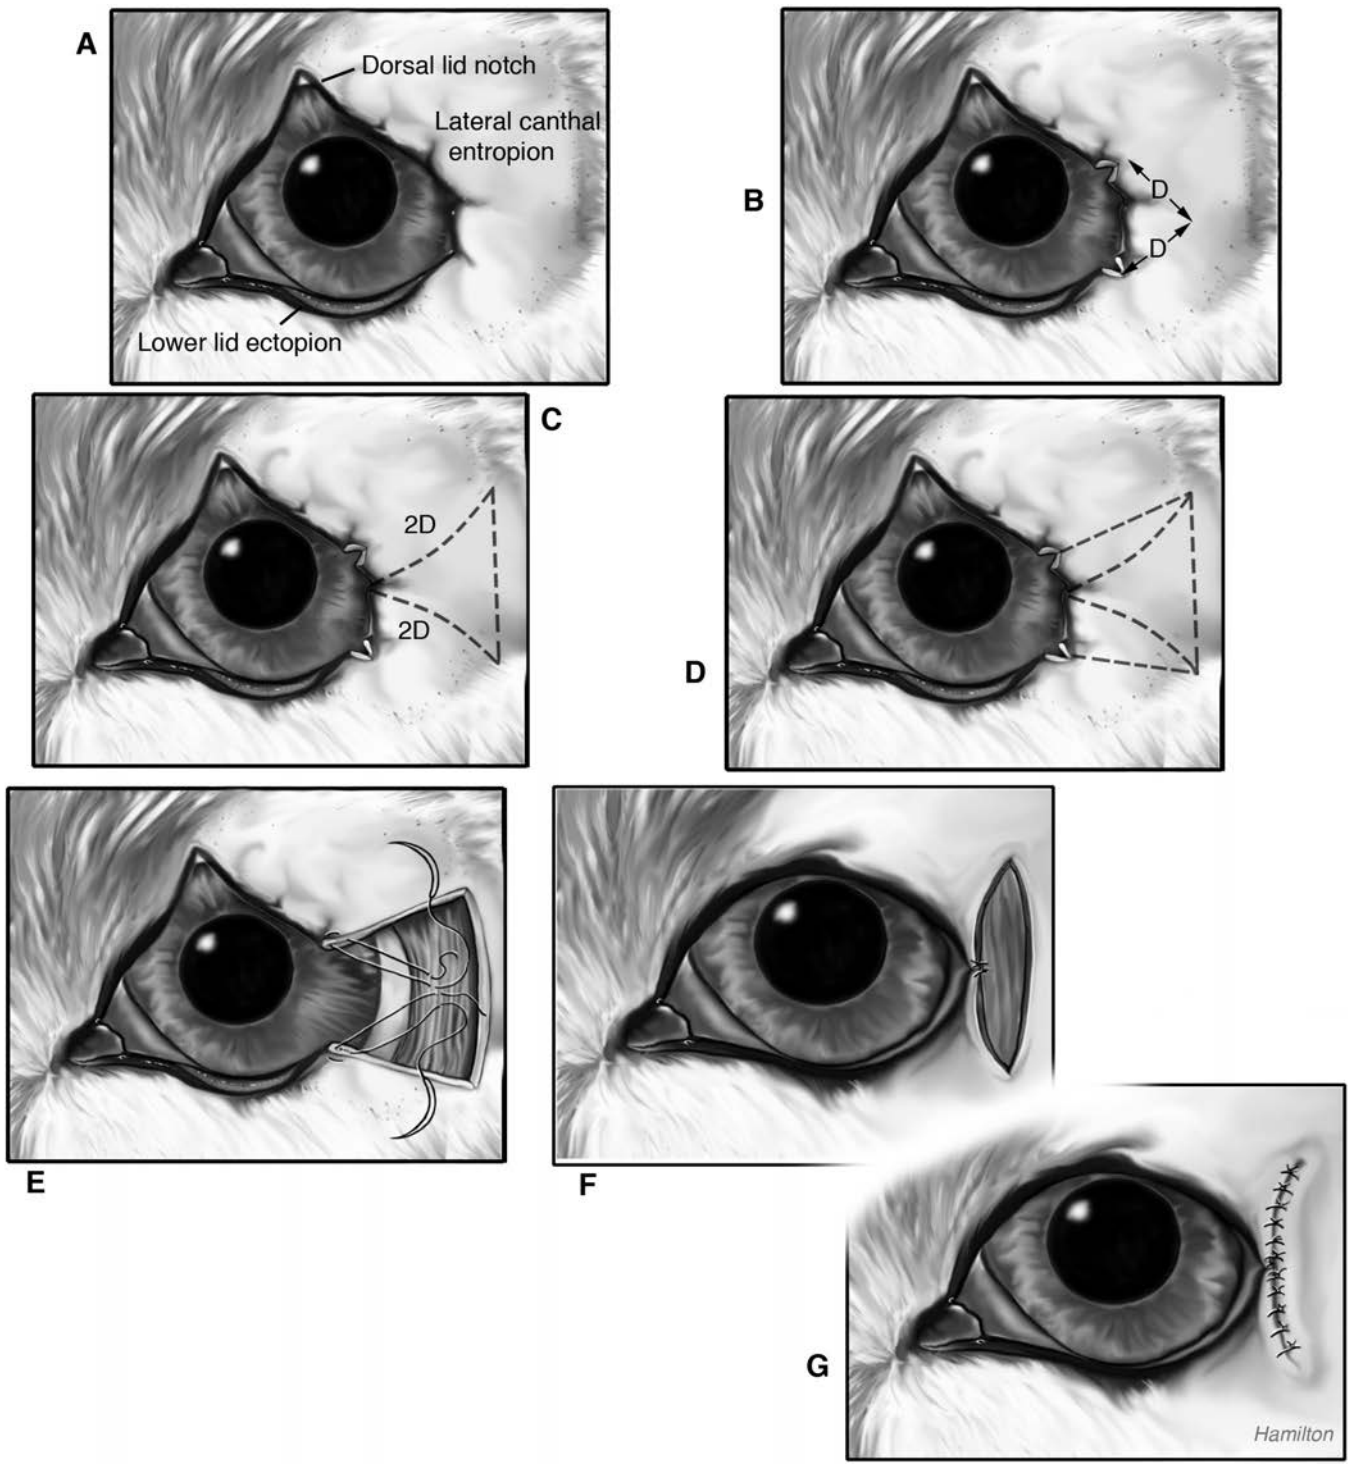

Figure 12-10. Correction of lateral canthal entropion, lower lid ectropion, and macropalpebral fissure (modification of Bigelbach's technique). **A.** Combination lateral canthal entropion, lower lid ectropion, and macropalpebral fissure. Many of these patients also have a defined "notch" of the upper eyelid margin due to tarsal plate malformation. **B.** Upper and lower eyelids are notched with scissor or scalpel. The distance D from notch to lateral canthus is noted. **C.** Sweeping skin incisions that roughly follow the curvature of the lid margins begin at the lateral canthus and extend a distance of approximately two times distance D. The distal tips of these skin incisions are connected with a skin incision. **D.** Using a Jaeger lid plate and scalpel or a scissor, the full thickness of the lids is cut at the previously notched sites extending to the tips of the skin incision. **E.** After removal of the full thickness lid pieces and triangular skin excision, the tarsal plate of upper and lower lids are tacked to a common point on the lateral orbital ligament using absorbable suture. **F.** The tarsal plate/lid stroma are tacked to the subcuticular tissue of the vertical portion of the skin incision. **G.** The points of the skin incisions of the upper and lower lids are sutured to a common point in the center of the vertical skin incision using a horizontal mattress suture of 4-0 nonabsorbable material. The remainder of the skin is closed with simple interrupted sutures of the same material.

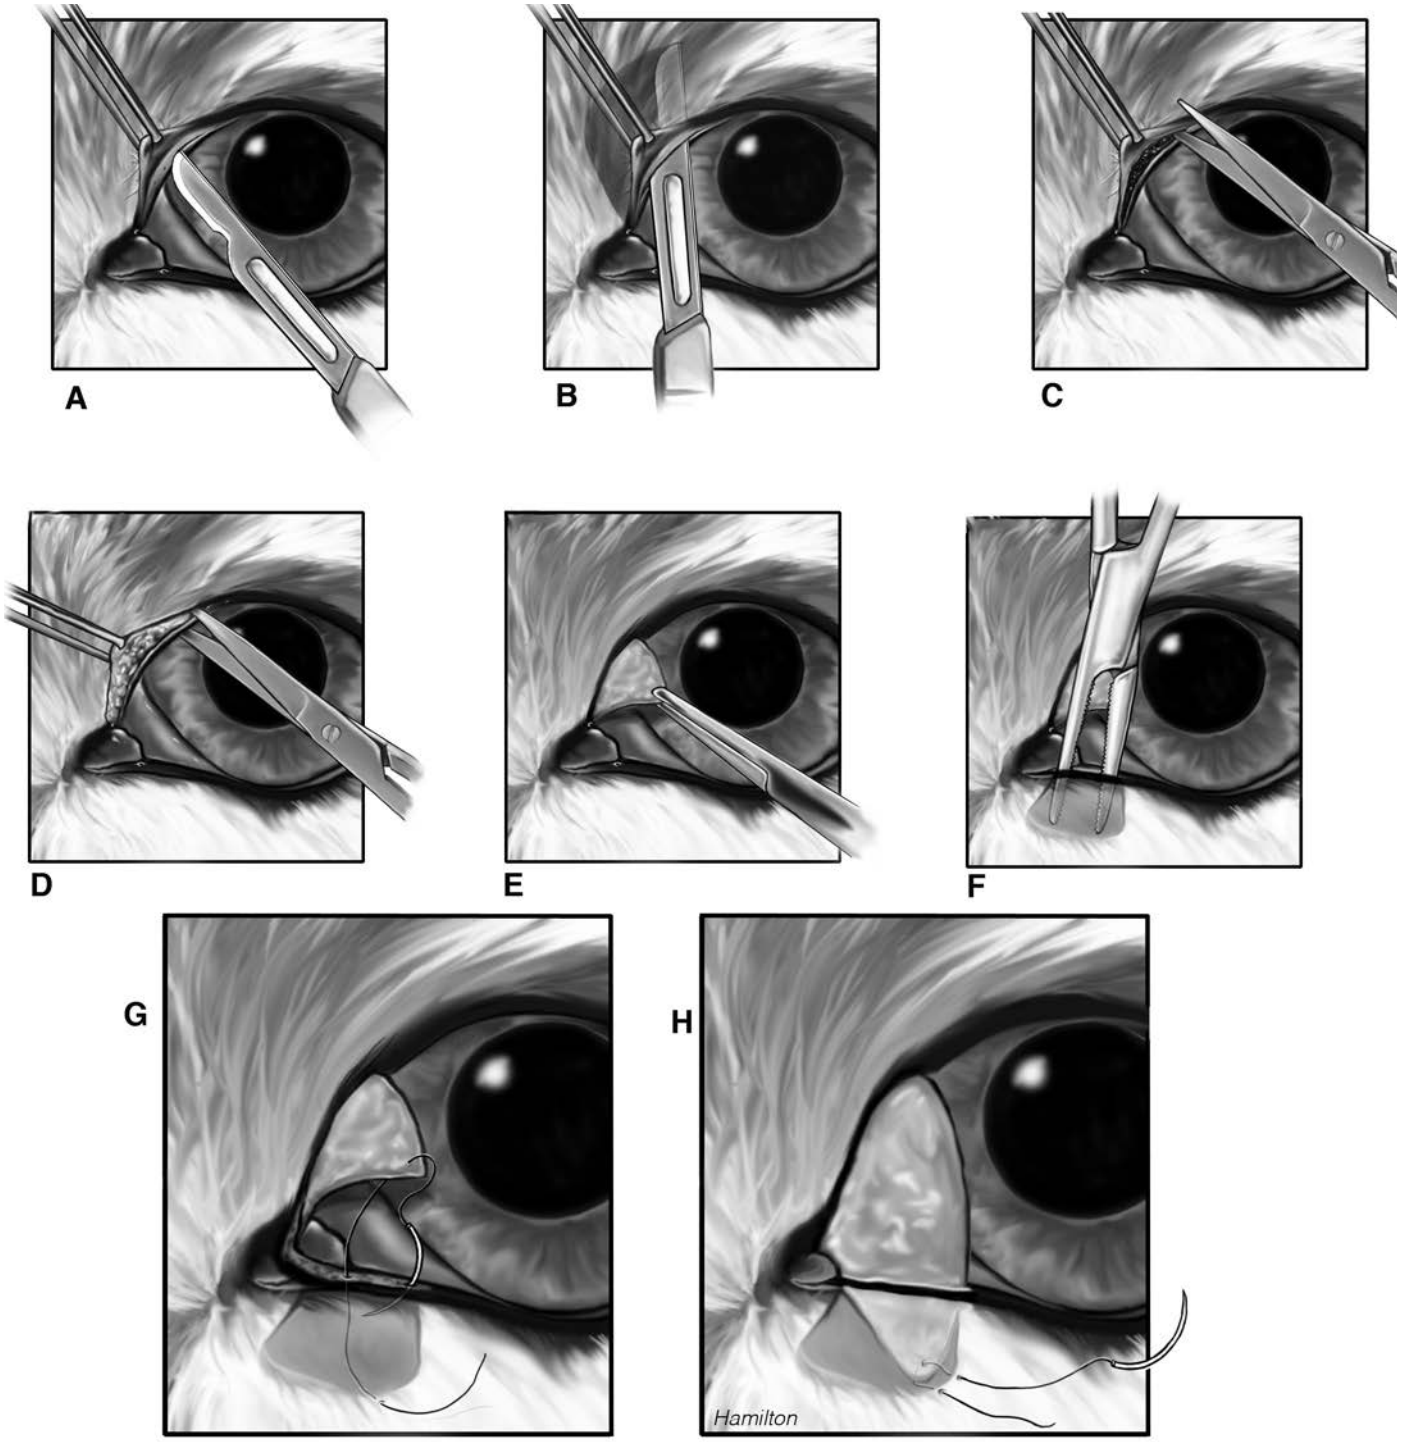

Figure 12-11. Medial canthoplasty technique (Roberts and Jensen "pocket-flap" technique). **A.** With the lid tensed laterally, the eyelid is split at the margin using a scalpel. Both upper and lower lids are split. **B.** The lid splitting is carried to a depth of approximately one centimeter. **C.** Using a small scissor, a strip of lid margin approximately 2 mm wide is excised from the edges of the lid splitting back medially to the medial canthus. The upper and lower lid excisions join at the medial canthus. **D.** A scissor is used to cut the innermost tarsal plate/conjunctival tissue of the upper lid perpendicular to the lid margin to a depth of one centimeter. **E.** The triangular flap of tissue is scarified on the conjunctival surface to the point of hemorrhaging. **F.** To anchor the upper lid flap of tissue into the lower lid pocket, suture is passed through the lower lid skin at the level of the depth of the pocket, into the pocket, and out the split lid margin. A mosquito hemostat passed into the ventral pocket and partially opened makes passage of the needle easier. **G.** The suture is passed through the tip of the flap tissue, and the needle is re-directed back into the ventral pocket and then out through the skin at the depth of the pocket. **H.** The suture is tied as the flap is worked into the deepest recess of the pocket. If non-absorbable silk has been used, the surgeon may choose to place the suture through a stent as described in the temporary tarsorrhaphy procedure. If absorbable suture has been used, the surgeon may choose to bury the suture and knot beneath the skin. **I.** The skin edges are closed with fine suture in two layers as described previously for the eyelid laceration closure.

The eyelid is grasped in the center with tissue forceps and tensed laterally. A #15 Bard-Parker scalpel (or #64 Beaver blade) is used to split the medial aspects of both eyelids (Figure 12-11A) to a depth of approximately 1-1.5 cm to create dorsal and ventral "pockets" (Figure 12-11B). The dissection plane is such that the superficial portion includes the skin, orbicularis muscle and the deep portion is the tarsal plate and conjunctiva. If a simple medial canthoplasty is being performed for medial entropion correction, the dissection extends from the medial canthus laterally to a point 1-2 mm from the nasolacrimal punctae. If the surgery is intended to reduce the size of the palpebral fissure, the dissection can be extended beyond the punctae. It is important to keep the plane of dissection external to the nasolacrimal punctae and their ducts if the dissection extends lateral to the punctae. Using a small tenotomy scissor, the upper and lower eyelid margins are excised from the lateral-most extent of the dissection back to the medial canthus (Figure 12-11C). A strip no more than 2 mm wide should be excised. Next, the tenotomy scissor is passed such that one blade is within the dorsal "pocket" and one blade is within the dorsal cul-de-sac (Figure 12-11D). The tarsal plate-conjunctival tissue is cut perpendicular to the lid margin for a distance of approximately 1-1.5 cm, thus creating a "flap" of tissue based at the medial canthus-upper eyelid (Figure 12-11E). The conjunctival surface of the "flap" is scarified with a scalpel to produce slight hemorrhaging. A small needle armed with 5-0 braided silk or synthetic absorbable suture (Vicryl) is passed through the lower eyelid skin into the ventral-most fornix of the ventral "pocket" and out through the eyelid margin opening (Figure 12-11F). The 5-0-suture needle pierces the tip of the dorsal "flap", and the needle is then passed back down into the deep fornix of the ventral "pocket" (Figure 12-11G) and then out through the skin (Figure 1-11H). When the suture is pulled tight ventrally, this will anchor the "flap" within the deep recess of the ventral "pocket". If absorbable suture is used, a small, partial thickness skin incision is made prior to tying the suture, and the suture knot is buried under the skin surface. If nonabsorbable suture (e.g. silk) is used, the external suture is knotted over a stent in the same manner as that described for temporary tarsorrhaphy. This inhibits the suture cutting into the skin and eases removal of the suture once the wound is healed. The edges of the skin margin of the lids can be closed in two layers similar to closure of a lid laceration (Figure 12-3).

The surgeon should realize that this technique sacrifices the upper nasolacrimal duct. If the dissection extends laterally beyond the ventral nasolacrimal punctum, the inferior duct, although patent, will not likely be functional and epiphora will result. If the dissection extends laterally beyond the punctae, the dorsal "flap" may incorporate Meibomian gland tissue. In this case, excision of glandular tissue prior to burying the "flap" within the "pocket" will prevent cyst formation at a later date due to buried glandular tissue. If the lacrimal caruncle on the palpebral surface of the third eyelid is large with long hairs growing from its surface, the surgeon may wish to excise this tissue and allow for healing by second intention to prevent future frictional irritation of the cornea by the lacrimal caruncle hairs.

Surgery of the Conjunctiva and Cornea

Jamie J. Schorling

Introduction

Conjunctival and corneal surgical procedures are performed to obtain tissue for diagnostic purposes or to reestablish the cornea's anatomic and functional integrity. Important goals for the surgeon include the maintenance of corneal clarity and curvature to preserve adequate optical function. Multiple variables determine the best course of surgical therapy for individual cases, with the primary goal of attaining the best visual outcome for the patient. Prior to proceeding with most corneal and conjunctival procedures, it is ideal to consult with and consider referral to a veterinary ophthalmologist. Consultation with an ophthalmologist will assist in attaining the best possible clinical outcome for the patient.

Anatomy

Surgery of the conjunctiva and cornea requires a working knowledge of the anatomy and physiology of these structures. This knowledge will aid the surgeon in appropriate tissue handling, thereby decreasing surgical trauma and increasing surgical success. The conjunctiva is composed of stratified epithelium overlying a thin layer of loose connective tissue. The palpebral conjunctiva begins at the internal margin of the eyelids and extends posteriorly, reflecting back onto the globe at the level of the fornix, where it becomes the bulbar conjunctiva. The bulbar conjunctiva lies loosely on the surface of the eye until reaching the perilimbal region, where the conjunctiva, underlying denser connective tissue called Tenon's capsule, and sclera become more tightly united. The conjunctival epithelium becomes continuous with the corneal epithelium at the limbus. Lymphatic follicles, goblet cells, blood vessels, and sensory nerves are located in the connective tissue layer of the conjunctiva. Lymphatics drain toward the eyelid commissures, and subsequently to the submaxillary lymph node medially and the parotid lymph node laterally. Goblet cells are individual glandular structures responsible for production of the inner mucin layer of the tear film. Increased densities of goblet cells are noted in the lower nasal and middle fornices and palpebral conjunctiva. The conjunctival vasculature is supplied by the anterior ciliary arteries, which are branches of the external ophthalmic artery, and most of the conjunctival venous drainage is provided by the deep facial vein. Sensory innervation is supplied by the ciliary nerves from the ophthalmic branch of the trigeminal nerve. The conjunctiva is the most exposed mucous membrane of the body and functions to prevent corneal desiccation, facilitate mobility of the lids and globe, and provide a structural and physiological barrier against opportunistic and pathogenic microbial organisms and foreign materials.

The cornea is the anterior fifth of the outer fibrous tunic of the globe, the remainder of which is provided by the sclera. In the dog, the cornea measures 15 mm horizontally and 14 mm vertically, while the cat cornea is slightly larger measuring 17 mm

horizontally and 16 mm vertically. Corneal cross-sectional anatomy consists of five layers, with a thickness of approximately 400 to 800 µm in the dog and 470 to 830 µm in the cat. The outermost layer is the epithelium, comprised of five to seven stratified squamous cells, which are in a constant state of renewal every seven to ten days. A basement membrane lies beneath the epithelium, followed by corneal stroma, which provides approximately 90% of the corneal thickness. Descemet's membrane is the acellular basement membrane of the corneal endothelium, which is a single layer of cells adjacent to the aqueous humor of the anterior chamber.

The cornea functions to protect and support the intraocular contents and to transmit and refract light. To accomplish these functions, the cornea is avascular, has low cellularity, and maintains a relative state of dehydration by a pumping mechanism in the endothelium and lipophilicity of the epithelial and endothelial layers. The corneal layers are thus nourished by the precorneal tear film, aqueous humor, and perilimbal vasculature. The corneal stroma is transparent and consists of parallel bundles of collagen comprising lamellae that span the entire corneal diameter and lie in layered sheets to provide most of the stromal volume. Low numbers of specialized fibroblasts called keratocytes, and leukocytes along with extracellular matrix comprise the remainder of the stroma. The corneal curvature and structural composition in the dog allows for approximately 40 to 42 diopters of refraction, and represents the most powerful refractive surface of the eye.

Instrumentation and Surgical Preparation

Surgical success improves with the appropriate use of specific ophthalmic surgical instruments. A comprehensive review of ophthalmic surgical instrumentation is beyond the scope of this chapter, however a discussion of required equipment is provided. Most surgical procedures involving the conjunctiva and cornea are performed more accurately using magnification. An operating microscope is ideal, although head loupe magnification of 2.5 to 4.5x with appropriate lighting is adequate for many cases.

Ophthalmic surgical instruments are more delicate and have finer tips than general surgical instruments, and specialized care is required to maintain instruments in the best condition. Surgical trays that keep instruments separate and protect the tips should be utilized, and gas sterilization is ideal to maintain instrument life. In contrast to instruments used in general surgery, many ophthalmic instruments have rounded handles and should be held like writing instruments. Many instruments also have spring handles instead of the more traditional finger rings for opening and closing blades. These qualities help minimize hand and arm movements, allowing finger movements to predominate, which provides finer surgical control.

Instruments required for conjunctival and corneal surgeries include tissue forceps, scissors, scalpel handles and blades, and needle holders that accommodate small needles and fine suture. Tissue forceps have three basic designs with regard to the teeth and appositional surfaces. Colibri-style and Castroviejo forceps have protuberant teeth, which aid in grasping and stabilizing tissues without crushing force. Colibri-style forceps are curved, which allow manipulation of tissue while keeping the handle of the instrument out of the magnified surgical field. Bishop-Harmon and similar forceps have teeth at right angles to each other and the handle. These forceps stabilize cut edges, where both sides of the tissue may be gently grasped. The third type of forceps has no teeth, only smooth appositional platforms. These instruments are indicated for tying fine suture material (eg. 6-0 and smaller). They should not be used to grasp tissues, as adequate fixation may only be obtained with crushing force resulting in possible damage to the tissue and instrument. Some Castroviejo and Colibri-style forceps incorporate a tying platform for suture behind the teeth. If the tying platform on these instruments is used, care is taken to avoid grasping and damaging suture with the forceps teeth.

Ophthalmic surgical scissors that are frequently utilized include blunt and sharp tipped tenotomy scissors. Blunt tips are usually preferred, as they are less likely to penetrate delicate tissues. Stevens tenotomy scissors, with ring finger holds, and Wescott scissors, with spring handles are our preference.

The scalpels and handles that are typically used in corneal surgery are Beaver brand. The handles are rounded and should be held like a pencil, and the blades are designed in various shapes. A #64 Beaver blade has a curved tip and cutting surfaces on the tip and on one side of the blade. This blade is used for performing corneal grooves as well as undermining keratectomy sites. Another instrument that may be used for keratectomies is a Martinez corneal dissector, which has a slightly curved semi-sharp blade allowing for dissection between parallel lamellae.

Needle holders have fine curved or straight tips, with either locking or non-locking handles. Most surgeons use slightly curved locking needle holders for corneal and conjunctival procedures. Needles should be positioned in the holders so that the shaft of the needle is perpendicular to the tips of the holders. Spatulated needles with swaged on suture are preferred to minimize disruption of corneal layers. Size 6-0 suture or smaller should be used with ophthalmic needle holders, as larger needles may damage the instrument. In general, 7-0 or 8-0 multifilament absorbable suture material is utilized for conjunctival and corneal procedures in small animals.

Proper patient preparation and positioning are essential for conjunctival and corneal procedures. Most cases require general anesthesia, though some may be performed with topical anesthetic and sedation or short acting anesthetic agents. Anesthetic risk and general patient health are vital considerations, and preoperative evaluation should include a complete physical examination as well as appropriate bloodwork. Excess hair should be carefully trimmed or clipped from the face, and unless infection is suspected and cultures are desired, any discharge or debris should be cleaned from the eye. Surgical scrub solutions should not be applied to the eye, and many antiseptic solutions are irritating to the conjunctival and corneal tissues. Dilute povidone solution (1:10 to 1:50 of the 10% stock solution) is non-toxic and may be gently applied to the eye by

lavage and then removed by rinsing with sterile saline. A cotton-tipped applicator soaked in dilute povidone-iodine is used to clean the cul-de-sacs. In preparation for most conjunctival and corneal procedures, the patient is placed in dorsal recumbency, with the head positioned so that it is stable and the cornea of the eye to be operated is parallel to the table. An eyelid speculum provides increased exposure of the eye and aids visualization of the surgical field, or alternatively, suture may be passed through the skin of the eyelid, parallel to the margin, to aid in retraction of the lids. Hemorrhage should be carefully controlled with dilute (approximately 1:10,000) epinephrine and sterile cotton tip applicators or cellulose sponges. It is essential that the cornea be kept moistened throughout the surgical procedure and is accomplished by dripping saline onto the eye every twenty to thirty seconds. In addition to an eyelid speculum, stay sutures may be placed to stabilize the globe and expose the areas of surgical interest. Stay sutures are placed using 5-0 or 6-0 non-absorbable suture, with the needle passed partial thickness through the sclera and parallel along the limbus. To avoid penetrating the globe, the needle should be nearly parallel to the surface of the sclera is it is passed through the tissue. Tags should be tied and left long to allow manipulation without obstructing the visual field (Figure 12-12). Caution is used to avoid traumatizing the cornea when the stay sutures are manipulated. In general, the globe is stabilized by grasping the tissue near the area of interest, thereby minimizing globe rotation. Tension on the globe caused by tissue retraction is not appropriate, and tension that causes deformation of the globe is dangerous to the health of the eye.

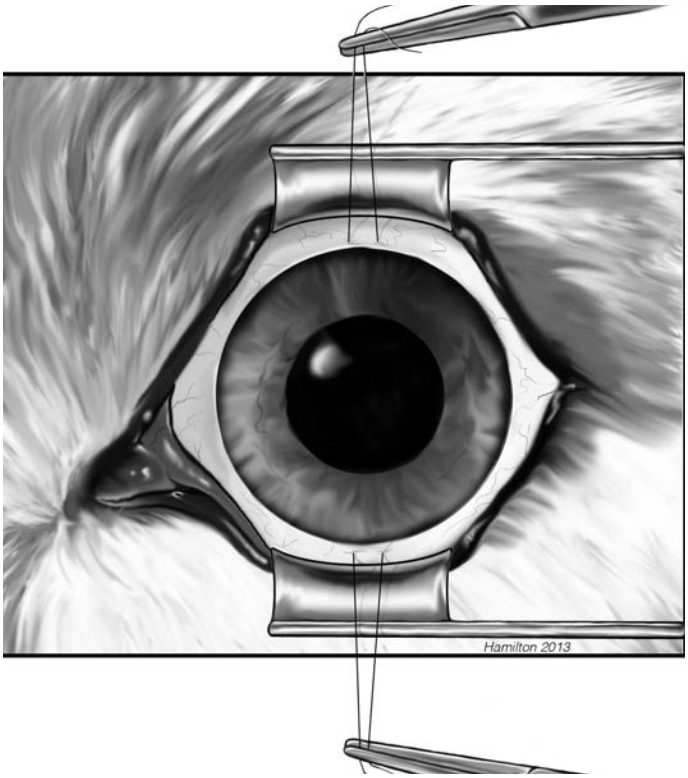

Figure 12-12. The eyelid speculum is placed through the central portions of the upper and lower lid margins to aid visualization. Stay sutures are placed parallel and posterior to the limbus with 5-0 or 6-0 suture material, allowing adequate manipulation and fixation of the globe.

Surgical Techniques

Lacerations

Conjunctival and corneal lacerations are traumatic injuries that often require very different approaches. Preliminary evaluation of conjunctival lacerations should allow the surgeon to localize the wound and assess the extent of the injury. Local swelling, hemorrhage, and patient discomfort may obscure the injury and general anesthesia may be required to explore the wound. The sclera, nasolacrimal system, cornea, and intraocular structures should be assessed for evidence of trauma. The patient is positioned in dorsal recumbency and magnification used to accurately assess the injury. An eyelid speculum or stay sutures are placed to increase exposure. If warranted, the nasolacrimal ducts should be cannulated and flushed to ensure patency. A 22 to 24-gauge intravenous catheter with the stylette removed may be used to cannulate the ducts, and the lids may be stabilized with Bishop-Harmon forceps. Instruments that will assist in wound exploration include Colibri or Castroveijo forceps to grasp the tissues and rotate the globe. Gentle and thorough flushing should be performed with sterile saline. Necrotic tissue should be carefully excised and hemorrhage should be controlled. The wound is systematically explored and evaluated for corneal and scleral injury, trauma to the extraocular muscles and periorbital tissues, and the presence of foreign material. Evidence of extensive trauma increases the short and long term chances of vision-threatening complications, such as endophthalmitis, intraocular hemorrhage, or retinal detachment. A description of surgical repair of extensive globe or orbital trauma is beyond the scope of this chapter, and referral to a veterinary ophthalmologist should be considered. If the wound is obviously contaminated, culture samples should be obtained. A conjunctival wound that is smaller than one centimeter, or one with copious drainage is allowed to heal by second intention. If the wound is larger than one centimeter, closure with 6-0 absorbable suture in a simple continuous pattern is appropriate. Care is taken to avoid suture tags or knots contacting the corneal surface.

Corneal lacerations are assessed differently than conjunctival lacerations. An important to determine the depth of the injury as early as possible. Full or partial thickness lacerations should be differentiated by evaluating for prolapse of intraocular contents, collapse of the anterior chamber, presence of blood or fibrin in the anterior chamber, or a positive Seidel test (apply fluorescein dye to the eye, and look for drainage of aqueous humor from the laceration). If a lens capsule rupture has occurred, lens removal may be required to save the eye from severe lens-induced uveitis. If the laceration is near the limbus, the conjunctiva and underlying sclera should be examined for injury. Assessing for the presence of vision, or of a consensual pupillary light reflex can determine the prognosis for vision prior to proceeding with surgery. In some cases of severe intraocular trauma, the owner and veterinarian must decide whether to attempt to save an avisual globe or consider a salvage procedure, such as enucleation or intraocular prosthesis. For these reasons, referral to a veterinary ophthalmologist is encouraged in cases of full-thickness corneal laceration.

Full thickness corneal lacerations require surgical repair. The

patient is anesthetized and carefully prepared with minimal neck restraint or manipulation of the globe. The patient is positioned in dorsal recumbency and use of an operating microscope is preferred. Prolapsed uveal tissue is either replaced with the aid of a viscoelastic agent and gentle separation of adhesions or excised if the prolapsed tissue is severely desiccated. Fine tipped Colibri forceps are used for corneal and iridal manipulations. Manipulation of iris tissue may cause significant hemorrhage, which must be controlled to avoid serious damage to the eye. Use of 1:10,000 dilute epinephrine will decrease hemorrhage and careful use of a fine-tipped cautery is sometimes necessary. Viscoelastic agents are used to maintain the formation of the anterior chamber while the corneal wound is assessed and repaired. Prior to completion of closure of a full thickness laceration, most of the viscoelastic agent should be flushed from the anterior chamber and replaced with a balanced salt solution.

Corneal tissue does not stretch, so the edges of corneal lacerations, whether full or partial thickness, should not be debrided or excised. Superficial lacerations may heal without surgical repair by application of prophylactic topical antimicrobial ointment. Many lacerations are deep and irregular, requiring placement of interrupted sutures to appose the edges. Sutures should be placed at approximately 75-90% corneal depth using 7-0 or 8-0 absorbable braided suture. In placing corneal sutures, the needle should be directed perpendicular to the corneal surface, approximately one millimeter from the wound edge, depending on the nature of the laceration. As the needle is advanced, the needle holders are rotated and repositioned to allow adequate suture depth and have the needle exit at approximately the same distance on the opposite side of the wound. The suture is tied, using a tying platform, usually with two or three throws on the first knot, so the wound edges are apposed and not crushed. The first suture should be placed near the middle of the laceration, with subsequent sutures placed to divide the remaining length of the wound until closure is complete. Spacing between sutures is usually one millimeter, but adjustments may be necessary for irregular lacerations. Post-operative care is described in the final section of the chapter, and the eye should be reevaluated in five days.

Conjunctival and Corneal Biopsy

The most common indication for conjunctival and corneal biopsies is to identify the cause of abnormal tissue proliferations or chronic inflammatory processes that are not responsive to medical management. Incisional biopsies for sampling small and freely moveable or pedunculated conjunctival lesions may be performed with topical anesthetic and sedation or short acting anesthesia. Unless culture is desired, the eye should be aseptically prepared with dilute povidone iodine solution. Adequate exposure often necessitates placement of an eyelid speculum. A drop of dilute epinephrine or 2.5-10% ophthalmic phenylephrine placed in the eye prior to biopsy will decrease hemorrhage. Incisional biopsies are obtained by stabilizing and placing gentle tension on affected tissue with Colibri or Castroveijo forceps. Stevens or Wescott scissors are used to incise the lesion towards its base, and the excised tissue should be placed in a cassette in ten percent buffered formalin and submitted for histologic evaluation. Conjunctival incisions of less than one centimeter in length do not require primary closure and will heal by second intention. Defects that are larger than one centimeter should be closed with 6-0 absorbable suture in a continuous pattern. Care should be taken to avoid allowing suture or knots to contact the corneal surface. Post-operative care is summarized in the final section of the chapter, and the patient should be rechecked in five to seven days.

If the tissue of interest is expansive or seems firmly adhered to the underlying sclera, there should be suspicion of possible intraocular involvement and more extensive disease. Though an incisional biopsy is still an appropriate initial approach, referral should be considered for ocular ultrasound and additional surgical options. If the lesion is near the limbus, or if it involves the cornea, a superficial keratectomy may be required, as described in a later section of this chapter.

Keratotomy

The primary indications for keratotomies are spontaneous chronic corneal epithelial defects (SCCEDs) that occur in middle-aged to older dogs. These lesions are also known as indolent ulcers, indolent erosions, and boxer ulcers. Ophthalmic examination typically reveals a chronic (weeks in duration), superficial, variably painful, non-infected, and non-progressive erosion or ulceration with a characteristic lip of loose epithelium surrounding the border of the defect. Many patients are reported to have sustained an ocular injury, but the lesion does not heal with topical therapy in an appropriate length of time. Diagnosis is made by clinical signs with the aid of fluorescein staining to evaluate for wicking of stain beneath the poorly adherent corneal epithelium at the edge of the lesion. No specific treatment has been shown to be effective in all cases, but successful therapy has included debridement, striate or punctate keratotomies, corneal gluing, third eyelid flaps, contact lens application, and superficial keratectomies. Most SCCEDs will heal with debridement and keratotomy, but approximately 20 to 30% of animals will require additional surgical procedures and referral to a veterinary ophthalmologist should be considered. To perform debridement of the defect, topical anesthesia is applied, and the patient manually restrained or sedated. Rarely, patients may require short-acting general anesthesia. A dry cotton tipped applicator is swabbed from the center of the lesion peripherally, peeling away loose epithelium in the process. Once the cotton swab is wet with tears, it is less effective and should be exchanged for a dry swab. Epithelium that is poorly adhered to the abnormal underlying stroma is debrided easily with this technique. Debridement is considered complete when a margin of more adherent corneal epithelium is encountered during swab application. The resultant defect will in many cases be considerably larger than the original lesion. For best results in healing, a punctate or striate keratotomy is performed following debridement. Striate (grid) keratotomy is technically easier to perform, with a lower risk of globe injury than punctate keratotomy. Patient restraint may be manual, or sedation or short acting anesthesia may be used. Loupe magnification for the surgeon is ideal. Topical anesthetic is applied, and a 25-gauge needle is held at an approximate 45° angle to the corneal surface with the bevel directed away from

the cornea. The surgeon's hand should rest on the table or on the patient's muzzle. The tip of the needle is then used to lightly scratch the corneal surface, and the pressure applied should be enough to cause a very faint needle mark in the corneal tissue. The scratches extend from normal epithelium across the defect and back into normal epithelium. The resultant grid consists of faint scratches approximately one millimeter apart, crossing in various directions over the lesion. The owner should be warned that the animal will show increased ocular discomfort for several days following the procedure. If successful, complete corneal healing should occur within two to three weeks. These patients should be treated to prevent infection and control inflammation, as described in the Post-Operative Care section, and they should be rechecked in three to seven days to ensure there is no evidence of infection or ulcer deepening.

Superficial Keratectomy

Corneal and limbal proliferations of abnormal tissue and SCCEDs are the most common indication for superficial keratectomies. Keratectomy is also indicated in the preparation of the cornea to receive a conjunctival flap or graft. Ideally, referral to a veterinary ophthalmologist should be considered, as the benefits of an operating microscope and advanced microsurgical skills will increase the success of surgery. The depth of the lesion should be considered prior to surgery, so that surgical planning may include a conjunctival flap if the lesion extends deeper than 30% of corneal thickness. If the lesion to be excised is deeper than approximately 75% of the cornea or if it is full thickness, more advanced or adjunctive surgical procedures may be required, necessitating referral to an ophthalmologist.

The patient is anesthetized, prepared for surgery and positioned in dorsal recumbency. An eyelid speculum and stay sutures are placed as needed to increase exposure of the eye. Topical dilute epinephrine (1:10,000) is used to control hemorrhage. A #64 Beaver blade is used to create a square or circular corneal groove surrounding the lesion. The groove should extend into slightly deeper corneal stroma than the deepest aspect of the lesion (Figure 12-13A). If the lesion is close to the limbus, the groove is made in a semicircular fashion around the lesion and adjacent to the limbal margin. Fine tipped Colibri or Castroviejo forceps are used to grasp the grooved edge of the cornea, and either a #64 Beaver blade or a Martinez corneal dissector is used to undermine the abnormal tissue. If a blade is used, it is held so that the blade is nearly parallel to the corneal surface and small circular motions used to undermine the lesion. A Martinez corneal dissector is held so that the dissecting blade is parallel to the corneal surface, and a sweeping motion is used to advance the instrument (Figure 12-13B). If the limbus is involved, the dissecting instrument is carefully advanced under the limbal tissue approximately two millimeters, using care to remain parallel to the ocular surface. Diseased conjunctiva that is adjacent to a limbal lesion is elevated using regular Colibris forceps and excised using tenotomy scissors. The conjunctiva at the margin of the lesion is tented and a small incision is made. The scissors are then advanced to bluntly undermine the conjunctiva prior to extending the incision, eventually elevating the entire affected region so that the only remaining conjunctival tissue attachments are at the limbus. Curved tenotomy scissors and forceps are then used to incise along the limbus and remove the affected corneal and conjunctival tissue *en bloc*.

The resulting corneal defect if it is less than 30% of corneal thickness does not require a conjunctival flap. If the limbus is involved, a conjunctival advancement, or hood flap may be performed to protect the limbal region and close the orbit. Keratectomy beds > 30% corneal thickness require a graft or flap to re-establish the structural integrity of the cornea, and some of these techniques

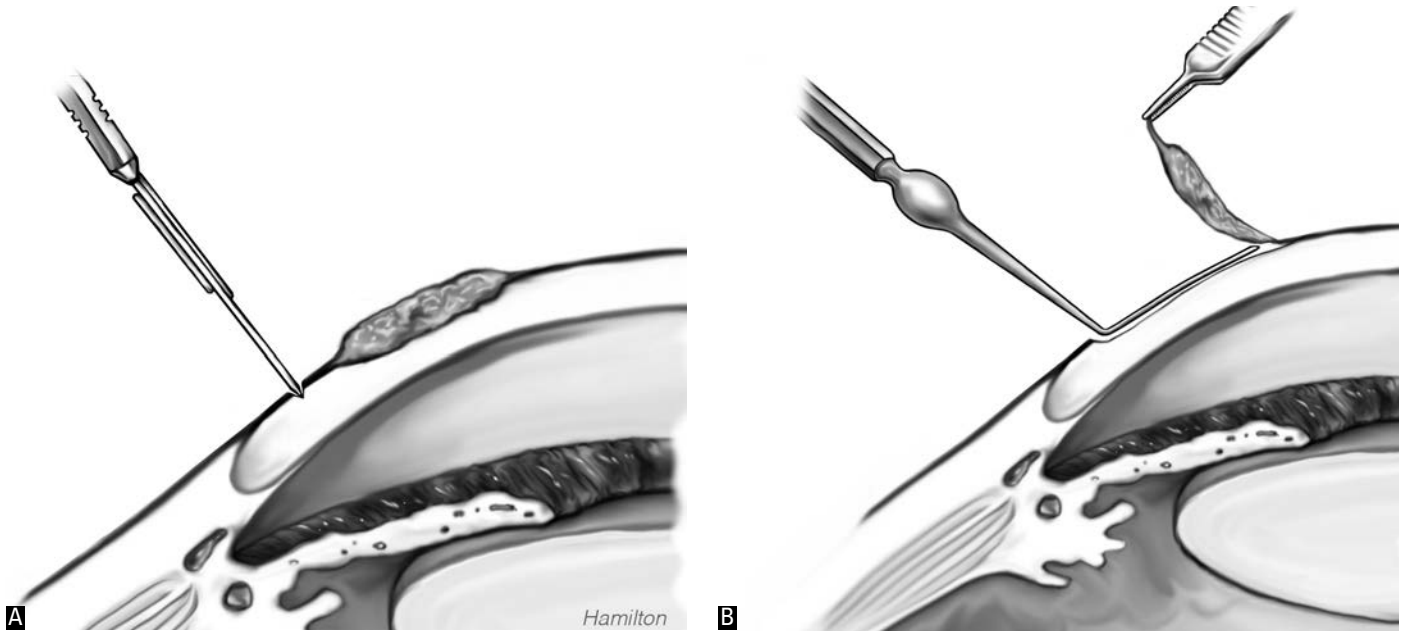

Figure 12-13 A. The cross-sectional view of the cornea demonstrates use of a Beaver blade to groove the cornea to a depth beneath the lesion. The blade is perpendicular to the corneal surface and is advanced to surround the lesion. **B.** The cross-sectional view of the cornea shows a Martinez corneal dissector advanced with a sweeping motion beneath a corneal lesion, with the blade of the dissector aligned with the corneal curvature.

are described in the following section. Post-operative medications are described in the final section of the chapter, and these patients should be rechecked in three to five days.

Conjunctival Flaps and Grafts

Conjunctival flaps and grafts differ in that flaps are attached to the tissue of origin with an intact blood supply, whereas grafts are completely severed from the donor site and must be revascularized from the recipient site to survive. The most common indication for conjunctival flap construction is to repair a loss of corneal integrity caused by keratomalacia, surgical wounds, and traumatic injuries. Corneal sequestra are an additional indication in cats. If corneal tissue is lost, as with keratomalacia, and a corneal perforation has resulted, tissue replacement with keratoplasty procedures may be indicated in addition to conjunctival flap techniques, necessitating referral to a veterinary ophthalmologist. The inciting cause and severity of corneal disease dictates which of the techniques described here are appropriate for use in individual patients. The benefits of conjunctival flaps include provision of physical support to weakened corneal tissue, a direct blood supply to naturally avascular tissue, and a source of cellular components to accelerate healing. Overall, the success rate of conjunctival flap procedures is approximately 90%, however, failure of adhesion, excessive tension resulting in flap dehiscence, flap necrosis, continued leakage of a ruptured globe, and refractory keratomalacia, are examples of complications that may occur following conjunctival flap surgery. In most cases, referral to a veterinary ophthalmologist should be considered, as surgical experience and technique are factors in establishing a successful outcome.

Conjunctival Pedicle Flap

Conjunctival rotating pedicle flaps are the most common type of flap performed by veterinary ophthalmologists. The patient is anesthetized, prepared routinely for ophthalmic surgery and positioned in dorsal recumbency. Use of an operating microscope is recommended for best results. An eyelid speculum and stay sutures should be placed to aid in exposure of the surgical field. The corneal recipient bed is prepared using fine tipped Colibri forceps for stabilization, and the cornea is grooved around the perimeter of the lesion with a #64 Beaver blade. The groove may be rounded or squared, depending on surgeon preference, and the affected stroma within the confines of the groove is removed by a superficial keratectomy. If a keratectomy is not performed, a surgical blade, cellulose sponges, and fine corneal scissors are used to freshen the edges of the corneal defect. The width or diameter of the defect is approximated, and a correspondingly sized or larger piece of conjunctival tissue is obtained for the flap. The donor conjunctival site is typically the dorsolateral bulbar conjunctiva, due to the ease of access and relatively loose adhesions to the underlying connective tissue. However, if the lesion is markedly closer to the ventral limbus, a ventrally based flap may be more appropriate. The base of the flap, which will remain attached to the donor tissue, should be located such that the flap is vertically oriented when positioned over the corneal defect; this reduces friction and drag caused by eyelid motion. In designing a flap, the surgeon plans the width of the flap base to be approximately one millimeter wider than its distal margin. The free or distal margin of the flap is designated by drawing an imaginary horizontal line across the cornea from the ventral aspect of the corneal lesion to the donor bulbar conjunctiva (Figure 12-14A). Due to curvature of the globe, the resultant conjunctival flap will be slightly longer than necessary; however, it is easier to trim away excess tissue than it is to supplement a flap that is too small. Hemorrhage is controlled by use of dilute epinephrine (1:10,000) cellulose sponges, and cotton tipped applicators. The conjunctival tissue is tented gently using regular Colibri or Castroviejo forceps, and a small incision is made using blunt tipped tenotomy scissors approximately two millimeters posterior to the limbus. Conjunctival tissue is undermined by blunt dissection with tenotomy scissors prior to enlarging the incision, and the elevated tissue should be thin, allowing visualization of the scissor blades through the conjunctiva (Figure 12-14B). Care must be taken during dissection to avoid closing the scissor blades until they are completely withdrawn from tissue, as inadvertently cutting small holes in the flap will weaken its integrity. The incision is extended to the predetermined distal point of the flap, staying as close to the limbus as possible. The distal flap margin is then incised by directing the scissors posterior and cutting perpendicular to the initial incision. This incision is approximately one millimeter greater than the horizontal width of the corneal lesion. The third conjunctival incision is parallel to the initial perilimbal incision, with the scissors directed toward the base of the flap. This third incision should be parallel to but shorter than the initial incision to maintain vascular supply to the flap.

As the flap is rotated, the surgeon must ensure that the non-epithelialized surface of the conjunctiva is placed in contact with the corneal recipient site. Placement of the flap with the conjunctival epithelial surface in contact with the corneal defect will result in failure. The donor tissue is positioned over the corneal defect, and should lie where placed without continued traction or tension. If there is tension on the flap, the conjunctival tissue is further undermined to release residual remnants of the white connective tissue, Tenon's capsule. The flap is initially sutured with 7-0 to 9-0 multifilament absorbable suture using simple interrupted sutures placed at the corners of the corneal defect. Needle bites should include approximately one millimeter of flap tissue, and the needle should then enter the cornea at the base of the lesion, along the edge of the defect. The needle should then exit the normal corneal tissue one to two millimeters from the wound margin. The needle is passed cautiously so as to not penetrate the anterior chamber. If inadvertent penetration into the anterior chamber occurs, the suture is completely removed and placed in a different location. The perforation site will heal spontaneously, though some uveitis may occur. Ideally, the suture should penetrate to a depth that approximates 75-90% of the corneal thickness, though slightly shallower suture bites are acceptable for conjunctival flaps. Suture should be tied with two to three throws on the first knot, and the knot should be tied so as to appose but not crush tissue. Additional interrupted sutures are placed by dividing the distance between the initial sutures in half, then in half again, until sutures are spaced approximately one millimeter apart around the three exposed sides of the flap. The fourth side of the corneal lesion covered by the flap of conjunctival tissue close to the limbus is not sutured, as this would compromise vascular supply to the flap. A simple

continuous suture pattern may be used to suture the three sides of the flap rather than interrupted sutures. After corneal suturing, two anchoring sutures are placed from the base of the flap to the limbus on each side. These sutures help to decrease flap tension on the corneal recipient site. Closure of the conjunctival donor site is unnecessary, but may be performed with a simple continuous pattern of 7-0 to 8-0 multifilament absorbable suture. Figure 12-14C demonstrates the appearance of the flap sutured to the corneal surface. The patient should be treated as described in the Post-Operative Care section, and a recheck examination should be scheduled in five to seven days.

Five to eight weeks after surgery and following complete healing of the corneal wound the vascular supply to the flap may be severed to improve the cosmetic appearance of the eye. Ideally, corneal vasculature should reach the surgical site prior to incising the flap. Incising the flap is performed with manual restraint or with a combination of light patient sedation and ocular topical anesthesia. A drop of dilute epinephrine or 2.5 to 10% ophthalmic phenylephrine will help to control hemorrhage. The bridge portion of the flap, which is not attached to the cornea, is gently elevated with Castroviejo forceps, and a blunt tipped scissor blade is inserted between the flap and the corneal surface. As the scissor blades are closed the flap is cut and the free margin retracts toward the limbus. The remaining tag of tissue is then trimmed near the limbal attachments. Complications of this procedure include necrosis of the remaining island graft, iatrogenic corneal ulceration from the scissors, and mild

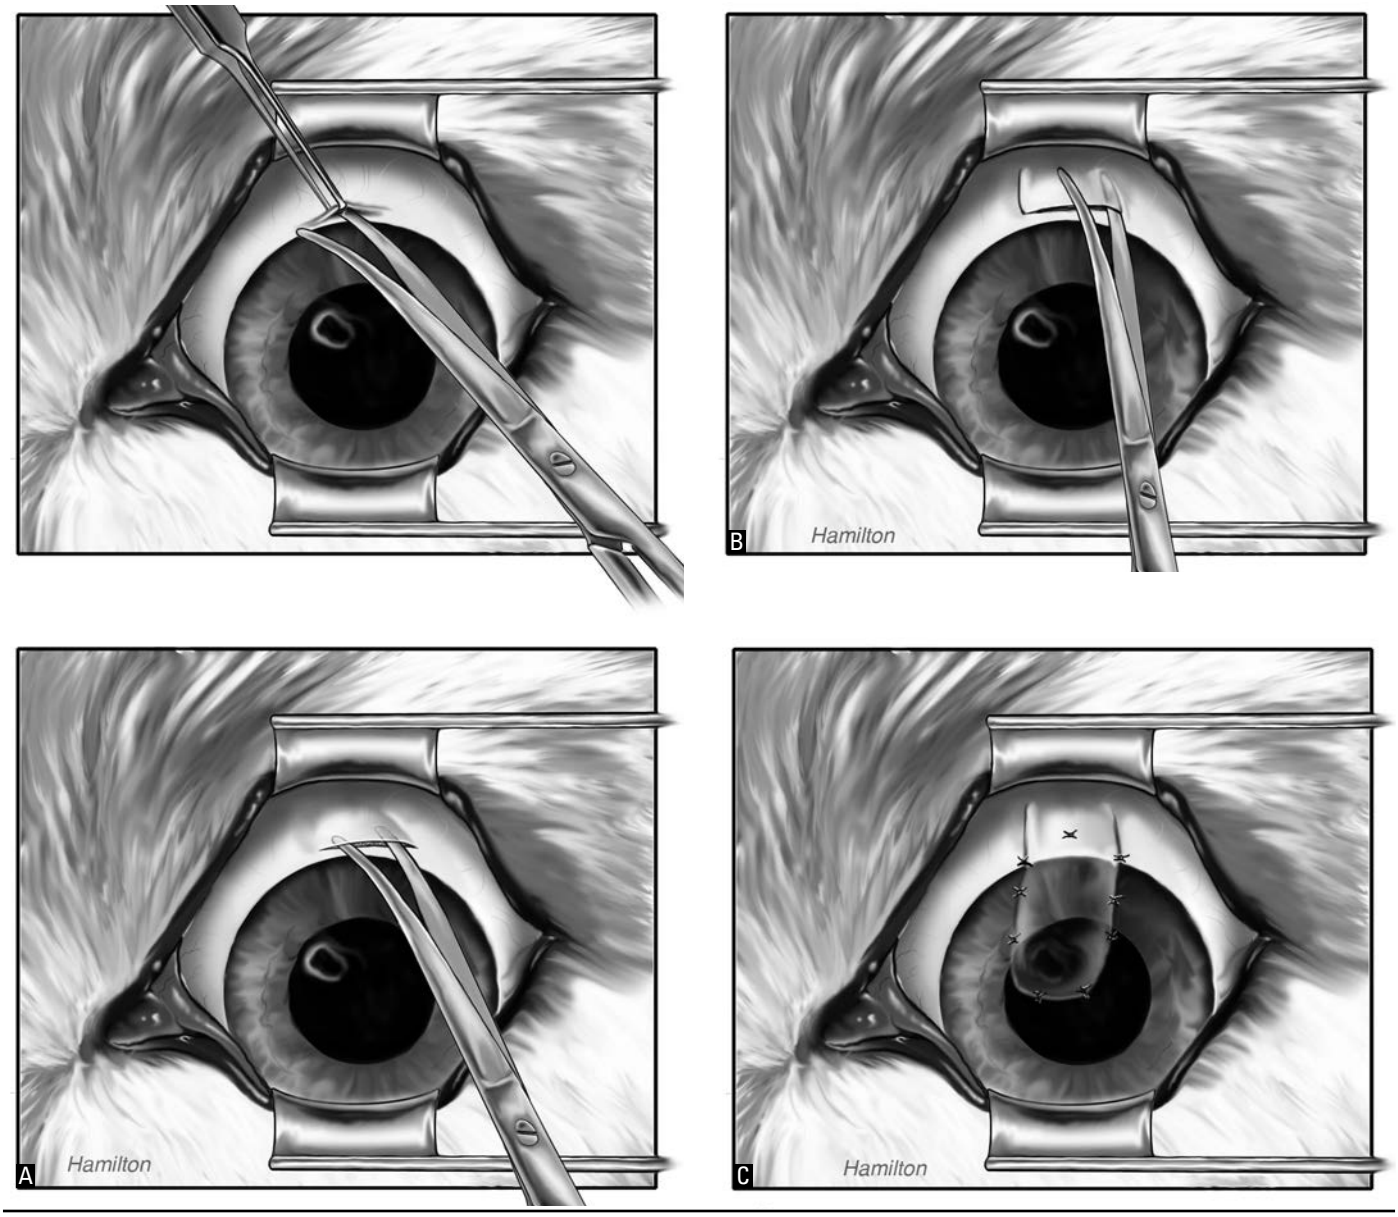

Figure 12-14. A. In elevation of a conjunctival flap, the conjunctiva is gently tented with Colibri style forceps and tenotomy scissors are used to incise the conjunctiva and bluntly dissect the thin conjunctival tissue from the underlying Tenon's capsule. **B.** Once the thin conjunctival tissue is elevated and undermined, tenotomy scissors are used to incise along the ventral extent of the flap, perpendicular to the limbus. An incision is then made parallel to the limbus and towards the flap base resulting in a flap approximately 1mm greater than the width of the corneal lesion. **C.** The conjunctival flap has been rotated into place and sutured along the three free margins to the corneal defect. Anchoring sutures are also placed where the flap traverses the limbus.

ocular discomfort for 2 to 3 days while the conjunctival incisions heal. Patients should be treated for five to seven days with prophylactic topical antimicrobials, and rechecked in two to three weeks.

Conjunctival Bridge Flap

The indications for performing conjunctival bridge flaps are similar to those for pedicle flaps. However, some ophthalmic surgeons feel that bridge flaps are more appropriate for exophthalmic breeds, providing for increased protection of the corneal surface during healing. The technique is similar to that described for pedicle flaps, with the exceptions described here. There is no distal or free margin to bridge flaps. The parallel conjunctival incisions extend 180° around the bulbar conjunctiva, leaving attachments dorsally and ventrally. The freed central portion of the flap is then placed onto the surface of the cornea, so that the lesion is completely covered (Figure 12-15). Only the medial and lateral edges of the corneal lesion are sutured to the corresponding edges of the conjunctival flap. Suturing the dorsal and ventral aspects of the flap would compromise vascular supply. Anchoring sutures are placed from the edges of the flap through the limbal tissues, both dorsally and ventrally. Postoperative management is similar to that for pedicle flaps, and these flaps are often severed after complete corneal healing occurs (5 to 8 weeks postoperatively) to release the nonadherent dorsal and ventral aspects of the tissue bridge.

Conjunctival Hood Flap

Conjunctival hood, or advancement flaps are indicated for perilimbal lesions of the cornea (Figure 12-16). The corneal recipient bed is prepared as described for rotating pedicle flaps. A perilimbal conjunctival incision is made by tenting the tissue with Colibri-style forceps and incising it with tenotomy scissors. The conjunctiva is then undermined in a direction radiating outward from the initial incision, extending posteriorly toward the fornix.

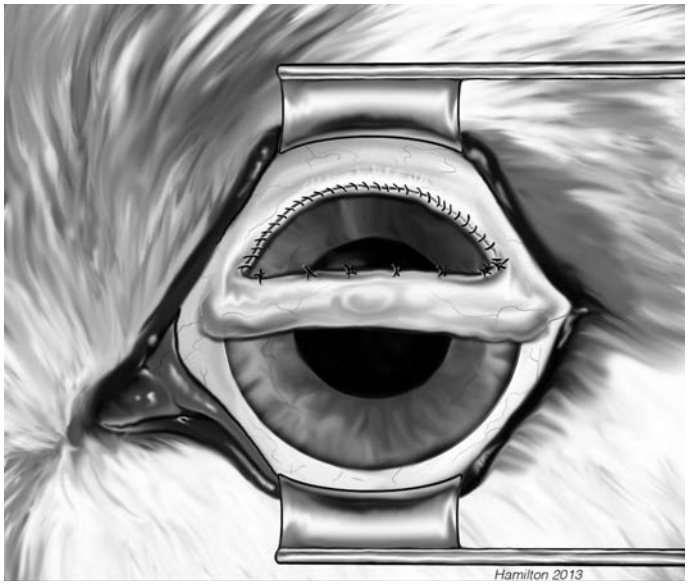

Figure 12-15. Placement of a conjunctival bridge flap with sutures on the medial and lateral aspects of the corneal lesion. Anchoring sutures are placed where the flap traverses the limbus dorsally and ventrally.

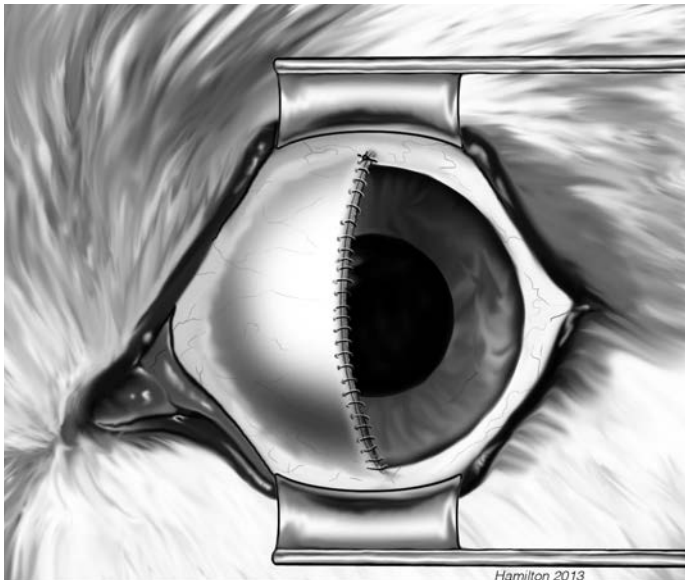

Figure 12-16. A conjunctival hood flap is advanced and sutured over a perilimbal corneal lesion.

The perilimbal incision is then extended to a distance one to two millimeters beyond the corneal lesion. The conjunctival tissue is advanced over the corneal defect. Interrupted sutures using 6-0 to 7-0 multifilament absorbable suture are placed from the edges of the advanced conjunctiva through the limbus so that the conjunctival hood completely covers the corneal lesion without tension. The conjunctiva is sutured to the edge of the corneal defect with absorbable multifilament 7-0 to 8-0 suture material. Postoperative management techniques are similar to those described for pedicle flaps.

360° Conjunctival Flap

The 360° conjunctival flap causes severe visual compromise and is considered a salvage procedure when most of the corneal surface has been severely damaged. The procedure is technically easier to perform than other conjunctival flaps, as no corneal sutures are needed. A perilimbal conjunctival incision is performed for 360°, and the conjunctival tissue is undermined posteriorly. The tissue is advanced over the cornea, and the cut edges of the conjunctiva are sutured in a simple interrupted or continuous pattern with 7-0 multifilament absorbable suture. Patient care postsurgically is described later.

Conjunctival Graft

Conjunctival grafts are performed by completely excising a portion of conjunctival tissue and then suturing the free tissue graft to a corneal defect. The graft provides structural support to the cornea, however the benefits of an intact vascular supply and cell-mediated healing provided by a flap are absent as the graft has no vascular supply. Indications for performance of a conjunctival graft are limited to chronic, inactive lesions that involve greater than 75% of corneal stromal loss. Corneal vascularization should be present at or near the edge of the corneal defect. Preparation of the corneal recipient bed is described earlier with conjunctival pedicle flap construction. The conjunctival donor graft is usually harvested from the dorsal or lateral

bulbar or tarsal conjunctiva. The conjunctiva is incised with tenotomy scissors and undermined. The final donor graft should approximate the shape of the recipient bed, and should be approximately two millimeters larger in diameter. The conjunctival graft is carefully placed onto the corneal defect with the non-epithelialized surface in contact with the cornea. The suture material and suturing technique is similar to that described for conjunctival flaps. Initially, the four corners or quadrants of the graft are sutured to the cornea. Additional sutures should be placed so that the distances between the previously placed sutures are divided equally. Post-operative management is similar to that described for conjunctival pedicle flaps.

Post-Operative Care

Post-operative care is similar for many patients following corneal or conjunctival surgery. Frequent recheck examinations are recommended in most cases to monitor for progress or possible postoperative complications. Broad spectrum topical antimicrobials are indicated to prevent post-operative infection and should be applied three times daily. More specific and aggressive therapy may be required in cases where established infection is recognized by culture and microbial sensitivity, and application frequency should be increased to every two to four hours in some cases. Autologous serum has antiproteolytic properties that inhibit corneal melting and supplies various growth factors that may assist in early post-operative healing, however, care must be taken to avoid microbial contamination of serum. The frequency of topical application varies from three to eight times daily, depending on the case. In cases of corneal melting, additional anti-proteolytic effect may be obtained using systemic doxycycline (5 mg/kg PO BID). Systemic antimicrobials are also indicated in cases of full thickness corneal defects or infected wounds. Secondary uveitis is treated with topical atropine applied once or twice daily for its mydriatic and cycloplegic effects. Systemic antiinflammatories, such as nonsteroidal anti-inflammatory drugs are indicated to decrease post-operative discomfort and inflammation. In many cases, a temporary tarsorrhaphy, will help to protect the eye during the initial postoperative period. An Elizabethan collar should be used to prevent self trauma, and exercise should be restricted during the initial two to three weeks of post-operative healing.

Imbrication Technique for Prolapsed Third Eyelid Gland Repair

Stacy E. Andrew

Introduction

Prolapse of the gland of the third eyelid (also known as "cherry eye") is a common occurrence in dogs less than 1 year of age. A breed predisposition has been noted in Boston terriers, Cocker spaniels, Bulldogs, and other brachycephalic breeds. Presenting complaints include ocular discharge, conjunctivitis and unacceptable cosmetic appearance due to protrusion of the gland above the third eyelid.

Because of its importance in tear production, replacement of the prolapsed third eyelid (TE) gland to its normal anatomic location is strongly recommended rather than excision of the gland. While numerous surgical techniques have been described for gland replacement, the two most frequently utilized procedures will be described in this chapter. The first technique is creation of a conjunctival pocket which is tried first in all cases. The second technique fixes the gland to orbital periosteum and is used for recurrent gland prolapses or with the pocket technique if the gland is chronically prolapsed and extremely hypertrophied.

Pocket Technique (Morgan Method)

Instrumentation Required

Small Bishop-Harmon forceps with 0.3 mm wide tips, 2 curved mosquito forceps or towel clamps, tenotomy scissors (Stevens or Westcott), an eyelid speculum (Castroviejo or Barraquer), needle holder (Castroviejo or Barraquer), and absorbable 6-0 suture material (polyglactin 910 or polyglycolic acid).

Surgical Procedure

The patient is placed under general anesthesia and positioned in sternal recumbency. The third eyelid surfaces as well as the periocular haired lid surfaces are swabbed three times with dilute (1:50) povidone-iodine solution. The affected eye is draped with either a sterile, disposable drape or with towels. An eyelid speculum is placed to retract the upper and lower eyelids. The leading edge of the TE is grasped with either mosquito forceps or towel clamps placed near the medial and lateral attachments of the TE to the globe. The clamps are used to maneuver the TE by retracting the lid forward and slightly dorsal such that the bulbar aspect of the TE is exposed.

A curvilinear incision is made in the conjunctiva with tenotomy scissors parallel to the base of the TE gland closest to the fornix (Figure 12-17A). The conjunctiva is best handled with small (0.3 mm) Bishop Harmon forceps. A second incision is made 2 to 3 mm from the free margin of the TE parallel to the gland (Figure 12-17B). The length of the incision corresponds to the length of the exposed gland, but usually approaches 1 cm. The incisions should not converge at either end. It is necessary to leave an

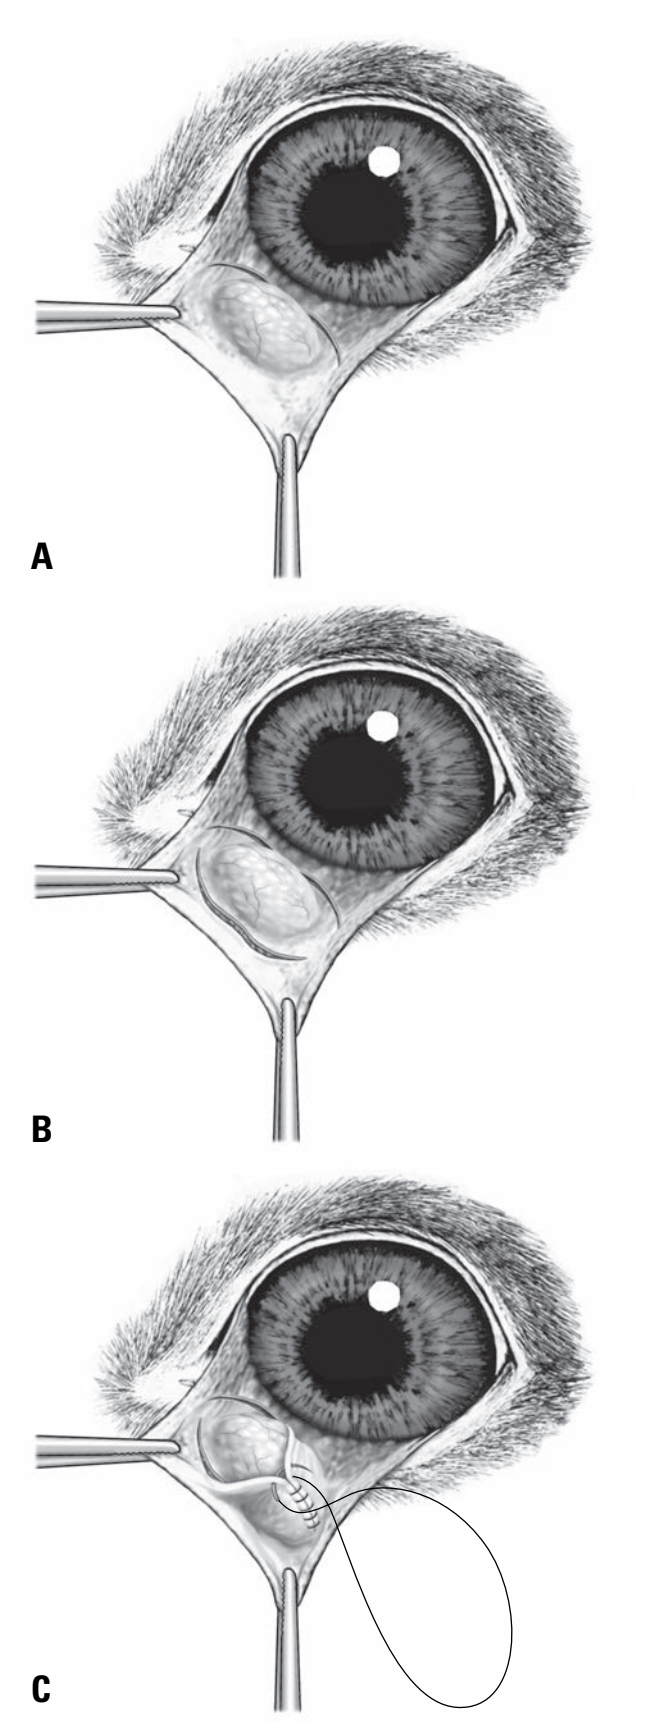

Figure 12-17. A. A curvilinear incision is made in the conjunctiva with tenotomy scissors parallel to the base of the TE gland closest to the fornix. **B.** A second incision is made 2 to 3 mm from the free margin of the TE parallel to the gland. **C.** The incisions are closed so that the third eyelid conjunctiva covers the gland.

area at both ends of the gland that is not incised to allow secretions from the gland to exit onto the ocular surface and not cause cyst formation.

The incisions are then closed so that the third eyelid conjunctiva covers the gland. (Figure 12-17C). A knot is tied on the anterior or palpebral surface of the third eyelid and the needle passed through the lid to the posterior or bulbar side near one end of the incision. The incisions are closed in a simple continuous pattern with 6-0 polyglactin 910 or polyglycolic acid. At the far end of the incision, the needle is again passed through the third eyelid and the knot is tied on the palpebral TE surface. This prevents the suture knots from causing corneal irritation or ulceration.

Postoperative Care

Animals are discharged and owners instructed to apply triple antibiotic ophthalmic ointment 3 times daily for 5 days. The TE gland will likely remain swollen for 2 to 3 days postoperatively, sometimes up to 7 to 10 days, and then return to more normal conformation. An Elizabethan collar may be necessary if the animal shows any tendency to traumatize the eye (s).

Orbital Tacking (Stanley Modification of the Kaswan Technique)

Instrumentation Required

Bard Parker blade (#11 or #15), small Bishop-Harmon forceps with 0.3 mm wide tips, 2 curved mosquito forceps or towel clamps, tenotomy scissors (Stevens or Westcott), eyelid speculum (Castroviejo or Barraquer), Derf needle holder, and 3-0 nylon on a cutting needle, 6-0 polyglactin 910, needle holder (Castroviejo or Barraquer).

Surgical Procedure

The patient is placed under general anesthesia and positioned in sternal recumbency. The hair ventral to the eye and over the zygomatic arch is clipped. The third eyelid surfaces as well as the clipped site are swabbed three times with dilute (1:50) povidone-iodine solution. The affected eye is then draped with either a sterile, disposable drape or with towels. A 5 mm long skin incision is made with a #11 or #15 Bard Parker blade, parallel to and just ventral to the periorbital rim (Figure 12-18A). An eyelid speculum is placed to retract the upper and lower eyelids. A second incision is made in the center of the ventral conjunctival fornix with tenotomy scissors on the anterior or palpebral side of the third eyelid (Figure 12-18B).

Using nylon suture, the needle is inserted through the skin incision and a portion of periosteum from the ventral orbital rim is engaged. The needle is then directed to exit the incision in the conjunctival fornix. The leading edge of the TE is grasped with either mosquito forceps or towel clamps placed near the medial and lateral attachments of the TE to the globe. The bulbar surface of the TE is then exposed by retracting the TE forward and slightly dorsal.

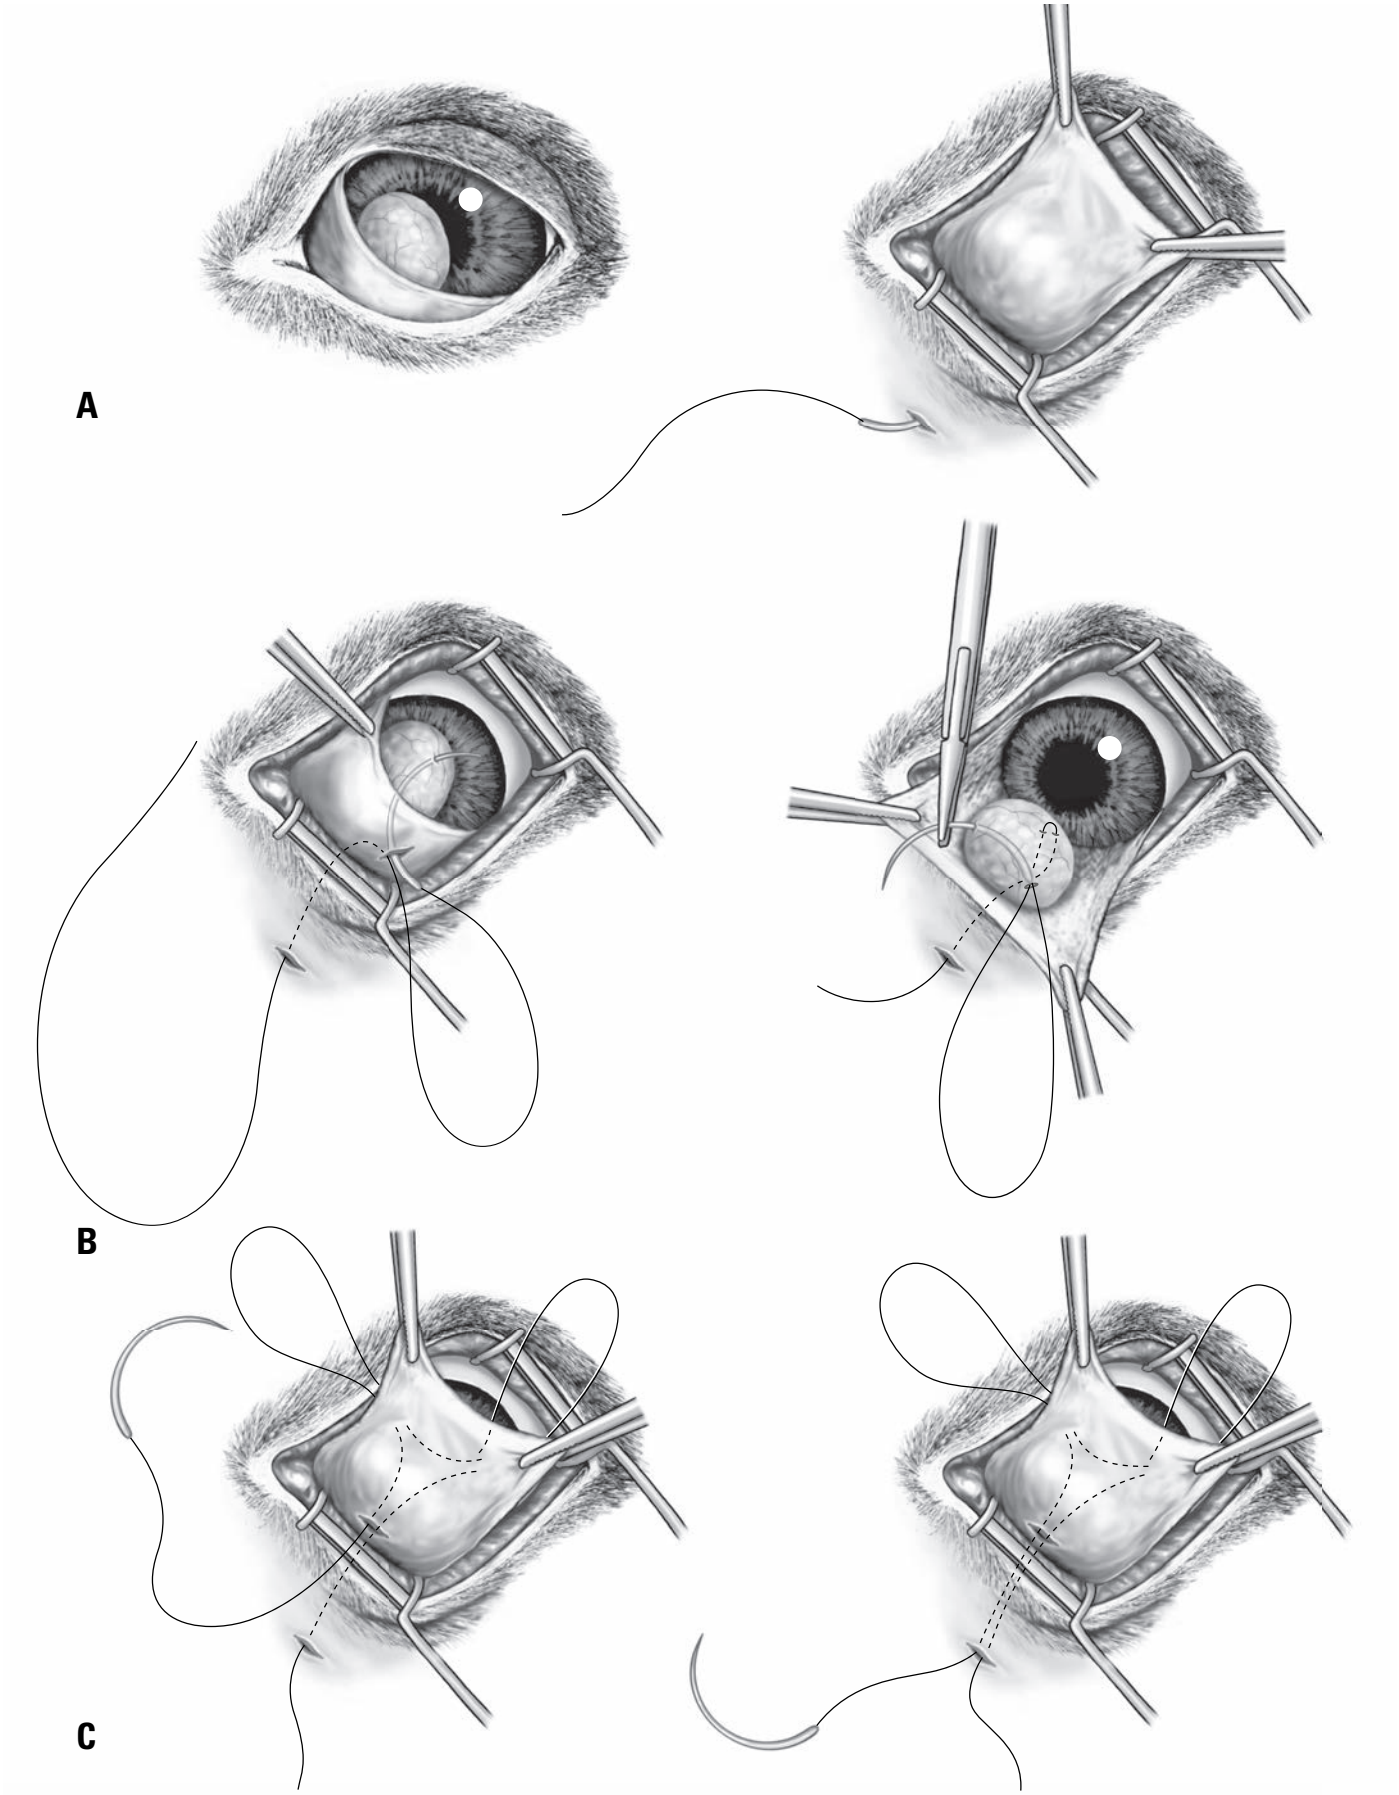

Figure 12-18. Orbital Tacking Technique. **A.** A 5 mm skin incision is made parallel to and just ventral to the periorbital rim. **B.** A second incision is made in the center of the ventral conjunctival fornix on the anterior or palpebral side of the third eyelid. **C.** Suture material anchors the gland to the periosteum.

Suture material is used to penetrate the gland in multiple directions to anchor it to the periosteum. The needle is inserted through the gland toward the leading edge of the TE and then back through the exit hole to cross horizontally or parallel to the leading edge (Figure 12-18C). The needle is passed back through the exit hole and directed towards the ventral fornix so that it emerges from the initial conjunctival incision. All suture should be covered with conjunctiva. The TE is then reflected back to its normal position and the suture needle is passed back beneath the skin to engage the orbital periosteum a second time. The nylon is tied in a secure knot being careful not to place too much tension on the suture and restrict the movement of the third eyelid. The conjunctival incision may be left open or closed with 6-0 polyglactin 910. Similarly, the skin incision may be left open or closed with nylon.

Postoperative Care

Animals are discharged and owners are instructed to apply triple antibiotic ophthalmic ointment 3 times daily for 5 days. An Elizabethan collar should be applied if the animal shows any tendency to traumatize the eye or surgical site. This technique may result in some TE immobilization which is usually not clinically significant.

Enucleation and Orbital Exenteration

Ian P. Herring

Some ophthalmic diseases or their consequences necessitate enucleation or orbital exenteration. Generally, enucleation refers to removal of the globe, whereas exenteration refers to removal of the globe and all orbital contents. The indications for enucleation and exenteration are different and are discussed in this chapter.

Pre-Operative Preparation and Surgical Positioning

Preoperative preparation of the surgical site is similar for enucleation and exenteration. Clipping the eyelids and liberal clipping of the periocular facial skin is recommended. Surgical scrubs are generally not used on or around the eye ,and although less important when the eye is to be removed, precautions to prevent surgical scrub contact with the contralateral eye are warranted. Dilute povidone-iodine solution (1:10 to 1:50 dilution of a stock 10% solution) is an effective topical antiseptic for surgical preparation and can be safely applied to the eyelids and corneoconjunctival surface. Perioperative intravenous antibiotic administration is also recommended.Surgical positioning is largely a matter of surgeon preference. I generally place dogs in lateral recumbency and rotate the head so that the palpebral fissure is near horizontal.

Enucleation

Indications for enucleation include most causes of a blind and painful eye. Specific diseases that often lead to enucleation in small animals include end-stage uncontrolled glaucoma, septic endophthalmitis, irreparable globe perforation and irreparable globe proptosis. Dogs with chronic glaucomatous eyes are good candidates for implantation of an intrascleral prosthesis, a surgical alternative that should be considered. Intraocular neoplasms constitute an additional indication for enucleation. However, depending upon the specific neoplasm, age of the animal and presence of secondary ocular complications, the necessity of and preferred timing for enucleation is variable. Many intraocular neoplasms follow a benign course with regard to metastasis (e.g. canine anterior uveal melanoma), whereas others commonly metastasize (e.g. feline diffuse iris melanoma). Additionally, some intraocular neoplasms are amenable to surgical resection or treatment by laser ablation. Consultation with and referral to a veterinary ophthalmologist is encouraged with cases of ocular neoplasia.

The two most commonly utilized methods for enucleation in dogs and cats, transconjunctival and transpalpebral will be described. The tissues removed with both approaches are the same and the approach utilized is often a matter of surgeon preference. However, there are specific clinical indications for utilizing the transpalpebral method. The transpalpebral method is indicated in cases where sepsis or neoplasia involves the corneoconjunctival surface, as the closed conjunctival sac formed with this approach serves to prevent orbital contamination during surgery. I prefer the transconjunctival approach in most cases due to improved visualization and less operative hemorrhage than with the transpalpebral technique. With either approach, a minimum of traction should be applied to the globe during surgery. Excessive globe traction or orbital pressure may stimulate an oculocardiac reflex, which causes bradycardia and is occasionally fatal. Additionally, excessive traction may result in trauma to the optic chiasm or contralateral optic nerve, causing vision loss or blindness in the contralateral eye. The latter complication is a particular concern in cats.

Transconjunctival Approach

Preoperative preparation involves periocular hair clipping and aseptic preparation of the eyelids and ocular surface utilizing dilute (1:10-1:50) povidone-iodine solution. Placement of an eyelid speculum improves visualization. Additionally, a lateral canthotomy is often helpful in cats, dogs with tight eyelid apertures and chronic glaucoma cases where severe buphthalmos encumbers globe removal through an intact eyelid opening (Figure 12-19).

Utilizing curved scissors, a 360° incision is made through the conjunctiva and Tenon's capsule to expose the sclera (Figure 12-20). Placement of this circumferential incision 2-3 mm posterior to the limbus and leaving a small rim of conjunctiva adherent to the eye is useful, as the surgeon can grasp this tissue to fixate the eye during subsequent globe manipulations. Next, the scleral insertions of the rectus and oblique extraocular muscles are identified and transected (Figure 12-21). Muscles can be identified easily by placing one blade of a curved scissor on the posterior surface of the globe and sweeping it anteriorly. The scissor blade will slip underneath the muscle belly and as it is drawn anteriorly will

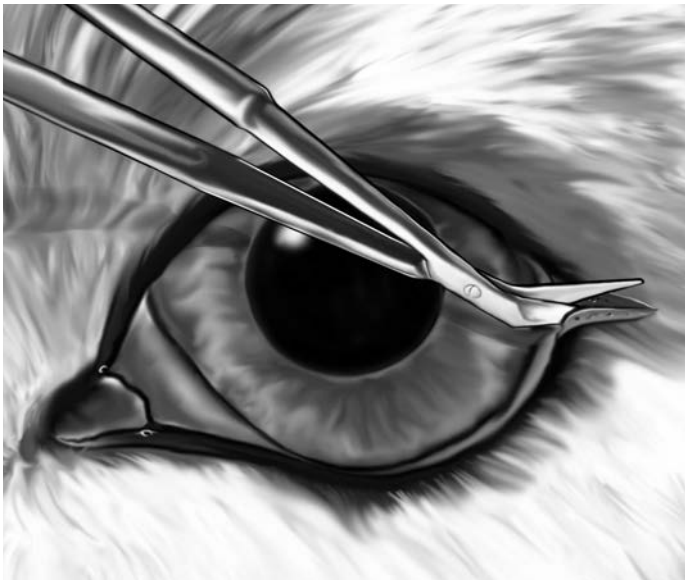

Figure 12-19. Lateral canthotomy improves surgical exposure.

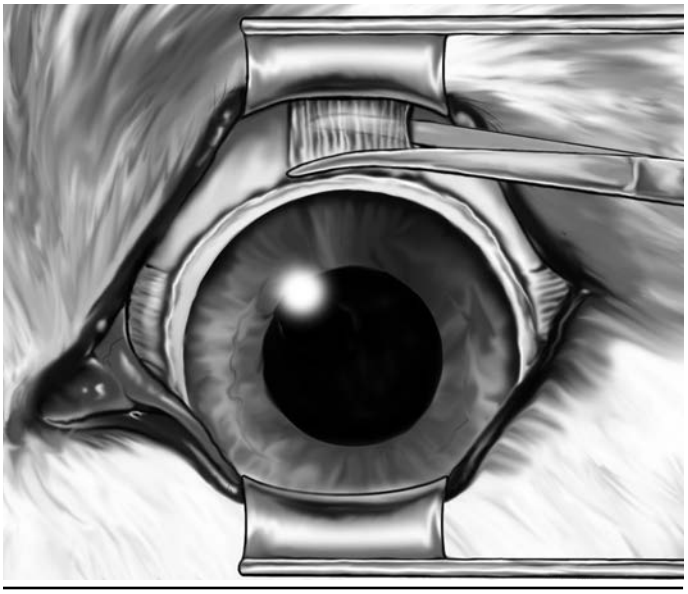

Figure 12-21. Extraocular muscles are identified using the scissor blade in an anterior sweeping motion and are transected at their scleral insertions.

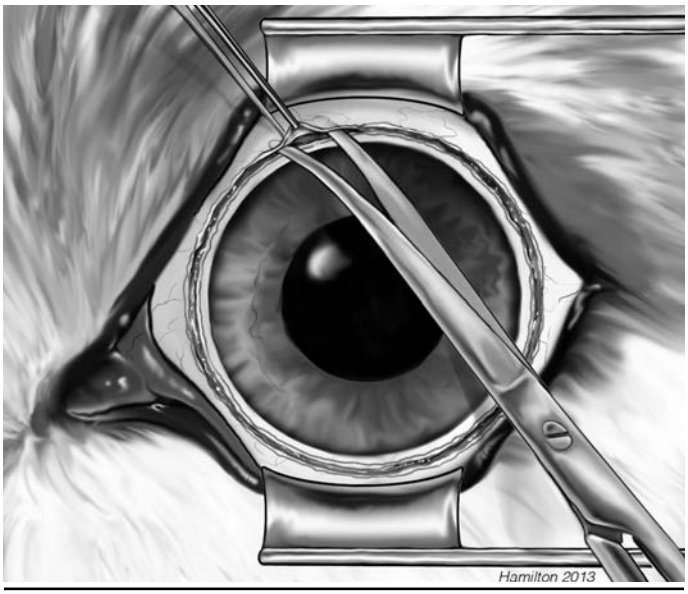

Figure 12-20. Circumferential conjunctival incision placed 2-3 mm posterior to the limbus exposes the sclera and provides a rim of conjunctival tissue attached to the globe to facilitate manipulation.

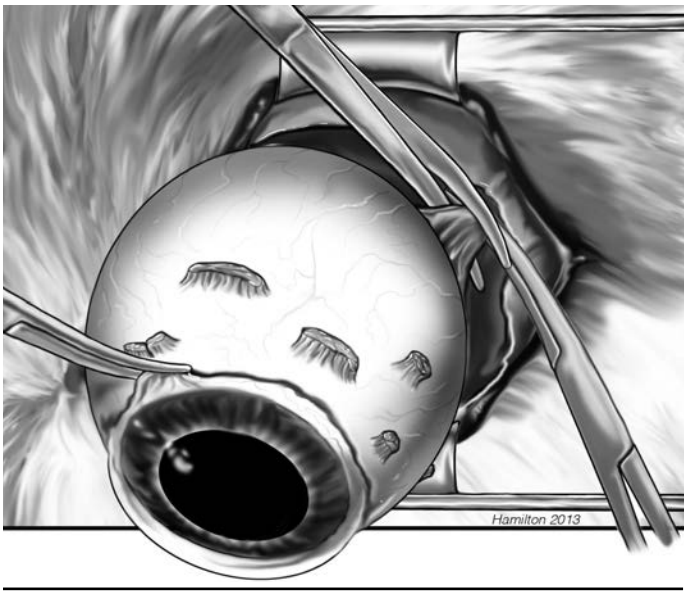

Figure 12-22. The optic nerve bundle is severed, with or without prior placement of a hemostatic clamp.

stop at the muscle's scleral insertion, at which point the scissors are closed to transect the muscle tendon. Muscle transection is performed at the level of scleral insertion rather than mid-body to reduce hemorrhage. The retractor bulbi muscles are then severed by sliding curved, blunt-tipped scissors posteriorly along the scleral surface and gently cutting the muscles at their scleral insertions. After all extraocular muscles have been severed, the globe should rotate rather freely. A curved hemostat is used to clamp the optic nerve and associated vasculature prior to transecting these structures between the clamp and globe using curved scissors (Figure 12-22). The clamp may be left in place for several minutes during subsequent steps of the surgery to maintain hemostasis. Although seldom necessary, absorbable suture can be used to ligate the optic nerve and associated vasculature prior to removing the hemostat. Again, traction on the optic nerve should be minimized. Some surgeons advocate not using a hemostatic clamp at all by simply transecting the optic nerve and achieving hemostasis with gauze packed into the orbit for several minutes following globe removal.

After the globe is removed, the nictitating membrane (3rd eyelid) and its associated gland are excised, followed by removal of the remaining conjunctival tissue.(Figures 13-23 and 13-24) The lacrimal gland can be identified in the dorsolateral region of the orbit and excised, although cyst formation seems rare even when the gland is left in situ. Finally, the margins of the eyelids are removed using Mayo scissors. Excision of the eyelid margins must incorporate the meibomian glands which requires removal of

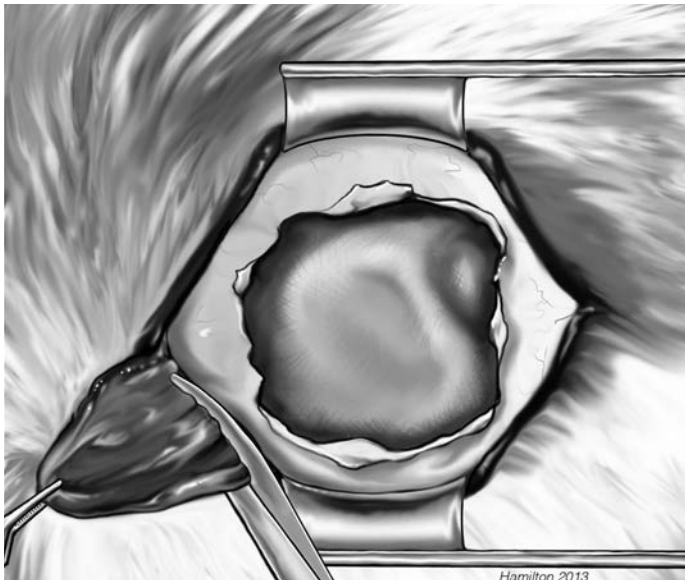

Figure 12-23. The nictitating membrane and associated gland are excised.

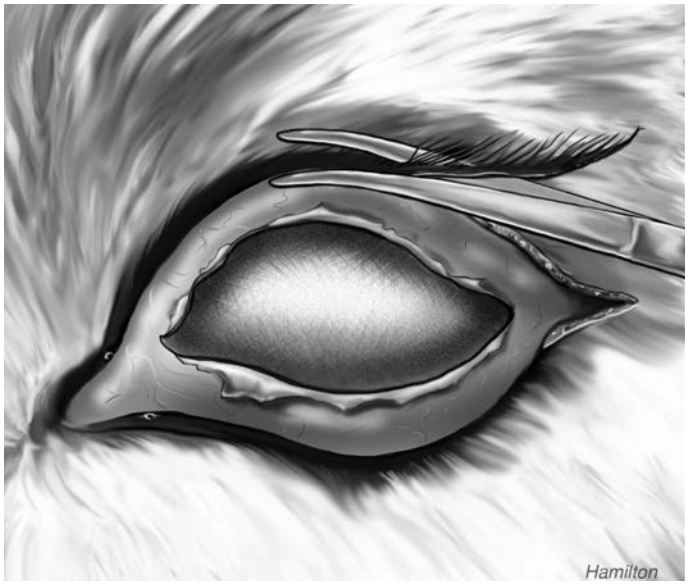

Figure 12-24. Removal of the eyelid margins should incorporate the meibomian glands, necessitating removal of approximately 4-5 mm of eyelid margin tissue.

approximately 4 mm of marginal eyelid tissue (Figure 12-25). Due to the presence of secretory structures, failure to excise the lacrimal or meibomian glands may lead to intraorbital cyst formation and dehiscence of the surgical closure.

Prior to wound closure, the orbit is flushed copiously with isotonic sterile irrigating solution. A silicone prosthetic sphere can be placed which improves post-operative cosmesis by preventing the sunken appearance associated with the anophthalmic orbit. Closure involves apposition of the deep orbital fascia using 3-0 to 5-0 absorbable suture in a simple continuous pattern. If a silicone sphere is placed, the deep orbital fascia is sutured over the sphere. Subcutaneous closure is performed using 4-0 to 5-0 absorbable suture in a continuous pattern. The skin is closed with 4-0 to 5-0 non-absorbable suture material in a simple interrupted pattern.

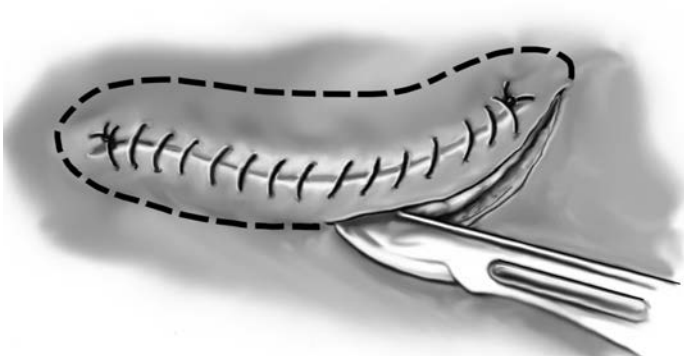

Figure 12-25. Following suture closure of the eyelids for transpalpebral enucleation an elliptical skin incision is performed, incorporating the meibomian glands of the eyelids.

As an alternative to placement of a silicone prosthetic sphere, 3-0 to 4-0 non-absorbable suture can be used to span the rostral orbital opening to prevent post-operative sinking of the skin. This suture is anchored in orbital periosteum and run back and forth across the orbital opening to form a tight meshwork of suture. This is performed after closure of the deep orbital fascia and prior to skin closure.

Transpalpebral Approach

Presurgical preparation of the surgical site is identical to that described for the transconjunctival approach. The eyelids are apposed and sutured shut using 3-0 nylon in a continuous pattern. An elliptical skin incision is made with a scalpel paralleling and 4-6 mm from the eyelid margins, converging at the medial and lateral canthus (Figure 12-26). The medial and lateral canthal tendons must be severed completely before progress can be made in dissecting down to the sclera. Although not required, Allis tissue forceps can be placed on the apposed eyelid margins to aid in subsequent globe manipulations. A combination of blunt and sharp dissection using Metzenbaum scissors is used to

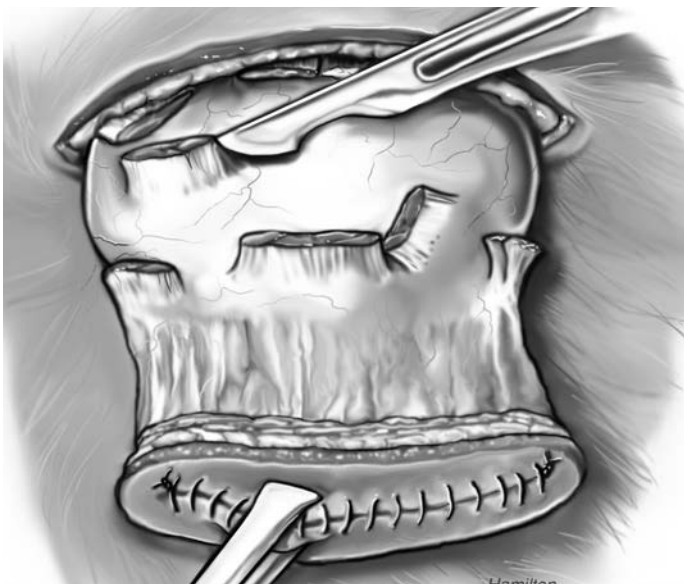

Figure 12-26. After penetrating the orbital septum, dissection to the sclera reveals extraocular muscles, which are transected at their insertions.

approach the conjunctiva. Care must be taken not to penetrate the conjunctival surface or the aseptic advantage of the transpalpebral technique is lost. If the conjunctiva is inadvertently incised in cases of ocular surface neoplasia or sepsis, the hole in the conjunctiva should be closed before continuing with dissection. Dissection to the scleral surface just posterior to the limbus allows identification of the rectus and oblique extraocular muscles, which are transected at their scleral insertions. The retractor bulbi musculature is then transected at or near their scleral insertions. The optic nerve is then transected after liagation of the nerve and its vasculature with absorbable suture. Depending on the extent of dissection in the dorsolateral aspect of the orbit, the orbital lacrimal gland may or may not be incorporated in the tissues removed. This can be confirmed by careful palpation in the dorsolateral region of the orbit. After the orbit is irrigated copiously with sterile isotonic solution, surgical closure is performed as described for the transconjunctival approach.

Exenteration

Exenteration refers to the surgical removal of the eyelids, globe and all orbital contents including the conjunctiva, extraocular muscles, orbital lacrimal gland, nictitating membrane and associated gland, orbital connective tissue and orbital fat. The most common indications for exenteration include extrascleral extension of intraocular neoplasms and primary orbital neoplasms that are not surgically resectable without concurrent removal of the globe. However, if orbital neoplasms have invaded the bony structures of the orbit or extended beyond the confines of the orbit, exenteration would be palliative and more aggressive surgical procedures such as orbitectomy should be considered. Rarely, medically uncontrollable orbital infection may necessitate exenteration.

Exenteration is generally performed in a manner similar to transpalpebral enucleation, with wider excision margins to incorporate removal of the orbital contents, including the globe, extraocular muscles, nictitating membrane and gland, orbital lacrimal gland and orbital fat. Occasionally, removal of periosteum is indicated, as when neoplastic disease abuts this tissue. The eyelids are sutured shut with 3-0 monofilament suture in a continuous pattern. A surgical blade is used to perform an elliptical skin incision outside of the eyelid margins as for transpalpebral enucleation. This incision may be carried further from the eyelid margins, as necessary, to ensure removal of diseased tissue. However, sufficient skin must be left to allow skin closure without tension on the suture line. Following completion of the skin incision, subcutaneous dissection is continued to the bony margin of the orbit, where the orbital septum is incised. Bands of connective tissue that attach the medial and lateral canthus to the orbital wall, the medial and lateral canthal ligaments, must be sharply incised. The goal of the remainder of the surgery is to continue dissection towards the orbital apex, staying outside of the extraocular muscle cone. Blunt dissection is continued with Metzenbaum scissors and should follow the bony wall of the orbit dorsally and medially proceeding towards the orbital apex. The origin of the ventral oblique muscle is encountered ventromedially and is incised. Dorsolaterally, dissection should proceed underneath the orbital ligament, using care not to transect this structure. Ventral dissection should avoid trauma to or excision of the zygomatic salivary gland, unless it is involved in the disease process, in which case it should also be removed. When dissection to the orbital apex is complete, a curved hemostat is placed around the optic nerve and extraocular muscle cone near the posterior wall of the orbit and these structures are transected with curved Metzenbaum scissors near the clamp. A ligature using absorbable suture is placed around the optic nerve and vasculature posterior to the clamp. The orbit is then irrigated with sterile isotonic solution prior to wound closure.

Two layer wound closure is performed as described for enucleation. Since more extensive orbital tissue removal occurs with exenteration, the sunken appearance of the orbit will be greater than occurs with enucleation. Post-operative cosmesis can be improved by the use of non-absorbable suture material to bridge the anterior opening to the orbit prior to skin closure, as described under transconjunctival enucleation closure. Silicone sphere implants can also be used, but the likelihood of dehiscence and sphere extrusion may be increased due to the lack of deep orbital connective tissue to close over the sphere prior to skin closure. If exenteration is performed due to uncontrollable orbital infection, both methods for improving cosmesis are contraindicated.

Post-operative Care

Postoperative considerations include provision of analgesia, prevention of infection and prevention of self-trauma. The use of opiate analgesics in the early post-operative period followed by oral non-steroidal anti-inflammatory medications for a period of 7 days is recommended. An Elizabethan collar may be used to prevent self-trauma of skin sutures. Dogs are more likely than cats to require an Elizabethan collar. Owners should be advised to keep the incision clean to help prevent localized infection. Systemic antibiotics are generally not required beyond the perioperative period, unless pre-existing sepsis is present.

Complications

Operative complications of enucleation and exenteration include hemorrhage and the previously described complications of oculocardiac reflex stimulation and potential damage to the optic chiasm due to excessive globe or optic nerve traction. Postoperative orbital swelling is common and sometimes severe if related to hemorrhage confined to the orbital space. Although not considered a complication, it is also common to note serosaguinous discharge from the ipsilateral nares for a few days post-operatively as fluid passes through the severed nasolacrimal canaliculus to the nasal ostium. Orbital emphysema is occasionally encountered following enucleation, particularly in brachycephalic dogs, presumably due to air being forced up the nasolacrimal duct and accumulating in the closed orbit. Orbital infection, seroma and cyst formation are rare. Cyst formation is more likely to occur when secretory tissues (e.g. nictitans gland, lacrimal gland) are left in the orbital space. When orbital silicone spheres are placed to improve post-operative cosmesis, sphere extrusion is a potential complication that can be minimized by ensuring that adequate deep orbital fascia covers the sphere

prior to skin closure. This complication is more common in cats than dogs.

Chapter 13

Ear

Pinna

Suture Technique for Repair of Aural Hematoma

Paul E. Cechner

Aural hematomas occur most frequently in dogs with pendulous ears and occasionally in dogs with erect ears and in cats. Hematomas are most apparent in the concave surface of the ear. The etiology is not clear, but the most accepted theory is that the lesion is self-inflicted from head shaking, scratching, and rubbing the ear.

The auricular cartilage is pierced by many foramina, a configuration that permits passage of numerous vessels from the great auricular artery. Shearing forces from trauma are believed to tear some of the vessels. Blood accumulates between the skin and the layers of cartilage of the pinna. Bleeding continues until the internal pressure equals the pressure of the feeder arteries. The underlying causes for irritation to the ear should include all the external factors and diseases that predispose an animal to otitis externa, including immune-mediated diseases, food, and inhalant hypersensitivities.

Treatment Considerations

Hematomas should be treated immediately after diagnosis. Untreated hematomas usually cause various cosmetic alterations resulting from fibrous contracture. Some ears have a cauliflower-like appearance, which is a permanent alteration. Identification and treatment of the underlying cause are critical to long-term management of patients with aural hematoma.

Suture Technique

In my experience, incisional drainage combined with suturing has consistently been the most successful treatment for aural hematomas. The pinna is surgically prepared on both sides. Hematomas have been opened using longitudinal, S-shaped, and cruciate incisions, depending on the surgeon's preference. I prefer the longitudinal incision, and it is not necessary to remove additional skin to widen the incision.

The fibrin clot is removed, and the cavity is curetted and flushed with saline. Horizontal mattress sutures are placed in rows parallel to the skin incision (Figure 13-1). The first row of sutures are placed at the outer edge of the hematoma cavity with each new row placed toward the skin incision. The spacing of sutures varies with the size and shape of the pinna and the size and location of the hematoma.

Mattress sutures are 5 to 10 mm wide, 5 to 10 mm apart in each row, and 5 to 10 mm between each row, and the last row of sutures is 2 to 5 mm from the skin incision. Usually, 2 to 5 rows of

sutures are placed on each side of the incision. To promote wound drainage, the skin incision is not sutured. The same procedure is recommended for cats; however, the suture spacing is 2 to 4 mm apart. The sutures should not be placed perpendicular to the skin incision in either species (Figure 13-2).

The sutures penetrate the full thickness of the pinna and are tied on the convex surface of the ear (Figure 13-3). When placing the sutures, the surgeon should avoid the three main great auricular branches, which are visible on the convex surface of the pinna. Suture tension is subjective. As a guideline, sutures should be placed with just enough tension to permit insertion of the needle holder tips to the level of the hinge.

Various suture materials have been used. My preference is 2-0, 3-0, or 4-0 nylon or polypropylene swaged onto a straight cutting needle. The use of stents or suturing through material, such as radiographic film, is usually not necessary if sutures are placed properly.

Figure 13-1. Correct placement of sutures after removal of an aural hematoma.

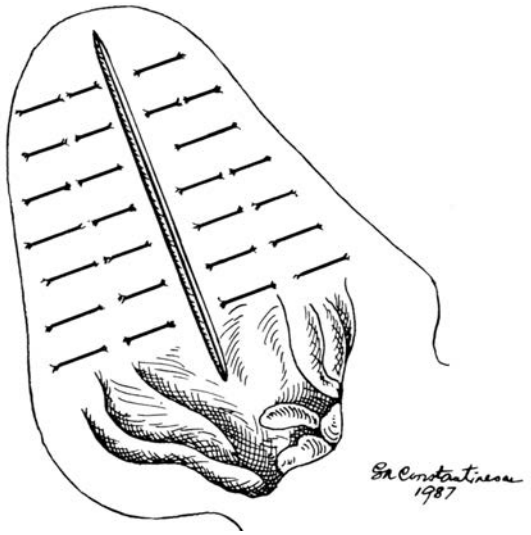

Figure 13-2. Incorrect placement of sutures after removal of an aural hematoma. Placement of sutures with tranverse orientation may decrease blood supply to the cartilage and skin of the pinna.

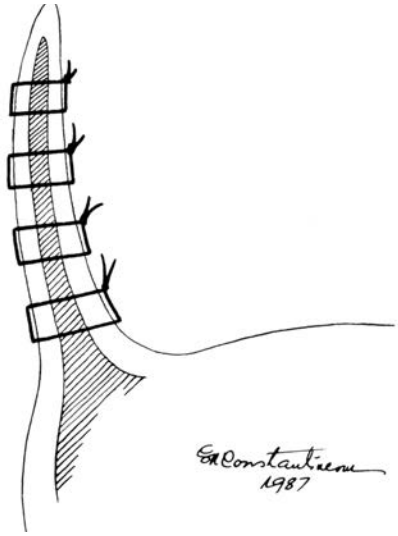

Figure 13-3. After removal of an aural hematoma, sutures are placed through the full thickness of the ear and tied on the convex surface. See Figure 13-1 for correct placement of sutures.

Postoperative Care

A light protective bandage is applied to protect and immobilize the ear. Pendulous ears are bandaged over the head or neck. Erect ears are bandaged to maintain a normal erect position. Ear bandages should not occlude the opening of the vertical canal. The bandage is changed in 3 days and is removed in 7 days. The sutures are removed in 3 weeks. An Elizabethan collar is recommended to prevent scratching of the unband-aged ear.

Complications

The most common complications of aural hematomas are cosmetic alterations and recurrence. Necrosis of the pinna has been reported from improper suture placement. Cosmetic alterations are usually the result of delayed treatment, improper suture placement, and excessive suture tension.

Aural hematomas can recur at the same site, but they are more likely to recur adjacent to the original hematoma. Recurrence of a hematoma is likely when inadequate numbers of sutures are used or inappropriately placed or when the underlying causes of the hematoma are not identified and treated appropriately. Necrosis of the pinna can be prevented by avoiding the ascending branches of the great auricular artery through the use of suture placement parallel, rather than perpendicular, to the incision.

Client Education

Communication with the animal's owner regarding all aspects of aural hematomas and their management will help to avoid misunderstandings, especially if complications occur. Owners should also understand that to treat the underlying causes properly, further investigation and expense will be required.

Sutureless Technique for Repair of Aural Hematoma

M. Joseph Bojrab and Gheorghe M. Constantinescu

One disadvantage of suture techniques for repair of aural hematomas is the possibility that the treated ear may thicken, wrinkle, and resemble a cauliflower. These unwanted changes do not occur with the sutureless technique described in this section.

After the pinna has been clipped, thoroughly cleaned, and prepared, an elliptic incision is made on the concave surface over the swelling. The incisions should expose the hematoma cavity from end to end. The cavity is thoroughly curetted and copiously irrigated. The ear is firmly taped so the incision is exposed (Figures 13-4 and 13-5), and the pinna is then reflected over a large roll of cast padding and is taped in place (Figure 13-6). A nonstick Telfa surgical dressing covered by a Tendersorb Wet Pruf (Ken Vet Animal Care Group, 100 Elm Street, Walpole, MA 02081) pad is applied to the incision surface and is changed as needed. Sutures are not used.

The ear is left firmly immobilized for 3 weeks. Healing is by second intention. The elimination of sutures helps to keep the pinna flat and prevents thickening, wrinkling, and cauliflowering.

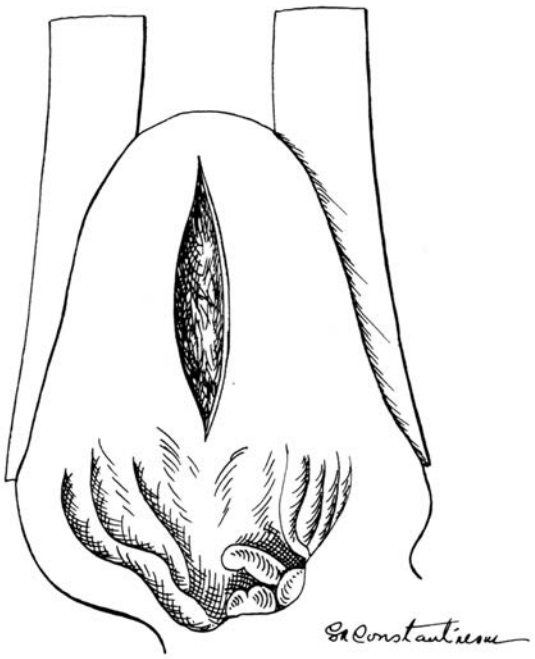

Figure 13-4. Short pieces of tape are placed on the rostral and caudal borders of the convex side of the pinna. The tape extends beyond the ear border. The elliptic incision into the hematoma cavity is shown.

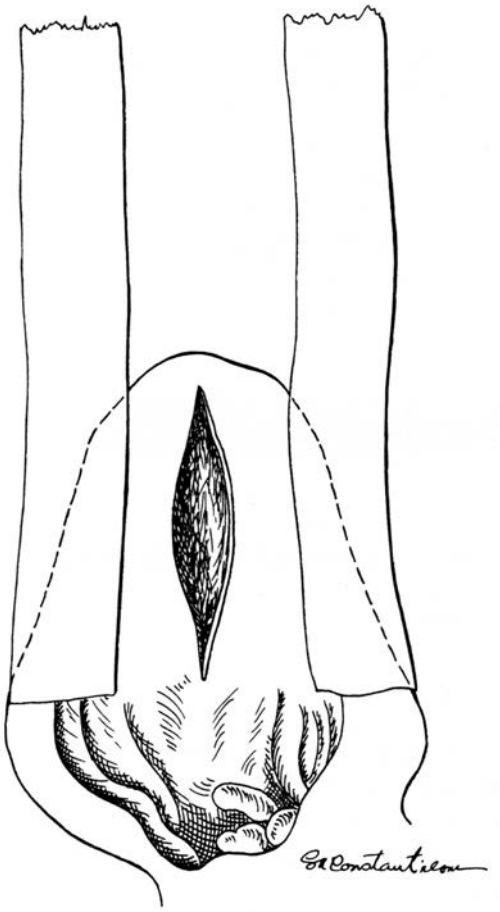

Figure 13-5. Long pieces of tape are placed on the concave side of the rostral and caudal borders of the pinna. These tapes also extend beyond the ear border and contact the tape on the opposite side.

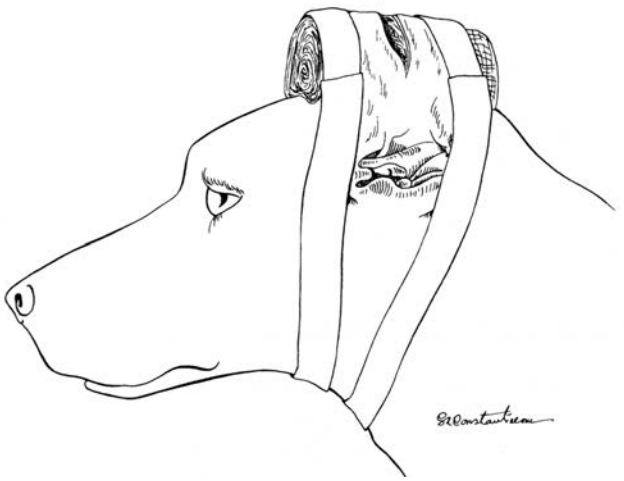

Figure 13-6. The pinna is then reflected up over a large roll of cast padding, and the tape is brought around the neck, to secure the ear in place.

External Ear

Treatment of Otitis Externa

M. Joseph Bojrab and Gheorghe M. Constantinescu

Otitis externa is an inflammation of the epithelium of the external ear canal characterized by an increased production of ceruminous and sebaceous material, desquamation of epithelium, pruritus, and pain. The condition is caused by one or more etiologic agents including parasites, bacteria, and fungi. In addition, allergy and trauma may play a role in otitis externa. The conformation of the ear canal and that of the pinna can predispose to development of acute and chronic otitis externa. For example, the high incidence of the disease in poodles and cocker spaniels indicates that the pendulous pinna and hair-filled external ear canal predispose to otitis externa. The high relative humidity of the external ear canal, in addition to the warmth, darkness, and enclosed nature of the ear canal of some breeds of dogs, provides an excellent environment for the growth of infective agents. Chronic otitis externa can permanently change the size and character of the external ear canal. The epithelium becomes thickened and fibrous and can become ulcerated. The ear canal can become stenotic if the epithelium becomes excessively scarred or undergoes metaplastic proliferation.

Diagnosis and Medical Treatment

A complete otoscopic examination of each ear, including visualization of the tympanum, is imperative for proper diagnosis and assessment of otitis externa. The initial treatment of this disease consists of irrigating and cleansing the external ear canal. Additional treatment consists of the use of ceruminolytic agents and, depending on the origin of the otitis, antibiotics (aqueous solutions) locally or parenterally, antifungal agents or parasiticides locally, and pH alteration. Bandaging the ears over the top of the animal's head allows better ventilation of the ear canal.

Culture and sensitivity tests in cases of severe or repeated occurrences of acute otitis externa may obviate a future ear canal operation by identifying the bacterial etiologic agent and thus the antibiotic that should effectively eliminate that agent. Chronic otitis externa must be treated more vigorously. Instillation of "swimmer's solution" (three parts 70% isopropyl alcohol and one part white vinegar) is useful for long-term treatment; it provides a cleaning-drying action and lowers the pH of the ear canal.

Surgical Treatment (Lateral Ear Canal Resection)

Indications

When otitis externa becomes unresponsive to medical therapy, a lateral ear canal operation is indicated. Lateral ear canal resection is also indicated for frequent recurrence of otitis externa, for chronic otitis externa resulting from inadequate treatment or lack of treatment, for external ear canal thickening that does not concurrently obstruct the horizontal portion of the external ear canal, and for exposure and removal of small tumors or polyps.

The purpose of lateral ear canal resection is to provide environmental alteration by means of ventilation so moisture, humidity, and temperature are decreased. Lateral ear canal resection also provides drainage for exudates and moisture in the ear canal.

Surgical Technique

The patient is placed in lateral recumbency and is draped so the pinna and external ear canal region are left exposed and all anatomic relationships are identifiable (Figure 13-7). The veterinary surgeon initially is positioned ventral to the patient. A probe is inserted into the ventral ear canal to determine the canal's depth. Two skin incisions are extended ventrally, parallel to each other, from the intertragic notch and the trago-helicene notch. These vertical incisions should be 1.5 times the length of the vertical ear canal. A transverse incision is made joining the vertical incisions ventrally (Figure 13-8). The skin is reflected to its dorsal attachment on the dorsal rim of the vertical ear canal. An incision is made through the subcutaneous tissue of the lateral surface of the cartilaginous vertical canal. With scissors, the subcutaneous tissue is reflected rostrally and caudally off the vertical ear canal (Figure 13-9). In similar fashion, the parotid salivary gland is reflected ventrally. The lateral aspect of the vertical ear canal should be exposed at this point.

The next portion of the surgical procedure is best performed from the dorsal aspect of the head. With scissors, two incisions are made in the cartilaginous vertical canal, one along the rostrolateral aspect of the canal and one along its caudolateral aspect. For the incisions to be made properly, the pinna and the skin flap must be pulled dorsally and the vertical portion of the ear canal visualized. One blade of the scissors is placed into the vertical canal (Figure 13-10), which is then incised from the tragohelicene notch ventrally approximately half the length of the vertical ear canal. Both the rostral and caudal ear incisions should be alternately extended until the floor of the horizontal ear canal limits further advancement of the scissors. The lateral wall of the vertical ear canal is now reflected ventrally (Figure 13-11).

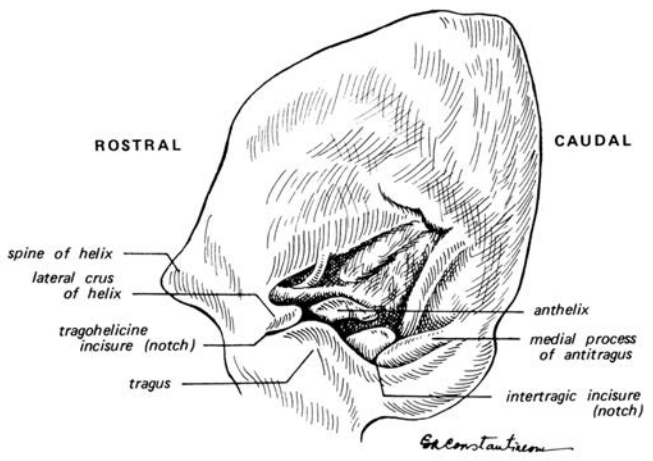

Figure 13-7. Anatomic relationships of the ear.

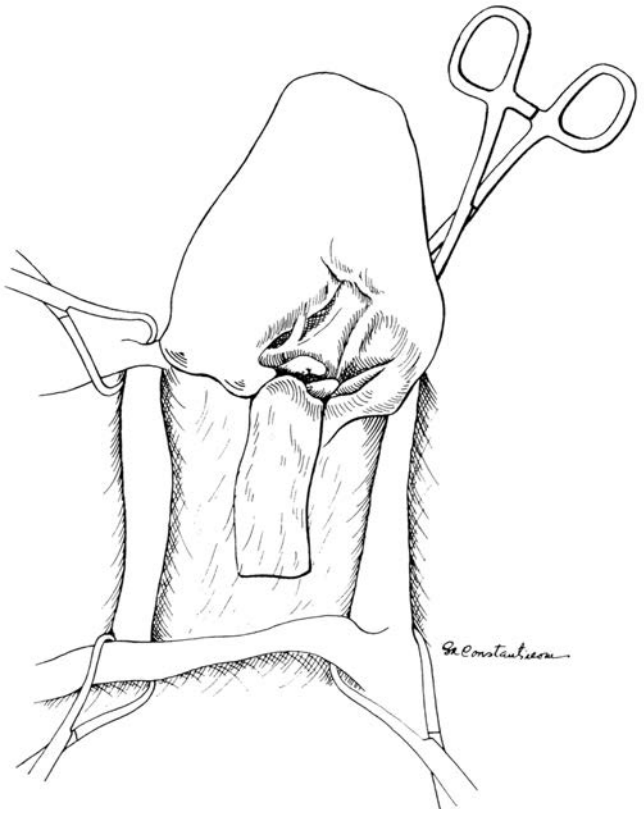

Figure 13-8. The skin incisions are made to extend 1.5 times the length of the vertical canal.

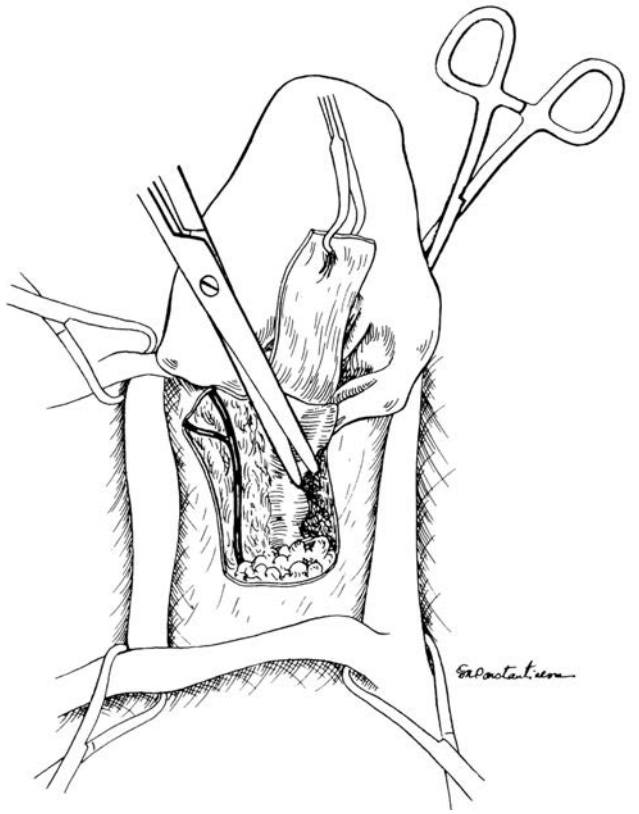

Figure 13-9. The subcutaneous tissue and parotid salivary gland are reflected, exposing the cartilaginous canal.

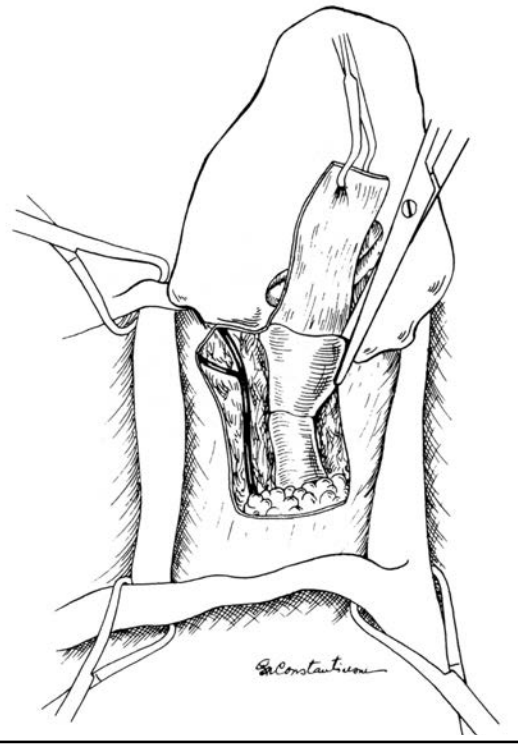

Figure 13-10. After the subcutaneous tissue is reflected, the vertical ear canal is exposed and is ready for cutting with scissors.

If the incisions have been made properly, the lateral wall will have a base of attachment equal to the width of the floor of the horizontal ear canal. Next, the skin flap and all but the proximal 2 cm of the lateral wall are removed. This section is used as the "drain board" flap.

The lateral flap is pulled ventrally. Size 3-0 nonabsorbable, preferably swaged-on suture material is used to suture the lateral ear canal flap and the remaining vertical ear canal to the adjacent skin in a simple interrupted pattern (Figure 13-12). The first suture is placed through the rostroventral edge of the epithelium and cartilage of the "drain board." This suture is angled rostroventrally and is sutured to the skin. Similarly, the second suture is placed through the caudoventral edge of the flap and is sutured caudoventrally to the skin. The skin is adjusted before placement of this suture, so no redundant skin persists between these two sutures. The next two sutures should anchor the skin to the rostral and caudal walls of the opening of the horizontal ear canal. Additional interrupted sutures are placed to join the lateral ear canal flap to the skin and the edges of the vertical ear canal to the skin in cosmetic fashion.

The ear is placed approximately in its normal position, and the ear canal is checked for possible obstruction to drainage and ventilation by the anthelicene tubercle or proliferative ridges of tissue. If these tissues cause obstruction, they should be excised, and the resultant wound should be allowed to heal by second intention.

After all incisions have been closed, the pinna needs to be anchored over the head of the dog to provide ventilation and to prevent damage from head shaking. A porous bandage may be

placed over the surgical site to protect it from scratching. Paw pads may be fashioned, or the patient's legs may be hobbled as additional measures to protect the ear from self-trauma.

Postoperative Care

Postoperative care includes treatment with appropriate systemic antibiotics and management of self-trauma and ear movement. Coping with the prolonged healing time may be difficult. Healing time averages 10 to 14 days; if the suture line breaks down, healing may take longer. If lateral ear resection fails to control otitis externa, ear canal ablation needs to be considered. This procedure is discussed in the next section of this chapter.

Editor's Note: To be effective, lateral ear canal resection must be performed early in animals with recurring otitis externa. If chronic tissue change such as skin hyperplasia/hypertrophy occurs as a result of chronic otitis, the efficacy of lateral ear canal resection is poor. Lateral ear canal resection should not be expected to cure otitis but rather acts as an adjunctive procedure improving ventilation and drainage to make ongoing medical therapy more effective.

Modified Ablation Technique

M. Joseph Bojrab and Gheorghe M. Constantinescu

An alternative surgical technique for chronic otitis externa has been used when the entire vertical canal is grossly distorted or filled with hyperplastic mucosa.

This technique combines the advantages of ablation (removal of the chronically infected vertical canal) with those of lateral ear

canal resection (maintenance of drainage and hearing).

The preparation of the patient (Figure 13-13), skin incision, and vertical canal isolation are the same as described for lateral ear canal resection in the previous section of this chapter. Isolation of the vertical canal is continued medially until the entire canal is isolated (Figure 13-14). The auricular cartilage and skin are cut just dorsal to the opening of the vertical canal at the base of the pinna (Figure 13-15). This method allows complete mobilization of the vertical canal, which remains attached ventrally to the horizontal canal. The vertical canal is cut approximately 2 cm dorsal to the horizontal canal (Figure 13-16) and is discarded. The remaining vertical canal is incised both rostrally and caudally down to the horizontal canal (See Figure 13-16, inset), thus creating two rectangular flaps, a dorsal flap and a ventral flap (Figure 13-17). The ventral flap is sutured as described in the previous section of this chapter on treatment of otitis externa. The dorsal flap is sutured as depicted in Figure 13-17.

Aftercare consists of bandaging the patient's ear over the head for 1 week and administering systemic antibiotics as determined by culture and sensitivity tests.

Total Ear Canal Ablation and Subtotal Bulla Osteotomy

Daniel D. Smeak

Introduction

Otitis externa is an insidious disease that is not usually debilitating, and the associated clinical signs are generally controlled until medical therapy is withdrawn. When multiple attempts at medical treatment fail, ear disease invariably progresses, and more extensive surgery is indicated to permanently relieve the clinical signs. Owners must understand that the frequency and severity of intra- and postoperative complications increase in proportion to the degree of surgery required. Thus, for the most part, early surgical intervention should be strongly advised when appropriate medical treatment for otitis externa fails or the condition becomes recurrent.[1] As the ear tissue damage becomes irreversible from chronic infection, drainage procedures fail and removal of the entire horizontal and vertical ear canal is required. This salvage procedure is known as total ear canal ablation (TECA).[2]

Secondary middle ear infection frequently develops in dogs with end-stage otitis externa.[3] Consequently, variable results and high complication rates have been reported when TECA is preformed without a means of middle ear exposure and debridement (bulla osteotomy and curettage). Because TECA eliminates a primary pathway for exudate drainage, the external canal, recurrent deep infection occurs unless the middle ear is adequately evacuated. Inadequate removal of the secretory epithelium within the bulla or short osseous ear canal is responsible for such long-standing complications as persistent fistulation and abscessation.[1,4] For these reasons, most surgeons routinely combine lateral bulla osteotomy (LBO) through the same approach used for TECA. These combined procedures are described in this chapter.

Indications

TECA is most often performed for irreversible inflammatory ear canal disease in dogs. Other less common indications include severe ear canal trauma, neoplasia, and certain congenital malformations obstructing horizontal ear canal drainage. Irreversible inflammatory ear canal disease is present when one or a combination of the following is observed: hyperplasia of the epithelium occluding the horizontal ear canal, collapse or stenosis of the horizontal ear canal caused by infection within the cartilage or bone, or severely calcified periauricular tissue noted by palpation or observed on skull radiographs.

Many dogs that present to the veterinarian for surgical treatment of inflammatory ear disease have one or more irreversible conditions or indications for TECA. If medically unmanageable otitis externa is related to an ongoing generalized skin condition such as atopy or hypothyroidism, treatment of the primary dermatological disorder often helps control the ear disease. Concurrent skin disorders are very common in dogs with otitis externa. Almost 80% of dogs undergoing TECA in one report had one or more primary dermatological diseases including seborrhea, pyoderma, hypothyroidism, and atopy.[5] When the related primary skin condition has been thoroughly diagnosed and appropriately treated but continues to be unresponsive, I prefer TECA for treatment of persistent otitis externa instead of surgical drainage procedures such as lateral ear canal resection. As the skin disorder progresses, so will the ear disease in most circumstances, and a lateral ear resection or vertical ear canal ablation will subsequently fail due to progressive inflammatory changes in the remaining canal. Similarly, if owners are incapable or unwilling to treat the skin or chronic ear disease appropriately, TECA may be indicated **before** irreversible changes exist.

Although TECA combined with LBO is indicated for a number of conditions in the dog, it is less commonly performed on cats. Irreversible, proliferative inflammatory changes resulting from long standing otitis externa do not appear to form as readily in cats as they do in dogs. Cats with otic tumors, such as ceruminous adenocarcinoma or basal cell carcinoma, diffuse polypoid disease, or those sustaining severe trauma to the ear canal are potential candidates for TECA.[6] TECA is not usually required for cats affected with otitis media or inflammatory middle ear polyps, since the external ear canal is usually not severely affected, and exposure to the source of the clinical problem is best achieved with a ventral approach (ventral bulla osteotomy).

Owner Education

The owner must be made fully aware of the purpose of TECA as well as the possible sequelae before contemplating surgery. The surgeon should remind owners that the principle aim of TECA is to make their pet more comfortable by removing the source of pain and chronic infection. Elimination of further ear cleaning duties and the malodorous discharge are added benefits. Before surgery, however, owners seem to be concerned most about the appearance of their pet and whether their animal will be deaf after surgery. Generally, the appearance of floppy-eared dogs following TECA is unchanged. In erect-eared dogs, the extent of auricular and pinna cartilage removed determines whether the ear will stand following surgery. Removal of extensive proliferative tissue well up into the pinna will cause the erect ear to fall owing to lack of support at the ear base. The ear will remain somewhat erect if more than the proximal third of the vertical canal cartilage is preserved in dogs and cats. A simple modification of the TECA skin incision to create a single pedicle advancement flap has been found to maintain normal ear carriage in cats.[7] The surgeon should not limit the amount of canal resection because of pressure from owners who want preservation of ear carriage at all costs. Continued irritation and pain can be expected if proliferative ear canal tissue remains following TECA.

Because TECA obliterates the external auditus, most owners are skeptical about their pet's future hearing ability. Although the possibility of causing complete deafness remains, TECA combined with LBO should not be expected to affect hearing appreciably in most cases. Although air conducted sound may not be detected by brain evoked auditory testing after TECA, the ability to hear bone conducted sound is apparently preserved.[8,9] I warn owners that the quality of sound their dog can discern may

change after surgery, but some hearing ability usually can be expected. Most complaints about hearing difficulty after TECA stem from inadequate owner evaluation or awareness of the pet's hearing condition beforehand. The surgeon should try to make the owner aware of their dog's hearing deficits before surgery to minimize this misunderstanding. Owners must be prepared for serious and potentially long-standing problems resulting from TECA. If nystagmus, circling, or loss of balance are present before surgery, exacerbation of these signs is common afterwards in the author's experience. These signs usually improve if middle ear infection is eliminated but they may persist indefinitely. Transient, or more rarely, permanent facial nerve dysfunction may occur causing drooling from ipsilateral lip paralysis. Hemifacial spasm or facial nerve deficits that are present before surgery may indicate that the facial nerve is invaded by neoplasia or, more likely, that it is embedded in the horizontal canal or serious secondary middle ear infection is present. More dissection and retraction of the nerve may be required to free it up during TECA; this greatly increases the risk of iatrogenic facial nerve damage. Ocular problems from a diminished eye-blink response may be disastrous, particularly in exophthalmic dog breeds or those with inadequate tear production. Unresolved middle ear infection or any retained secretory tissue can cause recurrent abscessation and fistulation which may create conditions far worse for the owner and their pet than the presenting otitis externa problem.[4] Proper preparation of owners for these potential problems by counseling before surgery is recommended.

Preoperative Considerations

A complete preoperative workup is essential to determine the extent and nature of the disease process and to predict possible surgical complications. Following routine physical examination, the external ear is inspected and palpated. A sharp pain response elicited during deep palpation of the ear canal usually indicates middle ear infection. Thickened and firm (calcified) ear canal tissue is a manifestation of irreversible inflammatory change. Evidence of a head tilt without other signs of inner ear disease (nystgmus, circling, loss of balance) usually indicates severe pain in the ear on the lower side. Neoplasia should be highly suspected if the ear drainage appears mostly as blood versus the more typical thick, foul-smelling exudate of an inflammatory otitis externa.

A complete neurologic examination should be performed to evaluate for facial nerve dysfunction (hemifacial spasm, poor palpebral reflex, lip droop) and inner ear involvement, especially in patients with chronic otitis externa. During preoperative workup, approximately 15% of patients with end-stage otitis are found to have partial or total facial nerve deficits.[1] It is important to identify patients with concurrent otitis media because they more often develop complications such as cellulitis, persistent fistulation, or abscessation following TECA.[4] In addition, their postoperative care is more demanding and costly. Any hearing deficits or other neurologic problems should be clearly noted in the medical record and brought to the owner's attention **before** TECA; otherwise, the owner may blame the surgeon if these deficits are noticed after surgery.

If the ear problem is a possible manifestation of a systemic skin disorder, a complete dermatologic examination should be performed and appropriate tests should also be completed. Postoperative head shaking and self-inflicted irritation to the remaining ear tissues may persist if the primary skin condition is neglected or inappropriately treated. This can be seen as a failure of the surgical procedure from the owner's point of view.

The remaining preoperative workup is best performed while the patient is anesthetized. Thorough ear cleaning must be accomplished to allow maximal visualization of the canal during otoscopic examination. Otoscopic examination of **both** canals is indicated, even if one side superficially appears normal or if the condition of both ears is severely proliferative. Attention is directed at locating tumors or polyps, as these are not infrequent in older patients with long standing otitis externa. Otitis media is present if the tympanic membrane is not found and the tympanic bulla is filled with debris. Samples of suspicious tissues are submitted to help diagnose occult neoplasia, which may drastically change the prognosis as well as the owner's wish to allow surgery on their pet. If neoplasia is suspected, local lymph nodes are examined and fine needle aspirates are evaluated cytologically for tumor staging. Chest radiographs are evaluated for evidence of metastatic disease or other occult thoracic problems. Rather than culturing the exudate at otoscopic examination, a more reliable result may be obtained if deep wound tissue and middle ear exudate are sampled at the time of surgery.

Skull radiographs help confirm the extent and severity of the ear canal pathology and may alert the clinician that otitis media or neoplasia is present. The ventrodorsal skull view may be used to help determine the horizontal canal patency and its diameter, and whether the canal walls have undergone irreversible change. Open mouth plain radiographic views of the bulla are best to evaluate for subtle middle ear change.[10] Oblique lateral views may help demonstrate lytic neoplastic changes of the petrous temporal bone.

Radiography should not be regarded as a highly sensitive tool for the diagnosis of otitis media.[11] Positive radiographic signs such as thickening and calcification of the bulla indicate the presence of middle ear pathology, but false negative radiographs are common. The presence of predominately lytic changes in the rostroventral aspect of the bulla on oblique lateral views most often is a result of chronic inflammation in my experience. Conversely, evidence of bone lysis in other areas, particularly in the petrous temporal bone, suggests a neoplastic process. In summary, despite the lack of sensitivity, radiographic evaluation is recommended to evaluate for the presence of neoplastic invasion of bone, particularly when otoscopic examination of deep structures is not possible. Normal appearing skull radiographs do not rule out otitis media or neoplasia. CT imaging is a more sensitive modality to identify neoplastic and middle ear disease.

Surgical Anatomy

The surgeon must be aware of certain important structures before surgery (Figures 13-18 and 13-19). Branches of the great auricular and superficial temporal vessels should be avoided

when incising through and dissecting medial to the vertical ear canal cartilage. The V-shaped parotid gland overlays the lateral and ventral areas of the ear canal, and it may be damaged if not retracted during horizontal ear canal exposure. Deep to the parotid gland are the facial nerve, internal maxillary vein, and branches of the external carotid artery. These structures are difficult to identify and preserve when dissecting deeply around the horizontal ear canal and tympanic bulla. The facial nerve emerges from the stylomastoid foramen, located just caudal to the ossesous portion of the ear canal, and travels rostroventrally directly under the horizontal ear canal. Additionally, the terminal branches of the facial nerve and auriculotemporal branch of the mandibular portion of the trigeminal nerve should be avoided rostral to the ear canal. Careful retraction of tissues and hemostasis, meticulous dissection, and staying close to the external ear canal cartilage and osseous bulla will reduce the risk of iatrogenic damage to many of the structures.

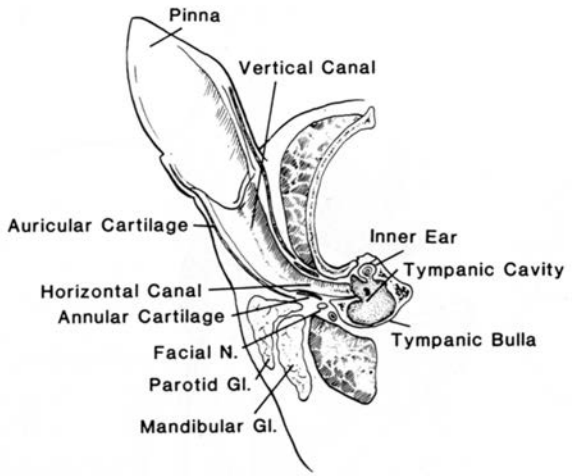

Figure 13-18. Transverse section of the head showing ear canal, middle ear, and inner ear structures.

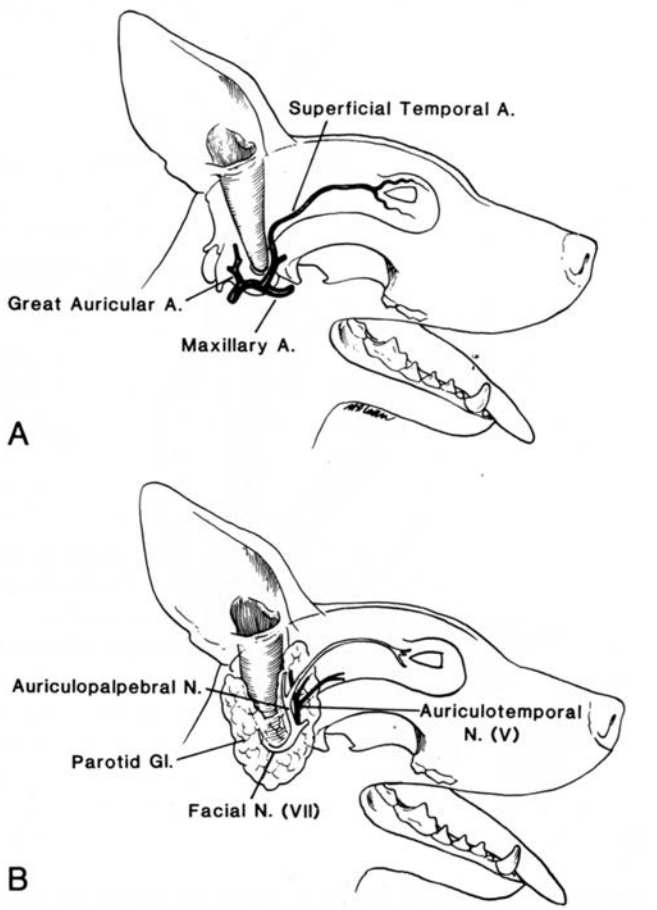

Figure 13-19. A. Location of branches of the external carotid artery in relation to the ear canal. **B.** Location of the facial *(VII)* and auriculotemporal *(V)* nerves in relation to the ear canal.

The external carotid artery and maxillary vein lie immediately ventral to the tympanic cavity and these must be safely retracted away from the tips of the ronguers during removal of the ventral aspect of the bulla (Figure 13-20). Sharp dissection and curettage of the rostral aspect of the osseous ear canal should be avoided to reduce the risk of retroarticular vein damage (Figure 13-21). During evacuation of debris and epithelium from the tympanic cavity, curettage should be avoided in the rostrodorsal and

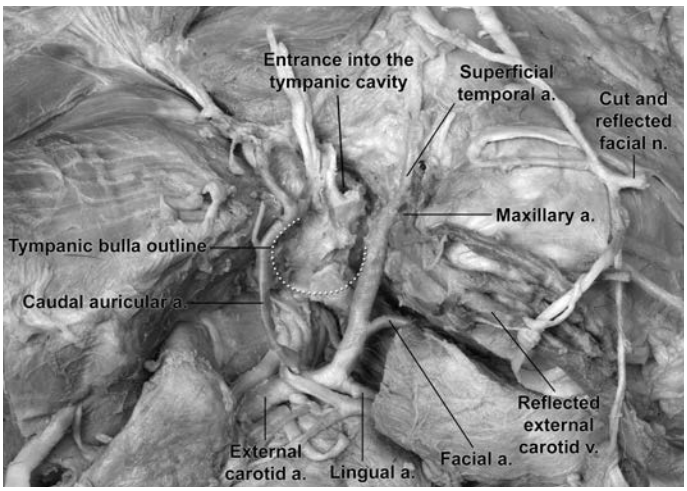

Figure 13-20. Lateral view of dissected head showing entrance into the tympanic cavity after the annular cartilage and entire cartilaginous external ear canal has been excised from the rim of the osseous EAM. Note the close approximation of the facial nerve (cut and reflected upward), and maxillary artery to the rim of the EAM.

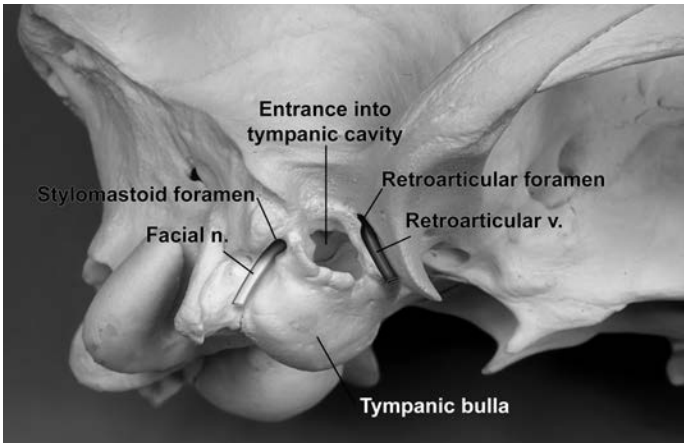

Figure 13-21. Close-up oblique ventrolateral view of important deep structures surrounding the tympanic bulla of the skull. A distinct bony rim separates the osseous EAM from the stylomastoid foramen where the facial nerve exits the skull.

medial aspect of the bulla to preserve the ossicles and sensitive inner ear structures. The internal carotid artery can be damaged if the thin bone wall between the carotid canal and tympanic cavity has been eroded by chronic infection or neoplasia, or it may be disturbed by excessive medial pressure during curettage of the medial bulla wall (Figure 13-22).

Surgical Technique

Total Ear Canal Ablation

The ear canal is difficult to prepare aseptically, and contamination is inevitable during surgery. Therefore, a broad spectrum, bactericidal, intravenous antibiotic is given before and during surgery so that adequate blood levels are maintained in tissues during dissection. Alternatively, administration of antibiotics may be delayed until cultures of the osseous bulla are obtained during surgery. In either case, antibiotics are continued until the results of the intraoperative culture and susceptibility are available. The surgeon should use these susceptibility results to choose the appropriate drug for long-term therapy.

After anesthesia is induced, ample surrounding skin, the ear canal, and pinna are routinely prepared for aseptic surgery. The patient is placed in lateral recumbency with the head elevated by a towel to a level parallel with the chest wall. Figure 13-23 illustrates the TECA and LBO procedure. A T-shaped skin incision is made; the horizontal incision is parallel and just below the upper edge of the tragus between the tragohelicine and intertragic notch (Figure 13-23A). The vertical incision is created perpendicular from the midpoint of the horizontal incision to a point just ventral to the horizontal canal. The surgeon undermines and retracts the two resulting skin flaps, and exposes the lateral aspect of the vertical canal from the surrounding loose connective tissue (Figure13-23B). With curved Metzenbaum scissors, bluntly dissect around the proximal and medial portion of the vertical canal staying as close as possible to the cartilage. Starting from the caudal aspect, cut through the medial vertical canal wall with serrated Mayo scissors and continue cutting rostrally until the ends of the original horizontal skin incision connect (Figure 14-23C). One must avoid inadvertent damage to the branches of the great auricular vessels that travel in a dorsal direction just deep to the medial canal wall. Damage to these branches can lead to a vascular necrosis of pinna skin, particularly in the area of the posterior incisure and cornu of the antitragus. Starting at the dorsal and rostral aspect, free the remaining vertical canal of tissue connections and continue to dissect dorsally close to the horizontal canal cartilage down to the rim of the boney external auditory meatus. (Figure 13-23D). Damage to the facial nerve and parotid gland is avoided by carefully retracting these structures away from the dissection plane at the **ventral** and **caudal** aspect of the horizontal canal. These aforementioned areas are approached last, so that soft tissues can be retracted sufficiently to allow maximal exposure during dissection. Occasionally, the facial nerve is entrapped and is hidden from view within extensively thickened and calcified horizontal canal tissue. In such cases, I first search for peripheral small facial nerve branches (internal auricular nerves) that perforate the cartilage on the caudal and more superficial aspect of the horizontal canal; these branches lead to the seventh nerve trunk. Alternately, one may palpate for a small sharp protuberance (ridge) which is the rim separating the caudal osseous ear canal from the stylomastoid foramen (origin of the facial nerve). Once this area is located, one follows the most proximal portion of the nerve as it courses directly lateral from the foramen. Entrapment is generally found as the nerve exits the foramen and begins its rostral course. Carefully dissect the remaining nerve from the canal. To avoid iatrogenic nerve trauma, one should always incise the horizontal canal attachment to the external auditory meatus away from the course of the facial nerve. Branches of the superficial temporal vessels originating from the retroarticular vein (retroarticular foramen) may be encountered during dissection of the rostral aspect of

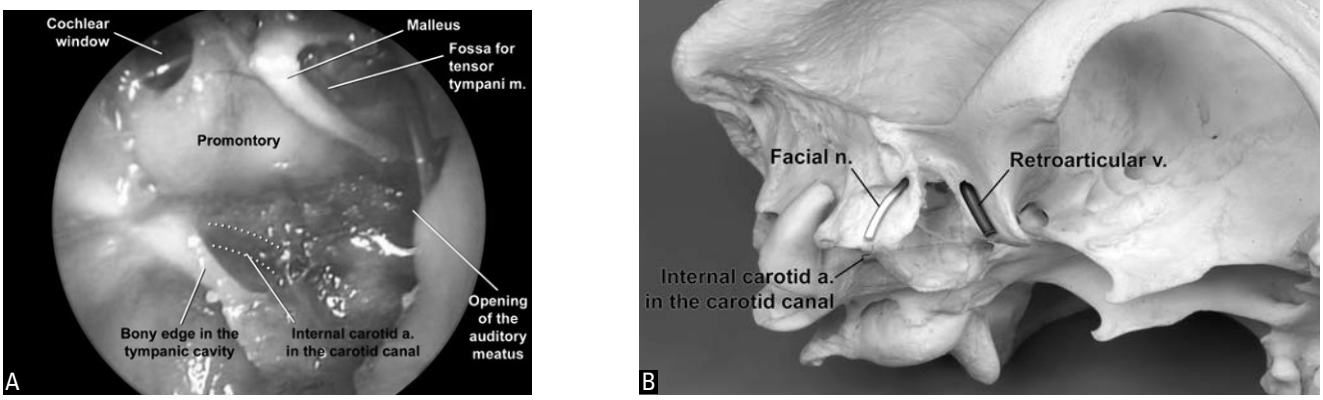

Figure 13-22. A. Oblique ventrolateral view of important structures within rostrodorsal compartment of the tympanic cavity. The arch-shaped malleus is located in the rostrodorsal aspect of the cavity, referred to as the epitympanic recess. The opening of the auditory tube is in the most rostral aspect of the cavity, an area often lined with ingrown secretory epithelium from the external ear canal. This epithelium must be completely excised during the LBO. Note the promontory and cochlear window, which house the inner ear structures. A portion of the large fundic compartment of the tympanic cavity is exposed caudally. **B.** Oblique ventrolateral view of the skull after the lateral wall of the tympanic bulla is removed. The internal carotid artery, a major blood supply to the brain, is illustrated. The internal carotid artery enters the caudal carotid foramen in the petro-occipital fissure and transverses in the carotid canal. The medial wall of the tympanic bulla forms the lateral wall of the carotid canal.

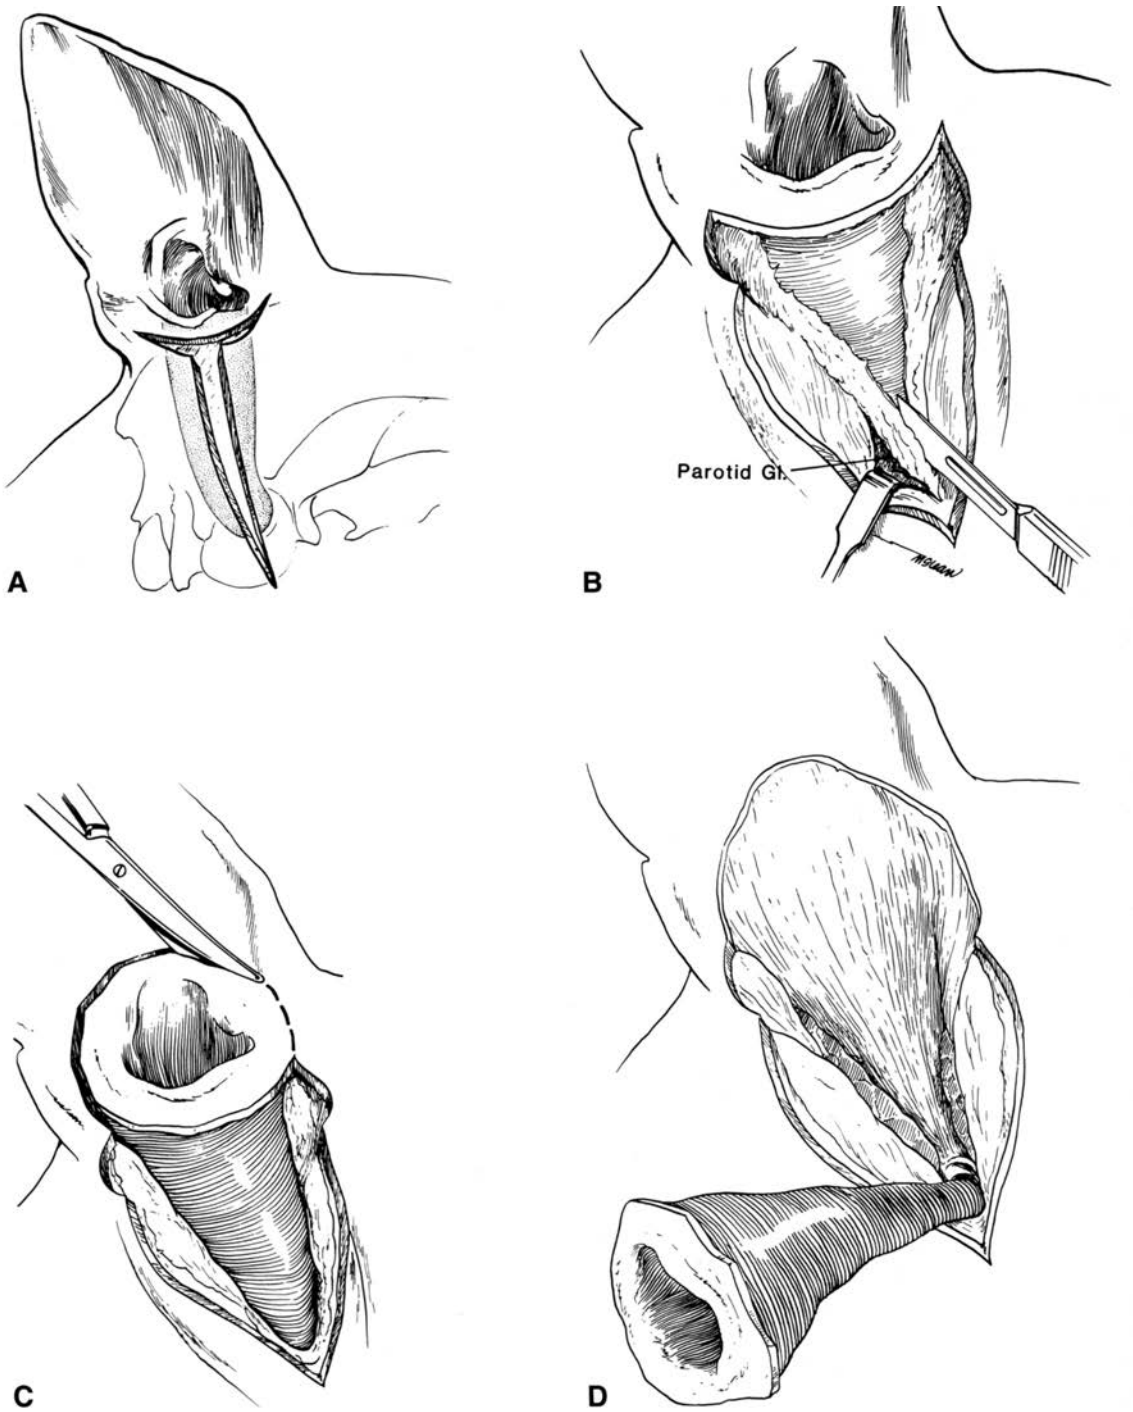
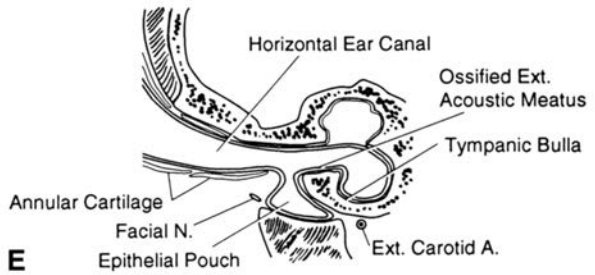
the canal from bone. Electrocoagulation or bone wax may be required to stop excessive hemorrhage. The entire canal should be removed and submitted for histologic examination. Rongeurs are usually required to excise remaining calcified attachments until the entire circumference of the external auditory meatus is seen as a white glistening edge.

In severely affected ears, a greenish-brown epithelial pouch (similar to the shape of a "sock") is present within the external auditory meatus and tympanic cavity extending lateral and ventral to the tympanic bulla (Figure 13-23E). Removal of all secretory tissue is critical to the success of the surgery since chronic fistulization will occur if secretions form within this enclosed area. Grasp the dorsal aspect of the pouch and with traction, "tease out" the pouch in one piece if possible with a Freer elevator. A curette should be used to remove **any** remaining secretory tissue that is adherent to the walls of the boney meatus. This tissue is submitted for culture and susceptibility testing.





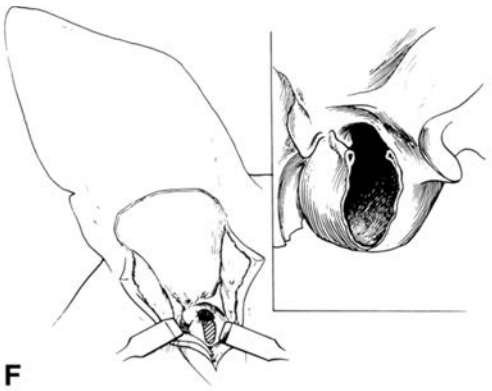


Figure 13-23. Summary of surgical technique of TECA and lateral bulla osteotomy. **A.** T-shaped incision to expose the vertical ear canal. **B.** Loose connective tissue is reflected from the vertical ear canal. The parotid gland is ventrally retracted to avoid damage during dissection of the ventral portion of the vertical ear canal. **C.** The dorsomedial aspect of the vertical cavity is sharply incised with scissors connecting the ends of the original horizontal skin incision. **D.** The vertical and horizontal ear canals are isolated from surrounding soft tissues by blunt and sharp dissection.

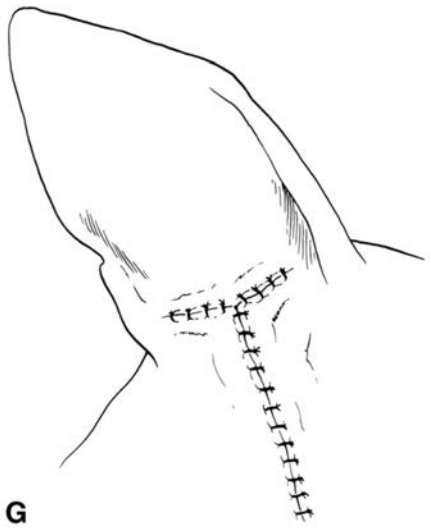

Figure 13-23 (continued) E. A pouch of secretory epithelium often forms between the tympanic bulla and annular cartilage extending into the external auditory meatus. This should be completely excised. **F.** Lateral view of skull showing aggressive excision of the lateral bulla through exposure of the tympanic cavity. The dotted line indicates the excision margin of the tympanic bulla (Left); Lateral view of the skull with limited excision of the tympanic bulla. Dotted line shows the extent of the bone removed – this limited approach provides poor exposure. **G.** Subcutaneous and skin sutures are placed to form a T-shaped wound.

Lateral Subtotal Bulla Osteotomy[1]

As the surgeon approaches the tympanic bulla, it is important to note that the bulla may be extensively remodeled (expanded) from a mounting cholesteatoma or chronic bulla osteitis. Important neurovascular structures may be more tightly draped around an expanded bulla. This close anatomic relationship greatly increases the risk of iatrogenic damage if the following steps are not carefully completed. The location of the facial nerve is important and retractors should be placed laterally (or more superficially) to spare the nerve (Figure 13-24). The author believes overzealous retraction during attempts at exposing deep structures during LBO is a major cause of temporary postoperative facial nerve dysfunction. Bluntly dissect soft tissue directly from the lateral and ventral aspects of the tympanic bulla with a Freer periosteal elevator. Stray dissection away from the bulla is avoided particularly rostral to the external auditory meatus (EAM) to spare the retroarticular vein and ventral to the bulla (to avoid the carotid artery, maxillary vein, and their branches). Soft tissue is elevated and retracted from the ventral aspect of the bulla using Freer elevators. During the entire LBO procedure, the surgeon is careful to visualize what is caught in the jaws of the ronguers to help avoid inadvertent damage to important surrounding soft tissue. Bone removal is begun with Cleveland or Lempert rongeurs; this choice depends on the thickness of bone and size of the patient. Controlled bites of bone are taken from the floor of the EAM. This will create a notch in the soft tissue lining and ventral bony floor of the EAM. (Figures 13-25 and 13-26). The remaining soft tissue is peeled from the osseous

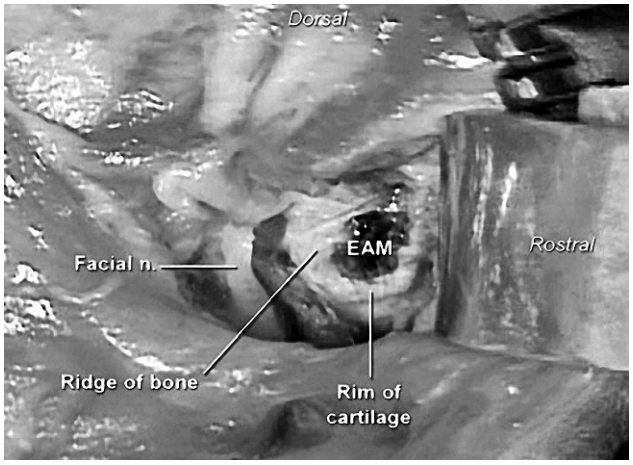

Figure 13-24. Surgeon's lateral view of EAM after the cartilaginous ear canal has been excised. A thin rim of cartilage remains attached at the EAM. Note the location of the facial nerve and stylomastoid foramen. Arrow points to a prominent ridge (a consistent landmark) dividing the EAM from the foramen.

ear canal by starting blunt dissection with Freer elevators at the cut edge of epithelium just adjacent to the notch. Once this dissection is complete, the EAM will appear as a shiny white surface throughout its circumference. The osseous ear canal is usually the thickest part of the tympanic bulla removed during LBO. The surgeon continues bone removal from the ventral osseous ear canal and into the ventral tympanic cavity with bone rongeurs. Samples of tissue and debris are collected and

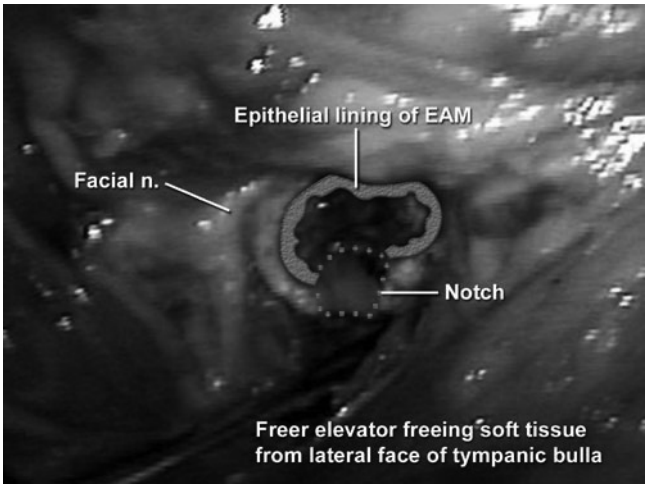

Figure 13-25. Soft tissue has been reflected and retracted away from the lateral face of the tympanic bulla with a Freer elevator. A rongeur is used to create a notch in the ventrolateral floor of the osseous EAM. The maneuver helps free edges of epithelium lining the osseous EAM so the lining can be removed completely in one piece.

submitted for biopsy and culture/susceptibility. The facial nerve trunk is gently elevated from the caudal (vertically oriented) shelf of bone between the stylomastoid foramen and the EAM. Next, this vertical sharp bony ridge is carefully removed with Lempert ronguers (Figure 13-27). This will allow gentle elevation of the facial nerve from the lateral face of the caudolateral tympanic bulla. Keeping the nerve safely retracted with the Freer elevator, one should try to angle Cleveland or Lempert rongeurs into the EAM and remove the bone on the lateral aspect of the caudal tympanic bulla. If this is not possible, I prefer Kerrison rongeurs to begin bone removal ventral to the stylomastoid foramen just caudal to the EAM (Figure 13-28). Bone is very brittle and hard in this area, but once the shelf and bone just caudal to the EAM have been removed, the remaining caudolateral bulla bone is usually thinner and easier to excise, and Lempert rongeurs will suffice for bone removal. One should not attempt to rongeur bone rostrally since structures of the epitympanic recess could be damaged and the retroarticular vein may be torn. The retroarticular vein cannot be exposed readily and usually is not evident to the surgeon unless it is damaged. If brisk hemorrhage is encountered in the rostral aspect of the EAM, a cotton tipped swab should be used to hold direct pressure on the origin of the bleeding area. It should be noted that the retroarticular foramen opens ventrally, not laterally, just rostral to the EAM, so bone wax must be pushed in a dorsomedial direction to fill the foramen and maintain hemostasis. The LBO is completed once most of the lateral and ventral aspects of the tympanic bulla have been removed. This will create a large window to adequately view the tympanic cavity interior (Figure 13-23F).

The interior aspect of the tympanic cavity is carefully inspected after irrigating the area with tepid sterile saline solution. When normal, the bulla is lined with a thin transparent epithelium, which does not need to be disturbed. If the external ear disease is chronic and there are signs of bulla osteitis, the tympanic cavity is usually (either partially or completely) lined with a greenish-brown to dark brown hyperplastic epithelial tissue. In most cases, a small cavity is found just within the rostral tympanic cavity (adjacent to the opening of the auditory tube), in which a "sock" of epithelium (sometimes coined "false middle ear or acquired cholesteatoma") is found.[14,15] In either case, all abnormal epithelium inside the tympanic cavity should be removed (Figure 3-23E). The sock of epithelium is generally easy to remove; the edge of the epithelium is grasped with hemostats, and while placing traction on the tissue, Freer elevators or Daubenspeck curettes are used to separate the attachments and remove the entire undisturbed epithelial cuff. If discolored or abnormal soft tissue clings from the dorsal compartment, it is carefully teased off with fine tipped curved hemostats. The ossicles are usually found tucked in the dorsal epitympanic recess just medial to the bony dorsal rim of the EAM. There is no need to remove the ossicles unless abnormal soft tissue or the tympanum is adhered to them. Curettage is avoided around the thin promontory areas, located dorsomedially that houses the sensitive inner ear structures (Figure 13-29). Excessive downward (medial) force with the curette on the medial surface of the tympanic cavity should be avoided since bone covering the carotid canal (housing the internal

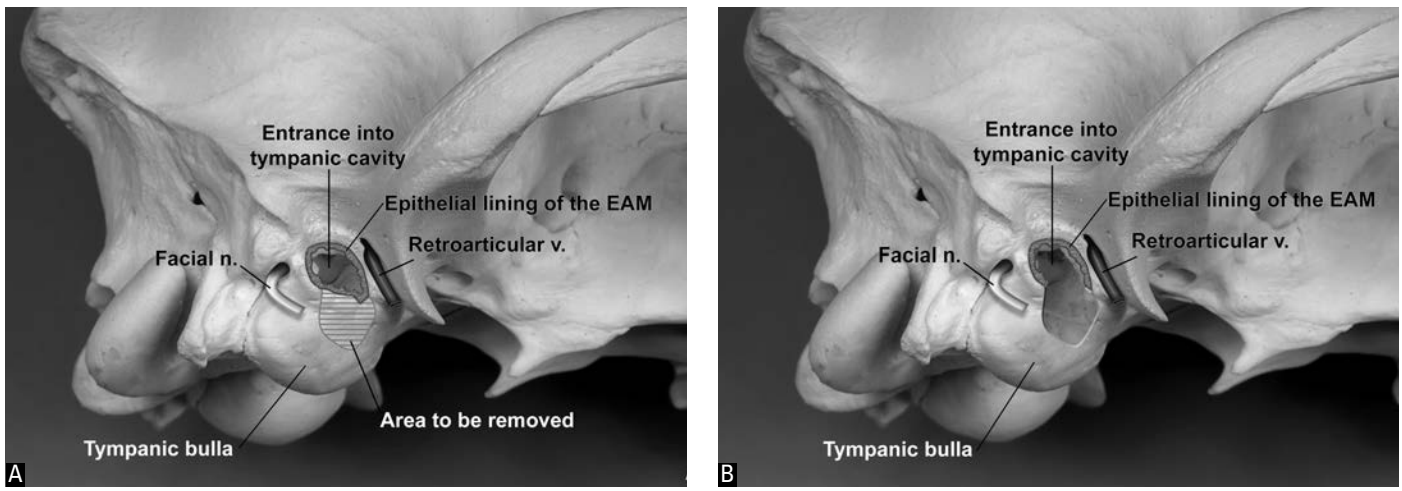

Figure 13-26. Lateral aspect of skull showing epithelial lining of EAM. **A.** The hatched area denotes the notch created in the ventral floor of the osseous ear canal described in Figure 13-25. The epithelial tissue lining of the ear canal is shown as the shaded area. **B.** While grasping the freed edge, the epithelial "cuff" is elevated both rostrally and caudally from the osseous ear canal beginning in the notched area. The ridge of bone separating the EAM from the stylomastoid foramen is now well exposed.

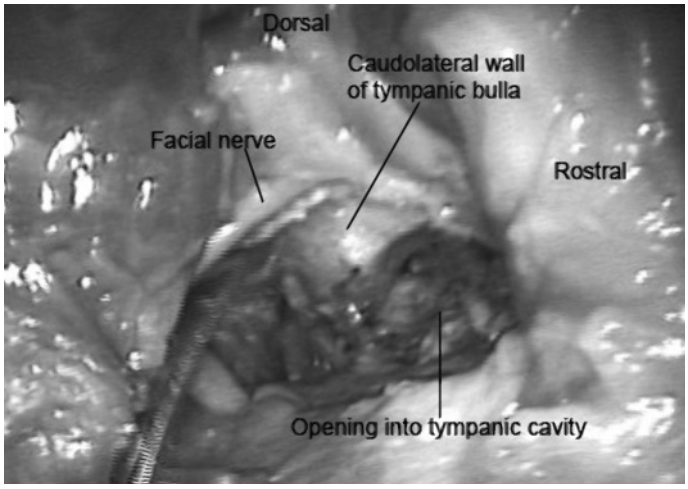

Figure 13-27. While protecting the facial nerve with a Freer elevator, the ridge of bone between the EAM and foramen has been removed with Lempert rongeurs and the facial nerve is isolated and retracted caudally.

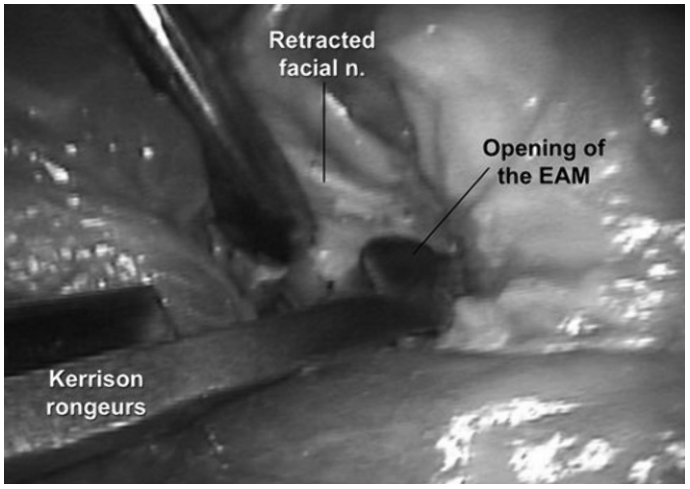

Figure 13-28. A Kerrison rongeurs is used to begin removal of the caudolateral aspect of the tympanic bulla while the facial nerve is protected with the elevator.

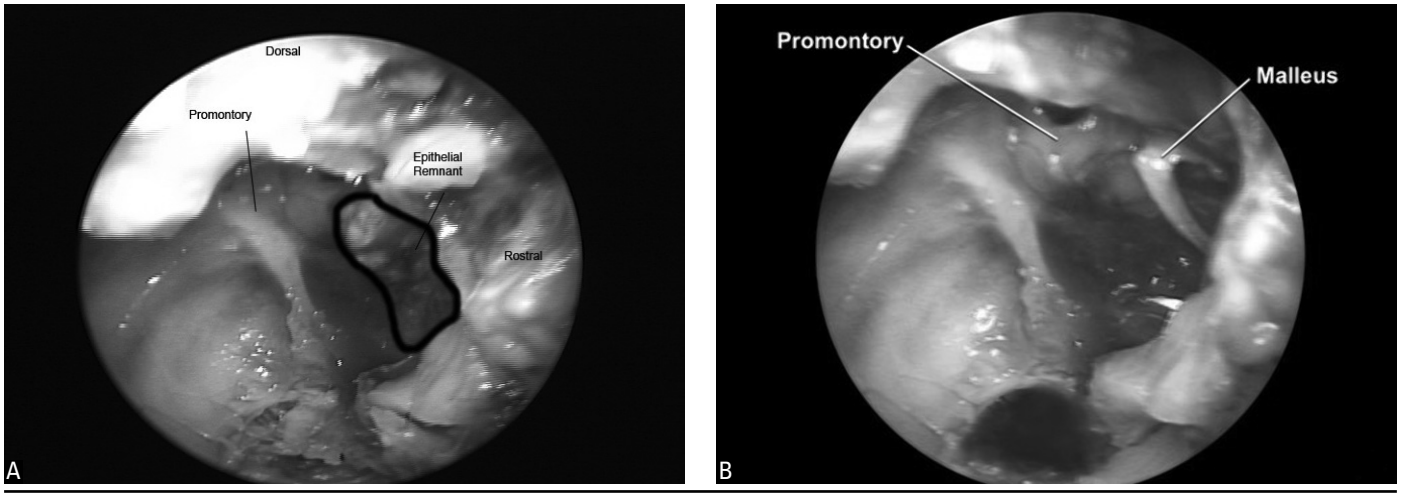

Figure 13-29. Lateral views of tympanic bulla after removing the caudal and lateral aspects of the bulla. **A.** Note the in vivo epithelial remnant (circled) in the rostral compartment of the cavity, which must be removed entirely without damaging the malleus and promontory areas (labeled). **B.** Excellent exposure of the completely evacuated tympanic cavity is achieved with the described subtotal bulla osteotomy technique.

carotid artery) can be penetrated causing profuse hemorrhage. If this occurs, the tympanic cavity is tightly packed with gauze stripping, and one should wait at least 5 minutes until hemostasis is established, and then the packing should be removed slowly to continue the inspection. Daubenspeck or malleable curettes are used to scrape the rostral, ventral and caudal tympanic cavity. Abnormal tissues are submitted for histologic evaluation. The epitympanic recess and the EAM should be carefully inspected for remnants of abnormal epithelium or retained tympanum. The entire tympanic cavity should be irrigated and inspected again and any remaining suspicious tissue and bony fragments are removed. Thorough irrigation of the entire wound, especially the dead space just medial to the base of the pinna is performed with sterile saline.

Ideally, an active suction drain system (Jackson-Pratt) is recommended in those patients with heavy contamination intra-operatively, uncontrolled bleeding, concurrent para-aural abscessation, or when the bulla is difficult to clean out properly. Alternately, if a closed suction system is not available, a passive surgical drain (Penrose drain) may be used. If the tissue surrounding the wound has minimal contamination, inflammation or hemorrhage, and the tympanic cavity is thoroughly evacuated, there is usually no need for wound drainage.[16] Dead space is closed in the subcutaneous tissue with 4-0 monofilament absorbable material. The skin is closed routinely with simple interrupted 4-0 monofilament nonabsorbable material to complete the total ear canal ablation.

Postoperative Care

If a drain is used, a loose, padded head bandage is placed to cover the drain and surgical site until the drain is removed, usually within 48 to 72 hours. Significant pharyngeal swelling can result particularly if TECA and bulla osteotomy are performed bilaterally. In addition, bandages may further reduce pharyngeal airway size and this can cause suffocation in the early postoperative period. These patients should be closely monitored for signs of dyspnea especially during the first 24 hours. An Elizabethan collar is used when needed to reduce self-trauma until sutures are removed in

10 to 14 days. During bandage changing, wounds are examined for evidence of fluid accumulation or ensuing infection. If signs of acute postoperative infection occur, sutures in the vertical portion of the wound are removed and the wound is opened fully to allow adequate drainage. Systemic antibiotics, based on the intraoperative culture and susceptibility results, are administered for a minimum of three weeks. Postoperative treatment for any underlying systemic skin disorder is continued.

Patients undergoing TECA and LBO often show evidence of extreme postoperative pain due to inflammation and nerve stimulation from deep wound dissection and bone removal. The surgeon must be prepared to aggressively manage this pain both preemptively and postoperatively. General postoperative guidelines for management of small animals after TECA and LBO are beyond the scope of this chapter, and are discussed elsewhere. (See Chapter 9) I prefer to give injectable opioid medications and NSAIDS in advance of surgery to reduce the amount of postoperative analgesics required to maintain patient comfort. A fentanyl patch can be applied 24 hours before surgery as another preemptive analgesic option. Postoperatively, injectable opioid analgesics combined with local anesthetic patches or constant local anesthetic infusion are also good options. The patient is released from the hospital and NSAID treatment is continued for 3 to 5 days if indicated.

Complications and Treatment

Many complications have been reported after TECA.[17-21] Most complications related to the surgery (wound infections and seromas) are short-lived and resolve within two weeks if treated appropriately. Extensive bacterial numbers are present in occluded chronically infected ear canals even after proper aseptic preparation of the area. Acute postoperative wound infection is not uncommon after TECA since wound contamination is inevitable. Proper intraoperative wound irrigation, antibiotic administration, and drainage help reduce this problem. Evidence of avascular skin slough at the proximal caudal skin margin and acute cellulitis are managed with open wound management and debridement until the area heals completely. Animals afflicted with inner ear signs before surgery may deteriorate immediately after anesthetic recovery and these signs may persist indefinitely in my experience. Until proven otherwise, inner ear signs that first develop in a patient a week or more after surgery are attributable to a fulminant abscess within the middle ear. Surgically induced Horner's syndrome tends to occur from middle ear curettage during TECA only in the cat. This will usually resolve within several weeks provided middle ear infection has been eradicated.

Many dogs experience slow or incomplete eye blink response and ear or lip droop immediately after surgery owing to paresis of muscles innervated by the facial nerve. Artificial tears or ointments are used prophylactically until the affected eyes regain full function, usually within five days after surgery. If no evidence of eye blink is appreciable by four weeks following surgery, permanent damage can be expected. Overall, about 10% to 15% of dogs have permanent facial nerve damage following TECA.[17] This does not cause significant disability in my experience, provided normal tear flow is present and the eye is not predisposed to exposure keratitis from exophthalmia. In summary, most facial nerve damage is iatrogenic and transient and is most often caused by overzealous retraction during ear canal dissection in my experience. Dissection of an entrapped facial nerve or en bloc resection of neoplasia may cause permanent damage.

Fistulization or skin sinus formation and middle ear infection are considered the most serious complications from TECA since these problems can cause clinical disability worse than the original chronic ear disease. Long-term antibiotic treatment and wound drainage rarely eliminate the problem in my experience. Persistent infection usually requires wound exploration for successful treatment, a costly and difficult procedure.[4] Persistent wound drainage or fistulization forms anytime from one month to over two years after surgery in about 5% to 10% of patients undergoing TECA and LBO for chronic otitis.[4] Persistent infection is most commonly attributed to a remnant of secretory tissue within the external auditory meatus or tympanic cavity. Isolation and removal of retained secretory epithelium with proper drainage of exudates permanently eliminates the problem. Ventral or LBO may be required depending on the suspected source of the persistent infection.[4,22] CT imaging is useful in helping the surgeon decide which approach is best. I, and others, prefer to use the lateral approach through the original incision site if retained horizontal ear canal tissue is the cause of the fistulization.[22] Ventral bulla osteotomy is the preferred route for exploration if the nidus is believed to be located in the middle ear because it avoids dissection through the previous surgery site and allows maximal exposure of the tympanic cavity. Approximately 70%-85% of patients explored for persistent infection will be cured.[4,22] Despite the expense and potential for serious complications following TECA, most owners are satisfied with the procedure and improvement in their dog's demeanor.

Ventral Bulla Osteotomy

David Holt

Indications

Ventral bulla osteotomy is indicated in dogs to treat chronic otitis media that has not responded to appropriate medical therapy, benign neoplasia affecting the middle ear, and cholesteatomas. In dogs with chronic otitis media, the surgeon must carefully evaluate the condition of the external ear canal before performing a ventral bulla osteotomy. Dogs with marked otitis externa causing narrowing or stenosis of the external ear canal usually require total ear canal ablation. In these cases, a concurrent lateral rather than ventral bulla osteotomy is performed. Ventral bulla osteotomy has been used to successfully treat recurrent or ongoing otitis media in dogs after total ear canal ablation and lateral bulla osteotomy. In addition, the surgical approach used to expose the ventral aspect of the bulla is very useful when exploring for foreign bodies that have pentrated the caudal pharynx or for evaluating neoplasia that may occur in this area of the head and neck.

Refractory otitis media requiring surgical drainage is less common in cats than in dogs. In cats, the most frequent indication for ventral bulla osteotomy is exploration to remove the middle ear component of aural or nasopharyngeal polyps. Rarely, the ventral approach has also been used in cats to treat benign and malignant masses involving the middle ear.

Bulla Anatomy

The tympanic bulla in dogs is part of the petrous temporal bone and forms a pear-shaped cavity. The larger main portion of the bulla extends ventrally. The smaller epitympanic recess extends dorsally and contains the auditory ossicles, the malleus, incus and stapes, which extend from the tympanic membrane to the vestibular window (Figure 13-30). Medial to the epitympanic recess is a bony eminence, the promontory, which contains the cochlea. The cochlear window is located on the caudolateral aspect of the promontory (Figure 13-31). Curettage of the epitympanic recess and in the area of the promontory should be avoided to prevent iatrogenic damage to the vestibular and cochlear windows. Damage to these structures may cause postoperative otitis interna and balance/equilibrium problems for the dog.

In the cat, the middle ear is divided by an incomplete boney septum into a large ventromedial compartment and a smaller dorsolateral compartment. During ventral bulla osteotomy in cats, the larger ventromedial compartment is invariably entered first. The septum runs obliquely from craniomedial to caudolateral in the rostral one-third of the bulla. Removing this septum and opening the dorsolateral compartment is mandatory during bulla osteotomy for polyps as this compartment contains the opening of the Eustachian (auditory) tube. Once the septum is removed, the complete extent of the oval promontory can be visualized (Figure 13-32). The cochlear window is located in the caudolateral aspect of the promontory. Postganglionic sympathetic nerve fibers from the cranial cervical ganglion enter the bulla caudally and fan out over the promontory where they may be damaged by curettage.

Surgical Technique

The ventral approach to the bulla is similar in cats and dogs. The animal is positioned in dorsal recumbency with a folded towel placed under the neck and tape is used to secure the rostral mandibles to the surgery table. Each bulla lies medial and slightly caudal to the vertical ramus of the mandible in a paramedian position. The bulla is palpable percutaneously in most cats but rarely in dogs. It is helpful to identify the mandibular salivary gland located at the bifurcation of the jugular vein by palpation immediately before surgery. A longitudinal paramedian skin incision is made between the larynx medially and vertical ramus of the mandible laterally, starting just rostral to the larynx and extending 1-5 cm caudal to it, depending on the size of the animal. The platysma muscle is incised longitudinally and the mandibular salivary gland identified. Dissection continues medial to the salivary gland, which must be carefully separated from the linguo-

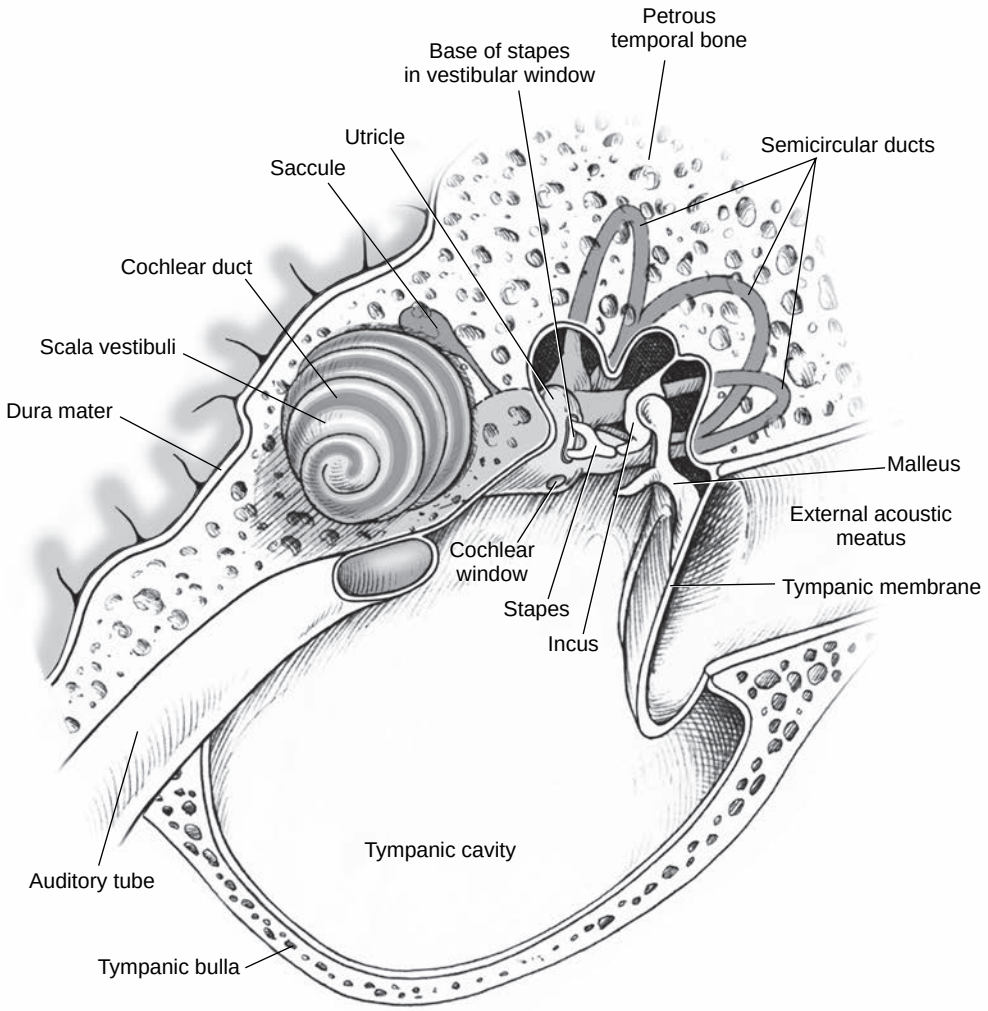

Figure 13-30. The middle ear of the dog illustrating the large ventral bulla cavity and the more dorsal epitympanic recess. The auditory ossicles extend from the typmpanic membrane to the vetibular window.

facial branch of the jugular vein (Figure 13-33). A small venous branch draining from the salivary gland into the linguofacial vein may require ligation and division. The separation between the large digastricus muscle laterally and the myelohyoideus muscle medially is identified. Correct location of this dissection plane is crucial for this approach. If this plane is correctly identified and dissected, the hypoglossal nerve will be visible coursing cranially on the medial aspect of the surgical field. The hypoglossal nerve is gently retracted and protected from injury throughout the procedure. Surgical exposure is maintained by careful placement of hand-held or Gelpi tissue retractors.

At this point, it is important to accurately identify the bulla by palpation. In cats, the large ventral dome of the bulla is easily palpable. In dogs, especially those with chronic otitis media, the bulla is not as apparent on palpation, feeling more flat than domed. To further localize the bulla, the surgeon should gently palpate for the stylohyoid bone coursing dorsally and laterally from the remainder of the hyoid apparatus. The hyoid apparatus in both species is attached to the caudal and lateral aspect of the bulla by the tympanohyoid cartilage, a small extension of the stylohyoid bone. In dogs, the paracondylar process of the occipital bone can often be palpated as a pointed structure protruding ventrally from the skull just caudal to the bulla. As an additional means to confirm the bulla's location, a non-sterile assistant can place an index finger into the mouth and palpate the hamular processes of the pterygoid bones. The assistant moves a finger to the bulla, which lies just caudal and lateral to this process on either side of the skull. The surgeon palpates the assistant's finger to confirm the location of the bulla.

Once the bulla is accurately identified, dissection proceeds dorsally. The bulla lies in a "V" formed by the internal and external branches of the carotid artery. These branches should be identified and carefully dissected or protected in the dog. In dogs, the thin muscular tissue lying immediately ventral to the bulla is bluntly separated parallel with the orientation of its fibers. In cats, the loose areolar tissue covering the bulla is bluntly elevated or dissected. The periosteum of the bulla is incised and elevated from the entire ventral surface of the bulla. The surgeon should take the time to ensure adequate lateral dissection and exposure of the bulla in cats before opening the bulla to facilitate exposure of the dorsolateral bulla compartment. A sharp Steinman pin in a Jacob's chuck is used to make the initial opening into the bulla. Very little dorsal pressure is applied to the chuck to prevent the pin from lurching into the dorsal aspect of

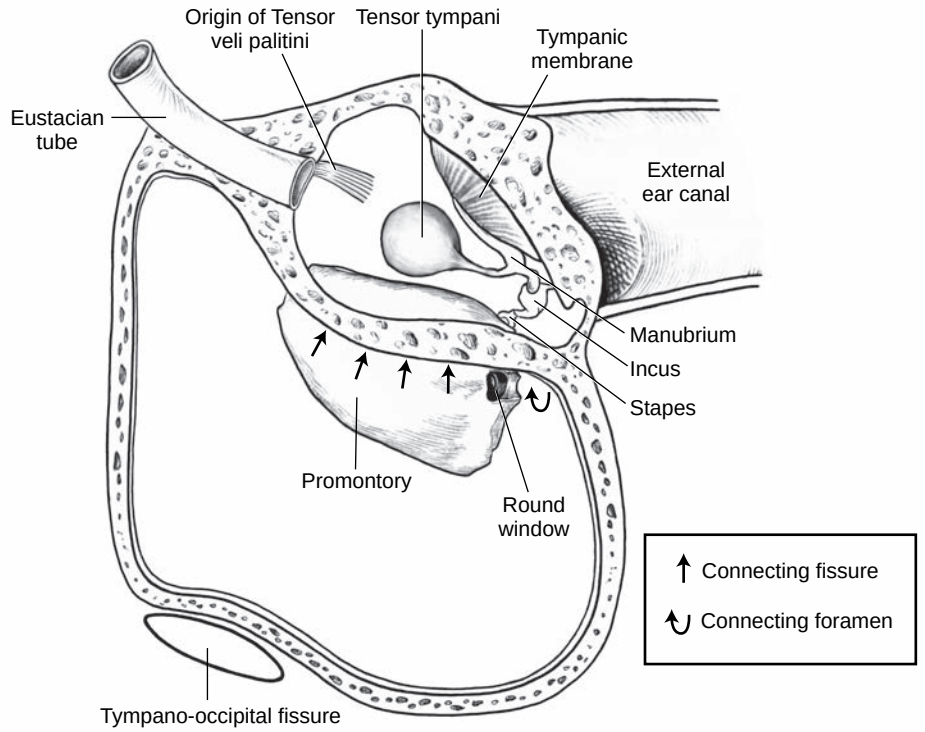

Figure 13-32. The feline bulla with part of the ventral wall removed. The medial compartment , bony septum and lateral compartment are visible. The cochlear (round) window is visible on the caudal aspect of the promontory.

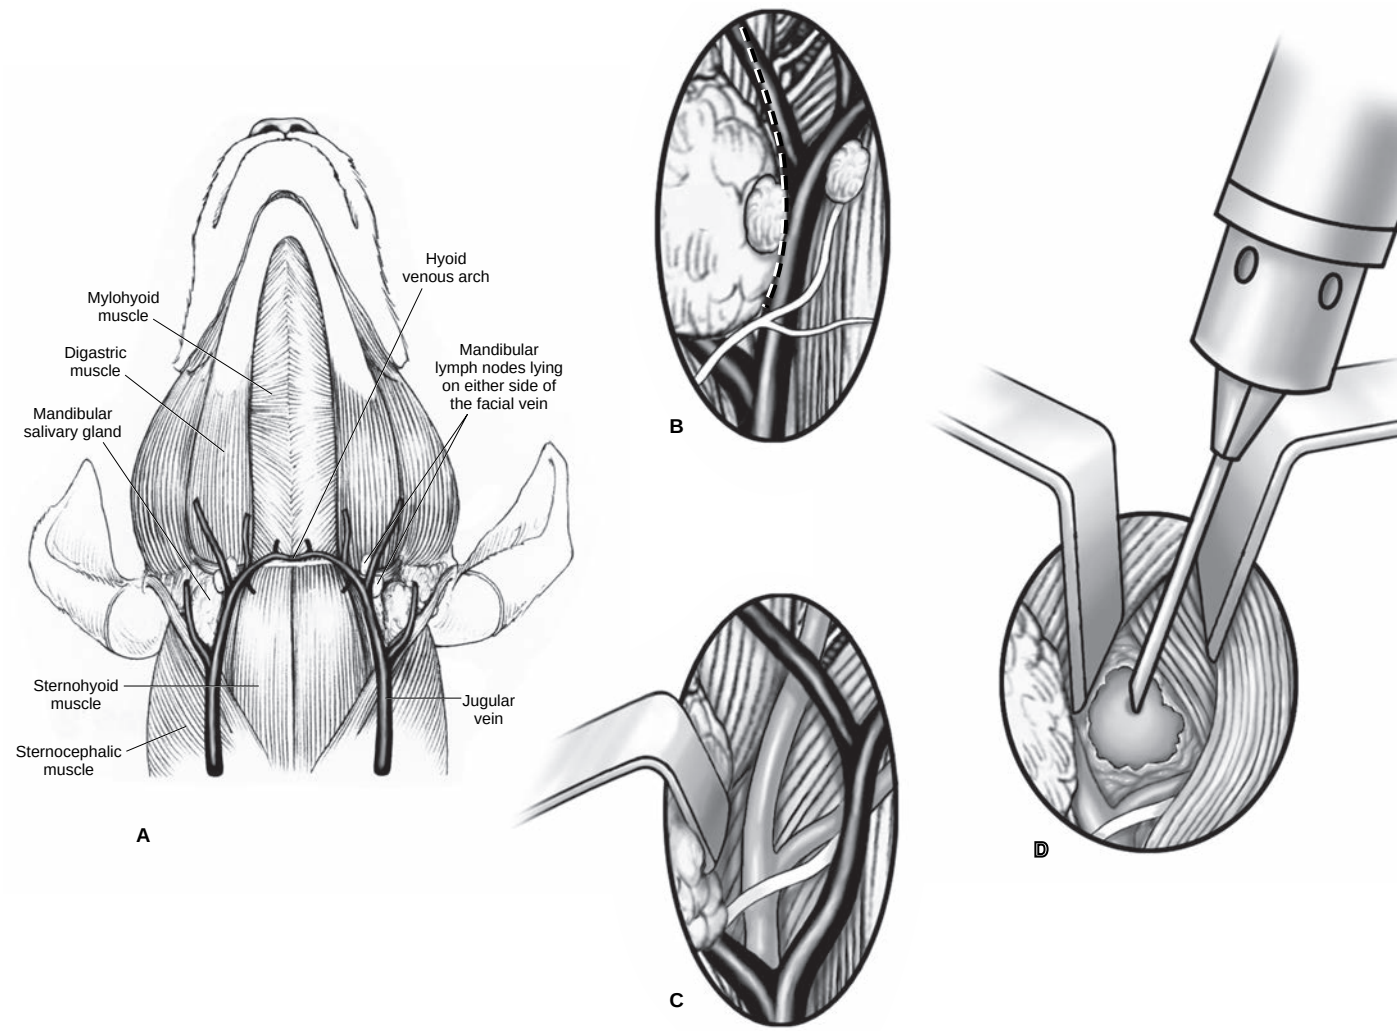

Figure 13-33. A. Superficial musculature, vessels, and salivary glands visualized during ventral bulla osteotomy dissection. **B.** Dissection for a right ventral bulla osteotomy. Once the platysma muscle has been incised, dissection proceeds medial to the submandibular salivary gland, which is separated from the jugular vein. A small branch of the vein is often ligated. **C.** Dissection proceeds between the digastricus muscle laterally and the myelohyoideus muscle laterally. The hypoglossal nerve is visible on the medial aspect of the surgical field. The bulla often lies in the "Y" formed by the bifurcation of the carotid artery. **D.** The bulla is identified by palpation and by location of the stylohyoid bone that attaches to the cranial and lateral surface of the bulla. The overlying tissue is dissected and retracted and the bulla opened using a Steinmann pin.

the bulla when it enters the tympanic cavity. In dogs with chronic otitis media and cats with long-standing polyps, the wall of the bulla can be quite thick and patience is required whle drilling with the Steinman pin. Alternatively, some surgeons prefer a powered drill for entrance to the bulla. Once an initial bulla opening has been made, it is enlarged with rongeurs.

In cats, the larger ventromedial compartment is opened first. The septum separating this compartment from the dorsolateral compartment is on the craniolateral aspect of the medial compartment. In some cats, the septum can be opened with a small, fine-tipped, single-action rongeur. In other cats, the septum must be penetrated by a Steinmen pin and the opening enlarged with rongeurs. With the bulla fully opened, the promontory is visible in both species as an oval shaped bony protuberance in the dorsal aspect of the bulla. Curettage over the promontory, particularly the caudal aspect, and in the epitympanic recess is avoided to prevent damage to the cochlear (round) and vestibular (oval) windows. Diseased or infected tissue is removed and samples are taken for biopsy and culture and sensitivity testing. The bulla cavity is thoroughly flushed with warm, balanced electrolyte solution and suctioned dry. Often, flushing and suctioning will identify residual tags of epithelial lining that are then removed. A latex drain is loosely placed into the bulla cavity without anchoring sutures. It exits through a separate small skin incision. The deeper layers of the surgical field are closed with a few single interrupted sutures of monofilament absorbable suture, taking care to avoid the hypoglossal nerve. The subcutaneous tissue and skin are closed in a routine manner. The latex drain is anchored to the skin with two single interrupted sutures.

Postoperative Care

Recovery from anesthesia is routine in most animals. The nasopharynx is inspected and suctioned while the animal is still under anesthesia as blood or flush solution can travel from the middle ear to the nasopharynx by the Eustachian tube and be aspirated after extubation if it is not removed. Cats with polyps in both middle ears that have undergone bilateral bulla surgery

must be carefully observed during anesthetic recovery. Swelling in the nasopharynx postoperatively can cause respiratory compromise. This can be alleviated by gently opening the cat's mouth to encourage mouth, rather than nasal breathing until the cat is fully recovered from anesthesia. Drains are usually removed 24-48 hours postoperatively.

Complications

Complications following ventral bulla osteotomy in dogs are uncommon but are usually associated with damage to structures of the inner ear. Clinical signs include nystagmus, head tilt, and circling. Neurologic signs are more common after ventral bulla osteotomy in cats with an 80% incidence of postoperative Horner's syndrome due to damage to the sympathetic nerve fibers in the middle ear. The clinical signs of Horner's syndrome, miosis, ptosis, and prolapse of the third eyelid resolve within 4 to six weeks in the majority of cats. Approximately 40% of cats may have clinical signs of otitis interna after ventral bulla osteotomy for polyp removal. These clinical signs are generally transient.

Section C

Digestive System

Chapter 14

Oral Cavity

Exodontic Therapy

Mark M. Smith

Introduction

Exodontics is the practice of tooth extraction. The most common indication for exodontic therapy in dogs is severe periodontal disease. Endodontic therapy is recommended for teeth affected by crown fracture exposing pulp, and pulpitis. However, it is not unusual to perform exodontic therapy when there is minimal crown available for restorative techniques, or when the owner does not authorize endodontic therapy. Exodontic therapy may also be used as a component of treatment for malocclusion.

Simple Exodontics

The periodontal ligament attaches the tooth to the bony alveolus or socket. The goal of exodontic therapy is to disrupt the periodontal ligament allowing movement of the tooth out of the alveolus. This component of the exodontic process is performed with periodontal elevators. There are various size and grip configurations for periodontal elevators. In dogs, basic periodontal elevators include instrument numbers 301s, 301, and 401.[1]

After the gingival attachment fibers are severed with a small scalpel blade, the periodontal elevator is inserted into the potential space between the tooth and alveolar bone. Initially, the elevator is rotated in the periodontal space to fatigue and tear the periodontal ligament. The position of the rotated periodontal elevator is maintained for 10 seconds to accomplish this goal. This maneuver is performed around the circumference of the coronal aspect of the root. As the exodontic procedure continues apically, the blade of the periodontal elevator is placed parallel to the root surface; the handle is dropped to be perpendicular to the long axis of the root; and the blade is turned 90°. This allows the edge of the elevator to engage the side of the root and "elevate" the root form the alveolus. Again, after movement is maximized, the position of the periodontal elevator is maintained for 10 seconds. Progress during the exodontic procedure will be noted by increased movement of the root and crown as the periodontal space expands secondary to hemorrhage and disruption of the periodontal ligament. Controlled force and patience will allow most single-rooted teeth or tooth segments to be extracted with periodontal elevators and digital manipulation. Extraction forceps are used only after the tooth is so mobile that the clinician considers the tooth or tooth segment removable with digital manipulation. The extraction forceps should engage the tooth as far apically as possible in order to decrease leverage forces on the root which could lead to root fragmentation (Figure 14-1). Generally, these non-surgical techniques are effective for incisors, first premolars, and third molars regardless of the health status of the periodontium. Multi-rooted teeth with periodontal disease and secondary mobility may be extracted using similar techniques.

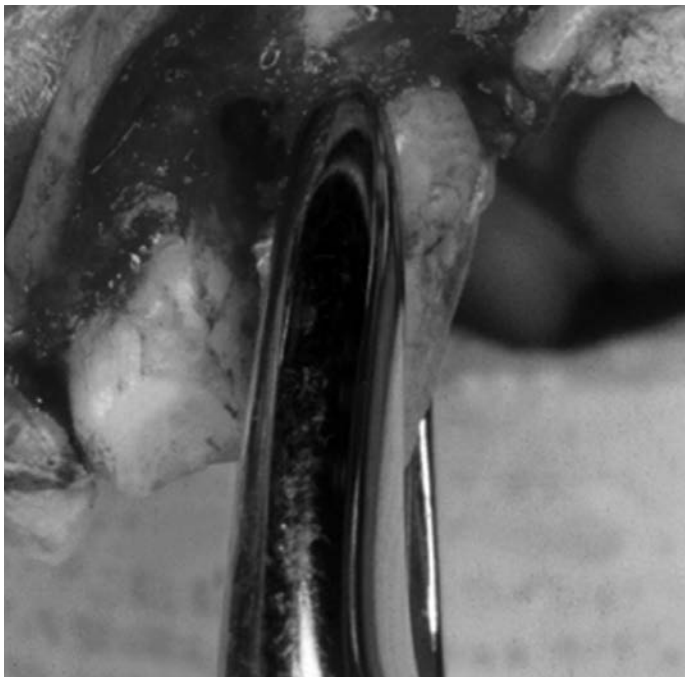

Figure 14-1. Photograph showing extraction forceps engaging as much of the crown and tooth root as possible while applying gentle force to complete the extraction of the mesiobuccal crown/root segment of the right maxillary fourth premolar tooth.

Complicated Exodontics

Non-mobile, multirooted or canine teeth are considered difficult or complicated teeth to extract. This fact is based on the complexity of the root system and sufficient periodontal attachment to prevent mobility even when there is substantial periodontal disease. Periodontally disease-free teeth with endodontic disease or malocclusion may be particularly difficult to extract based on having normal periodontal attachment. Surgical techniques are usually required for exodontic therapy of these teeth. Principles for surgical exodontic therapy include periodontal flap elevation, removal of alveolar bone to partially expose the root (s), sectioning the crown in multi-rooted teeth, crown/root segment elevation, alveoloplasty to smooth rough bone edges, and suturing of the periodontal flap over the alveolus. These principles will be highlighted in the following paragraphs describing surgical exodontic techniques for the maxillary fourth premolar, mandibular first molar, maxillary canine, and mandibular canine teeth.

Maxillary Fourth Premolar

The maxillary fourth premolar is a tri-rooted tooth with a large distal root and 2 mesial roots (mesiobuccal and mesiopalatal) emanating from a common root trunk. The procedure begins by using a #15 scalpel blade to incise a mucogingival periodontal flap. The mesial and distal incisions are made along the line angles of the tooth. Care should be taken to avoid the gingiva at the distal aspect of the maxillary third premolar and the mesial aspect of the maxillary first molar. Dorsal length of the incisions are dependant upon the size of the tooth, usually extending between 1.5 and 2.5 cm. As the mesial incision is advanced dorsally, another area to avoid is the infraorbital foramen which can be palpated through the mucosa between the maxillary third and fourth premolars. The infraorbital artery and nerve exit this foramen as they course in a rostral direction. After these vertical incisions are made, gingival fibers are incised form their attachment using either a #15 scalpel blade or a small, sharp periosteal elevator. The gingival is thin and easy to perforate when suing a sharp instrument. The technique of placing the scalpel blade parallel to the tooth surface and below the gingival, followed by short stab and prying motions is an effective way to elevate this tissue. As the mucogingival line is approached, a sharp periosteal elevator is used to elevate the buccal mucoperiosteum completing the flap.

Alveolar bone is removed form the buccal aspect of the distal and mesiobuccal roots using a high-speed hand piece and a round or pear-shaped bur. Usually the coronal one-half to two-thirds of the root is exposed by using light hand pressure to bur away this thin bone. During the alveolectomy process, it is helpful to drill slots on the mesial and distal aspects of these roots. Such bony slots provide a location to place the periodontal elevator. An analogy for this maneuver might be toe-hold during mountain climbing. During the alveolectomy, developing these "toe-holds" for the periodontal elevator will speed the extraction process. If a high-speed hand piece is not available, other instrumentation may be used for alveolectomy including bone file, rongeurs, curette, or a hobby drill with a sterilized round bur.

Crown sectioning is performed using a tapered-fissure or crosscut bur. The critical landmarks for crown sectioning are the buccal and mesial furcation entrances. Using these landmarks ensures crown sectioning with one root per crown segment (Figure 14-2). An exact "hemisection" is not necessary; however the crown must be completely cut beginning at the furcation entrances indicated. If a high-speed hand piece is not available, other instrumentation may be used for crown sectioning including a hobby drill, hack saw, or large bone cutter. This latter instrument will likely shatter the crown however crown integrity is not an important factor; only separation of the crown at the furcation.

The crown/root segments are elevated and removed using simple exodontic techniques described previously. Since the buccal alveolar bone has been removed, the crown/root segments are not elevated as much as luxated in a buccal direction. Therefore, this maneuver is easier with removal of increased amounts of buccal bone.

Figure 14-2. Photograph showing crown sectioning of the right maxillary fourth premolar tooth. The crown has been sectioned at the buccal and mesial furcations. Note the extracted mesiopalatal crown/root segment.

Following removal of the crown/root segments and confirmation that the roots have been completely removed, sharp bony edges are reduced (alveoloplasty) using a high-speed hand piece and around or pear-shaped bur. Other instruments may be used for alveoloplasty as described for alveolectomy. Alveoloplasty minimizes perforation of the periodontal flap by sharp bony edges. It also removes edges of bone which would likely require resorption during osseous healing.

Dilute chlorhexidine (0.12%) may be used to lavage the wound followed by positioning of the periodontal flap over the extraction site. The flap is sutured to the buccal mucosa and mucoperiosteum of the hard palate using chromic gut or polyglactin 910 in a simple interrupted pattern. Polydioxanone is not recommended because of its prolonged resorption time which is not necessary for routine oral wounds. Space is provided between individual sutures so that drainage may occur form the extraction site.

Mandibular First Molar

Similar exodontic techniques are used for the mandibular first molar as the maxillary fourth premolar. The periodontal flap, lateral alveolectomy, and alveoloplasty are performed as described previously (Figure 14-3). It should be noted that when compared with alveolectomy of the maxillary fourth premolar, the thickness of bone on the buccal aspect of the mandibular first molar is substantially greater. Crown sectioning is also recommended for this tooth with the shortest path being through the crown from the furcation in a distal direction. Lateral alveolectomy, visualization of the mesial and distal roots, and controlled root elevation decrease the incidence of iatrogenic mandibular fracture.

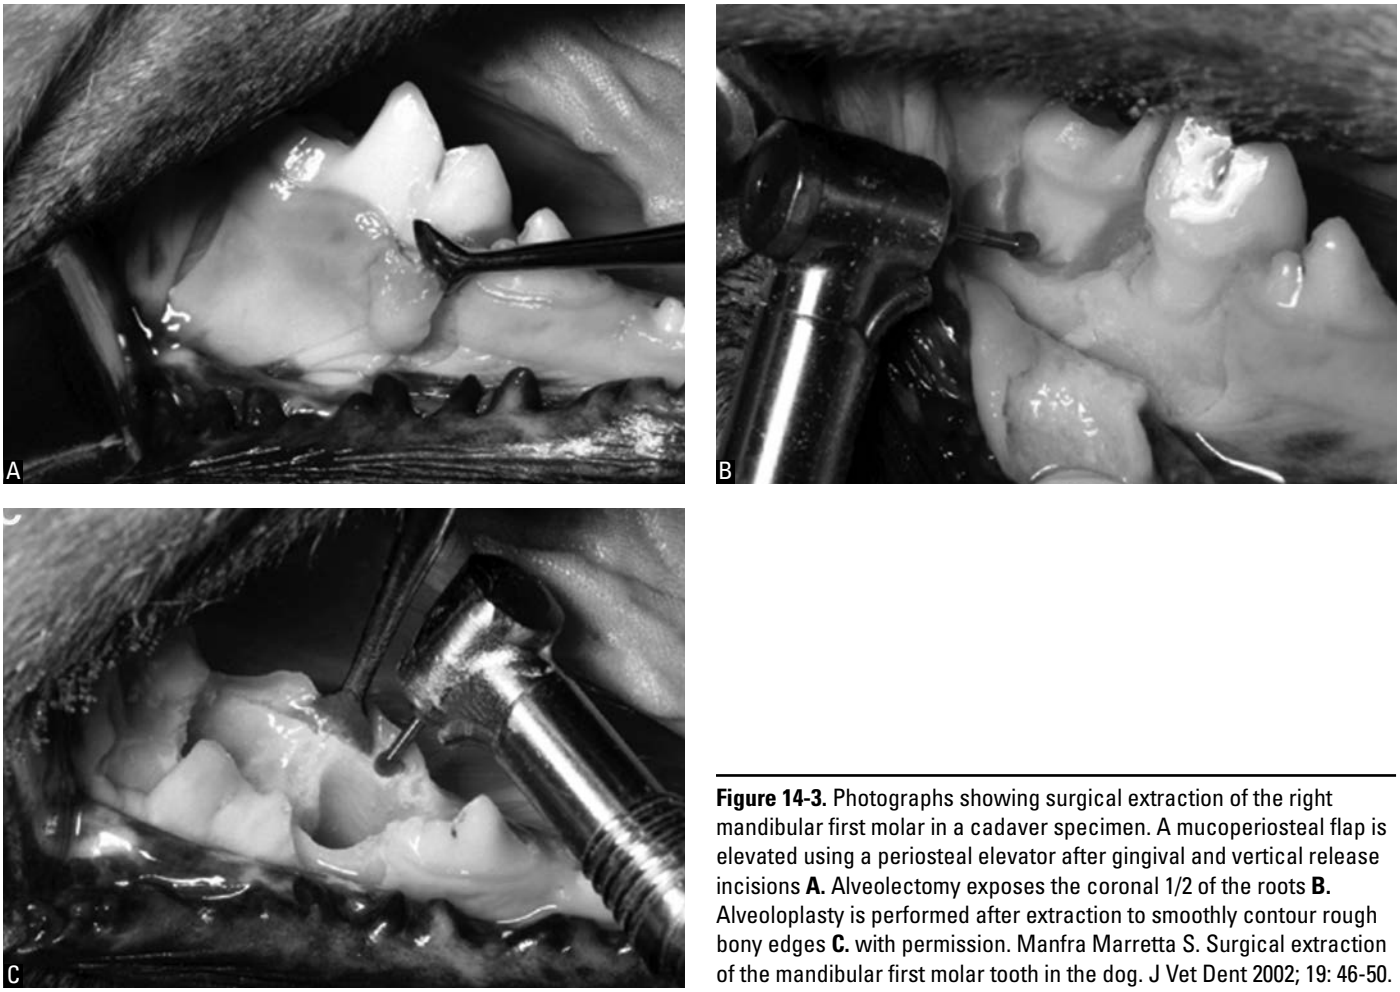

Figure 14-3. Photographs showing surgical extraction of the right mandibular first molar in a cadaver specimen. A mucoperiosteal flap is elevated using a periosteal elevator after gingival and vertical release incisions **A.** Alveolectomy exposes the coronal 1/2 of the roots **B.** Alveoloplasty is performed after extraction to smoothly contour rough bony edges **C.** with permission. Manfra Marretta S. Surgical extraction of the mandibular first molar tooth in the dog. J Vet Dent 2002; 19: 46-50.

Maxillary Canine

The maxillary canine is a large, single-rooted tooth which is difficult to extract using non-surgical techniques. Canine teeth affected by severe periodontal disease may be extracted suing non-surgical methods, however if the tooth has a healthy periodontium, it is essential to use surgical exodontic techniques. It is important to note that the root of the maxillary canine courses in a dorsal and distal direction with its apex directly above the mesial root of the maxillary second premolar. The periodontal flap incision begins in the buccal mucosa over the maxillary second premolar and is directed mesially, sloping towards the gingival at the distal line angle of the canine tooth. The gingival attachment fibers are incised along the canine tooth in a manner described previously. The flap incision is completed with a vertical relief incision form the gingival along the mesial line angle approximately 3/4 the length of the canine tooth root (Figure 14-4). Following gingival elevation, the buccal mucosa is relatively easy to mobilize form the buccal alveolar bone. An alternate flap design includes a peninsula-shape flap with mesial and distal incisions over the tooth's line angles (See Figure 14-4). Generally, regardless of flap design, the flap is sutured over bone. Therefore, the alveolectomy should be offset when compared with the periodontal flap. Lateral alveolectomy is performed using methods described previously. The alveolectomy begins near the cementoenamel junction and continues apically along the canine root (Figure 14-4). The cementum has a tan color and is readily identified compared with the hemorrhagic alveolar bone on the medial and distal sides of the tooth. During the alveolectomy process, it is helpful to purposely make gauges or slots in the alveolar bone on both the mesial and distal aspects. These focal areas of bone loss provide locations for application of the periodontal elevator (See Figure 14-4).

The canine root is elevated with the tooth being displaced in a lateral or buccal direction. If the angle of buccal displacement is acute, the root apex may fracture through the thin alveolar plate of bone separating the alveolus form the nasal cavity. If fracture leading to perforation occurs, hemorrhage may be noted form the ipsilateral nares. This problem is treated by primary wound closure of the periodontal flap over the alveolus. Incising the periosteum at the base of the periodontal flap improves flap mobility and decreases wound tension during primary closure (Figure 14-5).

Mandibular Canine

A buccal (lateral) approach has been recommended for surgical extraction of the mandibular canine tooth.[2-5] This approach requires consideration of anatomic structures including the prominent soft tissue attachment (frenulum) of the lip, the neurovascular structures exiting the mental foramen, and the roots of the first and second premolar. Considering the orientation of the root of the mandibular canine tooth is in a lingual (medial)

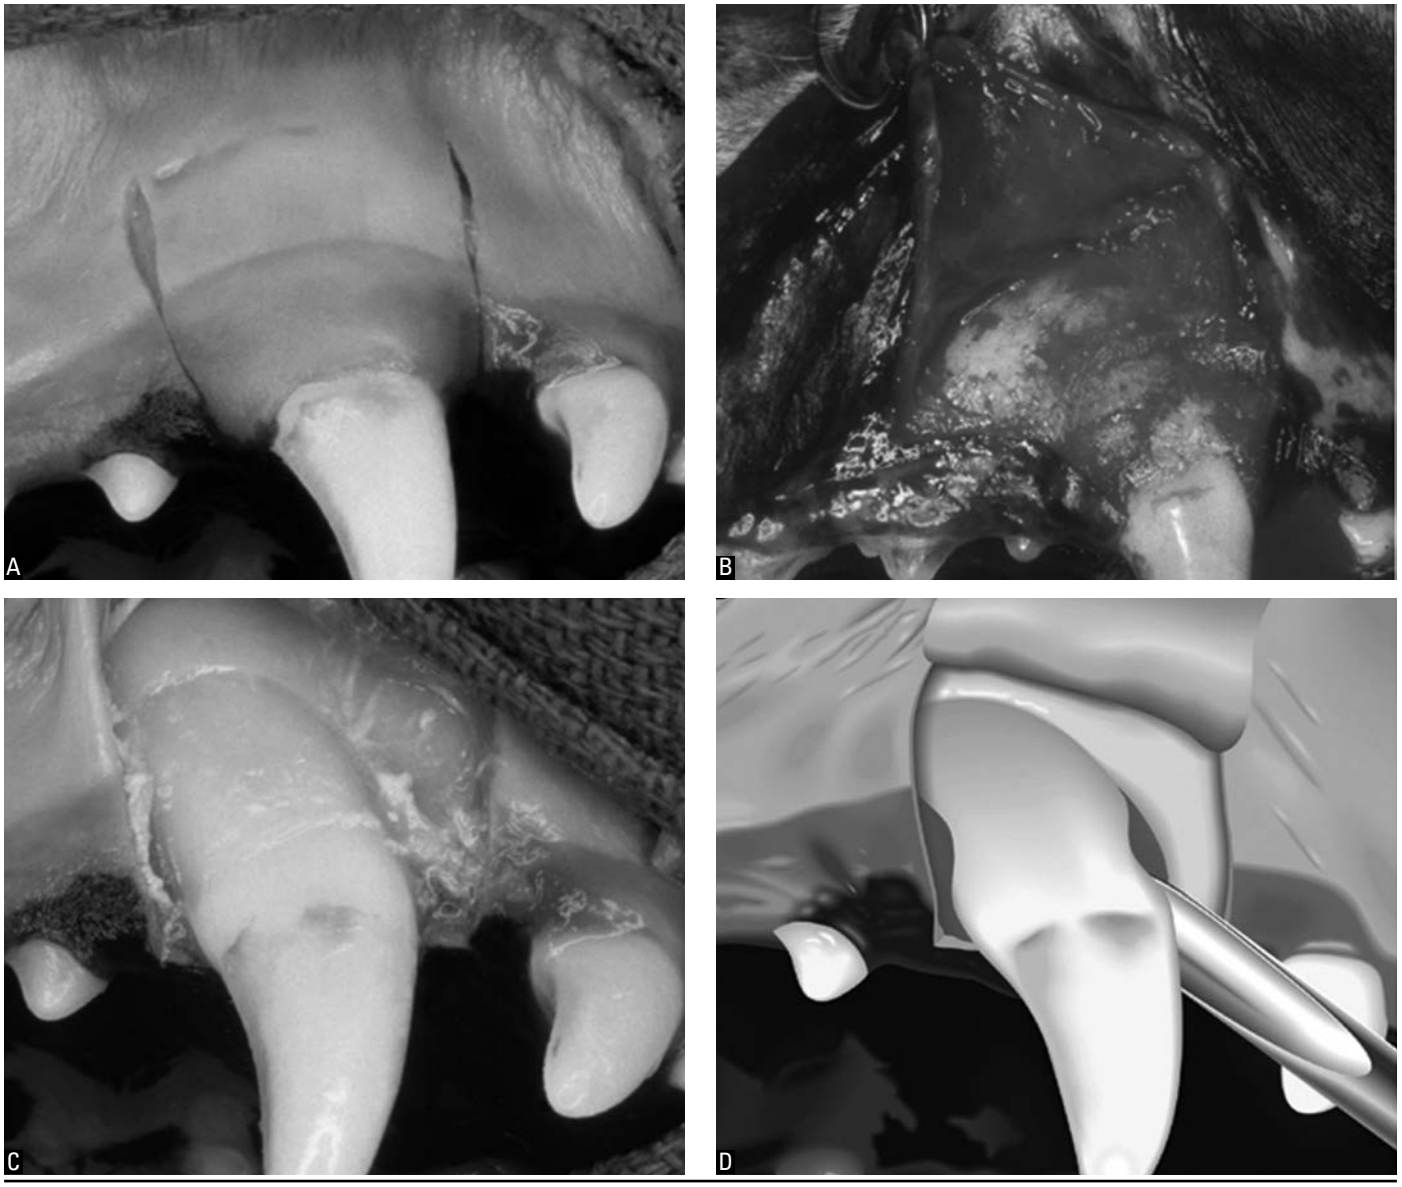

Figure 14-4. Photographs showing extraction techniques for the maxillary canine tooth. Flap design includes a peninsula flap with 2 vertical release incisions **A.** or a triangular flap with one vertical release incision **B.** Alveolectomy provides exposure to approximately 1/2 of the root **C.** while strategic exaggerated bone/tooth removal provides locations for placement of the periodontal elevator **D.** with permission. Frost Fitch P. Surgical extraction of the maxillary canine tooth. J Vet Dent 2003; 20: 55-58.

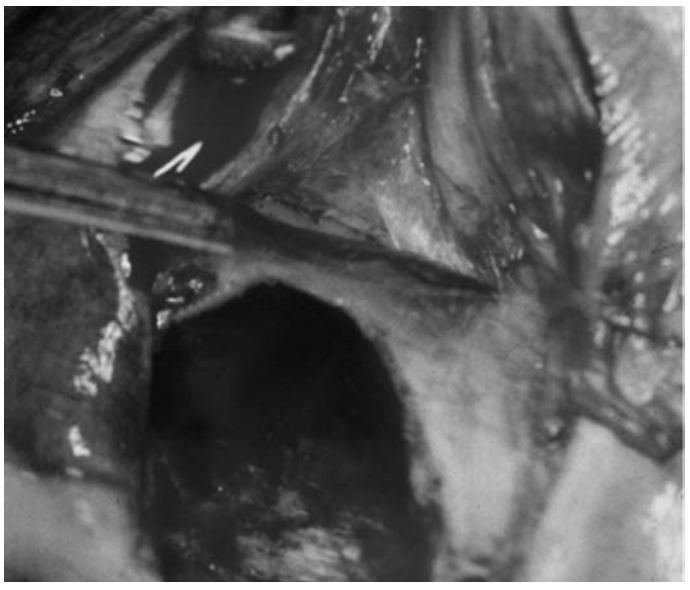

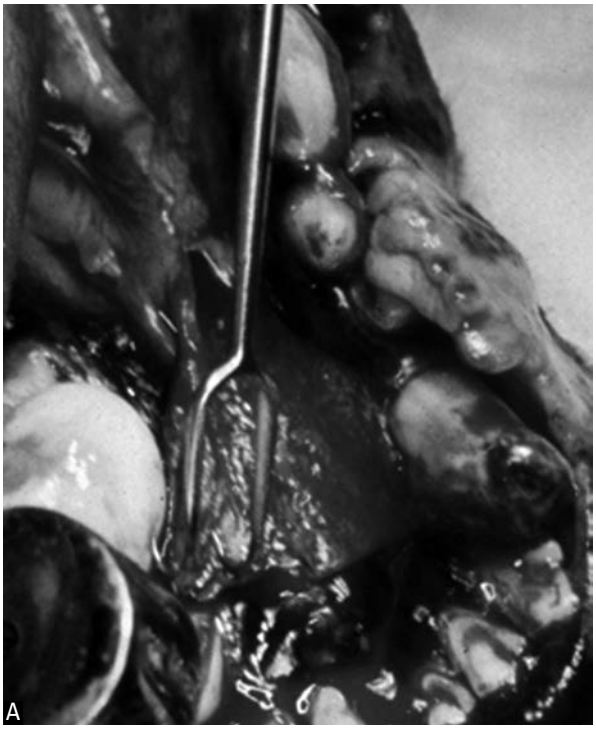

Figure 14-5. Photograph showing the periodontal release incision that enhances mobility of the flap and allows primary wound closure without tension.

direction, it would seem appropriate to consider an approach that could be performed directly over the root. Such an approach would avoid disruption of lip frenulum, potential hemorrhage from the mandibular artery and vein at the mental foramen, and iatrogenic trauma to adjacent tooth roots. A lingual approach for for surgical extraction of the mandibular canine tooth has been developed based on anatomic observations of tissues and structures of the rostral mandible and lingual orientation of the mandibular canine tooth root.[6]

The initial component of the procedure is elevation of a lingually based, full-thickness, mucoperiosteal flap. The flap is based on the symphyseal surface near the mandibular symphysis (Figure 14-6). The flap apex includes the gingival of the lingual aspect of the mandibular canine tooth. Generally, the flap base is approximately twice the width of the flap apex. A nitrogen-powered dental unit with a high-speed hand piece and round bur are sued to perform lingual alveolectomy (See Figure 14-6). Length of alveolectomy ranges form 10 to 20 mm in dogs. Periodontal elevators and extraction forceps are used to complete the extraction. The remaining alveolus is lavaged with 1.12% chlorhexidine and the flap is apposed to the buccal gingival using 3-0 polyglactin 910 in a simple interrupted pattern (See Figure 14-6).

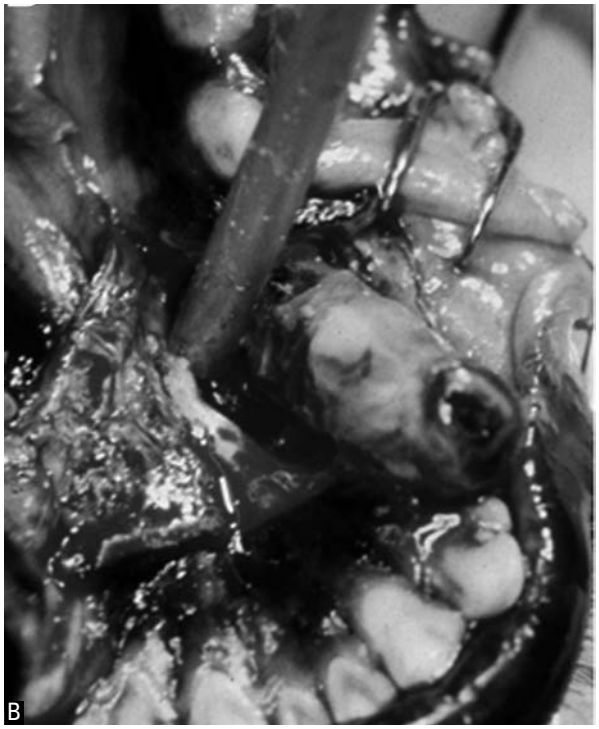

Figure 14-6. Photographs showing extraction techniques for the mandibular canine tooth. Access to alveolar bone is attained using a flap based on the lingual aspect **A.** followed by lingual alveolectomy **B.** Following extraction, the flap is apposed to the elevated gingival mucosa using absorbable suture in a simple interrupted pattern **C.**

Repair of Cleft Palate

Eric R. Pope and Gheorge M. Constantinescu

Introduction

Congenital palate defects can affect the primary palate, secondary palate, or both. The primary palate extends from the lip to the caudal border of the premaxilla (incisive bone). The secondary palate includes the remainder of the hard palate and the soft palate. Incomplete fusion of these structures results in cleft of the primary palate (harelip), cleft of the secondary palate, or both. Clefts of the primary palate can involve the lip (cheiloschisis), the alveolar process (alveoloschisis), or both (cheiloalveoloschisis). Clefts of the secondary palate include midline defects of the hard or soft palate and unilateral or bilateral lateral clefts of the soft palate.

Most clefts are believed to be inherited as either recessive or irregularly dominant traits. Nutritional, hormonal, and mechanical factors have also been incriminated as causes, but these factors are more likely to affect the severity of the cleft in predisposed individuals rather than being a sole cause. Intrauterine infections and exposure to toxins at specific periods during gestation can also result in cleft palate. Cleft palate has been reported in many different breeds of dogs, but the brachycephalic breeds appear to be overrepresented. The Abyssinian, Siamese, and Manx breeds of cats seem to be at increased risk.

Clinical Signs

The clinical signs vary with the location and severity of the cleft. Clefts of the primary palate involving only the lip are primarily a cosmetic defect associated with few clinical signs. Primary clefts involving the lip and premaxilla may interfere with the ability to suckle and may allow milk to enter the nasal cavity resulting in rhinitis. Because the defect is readily apparent, the inability to nurse properly is likely to be recognized earlier by observant owners and hand rearing instituted. Clefts of the secondary palate may also interfere with the ability to nurse, but because these defects are less apparent, some neonates may die of malnutrition or aspiration pneumonia before other signs are recognized. Milk or food in the nasal cavity frequently causes sneezing or gagging. Milk may be seen running from the nose. The resulting rhinitis causes a serous to mucopurulent nasal discharge that may be malodorous. Aspiration of milk or food causes coughing, and aspiration pneumonia is a common sequela. Clefts involving only the distal half of the soft palate are unlikely to result in significant clinical signs.

Preoperative Patient Evaluation and Care

Animals with clefts of the primary palate that involve only the lip often need no special care. Except for their being "sloppy eaters," the defect is usually well tolerated. Tube feeding can be instituted if the defect prevents effective nursing. Repair of these defects can be delayed until the patient is older (3 months or more), when visualization is improved and tissue manipulations are easier. Animals with clefts involving the premaxilla are more likely to have difficulty in nursing and require tube feeding. Earlier repair (7 to 9 weeks of age) can be performed in these animals to reduce the severity of the rhinitis secondary to entrance of food into the nasal cavity if oral feeding is begun at weaning. Tube feeding is recommended for patients with clefts of the secondary palate to reduce the severity of the rhinitis associated with the passage of milk into the nasal cavity and to reduce the potential for aspiration pneumonia. Depending on the size of the patient, repair of clefts of the secondary palate can be performed between 7 and 9 weeks of age if clinical signs are severe but I prefer to wait until the patient is 12 to 14 weeks old when access to the oral cavity for tissue manipulation is better and the tissues are less friable.

The diagnosis is generally obvious on physical examination. A complete examination is necessary to rule out other congenital defects. I routinely take thoracic radiographs of patients with clefts of the secondary palate before surgery to document the presence or absence of aspiration pneumonia. Aerobic and anaerobic bacterial cultures are performed on patients with purulent rhinitis, and appropriate antimicrobial therapy is initiated. Patients with minimal rhinitis are given a broad-spectrum antimicrobial perioperatively (administered when the intravenous catheter is placed before anesthesia induction and continued for up to 24 hours). Food is withheld the morning of surgery, but the operation should be performed as early in the day as possible to avoid hypoglycemia. Rhinoscopy should be considered on patients with purulent rhinitis immediately before the surgical procedure because some patients may have foreign bodies (typically plant material) that might not be dislodged by flushing during surgical preparation and result in persistent rhinitis postoperatively.

Surgical Technique

A cuffed endotracheal tube is placed after induction of anesthesia and secured to the lower jaw. Access to the pharyngeal area can be improved by pharyngotracheal intubation, but it is generally unnecessary. Clefts of the primary palate are repaired with the patient placed in ventral recumbency and the head elevated on a cushion under the mandible. Elevating the head in this manner

allows the lips to hang in a normal position and provides good surgical access. An oral speculum can be placed if the premaxilla is involved and better access to the oral cavity is needed. The hair on the muzzle is clipped, and the skin is prepared routinely. The oral cavity is prepared with dilute chlorhexidine or povidone-iodine solution.

Clefts of the secondary palate are repaired with the patient placed in dorsal recumbency (Figure 14-7). The head is placed on a soft pad or beanbag, and the maxilla is immobilized with 1-inch tape placed over the incisors or canine teeth and secured to the operating table on each side. Access to the oral cavity is obtained by taping the animal's lower jaw, tongue, and endotracheal tube to an ether screen. A malleable retractor is also useful for retracting the tongue and endotracheal tube during repair of clefts of the soft palate. Pharyngotracheal intubation can be performed if greater access is needed. The nasal cavity should be liberally flushed with saline to remove purulent exudate and possible foreign bodies before swabbing the oral cavity with dilute chlorhexidine or povidone–iodine solution.

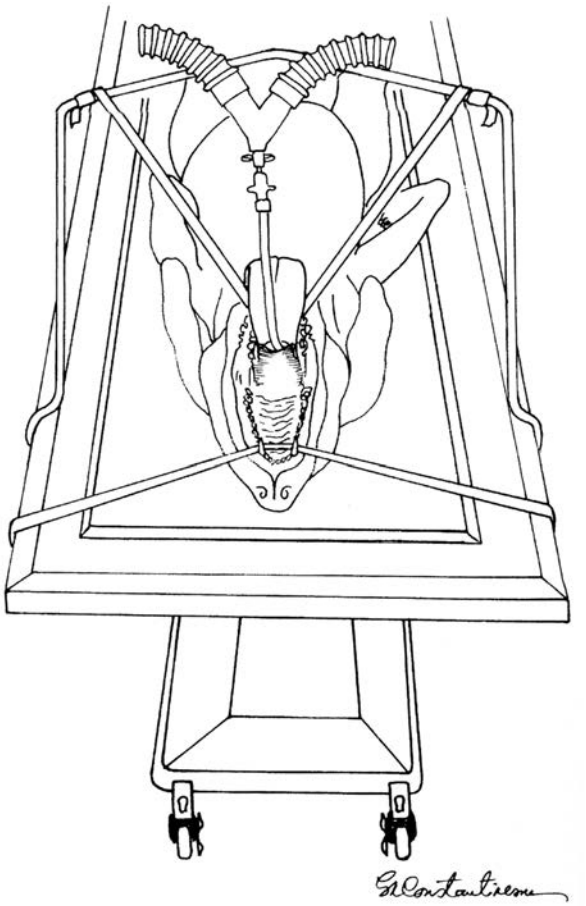

Figure 14-7. Patient positioning for surgery of the hard or soft palate.

Gentle tissue handling using skin hooks or bent hypodermic needles reduces tissue trauma. The use of electrosurgery should be minimized. Pinpoint coagulation of bleeders is acceptable, but use of the electroscalpel for making incisions and elevating flaps is not recommended. Two-layer closure in which suture lines on the nasal and oral cavity sides are offset is preferred. An airtight closure, free of tension, is mandatory. I prefer to use polyglactin 910 suture material in the oral cavity because the knot ends are not stiff and it is generally extruded by 14 to 21 days after surgery. Some of the new rapidly absorbed monofilament suture materials are preferred by some veterinary surgeons.

Cleft of the Primary Palate

The main objective in repairing a cleft of the primary palate is to establish the normal separation between oral and nasal cavities. Clefts of the primary palate involving only the lip are easy to repair. Although complex flap techniques to reconstruct the nostril and columella accurately have been described, they are generally unnecessary because of the abundance of labial tissue in animals. The edges of the cleft defect are incised to a depth of 2 to 3 mm along the entire margin of the defect to create an inner mucosal layer and outer cutaneous layer (Figures 14-8A and B). Beginning at the most dorsal point, the mucosal edges are apposed with interrupted 4-0 absorbable sutures (Figure 14-8C). Accurate tissue apposition without tension is required. Skin closure should progress from the lip margin to avoid a step deformity using 3-0 to 4-0 monofilament nonabsorbable suture material in an interrupted pattern.

If the cleft also involves the premaxilla, closure is more difficult, but the objective is the same. The critical step is achieving closure of the oronasal communication. Careful preoperative planning is necessary to identify the best source and orientation of mucosal flaps to allow tension-free closure. Abnormal development of the premaxilla may necessitate extraction of teeth to facilitate the reconstruction. Mucosal flaps based on the nasal or oral mucosa are elevated from each side of the defect and are sutured together with fine (4-0 or 5-0) absorbable suture material. Although a two-layer closure is preferred, there may not be sufficient tissue in all cases. If only a one-layer closure is performed, the nasal epithelial side should be reconstructed and the oral mucosal side allowed to heal by second intention. Finally, reconstruction of the lip is performed as previously described. Potentially, all or part of the oral mucosal defect can be covered as the lip is reconstructed.

Cleft of the Secondary Palate

The technique for closing clefts of the secondary palate depends on the extent of the defect (i.e., hard and soft palate versus either individually), the width of the defect, and the availability of tissues to close the defect. In most cases, one of the following techniques can be successfully used. Key points to consider are: 1) two-layer closures that re-establish the nasal and oral epithelial surfaces are stronger and provide the potential for bony union across the defect; 2) tension on the suture line is probably the most common reason for failure and must be avoided; and 3) preserving the blood supply to the flap, whether from the palatine vessels (Figure 14-9) in advancement flaps or the nasal cavity in "hinged" flaps, may limit the size or mobility of the flaps.

Double-Layer Mucoperiosteal Flap Technique

This technique is most useful for clefts involving less than one-third of the width of the hard palate. The first step is to create unilateral or bilateral "hinged" flaps based on the edges of the cleft that are rolled back over the defect to create an epithelium-lined closure

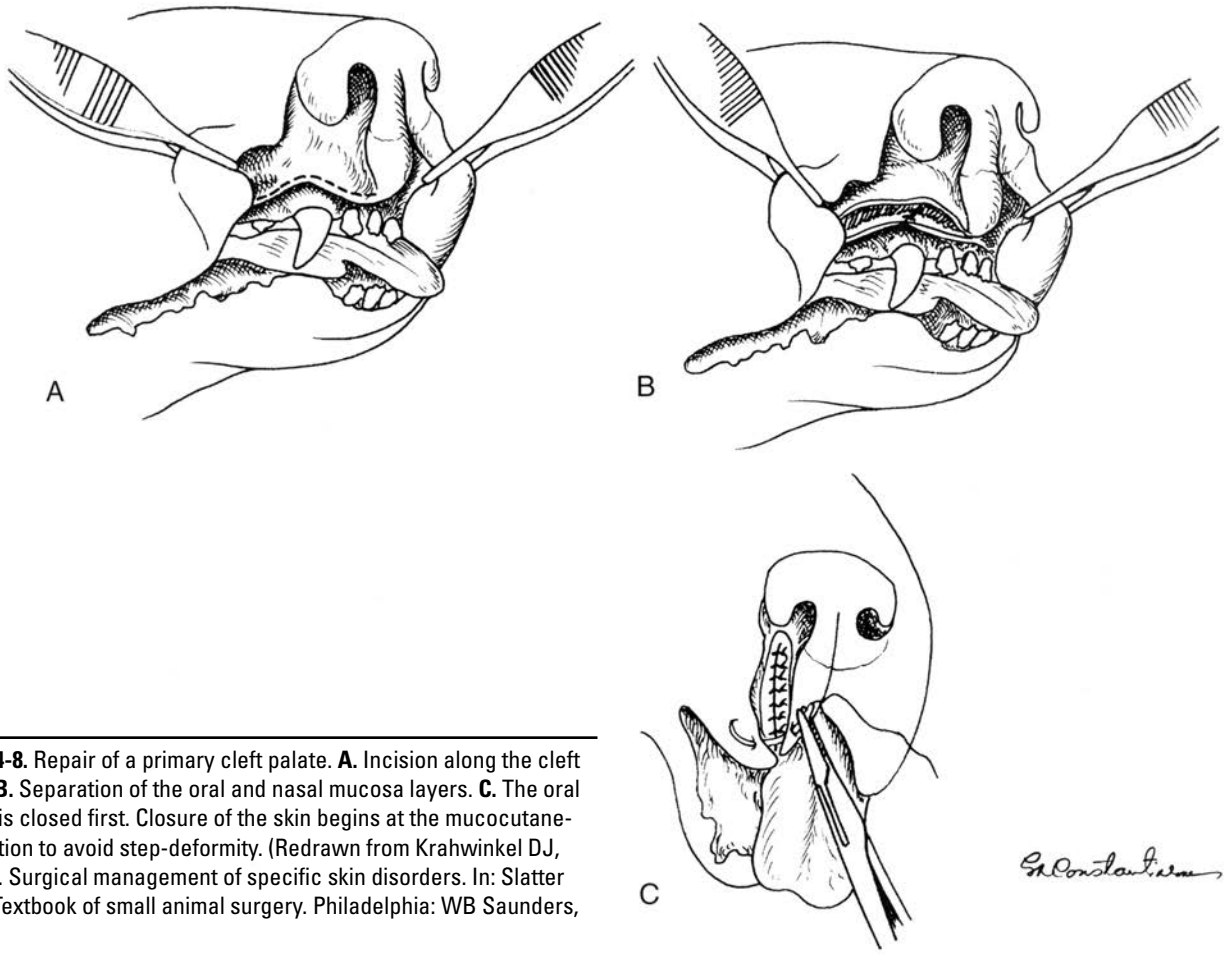

Figure 14-8. Repair of a primary cleft palate. **A.** Incision along the cleft margin. **B.** Separation of the oral and nasal mucosa layers. **C.** The oral mucosa is closed first. Closure of the skin begins at the mucocutaneous junction to avoid step-deformity. (Redrawn from Krahwinkel DJ, Bone DL. Surgical management of specific skin disorders. In: Slatter DH, ed. Textbook of small animal surgery. Philadelphia: WB Saunders, 1985.)

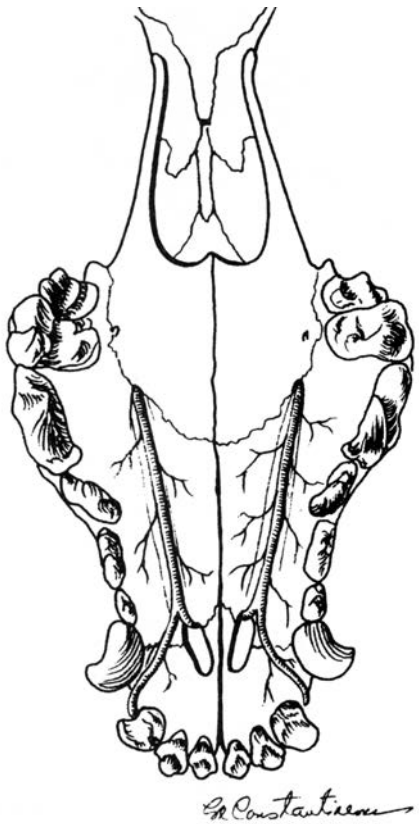

Figure 14-9. Location of the major palatine arteries.

of the floor of the nasal cavity. A unilateral flap is preferred if the cleft is not too wide (approximately 10% of the width of the palate) because the suture lines from this layer and the bipedicle mucoperiosteal advancement flap of the second layer can be offset, potentiating an airtight closure. Bilateral flaps are used on wider clefts to reduce tension on the palatine arteries as the mucoperiosteal flaps are advanced to close the oral cavity side of the defect.

In the unilateral flap technique (Figure 14-10), the hard palate mucosa is incised parallel to the cleft to create a flap that is slightly wider than the cleft. Perpendicular incisions are made at the rostral and caudal extents of the cleft to complete the flap. The flap is undermined with a periosteal elevator just to the edge of the bony defect, with care taken to preserve the blood supply coming from the nasal side. On the opposite side, the mucosa is incised along the edge of the defect to create a nasal side and an oral cavity side. The flap is rolled back toward the midline and is sutured to the nasal mucosa on the opposite side with preplaced 4-0 synthetic monofilament sutures using an interrupted pattern with the knots placed on the nasal side of the flap. The second layer of closure is started by making a releasing incision along the dental arcade on the side opposite the hinge flap to create a bipedicle flap. A periosteal elevator is used to undermine the flap beginning at the midline, with care taken to preserve the palatine arteries that enter the flap midway between the midline and the dental arcade approximately at the level of the caudal edge of the carnassial tooth (See Figure 14-9). The flap is advanced over the fistula and is sutured to the cut edge of the mucoperiosteum

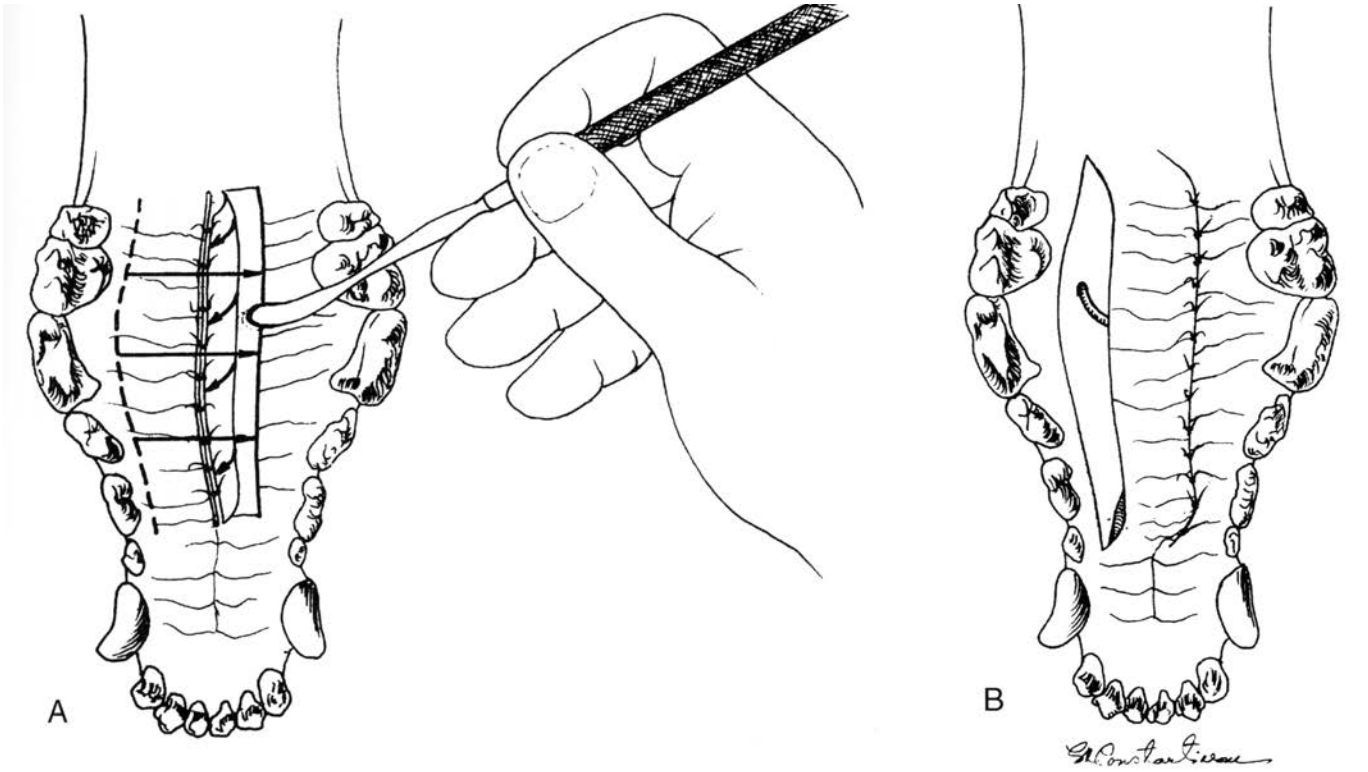

Figure 14-10. Two-layer closure using a unilateral hinge flap. **A.** Incision is made along one side of the cleft separating the nasal and oral mucosa. A unilateral hinge flap is elevated from the opposite side, "rolled" back over the defect, and sutured to nasal mucosa. A releasing incision is made along the dental arcade creating a bipedicle mucoperiosteal flap. **B.** The flap is advanced over the first layer and is sutured to the mucoperiosteum on the opposite side.

on the first side. The donor site along the dental arcade heals by second intention.

When wider defects are present, hinged flaps are elevated bilaterally, rolled back, and sutured together over the middle of the defect (Figure 14-11A-C). The second layer of the closure involves the development of bilateral, bipedicle mucoperiosteal flaps, which are advanced toward the midline and are sutured together. The hard palate mucosa is incised just medial (palatal) to the dental arcade, leaving the flap attached rostrally and caudally. The flaps are advanced toward the midline and are sutured together with 3-0 to 4-0 absorbable suture material.

The defects along the dental arcade can be allowed to heal by second intention, or they may be covered by buccal mucosal transposition flaps. Potential complications associated with allowing the defects to heal by second intention are shortening and narrowing of the maxilla, but we have not found this to be a common clinical entity. Single-pedicle or double-pedicle buccal mucosal flaps can be mobilized to cover the palatal donor sites. The buccal mucosa donor sites usually can be easily closed with a simple continuous pattern. Two weeks later, the bases of the pedicle flaps are incised and sutured.

This technique may be difficult to perform without creating excessive tension on the suture lines or palatine vessels when wide defects are present. Although the technique can also be performed as a single tissue layer closure by creating bilateral, bipedicle mucoperiosteal flaps and advancing them to the midline, the suture line lies over the center of the defect, making it more difficult to achieve an airtight closure. Moreover, constant movement of the suture line with respiration and tongue movements predisposes to dehiscence. Therefore, when wide defects are present, the following technique is recommended.

Howard Mucoperiosteal Hinge Flap

The hard palate mucosa is incised parallel to the edge of the defect so a mucoperiosteal flap slightly wider than the defect can be raised (Figure 14-12). The flap is undermined toward the midline, with care taken to maintain the blood supply from the nasal mucosa. The major palatine vessels are identified and ligated. The edge of the cleft on the opposite side is incised, and the oral mucosa is undermined for a depth of 2 to 3 mm. The mucoperiosteal hinge flap is rolled back over the defect. If it appears likely that tension will be present, a releasing incision is made along the dental arcade on the side opposite from the hinge flap. The bipedicle flap is undermined as previously described and is advanced toward the midline to eliminate the tension. The edge of the hinge flap is sutured to the underside of the mucoperiosteum on the opposite side with preplaced interrupted sutures using a mayo mattress pattern. Overlapping the edges in this manner achieves an airtight closure and minimizes movement along the suture line. The donor site(s) are allowed to heal by second intention.

Closure of Soft Palate Defects

Midline soft palate defects commonly accompany hard palate defects (Figure 14-11D-E). If possible, a two-layer overlapping technique is used. One flap is based on the nasal mucosa, and

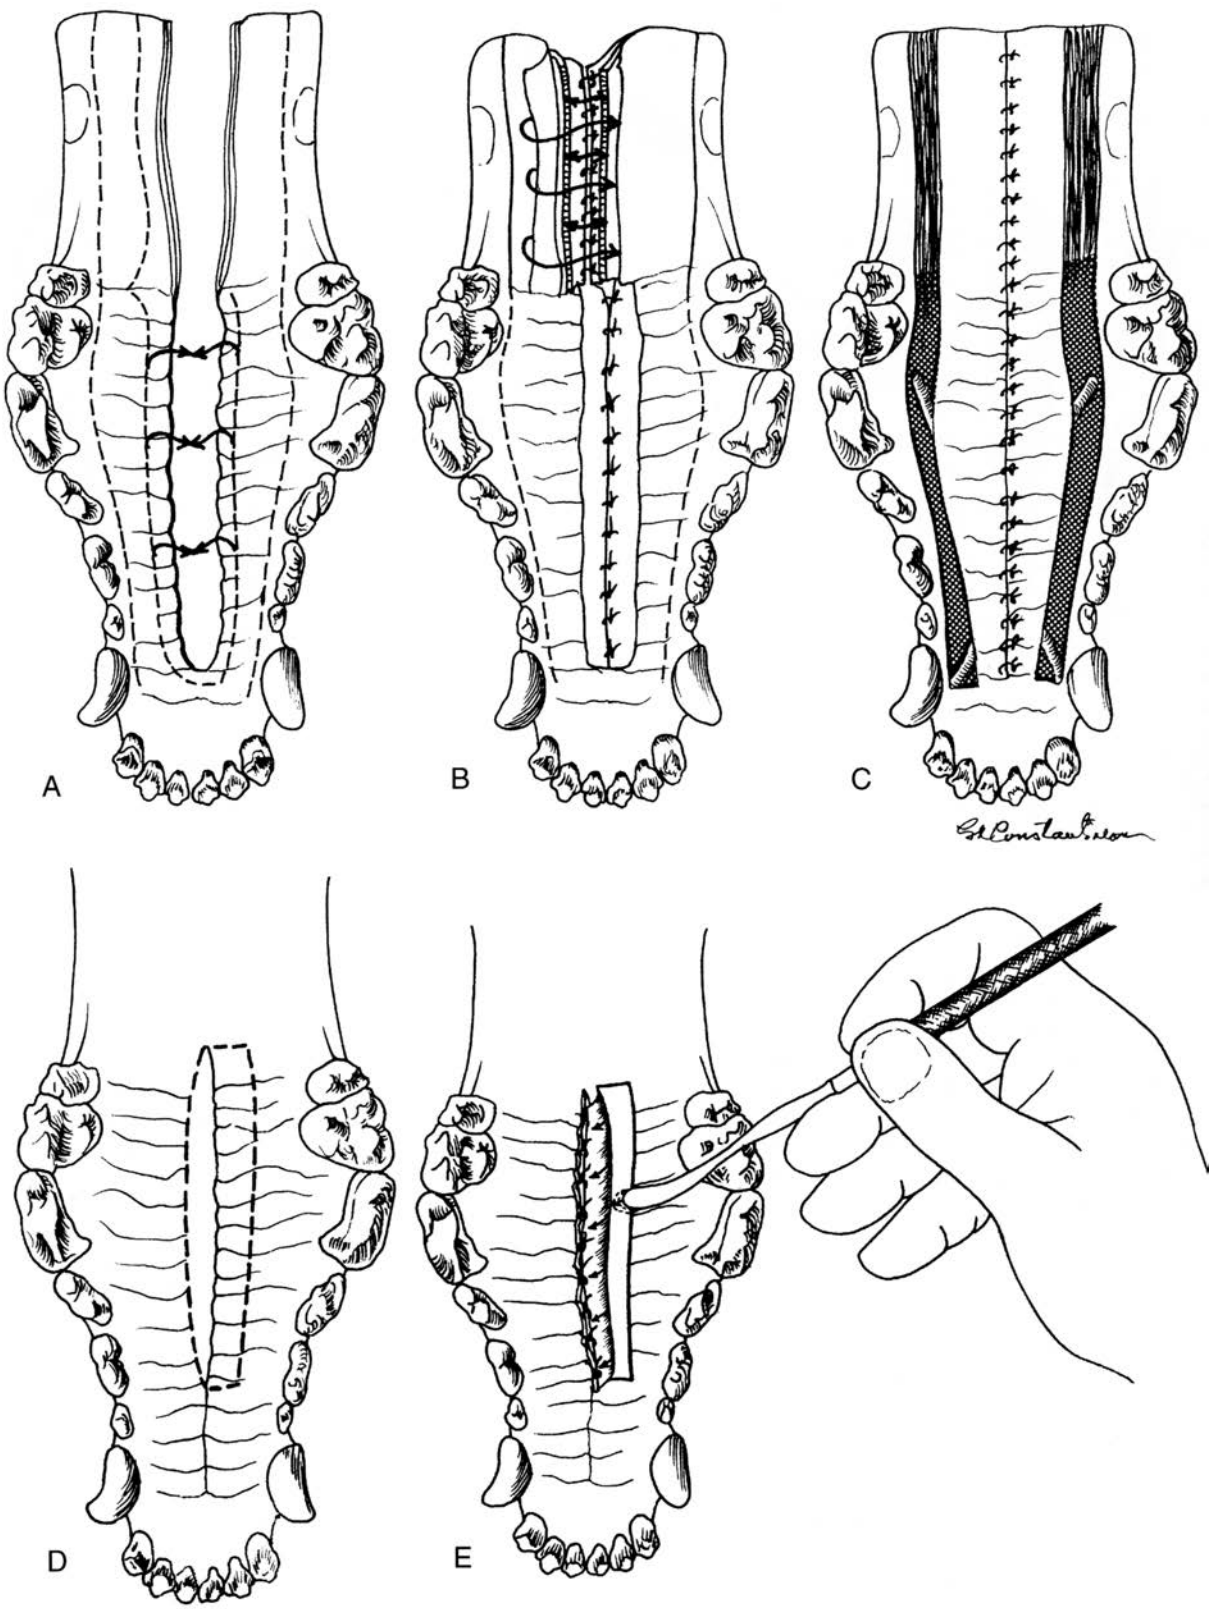

Figure 14-11. Two-layer reconstruction of a cleft of the hard palate using bilateral hinge flaps. **A.** Bilateral hinge flaps are elevated and "rolled" over the defect. The flaps are sutured together on the midline. **B.** Releasing incisions are made along the dental arcade creating bipedicle mucoperiosteal flaps. **C.** The bipedicle mucoperiosteal flaps are elevated, advanced over the first-layer closure, and sutured together on the midline. **D** and **E.** Soft palate reconstruction using an overlapping flap technique. **D.** Partial-thickness incision is made on the nasal surface of the soft palate on one side and the oral surface on the opposite side (dotted line closest to defect). The flaps are undermined to the midline. **E.** The oral mucosa-based flap is sutured to the nasal mucosa on the opposite side. Muscles are apposed if possible. The nasal mucosa-based flap is sutured to the oral mucosal on the opposite side to complete the repair. Releasing incisions are made along the pharyngeal wall, if necessary, to relieve tension. (Redrawn from Nelson AW. Upper respiratory system. In: Slatter DH, ed. Textbook of small animal surgery. 2nd ed. Philadelphia: WB Saunders, 1993.)

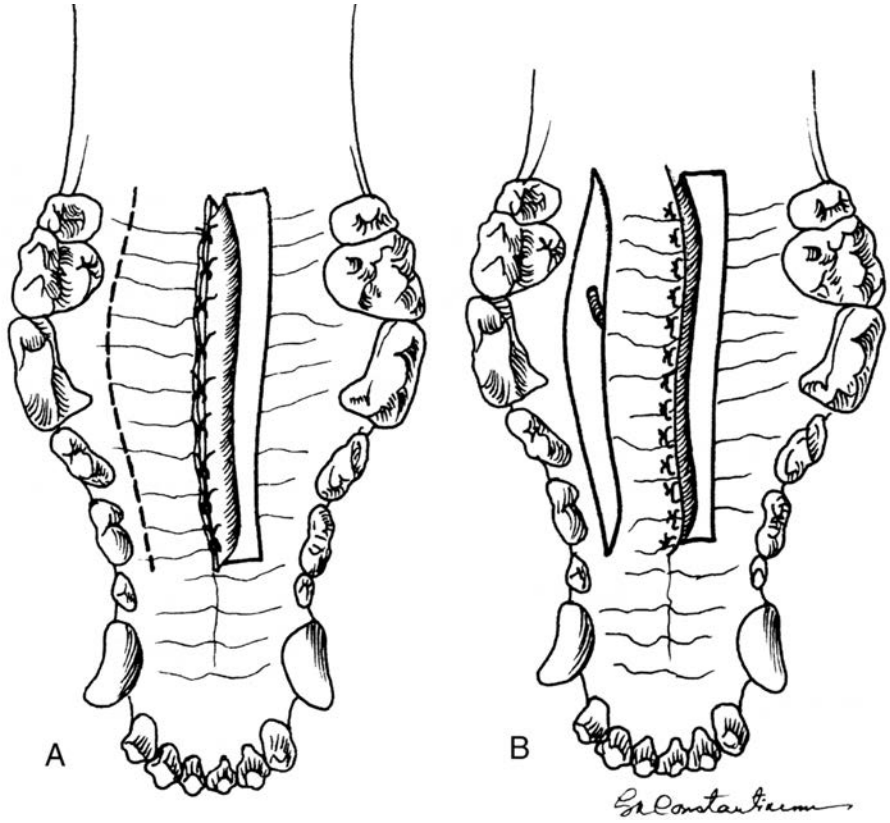

Figure 14-12. Howard mucoperiosteal hinge flap. **A.** Mucoperiosteal flap based on the edge of the cleft is elevated. An incision is made along the edge of the cleft on the opposite side, and the mucoperiosteum is undermined for several millimeters. **B.** If the flap is wide enough, mattress-type sutures are preplaced to pull the edge of the hinge flap under the mucoperiosteum on the opposite side. If tension is present, a releasing incision is made along the dental arcade and the mucoperisoteum is undermined so it can slide toward the midline and relieve the tension.

the second flap is based on the oral mucosa. The soft palate on one side is retracted laterally and rostrally to expose the nasal mucosa. The mucosa is incised the same distance from the edge as the width of the defect to create an orally based flap. On the opposite side, the oral mucosa is incised the same distance from the edge as the first flap to create a nasal mucosa-based flap. The flap based on the nasal side (i.e., side in which incision was made in the oral mucosa) is rolled back and is sutured to the lateral edge of the incision in the nasal mucosa on the other side of the defect. An attempt is made to suture the palatine muscles along the midline. The oral mucosa-based flap is moved across and is sutured to the oral mucosa incision on the opposite side. If any tension is present, releasing incisions are made in the oral mucosa laterally near the wall of the pharynx.

Lateral and bilateral clefts of the soft palate are occasionally seen. Lateral clefts can be repaired by direct closure if minimal tension is present or with flaps elevated from the dorsolateral pharyngeal wall if excessive tension is present. Direct closure is performed by incising the edge of the palate defect to create an oropharyngeal and nasopharyngeal side. The pharyngeal mucosa dorsolateral to the tonsil is incised. A two-layer closure is performed beginning with the dorsal (nasopharyngeal) side. I prefer to use a monofilament absorbable material (3-0 to 4-0) in a continuous pattern on the nasopharyngeal side of the defect. I prefer to close the oropharyngeal layer with interrupted cruciate sutures using the same suture material.

Bilateral clefts are much more difficult to close. I have not been able to re-establish normal length of the soft palate but in the limited number of cases I have done clinical signs have been alleviated or markedly improved if more than one-half of the normal length of the soft palate has been achieved. Trying to extend the soft palate much beyond this point has resulted in excessive tension and postoperative dehiscence. If sufficient pharyngeal tissue can be mobilized, the defects are closed as described above but generally this type of closure will result in excessive tension and predispose to dehiscence. A tension-free closure is more likely achieved by making releasing incisions in the pharyngeal mucosa which essentially creates bipedicle advancement flaps. Alternatively single pedicle flaps can be elevated bilaterally from the pharyngeal mucosa dorsolateral to the tonsillar crypt and sutured to the soft palate after incising it along the edge. A one layer closure is performed with 3-0 to 4-0 monofilament suture material using a cruciate suture pattern. The donor site is left to heal by second intention.

Postoperative Care

Intravenous fluids are continued until the patient recovers from anesthesia. Immature animals are given a liquid meal replacement diet or gruel after recovery from anesthesia. Placement of an esophagostomy tube should be considered if tension exists on the suture line. Tube feeding is continued for at least 1 week until healing is confirmed. A soft diet is fed for a minimum of 1 month. Chew toys and other hard objects should also be withheld for a minimum of 1 month.

Dehiscence is the most common complication of cleft palate repair. The incidence can be minimized by performing tension-free closures and by gentle tissue handling. Repair of palatal dehiscences\should be delayed for 3 to 4 weeks to allow inflammation from the initial surgery to decrease. Owners should be cautioned at the initial examination that more than one operation may be necessary to achieve complete closure of the palatal defect.

Repair of Oronasal Fistulas

Eric R. Pope and Gheorghe M. Constantinescu

Introduction

Oronasal fistulas most commonly result from dental disease or its treatment (i.e., poor extraction technique), but they may also be caused by trauma, electrical burns, complications of maxillary fracture, and excision of nonneoplastic masses involving the hard palate, as well as by complications of surgery, radiation, or hyperthermia treatment of maxillary neoplasias. Common clinical signs of oronasal fistula include sneezing and serous, serosanguineous, or purulent nasal discharge. Food particles or foreign bodies are occasionally seen in the nose. The diagnosis is often obvious during physical examination. Oronasal fistula due to periodontal disease or periapical infection is usually diagnosed by periodontal probing or radiography. The palatal surface of the maxillary canine teeth is a common site of oronasal fistula in small breeds of dogs.

Preoperative Evaluation

A complete physical examination and laboratory studies appropriate for the patient's anesthetic classification are indicated. Thoracic radiographs should be obtained when patients present with a cough or increased respiratory sounds (or history of either), to rule out aspiration pneumonia. Patients usually require anesthesia for thorough examination of the mouth and for skull radiography. The periodontal probe is useful for identifying small oronasal fistulas, particularly those associated with periodontal disease. Intraoral radiographic techniques are preferred for identifying periodontal and periapical disease. Rhinoscopy should also be considered in patients with obvious oronasal fistula and purulent nasal discharge because foreign bodies may enter the nasal cavity through the fistula and may contribute to the rhinitis. Bacterial culture and sensitivity testing are performed on patients with severe purulent rhinitis or aspiration pneumonia. Culture samples are collected by bronchoalveolar or transtracheal wash in patients with aspiration pneumonia. Alternatively, a broad-spectrum antimicrobial with efficacy against anaerobes can be given empirically. Treatment is continued for 10 to 14 days. In patients with minimal signs of infection, perioperative antimicrobials are administered intravenously when the catheter is placed before induction of anesthesia and are continued for 24 hours only.

Surgical Techniques

Successful repair of oronasal fistulas requires a well-supported, airtight closure that is free of tension. The options for surgical closure of oronasal fistulas are determined by the size, location, and chronicity of the fistula. Although many different techniques have been described, our preference is to perform a double-flap closure that reestablishes continuity of the nasal and oral mucosa whenever possible. Chronic fistulas, in which the nasal and oral mucosa have healed together, provide the option of creating "hinge" flaps based on the edge of the fistula similar to those described in the discussion of cleft palate repair in an earlier section of this chapter. These flaps receive their blood supply from vessels in the nasal mucosa that anastomose with vessels in the oral mucosa during the healing process.

Alveolar Ridge Fistulas

The technique used for repairing oronasal fistulas located along the dental alveolar ridge is determined primarily by the size and chronicity of the defect. Small fistulas resulting from advanced periodontal disease or tooth extraction are closed with a one-layer or two-layer technique, depending on whether the fistula is acute or chronic. Acute fistulas are corrected with single-pedicle advancement or transposition flaps from the buccal mucosa. My preference is to excise a 2- to 3-mm wide rim of mucosa from the palatal, rostral, and caudal edges of the fistula so the suture line lies over bone. This technique helps to stabilize the flap against movement and aids in the formation of an airtight seal. Necrotic tissue and sharp bone edges are removed, and the wound is thoroughly lavaged. Single-pedicle advancement flaps are used unless they will restrict lip movement excessively (Figure 14-13). Slightly diverging incisions are made in the gingival and labial mucosa starting at the rostral and caudal borders of the fistula and extending laterally. The labial mucosa and submucosa between the incisions is elevated by sharp and blunt dissection from the underlying bone. If a longer flap is needed, the dissection is continued toward the lip margin separating the layers of the lip. The flap should be sufficiently long that it can be advanced across the defect without tension. The flap is sutured with simple interrupted or cruciate mattress sutures using 3-0 to 4-0 synthetic absorbable suture material.

If the single-pedicle flap is likely to restrict movement of the lip, a transposition flap is used to repair the fistula (Figure 14-14). Because of the abundance of cheek tissue in most breeds of dogs,

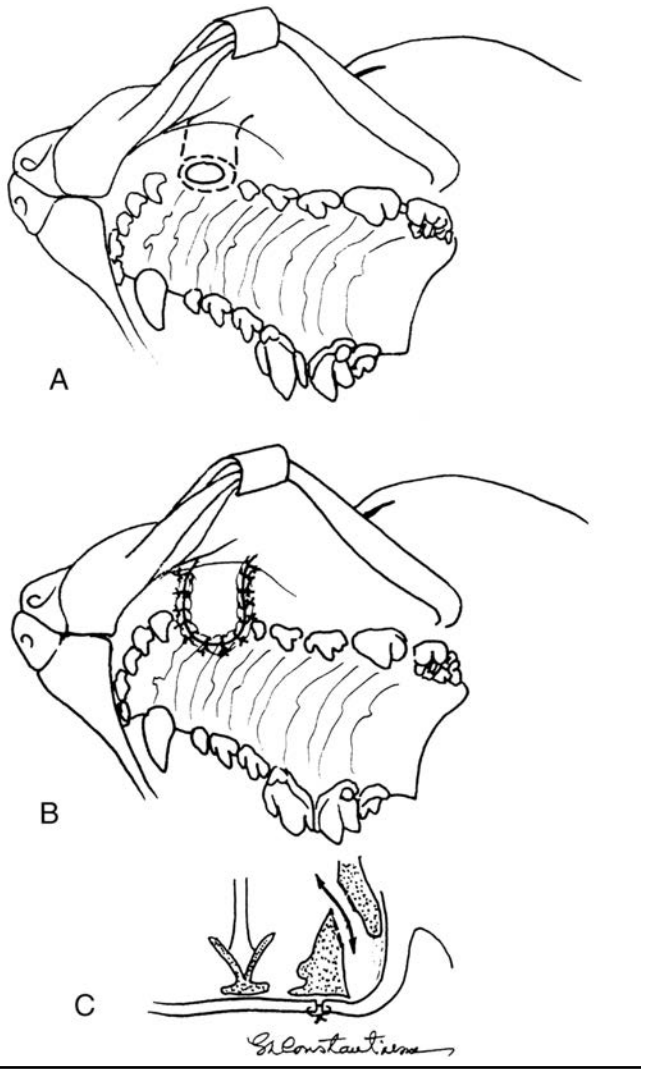

Figure 14-13. Repair of an oronasal fistula with a single pedicle advancement. **A.** A 2-to 3-mm rim of mucosa is removed around the edge of the fistula. Slightly diverging incisions are made in the mucosa starting at the rostral and caudal borders of the defect. **B.** The flap is undermined, advanced over the defect, and sutured. **C.** Excising the rim of mucosa places the suture line over bone, providing better support.

I usually base transposition flaps on the rostral extent of the fistula and develop the flap caudally if the defect is located rostrally. The first incision is made beginning at the caudal most point of the lateral border of the fistula and then continued caudally. The flap should be long enough to allow transposition of the flap over the flap without tension. A second incision is made parallel to the first one, so the width of the flap is equal to the width of the defect. The incisions are connected caudally. The flap is undermined by sharp and blunt dissection to make the flap as thick as possible. The flap is rotated over the fistula and is sutured as previously described. The donor site is closed with an interrupted or simple continuous pattern. Conversely, I make the base of the flap at the caudal extent of the fistula if it is located more caudally in the alveolar ridge.

Chronic fistulas, in which the oral and nasal mucosa have healed together, can be repaired using a double-flap closure technique that provides a mucosal surface on both oral and nasal sides of the fistula. The first step is to create one or two "hinge" flaps based on the edge of the fistula that are rolled back over the fistula so the mucosal surface is on the nasal side (See Figure 14-14D). If a single flap is used, it is usually raised from the hard palate. The alternative is to create opposing flaps from the hard palate and the labial (buccal) gingiva that are rolled back over the fistula. After the flaps have been created, the rostral and caudal edges of the fistula are incised to create nasal and oral sides. The hinge flaps are sutured to the nasal mucosa laterally or to each other at the center of the defect and to the rostral and caudal edges with interrupted sutures using 3-0 to 5-0 synthetic absorbable suture material. The second step is to create a flap from the buccal mucosa to cover the first layer of closure and the donor site on the hard palate completely. This step generally requires a transposition flap, as described earlier.

Large oronasal fistulas, resulting from the excision of neoplasms, are repaired with labial mucosa and submucosa advancement flaps (see the discussion of maxillectomy in the next section of this chapter). After completion of the maxillectomy, hemorrhage is controlled by packing the wound with gauze sponges. Diverging incisions are made in the labial (buccal) mucosa and submucosa extending toward the lip margin as far as necessary to allow closure of the defect without tension. The flap is created by undermining the mucosa and submucosa between the incisions by sharp and blunt dissection. The flap is sutured to the hard palate in two layers using synthetic absorbable suture material. The first layer apposes the submucosa of the labial flap with the mucoperiosteum of the hard palate. The sutures are placed so the knots lie in the nasal cavity. The second layer of sutures apposes the flap and hard palate mucosa with the knots in the oral cavity.

Central Hard Palate Fistulas

Oronasal fistulas in the central portion of the hard palate are often more of a challenge given that reconstruction with labial (buccal) flaps is not an option because of the dental arcade. Oronasal fistulas rostral to the upper fourth premolar are amenable to closure with hard palate mucoperiosteal transposition flaps. Central hard palate oronasal fistulas at the level of the upper fourth premolar, or more caudal, can often be more easily closed with a partial-thickness transposition flap or a hinge flap from the soft palate. Another recently described option is the angularis oris axial pattern flap. The mucoperiosteal transposition flap is planned so one edge of the defect is incorporated into one side of the flap (Figure 14-15A). Laterally, an incision is made parallel to the defect so the flap is 2 to 3 mm wider than the defect, if possible. The transverse diagonal (distance between the most lateral extent of the base of the flap and the rostral edge of the fistula) is measured to ensure creation of a flap of adequate length. Because the mucoperiosteum contains little elastic tissue, the pliability of these flaps is limited. Moreover, these flaps do not stretch, so the flap must be made long enough to avoid tension. Once the dimensions of the flap have been determined, the mucoperiosteum is incised. I make the side incisions first and the rostral incision last. By making alternating short incisions from the lateral and medial edges, the major palatine artery can usually be identified and clamped with hemostats before transection. Although some veterinary surgeons just

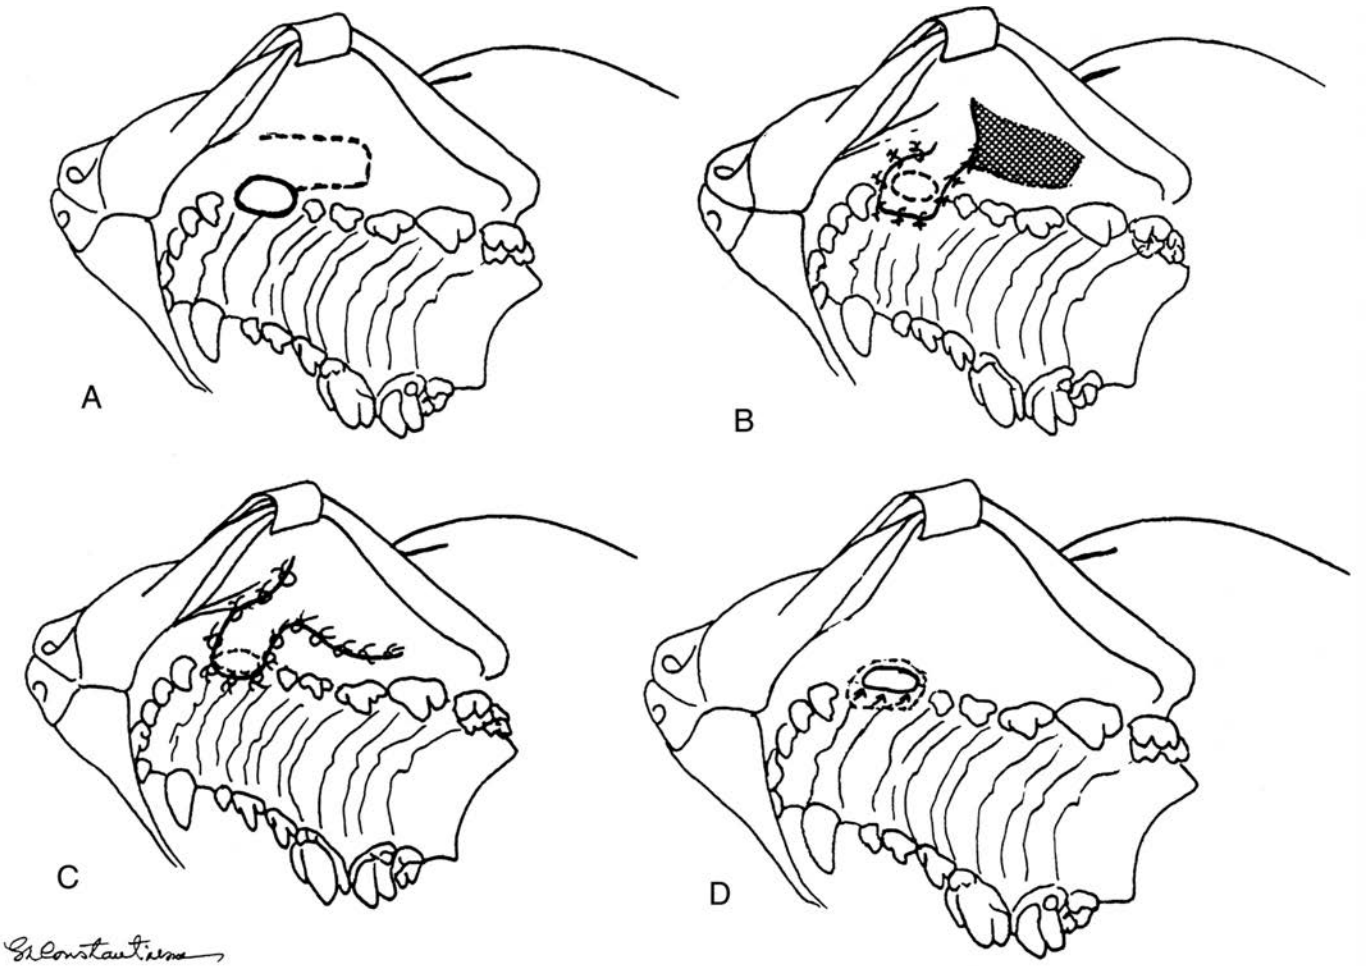

Figure 14-14. Oronasal fistula repair using a transposition flap. **A.** Incisions for a rostrally based flap. **B.** The flap is undermined and transposed over the defect. **C.** Closure of the donor and recipient sites. **D.** When chronic fistulas are present, a hinge flap can be raised from the hard palate side of the defect and sutured laterally. A transposition flap is used to cover the flap and donor site.

sever the vessel as the rostral incision is made, retraction of the vessel rostrally may make grasping it for ligation difficult. The flap is elevated from bone with a periosteal elevator, with care taken not to injure the major palatine artery. The flap is transposed to cover the defect. In some instances, removing a triangular segment of mucoperiosteum from the caudal aspect of the fistula to the base of the flap is necessary to facilitate transposition of the flap over the defect. Because no soft tissue secures the flap on one side of the fistula (the side adjacent to the donor site), holes can be drilled in the hard palate bone with a small K-wire to allow placement of sutures to secure the flap along the edge of the fistula (Figure 14-15B). These sutures should be preplaced. The remainder of the flap is sutured in one or two layers with synthetic absorbable suture material. The exposed bone of the donor site is allowed to heal by second intention.

Fistulas located more caudally can be reconstructed using a partial-thickness flap from the soft palate. The transposition flap is designed to incorporate the edge of the defect into one side of the flap (Figure 14-15C). The oral mucosa of the soft palate is incised, and a partial-thickness flap is elevated by sharp and blunt dissection. Again, one must elevate a flap of sufficient length to avoid tension on the closure. The flap is moved over the defect and is sutured with synthetic absorbable suture material. The donor site is allowed to heal by second intention.

The angularis oris axial pattern flap has been recommended for reconstructing difficult or recurrent palate defects. Depending on head conformation, this flap can be used to reconstruct defects caudal the canine teeth. Maximum length is achieved when the flap is elevated as an island sized flap leaving only the vessels and a small amount of surrounding soft tissue attached at the donor site. Identification of the vessels can be difficult even with the use of transillumination and a pencil Doppler probe. Anatomic review and practice on cadavers is highly recommended before attempting this procedure on a clinical patient.

Postoperative Care

The pharyngeal area should be examined and any blood suctioned before extubation. Most patients are allowed nothing by mouth overnight. A soft diet is recommended for 3 to 4 weeks. Use of chew toys and other hard objects should also be avoided during this time. An esophagostomy tube can be placed if one desires to avoid oral feeding. In most instances, problems with healing become evident within the first week. If dehiscence occurs, the feeding tube can be maintained until another repair is attempted in 3 to 4 weeks. Tube feeding decreases the amount of material that can enter the nose and worsen the inflammatory response. Most complications can be avoided by gentle tissue handling, by achieving a tension-free closure, and by accurate

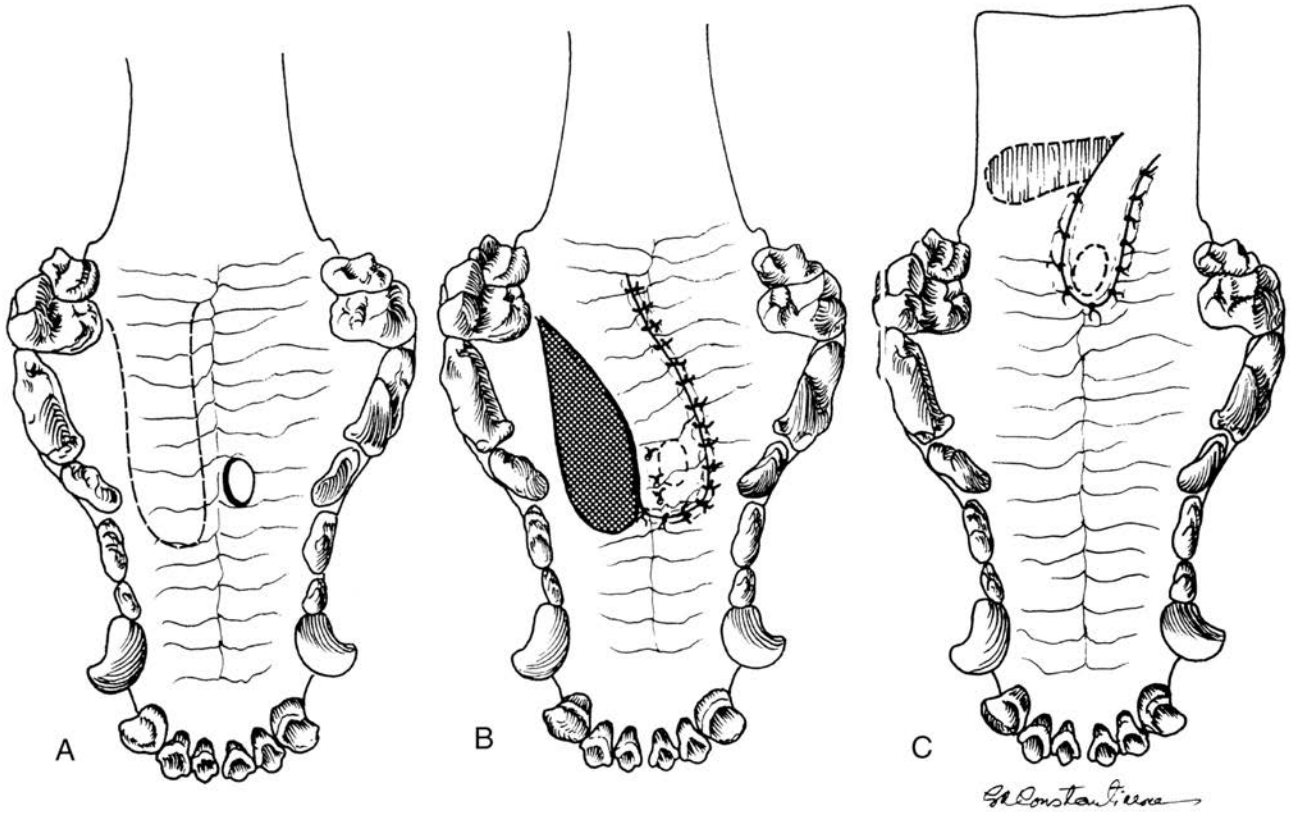

Figure 14-15. Central palate fistulas can be closed with transposition flaps **A** and **B** from the hard palate mucoperiosteum or with partial thickness flaps from the soft palate **C**.

suture placement. Although most fistulas can be successfully closed, instances of failure have been reported even after multiple attempts at surgical correction. Several different types of obturators have been used to create a barrier to movement of materials into the nasal cavity. A simple and successful technique is to use a nasal septal button to achieve obturation. The device is self-retaining but can be removed if necessary.

Maxillectomy

William Culp, William S. Dernell and Stephen J. Withrow

Maxillectomy

Maxillectomy is the resection of variable portions of the maxillary, incisive, and palatine bones and closure of the resulting oronasal defect with a labial mucosal-submucosal flap. The remaining bony structure of the muzzle maintains adequate stability and contour, eliminating the need for bone replacement. Closure of the maxillectomy site is limited by the availability of normal labial mucosa. Tumors that extensively involve the labia or cross the midline of the hard palate may not be amenable to complete resection because of the inability to close the defect. Appearance and function generally are good to excellent after maxillectomy. One study found that 85% of owners surveyed were satisfied with the outcome of a mandibulectomy or maxillectomy procedure. Forty four percent cited difficulty in eating as a complication; reduction in pain and improvement in quality of life were perceived and resulted in the overall satisfaction.[1]

Indications for maxillectomy are similar to those for mandibulectomy and include oral neoplasia, chronic osteomyelitis, and maxillary fractures with severe bone or soft tissue injury or loss. Another indication for maxillectomy is oronasal fistula.[2-4] A maxillectomy is most often performed for local disease control of oral cancer. The oropharyngeal region is the fourth most common site of malignant neoplasia in the dog. The most common

oropharyngeal neoplasms in the dog are malignant melanoma, squamous cell carcinoma, fibrosarcoma, and epulides or tumors arising from the periodontal ligament.[5-8] In the cat, squamous cell carcinoma is the most common oropharyngeal cancer, followed by fibrosarcoma, undifferentiated sarcoma, hemangiosarcoma, lymphoma, and osteogenic sarcoma. Malignant melanoma and epulides occur rarely in the cat.[8,9] Odontogenic tumors, such as inductive fibroameloblastoma, are the most common benign oral tumors in the cat.[10] Oropharyngeal tumors tend to be locally aggressive and slow to metastasize, except malignant melanoma, caudal tongue tumors,[11] and pharyngeal and tonsillar squamous cell carcinoma.[6-8] Morbidity and mortality often result from local disease rather than from distant metastasis; many animals die or are euthanized because of signs of local disease, such as infection, dysphagia, and aspiration pneumonia, before metastases occur.

Control of local disease is the first goal of most surgical treatments for oral cancer. Limited soft tissue excisions without concurrent ostectomy for attempted cure of oral tumors often fails because of recurrence of the tumor at the primary surgical site. Maxillectomy accompanied by en bloc soft tissue resection for oral tumors has the potential for prolonged remission or cure in certain malignant diseases. Control of local disease improves the quality of life even though distant metastasis may ultimately occur. Surgical resection should be considered as a first line of treatment for almost all oral neoplasms. Radiation therapy can be considered as primary treatment for tumors that show consistent responses to radiation, such as lymphoma, other round cell tumors and acanthomatous epulis. Radiation often serves in an adjuvant role to surgery for treatment of oral tumors. Chemotherapy is indicated for oral neoplasia with a high probability of metastasis; however, highly metastatic oral tumors such as malignant melanoma tend to have only a moderate response to chemotherapy.[12]

Four basic maxillectomy techniques are available to the veterinary surgeon:[2,4] unilateral rostral maxillectomy, bilateral rostral maxillectomy, total unilateral maxillectomy and caudal maxillectomy. The need to perform an incisivectomy, or removal of the incisive bones (region rostral to the canine teeth) is generally not encountered. The combination of bilateral rostral maxillectomy and nasal planum resection has also been described for disease that involves the planum.[13,14] Maxillectomy can be combined with resections of the ventral orbit, zygoma, dorsal orbit and calvarium (orbitectomy procedures) for more extensive, caudal disease.[15]

Preoperative Evaluation

The preoperative workup for maxillectomy is similar to that for mandibulectomy. The minimum database includes a complete blood count, biochemical profile, urinalysis, and thoracic radiographs for detection of distant metastasis. Regional lymph node aspirates should also be examined cytologically to detect nodal disease. A technique for surgical staging oropharyngeal lymph nodes has been described and may be helpful for establishing prognosis and treatment plans for malignant melanoma.[16,17] Evidence of systemic disease or metabolic abnormalities may preclude or alter the mode of therapy and prognosis.

Radiographs alone (of the skull and tumor site) are adequate for assessing bone involvement and preoperatively planning margins for smaller tumors rostral to the 3rd premolar tooth and showing little involvement with the maxillary or nasal bones. Radiographs should be taken while the patient is under general anesthesia. Lateral, ventrodorsal, and oblique radiographs may be helpful, however, the ventrodorsal or dorsoventral intraoral view is generally the most useful view. For caudal and more extensive tumors (that involve various portions of the orbit, zygoma, and mandibular ramus), computed tomography (CT) or magnetic resonance imaging (MRI) are important, if not essential. Generally, CT is preferred because of the affinity for bone detail as the degree of bone involvement will often dictate surgical margins and feasibility of the operation. With improvements in technique and interpretation of MRI, this modality may become preferred under certain circumstances.[18] The radiographic assessment should include evaluation of cortical bone continuity, alterations in bone density, periosteal new bone formation, and involvement of adjacent soft tissues.

An incisional biopsy for accurate tissue identification is also important before definitive therapy is undertaken. The biopsy site should be selected so complete resection of the mass (See Chapter 5) and labial flap closure is not compromised. Each patient can be assigned a World Health Organization staging classification (TNM; tumor, node, metastasis) and clinical stage which are prognostic for disease outcome and can help dictate treatment planning.[19]

General Surgical Considerations

Boundaries for maxillectomy for oral neoplasms with or without cortical bone penetration and destruction are determined by preoperative imaging and oral examination. Minimally, a 1 cm or larger, grossly visible, tumor free margin should be obtained on all cut surfaces, however, this is dependent on tumor type, site, histologic grade and overall treatment goals.

As a rule, an oronasal defect created after resection of tumors that cross the caudal midline is more difficult to close than a defect created from resection of tumors that do not cross the midline. Availability of normal labial and palatal mucosa generally is the limiting factor. New techniques are continuously being developed and evaluated for closure of more extensive oronasal defects which may allow closure of tissue excisions which cross midline. Aggressive preoperative imaging and surgical planning (including closure options) must be done in cases where aggressive resection is being considered to maximize success.[20-25] The use of preoperative modeling may assist surgical planning, especially for resections in sensitive skull sites. Three-dimensional models can be created from CT or MRI images which can allow better visualization of disease extent and involvement of surrounding tissues (Protomed Custom Anatomical Models, Arvada, CO). If bone change is evident on preoperative imaging, the excised tissue should be imaged immediately following resection to determine whether adequate bone disease free surgical margins were obtained, prior to closure.

The pathologist must ascertain any extension of neoplasia to a cut edge. Margins of interest (osteotomy edges and closest soft tissue margin) should be identified with India ink or other suitable marking system, or tissue margins should be submitted in separate containers. This technique aids the pathologist in determining the adequacy of mass removal (See Chapter 5). Specimens should be placed in 10% buffered formalin and submitted for histopathologic evaluation. Tumor extension to a cut margin generally implies the need for additional surgery or adjuvant therapy such as chemotherapy or, more commonly, radiation.

Perioperative antibiotics are recommended. Antibiotic therapy for more than 24 hours is not indicated unless dictated by the situation. Although surgery of the oral cavity is considered contaminated or "dirty," infection is rarely a postoperative complication. The antibiotic chosen should be effective against the bacterial flora normally found in the oral cavity, including gram positive cocci (e.g., Staphylococcus sp. and Streptococcus sp.) and gram negative rods (e.g., Proteus and Pasteurella spp.). The first generation cephalosporins, penicillins, and synthetic penicillins are generally considered effective prophylactic oral antibiotics.[26]

In the authors experience, polydioxanone (PDS, Ethicon, Inc., Somerville, NJ), polyglactin 910 (coated Vicryl, Ethicon, Inc.), polyglycolic acid (Dexon, Davis and Geek, Inc., American Cyanamid Co., Manati, PR), and polyglyconate (Maxon, Davis and Geek, Inc.) sutures (3-0 or 4-0) are prefered for wound closure after maxillectomy. These relatively nonreactive sutures minimize oral mucosal irritation and maintain adequate tensile strength during the critical early period of healing. Polydioxanone and polyglyconate have the advantages of being monofilament and absorbable. Their absorption is slower (than polyglactin 910 and polyglycolic acid), however, and food can cling to the suture, or suture knots can be irritating, resulting in oral mucosal ulceration if the suture is not removed after healing. Although polyglactin 910 and polyglycolic acid are absorbable, they are braided suture materials and may increase the possibility of bacterial adherence or may result in a greater inflammatory response causing oral mucosal irritation. These latter two suture materials lose tensile strength sooner than the monofilament absorbables, a characteristic that should be considered if adjuvant radiation or chemotherapy may be administered postoperatively or if other patient factors exist that might result in delayed wound healing. The absorption rate of various suture materials has been evaluated in vivo for use in the oral cavity in cats.[27] A reverse cutting swaged on needle has been beneficial in suturing the tough, fibrous soft tissues of the oral cavity. This type of needle causes less surgical trauma when passed through tissues and provides better suture purchase into the soft tissues than other needle types.[28] Use of electrocautery should be kept to a minimum. Incisions within the oral cavity made with electrocautery are more likely to have delayed healing or to become dehiscent than incisions made with a scalpel.[2,29]

The choice of preanesthetic medication and induction agents is based on preoperative evaluation, personal preference, and expertise. The use of a narcotic is generally recommended for its analgesic effects. Adequate postoperative analgesia for 2 to 3 days is indicated, usually involving a combination of narcotics and non-steroidal anti-inflammatory agents. Some dogs may need to be treated with additional agents, depending on pain response. Preoperative or intraoperative nerve blocks using a long acting local anesthetic to the infraorbital nerve ventral to the zygoma may decrease anesthetic needs and postoperative pain.[30,31]

After induction, general anesthesia should be maintained with a gas inhalant and oxygen. An endotracheal tube with an inflatable cuff is used to prevent aspiration of blood and fluid. Once the animal is positioned, prior to the start of surgery, the inflation of the endotracheal tube cuff should be checked again, and upon recovery, extubation with the cuff partially inflated may assist in removal of blood that has accumulated in the oropharynx. The tube should be secured to the animal's lower jaw to minimize surgical interference. Because intraoperative hemorrhage can be significant, a patent intravenous access catheter must be maintained at all times. A balanced electrolyte solution (10 ml/kg per hour) is started immediately after induction and is continued throughout the surgical procedure until the animal has recovered. Fluid levels may need to be increased, or whole blood, plasma, or colloids may need to be considered, depending on the degree of blood loss or hypotension. If the planned resection involves only intraoral tissues, clipping the patient's hair is either not necessary or minimally required. The exception would be when using the combined approach for dorsally located maxillary tumors (see total unilateral and caudal maxillectomy section below) where the muzzle on the surgical side should be clipped and prepped for surgery.[32]

Temporary unilateral or bilateral carotid artery occlusion has decreased blood volume loss and has improved visualization of the surgical field during maxillectomy.[33] This procedure can be considered but is not routine. After removal of the tissue to be excised, and if carotid artery ligation was performed, blood flow is reestablished to allow maximum circulation to the surgical site. The blood flow to the nasal cavity and palatal mucosa originates from terminal branches of the maxillary artery, the main continuation of the external carotid artery. Experimentally and clinically, the common carotid artery has been permanently occluded both unilaterally and bilaterally in dogs without causing neurologic or ischemic deficits.[33,34] This situation may not be true, however, in the cat.[35]

Positioning of the patient is critical to visualize the entire surgical field. In our experience, placement of the animal in dorsal recumbency with the mouth taped open provides the greatest exposure. The lower jaw, tongue, and endotracheal tube are taped to an anesthesia screen. Movement of the head should be restricted by adhesive tape (Figure 14-16). For more dorsally located tumors involving the maxillary and nasal bones, a combined intraoral and translabial approach can aid in resection exposure. In these cases, lateral or ipsilateral positioning and the placement of a mouth gag are preferred. The oral cavity is prepared by repeated flushing and swabbing with a 10% dilution of povidone iodine solution (Betadine, Purdue Frederick Co., Norwalk, CT). The surgical site is draped, with drapes applied to the mucocutaneous junction of the upper labia as well as to the lower jaw.

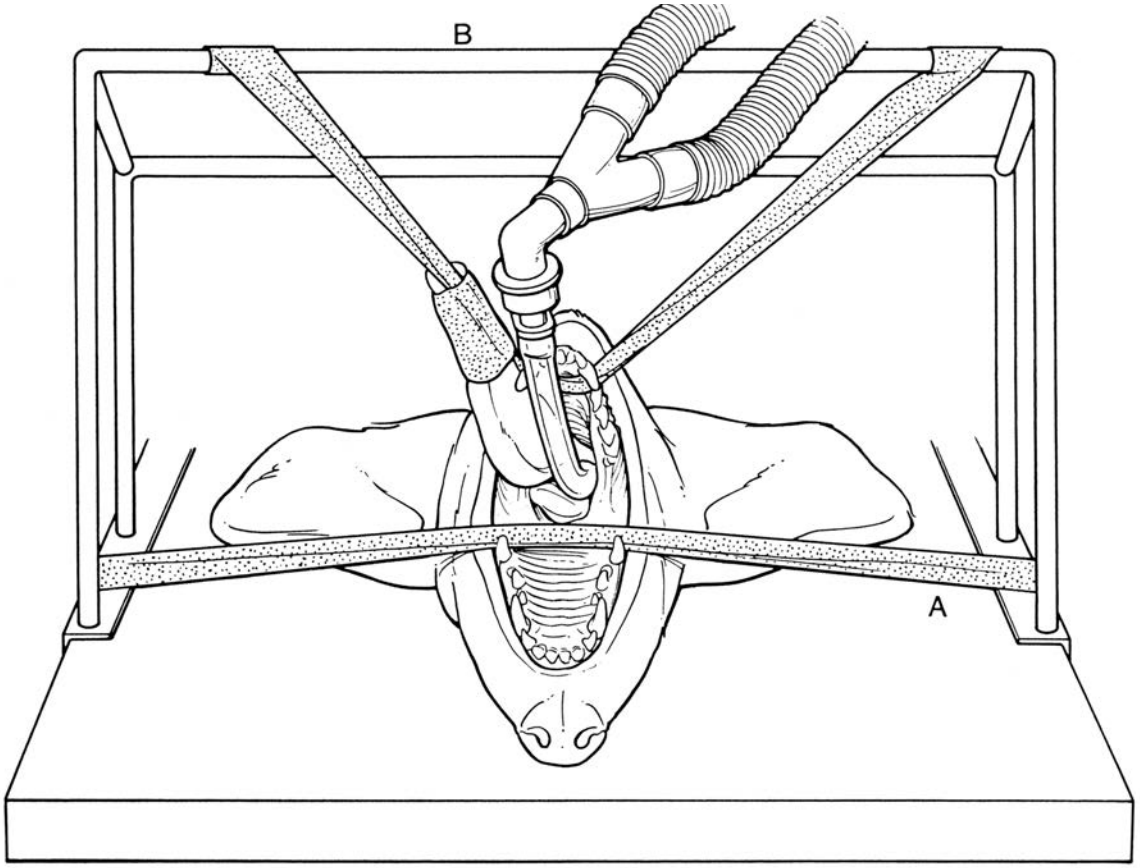

Figure 14-16. The dog is placed in dorsal recumbency with the upper jaw secured to the surgical table with adhesive tape *A.* The lower jaw, tongue, and endotracheal tube are suspended by tape from an anesthesia screen *B.* A gauze sponge has been placed in the caudal oropharynx to prevent passive aspiration.

Surgical Techniques

Unilateral Rostral Maxillectomy

Unilateral rostral maxillectomy is indicated for lesions that are located rostral to the second premolar and do not come up to or cross the midline. The labial and gingival mucosa rostral and lateral to the tumor is incised at least 1 cm from the gross margins of the lesion. The incision is continued through the hard palate mucosa caudal and medial to the lesion (Figure 14-17A). Hemorrhage from the hard palate mucosal incision generally is marked and requires ligation, electrocoagulation, and pressure to control. An oscillating bone saw or an osteotome and mallet may be used to cut the underlying bone following the mucosal incision lines. The surgeon should try to create curved bone margins, rather than square edges, to assist tissue apposition and healing. The incised segment of bone is freed of soft tissue attachments and is levered en bloc out of the surgical site. Branches of the major palatine artery may be visualized and require ligation. Nasal turbinates should be visible at this time. If tumor has penetrated the bone or if the turbinates are traumatized during the resection, they should be excised with a scalpel or scissors and submitted for histologic examination. Before closure, the surgical site is copiously lavaged with sterile physiologic saline.

The oronasal defect created is covered with a labial mucosal submucosal flap. The flap should be designed so sufficient tissue is obtained to cover the defect without tension. The flap should consist of mucosa, submucosa, and as much subcutaneous tissue as possible. The flap is elevated at the level of the dermis, is left attached at both ends, and is elevated only to the point that allows defect coverage without tension. The surgeon often can establish a tissue plane when undermining the labial mucosa and submucosa with Metzenbaum scissors (Figure 14-17B). Adequate blood supply and minimal tension are the critical factors for the survival of the mucosal-submucosal flap. The base of the pedicle must be of sufficient width to allow adequate vascularity to reach the tip of the flap.

The flap is sutured into position with a one layer or two layer closure. In a two layer closure, the first or deep layer consists of simple interrupted sutures placed from labial submucosal tissue to palatal submucosa or through holes predrilled in the bony hard palate. This deep layer is especially important for patients that are anticipated to undergo adjuvant radiation or chemotherapy, because of the effects on wound healing. The second or superficial layer consists of simple interrupted or continuous sutures that appose the palatal mucosa to the labial mucosa (Figure 14-17C). This superficial closure is used alone if a single layer closure technique is chosen. Undermining the palatal mucosa 2 to 3 mm may help in tissue apposition in this closure (Figure 14-18). If tension is encountered, additional undermining of the labial flap (toward the mucocutaneous junction) should first be attempted. If this does not relieve tension, mattress sutures can be placed in addition to the primary sutures.

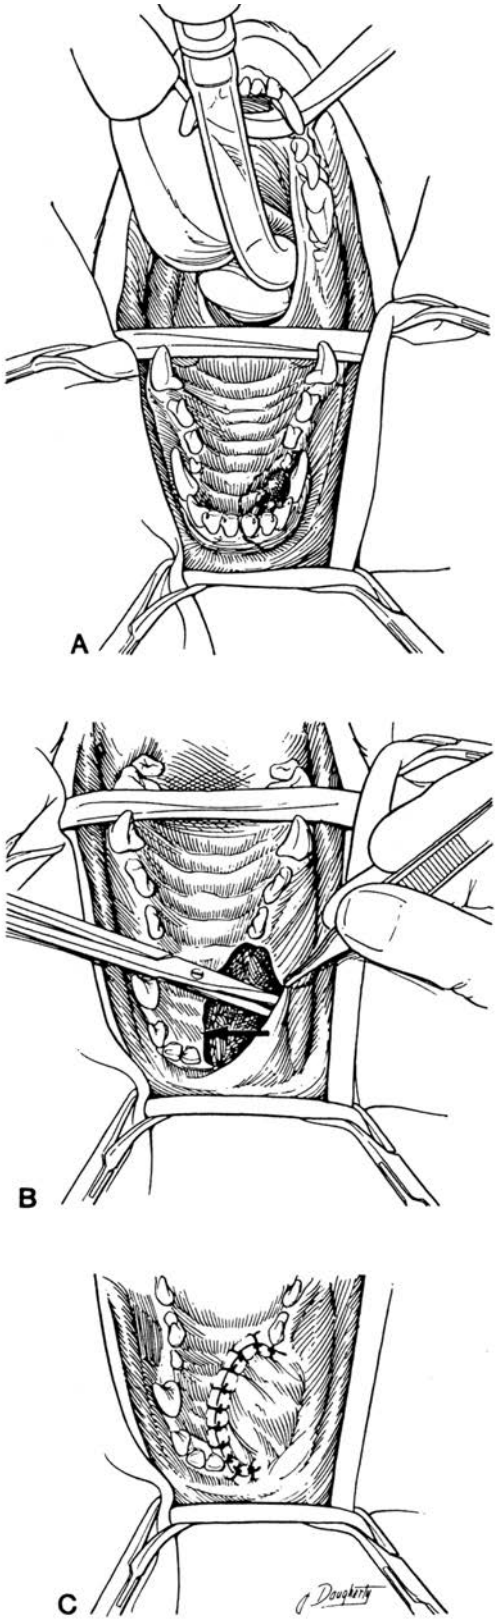

Figure 14-17. Unilateral rostral maxillectomy. **A.** Mucosal incision is indicated by the dotted line. **B.** Undermining the labial mucosa-submucosa for a lip margin based flap in which the mucosal surface faces the oral cavity. **C.** Simple interrupted or continuous closure of the mucosal flap.

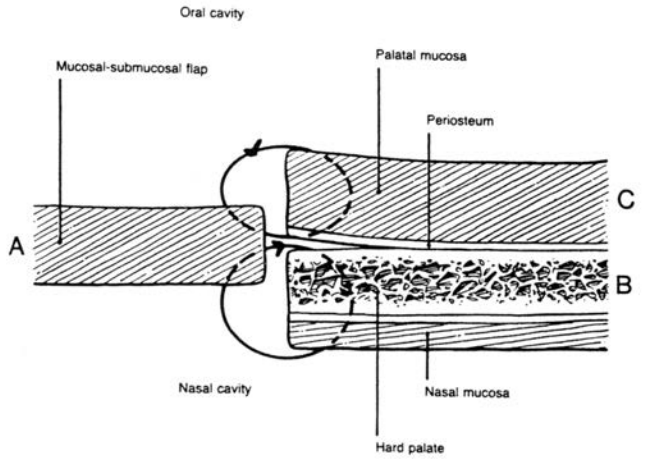

Figure 14-18. A two layer closure *A.* is used to position the mucosal submucosal flap over the defect created in a unilateral rostral maxillectomy. The first or deep layer *B.* consists of simple interrupted sutures placed from the submucosa through predrilled bone holes in the bony hard palate. The second or superficial layer *C.* consists of simple interrupted or continuous sutures opposing the labial mucosa to the mucoperiosteum of the hard palate.

Bilateral Rostral Maxillectomy

Bilateral rostral maxillectomy is indicated for lesions that come up to or cross the midline and are rostral to the second premolar. In essence, this procedure is similar to unilateral rostral maxillectomy, except the entire rostral bony floor of the nasal cavity is excised (Figure 14-19A). Resections rostral to the canine teeth will not result in any deformity of the nasal planum or bridge of the nose. Resections caudal to the canine teeth will at least result in a slight drop of the planum and a ventral sloping of the bridge of the nose. At this level, disruption of the nasal passages is rare. Resections more caudal than the immediate distal border of the canine teeth may result in sufficient soft tissue (ventral) deviation to disrupt normal air passage. In these cases, additional measures are needed to support the nose. The placement of dorsal supporting (tacking, imbricating or plication) sutures may be all that is necessary to support the tissues until fibrosis occurs. More rigid support in the form of an external splint (plastic or aluminum plate or rod) sutured to the soft tissues may also be effective. The combination of bilateral rostral maxillectomy or incisivectomy with nasal planum resection has been described for tumors affecting both the rostral maxilla and the planum.[13] This combination resection may be indicated for more caudally located maxillary tumors where resection will result in extensive loss of support of the soft tissues of the nose.

Closure is similar to that in the unilateral procedure, only performed bilaterally. Half the flap is undermined from each side of the maxillectomy defect (Figures 14-19B and C). Submucosa can be attached to predrilled bone holes in the hard palate (Figure 14-19D-F). The caudal half of each flap is sutured to the palatal mucosa from that side to the midline. The rostral halves are sutured together to form a T shaped closure. The labial mucosa is sutured to the palatal mucosa and the opposing labial mucosa using simple interrupted or simple continuous sutures (Figure 14-19G).

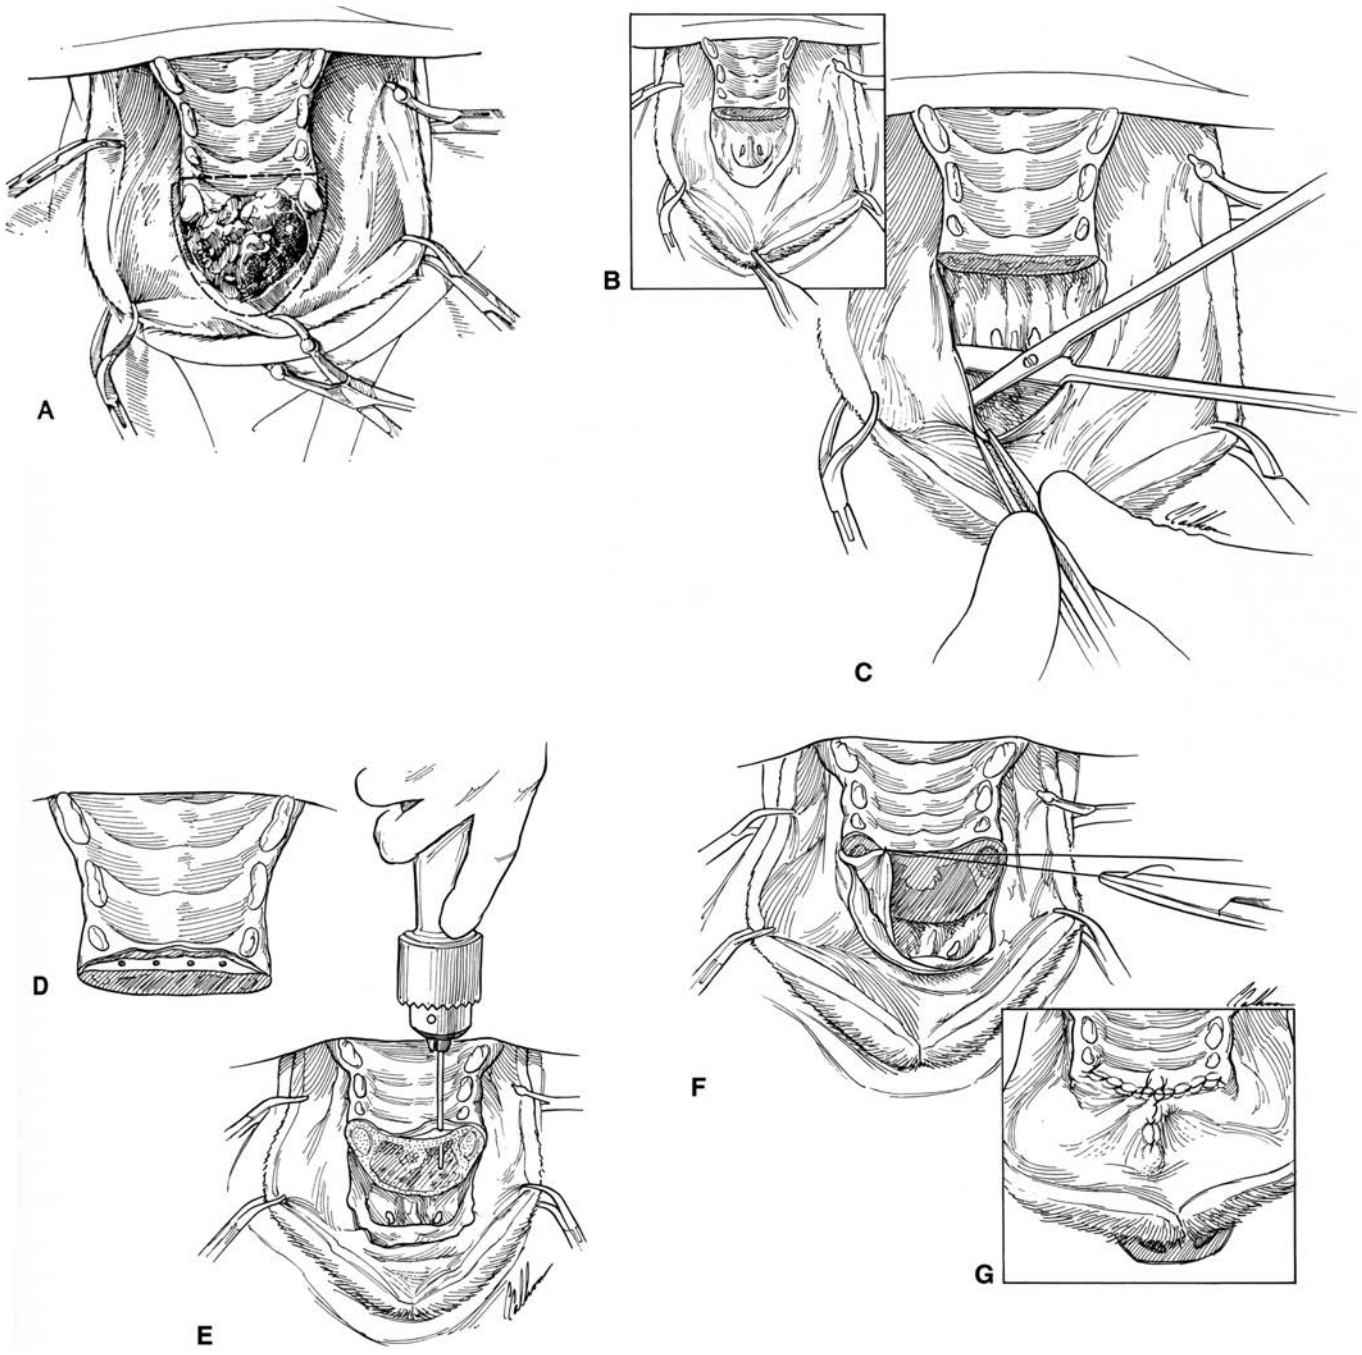

Figure 14-19. Bilateral rostral maxillectomy. **A.** The dotted line indicates the area to be excised. (Reprinted with permission from Withrow SJ, Nelson AW, Manley PA, et al. Premaxillectomy in the dog. J Am Anim Hosp Assoc 1985;2 1:50. **B.** The labial mucosa is incised perpendicular to the cut edge of the maxilla extending rostrally to the lip margin. **C.** Both sides of the labial mucosa are undermined deep to the submucosa and extending to the lip margins. **D** and **E.** Two to four bone holes can be placed in the rostral edge of the bony hard palate. **F.** Submucosa immediately under the mucosa is attached to the predrilled bone holes using preplaced simple interrupted sutures. **G.** Mucosal closure is completed by suturing half of the flap from each side to the mucoperiosteum of the hard palate and the remainder to the opposite side using simple interrupted or simple continuous sutures.

Total Unilateral Maxillectomy and Caudal Maxillectomy

The most aggressive of the maxillectomy procedures described here, total unilateral maxillectomy, is indicated for tumors that involve the majority of the hard palate on one side without crossing the midline. It involves removal of the oral mucosa, teeth, and portions of the incisive, maxillary, palatine, and zygomatic bones. The degree of resection is dictated by the size of the lesion, its location, the degree of tissue involvement, and the expected biologic behavior and grade of the tumor. Any portion of the maxilla can be excised unilaterally and still can result in normal function and acceptable cosmetics. Caudal maxillary resections can be combined with resections of portions of the inferior orbit, zygoma, or mandibular ramus, depending on the degree of tissue involvement (Figure 14-20).[15]

For the combined dorsolateral and intraoral approach utilized with total unilateral maxillectomy, the dorsal approach involves an incision made through the skin of the lip or muzzle at or above the dorsal aspect of the mass; this incision is made parallel to the lip margin. If there is a biopsy tract in the skin, the incision is carried around this tract to leave it attached to the specimen (as an island) to be resected. The skin and/or subcutaneous tissue are undermined dorsal to the mass, extending to the mucosal reflection dorsal to the dental arcade. Adequate soft tissue margins must be maintained around the tumor. The buccal mucosa is incised at this point to allow communication with the intraoral dissection (see below). This creates a bipedical skin/mucosal flap over the resection site, facilitating exposure.[32]

The mucosal incision is begun rostrally at the labial-gingival junction dorsal to the incisors and is continued lateral and caudal to the level of the last molar tooth. Medially, the incision begins between the central incisors and extends along the midline of the hard palate. The two incisions are joined together just caudal to the last molar tooth at the junction of the hard and soft palate (Figure 14-21A). Hemorrhage is often marked and is controlled with ligation, electrocautery, and pressure. An ostectomy is then performed along the incision lines with either an oscillating saw or an osteotome and mallet.

The caudal osseous incisions are at the rostral aspect of the zygomatic arch. The terminal branches of the maxillary artery are in this region and need to be identified and ligated. Once the ostectomy incisions are complete, the tissue to be resected is levered loose, soft tissue attachments are excised, and the section is removed intact from the surgical site. Exposed or transected vessels can be identified and ligated at this time. If temporary occlusion of the common carotid artery has been performed, blood flow should be reestablished to allow identification of transected vessels. When tumor penetrates the bone of the hard palate, the nasal turbinates, which overlie this area, should be excised with scissors or a scalpel and submitted for histopathologic examination. Turbinate hemorrhage can be controlled with a combination of ligation, electrocoagulation, and pressure. The use of mandibular symphysiotomy to facilitate exposure for caudal maxillectomy has been reported.[36]

A lip margin-based flap is created by undermining the labial mucosa and submucosa from the maxillectomy site toward the lip margin (Figure 14-21B). The mucosal-submucosal flap must be of adequate size and sufficiently undermined so it can be brought into apposition with the mucoperiosteum of the hard palate without tension. After thorough irrigation of the surgical site and confirmation of complete hemostasis, the labial mucosal-submucosal flap is sutured to the subperiosteally elevated edge of the hard palate mucoperiosteum with simple interrupted or

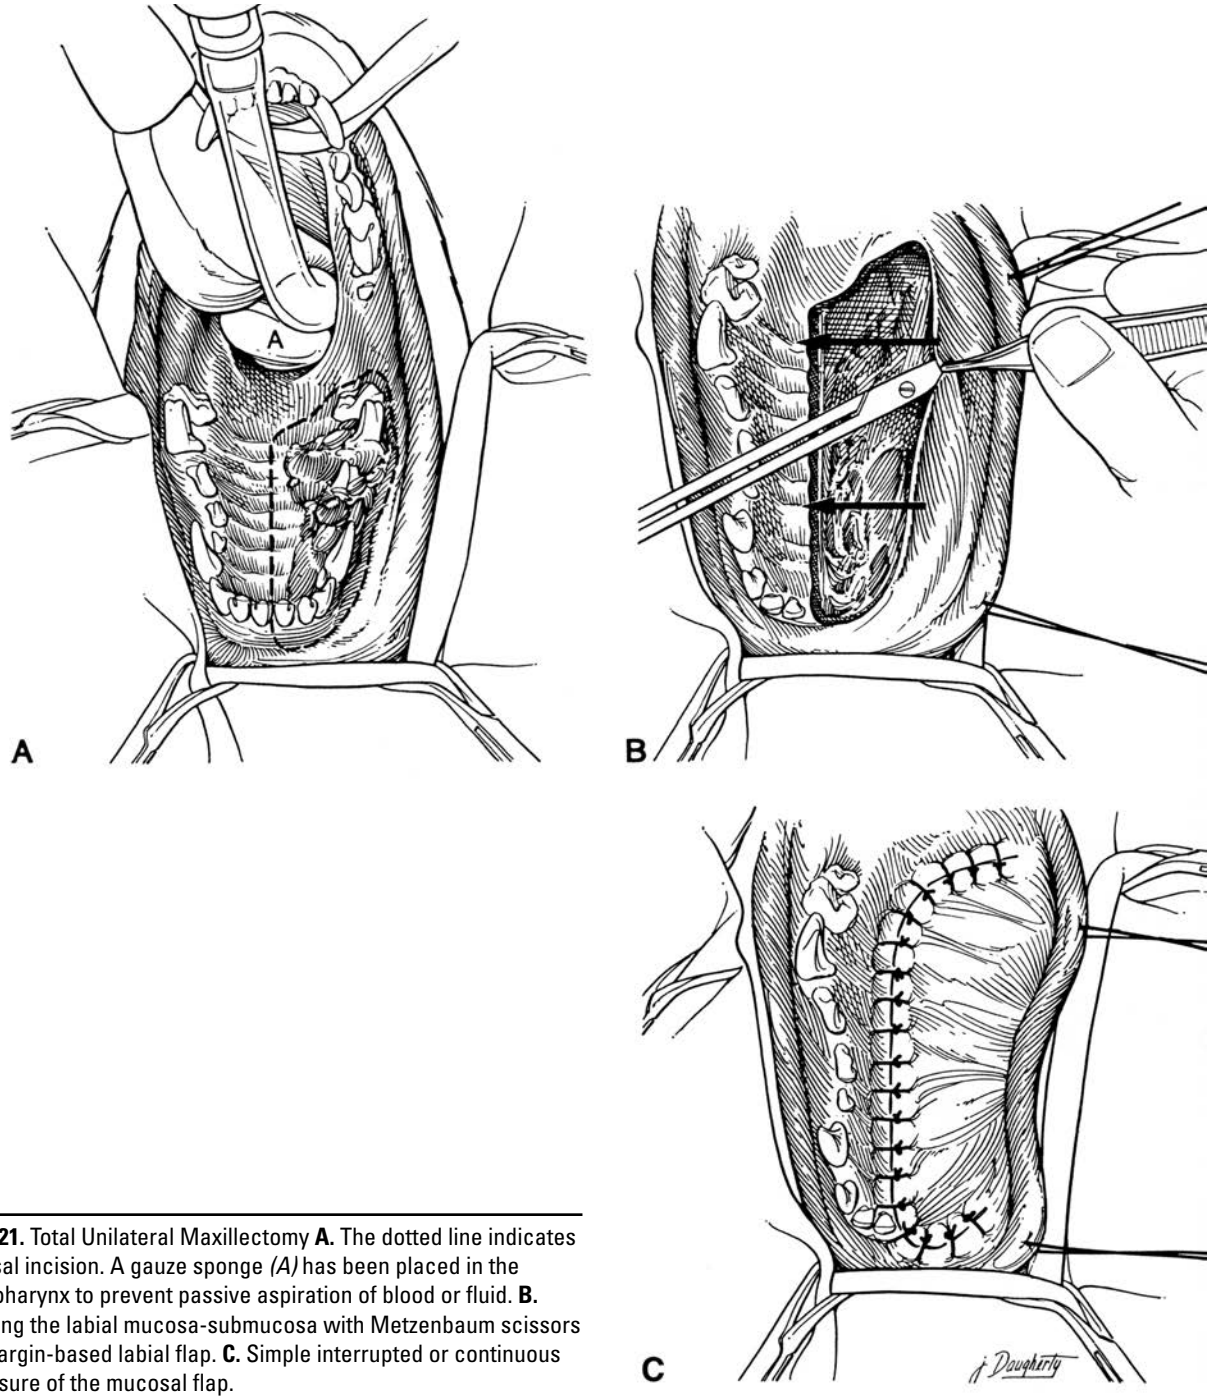

Figure 14-21. Total Unilateral Maxillectomy **A.** The dotted line indicates the mucosal incision. A gauze sponge *(A)* has been placed in the caudal oroharynx to prevent passive aspiration of blood or fluid. **B.** Undermining the labial mucosa-submucosa with Metzenbaum scissors for a lip margin-based labial flap. **C.** Simple interrupted or continuous suture closure of the mucosal flap.

simple continuous sutures (Figure 14-21C). If indicated, submucosal sutures can be placed through predrilled bone holes in the hard palate before closing the mucosal flap. The oropharynx is suctioned of blood before the animal is allowed to recover from anesthesia.

For cases with persistent, excessive blood loss from the nasal turbinates, placement of a Foley catheter can aid in control of hemorrhage. The tip of the catheter is placed through the external nares and passed along the ventral meatus to the site of the hemorrhage. The cuff is either inflated at the site of loss, or, if the site cannot be identified, it is inflated at the very caudal aspect of the nasal cavity. Inflation of the cuff directly over the site will apply pressure and assist in control of hemorrhage. Inflation of the cuff caudal to the site will force the blood loss out of the nasal cavity and allow better quantitative measurement. Without this, large volumes of blood can be swallowed by the patient after recovery masking the true volume of loss and preventing appropriate support. The Foley catheter can then be removed once hemorrhage has subsided. Another option is to pack the nasal cavity with gauze from a roll, exiting the end of the gauze from the external nares. Once hemorrhage subsides the gauze can then be carefully pulled. This may require heavy sedation or a short general anesthetic.

Postoperative Care and Sequelae

Because of the aggressiveness of maxillectomy procedures, the animal should be supported for the first 24 hours postoperatively

with parenteral fluids and analgesics. Close observation within a critical care unit is preferred, especially following larger resections. The use of continuous rate infusion narcotic agents will often result in smoother recovery and maintenance of pain control. An Elizabethan collar is often necessary to prevent self induced trauma to the surgical site. The patient is allowed water after recovery from anesthesia, and soft foods are offered 24 to 48 hours after surgery. Feeding small meatballs made from canned food for the first few days can assist the patient in prehending food and decrease messiness associated with eating immediately postoperatively. Pharyngostomy, esophagostomy, and gastrostomy tubes rarely are necessary in dogs. In the authors' experience, cats undergoing maxillectomy procedures are best supported by enteral feeding tubes during the immediate postoperative period.

The surgical site should be visualized for evidence of dehiscence and should be kept free of debris by flushing the mouth with water daily. Wound breakdown is the most significant postoperative complication after maxillectomy. Suture line tension, excessive use of electrocautery, ischemic necrosis of the mucosal submucosal flap, and tumor recurrence are the major causes of dehiscence. Except for tumor recurrence, most problems result from technical error by the surgeon and can be eliminated by following proper case selection and technique and by minimizing surgical trauma. If the sutures holding the flap in place break down after surgery, the animal should be reanesthetized and the flap resutured. At the time of resuturing, rebiopsy of the surgical site is always indicated; what appears to be granulation tissue can easily be residual tumor. Up to 33% of maxillectomy patients have some degree of dehiscence during the postoperative period.[13,37] Not all cases of dehiscence, however, are of clinical significance. Dehiscence is most commonly noted after caudal maxillectomy or total unilateral maxillectomy, when tumors cross the midline, and whenever mucosa has been sutured next to a tooth on the occlusal margin of the ostectomy. Tension free closure at the level of the ostectomy can be achieved by extracting an additional tooth, by elevating the palatal and labial gingiva, and by suturing the mucosal flaps over the alveolar bone. If dehiscence results in oronasal fistula formation, secondary closure should be attempted to avoid additional complications. Techniques for closure of oronasal fistulas are described in (See Chapter 14 on Repair of Oronasal Fistulas).

A concave deformity of the muzzle contour can occur after partial maxillectomy and repair with a labial mucosal-submucosal flap. Such indentation generally results from an insufficient amount of normal labial tissues. It generally can be corrected by incising the base of the labial flap 3 weeks after surgery to allow the lip to return to its normal position. This procedure is rarely indicated because function is generally unaffected by the lip indentation.

Recently, the development of a salivary mucocele following a caudal maxillectomy was reported. Initial clinical signs developed 15 days postoperatively, and included swelling of the left side of the face, exophthalmos, third eyelid protrusion and pain when the mouth was opened.[38] The most common complications following maxillectomy have been reported.[39]

In patients that undergo bilateral rostral maxillectomy, removal of the bony hard palate caudal to the canine teeth may shorten the nose. In some cases, the upper lip may actually be positioned caudal to the lower canines when the mouth is closed, especially if imbrication or plication sutures are used. Drooping of the nares and rostral muzzle also occurs when the mouth is open.

Follow up

Initial re-evaluation is recommended 7 days following maxillectomy. This is the time period where dehiscence is most common, therefore a thorough oral exam is indicated to evaluate for dehiscence or other complications. At the same time, sutures that have loosened and are causing irritation can be removed. Maxillectomies performed for excision of tumor should then be evaluated at 1 month and then every 3 months during the first postoperative year. Evaluations should include both visualization and palpation of the oral cavity, muzzle, and regional lymph nodes. Thoracic radiographs, depending on tumor type, may also be indicated for detection of distant metastasis. If gross evidence of local tumor recurrence or suspicious areas can be detected, an incisional biopsy should be performed. Skull radiographs or advanced imaging may be beneficial, but they are often difficult to evaluate, especially in the distinction of tumor and bony reactions resulting from surgical trauma. Complete surgical excision with adequate tumor free margins generally is difficult to obtain after documentation of local tumor recurrence. Chemotherapy and radiation therapy are alternative adjunctive therapies to consider in such cases.

Table 14-1 lists approximate reported local recurrence and median survival rates after maxillectomy for the major histopathologic tumor groups found in the dog.[1,3,13-16] A lack of reported cases in the cat precludes drawing any conclusions concerning survival rates.

Table 14-1. Approximate Reported Local Recurrence and Survival Data for Oral Tumors Treated with Maxillectomy

Tumor Type	Number	Local Recurrence (%)	Median Survival (months)
Acanthomatous epulis	10	10	26
Ameloblastoma	23	13	22
Malignant melanoma	40	40	8
Squamous cell carcinoma	16	31	18
Fibrosarcoma	35	46	12
Osteosarcoma	17	35	5

Mandibulectomy

William Culp, William S. Dernell and Stephen J. Withrow

Mandibulectomy

Mandibulectomy is the resection of variable sections of the mandible and closure of the surgical site with lingual and labial mucosa and submucosa. No replacement of bone or stabilization is required in most cases. Appearance, owner acceptance, and function are generally excellent after mandibulectomy.[1]

Six mandibular removal procedures have been described:[2-4] 1) unilateral rostral mandibulectomy (resection including three incisors, canine and first and second premolars); 2) bilateral rostral mandibulectomy (resection including all incisors, both canines and first and second premolars of both mandibles); 3) total unilateral mandibulectomy; 4) caudal mandibulectomy; 5) segmental horizontal body mandibulectomy; and 6) mandibular rim excision. Variations and combinations of these are used, depending on lesion type and location. Mandibulectomy can be combined with resections involving the maxilla and orbit, depending on the severity of disease.[4]

Indications

Mandibulectomy is performed for local control of oral neoplasia, for treatment of chronic mandibular osteomyelitis, and for salvage of patients with mandibular fractures with severe bone or soft tissue injury. Removal of oral tumors is the most common indication for mandibular resections. The oropharyngeal region is the fourth most common site of malignant neoplasia in the dog. The most common oropharyngeal neoplasms in the dog are malignant melanoma, squamous cell carcinoma, fibrosarcoma, and epulides or tumors arising from the periodontal ligament.[5-8] In the cat, squamous cell carcinoma is the most common oropharyngeal cancer, followed by fibrosarcoma, undifferentiated sarcoma, hemangiosarcoma, lymphoma, and osteogenic sarcoma. Malignant melanoma and epulides occur rarely in the cat.[8,9] Odontogenic tumors, such as inductive fibroameloblastoma, are the most common benign oral tumors in the cat.[10] Oropharyngeal tumors tend to be locally aggressive and slow to metastasize, except malignant melanoma, caudal tongue tumors,[11] and pharyngeal and tonsillar squamous cell carcinoma.[6-8] Without treatment, morbidity and mortality often result from local disease rather than from distant metastasis.

Control of local disease is the first goal of most surgical treatments for oral cancer. However, limited soft tissue excisions for attempted cure of oral tumors often fail because of recurrence of the tumor at the primary surgical site. Mandibulectomy accompanied by en bloc soft tissue resection for oral tumors has the potential for prolonged remission or cure in certain malignant diseases. If nothing else, the quality of life can be dramatically improved, even though distant metastasis may ultimately occur. Surgical resection should be considered as a first line of treatment for all oral neoplasms. Radiation therapy can be considered as primary treatment especially for tumors that show consistent responses to radiation, such as lymphoma, other round cell tumors and acanthomatous epulis. Radiation can be used in combination with surgical resection to improve local control where complete resection is not feasible or does not result in long term local control.[12]

Preoperative Evaluation

Routine hematologic and biochemical profiles, as well as urinalysis, should be performed on all candidates for mandibulectomy for anesthetic considerations and to identify any coexisting medical problems such as anemia. In cases of oral neoplasia, the tumor should be clinically staged according to the World Health Organization staging systems using the TNM (tumor, node, metastasis) classification, before definitive treatment is selected.[13] Staging requires an incisional biopsy while the patient is under general anesthesia (See Chapter 5), as well as analysis of a regional lymph node aspirates and thoracic radiographs to detect regional and distant metastasis. Preoperative staging helps to determine the appropriate treatment and prognosis and also helps the client to decide whether to pursue therapy. The evaluation of sentinel lymph nodes is increasing in popularity and new techniques are being developed that can better characterize the major draining lymph nodes or oral tumors.[14]

Imaging of the mandible taken while the patient is under general anesthesia should be obtained preoperatively in all cases of oral cancer. Radiographs should include lateral, ventrodorsal, and oblique views, as well as an open-mouth view if the tumor involves the rostral mandible. Fine detail screen with high-contrast film at low kilovolt potential is recommended. Advanced imaging modalities, such as computed tomography or magnetic resonance imaging, are often necessary for evaluation of tissue involvement and for planning surgical margins, especially for caudal lesions that involve the ramus and temporomandibular joint.[15] Patients with tumors that are adherent or "fixed" to the underlying mandible without radiographic evidence of invasion are still candidates for mandibulectomy since bone removal is often the only way to obtain (deep) normal tissue margins.

Boundaries for mandibulectomy for benign neoplasms with or without evidence of cortical bone penetration into the medullary cavity should be determined with image-guidance and by oral examination. Cortical bone penetration by malignant neoplasms with suspected bone marrow involvement is the main indication for total unilateral mandibulectomy versus segmental or rostral mandibulectomy. If tumor cells follow the neurovascular bundle within the medullary cavity of the mandible, the entire mandible (minimally, the mandibular body) must be removed to excise the tumor completely. This is especially important in patients with malignant melanoma, fibrosarcoma, and osteosarcoma.

Cases with disease that is invasive into labial or intramandibular skin may still be candidates for mandibulectomy. Various options for soft tissue reconstruction are available.[16] Such closure will likely result in haired skin lying within a portion of the oral cavity. This is generally well tolerated, however, increased salivation can be seen as well as mild dermatitis of the skin of the chin in these cases due to salivary soiling.

Mandibulectomy is also performed for treatment of chronic osteomyelitis or extensive bone or soft tissue injury. Often, these patients are presented in a debilitated condition. A gastrostomy tube can be placed to assist the anorectic preoperative and postoperative patient to maintain proper nutrition and hydration. Because most mandibular fractures are open fractures, broad spectrum antibiotics are recommended. The duration of antibiotic therapy depends on the type and severity of infection.

General Surgical Considerations

When mandibulectomy is performed for treatment of an oral neoplasm, at least a 1 cm, grossly visible, tumor free margin should be obtained on all cut surfaces. If bone change is evident on preoperative imaging, the removed section of mandible should be radiographed to aid in determining whether adequate bony disease-free surgical margins were obtained. Margins of interest (osteotomy edges and soft tissue margins) should be identified with India ink or other suitable marking system, or margins should be submitted in separate containers. This procedure aids the pathologist in determining the adequacy of mass removal (See Chapter 5). The entire specimen is then placed in 10% buffered formalin and is submitted for histopathologic evaluation. Tumor extension to the cut margins generally implies the need for additional surgery or adjuvant radiation.

Mandibulectomy is considered a contaminated or "dirty" surgical procedure. Therefore, therapeutic levels of antibiotics are indicated at the time of surgery. Parenteral prophylactic antibiotic therapy begun preoperatively or intraoperatively and continued for a maximum of 24 hours is recommended when osteomyelitis is not already established. The antibiotic chosen should be effective against the bacterial flora normally found in the oral cavity, including gram positive cocci (e.g., Staphylococcus sp. and Streptococcus sp.) and gram negative rods (e.g., Proteus and Pasteurella spp.). The first generation cephalosporins, penicillins, and synthetic penicillins are generally considered effective prophylactic oral antibiotics.[17]

In the author's experience, polydioxanone (PDS, Ethicon, Inc., Somerville, NJ), polyglactin 910 (coated Vicryl, Ethicon, Inc.), polyglycolic acid (Dexon, Davis and Geek, Inc., American Cyanamid Co., Manati, PR), and polyglyconate (Maxon, Davis and Geek, Inc.) sutures (3-0 or 4-0) are prefered for wound closure after mandibulectomy. These relatively nonreactive sutures minimize oral mucosal irritation and maintain adequate tensile strength during the critical early period of healing. Polydioxanone and polyglyconate have the advantages of being monofilament and absorbable. Their absorption is slower than polyglactin 910 and polyglycolic acid, however, and food can cling to the suture, or suture knots can be irritating, resulting in oral mucosal ulceration if the suture is not removed after healing. Although polyglactin 910 and polyglycolic acid are absorbable, they are braided suture materials and may increase the possibility of bacterial adherence or may result in a greater inflammatory response causing oral mucosal irritation. These latter two suture materials lose tensile strength sooner than the monofilament absorbables, a characteristic that should be considered if adjuvant radiation or chemotherapy may be administered postoperatively or if other patient factors exist that might result in delayed wound healing. The absorption rate of various suture materials has been evaluated in vivo for use in the oral cavity in cats.[18] A reverse cutting swaged on needle has been beneficial in suturing the tough, fibrous soft tissues of the oral cavity. This type of needle causes less surgical trauma when passed through tissues and provides better suture purchase into the soft tissues than other needle types.[19] Use of electrocautery should be kept to a minimum. Incisions within the oral cavity made with electrocautery are more likely to have delayed healing or to become dehiscent than incisions made with a scalpel.[2,20]

The choice of preanesthetic medication is based on the preoperative evaluation and on personal preference. A narcotic is often recommended for its analgesic effect. A local nerve block of the inferior alveolar nerve preoperatively or intraoperatively using a long acting local anesthetic may also decrease postoperative pain and may lower anesthetic requirements.[21,22]

After induction of anesthesia, an endotracheal tube should be inserted, and anesthesia should be maintained with a gas inhalant and oxygen. A cuffed endotracheal tube is mandatory to prevent passive aspiration of blood and fluid. Once the animal is positioned, prior to the start of surgery, inflation of the endotracheal tube cuff should be checked again, and upon recovery, extubation with the cuff partially inflated may assist in removal of blood that has accumulated in the oropharynx. The tube is anchored to the patient's muzzle to minimize its interference during surgery. Isotonic crystalloid fluid therapy is started immediately after induction at an initial dose of 10 ml/kg per hour. At times, hemorrhage is brisk, and the dose should be increased as dictated by the situation. Whole blood, plasma or colloids may be indicated, depending on the degree of blood loss. The patient is placed on a protected hot water blanket and is monitored at all times with a continuous electrocardiogram and preferably with either direct or indirect blood pressure measurements. Before the surgical procedure is begun, the cuffed endotracheal tube should be checked again to ensure that an airtight seal has been created with the trachea to prevent the aspiration of blood.

Depending on the type of mandibulectomy performed, the hair over the dorsal or ventral muzzle may or may not need to be clipped. Procedures done entirely through an intraoral approach usually do not require clipping. For procedures requiring caudal approaches, such as total unilateral mandibulectomy and caudal mandibulectomy, hair should be clipped in the region of the commisure of the lip caudally to the base of the ear. Clipped regions are routinely prepared for aseptic surgery. The oral cavity should be swabbed with a 10% dilution of povidone iodine solution (Betadine, Purdue Frederick Co., Norwalk, CT). A mouth speculum is placed between the teeth on the normal side to keep the mouth open to assist in exposure. The surgical area is draped as aseptically as possible.

Surgical Techniques

Unilateral Rostral Body Mandibulectomy

Tumors or injuries involving the incisors, lower canine, or first two premolars on one side are indications for unilateral rostral body

mandibulectomy. The soft tissues medial to this region must be free of tumor to obtain a tumor free margin and to allow for adequate soft tissues for closure (Figure 14-22A). A bilateral rostral body mandibulectomy should be considered if the medial soft tissue structures are involved or if an adequate tumor free margin cannot be obtained.

The animal is placed in lateral or dorsal recumbency with the affected mandible placed upwards. The labial mucosa is incised at a minimum of 1 cm outside the visible limits of the tumor (Figure 14-22B). The dissection is continued around the body of the mandible to the sublingual mucosa until the symphysis and the caudal limit of the proposed ostectomy are exposed (Figure 14-22C). The sublingual and mandibular salivary gland ducts open under the body of the tongue on the sublingual caruncle and are generally preserved. If excising this area is necessary, an attempt should be made to ligate these ducts.

After exposure of the symphysis, the tough fibrous joint is split with an osteotome and mallet or oscillating saw to separate the two mandibles (Figure 14-22D). If the tumor has crossed over or is adjacent to the symphysis, the rostral osteotomy should be directed eccentrically between the incisors or canine tooth on the opposite hemimandible to excise the symphyseal joint completely. Because the body of the mandible is dense and brittle, an oscillating saw or Gigli wire is used to make the caudal osteotomy. Tapering the osteotomy at the occlusal margin decreases suture line tension on the mucosal closure (Figure 14-22E). This may require the removal of an additional tooth. Hemorrhage from the mandibular medullary cavity is from the mental artery and vein and may be brisk. Bleeding is best controlled with ligation, however, cautery or bone wax can be used, especially in smaller dogs where the medullary canal is too small to access the vessels for ligation. Remaining portions of abnormal tooth roots should be removed. No attempt is made to stabilize the two mandibles together (Figure 14-22F).

An one layer simple interrupted or continuous suture closure of the sublingual mucosa to the labial mucosa attached to the skin is accomplished with 3-0 or 4-0 suture (Figure 14-22G). The areas with the highest incidence of dehiscence are at each end (rostral and caudal) of the incision line. The use of a single simple interrupted suture at these points, potentially encircling an adjacent tooth (passing the suture subgingivally beneath the tooth crown) can aid to decrease the incidence of dehiscence. These interrupted sutures are in addition to the remaining suture line. The hair of the skin is partially in the mouth, and care should be taken to prevent inversion of the suture line. In some cases, tumor may adhere to the skin, thus requiring its excision. In these patients, partial closure and allowing the defect to heal by second intention should result in a cosmetically acceptable appearance. Alternatively, direct closure of haired skin of the lip to sublingual mucosa can be performed. Increased salivation can be seen as well as mild dermatitis of the skin of the chin in these cases due to salivary soiling.

Bilateral Rostral Mandibulectomy

Bilateral rostral mandibulectomy is indicated for tumors or injuries that cross the midline rostral to the second premolar (Figure 14-23A). This procedure is commonly used in cancer patients because of the frequent soft tissue involvement of the opposite mandible. Even with unilateral disease, some patients function better with a bilateral resection. If the surgeon has any question about the extent of disease (crossing the midline or not), bilateral resection should be performed.

The patient can be placed in lateral, dorsal, or sternal recumbency. Dorsal recumbency affords the greatest exposure for dissection and osteotomy, whereas ventral recumbency affords the greatest exposure of the oral cavity for more difficult closures (Figure 14-23B). This procedure is similar to unilateral rostral mandibulectomy, except bilateral resection is performed. No attempt is made to stabilize the two mandibles together, although an experimental study showed rapid bony union and adequate patient tolerance of a combination of plating and implantation of bone graft or synthetic graft. Redundant skin may need to be removed before it is sutured to the sublingual mucosa during closure. This is easily accomplished by excising a V shaped wedge of skin with the apex located ventrally. The excision can be performed at the most rostral tip of the exposed skin or just lateral to this point. The location selected should be based first on location of the tumor and second on cosmetics. Any adherent skin overlying the tumor should be excised, to ensure a tumor free margin. During suturing of the labial mucosa to the sublingual mucosa, the surgeon should attempt to create a soft tissue ridge rostrally to help keep saliva in the mouth (Figure 14-23C). The hair of the skin may be partially in the mouth, but care should be taken to prevent inversion of the suture line. In some cases, tumor may adhere to the skin, thus requiring its excision. As with unilateral rostral mandibulectomy, partial closure and allowing the defect to heal by second intention should result in a cosmetically acceptable appearance. Alternatively, direct closure of haired skin of the lip to sublingual mucosa can be performed. Increased salivation can be seen as well as mild dermatitis of the skin of the chin in these cases due to salivary soiling.

Total Unilateral Mandibulectomy

Total unilateral mandibulectomy, the most aggressive form of mandibulectomy, entails removal of one mandible. The procedure is indicated for patients with tumors or injuries involving a large segment of the mandible or for those with tumors (e.g., malignant melanoma, fibrosarcoma, osteosarcoma) that appear to have penetrated the medullary cavity.

The patient is placed in lateral or ipsilateral recumbency, with the involved mandible placed upwards. The commissure of the lip is first incised at its midpoint, full thickness, to the rostral edge of the manibular ramus (Figure 14-24A). A modified incision, directed from the commissure to the coronoid process has been recently described that may improve exposure to deeper tissues.[23] The incision is then continued through the skin and the subcutaneous and fascial tissue to the level of the temporomandibular joint. Branches of the facial artery and vein are ligated or cauterized as necessary. The parotid duct is generally dorsal to this incision.

The labial mucosa is then incised, to ensure a visible 1 cm tumor free margin, beginning at the symphysis and extending caudally

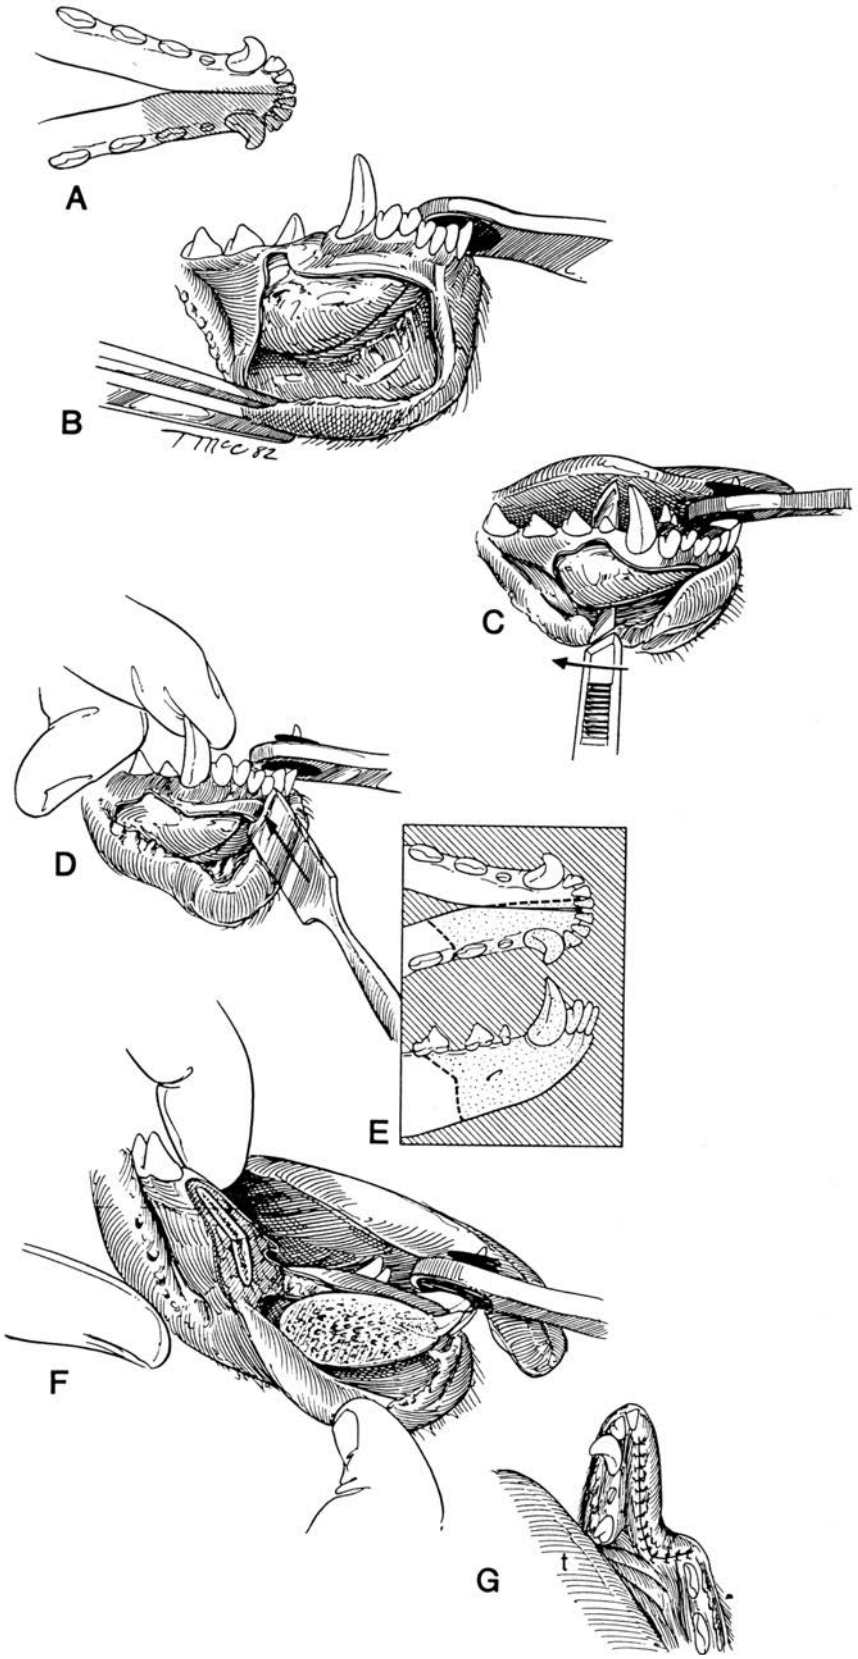

Figure 14-22. Unilateral rostral mandibulectomy. **A.** The shaded area represents the region of the mandible to be excised. **B.** The labial mucosa is incised and the rostral mandible is undermined to expose the symphysis and caudal limit of the proposed ostectomy. **C.** The sublingual attachments in the rostral intermandibular space are incised. **D.** An osteotome is used to split the symphysis. **E.** The dotted lines indicate the proposed osteotomy site for removal of the tumor adjacent to the symphysis. Note the eccentric osteotomy of the rostral mandible to include the symphysis and the tapered caudal osteotomy. **F.** Ostectomy site after unilateral rostral body mandibulectomy. Figure 14-23. Bilateral rostral mandibulectomy. **A.** The dotted line indicates the proposed ostectomy site for tumor excision. **B.** With the dog in sternal recumbency, the rostral lower jaw overhangs the surgical table and is taped to the table with adhesive tape. The upper jaw is taped to an anesthesia screen *(A)* along with the endotracheal tube. **C.** A soft tissue ridge or "dam" is created to help keep saliva in the mouth.

to the angle of the mandible (Figure 14-24B). The mandibular and sublingual ducts, if identifiable, are ligated at this time. The dissection is carried completely around the body of the mandible; the genioglossus, geniohyoideus, and mylohyoideus muscles are cut where they attach to the medial surface of the mandible. The sublingual mucosa is incised to free the lateral border of the tongue. As much mucosa as possible is saved to aid closure. Once the body is free of soft tissue attachments, the symphysis is cut with an osteotome and mallet or oscillating saw (Figure 14-24C). This technique allows free lateral movement of the affected mandible, enhancing visualization for caudal dissection.

For rostrally located masses with suspected bone marrow involvement, the body of the mandible can be resected at the rostral edge of the masseter muscle angling caudally toward the angular process, leaving the dorsal aspect of the mandibular ramus and the temporomandibular joint intact (Figure 14-24D). If this is performed, the surgeon can then move to closure (See Figure 14-25B and C).

If total unilateral mandibulectomy is performed, the masseter muscle is next sharply dissected off the ventrolateral surface and ventral margin of the ramus of the mandible and then is retracted dorsally and caudally (Figure 14-24E). The digastricus muscle is then incised at its insertion on the ventrocaudal border of the mandibular body (Figure 14-24F). With lateral retraction of the mandibular body, the pterygoideus muscles are incised where they insert medially on the ventrocaudal surface of the angle of the mandible (Figure 14-24G). Extreme care is necessary at this time to avoid accidental cutting of the inferior alveolar artery, a branch of the maxillary artery, before its identification and ligation. This vessel passes across the lateral surface of the medial pterygoideus muscle before entering the mandibular canal on the medial side. An attempt to ligate this vessel should be made in all patients, preferably prior to transection. The mandibular foramen is located ventromedial and just rostral to the border that extends between the angular and coronoid processes of the mandible. After the capsule of the temporomandibular joint is visualized and incised both medially and laterally, the joint is luxated (Figure 14-24H). This allows removal of the temporalis muscle as it inserts on the coronoid process of the mandible and of any remaining loose fascial attachments.

Closure is specific to each case, depending on the amount of soft tissue excised, but in all cases dead space must be closed, followed by mucosal apposition. A modification of the closure described below has been reported with similar cosmetic and functional outcome. The incidence of wound dehiscence was similar as well.[23] A three layer suture closure is recommended. The deep layer consists of opposing the pterygoideus, masseter, and temporalis muscles. The remaining closure sequence entails the stromal layer located below the mucosa followed by a mucosal layer. A continuous suture pattern works best in the mucosa to obtain a seal.

In the caudal third of the incision, the oral mucosa lateral to the base of the tongue and oropharynx is sutured to the mucosa of the soft or hard palate. In the middle third of the incision, the labial mucosa is sutured to the sublingual mucosa remaining lateral to the tongue. This is continued to the rostral edge of the commissure incision. Because removal of the entire mandible results in loss of lateral support for the tongue, lateral drifting of the tongue often occurs. Closing the commissure of the lip farther rostrally (than the original site) can help to maintain the normal position of the tongue. To do this, the margin of the upper lip, where it previously met the lower lip to form the commissure, is incised at full thickness along its margin to the level of the first premolar tooth (Figure 14-25A). A three layer suture closure consisting of mucosa, subcutaneous tissue, and skin is then performed (Figure 14-25B and C). Because of excess tension at the rostral extent of the suture line when the mouth is opened, a vertical mattress suture with buttons or a rubber stent may be considered. To complete the closure, the symphyseal oral mucosa is sutured to the lower labial mucosa, as described for a unilateral rostral mandibulectomy.

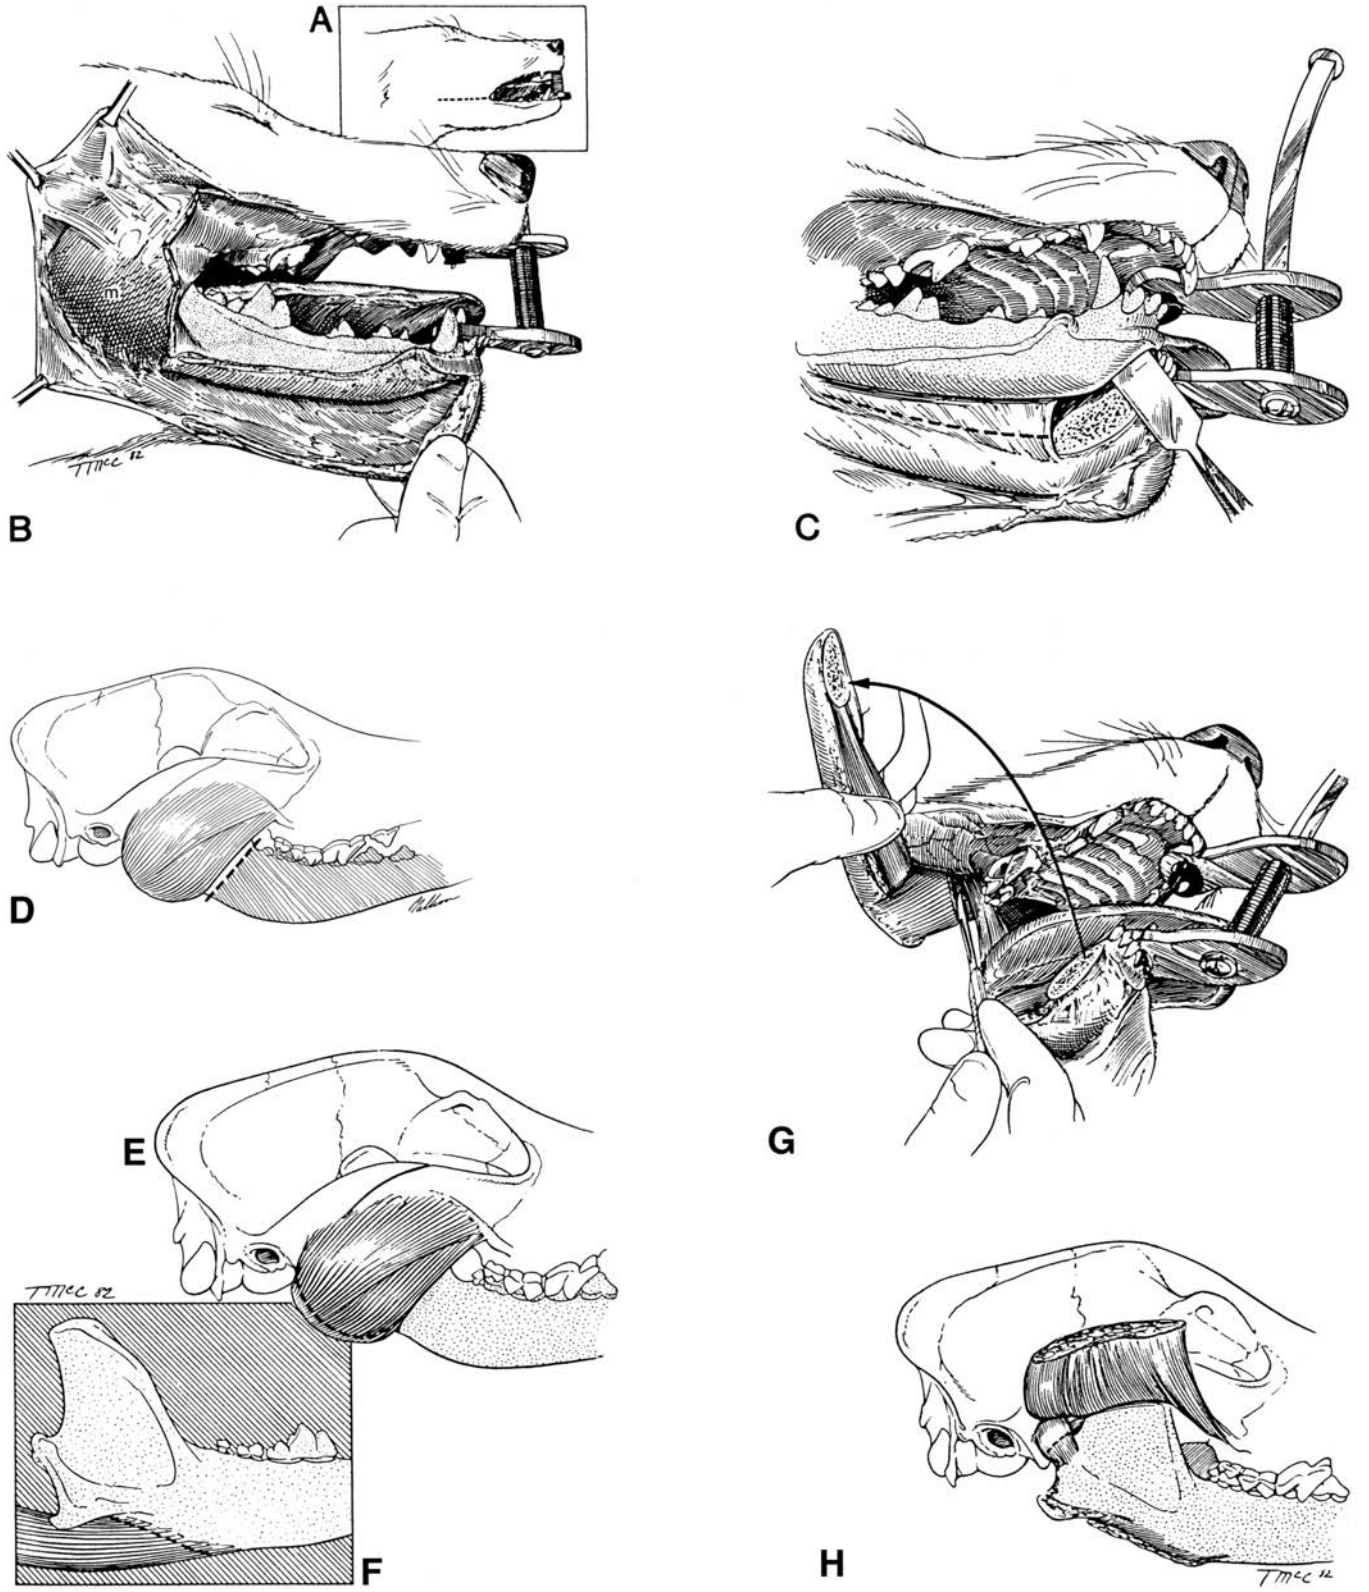

Figure 14-24. Total unilateral mandibulectomy. **A.** The dotted line indicates the skin incision. **B.** The labial mucosa is dissected free from the masseter muscle (m) and mandible, respectively, after being incised. The dotted area represents the area on the mandible involved by tumor. **C.** The symphysis is split with an osteotome. The dotted line represents the incision level for removal of the intramandibular muscles. **D.** The dotted line represents the level of resection for rostrally located tumors that involve the mandibular medullary cavity. The cavity ends at the level of the rostral attachment of the masseter muscle. **E.** The dotted line represents the masseter muscle incision. **F.** The attachment of the digastricus muscle. **G.** The pterygoideus muscles are incised medially. Care must be taken to avoid cutting the inferior alveolar artery before it is identified and ligated. **H.** The masseter muscle has been incised and elevated to expose the temporomandibular joint. Caudal Mandibulectomy

Caudal mandibulectomy (removal of part or all of the mandibular ramus) is indicated for tumors or injuries involving the angle, temporomandibular joint, or ramus of the mandible. This procedure is versatile enough to allow preservation of the temporomandibular joint or excision of the entire mandible caudal to the last molar. This procedure can be combined with resection of the zygoma or inferior orbit for lesions with more extensive tissue involvement.

The animal is placed in lateral recumbency with the affected side placed upwards. A curved skin incision is made over the length of the ventral aspect of the zygomatic arch (Figure 14-26A). Multiple small vessels are encountered, and several thin superficial muscles are incised as they cross lateral to the zygomatic arch. The periosteum is incised over the lateral surface of the zygomatic arch. With a periosteal elevator, the temporalis and masseter muscles are subperiosteally elevated off the dorsal and medial aspect and the ventral aspect, respectively, of the zygomatic arch (Figure 14-26B). Care should be taken not to injure the infraorbital artery, nerve, and vein as they course just medial to the zygomatic arch. Once the zygomatic arch is free of soft tissue attachments, it is cut with an oscillating saw or Gigli wire at its rostral and caudal margins (Figure 14-26C); an osteotome should not be used because it tends to shatter the hard, brittle bone of the zygomatic arch. Bleeding at the cut edges of the osteotomy site can be stopped with electrocautery or bone wax.

The masseter muscle is elevated ventrally off the lateral surface of the mandibular ramus. The temporalis muscle is similarly elevated off the medial and rostral aspect of the mandibular ramus. Care should be taken as the medial dissection is continued ventrally to avoid the inferior alveolar vessel. This vessel crosses the lateral surface of the medial pterygoideus muscle and enters the mandibular foramen located just rostral and ventral to the temporomandibular joint. If the temporomandibular joint is to be included in the excision, this vessel must be ligated and the medial pterygoideus muscle incised and elevated off the ventromedial aspect of the mandibular angle. The mandible is cut ventral and rostral to the involved bone with an oscillating saw or Gigli wire. Depending on the extent of the lesion to be removed, one may preserve the temporomandibular joint or include the joint in the excised bone (Figure 14-26D). At this point, the ramus can be easily removed by incising any loosely attached muscle and fascia; the temporomandibular joint is dislocated if necessary.

After copious lavage with physiologic saline, the muscle groups at the angle of the mandible are closed together to obliterate dead space. Replacing the osteotomized zygomatic arch is not necessary. The fascia of the masseter and temporalis muscles are then reattached to each other. Closure is completed with placement of subcutaneous and skin sutures.

Segmental Mandibulectomy

Segmental mandibulectomy is indicated for benign disease processes and for malignant tumors that do not penetrate cortical bone and are confined external to the cortex of the body between the first premolar and the last molar.

The animal is placed in lateral recumbency with the affected side placed upwards. The labial and lingual mucosa is incised 1 cm outside the visible limits of the tumor. Dissection is continued completely around the mandibular body until it is exposed for 360°. An oscillating saw or Gigli wire is then used to cut the mandibular body 1 cm rostral and caudal to the lesion. The dorsal aspect of the osteotomy should be angled away from the lesion (Figure 14-27A). Hemorrhage from the mandibular medullary cavity may be brisk. Bleeding is best controlled with ligation, however, cautery or bone wax can be used, especially in smaller dogs where the medullary canal is too small to access vessels for ligation. Normally, no attempt is made to replace the bony defect or stabilize the cut bone ends. Healing and eventual

stabilization is from fibrous tissue bridging the osteotomy gap. There have been reports of successful grafting or implant stabilization; additionally, the use of an osteoinductive factor (recombinant human bone morphogenetic protein-2) to stimulate bone formation has been described.[24,25] However, the vast majority of dogs function well with no effort made to fill the defect intra-operatively. There have also been reports of canine experimental models that have been used to assess bone regeneration in osteotomy sites using distraction techniques and a membrane barrier. Short and long term clinical effects and outcome have not been evaluated.[26] A one layer closure of sublingual mucosa to the remaining labial mucosa attached to the skin is accomplished with 3 0 or 4 0 suture material, similar to that used in unilateral rostral mandibulectomy (Figure 14-27B).

Mandibular Rim Excision

The mandibular rim excision procedure is a variation of a segmental mandibulectomy in that the ventral aspect of the mandible is not removed.[27] This procedure may prevent some of the postoperative complications noted in cases of segmental mandibulectomy (see below); however, the indications for this procedure are limited. Rim excision should only be considered in patients with very small tumors that are based on the occlusal surface and are not invading into the mandibular canal. Additionally, a preoperative CT scan is mandatory to assess these patients for disease that is more extensive than what can be palpated or seen grossly.

In general, patients are placed in sternal recumbency for a mandibular rim excision procedure and the surgical approach is similar to the segmental procedure except that 360° dissection is not necessary.[27] The ostectomy can be performed with an oscillating saw or burr; an attempt should be made to avoid the mandibular canal. While a right-angled rim excision can be performed, the curvilinear configuration is preferred.[27] At the

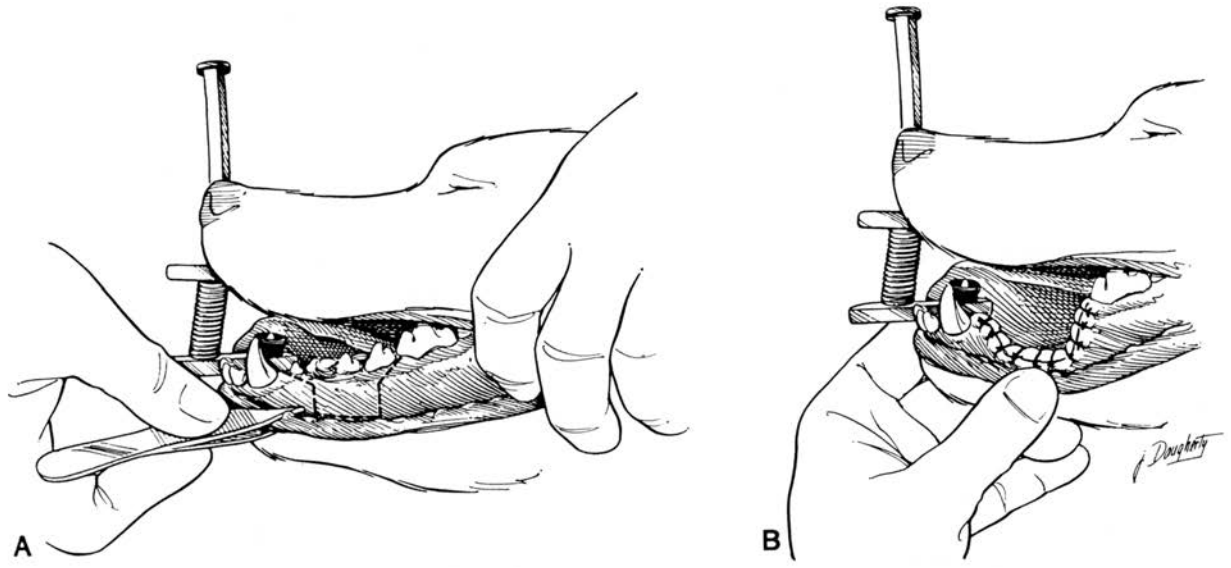

Figure 14-27. Segmental mandibulectomy. **A.** The dotted line indicates the proposed area to be excised. The osteotomies should be tapered away from the lesion on the occlusal surface to minimize suture line tension. **B.** Simple interrupted or simple continuous closure of mucosa.

completion of the ostectomy, the surgical site is flushed, and the adjacent gingiva is sutured over the bony defect using 3-0 or 4-0 monofilament suture material in a simple continuous pattern.[27]

Postoperative Care and Complications

Analgesics generally are indicated for the first 24 hours postoperatively, particularly after the more aggressive procedures (i.e., total unilateral mandibulectomy) Narcotic agents are often used in combination with non-steroidal anti-inflammatory drugs. A constant rate infusion of fentanyl can be considered. Maintenance parenteral fluids (20 ml/kg three times daily) also are recommended during this time. Antibiotics generally are not given for longer than 24 hours postoperatively. An Elizabethan collar should be placed on the patient as soon as it is sternally recumbent to prevent self induced trauma to the surgical site. The collar should be kept on the patient for the first 10-14 days.

Patients may have water and soft foods on the day after surgery for all types of mandibulectomy. Feeding small meatballs made from canned food for the first few days can assist the patient in prehending food and decrease messiness associated with eating immediately postoperatively. Most animals are able to maintain hydration and caloric intake by 24 to 48 hours postoperatively. Pharyngostomy, esophagostomy, or gastrostomy tubes are rarely necessary in dogs. The surgical site should be kept free of debris by flushing the mouth with water daily. After complete healing, return to the animal's normal diet is encouraged.

Complications are few after any type of mandibulectomy. Postoperative infection is rare unless a deep-seated infection was present at the time of surgery. The abundant blood supply to the oral cavity is a major reason for the low incidence of infection.

If dehiscence occurs at the surgery site, delaying closure for 7 to 10 days to allow better delineation of necrotic tissue and development of a healthy granulation bed is recommended. Dehiscence generally results from self induced trauma by the animal, excessive use of electrocautery, premature feeding of hard foods before adequate healing, or excessive tension at the suture line. Overall dehiscence rates are reported to be less than 13%.[28,29] Total unilateral mandibulectomy has the highest potential for dehiscence.

Excess tension is most often noted at the rostral extent of the cheiloplasty after total unilateral mandibulectomy or at the occlusal bone margin after unilateral and bilateral rostral mandibulectomy and segmental mandibulectomy. Tension free closure of the mucosal suture line at the level of the ostectomy can be achieved by angling the dorsal (occlusal) bone margin away from the lesion and by suturing the mucosa over the tapered bone. This may require extraction of an additional tooth. Drooping of the tongue to one side of the mouth can occur after total unilateral mandibulectomy if cheiloplasty is not performed or if the wound dehisces. Prehensile function of the tongue generally is normal, however.

If ostectomy is performed caudal to the second premolar bilaterally, loss of prehensile function and drooping of the tongue may occur after bilateral rostral mandibulectomy. This complication is a result of loss of support to the base of the tongue. In our experience, most animals regain complete control of tongue function in time. The owners and veterinarian must be willing to hand feed these animals during the recovery period. Different types of food should be tried (i.e., soft or hard), and a compliant and persistent owner is required. Oral feeding should be encouraged to allow the animal to adapt and develop a "new" prehensile function of the tongue.

After total unilateral mandibulectomy, edema or a "false" ranula may develop at the lateral base of the tongue on the surgically treated side. This condition is self limiting and generally disappears within 7 days. Removal of the sublingual and mandibular salivary glands is not necessary for resolution of this condition. Ligation or surgical trauma and inflammation with occlusion of the ducts of these glands at the time of surgery lead to atrophy of the glands.

The only common long term common complication of mandlibulectomy is shifting of the lower jaw toward the operated side. This shift results from loss of a portion of the mandibular support at either the temporomandibular joint or the symphyseal region. The malocclusion that results generally is clinically insignificant. Occasionally, filing down the top 20% of the remaining lower canine tooth may be necessary because of chronic irritation and ulceration of the hard palate mucosa. Mandibular drift can be more of a problem in cats. Extended nutritional support is often indicated for more extensive resections in cats. The most common complications following mandibulectomy have been reported.[30]

Follow up

Initial re-evaluation is recommended 7 days following mandibulectomy. This is the time period where dehiscence is most common, therefore a thorough oral exam is indicated to evaluate for dehiscence or other complications. At the same time, sutures that have loosened and are causing irritation can be removed. When mandibulectomy is performed for tumor excision, periodic checks should be then be performed at 1, 3, 6, 9, and 12 months. The animal should be evaluated for local tumor recurrence, nodal and distant metastasis. When the surgical margins of either the histologic sections or the postoperative radiographs suggest an incomplete or close surgical margin, more frequent rechecks are recommended. Less frequent rechecks are required when mandibulectomy is performed for treatment of benign neoplasia, chronic mandibular osteomyelitis or mandibular fractures.

Table 14-2 lists approximate recurrence and median survival rates reported for dogs undergoing mandibulectomy for oral tumors. In a series of 42 cats undergoing mandibulectomy, recurrence and survival rates at 1 and 2 years were 56% and 49%, 60% and 57%, respectively.[29]

Table 14-2. Approximate Reported Local Recurrence and Survival Data for Oral Tumors Treated by Mandibulectomy

Tumor Type	Number	Local Recurrence (%)	Median Survival (months)
Acanthomatous epulis	47	0	28
Ameloblastoma	44	22	19
Malignant melanoma	75	13	8
Squamous cell carcinoma	73	7	9
Fibrosarcoma	53	34	11
Osteosarcoma	64	16	13

Tongue, Lip, and Cheek Surgery

Laura D. Dvorak and Earl F. Calfee, III

Tongue

In dogs and cats the tongue is a muscular organ that assists in food prehension, mastication, swallowing, taste, thermoregulation, vocalization, and grooming. Most of the tongue is skeletal muscle consisting of the genioglossus and geniohyoid muscles. Indications for partial excision of the tongue include congenital anomalies (macroglossia), glossitis, traumatic injuries (lacerations, ulcerations and burns, chronic linear foreign bodies, and electrical injuries), hyperplastic lesions, and neoplasia. Neoplastic lesions of the tongue are rare and account for only 4% of all oropharyngeal tumors in dogs.[1] Glossectomy includes partial glossectomy (amputation of any portion or all of the free tongue rostral to the frenulum), subtotal glossectomy (amputation of all of the free tongue and a portion of the genioglossus muscle, geniohyoid muscle, or both, caudal to the frenulum), near total glossectomy (resection of 75% or greater of the entire tongue), and total glossectomy.[2]

General Surgical Considerations

Preoperative evaluation of patients with glossal disease should include a complete physical examination, complete blood count (CBC), and serum biochemical profile. Three-view thoracic radiographs, skull radiographs, computed tomographic scans, magnetic resonance imaging, and evaluation of associated lymph nodes by fine needle aspiration or surgical biopsy may be indicated for patients with potential neoplastic lesions. Incisional biopsy of tongue lesions not caused by trauma is strongly recommended to obtain an accurate preoperative diagnosis so that a therapeutic plan and accurate prognosis may be determined. Other diagnostic tests may be indicated to establish the overall general health of the patient, especially geriatric animals prior to anesthesia.

Food should be withheld for 12 hours prior to the surgical procedure. Rapid anesthetic induction and intubation are recommended for oral surgery. Intubation by temporary tracheostomy or pharyngeal intubation may be required depending upon lesion location to allow adequate surgical exposure and manipulation of the tongue. The cuff of the endotracheal tube should be properly inflated to prevent aspiration of blood and lavage fluid during the surgical procedure. The oral cavity should be lavaged to remove any particulate material prior to aseptic preparation. The head should be positioned appropriately for the procedure being performed. Sternal or lateral recumbency is preferred for most glossectomies. Dilute povidine–iodine soap scrub can be used in a three scrub cycle for preparation of the surgical area. Chlorohexidine scrub or solution should not be used on the face to prevent contact with the eyes. The head is draped appropriately for the surgical procedure being performed.

The tongue has an extensive vascular supply and profuse bleeding is commonly encountered and expected during lingual surgery. Hemorrhage can be controlled by use of electrosurgery, lasers, temporary occlusion of the carotid arteries, and

accurate suture placment.[3] All surgery involving the oral cavity is considered contaminated due to the wide variety of microorganisms present in the normal microflora however, systemic antibiotics are generally not indicated due to the tongue's vascularity, the antibacterial properties of saliva, and the presence of immunoreactive cells in the connective tissues.[4] Healing of the tongue is rapid and absorbable monofilament suture such as monocryl or PDS (poliglecaprone 25 or polydioxanone) promotes uncomplicated healing.

Depending on the extent of the surgical procedure being performed, alternative feeding methods may be indicated to provide adequate nutrition post operatively. Animals may be unwilling to eat or the oral cavity and surgical site may be bypassed to promote normal tissue healing. Percutaneously placed esophagostomy and gastrostomy tubes can be easily placed at the time of the glossectomy and maintained until the patient is able to return to oral alimentation (See Chapter 6). We recommend placement of feeding tubes in all patients undergoing major glossectomies (subtotal, near-total, and total). Most dogs will rapidly return to oral alimentation following partial glossectomy.

Surgical Techniques

Partial Glossectomy

A wedge glossectomy can be used to excise lateral lesions of the tongue. Stay sutures can be placed within the tongue to provide traction and improve the surgeon's visualization of the lesion. Pre-placement of wide through and through simple interrupted sutures beyond the line of excision provides rapid hemostasis and tissue apposition. These sutures should be 5 to 10 mm away from the proposed incision line. Full thickness resection of the tissue wedge is performed with a scalpel blade, electrocautery, or laser and the preplaced interrupted sutures are tied. Single interrupted sutures should then be placed between the preplaced sutures to appose the mucosal edges at the incision. A continuous suture pattern can also be used for mucosal apposition. The surgeon should be aware that large wedge excisions will result in lateral deviation of the tongue which may be clinically significant.

A partial transverse or hemi-glossectomy is used for unilateral disease that requires more tissue excision than is possible with a wedge glossectomy (Figures 14-28A and B). Pre-placement of horizontal mattress sutures 5 to 10 mm away from the caudal incision line, 5 to 10 mm apart, aids in providing hemostasis. The lingual artery should be dissected and ligated. The midline incision should be performed along the raphe. Mucosal apposition is achieved with simple interrupted absorbable sutures or a simple continuous suture pattern of polydioxanone or polyglicaprone. A complete transverse glossectomy is used to excise rostral disease that crosses the raphe. The recommended technique is similar to that required for partial transverse glossectomy. The frenulum, if involved in the incision, should be reattached ventrally with mattress sutures.

Subtotal and Near Total Glossectomy

Subtotal glossectomy involves excision of the entire free tongue and a portion of the genioglossus, the geniohyoid muscles, or both, caudal to the frenulum. A near total glossectomy refers to resection of at least 75% of the entire tongue.[2] The principles

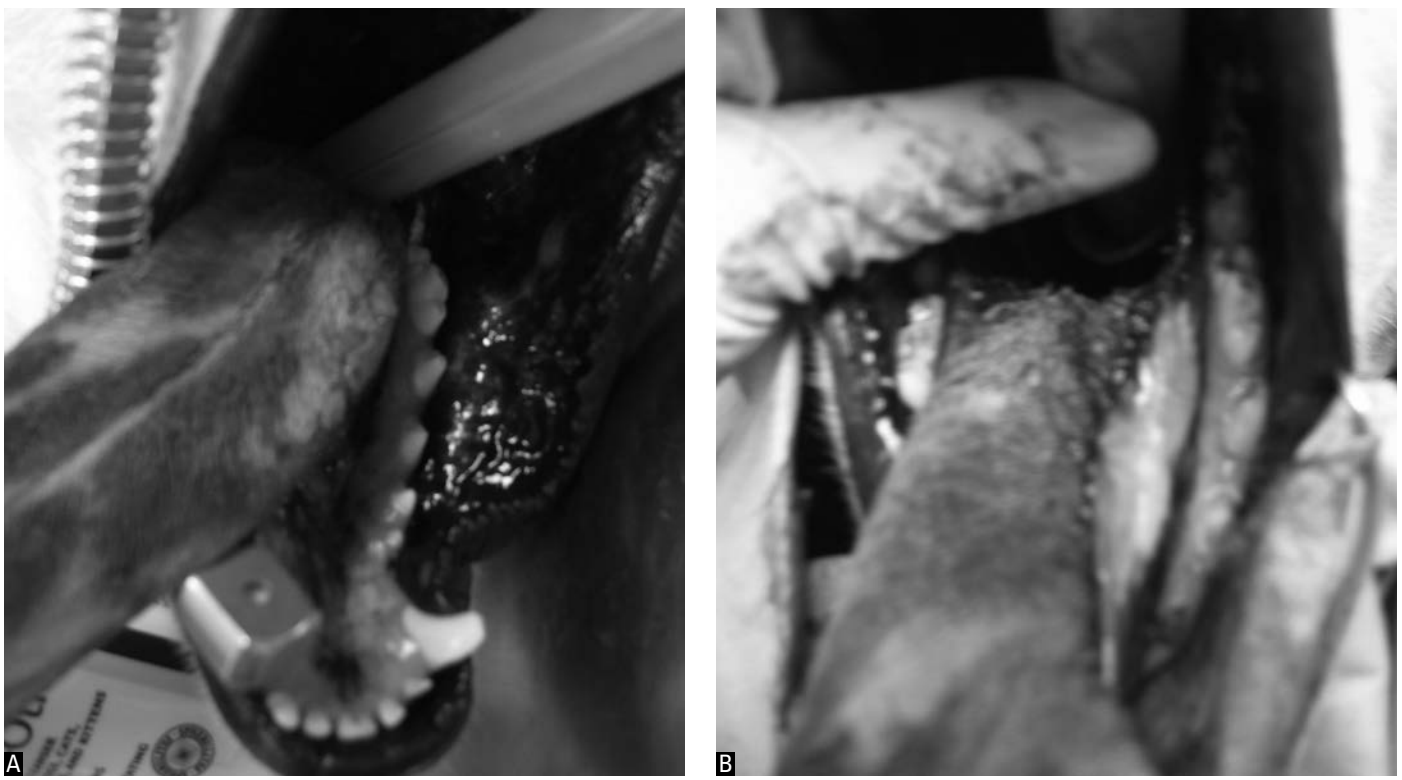

Figure 14-28. A. Preoperative view of a squamous cell carcinoma on the caudolateral aspect of the tongue of an 8-year-old castrated male mixed breed dog. **B.** Postoperative view of the tongue identified in Figure 14-29A, after partial glossectomy.

of hemorrhage control and mucosal apposition described for partial glossectomy should be followed for subtotal and near total glossectomies. Sutures are preplaced through the body of the tongue and the lingual arteries dissected and ligated to prevent excess hemorrhage. Mucosal apposition can be performed with either a simple interrupted or a simple continuous suture pattern using monofilament absorbable suture. Any remaining frenulum should be reattached ventrally to the tongue with mattress sutures (Figure 14-29).

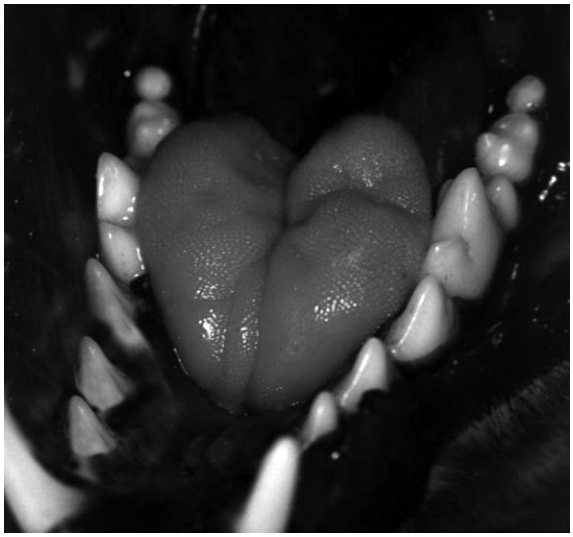

Figure 14-29. Gross appearance of a 5-year-old castrated male Schnauzer 2 years after subtotal glossectomy for chronic glossitis.

Total Glossectomy

A total glossectomy involves amputation or excision of the entire tongue. The only remaining tissue in these cases is the mucosa lining the ventral mandibular floor. If possible this mucosa should be apposed with a simple continuous suture pattern. Hemorrhage should be controlled by ligation of all bleeding vessels, especially the lingual arteries. Dogs are able to learn glutition without a tongue however self-grooming is impossible thus owners should regularly groom the animal to maintain the animal's hair coat.

Postoperative Care and Complications

Analgesics and parenteral fluids are indicated for the first 24 hours postoperatively. The duration of analgesic and fluid therapy depends upon the extent of glossectomy. Antibiotics, if administered are indicated for 24 hours after the surgical procedure and then discontinued unless treating bacterial glossitis. An Elizabethan collar or basket muzzle is often necessary to prevent self-induced trauma to the surgical site. Food and water should not be offered for the first 12 to 24 hours after the procedure. For patients with an esophagostomy or PEG tube, feedings can begin as soon as possible based on tube placement. Patients undergoing major glossectomies (subtotal, near-total, and total glossectomies) may require training to be able to eat effectively orally. Previous reports suggest that chilled meatballs formed from canned dog food can be used to teach the patient how to pick-up the food and move it to the back of their mouths. The patient's muzzle may need to be elevated once the meatball is placed in their mouth to assist in food prehension and swallowing. Once the patient has learned how to pick up and swallow a meatball on their own, they can be encouraged to drink water by placing the meatball in a bowl of water. This will allow them to adapt to having their muzzles under water. Many dogs in previous case reports ultimately learned how to suck in water like a vacuum.[2] Cats are likely to have greater difficulty with prehension following glossectomy and will often require long-term or permanent assisted feeding with a feeding tube.

The surgical incision closure should be monitored for evidence of dehiscence and should be kept clean of food and debris by rinsing the mouth with water daily. Healing of the tongue is generally rapid due to its extensive vascularity. Lateral deformation of the tongue can occur with partial glossectomies, especially wedge recession. Hyperptyalism is a commonly reported complication in human glossectomy patients and has been reported in canine glossectomy patients but the incidence remains unknown.[2,5,6] Complications related to esophagostomy and PEG tubes are a potential and are described elsewhere.

Lip and Cheek

The lips and cheek have an extensive vascular supply with significant collateral circulation. Arterial blood supply to the maxillary lip and cheek is provided by the infraorbital artery which is a direct branch of the maxillary artery. The mandibular lip and cheek are supplied by the mandibular alveolar and facial arteries. This rich blood supply can be used to construct broad based mucogingival advancement or rotation flaps for reconstruction of defects associated with the maxillary and mandibular arcade. These flaps are often required to close defects created following surgical excision of oral tumors and repair of congenital or traumatic defects.[7]

Anatomy

The lips form the rostral and lateral boundaries of the vestibule. The mandibular and maxillary labia meet caudally at an angle, forming the commisure. The philtrum is the deep cleft at the rostral midline union of the maxillary labia. The mandibular labia have firm attachments of the buccal mucosa between the mandibular canine and first premolar. This interdental attachment maintains the position of the mandibular labia and prevents sagging.[8] The cheeks are histologically similar to the lips and are continuous with them. Both have two epithelial surfaces, an outer dermis and an inner mucosa. Between these two layers are two thin muscles, the outer orbicularis oris muscle and the inner buccinator muscle.[8] Other cheek muscles include the platysma, mental buccinator, zygomatic, canine, nasolabial and incisive muscles.[9] Innervation is provided by the facial nerve (motor) and trigeminal nerve (sensory).[9]

Surgical Techniques

Limited information exists in the veterinary literature regarding surgical procedures of the lips and cheek. Information is available regarding surgical treatment of traumatic lip avulsions, reconstructive procedures for maintenance of the lip margin following tumor excision, correction of "tight lip syndrome" in Shar Pei's, anti-drool procedures (cheiloplasty), tissue excision for lip fold dermatitis, surgical correction of dental arcade mucoperiosteal

defects, reconstructive procedures of the eyelid margins and surgical repair of primary cleft palates.

Lip avulsion injuries are generally associated with the rostral mandibular lip and are the result of a shearing injury. Shearing force causes avulsion of the gingival mucosa from its area of insertion on the rostral mandibles just ventral to the incisors. Surgical correction of lip avulsion involves debridement of any devitalized tissue and reattachment of the mandibular skin at the gingival line of the incisors. This can be accomplished by taking large bites of tissue from the avulsed lip with polydioxanone suture and subsequent passage of the suture through holes drilled in the rostral mandible or by encircling the mandibular incisors. Because of the rich blood supply, tissue healing is generally uncomplicated provided appropriate surgical debridement is performed prior to reattachment of the lip.

Lip Margin Reconstruction

Several techniques exist for excision of lip neoplastic lesions and for closure of the resulting defects. In all cases, the mucosa should be anatomically apposed if possible to assure proper cosmetic alignment of the lip. This alignment should be achieved without undue tension on the suture line so that normal function of the jaw is maintained. Full-thickness triangular or wedge resection of the lip allows realignment of the mucosal and lip edges however, the tissue margins obtained with this excision may be inadequate for malignant neoplasms. Full-thickness square or rectangular resection can be performed to obtain a wider tissue margin. The defect created with this technique can be closed in a "Y" fashion or with a full-thickness labial advancement flap (Figures 14-30A-D). Labial advancement or rotational flaps can be mobilized from either the upper or lower lips.

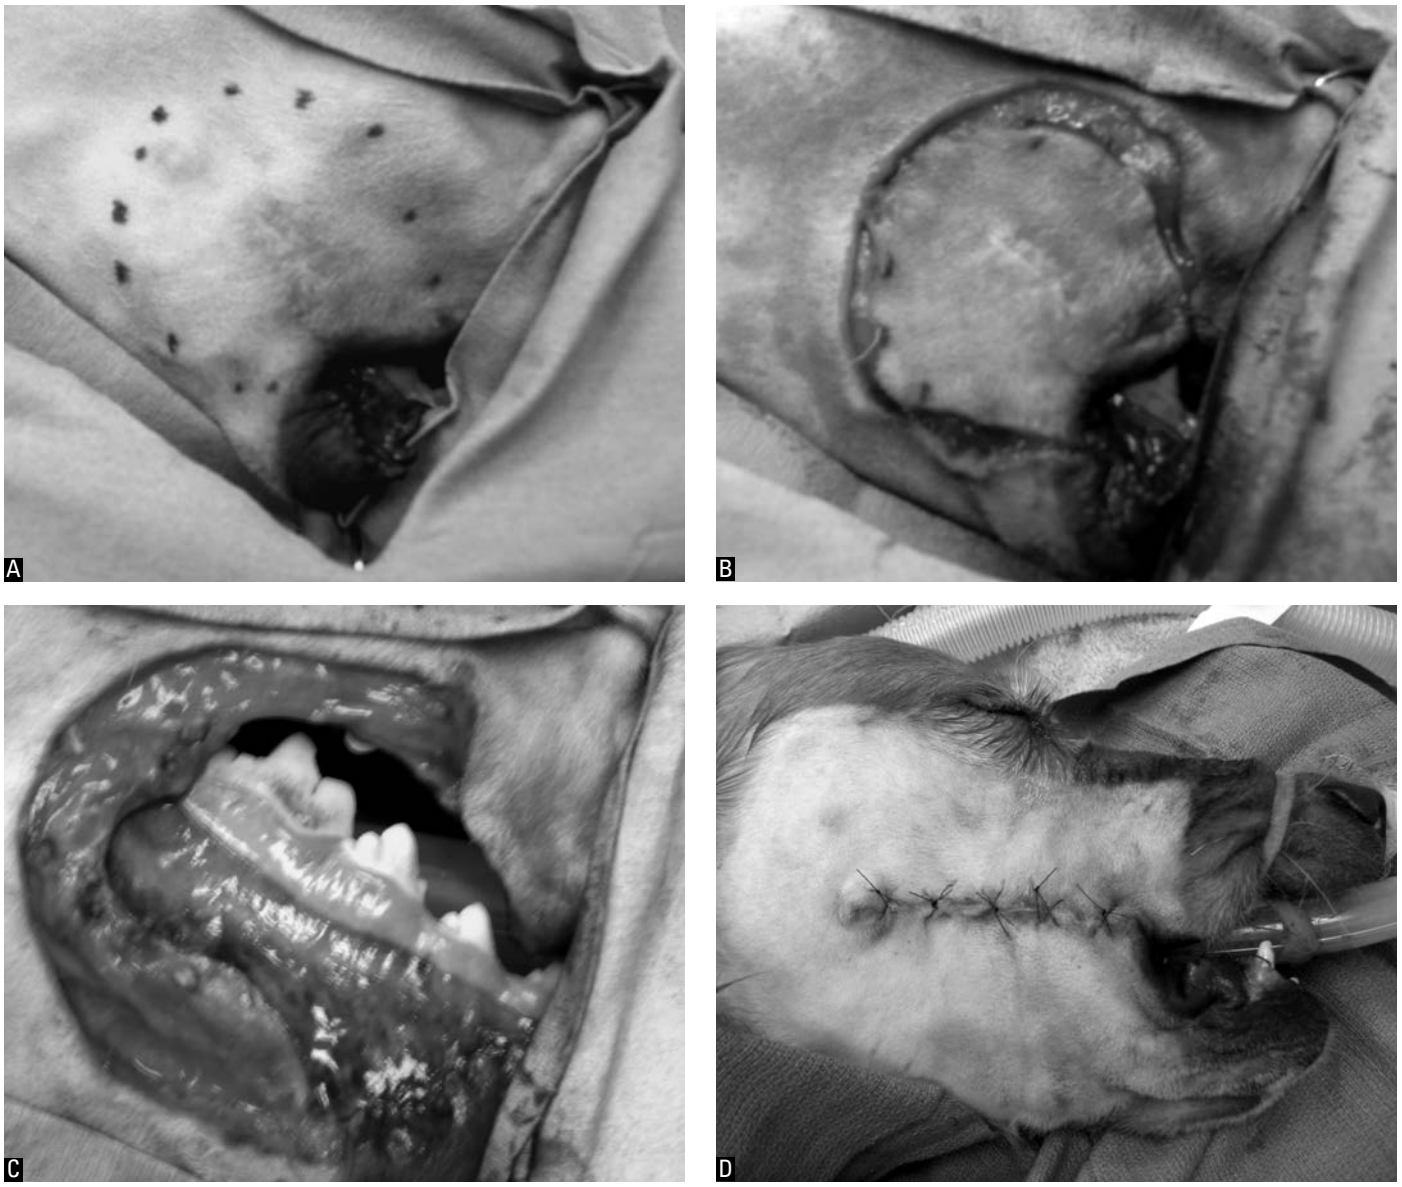

Figure 14-30. A. Preoperative view of a 3-year-old Golden retriever with an incompletely excised grade II mast cell tumor of the cheek. **B.** Intraoperative view of the dog identified in Figure 14-30A with 2 centimeter margins indicated on all sides of the prior incision. **C.** Intraoperative view of the dog identified in 14-30A after complete full thickness labial excision of the mast cell tumor. **D.** Postoperative view of the dog identified in Figure 14-30A after three-layer closure of the surgical defect.

These pedicles are supplied by the superior or inferior labial arteries and veins.[10,11] It is important that lip defects be closed in a two or three-layer closure of the mucosa, fascia and skin. The initial suture should be placed at the labial margin to avoid defects in the lip margin. The mucosal layer is apposed first in either a simple interrupted or simple continuous fashion using absorbable suture. If a muscular fascial plane is present, closure of this tissue with absorbable suture will reduce tension on the defect. Finally, the dermis is apposed.

In the "tight lip syndrome" of Shar Pei's the rostral mandibular skin curls dorsally over the mandibular incisor and canine teeth and can interfere with normal mastication. This condition is best treated at an early age (3 months) as the restriction in jaw movement can interfere with normal development of the mandible. Surgery involves incision of the mandibular skin attachment at the mucogingival junction from the incisors extending to the first premolar bilaterally. The mandiblar skin and its attachments to the mandible are periosteally elevated allowing the mandibular skin to displace ventrally.[12] The wound created is allowed to heal by second intention. As the wound heals, it is important for the veterinarian or owner to digitally break down any adhesions of tissue that may cause adherence of the skin in a restrictive position.[12]

Anti-drool cheiloplasty procedures are most commonly performed on large or giant breed dogs such as Newfoundlands. The goal of surgery is to redirect saliva to the caudal aspect of the oral cavity. The procedure is simple to perform and involves a mucosal and submucosal incision in the buccal surface of the mandibular and maxillary cheek. The mandibular incision is made several centimeters rostral to the oral commisure in the freely moveable gingiva of mandibular cheek. The lower incision is then apposed to a corresponding maxillary incision and the two mucosal edges sutured.[13] The apposition of these two surfaces creates a channel that redirects saliva into the caudal oral cavity where it is swallowed (Figures 14-31A-E).

Lip fold dermatitis and pyoderma is seen in animals with abnormal lip skin confirmation. Redundant folds of mandibular lip skin entrap moisture and saliva creating a local environment conducive to bacterial overgrowth. Spaniel breeds, St. Bernards, and Newfoundlands are breeds commonly affected. Antibiotics are not effective in the long-term resolution of clinical signs. The goal of surgery is to resect redundant folds of mandibular lip tissue while maintaining a normal range of motion in the oral cavity. The affected inflamed or infected tissue is excised longitudinally and the wound closed with simple interrupted sutures (Figure 14-32).

Full thickness rotational flaps based on the lateral maxillary cheek to reconstruct the lower eyelid margins following surgical resection of periocular neoplasms have been previously described in dogs and cats. By transferring the lip margin the lower eyelid margin can be functionally reconstructed.[14,15] Special attention is paid to exact apposition of the reconstructed lip and eyelid margins for functional and cosmetic reasons. It is also important to not excessively rotate the skin flap potentially compromising the subdermal plexus blood supply.

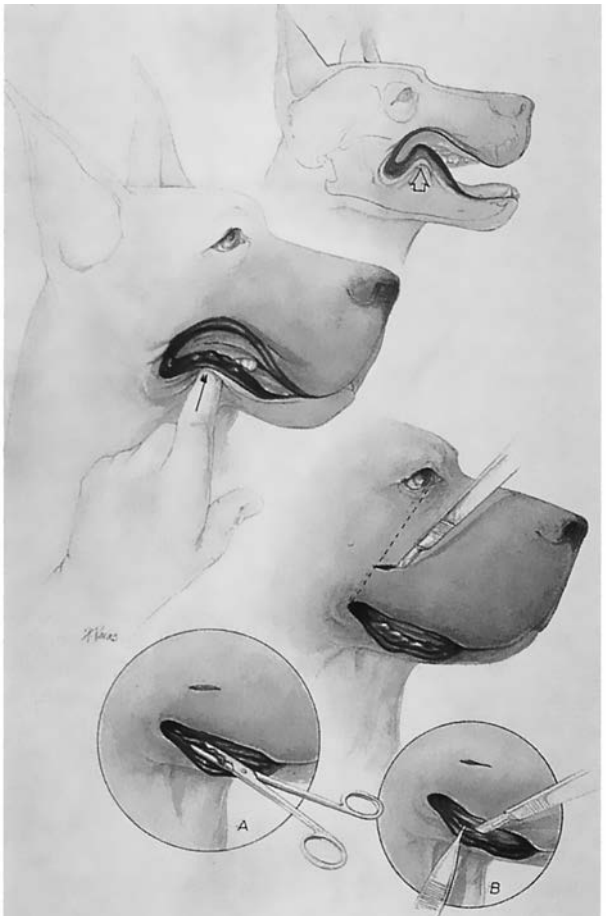

Figure 14-31A. The lower lip, 2 to 3 cm rostral to the commisure, is digitally elevated until the lip is taut when the mouth is fully opened to mark the dorsal extent of the horizontal cheek incision. A full-thickness horizontal cheek incision is completed. The caudal aspect of the incision intersects a line drawn from the medial canthus to the commisure (*dotted line*). *A.* A 2.5-cm long mucocutaneous border is excised from the lower lip. *B.* The incised edge of the lower lip is split in half to form a cutaneous and a mucosal flap.

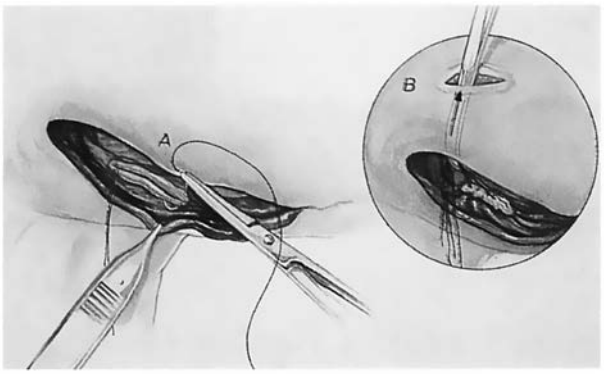

Figure 14-31B. *A.* Stay sutures are placed in the rostral and caudal aspects of the lower lip incision. *B.* The lower lip flaps are pulled through the cheek incision with the stay sutures. From Smeak DD: Antidrooling cheiloplasty clinical results in 6 dogs. J Am Anim Hosp Assoc 25:181, 1989.

Figure 14-32. Gross appearance of a patient 2 weeks postoperative after a cosmetic cheiloplasty performed following a hemimandibulectomy.

In dolicocephalic breeds following unilateral mandibulectomies, cheiloplasty procedures may be beneficial to maintain the tongue within the oral cavity for cosmetic reasons and to prevent excessive drooling. This is accomplished by performing a full-thickness lip margin excision along the ventral and dorsal borders of the oral commisure. The mandibular and maxillary cheek is then apposed in three layers. Absorbable suture material is used for the buccal mucosa in a simple continuous or interrupted pattern. The deep muscular layer is closed similarly to the mucosa and skin sutures are used for skin apposition. Specific attention must be paid to establishing a balance between restriction of the tongue into the oral cavity and interference with normal eating. (See Figure 14-31).

Postoperative Care and Complications

The specifics of post-operative care following surgery of the lips and cheek are dependent on the site of operation. In all animals, activities such as pulling ropes and chewing bones, sticks and rawhides should be avoided until tissue healing is complete. An Elizabethan collar may be required to prevent self-trauma of the incision. Animals are typically fed a soft diet for two weeks following surgery while tissues heal. During surgery specific attention is paid to prevent excessive restriction of opening of the mouth during resection of lip and cheek tissues. If opening of the mouth is significantly limited because of the necessity to remove large portions of the caudal lip margin a nylon or tape muzzle may be beneficial to protect the surgical site for 3 to 4 weeks following surgery. Another option is suturing buttons along the incision for tension relief. After this time the tissue should be strong enough to tolerate the normal stresses associated with movement of the oral cavity.

Chapter 15

Pharynx

Cricopharyngeal Dysphagia

Eberhard Rosin

Cricopharyngeal dysphagia, although an uncommon condition, is considered in the differential diagnosis of persistent dysphagia of young dogs. This condition is characterized by inadequate or asynchronous relaxation of the cricopharyngeal sphincter that prevents the normal movement of food from caudal portions of the pharynx into the cranial esophagus. The etiologic basis of this failure of reflex relaxation has not been established. Dogs with cricopharyngeal dysphagia usually have a history of dysphagia persisting since weaning. Attempts to swallow solid food result in anxiety, gagging, and expulsion of food from the mouth by forward movements of the tongue. After repeated ingestion of the masticated food, the entire meal passes into the stomach.

Diagnosis

Except for slight nasal exudate and occasional coughing, physical examination reveals no abnormality. Examination of the pharynx reveals no inflammatory or obstructive lesions. While the patient is under anesthesia, an esophagoscope can be passed into the stomach without difficulty. The resting pressure provided by the closed sphincter, as encountered by passage of the endoscope and as measured by manometry, is normal.

Radiographs of a barium swallow study reveal contrast material remaining in the pharynx. In some dogs, barium is aspirated into the lungs. Fluoroscopic examination of a barium swallow demonstrates normal movement of the barium bolus into the oropharynx by elevation of the tongue and contraction of the pharyngeal musculature. Despite the presence of sufficient force to distend the caudal pharyngeal wall, inadequate or asynchronous relaxation of the cricopharyngeal sphincter prevents normal movement of the barium bolus into the proximal esophagus. The thin stream of barium that passes through the sphincter moves into the stomach with no evidence of failure of reflex relaxation of the gastroesophageal sphincter. This cycle is repeated in rapid succession until all the barium is swallowed. As the epiglottis, which closes the glottis in normal fashion during swallowing attempts, opens during inspiration, the residual barium filling the caudal pharyngeal region may be aspirated into the trachea and discharged by coughing.

Immediate relief of the dysphagia is achieved by cricopharyngeal myectomy. Complete division of muscle fibers of the cricopharyngeal muscle is essential for permanent elimination of the condition.

Technique for Cricopharyngeal Myectomy

The dog is anesthetized, intubated, and placed in dorsal recumbency. A midline incision is made from the cranial aspect of the larynx to the thoracic inlet. Exposure of the trachea and esophagus is by midline dissection of the ventral neck musculature. Partial incision of the insertion of fibers of the sternohyoid muscle on the basihyoid bone may be necessary. The bisected sternohyoid muscle is retracted to expose the trachea. Dissection is continued to the left of the trachea by transection of the insertion of the left sternothyroid muscle to the lateral surface of the thyroid lamina. The left thyroid gland is exposed between the trachea and the sternothyroid muscle. Several small branches of the cranial thyroid artery that supply the upper aspect of the left thyroid gland are ligated and transected (Figure 15-1). The left recurrent laryngeal nerve should be preserved.

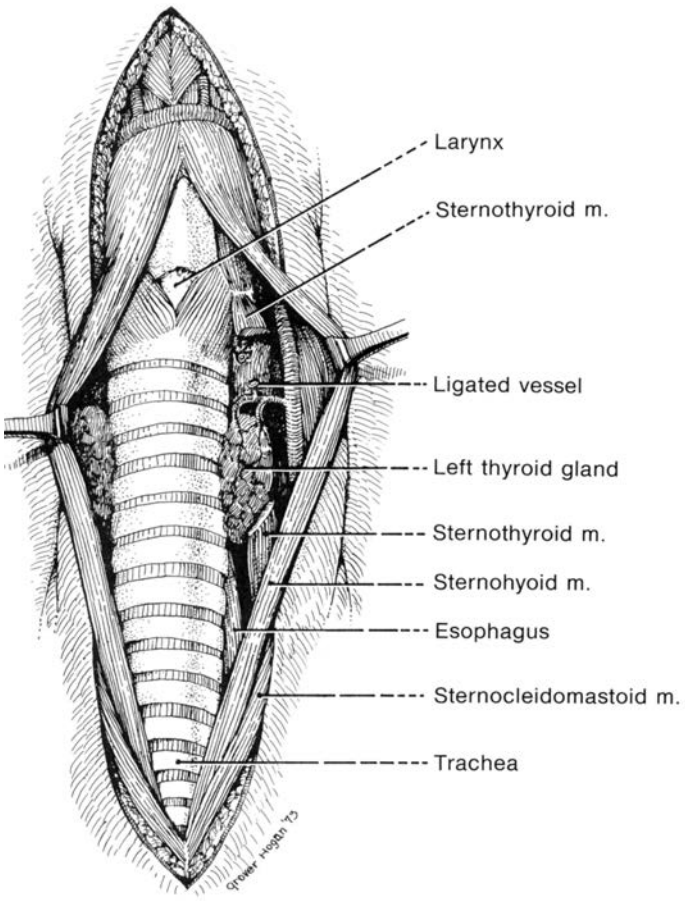

Figure 15-1. Mobilization of the leftside of the trachea and the cranial esophagus.

The cricopharyngeal muscle and dorsal proximal esophagus can be exposed by grasping the larynx and rotating it. The cricopharyngeal muscle can be identified as a bundle of transverse muscle fibers converging on the dorsal midline and blending into the longitudinal muscle fibers of the cranial esophagus. Two parallel incisions, approximately 2 mm apart, are made on the dorsal midline through the cricopharyngeal muscle and onto the cranial esophageal musculature (Figure 15-2). The esophageal mucosa is not incised. The incised muscle fibers are separated from the mucosa and are excised. Bleeding is controlled by use of gauze and pressure; the myectomy is not sutured.

Closure of the incision is initiated by apposition of the sternohyoid muscle with simple interrupted 3-0 absorbable sutures. Suturing the transected insertion of the sternothyroid muscle is not necessary. The subcutaneous tissue and skin are sutured routinely. Although other tissue planes that were separated for exposure are not sutured, seroma formation is uncommon.

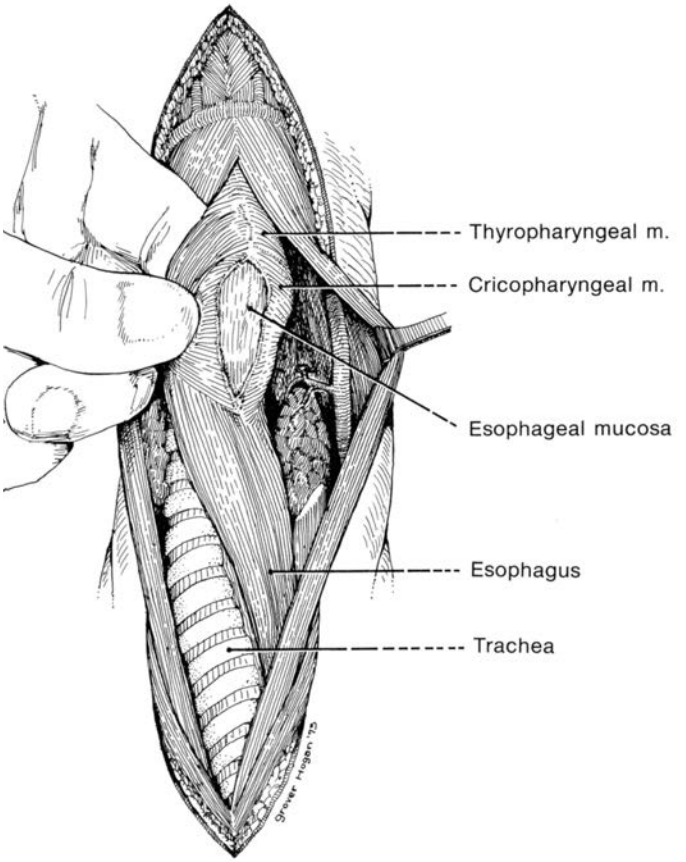

Figure 15-2. Myectomy through the length and thickness of the cricopharyngeal and the cranial esophageal musculature. The esophageal mucosa is not incised.

Postoperative Care

No special postoperative care is required. Patients tolerate solid food the day after the operation. Recurrence of dysphagia because of fibrosis and constriction at the myectomy site is prevented by adequate removal of sphincter muscle fibers during the original surgical procedure.

Editors Note: Suspicion of Cricopharyngeal dysphagia should prompt the primary care veterinarian to refer the case to a specialist. Fluroscopic contrast swallowing studies are indicated to properly diagnose this uncommon condition prior to any surgical intervention.

Otopharyngeal/Otic Polyps in Cats

Jacqueline R. Davidson

Introduction

Otopharyngeal polyps, also termed nasopharyngeal polyps or inflammatory polyps, are benign pedunculated growths that arise from the oropharyngeal mucous membranes. The polyp stalk may originate from the nasopharynx, the auditory canal, or the tympanic cavity.[1,2] The polyp may grow into the nasopharynx or tympanic cavity or both. The mucosal lining from the nasopharynx to the tympanic cavity is continuous and histologically similar, so it is difficult to identify the origin of polyps. Polyps are composed of variable amounts of submucosal lymphocytic plasmacytic cellular infiltration with fibroplasia and the epithelium ranges from stratified squamous to ciliated columnar cells.[2,3]

The exact cause of the polyps is unknown. The presence of submucosal inflammatory cells suggests that polyps may arise from infection or chronic inflammation. Polyps are also associated with rhinitis or otitis media, suggesting a viral or bacterial etiology. However, any potential role played by infectious agents remains unclear and it may be that the etiology is multifactorial.[4] Because polyps have been identified in very young kittens, a congenital origin has also been suggested.[5,6]

Otopharyngeal polyps occur in cats of any age, although these animals are often less than two years old and may be seen in kittens as young as 4 weeks of age.[1,5,7,8] There is no apparent sex or breed predisposition. Although polyps are most commonly unilateral they can be bilateral. Polyps have also been reported in dogs, but are less prevalent than in cats.[9-11]

Clinical signs may be present for weeks to years before a polyp is diagnosed, and the signs vary depending on polyp location.[3,12] Polyps in the nasopharyngeal region may cause obstruction resulting in respiratory stridor, dyspnea, dysphagia, or voice changes.

Respiratory distress, cyanosis and syncopal episodes may also occur. Nasopharyngeal polyps may cause signs of upper respiratory tract infection such as sneezing, coughing, and nasal or ocular discharge. The respiratory signs may be mildly responsive

to symptomatic treatment if a secondary bacterial infection is present. Polyps in the external or middle ear may be visible in the external canal and may be associated with infection or cause signs that mimic otitis externa, otitis media, or otitis interna. These signs include head shaking, ear scratching, head tilt, Horner's syndrome, and nystagmus. Ability to hear may be diminished in the affected ear,[13] although this may not be clinically apparent. Any cat with chronic upper respiratory tract disease should be evaluated for polyps. The differential diagnoses include upper respiratory tract infections such as feline calicivirus and feline rhinotracheitis virus, nasal foreign bodies, and nasopharyngeal masses such as cryptococcal granuloma and neoplasms.

In dogs, inflammatory polyps tend to occur in the middle ear rather than the nasophayrngeal region, and they present with clinical signs of otitis media, otitis externa, or bleeding from the external ear canal.[10] The differential diagnoses for signs related to the ear include neoplasia and otitis externa, media, or interna.

Preoperative Considerations

A thorough physical exam should be performed, including complete otoscopic and oropharyngeal evaluations. Polyps may rupture through the tympanic membrane and appear in the external ear canal. Examination of the external ear canal may reveal signs of otitis externa with a visible pink, red or grey, spherical mass occluding the canal. The surface is often smooth and glistens, due to the mucosa that covers the surface. An otoscope or video-otoscope may be needed to visualize a polyp that is causing the tympanic membrane to bulge, or has perforated the membrane and is protruding into the external auditory canal. If the history and physical findings are suggestive of a pharyngeal mass, sedation or general anesthesia is necessary to perform a thorough oral examination. Inspection of the oral cavity may reveal ventral displacement of the soft palate. The nasopharynx can be evaluated by retracting the caudal edge of the soft palate rostrally using a spay hook or stay suture. The nasopharynx can also be visualized by use of a flexible fiberoptic bronchoscope.

Skull radiographs should be performed with the cat under general anesthesia, with particular attention paid to the nasal cavity and middle ear. A nasopharyngeal polyp may be identified as a soft tissue density in the nasopharynx on the lateral radiographic view. Ventrodorsal, oblique lateral, and frontal open-mouth views are recommended to evaluate the osseous and tympanic bulla and petrous temporal bones. Thickening or sclerosis of the osseous bulla and sclerosis of the petrous-temporal bone indicate chronic middle ear involvement. The tympanic bulla may be best evaluated for increased soft tissue density using frontal open-mouth and lateral oblique radiographic views of the skull. Increased soft tissue density may also be seen within the external canal if a polyp is located there. Most cats with polyps have radiographic changes compatible with middle ear infection.

However, radiographic evaluation is not a highly sensitive method for diagnosing otitis media so a high level of suspicion for otitis media should be maintained in cats diagnosed with otopharyngeal polyps even with a lack of radiographic evidence.[2,14] Compared to skull radiographs, both computed tomography and magnetic resonance imaging provide more accurate assessment of soft tissue opacities and changes in the osseous bulla.

Surgical Technique

The treatment of choice is a ventral bulla osteotomy performed on the side associated with the polyp, along with polyp extraction. Regardless of whether the polyp is in the external ear canal or the nasopharynx, a ventral bulla osteotomy should be performed before removing the polyp to facilitate removal of inflammatory tissue and detachment of the pedicle.

Performance of a ventral bulla osteotomy is associated with a lower incidence of otic and possibly nasopharyngeal polyp recurrence, supporting the idea that polyps may originate in the middle ear.[1,2] A bulla osteotomy is recommended even if there is no evidence of bulla abnormalities on the diagnostic images.

To perform a ventral bulla osteotomy, the cat is placed in dorsal recumbency with the head and neck extended. The ventral wall of the tympanic bulla can usually be palpated between the angular process of the mandible and the larynx. A paramedian skin incision is made over the bulla beginning near the angle of the mandible and extending about 6 cm caudally, where the linguofacial vein may be identified. The incision is continued through the subcutaneous tissues and cutaneous muscles. Blunt dissection between the digastric muscle laterally and the hyoglossal and styloglossal muscles medially exposes the bulla, which is palpable cranial to the hyoid apparatus. The hypoglossal nerve, and the lingual artery and vein may be identified on the hyoglossal muscle and are retracted medially. The ventral branch of the external carotid artery is located lateral to the bulla. Self-retaining retractors may be used to maintain exposure, with care taken to avoid the hypoglossal nerve and the vessels. Connective tissue and periosteum is bluntly dissected off the ventral aspect of the bulla using a periosteal elevator. A Steinmann pin is used to create a hole in the ventral bulla. The hole should be large enough to accommodate one jaw of a small rongeurs. The ventral aspect of the bulla is then removed with the rongeurs.

The middle ear of the cat contains a septum that divides the bulla into a small dorsolateral and a larger ventromedial compartment.[15,16] This septum must be removed to gain access to the dorsolateral compartment of the bulla, where the external auditory meatus and the auditory os of the Eustachian tube are located (Figure 15-3). Removal of the septum is performed as described for removal of the ventral bulla. Both compartments of the bulla should be cultured. The bulla should undergo careful inspection and gentle curettage to remove the epithelial lining and any granulation tissue. Aggressive curettage or direct suctioning of the dorsomedial aspect of the bulla should be avoided to reduce the risk of damaging the postganglionic sympathetic nerve fibers, auditory ossicles, semicircular canals, and cochlea. Damage to these structures can result in Horner's syndrome and otitis interna. Any tissue removed from the bulla should be submitted for histologic evaluation. Before closing, the bulla is lavaged with sterile saline. Placement of a surgical drain is probably not necessary, but if one is used it should be placed to exit through a separate stab incision. A closed suction drain may be constructed by cutting the end from a butterfly infusion set[a] and creating several fenestrations in the tubing. Once the drain has been placed in the bulla and the wound has been closed, the needle is inserted into a vacutainer tube to provide

[a]E-Z Set. Becton Dickinson. Sandy, Utah

suction. This system is preferable to a Penrose drain because the quantity and character of the drainage can be easily monitored. The cutaneous muscles and subcutaneous tissues are sutured with 3-0 or 4-0 absorbable suture material in a simple continuous pattern. The skin may be closed using 4-0 absorbable suture material in a simple continuous intradermal pattern or using 4-0 nylon for external skin sutures. The drain should be sutured to the skin to prevent premature removal, and a bandage is placed around the head to stabilize the vacutainer tube. The vacutainer should be replaced twice daily to ensure it is providing negative pressure. The drain is removed when fluid production is, minimal which is usually within 3 to 7 days. If a Penrose drain is used, it is necessary to cover it with a bandage that is changed daily to monitor any drainage. The skin sutures may be removed 7 to 10 days postoperatively.

Simple traction using an Allis tissue forceps or alligator forceps is usually sufficient to remove the polyp. Hemorrhage is usually minimal and may be controlled by direct pressure. If the polyp is visible in the external canal, it may be extracted by traction after performing a ventral bulla osteotomy. A lateral ear canal resection may be performed to improve exposure, but is rarely necessary. Nasopharyngeal polyps can be removed by traction, using an oral approach. Endoscopy may provide better visualization of the nasopharyngeal region,[17] but is typically not necessary. Retraction of the soft palate rostrally with a spay hook usually provides adequate exposure. If necessary (rarely), exposure may be increased by making a longitudinal incision on the midline of the soft palate (Figure 15-4).

Figure 15-4. A midline incision has been made in the soft palate to improve exposure of a feline nasopharyngeal polyp.

Stay sutures may be used to retract the palate while the polyp is being removed. A three-layer closure is performed on the palate by suturing the nasal mucosa, submucosal tissue and oral mucosa separately using 4-0 or 5-0 absorbable suture material in a simple continuous pattern. The polyp should be submitted for histologic evaluation to confirm the diagnosis.

Surgical complications are related to the ventral bulla osteotomy, and the most common is damage to the postganglionic sympathetic nerve fibers, resulting in Horner's syndrome which is characterized by miosis, ptosis, enophthalmus and prolapse of the third eyelid (Figure 15-5). It usually resolves within one month, although it may be permanent.[2,8] Horner's syndrome is a rare complication in dogs, probably reflecting anatomical differences in the tympanic bulla between dogs and cats. Damage to the round and oval windows or vestibulocochlear apparatus result in vestibular disturbances, which include head tilt, ataxia, and nystagmus. Nystagmus usually resolves within 24 hours, but head tilt or ataxia may persist.[14,16] Damage to the hypoglossal nerve is less common, and results in deficits of swallowing, prehension, and mastication. Facial nerve paralysis has also been reported.[2,3] Deafness is not a reported complication of ventral bulla osteotomy. However, cats who are deaf prior to surgery may not be improved by it.[13]

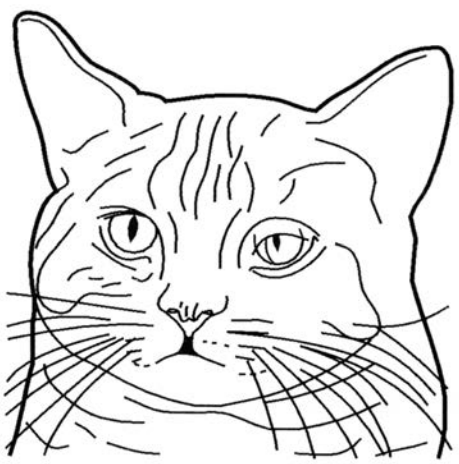

Figure 15-5. A cat with Horner's syndrome after ventral bulla osteotomy. Miosis, ptosis, enophthalmos, and prolapse of the third eyelid are present.

The prognosis is good with complete excision, but recurrence of the polyp may occur from months to years postoperatively.[3,12] Recurrence is less common when surgical removal is combined with bulla osteotomy.[2,14,16] Recurrence is less common for nasopharyngeal polyps than for aural polyps, even if removed by traction with no bulla osteotomy.[19]

Chapter 16

Salivary Glands

Michael D. King and Don R. Waldron

Salivary Gland Disease

Dogs and cats have four pairs of salivary glands of clinical significance. Knowledge of salivary gland and duct anatomy is important from a surgical perspective in treatment of salivary gland disease and to prevent iatrogenic salivary tissue injury during other surgical procedures in the head and cervical areas. The major salivary glands of both the dog and cat are the paired parotid, mandibular, sublingual and zygomatic glands (Figure 16-1).[1] The parotid gland is triangular in shape and closely adjacent to the lateral aspect of the auricular cartilage which makes up the external ear canal. The mandibular gland is a large gland, ovoid in shape, and surrounded by a fibrous capsule which is joined cranially to the sublingual gland. The mandibular gland is positioned dorsal and caudal to the mandibular lymph nodes and masseter muscle, and lateral to the external carotid artery. The monostomatic part of the sublingual gland continues cranially from the mandibular gland, following the mandibular duct, ending on a small papilla adjacent to the cheek teeth. The polystomatic section of the sublingual gland consists of multiple lobules positioned along the mandibular and sublingual salivary ducts; these lobules open separately into the oral cavity adjacent to the tongue. The zygomatic gland corresponds to the dorsal buccal glands in other species, and is located medial to the rostral attachment of the zygomatic arch.[1,2]

Clinical Disease

Disease of the canine and feline salivary glands include salivary mucoceles, neoplasia, sialadenitis, and sialolithiasis.[3] A phenobarbital-responsive sialodenosis and hypersialosis has been described in dogs.[4,5] This condition is characterized by bilateral, painless, and non-inflammatory enlargement of the parotid or mandibular glands. Clinical signs of sialodenosis include weight loss, vomiting, retching and difficulty in swallowing. Response to phenobarbital administration in these cases is usually rapid, though continuous treatment may be required to prevent recurrence.[4,5]

Salivary gland neoplasia is uncommon in the dog and cat.[6,7] Neoplasia has been reported in many breeds, though Siamese cats and Spaniel breed dogs have been overrepresented in some studies.[8,9] The parotid and mandibular glands are most commonly affected, with one study describing mandibular gland neoplasia occurring most often in cats and parotid gland tumors predominating in dogs.[8] Salivary gland tumors in dogs and cats may be simple or complex adenocarcinomas.[10] Definitive treatment involves surgical excision of the tumor and affected gland, with reported median survival times post-surgery for dogs and cats of 550 days and 516 days respectively.[8] Radiation therapy and several chemotherapy protocols have been used in conjunction with surgical excision but haven't been shown to improve survival times.

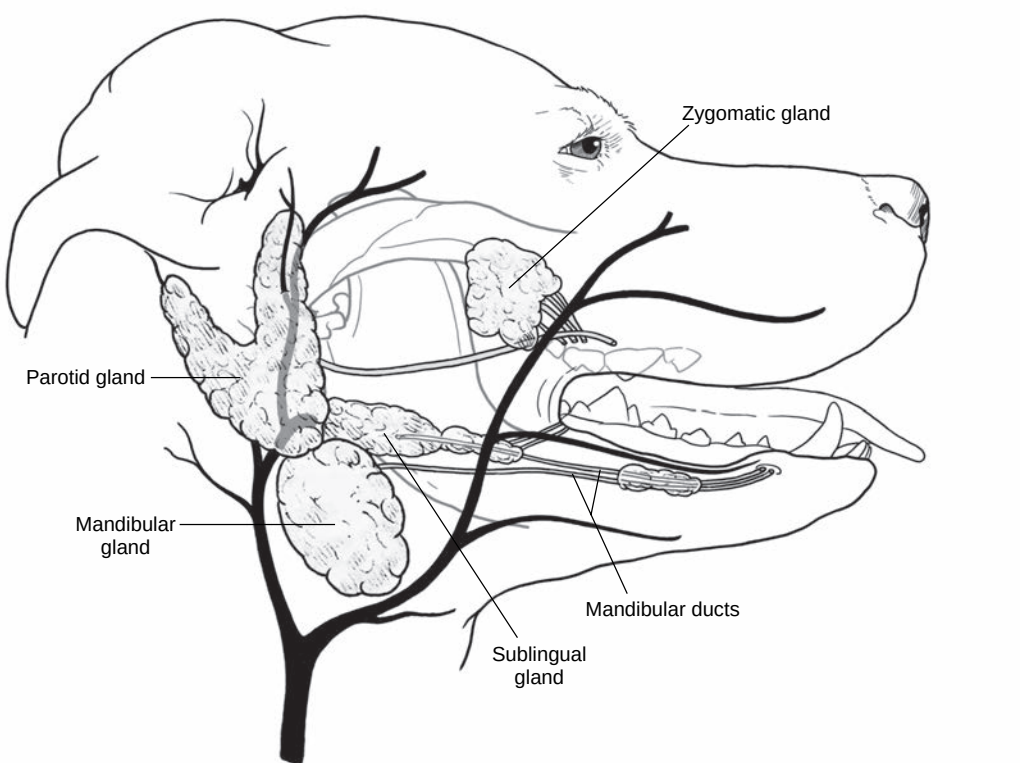

Figure 16-1. The four pairs of salivary glands in the dog and cat.

Salivary mucocele is a collection of saliva within tissues and is the most commonly diagnosed disease of the canine salivary glands. Mucoceles are rarely reported in the feline and have been associated with trauma.[11,12] It is thought that saliva accumulates due to leakage from a damaged salivary gland or duct although the cause of such leakage is unknown. Most mucoceles are associated with the sublingual gland/duct complex and occur in the cranial cervical or intermandibular subcutaneous tissue (cervical mucocele). Intraoral mucoceles associated with sublingual gland/duct defects are uncommon and include sublingual mucocele (ranula) and pharyngeal mucocele. The latter result from saliva accumulating adjacent to pharyngeal and laryngeal structures. Most forms of mucoceles are benign lesions associated with low patient morbidity; however intraoral mucoceles (ranula) may interfere with prehension and pharyngeal mucoceles may cause airway obstruction and dyspnea. Zygomatic gland mucoceles are rare in dogs. These mucoceles cause ophthalmologic signs such as exophthalmos and periorbital swelling.

Diagnosis of a cervical mucocele is usually achieved by aspiration of a thick, honey-colored, or blood-tinged mucoid fluid with a low cell count from the primary cervical swelling. The fluid can be confirmed as saliva by using a mucus-specific stain such as periodic acid-Schiff (PAS). The differential diagnosis for cervical mucocele includes abscess and neoplasia, especially lymphoma. Thyroglossal duct cysts or branchial cysts are rare congenital lesions similar to mucoceles.

The mandibular and sublingual glands and ducts are closely associated anatomically and definitive treatment of cervical, sublingual or pharyngeal mucoceles involves removal of both glands on the affected side.[13] Some authors advocate marsupialization of sublingual and pharyngeal mucoceles in an attempt to allow continuous drainage of the accumulated swelling. However, without concurrent removal of the affected glands marsupialization alone may lead to recurrence.[14,15] Determination of which side to operate in cases of cervical mucoceles is usually apparent or made during physical examination. If mucocele lateralization is not apparent, displacement of the mucocele may produce a swelling within the oral cavity, adjacent to the tongue on the affected side. Alternatively, placing the animal in dorsal recumbency when the animal is anesthetized usually results in the mucocele shifting laterally towards the affected side. Sialography has been recommended by some authors and can demonstrate a defect in the duct or glands radiographically, allowing accurate identification of which side is affected however, this requires cannulation of the sublingual ducts, which is difficult and time consuming.[13,15] Exploratory surgery is performed in some cases to confirm the affected side. Careful examination of the mucocele during surgery may allow identification of a small communication with the affected gland. In rare cases, when no side can be identified, removal of the mandibular and sublingual glands bilaterally can be performed with no deleterious effects to the dog.[16]

Surgical Technique

Mandibular and Sublingual Salivary Gland Excision

The patient is anesthetized and positioned in lateral recumbency with a pad positioned under the neck. The lateral aspect of the facial area from mid-mandible to the mid-cervical area is clipped and prepared for aseptic surgery. A skin incision is

made extending from the angle of the mandible caudally over the jugular vein and its bifircation (Figure 16-2). Subcutaneous tissue and platysma muscle are incised and the division of the jugular vein to the ventral linguofacial and dorsal maxillary veins is identified. Careful hemostasis using electrocautery and ligation is essential during surgery to maintain visibility within the surgical field. The mandibular gland is located just medial and cranial to the jugular vein bifurcation. The surgeon should not confuse the mandibular lymph nodes which are located ventrally to the linguofacial vein with the salivary gland complex. The nodes are smaller and are not lobulated as is the mandibular gland. An incision is made into the fibrous capsule of the mandibular gland and the gland dissected free with a combination of sharp and blunt dissection. Blood supply to the mandibular gland is located medial and dorsally and cauterization or ligation of the vascular supply is recommended. The mandibular gland is exteriorized and lateral traction used to allow dissection of the associated sublingual gland cranially to the level of the digastricus muscle. The sublingual gland dissection is completed with a combination of digital blunt dissection and a Kelly hemostat. Dissection is continued dorsal and cranial to the digastricus muscle, until the lingual nerve is identified rostrally and all glandular tissue is isolated (Figure 16-3). The mandibular and sublingual ducts are ligated caudal to the lingual nerve and the glandular complex removed. Inadvertent avulsion of the glandular complex sometimes occurs during dissection. If the avulsion occurs rostral to the lingual nerve no further action is necessary. If avulsion occurs caudal to the lingual nerve an effort is made to completely excise glandular tissue to the level of the lingual nerve. Suction is used to remove all mucus and saliva from the mucocele and a passive or active drain placed in the mucocele prior to closure and maintained for 2 to 3 days. Subcutaneous tissues and platysma are closed with absorbable suture, and skin closed routinely. The drain should be covered with a bandage, and removed once there is minimal discharge from the surgical wound.

Zygomatic Gland Excision

Zygomatic gland mucoceles are uncommonly diagnosed. Definitive therapy consists of zygomatic gland excision and drainage of the mucocele. The patient is anesthetized and placed in lateral recumbency with the head supported by a pad. An incision is made along the dorsal rim of the zygomatic arch and the palpebral fascia and retractor anguli muscle are incised and reflected dorsally (Figure 16-4A-F). The periosteum of the zygomatic arch is incised and reflected ventrally, allowing visualization of the dorsal aspect of the zygomatic gland. Further visualization is obtained by partially removing the dorsal half of the zygomatic arch with an osteotome or rongeurs, and by gentle dorsal retraction of the globe. The zygomatic gland is then bluntly dissected free, with care to avoid a branch of the deep facial vein ventrally. The mucocele is then drained and the surgical site lavaged with sterile saline. If the section of removed zygomatic arch is intact, it can be secured in place with suture through pre-drilled holes in the bone. The cut ends of the retractor anguli muscle are apposed, and the palpebral fascia is sutured to the zygomatic periosteum with absorbable suture material. Subcutaneous tissues and skin are closed routinely.

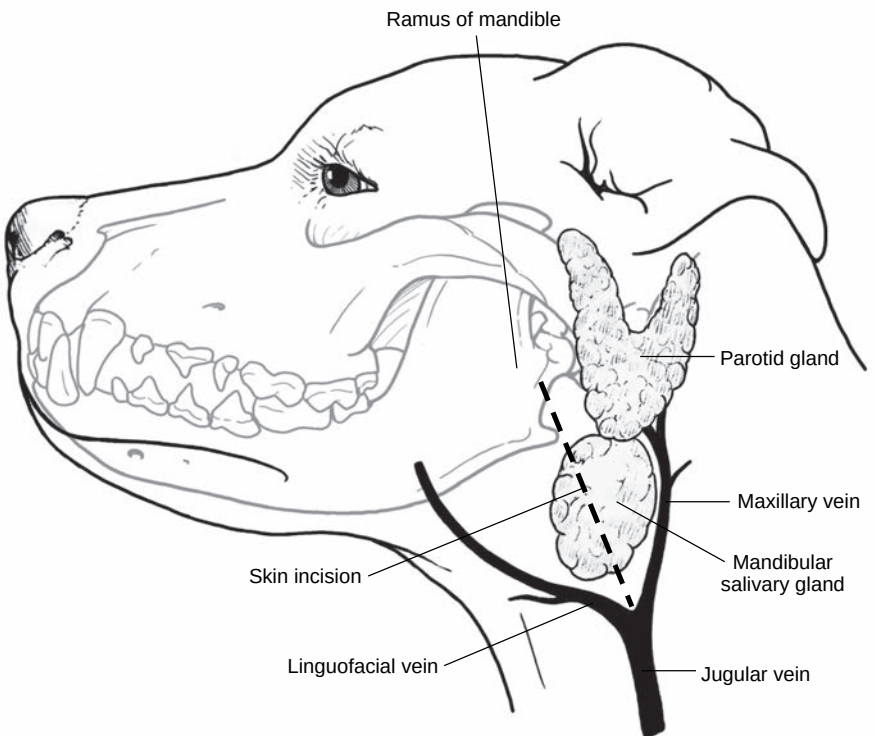

Figure 16-2. A skin incision is made from the angle of the mandible extending caudally over the bifurcation of the jugular vein.

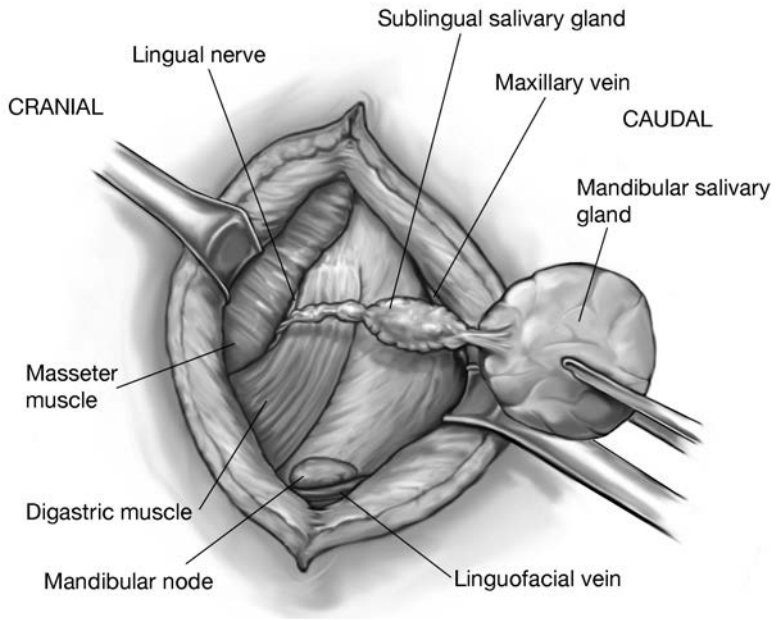

Figure 16-3. The mandibular and sublingual salivary gland complex is dissected and exteriorized after capsular incision. Caudal traction on the glandular complex assists in exposing the rostral sublingual complex to the level of the lingual nerve.

Chapter 17

Esophagus

Management of Esophageal Foreign Bodies

Michael S. Leib

Introduction

Most foreign material ingested by dogs and cats will either pass uneventfully through the gastrointestinal tract, cause mild vomiting and/or diarrhea, or be dissolved by gastric acid.[1] However, foreign bodies that lodge in the esophagus should be considered an emergency. The longer entrapped foreign bodies are present, the greater the chance of severe esophageal wall damage and possible perforation.[2] Sharp pointed objects can penetrate the esophageal wall leading to mediastinitis or occasionally broncho-esophageal fistula.[3] The most commonly encountered esophageal foreign bodies are bones, rawhide chew toys, dental chews such as Greenies®, fish hooks, and hairballs.[4]

Because of indiscriminate eating habits, swallowing of incompletely masticated food, and exposure to dental cleaners, foreign bodies occur more commonly in dogs than cats.[3,5,6,7] Hairballs vomited from the stomach can obstruct the esophagus in cats. Foreign bodies can occur in any age animal, but are most common in young dogs, or those frequently given bones or rawhide chew toys.[8] Foreign body entrapment may be more common in small dogs and terrier breeds.[3,4]

Pathophysiology

The esophagus is very distensible and most ingested foreign objects are passed into the stomach. Foreign bodies commonly lodge where the esophagus is restricted from distending: the thoracic inlet, base of the heart, or diaphragmatic hiatus. The entrapped foreign body stimulates secondary peristalsis, which can augment pressure necrosis of the esophageal wall.[9,10] Even though the esophagus is lined by tough stratified squamous epithelium, erosion, ulceration, and perforation can develop if the foreign body is not promptly removed. Fish hooks can lodge anywhere within the esophagus but the pharyngeal portion of the esophagus and heart base are most common.[6]

Clinical Signs

The most common clinical signs associated with esophageal foreign bodies are regurgitation, excess salivation, anorexia, odynophagia, and respiratory signs due to aspiration pneumonia. Foreign body ingestion may be observed or suspected by the owner. Clinical signs develop acutely. With obstructive lesions regurgitation of water occurs and dehydration can quickly develop. Perforation of the esophageal wall may result in pyrexia and depression. Mediastinitis with extension into the pleural cavity will lead to pleural effusion and progressive respiratory distress.

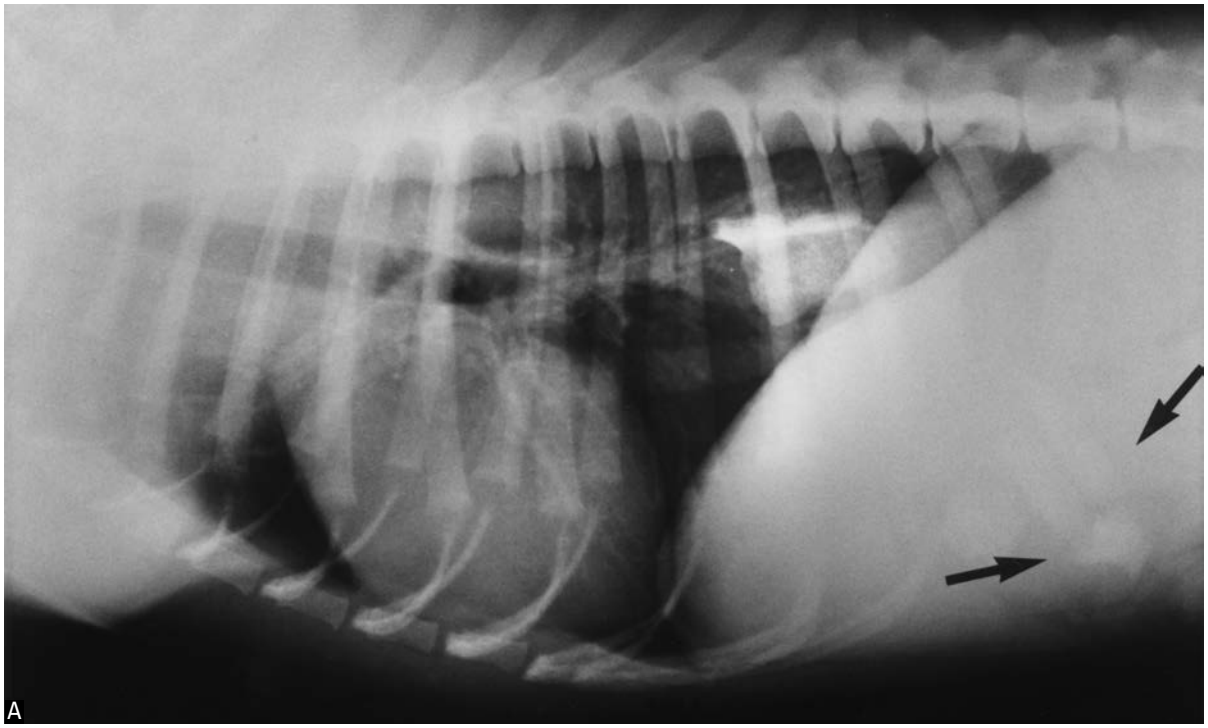

Figure 17-1A. Lateral survey thoracic radiograph from a 7 month old male West Highland white terrier showing a bone density cranial to the diaphragmatic hiatus. Several other bone fragments are visible in the stomach (arrows).

Diagnosis

Most esophageal foreign bodies are radiodense and clearly visible on survey radiographs (Figures 17-1A and B). Other common radiographic findings include a soft tissue density surrounding the foreign body (fluid in the esophagus, thickened wall, or localized mediastinitis) and air-filled dilated esophagus cranial to the foreign body.[11] Thin poultry bones can be difficult to visualize as they silhouette with ribs and vertebrae.

Although difficult to diagnose in cases with large entrapped bones, the presence of mediastinitis radiographically suggests esophageal perforation. Radiographic findings associated with mediastinitis include: increased mediastinal opacity and widening, extensive fluid density surrounding the foreign body, loss of detail around the mass, or obliteration of the shadow of the caudal vena cava.[3]

If perforation has occurred, thoracic radiographs taken after esophagoscopy may demonstrate pneumomediastinum. If perforation is suspected on survey radiographs, but cannot be confirmed, an iodine contrast study should be performed. Aqueous organic iodide contrast at 0.5-1.0 ml/kg can be administered.[12] Contrast studies should be performed after foreign body removal, because when the foreign body is still in place it may obstruct the perforation site, blocking leakage of contrast.[3]

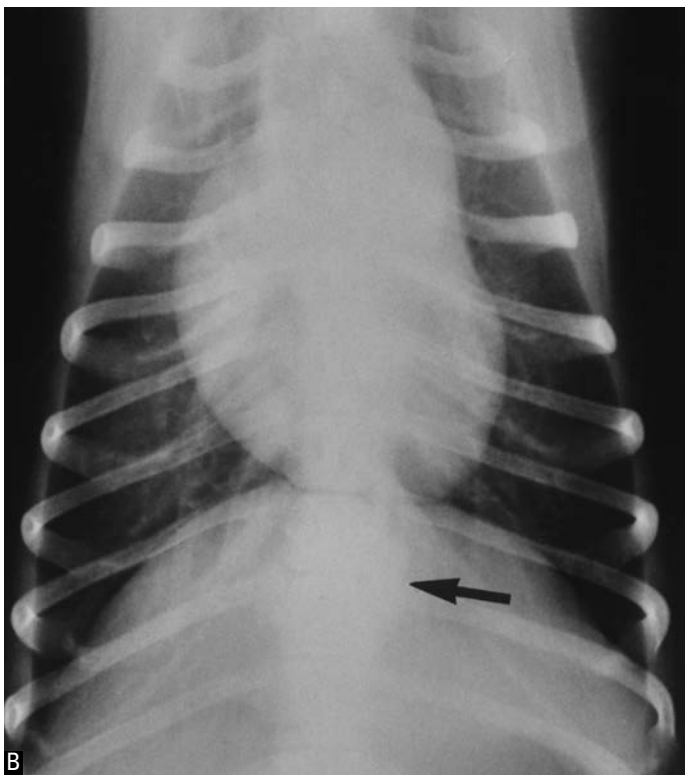

Figure 17-1B. Ventrodorsal survey thoracic radiograph from the same dog in figure 17-1A. The bone is difficult to see (arrow) because it is superimposed over the vertebral bodies.

Treatment

Most esophageal foreign bodies can be successfully removed endoscopically (Figure 17-2).[11] If foreign bodies cannot be endoscopically grasped and extracted from the esophagus, they can often be carefully pushed into the stomach with an orogastric tube under endoscopic visualization. In the stomach, gastric acid

Figure 17-2. Endoscopic appearance of a bone lodged within the esophagus.

will dissolve most bones, or foreign bodies can be removed via celiotomy and gastrotomy, or endoscopically, as more room is available for endoscopic manipulation.[5,9,11] Pushing an impacted foreign body into the stomach with an orogastric tube without endoscopic visualization should be performed carefully or not at all, because of the risks of severe mucosal damage or esophageal perforation. Surgery of the esophagus should be avoided if possible because of difficult exposure within the thorax, post-operative morbidity, and frequent complications. Surgical removal is indicated if a foreign body cannot be removed or pushed into the stomach, if the entire tip of a fishhook has penetrated the esophageal wall, or if esophageal perforation is present. A highly successful method of foreign body retrieval using forceps under fluoroscopic guidance has been reported, but is not practical for most practitioners.[4]

Large foreign bodies may be so tightly lodged within the esophagus, that flexible endoscopic forceps cannot grasp the object tightly enough for removal. These foreign bodies can often be retrieved using a rigid uterine or rectal biopsy forceps passed along the side of a flexible endoscope.[2] During removal, large foreign bodies may lodge at the pharynx, but can be delivered by grasping with curved carmalt forceps. Foreign bodies can also be removed using a rigid endoscope and rigid forceps.[5,6,8,11]

Esophagoscopy

To perform esophagoscopy, the animal should be positioned in left lateral recumbency.[13] A mouth speculum must be placed on the left upper and lower canine teeth to protect the endoscope. The tongue should be grasped and the head and neck extended by an assistant. A flexible endoscope is passed over the base of the tongue, through the pharynx dorsal to the endotracheal tube, and into the proximal esophagus. Lubrication is generally not necessary.

The esophageal mucosa is usually collapsed and appears in longitudinal folds.[14-16] It should be distended by insufflating air. The endoscope tip should be centralized within the lumen by adjusting the control knobs. Only minor tip adjustments are necessary, as the esophagus is a relatively straight tube. By advancing the endoscope only when the lumen is clearly visible, the endoscopist can dramatically reduce the risk of esophageal perforation. The endoscope should be advanced until the foreign body is visible. The mucosa surrounding the foreign body should be carefully inspected for erosion, ulceration, or perforation. If perforation is present or suspected, air insufflation should be limited, to avoid producing pneumomediastinum and possibly pneumothorax. Attempts should be made to gently slide the endoscope past the foreign body. This will allow assessment of mucosa not initially visible and help to plan foreign body extraction. The shape, contour, and composition of the foreign body will dictate the type of forceps necessary for extraction. The most helpful forceps are the rat-tooth, wire snare, 4-wire basket, and Roth net.

The foreign body forceps should be passed through the endoscope's biopsy channel into the lumen of the esophagus and opened by an assistant. An edge of the foreign body should be grasped and the forceps closed. The forceps should be withdrawn to pull the foreign body close to the endoscope's tip. Air should be insufflated during withdrawal of the endoscope to help dilate the esophagus and prevent damage to the esophageal mucosa as the foreign body is withdrawn.

Fishhooks can be difficult to remove, especially if embedded or if they are treble-barb hooks.[6] If the tip of the hook is protruding into the lumen, it can be grasped and the entire hook pulled through the mucosa and removed. If the tip of the hook is not visible but appears to be embedded only in the mucosa or submucosa, the hook can be gently torn through the mucosa, creating a superficial laceration that usually heals without complication.[6] If the hook appears to have passed through the esophageal wall, it should be surgically removed.

Hairballs, or trichobezoars, which occur most often in cats, often tear apart when grasped with foreign-body-retrieval forceps. Because of their tendency to fragment, hairballs may require multiple passes with extraction forceps to completely remove them. In addition, because of space limitations, it is usually not possible to place a wire snare or basket around the center of an esophageal hairball. In some cases, it is easier to push the hairball into the stomach for easier endoscopic manipulation, and where the hairball can be firmly grasped and removed. Esophageal perforation and resulting mediastinitis is a severe complication of esophageal foreign bodies. Small perforations can be managed medically by treating esophagitis, while large perforations require surgical repair and drainage.[8]

Mild esophagitis and erosions will heal quickly without complications. Food should be withheld for 24 hours followed by frequent feeding of small quantities of a gruel diet for 2-3 days. The gruel can be gradually thickened, the meal volume increased, and the feeding frequency decreased if regurgitation does not occur. Moderate or severe esophagitis and ulceration require more intensive medical management and a longer period of "resting the esophagus" by withholding oral food intake. In some cases, a percutaneous gastrostomy tube can be placed to provide nutrition while promoting esophageal healing and bypassing the esophagus. Cimetidine (10 mg/kg TID), ranitidine (2 mg/kg BID or TID), or famotidine (0.5 mg/kg BID) or a proton pump antagonist such as omeprazole (1 mg/kg SID) should be given to reduce gastric acid production and prevent further esophageal damage

from gastroesophageal reflux. Metoclopramide (0.2-0.4 mg/kg TID) can help increase gastroesophageal tone and reduce gastric reflux. Sucralfate suspension can bind to and coat eroded or ulcerated esophageal mucosa (1 gm/25 kg TID-QID). If severe mucosal damage is present, broad-spectrum antibiotics should be given for 1-2 weeks. Medical treatments should be continued for 1 week after normal feeding has been resumed. After the esophagus has healed, oral feeding can be started as described above. Until oral feeding begins, medications (except sucralfate) must be given parenterally or via the PEG tube.

Prognosis

The overall prognosis is good, but is dependent on the type of foreign body, the duration of time present, the degree and severity of esophageal damage, and the development of perforation.[4] The longer a foreign body is impacted within the esophagus, the harder it is to remove and the greater chance for perforation. Large perforations warrant a poor prognosis, despite aggressive surgical care.[3] Most cases with esophagitis, that receive appropriate medical care, will heal without complications.[8,10] Stricture formation following foreign body retrieval of bones is uncommon and is more likely following perforation or when severe damage to the esophageal wall has occurred, or after impaction of a dental chew.[7] Animals with severe esophagitis or ulceration should be endoscopically reevaluated in 7-10 days to assess stricture formation, which if present can be dilated with balloon catheters.

Hiatal Hernia Repair

Ronald M. Bright

Introduction

The hiatus of the esophagus is that portion of the diaphragm that allows the esophagus and vagus nerves to pass between the thoracic and abdominal cavities. A hiatal hernia (HH) can allow the protrusion of an abdominal structure(s) through an enlarged hiatus and into the thoracic cavity. The most common HH in the dog and cat is the axial hiatal hernia, which implies a cranial displacement of the gastroesophageal junction through the hiatus into the caudal mediastinum[1] (Figure 17-3A). Various amounts of stomach may reside within the thorax as well as other viscera that may move cranially. Most of the time this is a "sliding" hiatal hernia whereby the viscera is not fixed and moves back and forth between the thorax and abdomen.

Paraesophageal hernias occur when the esophagaogastric junction remains in its normal position below the diaphragm. (Figure 17-3B). However, the fundus and other parts of the stomach as well as other abdominal viscera can move through the hiatus into the mediastinum alongside the esophagus.

Hiatal hernias can be congenital or acquired, although the congenital type may not become symptomatic until adulthood.[2,3] There appears to be a congenital predisposition in the Chinese Shar Pei breed. This breed has also been shown to have an increased incidence of esophageal motility disorders and esophageal redundancy, although these can be incidental radiographic findings not associated with any clinical signs.[4,5] Acquired hiatal hernias are often associated with some form of trauma although there is some evidence to suggest that they can occur in dogs and cats with no history of trauma but in association with cardiopulmonary, neuromuscular, or metabolic disease.[6]

Pathophysiology

The terminal esophagus (abdominal portion) incorporates the lower esophageal sphincter (LES) and extends approximately 2 cm below the diaphragm. Normally, the LES relaxes to allow a bolus of food or liquid to pass into the stomach and quickly closes to prevent excessive gastroesophageal reflux (GER). Any change to the normal anatomic relationship between the LES, the hiatus, and the phrenicoesophageal ligament can disrupt the high pressure zone (unrelated to the cranial displacement

of the LES) and contribute to excessive GER by impairing the competency of the sphincter.[7,8] Other anatomic factors that may contribute to excessive GER include the loss of the oblique angle at which the stomach and esophagus join and the distortion of the muscular sling produced by the lesser curvature of the stomach.[8] In most cases of hiatal hernia in the dog and cat, a primary disorder of the LES is unlikely.[7]

Trauma, a well-recognized cause of acquired HH, may result in weakening of the attachments at the hiatus. Hiatal hernias have been seen associated with chronic diaphragmatic herniation.[2,9] However, non-traumatic causes may be related to the "bellows" effect of the thorax.[6] Brachycephalic breeds such as the Bulldog have been shown to have a relationship between more severe forms of the brachycephalic syndrome and hiatal hernias.[6] It is speculated that severe inspiratory disorders can result in negative intraesophageal and intrapleural pressure, leading to the esophagus and stomach being drawn into the thorax, worsening a mild preexisting hiatal hernia and associated signs.[6,10]

The esophagitis that results from HH and GER is caused by the reflux of acidic gastric contents along with pepsin. Esophagitis can induce vomiting (less likely) or regurgitation. The regurgitation is usually intermittent and the contents of the regurgitated material can be blood-tinged and contain undigested food, clear liquid, and foam.

Differential diagnoses for reflux esophagitis associated with HH would include congenital megaesophagus, and acquired megaesophagus due to dysautomonia, myasthenia gravis, neoplasia, foreign bodies, lead poisoning, hypothyroidism, hypoadrenocorticism, and polymyositis.

Diagnosis

To some degree, signalment is important as the Chinese Shar Peis and English bulldogs appear to be predisposed to HH.[4,6] However, most animals with the congenital form of HH will have signs before they are 1 year of age, although diagnosis may be delayed.[11] Animals with the acquired form of HH may develop signs at any age.

Not all animals with a HH are symptomatic and hernias may be identified on thoracic radiographs as incidental findings.[2] Animals with symptomatic HH will consistently have regurgitation and pain from esophagitis, may have hypersalivation, anorexia, and aerophagia. Odonydysphagia, chronic weight loss, and a soft moist cough may be seen. Coughing may indicate aspiration which in severe cases results in aspiration pneumonia.

Physical examination signs may be limited to increased lung sounds (if aspiration is a problem), a thin body condition, and possibly hypersalivation. In addition, the affected animal may be febrile and dehydrated.

The most helpful diagnostic tools are radiography and endoscopy. Survey radiographs of the thorax usually demonstrate a megaesophagus and an abnormal soft tissue density in the caudodorsal thorax. With sliding hernias, however, repeat radiographs may be necessary to finally demonstrate the displaced viscera. The gas within the stomach will help identify any gastric displacement and pneumonia may be seen.

A barium contrast esophagram should be performed as it helps identify the gastroesophageal junction and/or gastric rugal folds. The degree of megaesophagus can be defined better with the aid of contrast material. Fluoroscopy is useful in demonstrating the intermittent (sliding) nature of the hernia. The presence of

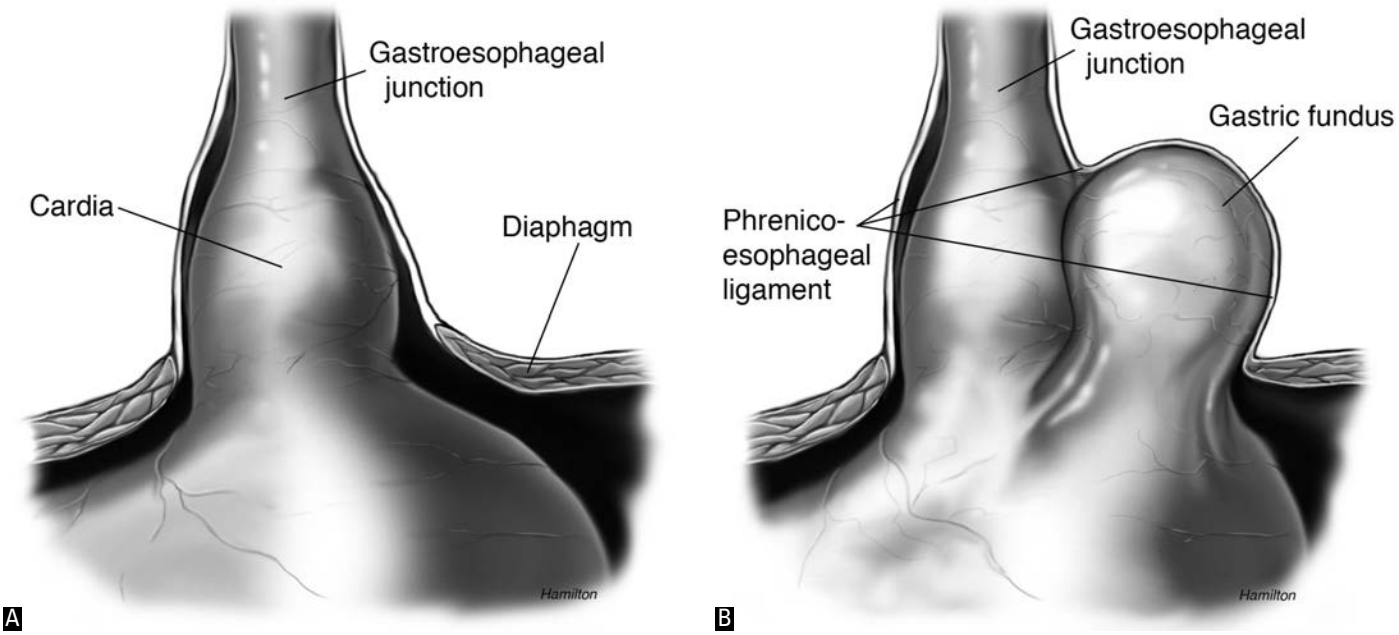

Figure 17-3. A. The "sliding" axial hernia allows the distal esophagus, gastroesophageal junction, and a portion of the stomach to protrude into the thorax. **B.** The paraesophageal hernia allows the protrusion of viscera through a diaphragmatic defect adjacent to the hiatus. The gastroesophageal junction remains fixed in position.

gastroesophageal reflux and the severity of hypomotility can also be analyzed. If a paraesophageal hernia is present, the gastroesophageal junction remains in its normal position while the stomach and other displaced viscera are displaced cranially into the thorax along with and adjacent to the distal esophagus.

Endoscopy will assist in identifying not only the HH but secondary inflammatory changes of the distal esophagus as well. Endoscopy may demonstrate enlargement of the hiatal opening, cranial displacement and dilatation of the cardia, and rugal folds of the stomach.[12] Visualization of the cardia and gastroesopahgeal junction is often easiest with the scope in the retroflex position.[12]

Medical Therapy

The goal of medical therapy is to alleviate the signs caused by reflux esophagitis and any aspiration pneumonia that may be present. Animals with minimal symptomatology may benefit from dietary modification alone. Modification should include a soft diet low in fat, decreasing the volume of food given at each meal while increasing the frequency of feeding, and feeding from an elevated position. Some obese animals will also benefit by losing weight.

In those cases that fail to respond to dietary changes, raising the gastric pH with an H2-receptor antagonist will help neutralize the effects of gastric secretions on the esophageal mucosa and decrease the esophagitis. The improvement in esophagitis indirectly helps increase the tone of the LES thereby diminishing the amount of GER. A proton-pump inhibitor (omeprazole, Prilosec, Astra Zeneca) can be substituted for the H2-receptor antagonist. A prokinetic drug such as metoclopramide (Reglan, Wyeth Pharmaceuticals) or cisapride can be used to help increase the LES tone and hasten gastric emptying resulting in less GER. Cytoprotective agents such as sucralfate (Carafate, Hoechst Marion Roussel) has been shown to be effective by coating the distal esophagus and providing protection against the effects of gastric acid, pepsin, and bile salts. This is given as a slurry or suspension when used for esophagitis.

If the hiatal hernia is small and there is minimal displacement of abdominal contents, the reflux esophagitis is not severe and medical treatment alone is often effective. However, animals that remain symptomatic in spite of aggressive medical therapy will require surgical intervention. Some owners may also choose surgery initially because of their inability to comply with the rigorous requirements of medical therapy.

Surgical Therapy

Veterinary surgeons have historically performed plication of the gastric fundus around the distal esophagus to reverse the effects on GER caused by a hiatal hernia.[3,10] However, Prymak and colleagues advised against this as a component of surgical therapy for hiatal hernia since a LES disorder is not thought to be the primary problem associated with an HH.[7] Surgical repositioning of the displaced stomach and gastroesophageal junction to its normal abdominal location, reduction in size of the esophageal hiatus by plication of the lumbar crus of the diaphragm, and esophagopexy/gastropexy are the procedures associated with the greatest degree of success and fewest complications.[7]

A cranial midline celiotomy is performed to access the cranial abdomen, diaphragm, and distal esophagus. The stomach and esophagus are gently retracted caudally while standing on the left side of the animal that is placed in dorsal recumbency. An assistant maintains slight caudal traction on the stomach and esophagus that helps reposition the distal esophagus below the diaphragm. The small intestine is packed in warm saline-soaked laparotomy pads outside the abdominal cavity to the right of the midline. The triangular ligament of the liver is incised and the liver lobes retracted laterally toward the right side of the abdomen to aid in visualization of the esophageal hiatus. The ventral portion of the esophagus is carefully dissected away from the phrenicoesophageal ligament to allow the caudal portion of the esophagus and the LES to be withdrawn into the abdomen. During this dissection, the ventral trunk of the vagus nerve and blood vessels should be avoided. The right and left crura of the diaphragm are then approximated (hiatal plication) with polypropylene or monofilament synthetic suture to reduce the hiatus to a diameter of 1-2 cm, or to the size, which would allow the passage of one finger adjacent to the esophagus.[7] Polypropylene or a monofilament synthetic suture is preferred for the plication (Figure 17-4A).

The esophagus is then "fixed" to the diaphragm to maintain the LES in the abdominal cavity caudal to the esophageal hiatus. This esophagopexy is accomplished by placing 2 sutures on each side of the hiatal opening between the diaphragm and the tunica muscularis along the ventrolateral surface of the esophagus, again taking care to avoid the vagus nerve (Figure 17-4B). Finally, a left-sided incisional gastropexy is performed while the fundus is under a slight amount of caudal traction. The incision on the abdominal wall is made slightly caudal to the incision on the fundus of the stomach so that when traction is applied to the fundus, the two incisions will be in alignment. In cats, the abdominal wall incision for gaqstropexy is placed more caudally to ensure a moderate amount of traction on the fundus when the abdominal wall and gastric incision are aligned.

Postoperative Care

The animal is maintained on medical therapy and special feeding techniques as described under medical therapy for 2-3 weeks postoperatively. If aspiration pneumonia is a concurrent problem, antibiotics, coupage, oxygen therapy, and nebulization may be necessary. Some degree of regurgitation may continue postoperatively but usually resolves in 3-7 days. If reflux esophagitis is severe, a tube gastrostomy can be performed at the time of hiatal hernia repair and the animal fed in this manner until regurgitation is absent and esophagitis has decreased. Resolution of the megaesophagus and improved esophageal motility has been documented as early as 7 days after hiatal hernia correction.[7]

In most cases, the prognosis following hiatal hernia correction is good. Some animals may still require feeding from an elevated position and small frequent feedings especially if there is a generalized gastrointestinal motility disorder.[13]

In some cases where resolution of clinical signs is not complete, a primary LES disorder may exist. These cases may benefit from

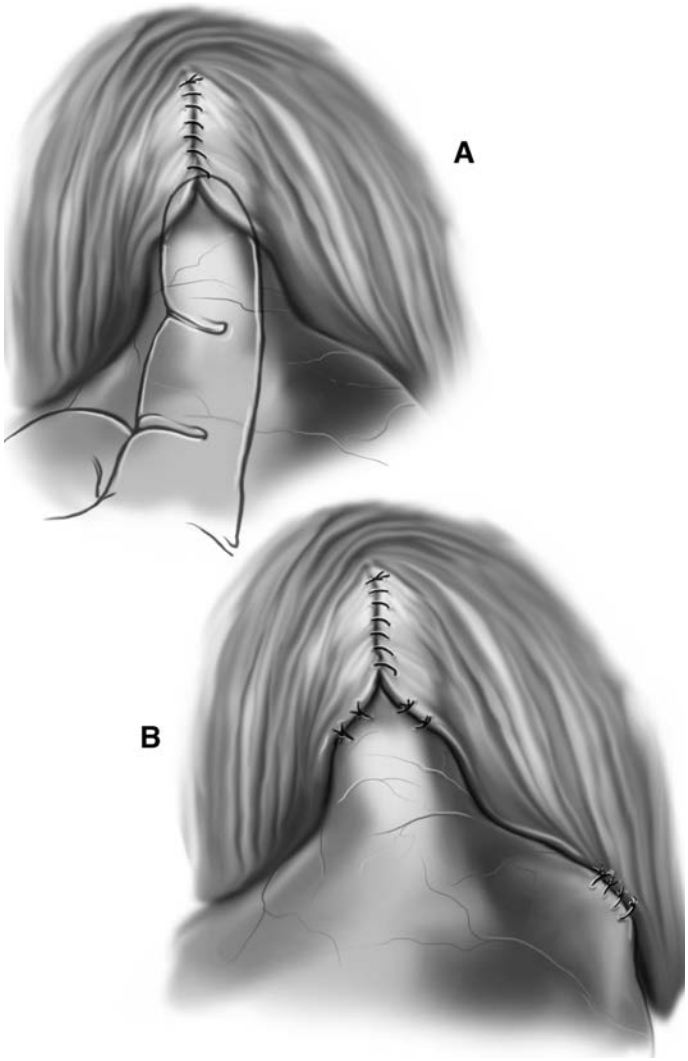

Figure 17-4. A. The stomach and distal esophagus are returned to their normal position. The hiatus is plicated to within 1-2 cm of the esophagus which allows a finger to slide between the hiatus and the esophagus. **B.** An esophagopexy is done by placing sutures between the tunica muscularis of the esophagus and the diaphragmatic portion of the hiatal ring. Lastly a left side gastropexy is done while the fundus has a small amount of caudal traction applied to it.

a fundoplication which is a valvuloplasty technique designed to increase the tone of the LES and decrease reflux.[3,14] This procedure is technically demanding and requires an experienced surgeon to achieve good results. This surgery may also be associated with serious complications such as gastric dilation, stricture, and dysphagia.[15-19]

Chapter 18

Exploratory Celiotomy

Harry W. Boothe, Jr.

Introduction

Exploratory celiotomy or laparotomy is a commonly performed major surgical procedure in small animals. Performing a celiotomy is similar to performing a physical examination and the veterinary surgeon should be thorough, efficient, and consistent when performing surgery to avoid missing disease within the abdominal cavity. Exploratory celiotomy may be indicated for diagnostic, prognostic, or therapeutic purposes. Ideally, exploratory celiotomy provides an opportunity for both a definitive diagnosis and therapeutic intervention. While noninvasive or minimally invasive methods for evaluating many abdominal tissues have been described, complete exploratory celiotomy with biopsy of appropriate tissues/organs remains an efficient method of assessing the abdominal cavity.

This chapter reviews the principles of exploratory celiotomy with emphasis placed on selected biopsy techniques in small animals, including indications, decision-making, timing and specific surgical techniques.

Indications

Indications for exploratory celiotomy include abnormal accumulations of fluid or objects within the abdominal cavity or abdominal viscera, nonresponsive pain, major organ disruption, nonresponsive dystocia, and abnormal discharges originating from an abdominal tissue. Additionally, exploratory celiotomy is indicated whenever abdominal contents can be evaluated most effectively by inspection and palpation, or when diagnosis is dependent on microbiologic testing or biopsy and histologic analysis of relatively inaccessible regions of the abdomen. Many disease processes are indications for exploratory celiotomy however, trauma, foreign body, and neoplasia are probably the most common reasons for performing surgery.

Decision-Making

Decision-making and surgical judgment are an important part of the surgical process. When to perform surgery, when and what tissues to biopsy, and how to provide therapeutic intervention should be carefully considered preoperatively to produce the best results for the patient.

Timing

When to perform exploratory surgery is one of the most critical decisions to be made. Surgery should be timed to maximize the potential for success, both diagnostically and therapeutically, and to minimize patient risk and morbidity. The chronology of changing historical and physical findings is usually helpful in deciding when to perform surgery and minimizing patient risk and morbidity.[1] Timing is particularly critical when dealing with a septic or traumatized patient.[2] Delay in performing surgery often reduces the potential for success; however, deciding to perform surgery too quickly may result in an inappropriate or unneeded surgical procedure and more trauma to the patient.

Diagnostic peritoneal lavage can reduce uncertainty concerning when to perform an exploratory celiotomy; particularly in abdominal trauma situations.[3,4] The presence of abdominal sepsis is a clear indication for exploratory surgery. Indications of sepsis include free air within the abdomen seen radiographically or the presence of intracellular bacteria on cytologic specimens. While few absolutes guide the surgeon regarding the timing of surgery beyond those relating to a septic abdomen, exploratory celiotomy generally should be performed as soon as it is clear that the patient with abdominal disease is not responding sufficiently to therapy. Additionally, exploratory celiotomy should be scheduled to allow the surgeon adequate time to properly perform all surgical procedures appropriate to the case.

Determining when and what tissues to biopsy during an exploratory celiotomy are also important decisions. Historical and physical findings, preoperative blood work, and imaging studies should guide the surgeon as to which body systems should be sampled. Gross surgical findings also influence the decision of which tissues are to be sampled; all abnormal tissues that cannot be definitively assessed grossly should have biopsies evaluated histologically. Generally, one or more body systems are identified presurgically as target tissues for both careful evaluation and possible biopsy or culture. The sequence of tissue/organ biopsy should be influenced by the contamination potential associated with each biopsy procedure. Procedures with lower risk of contamination such as kidney biopsy are performed first, while those with higher risks of contamination such as intestinal biopsy are performed last.

Biopsy of appropriate tissues and submission of tissue samples for histologic examination should be considered a routine part of most exploratory celiotomies. With the exception of intestinal foreign bodies or hemorrhage secondary to trauma, histologic evaluation of tissues is indicated, particularly when a definitive surgical diagnosis is not apparent at the time of surgery. If the surgeon relies on gross evaluation and interpretation alone (without biopsy) during exploratory celiotomy a correct definitive diagnosis will be missed in many cases.

Aerobic and anaerobic bacterial cultures may be indicated in cases of abscessation, peritoneal fluid accumulation, prostatic disease, hepatobiliary disease, or renal disease. Urine cultures are commonly performed when urinary tract infection may be present.

Therapeutic Intervention

Therapeutic intervention during exploratory celiotomy is directed toward the lesions identified during the procedure. Specific therapeutic goals of exploratory celiotomy include hemorrhage control, correction of contaminating sources, correction of causes of pain, removal of mass lesions or obstructions, and elimination of abnormal fluid accumulations. By effective decision-making and appropriate time management during exploratory celiotomy, there is an opportunity for the veterinary surgeon to

achieve both a definitive diagnosis and provide an appropriate therapeutic procedure for a specific disease process.

Surgical Techniques

Technical considerations when performing a celiotomy include appropriate patient preparation, proper positioning for surgery, surgical approach, equipment needs, method of exploration, biopsy techniques, intra-operative peritoneal lavage, and wound closure.

Patient Preparation and Positioning

The patient is prepared for surgery so that surgical options are maximized for any disease process encountered. Liberal clipping of hair and aseptic preparation is performed over an area extending beyond the limits of the ventral abdomen. Poor or incomplete patient preparation is unacceptable since it could limit surgical options or result in incomplete surgical evaluation, or contamination of the surgical field. In most cases, the patient is positioned in dorsal recumbency on a level table. Centering the animal in dorsal recumbency without lateral "leaning" is important in approaching the ventral midline with the least tissue trauma. Slight downward tilting of either end of the surgical table may be helpful, particularly during surgical exploration.

Surgical Approach

The standard surgical approach for exploratory celiotomy is the ventral midline approach. To examine the abdomen completely, a skin incision is made from the xiphoid process to just cranial to the pecten (pubis). The skin incision is extended parapreputially in the male dog to properly expose the caudal abdominal cavity. Occasionally, extension of the midline incision paracostally may improve visualization of the craniodorsal abdomen (especially liver and diaphragm). The paracostal incision is initiated at the xiphoid process and continued parallel and 3 to 4 cm caudal to the costal arch, and ends level with the tip of the last rib. The abdominal incision may be modified to accommodate specific tissues of interest; however, a large enough skin incision is imperative so as to not compromise appropriate exploration of the abdomen. On entrance into the abdominal cavity the prominent fatty falciform ligament is found between the xiphoid process and umbilicus. Excision of the falciform ligament from its peritoneal attachment by electrocautery or sharp dissection improves visibllity of the cranial abdomen and permits precise closure of the abdominal wall at the completion of the procedure.

Equipment Needs

Surgical instrumentation required for exploratory celiotomy is minimal beyond that of a standard soft tissue surgical pack. Useful additional surgical instruments that should be available include tissue retractors, suction (including tip, tubing, and apparatus), noncrushing intestinal and vascular forceps, and electrocautery. Self-retaining abdominal retractors (e.g.[a] Balfour retractor) markedly improve visibility and access to the peritoneal cavity (Figure 18-1). Balfour retractors are placed with moistened laparotomy sponges positioned to protect the abdominal wall. Suction permits removal of blood, exudate, and

Figure 18-1. The use of Balfour retractors placed over moistened laparotomy sponges is shown. Self-retaining retractors improve visibility and access to the peritoneal cavity.

lavage fluid from the abdominal cavity. A Poole suction tip[b] is usually most effective in body cavities.[5]

Properly placed noncrushing intestinal forceps will assit the solo surgeon in decreasing spillage of intestinal contents while minimizing intestinal trauma during biopsy, enterotomy, or intestinal resection and anastomosis. Hemostatic forceps may provide short-term hemorrhage control until definitive hemostasis is achieved by ligation or electrocautery. Electrocautery is a secure and efficient method of hemostasis when used on smaller vessels. Inappropriate use of electrocautery may result in delayed hemorrhage or an increased rate of wound infection.[5]

Method of Exploration

The technique used in abdominal exploration should be the same regardless of the clinical signs of the patient.[6] After entry into the peritoneal cavity; samples of free peritoneal fluid, if present, are collected for microbial culture. Small amounts of transudate are commonly seen in young animals and are normal. The abdomen is scanned for obvious lesions initially and sources of active hemorrhage or gastrointestinal leakage are identified and treated immediately. Lesions that do not involve active hemorrhage or gastrointestinal leakage are initially ignored in favor of a complete exploration of the abdomen.

The surgeon should perform a thorough, systematic exploration of the abdomen.[1,6-10] Abdominal tissues are evaluated for location, size, shape, color, consistency, and surface contour. Tissues or fluid accumulations are cultured, if indicated, at the time of biopsy sample collection. The cranial aspect of the abdomen is

[a] Balfour retractor, V. Mueller, Baxter Healthcase Corp, McGaw Park, IL. 60085. [b] Poole suction tip, Cardinal Health, McGaw Park, IL 60085.

examined first by evaluating the caudal surface of the diaphragm while carefully retracting the liver lobes caudally. Each liver lobe should be inspected and gently palpated for mass lesions. The hepatic hilus, including the gall bladder, hepatic ducts, hepatic artery, and terminal portal vein branches are examined while gently retracting the stomach caudally. Bile duct patency can be checked if indicated, by attempting to gently express gall bladder contents into the duodenum. Observe and palpate the biliary tract including the bile duct as it traverses the hepatoduodenal ligament. The stomach is thoroughly palpated from the gastroesophageal junction and cardia to the pylorus, including all anatomic surfaces and the greater and lesser omentum.

The spleen is exteriorized to thoroughly evaluate the parenchyma for mass lesions and its vascularity visually and by palpation. Siderotic plaque is commonly seen and appears as grey to greenish colored plaques on the splenic edges. These plaques are regarded as normal and do not require biopsy. Next, inspect and gently palpate the pancreatic body and left pancreatic limb as it extends along the caudal surface of the stomach. Identify and grasp the descending colon and use the mesocolon as an anatomic retractor for abdominal contents by positioning the colon ventrally and to the right. Colonic retraction exposes and allows examination of the left paravertebral region, including the left kidney and proximal ureter, left adrenal gland, aorta, and left ovary and uterine horn.

The spleen is returned to the abdomen or exteriorized and wrapped in a moistened laparotomy pad, which facilitates evaluation of the intestines. The small intestine is evaluated by assessing mesenteric arterial pulsations and peristaltic activity. Examination is initiated at the pylorus, and the duodenum is retracted to evaluate the right pancreatic limb. The pancreas should be gently palpated for the presence of mass lesions. Use the mesoduodenum as a retractor by positioning the duodenum ventrally and to the left side of the abdominal cavity. This maneuver permits examination of the right paravertebral region, including the portal vein, caudal vena cava, celiac artery, epiploic foramen, hepatic lymph nodes, right kidney and proximal ureter, and right ovary and uterine horn. The right adrenal gland can be palpated just dorsal to the caudal vena cava and medial to the right kidney. Trace the duodenum distally to the duodenocolic ligament, which limits exteriorization of the caudal duodenal flexure and proximal jejunum. The surgeon should carefully visualize and palpate the distal duodenum and jejunum, ileum, cecum, and colon.

Evaluate the mesentery of the intestine and its associated lymph nodes, vascularity, and lacteals. Finally, the caudal abdomen, including the distal colon and associated lymph nodes, urinary bladder, distal ureters, proximal urethra, regional lymph nodes (medial iliac, sacral, and hypogastric), prostate and ductus deferens, or uterine body and vagina are visualized and gently palpated.

Biopsy Techniques

After a thorough and systematic abdominal examination, appropriate tissues are biopsied or specific surgical therapeutic intervention is performed. Biopsies of the liver, intestine, lymph node, and kidney are most commonly performed during exploratory celiotomy.

Liver

Liver samples for biopsy may be obtained by various methods.[11-13] One of the simplest and most frequently performed is the "guillotine" method.[11] A loop of monofilament absorbable synthetic suture material is placed around a peripheral portion of a liver lobe and the ligature tightened to cut through and crush the hepatic parenchyma and rest on the hepatic vessels and biliary ducts. A scalpel blade or scissors is used to excise the hepatic tissue approximately 5 mm distal to the ligature.

Another hepatic biopsy method is the finger or instrument fragmentation technique.[12] This method is also limited to sampling the edge of a liver lobe. The proposed biopsy site is isolated from the remaining lobe by carefully crushing hepatic parenchyma using an instrument (e.g., Crile hemostatic forceps[c]) or tips of the thumb and index finger. Parenchymal crushing exposes blood vessels and bile ducts to the isolated section. Ligatures of synthetic absorbable suture material are placed on exposed blood vessels and bile ducts in the isolated lobar section. The exposed vessels and ducts are divided distally to the ligatures and the hepatic sample excised.

Wedge resection of peripheral hepatic tissue is another biopsy option.[12] The proposed biopsy site is isolated by placing and tying one or two rows of full-thickness horizontal mattress sutures of synthetic absorbable suture material in the liver. The biopsy specimen is excised by sharp dissection distal to the sutures. If necessary, additional horizontal mattress sutures may be placed near the incised edge of the liver lobe to achieve hemostasis.

A more versatile hepatic biopsy method involves use of a cutaneous biopsy punch.[d] Any portion of the liver may be sampled; however, smaller, partial thickness samples are obtained.[11] The biopsy punch is placed into the lesion or hepatic tissue and the biopsy obtained by twisting the instrument to free the tissue specimen. Avoid excessive tissue penetration to preserve larger vessels located in the deeper hepatic parenchyma. Hemostasis is achieved by inserting either a topical hemostatic agent (e.g., absorbable gelatin sponge[e]) or a vascularized omental tag into the biopsy defect.[11]

Intestine

Selected upper and lower intestinal regions are accessible to mucosal endoscopic biopsy,[14] however full-thickness surgical intestinal biopsy samples may be taken from any site. Relative advantages of endoscopic, laparoscopic-assisted, and surgical biopsies have been described.[15-17] Principles of intestinal biopsy collection during exploratory celiotomy include the collection of multiple samples along its length, full-thickness sample collection, and protection of the properly-closed biopsy site.[18,19] Technical surgical considerations include closure technique and incisional protection method.

A cutaneous punch[d] is used to penetrate full-thickness into the lumen and obtain the sample.[20] The intestinal defect is closed

[c] Crile hemostatic forceps, Cardinal Health, McGaw Park, IL 60085. [d] Baker's 6 mm biopsy punch, Baker Cummings, Key Pharmaceuticals, Miami, FL 33169. [e] Gelfoam, Pharmacia & Upjohn Company, Kalamazoo, MI 49001.

Figure 18-2. A disposable cutaneous punch (6 mm in dogs and 4 mm [shown here] in cats) is used to obtain an intestinal biopsy sample. The circular defect is closed transversely with simple interrupted sutures using 4 monofilament synthetic suture material.

in a single layer with an appositional suture pattern (e.g., simple interrupted) and monofilament synthetic absorbable suture material (e.g., polydioxanone). Transverse closure of the circular defect is recommended.[21] Leak testing of the biopsy site(s) is performed by isolation of the biopsy site with fingers or Doyen clamps and injection of saline into the isolated intestinal segment.[22] Intestinal incision protection can be provided by using greater omentum or a serosal patch to reinforce the closure technique.[19,23] Greater omentum is placed over the biopsy site if normal wound healing is expected. A serosal patch is performed by placing an adjacent intestinal loop onto the biopsy site and placing serosal to serosal sutures when delayed wound healing is anticipated (e.g., hypoproteinemia, peritonitis).[17,23]

Lymph Node

The following abdominal lymph nodes are frequently biopsied during abdominal surgery: medial iliac, mesenteric (jejunal), pancreaticoduodenal, and colic lymph nodes. Mesenteric (jejunal) lymph nodes may yield less definitive information.[24] While results of fine-needle lymph node aspiration correlate well with those of lymph node histology in small animals with solid tumors, incisional or excisional lymph node biopsy samples are preferred because they provide morphologic information.[25] The blood supply to adjacent tissue (intestine) is carefully preserved when excising a lymph node. Divide the blood supply to the lymph node between sutures, and carefully dissect the lymph node from adjacent tissues.[26,27] The lymph node is handled gently to avoid creation of tissue artifact.

Kidney

Biopsy of the kidney is frequently performed to provide both diagnostic and prognostic information.[27] Surgical biopsy methods include needle biopsy and wedge resection. The needle biopsy technique is less traumatic but yields smaller specimens. The needle[f] is placed through the renal capsule at the caudal aspect of the kidney and directed within the cortex toward the cranial pole. Remove the biopsy needle and apply digital pressure or an interrupted suture over the needle puncture site to achieve hemostasis.

Kidney wedge biopsy yields larger specimens but has a higher risk of hemorrhage. A wedge-shaped segment of renal cortex is excised using a scalpel blade. The defect is closed using mattress sutures of synthetic absorbable suture material placed through the renal capsule and parenchyma. If necessary, the greater omentum may be incorporated into the closure to provide hemostasis and cover the biopsy defect.

Intraoperative Peritoneal Lavage

Following abdominal exploration, specimen collection, and therapeutic intervention, the peritoneal cavity should be lavaged prior to closure. Intraoperative peritoneal lavage using relatively large volumes (1 to 3 L) of warm, isotonic solution assists in contaminant removal (e.g., soft tissue fragments, bacteria, fibrin, fat) and patient warming.[29,30] Use of lavage in patients with intra-abdominal infections is controversial, use in patients experiencing trauma or operative contamination seems appropriate.[29] All lavage fluid should be evacuated by suction prior to body wall closure, as residual saline solution impairs peritoneal defense mechanisms.[29]

Different agents (antimicrobials, antiseptics, or anticoagulants) have been added to peritoneal lavage fluid to reduce the incidence or severity of peritoneal contamination and improve survival.[5] Of these agents, anticoagulants have shown the most benefit and fewest complications.[31,32] Heparin has a beneficial therapeutic effect in experimental canine peritonitis by preventing further fibrin deposition thus reducing fibrinous bacterial entrapment.[30] The net beneficial effect is improved clearance of bacteria from the peritoneal cavity.[30] Heparin may be added to the lavage fluid at a dose of 100 u/kg.

Abdominal Closure

The abdominal wall is closed at the completion of abdominal exploration and after lavage fluid evacuation. Abdominal wall closure technique recommendations are based on biomechanical information of healing abdominal incisions in the dog.[33] Sutures should incorporate approximately 8 mm of tissue on each side of the wound. Sutures should incorporate the linea alba and external fascial sheath of the rectus abdominis muscle only, not muscle or peritoneum (Figure 18-3).[34,35] Incorporating the internal fascial sheath of the rectus abdominis muscle does not yield additional wound strength and is not recommended.[34] Suture tightness should be appropriate for wound edge apposition however excessively tight sutures yield lower long-term wound strength.[36] Either a continuous or interrupted suture pattern is performed using appropriate sized synthetic absorbable or nonabsorbable suture material.[34,37,38] The subcutaneous tissue and skin are closed in a routine fashion.

Summary

Exploratory celiotomy is a commonly performed procedure in small animals. When properly timed and performed, exploratory celiotomy can provide definitive diagnostic, prognostic, and therapeutic intervention to the patient. Critical decisions to be

[f] Coaxial achieve, Cardinal Health, McGaw Park, IL 60085.

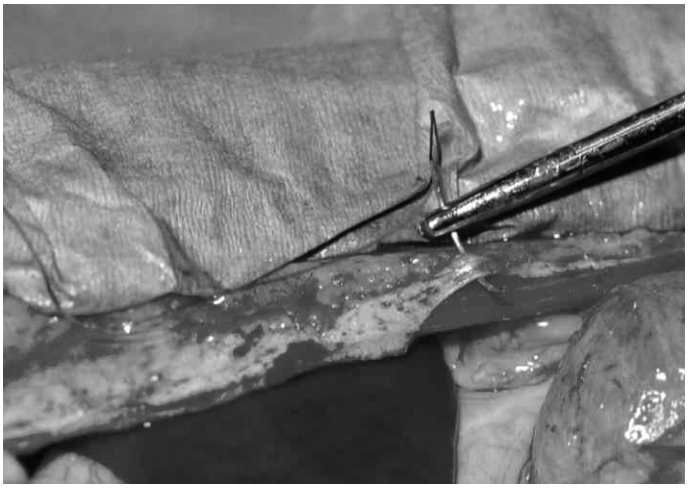

Figure 18-3. Closure of the abdominal wall is shown. Sutures should incorporate approximately 8 mm of fascia on each side of the wound.

made include why, when, and how to perform abdominal exploration, associated biopsy techniques, and the performance of specific surgical procedures.

Chapter 19

Stomach

Principles of Gastric and Pyloric Surgery

Maria A. Fahie

Introduction

The surgeon should consider specific principles of surgery to produce the best clinical outcome in animals undergoing surgical procedures of the stomach and pylorus. These principles are applicable to surgery involving all of the gastrointestinal tract although only procedures involving the stomach and pylorus will be described in this chapter (Table 19-1).

Table 19-1. Considerations in Gastric Surgery

Anatomical knowledge	Suture material and pattern
Potential secondary metabolic disease	Suture pattern
Neoplastic disease	
Prophylactic antibiotic administration	Stapling devices
Approach (ventral midline celiotomy)	Omental patching
Aseptic technique	Abdominal lavage
Atraumatic tissue handling	Postoperative pain management
Palpation techniques for foreign bodies	Postoperative alimentation/ nutrition

Anatomy

The stomach has a rich blood supply derived from the celiac artery. Branches of the left and right gastric, splenic and left and right gastroepiploic arteries provide the main blood supply to the stomach (Figure 19-1). Innervation of the stomach is an important anatomical consideration since its disruption intraoperatively could lead to postoperative gastric and biliary tract dysmotility. The primary innervation is parasympathetic, from the vagus nerve. The dorsal and ventral vagus trunks pass through the esophageal hiatus. The ventral trunk branches to supply the lesser curvature, pylorus and liver. The dorsal trunk supplies the lesser curvature, ventral stomach wall, and then follows branches of the celiac and cranial mesenteric arteries. Sympathetic gastric innervation stems from the celiacomesenteric plexus with fibers following the gastric branches of the celiac artery (Figure 19-2). The spinal ganglia responsible for gastric innervation can span from C2 to L5, and peak from T2 to T10.

The cardia of the stomach and pylorus are relatively fixed in place by the esophagus and hepatoduodenal ligament while the mid-portion of the stomach is more mobile.

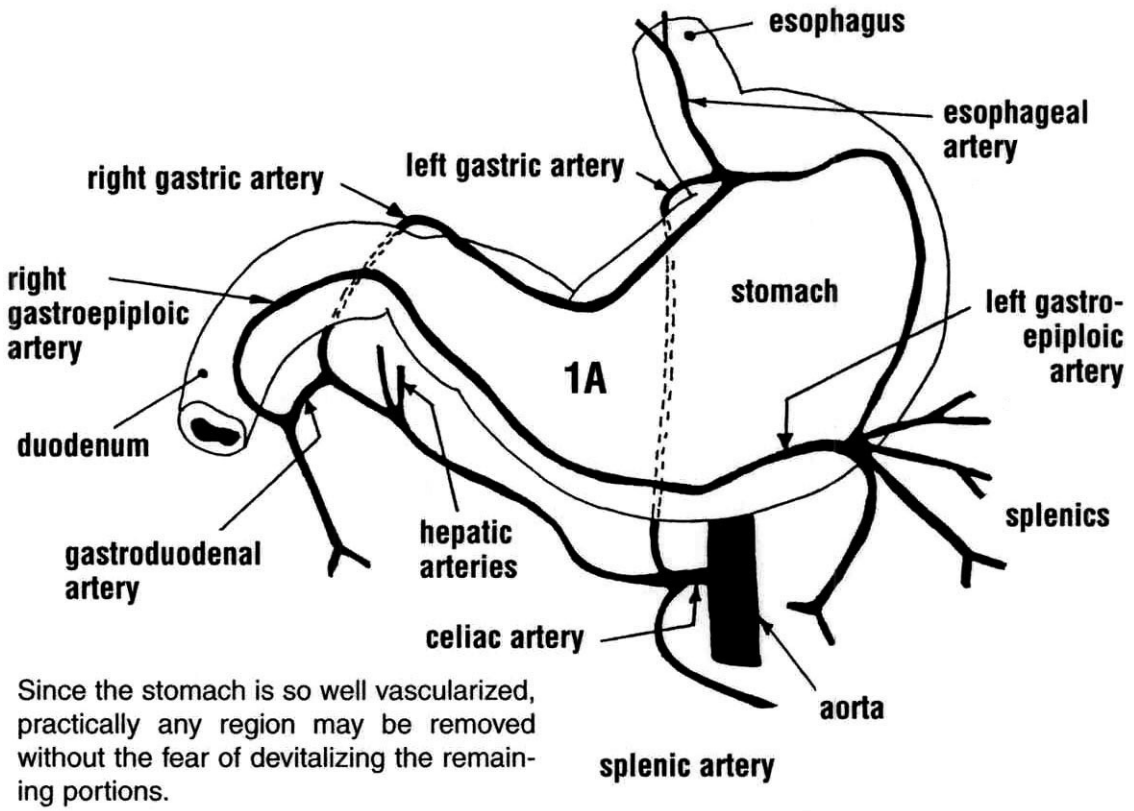

Figure 19-1. Pertinent gastric arterial anatomy. Reprinted with permission from: Anderson S, Gill P, Lippincott L, Somerville M, Shields S, Balfour R, Wilson E. Dimensions in Surgery: Partial Gastrectomy. Pulse (an official publication of the Southern California Veterinary Medical Association): May, 2002.

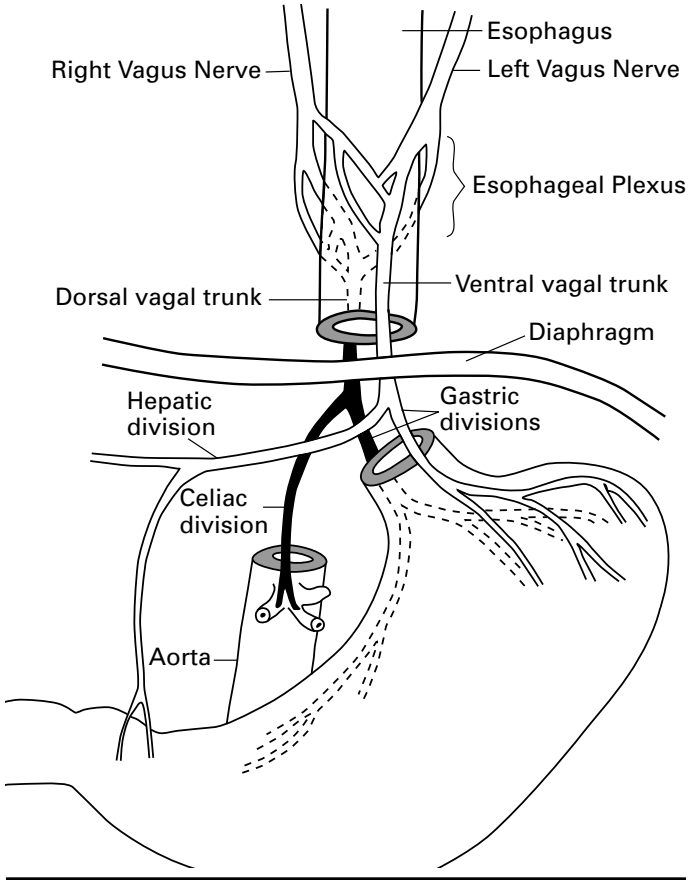

Figure 19-2. Gastric innervation.

In deep chested dogs, access to the stomach and pylorus can be limited by its omental and mesenteric attachments including the hepatoduodenal ligament, a part of the lesser omentum. This structure contains the hepatic arteries, lymphatics, vagus nerve branches, portal vein and bile duct, therefore its incision is associated with risk of damage to those structures (Figure 19-3). Exposure to the stomach is best enhanced by increasing the length of the abdominal wall incision cranially to the xiphoid cartilage of the sternum, and caudally past the umbilicus. When extending cranially, avoid inadvertent incision of the diaphragm resulting in iatrogenic pneumothorax. Exposure can also be enhanced with devices such as a Balfour abdominal retractor.

Metabolic Abnormalities

Animals that require gastric surgery have clinical signs such as vomiting, anorexia, dehydration, abdominal pain, and gastric distension. Medical management of these clinical signs may be necessary pre and postoperatively and may include antisecretory agents (H_2 receptor antagonists), proton pump inhibitors, mucosal protectants, prostaglandin analogues, prokinetic agents and/or antiemetic agents. With acute or chronic vomiting, fluid and electrolyte abnormalities and dehydration are common and should be corrected by intravenous fluid administration prior to anesthesia and surgery if possible. Serum chemistries and electrolyte levels should be obtained prior to surgery. Potassium loss in vomitus and urine can lead to hypokalemia. Hypochloremia can result due to loss of chloride-rich gastric secretions. Hypochloremia can also be exacerbated in hypokalemic patients with reduced renal nephron reabsorption of chloride. The acid-base status of the patient can be normal if loss of gastric hydrochloric acid and bicarbonate-rich duodenal fluid is simultaneous. Metabolic acidosis can be present due to dehydration, prerenal azotemia, and lactic acidosis from compromised tissue perfusion. Hypochloremic metabolic alkalosis indicates severe loss of gastric content and is most indicative of gastric outflow obstruction.

Neoplastic Disease

Dehiscence risk could be higher in patients with neoplasia undergoing gastrotomy for biopsy, although a study of 53 cats with alimentary LSA were not at higher risk.

Prophylactic Antibiotic Administration

Prophylactic antibiotic administration is controversial, since gastric content is generally not high in bacterial numbers in contrast to other regions of the small and large intestine. Opening the gastric lumen is considered a clean-contaminated surgical procedure. Factors that should prompt the surgeon to consider administration of antibiotics include geriatric or debilitated patients, prolonged intraoperative time or compromised aseptic technique. The choice of a specific antimicrobial drug should be based on the organisms within the lumen of the incised organ, or present on the skin at the ventral midline incision site. The duration of antibiotic administration depends upon whether the agent is being administered prophylactically or therapeutically. For prophylactic administration, the antibiotic is given immediately preoperatively (induction of general anesthesia) and continued for the first 12 hours postoperatively. For therapeutic use, the duration of administration should be based upon the pharmacokinetics of the agent used and may extend 10 to 14 days. Cephalexin (22 mg/kg IV or PO TID) is an easily administered, economical antibiotic that provides an adequate spectrum for most gastric procedures.

Approach

The surgeon should perform complete abdominal exploration prior to all gastric procedures in order to determine the extent of the primary disease process or to identify other disease. A ventral midline celiotomy incision is made, beginning at the xiphoid cartilage cranially and extending at minimum to the region of the umbilical scar caudally. An incision extending more caudally is necessary in some cases to perform complete exploration of all abdominal structures. The falciform ligament is prominent in the cranial aspect of the incision and can be either excised or retracted to aid the surgeon's visualization of abdominal structures and make closure of the incision more precise. Branches of the internal thoracic and cranial epigastric artery supply the cranial aspect of falciform tissue near the xiphoid and need to be ligated for hemostasis if it is excised. Smaller vascular branches running perpendicular to the linea into the falciform fat can be ligated or cauterized with electrocautery for hemostasis. Moistened laparotomy pads are placed to protect the edges of the abdominal wall, and self-retaining abdominal retractors such as Balfour abdominal retractors or blunt Weitlaner retractors are used to enhance visualization of the abdominal cavity. The surgeon must carefully avoid damage to the bile duct as it traverses the hepatoduodenal ligament (Figure 19-3). The surgeon should examine all

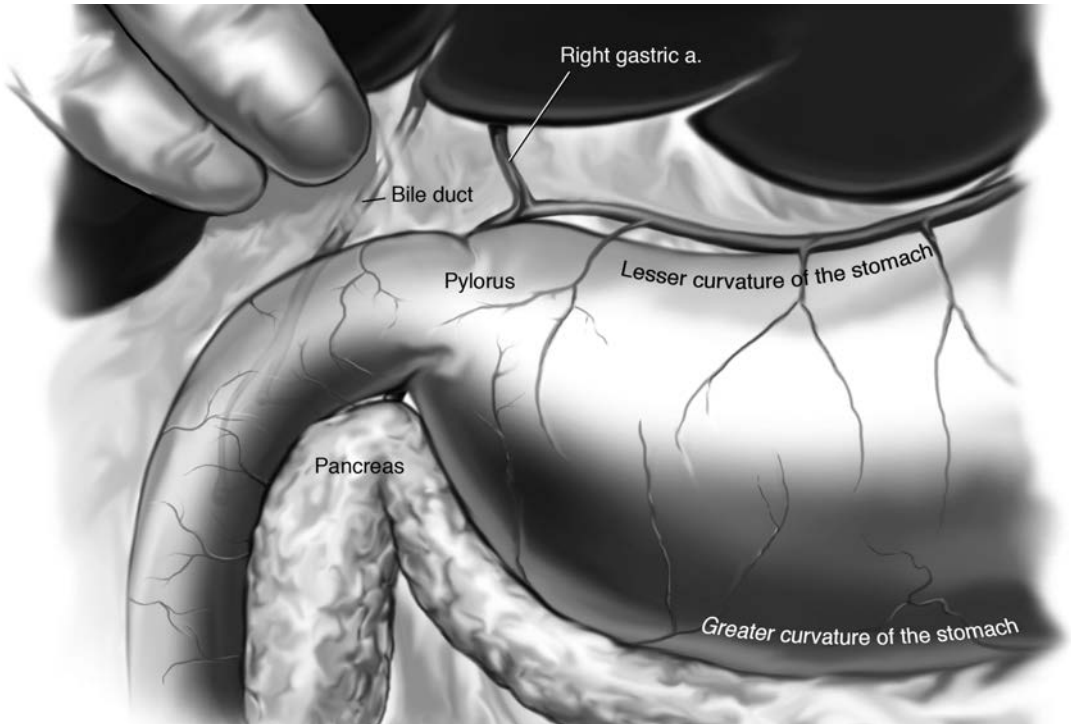

Figure 19-3. Anatomy of the bile duct. It is important to avoid damage to the bile duct as it traverses the hepatoduodenal ligament.

abdominal organs and the entire gastrointestinal tract prior to gastrotomy or enterotomy to reduce manipulation of these potentially contaminated tissues within the abdomen.

Aseptic Technique

The surgeon may use several techniques to decrease contamination of the abdominal cavity and incision during gastrointestinal surgery. Contamination of the abdomen after gastrotomy can be reduced by double-gloving. The surgeon wears an extra one-half sized larger pair of gloves during gastrointestinal tract surgery and removes the contaminated outer gloves prior to abdominal lavage and closure. Contamination of the abdomen by gastric content is reduced by packing off the stomach from the abdominal cavity with laparotomy pads. The stomach is exteriorized as much as possible from the abdomen by placement of stay sutures or Babcock forceps on the serosal surface. Stay sutures are positioned around proposed gastrointestinal incisions to maintain gentle tissue traction and to aid luminal visualization and prevent spillage of luminal contents. The stay sutures should be placed with a substantial (1cm) full-thickness inclusion of gastric wall to prevent accidental tissue tearing as tissues are manipulated. Frequent reapplication of warm saline to exposed tissues and the laparotomy pads is performed intraoperatively and prevents dessication of tissues. After closure of the gastric wall, contaminated laparotomy pads or sponges are removed and replaced. The abdomen is lavaged with warm saline to remove blood clots, tissue debris and to reduce bacterial numbers. Contaminated instruments are discarded and clean instruments used for abdominal wound closure.

Atraumatic Tissue Handling

Gastric tissues can be friable and atraumatic tissue forceps or an assistant's fingers induce less tissue trauma than some surgical instruments during tissue manipulation. Surgical instruments that are valuable for gastric surgery include DeBakey tissue forceps, Babcock forceps and Doyen intestinal forceps. As an alternative to Doyen forceps, Allis tissue forceps can be modified by placing moistened gauze sponges around the arms of the instrument to be applied to tissue. The thickness of the gauze determines the amount of pressure applied. Bobby pins can also be sterilized and used as atraumatic intestinal forceps if an assistant's fingers are not available.

Palpation of Gastric Foreign Bodies

Gastric foreign bodies can be difficult to palpate if there is excessive gastric content and/or if the object is relatively thin, flat and lying against the gastric wall. Gastric contents can be removed by orogastric tube passage and flushing intraoperatively prior to gastrotomy. Alternatively, contents can be carefully removed with suction after gastrotomy, using a Yankaeur or Poole suction tip. If necessary, the surgeon can manually remove gastric content using care to prevent spillage into the abdomen. Gentle and thorough palpation of the entire stomach will permit foreign body location and removal. Palpation of the dorsal gastric surface is aided by digitally creating a fenestration in the greater omentum adjacent and caudal to the greater curvature. If a gastric foreign body is retrieved intraoperatively, the entire intestinal tract should be carefully examined and gently palpated to ensure that no other foreign material is present that could cause an intestinal obstruction. Foreign bodies located in the caudal esophagus can sometimes be removed safely by a gastrotomy incision. Sterile water-soluble lubricant can be used to protect the esophageal and gastric mucosal surfaces during gentle digital palpation and retraction to move the object into the stomach.

Suture Material and Pattern

Many gastric closure techniques are described in the literature including: single-layer appositional or inverting, double layer-inverting or appositional seromuscular (excluding the mucosal layer); and double-layer, appositional and inverting full-thickness closure. The goal of gastric closure is a leak-proof seal with sufficient strength to heal. The submucosal layer, with its abundant collagen, offers the most strength for suture and should be incorporated in all types of closure. A potential justification for exclusion of the gastric mucosal layer is the potential for some types of suture material to wick gastric fluid to the serosa and peritoneum. An advantage of closure of the mucosal layer is reduced postoperative mucosal hemorrhage into the gastric lumen. The classic closure of a hollow viscus using a double-layer inverting pattern such as a Cushing pattern, followed by a Lembert pattern, is widely used and successful. Inverting closure patterns can be difficult to perform if gastric tissue is thickened, and can compromise lumen diameter compared with appositional patterns. Alternatively, some surgeons prefer to close the mucosa with a simple continuous appositional pattern followed by a Cushing pattern as the 2nd layer of closure. It is recommended that the surgeon apply additional throws to each end of continuous suture patterns (5 to 6 throws of suture) to ensure knot stability.

The ideal suture material for gastric closure is monofilament, absorbable [poliglecaprone 25-Monocryl™ (Ethicon, Somerville, NJ), glycomer 631-Biosyn™ (Syneture/Covidien, Norwalk, CT), polydioxanone-PDS II™ (Ethicon, Somerville, NJ) or polytrimethylene carbonate-Maxon™ (Davis & Geck, Chicago, IL)] with a tapered needle, usually 2-0 to 4-0 in size. Based on the speed of gastric tissue healing, there is little justification for use of non-absorbable suture materials. Pyloric obstruction following closure of a gastrotomy incision with polypropylene has been described. Recent studies of absorbable knotless barbed suture material demonstrated comparable bursting strength and closure time for gastrotomy.

Stapling Devices

Stapling devices provide a stronger anastomosis with shorter surgical time compared to hand suturing, however their use may be cost-prohibitive for some patients and procedures. Stapling devices should be considered for partial gastrectomy and/or gastroduodenostomy (Billroth I) diversion procedures. The linear thoracoabdominal (TA™ 30, 55, 90; (USSC, Tyco Healthcare Group LP, Norwalk, CT) and gastrointestinal anastomosis (GIA™ 60, 80; USSC, Tyco Healthcare Group LP, Norwalk, CT) are the most versatile stapling devices for gastric procedures. The TA applies a double staggered row of staples. The GIA applies two double staggered rows of staples and cuts between them.

Omental Patching

The potential benefit of enhanced vascular supply to healing gastric tissue is realized. In most cases, the omentum can be easily advanced over the incision site and tacked to the surrounding gastric serosa with a few simple interrupted sutures of monofilament absorbable.

Abdominal Lavage

Abdominal lavage is indicated following gastric procedures to dilute and/or remove any gastric content spillage. Any gastric incision sites should be lavaged locally after closure, while the stomach is still exteriorized from the abdomen. Prior to abdominal incision closure, copious abdominal irrigation is recommended with warm, isotonic, crystalloid solution such as 0.9% saline or lactated ringer's solution. Lavage should continue until the fluid collected is clear. The preferred temperature of lavage fluid should approximate normal body temperature 38.5°C (101.3°F). In hypothermic patients, fluid at 43°C (110°F) successfully increased body temperature during 2 to 6 minutes of lavage.

Postoperative Pain Management

Appropriate postoperative pain management is being recognized as a key factor in the successful recovery of surgical patients. In gastric surgery patients, nonsteroidal antiinflammatory agents and morphine derivative agents may have undesirable effects on gastric mucosa and gastrointestinal tract motility. Tramadol hydrochloride 50 mg (Tramadol®, 1-2 mg/kg PO-TID, Mutual Pharmaceutical Co. Inc., Philadelphia, PA) may provide necessary pain relief without the side effects discussed above. Maropitant, a neurokinin receptor antagonist and substance P blocker, may provide pain relief and anti-emetic benefits. (Cerenia™, 2-8 mg/kg PO once daily for up to 5 days or injectable, Zoetis, Florham Park, NJ). Gabapentin, an anticonvulsant and analgesic through incompletely understood mechanisms, may also be well tolerated. (Neurontin™, 10-20 mg/kg PO once to twice daily, Pfizer, New York, NY). The proper combination of medications, light activity and appropriate nutrition is necessary for a gradual return to normal function.

Postoperative Alimentation and Nutrition

The benefit of early introduction of nutrients on wound healing is realized. Complications including mucosal atrophy, ileus, and sepsis from bacterial translocation through the intestinal wall are all associated with malnutrition. Decisions regarding diet choice and initiation of oral alimentation must be made considering the preoperative condition, intraoperative findings and surgical procedures performed. Auscultation of gut sounds within 24 hours postoperatively is a positive indication that gastrointestinal motility is resuming. For a simple gastrotomy patient, oral alimentation can begin with water and/or a bland gruel within 24 hours postoperatively, provided no vomiting has been noted. Some patients undergoing gastric surgery might require an alternate route for alimentation postoperatively. Ultimately, this should be anticipated preoperatively, so that the feeding tube placement can occur simultaneously with surgery. In order to bypass the stomach, a jejunostomy tube might be indicated. Research suggests that intrajejunal nutrition enhances the gastrointestinal tract barrier and does not exacerbate pancreatitis. Intravenous total parenteral nutrition is another option but not as successful to prevent mucosal atrophy or increased collagen deposition. Supplementation of vitamin B12 (cyanocobalamin injection) should be considered in gastrectomy and gastroduodenostomy patients, since deficiency and anemia could result. The mechanism underlying the deficiency is the

reduction in numbers of parietal cells to secrete intrinsic factor, which is crucial for vitamin B12 to complex with and become absorbed in the intestine.

Gastrotomy

Maria A. Fahie

Indications

The most common indication for gastrotomy is for identification and removal of suspected foreign bodies or for gastric biopsy. Postoperative peritonitis and stricture are rare in simple gastrotomy patients.

In medium to large patients, with relatively small and smooth gastric foreign bodies, removal can occur with induction of vomiting. Alternatively, gastric lavage or endoscopy can be performed with general anesthesia. A recent retrospective study of 102 dogs undergoing endoscopic removal of esophageal and gastric foreign bodies (FB) concluded a low complication rate provided patients were > 10kg and did not have sharp bone FB or FB present for more than 3 days.

Surgical Technique

The optimal location for gastrotomy is the fundus region, avoiding branches of the left and right gastric and gastroepiploic arteries and associated nerves. Babcock forceps or stay sutures are placed 1-2 cm from each end of the planned gastrotomy site and used to maintain tissue tension to facilitate the incision (Figure 19-4). A scalpel blade (No. 10, 11, or 15) is used to make a controlled full-thickness stab incision. Alternatively, the scalpel blade can be used to make a partial-thickness incision through the serosa, muscularis and submucosa, and the mucosal incision performed alone using a similar blade technique. Metzenbaum scissors can be used to extend the stab incision as indicated in the individual case. Hemostasis is achieved using hemostats or electrocautery. Gastric contents are removed as needed in order to retrieve the foreign body or identify the lesion that prompted the gastrotomy. If a linear foreign body is identified, the section within the stomach should not be detached until the distal extent within the small intestine has been identified via enterotomy. Gastric biopsy is indicated in all cases requiring gastrotomy, whether or not gross abnormalities are detected. A full-thickness strip of tissue can be excised along the gastrotomy incision and submitted for histopathologic analysis.

Closure

Prior to closure, all potentially contaminated instruments, suture material, sponges, drapes and gloves are discarded and replaced. In general, I prefer a two layer gastric closure with a simple continuous appositional pattern using monofilament absorbable suture material usually 2-0 or 3-0 in size. The first layer incorporates the mucosa and the second layer incorporates the submucosa, muscularis and serosa. If there is concern that suture material exposed within the gastric lumen can wick fluid or contaminants into the gastrotomy incision or peritoneal space, then another closure pattern should be chosen. A double layer inverting pattern, such as continuous Cushing or Lembert, can be placed incorporating only the submucosa, muscularis and serosa (Figure 19-4).

Alternatively, stapling devices such as disposable skin staples (4.8 mm by 3.4 mm), or a linear stapling device (TA™) can be used. The primary advantage is reduction in operative time and strength of tissue apposition compared with hand suturing techniques. The primary disadvantage is cost and availability of stapling equipment. Considering these factors, the benefit of staplers is probably limited to larger gastrotomy incisions. The skin stapling technique is described as a double-layer closure, with mucosa/submucosa apposed using a simple continuous pattern of monofilament, absorbable suture material, and serosa/muscularis apposed using skin staples placed at 3 mm intervals facilitated by

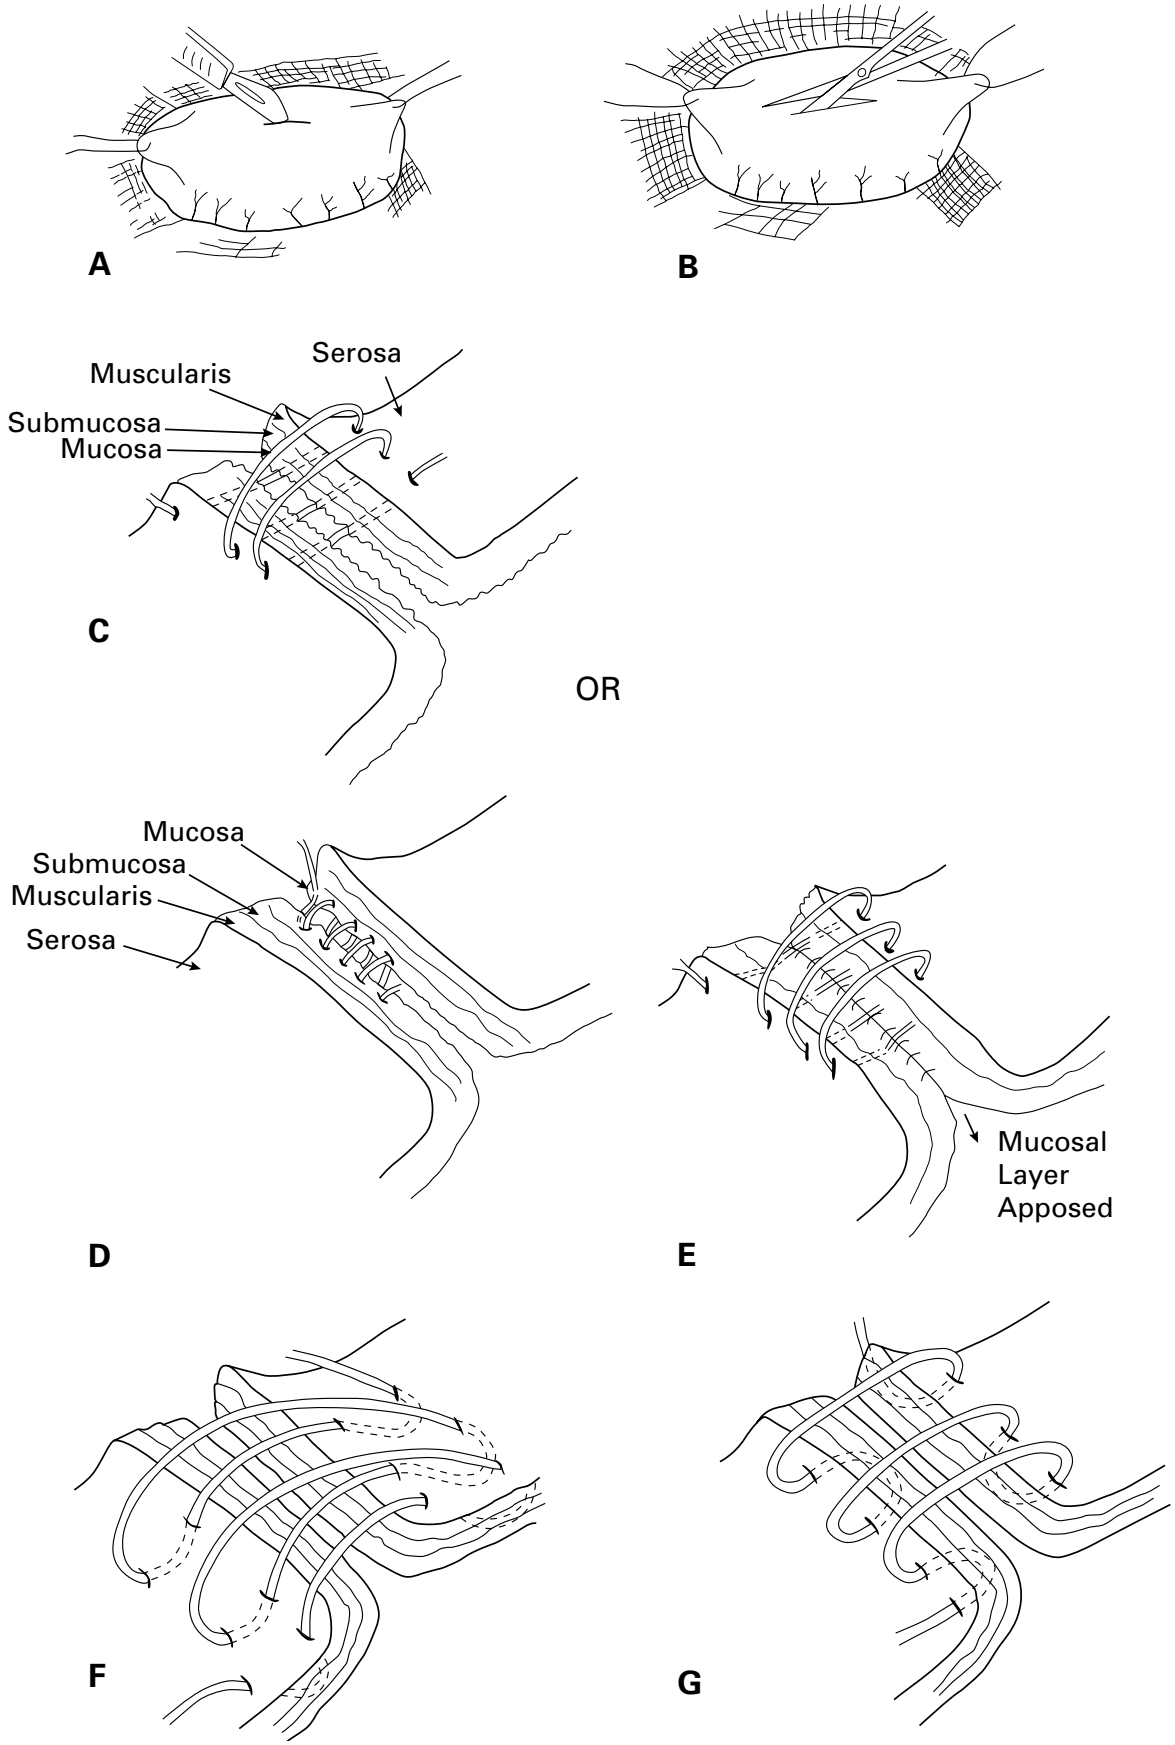

Figure 19-4. Gastrotomy. **A.** Stay sutures allow gentle tissue traction. An inverted #10, 11 or 15 blade is used to make a full-thickness stab incision into the stomach. A partial thickness initial incision is also acceptable. **B.** Extension of the incision with Metzenbaum scissors. **C.** Single-layer closure using a simple continuous appositional pattern incorporating mucosa, submucosa, muscularis and serosa simultaneously. **D.** Alternatively, a double-layer closure can be performed with the initial step of mucosal apposition using a simple continuous pattern. **E.** The second step is submucosal, muscularis and serosal apposition using a simple continuous suture pattern. **F.** Inverting Lembert pattern. **G.** Inverting Cushing pattern.

traction on stay sutures at each end of the incision. A TA™ can be applied to the gastrotomy site, providing an everted closure of all tissue layers at once, with a double staggered row of staples.

Partial Gastrectomy (Full-Thickness)

Maria A. Fahie

Indications

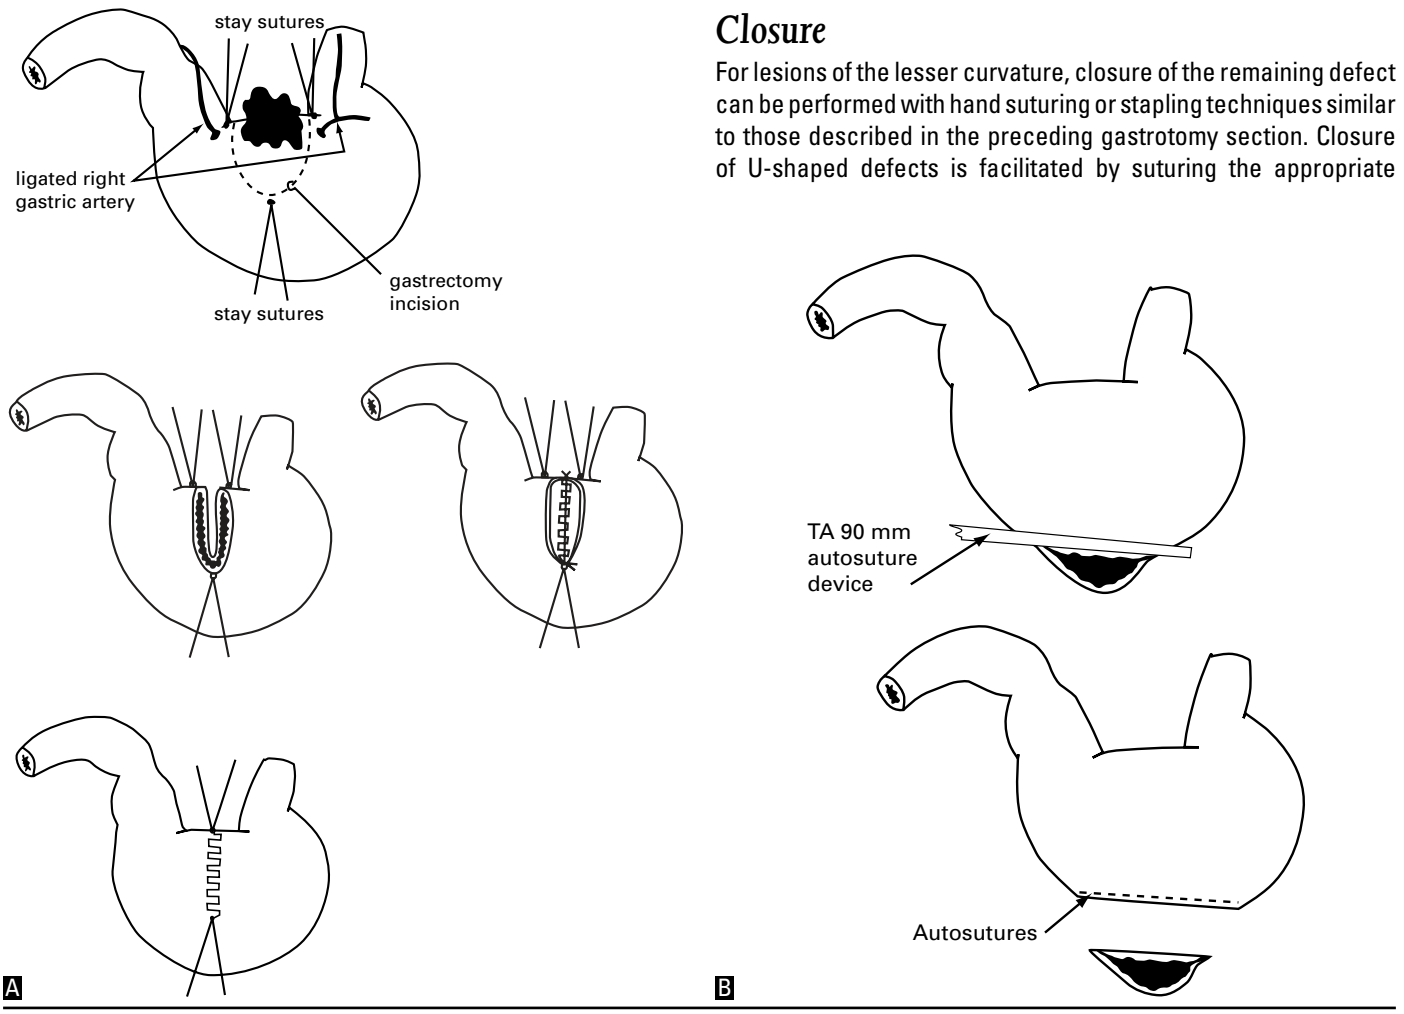
Benign gastric neoplasia, such as adenomatous polyps or leiomyoma, can be excised via partial full-thickness gastrectomy. Gastric ulcers that are not amenable to medical management can be excised via partial gastrectomy. Malignant gastric neoplasia (adenocarcinoma, leiomyosarcoma, lymphosarcoma and fibrosarcoma) has often metastasized to local lymph nodes, liver or lungs by the time of diagnosis. Partial gastric resection can only be considered palliative in these patients, since long term prognosis is guarded to grave. Up to 75% of the gastric fundus can be removed without significantly affecting food passage.

Surgical Technique

Abdominal exploration is always indicated prior to partial gastrectomy to evaluate the extent or presence of metastatic or other disease processes. The gastric abnormality to be resected is identified by visualization and palpation and an appropriate surrounding margin of grossly normal tissue is planned. Stay sutures facilitate exposure and manipulation. The vascular supply to the region will include branches of the left and right gastric and gastroepiploic vessels depending on the location of the lesion. Those branches supplying the area to be resected are identified and ligated. The stomach has extensive collateral circulation, therefore ligation of the vascular supply to the region of abnormal tissue can generally be performed without compromise to remaining gastric tissue. Atraumatic intestinal forceps, stay sutures, or assistant's fingers can be used to isolate the tissue that will be remaining. Carmalt forceps can be placed along the margin of the tissue to be resected in order to prevent abdominal contamination with gastric contents. The tissue is incised, removed and submitted for histopathologic analysis.

Closure

For lesions of the lesser curvature, closure of the remaining defect can be performed with hand suturing or stapling techniques similar to those described in the preceding gastrotomy section. Closure of U-shaped defects is facilitated by suturing the appropriate



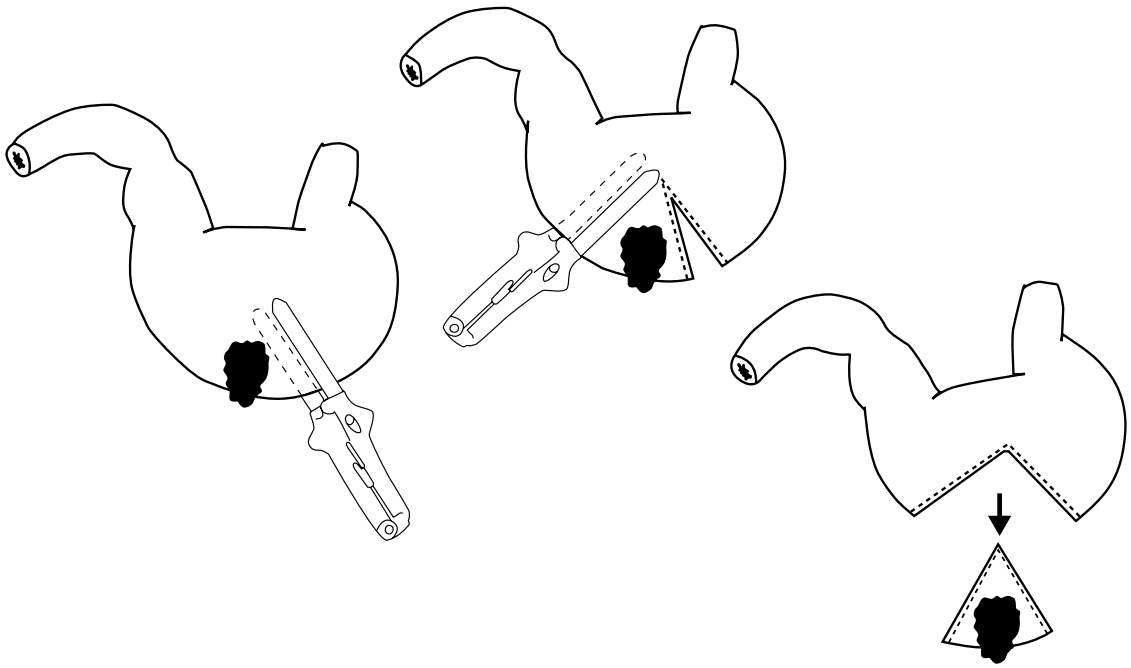


Figure 19-5. A. Hand suturing for closure of partial gastrectomy of lesser curvature. **B.** Linear stapling device for closure of partial gastrectomy of greater curvature.

C

Figure 19-5C. GIA stapling device for closure of partial gastrectomy on greater curvature. Figures 19-5A-C reprinted with permission from: Anderson S, Gill P, Lippincott L, Somerville M, Shields S, Balfour R, Wilson E. Dimensions in Surgery: Partial Gastrectomy. Pulse (an official publication of the Southern California Veterinary Medical Association): May, 2002.

sequence of tissue layers, beginning with the serosal, muscularis and submucosal layers of the dorsal surface of the stomach first which is the deepest layer intraoperatively. Next, the mucosal layer of the dorsal surface, continued to the mucosal layer of the ventral surface. Finally, the serosal, muscularis and submucosal layers of the ventral surface of the stomach. (Figure 19-5A). For lesions of the greater curvature, closure can be performed by hand-suturing similar to as described for gastrotomy. Alternatively, a linear stapling device can be employed (Figure 19-5B). A Carmalt forcep should be placed on the tissue to be resected prior to excision to prevent gastric spillage. An omental patch can be anchored to the stapling site, simply by mobilizing some omental adipose tissue and suturing it to the gastric serosa with several simple interrupted sutures. A GIA™ (USSC, Tyco Healthcare Group LP, Norwalk, CT) stapling device could also be used (Figure 19-5C). This device incises and applies a double layer staggered staple line on each side of the incision. The primary advantage is reduced risk of gastric spillage since the resected tissue also has a double row of staggered staples.

Partial-Thickness Resection via Gastrotomy Incision

Maria A. Fahie

Indications

This procedure is indicated for mobile, sessile or pedunculated mucosal masses in the cardia or fundus regions.

Surgical Technique

The stomach is exteriorized and isolated from the remainder of the abdominal contents with moistened laparotomy pads. Stay sutures are placed 1 to 2 cm from the ends of the planned gastrotomy. The gastrotomy incision is made in the body of the fundus, directly opposite the mass and midway between the greater and lesser curvature, avoiding gastric arteries and associated nerves (Figure 19-6). The mass is located and a stay suture is placed within it to

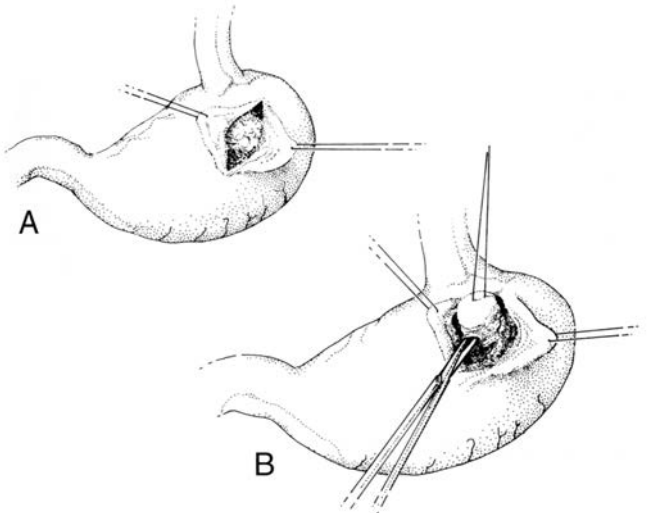

Figure 19-6. Partial thickness submucosal resection of midbody and cardia gastric lesions via gastrotomy. **A.** The gastrotomy incision is made in the fundic region avoiding gastric arteries and nerves. Stay sutures are placed to facilitate manipulation of the incision and avoid spillage of gastric contents. **B.** A stay suture is placed within the mass and traction is applied to allow transection of the surrounding mucosa and submucosa. Closure of the remaining mucosal/submucosal defect should begin prior to complete transection of the mass. A simple continuous appositional or inverting pattern is appropriate.

allow application of traction and to facilitate transection of the surrounding mucosa and submucosa.

Closure

The mucosal closure is initiated prior to completion of transection of the mass, and performed in stages as the mass is gradually transected. A simple continuous appositional or inverting pattern with monofilament absorbable 3-0 or 4-0 suture material is appropriate. The gastrotomy incision is closed as described previously.

Y-U Antral Flap Pyloroplasty

Maria A. Fahie

Indications

Delayed gastric emptying necessitates medical management with dietary and prokinetic therapy. In some cases, pyloroplasty is indicated in patients with gastric outflow obstruction and delayed gastric emptying due to congenital or acquired pyloric stenosis from benign proliferative disease of antral and pyloric mucosa (chronic hypertrophic pyloric gastropathy). Breeds with a predisposition to this congenital condition include some brachycephalic dogs (English bulldog, Boston terrier, Boxer) and the Siamese cat. Patients with acquired disease are usually middle-aged or geriatric small breeds such as the Lhasa apso, Shih tzu and Maltese. A study of 45 primarily geriatric patients demonstrated an 85% good to excellent response to surgical management of their hypertrophic disease.

Other intramural causes of acquired lesions affecting gastric outflow include neoplasia, foreign body, hypertrophic or eosinophilic gastritis and antral polyps. Extramural lesions of the liver or pancreas can also compress the pyloric region and affect gastric outflow. Pyloroplasty would not be recommended in those patients with malignant, inflammatory or extramural disease.

Pyloroplasty involves a full-thickness incision and reorientation of the pyloric tissue performed to increase the diameter of the gastric outflow tract. I recommend the Y-U antral flap pyloroplasty procedure, instead of pyloromyotomy (Fredet-Ramstedt) or transverse pyloroplasty (Heineke-Mikulicz), since the Y-U pyloroplasty allows for more resection of hypertrophied pyloric mucosa while significantly expanding the diameter of the gastric outflow tract and decreasing gastric emptying time.

Diagnostics to confirm gastric outflow obstruction are crucial and should include contrast radiographs, abdominal ultrasound and gastroduodenoscopy. Retention of a barium meal in the stomach can be difficult to interpret on contrast radiographic studies, since there is a wide range of gastric emptying times reported in normal dogs (5 to 15 hours). Generally, retention > 8-10 hours is considered prolonged and indicative of gastric outflow obstruction. Abdominal ultrasound can identify intramural submucosal/muscularis abnormalities not necessarily visible on radiographs or with endoscopy. Gastroduodenoscopy provides further detail regarding mucosal causes of pyloric obstruction. If pyloroplasty is performed in a patient without diagnostically confirmed gastric outflow obstruction, the procedure can actually cause delayed gastric emptying by overstimulation of the enterogastric reflex from the early passage of hyperosmolar gastric content into the duodenum. Diagnosis of delayed gastric emptying provides the greatest challenge to the surgeon. A review of diagnostic techniques is recommended.

Surgical Technique

The pylorus and pyloric antrum are identified and isolated using a combination of moistened laparotomy sponges and stay sutures. The pyloric ring is identified by palpation. Using a #10 scalpel blade, a "Y" shaped incision is made in the serosa with the base of the "Y" (Figure 19-7A) just oral to the pyloric ring, and each arm of the "Y" being 3 to 5 cm in length. The incision is extended into the gastric lumen through an initial stab incision with the scalpel blade, and extension with scissors. To facilitate advancement of the antral flap, and alleviate continued obstruction from proliferative pyloric mucosa, a rectangular shaped segment of the exposed hypertrophied pyloric ring tissue can be elevated submucosally, from the portion of the pylorus that is exposed by your incision, but not from the flap to avoid disruption of its vascular supply. Excised tissue can be submitted for histopathology. The muscularis and serosal layers (Figure 19-7B) remain intact, and the hypertrophied mucosal/submucosal layers (between e & f) are excised.

Closure

The mucosal/submucosal edges remaining after excision of proliferative tissue (e and f) are apposed in a simple continuous suture pattern with monofilament 3-0 or 4-0 absorbable material. The "Y" shaped incision is then sutured closed to form a "U" shaped incision (Figure 19-7C). Care should be taken to contour the tip of the flap to a "U" shape rather than a pointed "V" shape, since the vascular supply to the point may not be adequate. The most distal suture should be placed initially, to ensure proper flap advancement and placement. The remainder of the tissue can be closed using simple interrupted or continuous appositional sutures, both incorporating all 4 tissue layers (mucosa, submucosa, muscularis, serosa) simultaneously.

Postoperative Care

Appropriate postoperative management depends on the patient's preoperative status. Intravenous fluids should be chosen based on the patient's hydration status, electrolyte levels and acid-base status, and continued postoperatively until adequate oral alimentation is possible. Medical management of vomiting may be indicated. If there is no vomiting, a low-fat diet can be initiated on the first postoperative day to enhance gastric emptying.

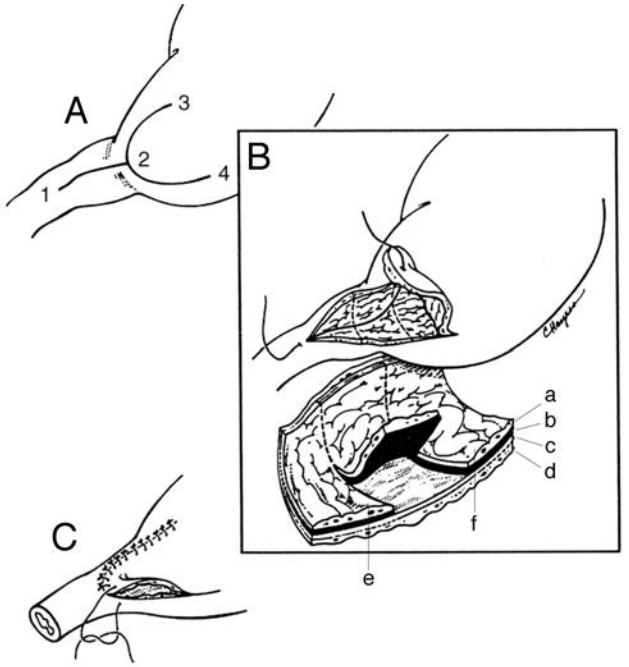

Figure 19-7. Y-U Antral Flap Pyloroplasty. **A.** The base of the "Y" incision extends slightly onto the stomach side of the pyloric ring (1-2). Each limb of the "Y" (1-2, 2-3, 2-4) is approximately 3 to 5 cm in length. **B.** a= sub-serosa, b=muscularis, c=submucosa, d=mucosa, e+f= proliferative tissue located in strip between these two letters; Pyloric submucosal resection of hypertrophied mucosal tissue. **C.** The pyloroplasty incision is closed by advancing the antral flap toward the duodenum, suturing tissue in region #2 to that of region #1. Tissue apposition can be performed using a simple continuous or simple interrupted approximating suture pattern.

Billroth I (Gastroduodenostomy)

Maria A. Fahie

Indications

Patients with gastric outflow obstruction due to malignant or inflammatory disease (such as adenocarcinoma or severe gastric ulceration) are candidates for pyloric resection and gastroduodenostomy. However, in a review of 24 dogs undergoing pylorectomy with gastroduodenostomy, median survival time with malignant neoplasia was only 33 days. Preoperative weight loss and malignant neoplasia are associated with shortened survival. Hypoalbuminemia and anemia occurred postoperatively in about 62 and 58% of dogs respectively. The goal of gastroduodenostomy is removal of the entire pylorus without disruption of surrounding structures including the extrahepatic biliary tree, or the biliary and pancreatic duct apertures at the major duodenal papilla. If this is not possible, a gastroduodenostomy procedure should not be performed. Gastrojejunostomy (Billroth II) with cholecystoduodenostomy and possible pancreatic enzyme replacement would be necessary for reconstruction after such an extensive resection. The gastroduodenostomy (Billroth I) requires less diversion from normal physiologic conditions compared with gastrojejunostomy (Billroth II) and as a result, there are fewer long term potential complications. In humans, there are fewer problems with gastritis, pancreatic function impairment and lower esophageal sphincter impairment in patients having gastroduodenostomy compared to those having gastrojejunostomy. In a study of 21 dogs having gastroduodenostomy for resection of adenocarcinoma and leiomyosarcoma, postoperative survival ranged from 3 days to 10 months due to recurrence of preoperative clinical signs. A recent retrospective study indicated that preoperative weight loss and diagnosis of malignant neoplasia were significant risk factors that shortened survival time post pylorectomy and gastroduodenostomy. Hypoalbuminemia and anemia commonly contributed to postoperative morbidity.

Approach and Asepsis

In performing gastroduodenostomy, the approach and aseptic technique are similar to that described in the preceding

gastrotomy section. It is crucial to identify and avoid the common bile duct prior to ligation or transection of any structures (See Figure 19-3). Division of the duodenocolic ligament will enable cranial displacement of the caudal duodenal flexure and facilitate approximation of the duodenum and stomach for gastroduodenostomy post-resection of affected tissues.

Surgical Technique

It is important to perform a complete abdominal exploratory to determine the extent of disease prior to gastric diversion procedures. The affected gastric region is identified by visualization and palpation. A surrounding margin of grossly normal tissue is planned. A minimum of 1 cm of duodenum must be maintained orad to the major duodenal papilla in order to avoid postoperative bile and pancreatic duct obstruction. The gastroduodenal artery, biliary tract, hepatic arteries and pancreas must be identified and avoided during manipulations. The vascular supply to the affected region is ligated in a fashion similar to that for a partial gastrectomy procedure (Figure 19-5). Atraumatic forceps are placed on the gastric and duodenal tissue that will remain. Carmalt forceps can be placed on the tissue to be resected. The pylorus is resected and submitted for histopathologic analysis.

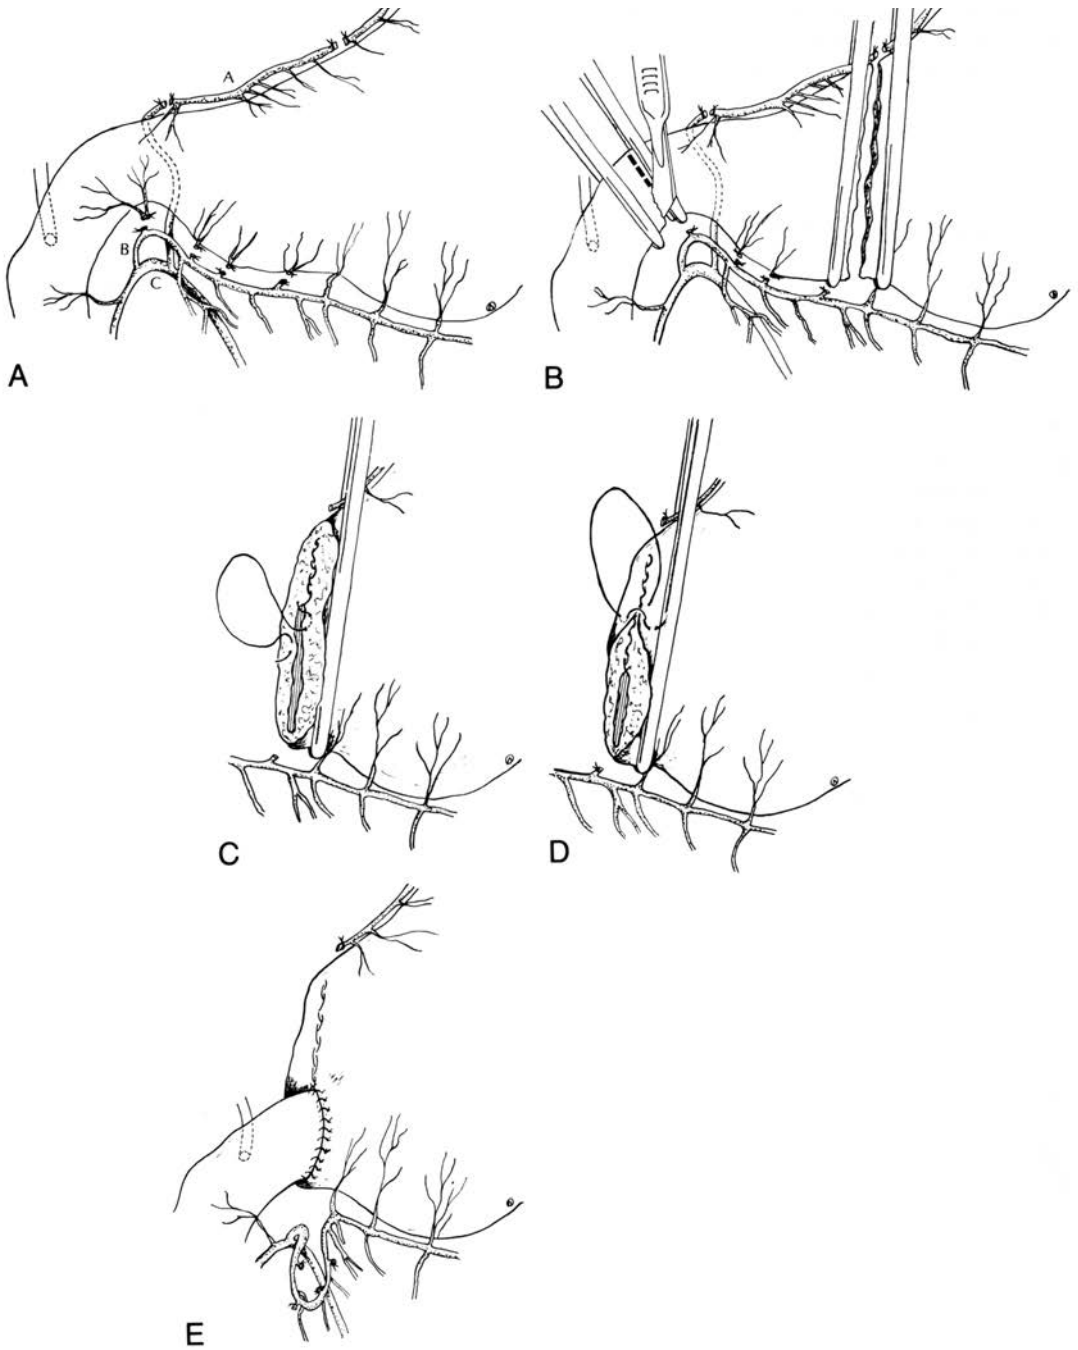

Figure 19-8. Gastroduodenostomy (Billroth I)- Hand suturing **A.** Arteries to be ligated are right gastric (A) and right gastroepiploic (B); avoid the gastroduodenal artery (C). **B.** Excision of pyloric sphincter and canal. **C.** Apposition of gastric mucosa in simple continuous or inverting Cushing or Lembert pattern. **D.** Apposition of gastric seromuscular layers in simple continuous or inverting Cushing or Lembert suture pattern. **E.** Completed anastomosis between stomach and duodenum.

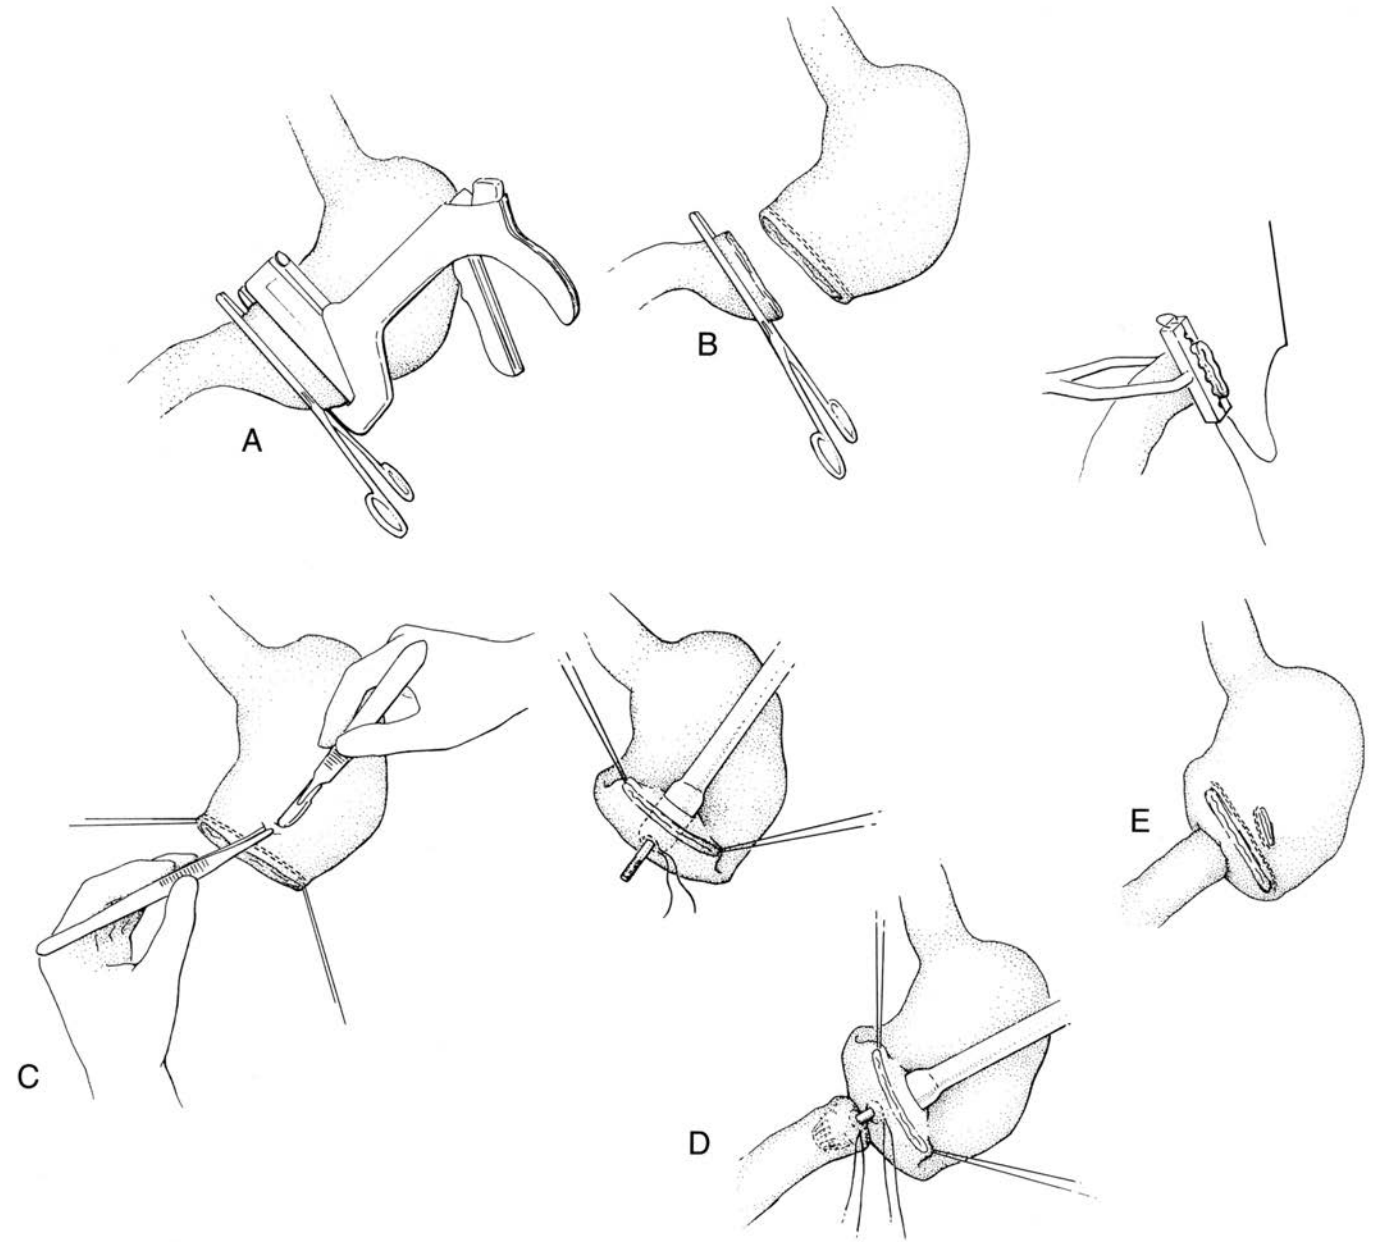

Figure 19-9. A. Technique for side-to-end gastroduodenostomy (Billroth I) using TA and EEA stapling devices to form a circular anastomosis. After ligation and division of omental vessels, the gastric pouch is closed using an appropriate size thoracoabdominal instrument. The instrument is placed proximal (oral) to the mass, leaving appropriate margins of grossly normal tissue and at least 1cm oral to the major duodenal papilla. Tissue forceps are placed adjacent to the mass, and the stomach is transected with a scalpel blade, using the instrument edge as a cutting guide. **B.** The pursestring instrument (Furniss clamp) is placed around the duodenum, distal (aboral) to the mass, leaving appropriate margins of grossly normal tissue. Monofilament 3-0 suture is passed through the superior jaw of the pursestring instrument and returned through the inferior jaw. Tissue forceps are placed adjacent to the mass, and the duodenum is transected using the pursestring instrument edge as a cutting guide. **C.** The pursestring instrument is removed and the appropriately sized end-to-end anastomosis (EEA) cartridge is chosen on the basis of the luminal diameter of the proximal duodenum. A stab incision is made in an avascular portion of the ventral aspect of the stomach, approximately 3 cm away from the edge of the TA staple line. Stay sutures aid in the retraction of the stomach. **D.** The EEA instrument is introduced, without the anvil, through the stab wound on the ventral surface of the stomach. The center rod of the instrument is exited through a small stab incision in the center of a pursestring suture that has been placed on the dorsal surface of the stomach. The pursestring suture is tied on the stomach side, and the anvil is placed on the central rod. The anvil is introduced into the duodenal lumen and the pursestring suture is tied. The EEA instrument is then closed and fired. A circular, double-staggered row of staples joins the organs, and the circular blade in the instrument cuts a stoma. **E.** Completion of the gastroduodenostomy. The EEA instrument has been gently removed from the entry site on the ventral surface of the stomach and the staple line inspected for hemostasis. The gastrotomy incision has been closed with a TA instrument. The completed anastomosis consists of two linear staple closures on the stomach and a circular stapled anastomosis forming the gastroduodenostomy.

Closure

Once abnormal gastric/pyloric tissue is resected, the incisions of the remaining gastric and duodenal segments are anastomosed using hand suturing or stapling devices such as a GIA™ (gastrointestinal anastomosis) (USSC, Tyco Healthcare Group LP, Norwalk, CT), or TA (thoraco-abdominal) 30, 55, or 90™ (USSC, Tyco Healthcare Group LP, Norwalk, CT) depending on the dimensions. When hand suturing, an end-to-end gastroduodenostomy anastomosis is most simple (Figure 19-8). If there is significant disparity between the gastric and duodenal lumen diameters, the antimesenteric border of the duodenum can be incised longitudinally ("fish mouthed") to increase its lumen diameter. The anastomosis should be created to resemble the normal anatomic position of the duodenum in relation to the remaining gastric fundus as much as possible, rather than creating a potential blind sac. Gastric mucosal closure is initiated at the margin of the lesser curvature in either a single-layer simple continuous appositional pattern (incorporating mucosa, submucosa, muscularis and serosa) or a double-layer simple continuous appositional pattern (incorporating mucosa first, then the other 3 layers), both with 2-0 to 4-0 monofilament absorbable material depending on patient size. Once the remaining gastric mucosa is a diameter approximating the normal pylorus, full-thickness simple interrupted or continuous, appositional sutures are used to anastomose the duodenum and stomach. The anastomotic site can be tested for leakage by temporarily occluding the tissue on either side of the site and injecting warm saline solution with a 22G needle and syringe. An omental patch can be anchored over the anastomotic site using a few simple interrupted sutures to anchor omentum to the gastric and duodenal serosa.

Alternatively, stapling devices can be used to create a side-to-end gastroduodenostomy with the dorsal surface of the stomach (Figure 19-9). The pyloric antral margin is closed using a linear stapling device of appropriate size. A purse-string suture is placed in the remaining duodenal margin. A small gastrotomy incision is made (using a scalpel blade or GIA™ stapling device) to allow access of the EEA™ (USSC, Tyco Healthcare Group LP, Norwalk, CT) (end-to-end anastomosis) stapling device. A purse-string suture is placed at the proposed anastomotic site on the dorsal gastric wall and a second gastrotomy incision is performed to allow placement of the EEA™ circular stapling device center rod. The anvil is attached to the center rod and introduced into the duodenal segment. Both purse strings are tied. The EEA is fired, released and removed. The result is a gastroduodenostomy with a staggered row of staples that incorporated the second gastrotomy site. The gastrotomy site used for access of the EEA to the stomach is closed using a TA stapling device of appropriate size.

Postoperative Care

Since the pancreas is in close proximity to the tissues being manipulated, postoperative pancreatitis is possible. Refer to the preceding section on postoperative alimentation and nutrition. Appropriate intravenous fluids and medical management are indicated if vomiting occurs.

Gastric Dilatation-Volvulus

Jacqueline R. Davidson

Acute gastric dilatation with volvulus (GDV) is a medical and surgical emergency, which can be life-threatening. Acute GDV is usually a disease of large and giant breed dogs,[1] but can occur in any breed of dog or cat. It typically affects middle-aged or older dogs,[1] but there is no sex predilection.

Pathophysiology

Gastric dilatation is generally thought to precede volvulus, although this has not been proven. The composition of entrapped air within the gastric lumen suggests that it is secondary to aerophagia, but may also contain gases produced by fermentation of carbohydrates or diffusion from blood.[2] As the stomach continues to dilate, gastric outflow becomes obstructed by compression of the duodenum and esophagus. The stomach rotates around the long axis of the esophagus, with the pylorus moving cranioventrally from right to left (Figure 19-10). The typical location for the pylorus during GDV is dorsal to the esophagus and fundus, on the left aspect of the abdominal cavity. The degree of gastric rotation may range from 0° to 360°, but most are between 180° and 270°. The spleen is attached to the greater curvature, so it is displaced as the stomach rotates and becomes congested. Gastric dilatation-volvulus can cause severe changes in cardiovascular, respiratory, and gastrointestinal physiology.

Gastric dilatation and increased intraabdominal pressure causes obstruction of the portal vein and caudal vena cava, which causes decreased venous return to the heart and portal hypertension with splanchnic vascular pooling. This results in decreased

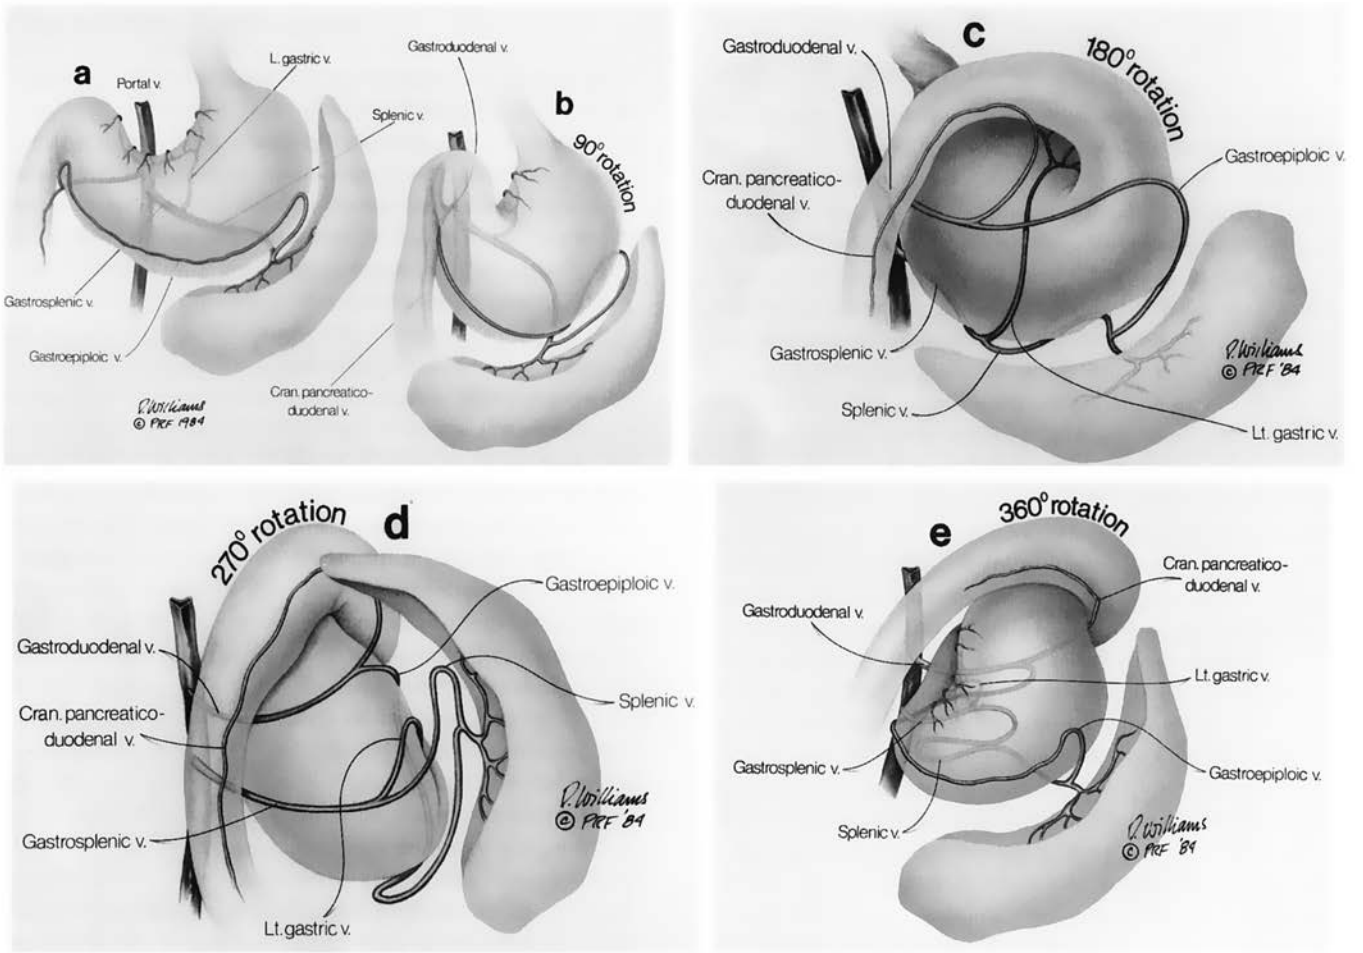

Figure 19-10. *A.* Normal stomach position when viewed in a ventrodorsal position. *B-E.* In gastric dilatation-volvulus, the stomach is rotated about the esophagus in a clockwise direction causing malposition of the pylorus, fundus, and spleen. For illustrative purposes, the gastric dilatation has not been pictured. Vessels are included for orientation.

cardiac output with decreased systemic blood pressure and decreased tissue perfusion to major organs. Portal hypertension also causes interstitial edema, which further compromises the microcirculation of the abdominal viscera and contributes to a reduced vascular volume. When there is lack of blood flow to the tissues, waste products and toxins may accumulate in the hypoxic cells. As blood flow is restored, oxygen free radicals may form and cause tissue damage, known as reperfusion injury.

Although cardiac arrhythmias commonly occur with GDV, the etiology is unclear.[3] Reduced tissue perfusion stimulates the release of catecholamines, which cause peripheral vasoconstriction and increased heart rate, thereby increasing myocardial oxygen demand. Myocardial ischemia has been implicated as a leading cause of the cardiac arrhythmias.[4] Coronary blood flow may be reduced because of the poor venous return and also because of the shortened diastole that occurs with tachycardia. Other factors that could contribute to arrhythmias include substances that are released in association with tissue hypoperfusion or systemic inflammation, electrolyte and acid-base imbalances, and endotoxemia.

Stomach distension prevents normal diaphragmatic excursions, thereby reducing tidal volume. Respiratory rate and effort are increased as a compensatory mechanism, but respiratory acidosis may result. This can exacerbate a metabolic acidosis. Aspiration may occur secondary to vomiting, and this may also impair respiratory function.

Increasing gastric intraluminal pressure impairs perfusion of the gastric wall resulting in hemorrhage, edema, ulceration or necrosis, particularly to the gastric mucosa. More severe pressure will compromise perfusion of the seromuscular layers, and can result in full thickness necrosis with perforation and subsequent peritonitis. Both reduced cardiac output and mechanical kinking or avulsion of vessels can further compromise blood flow to the stomach wall. The short gastric vessels are often affected, but the extensive gastric collateral blood supply makes full-thickness necrosis uncommon.

Local lymphatic tissue that has suffered ischemic damage is unable to prevent translocation of intestinal pathogens from the gastrointestinal mucosa into the circulatory system. Translocation of bacteria to the gut-associated lymphatics is believed to stimulate production of numerous cytokines, which is a factor in promoting the systemic inflammatory response syndrome and multiple organ dysfunction syndrome.[6] In addition, impaired return of lymphatic and venous fluid inhibits delivery of pathogens to the immune centers. When circulation is restored, there is potential for release of pathogens and endotoxins into

the systemic circulation. Systemic effects include decreased systemic vascular resistance and increased cardiac output, increased vascular permeability, hepatocellular dysfunction, renal tubular damage, microvascular occlusion, and disseminated intravascular coagulation.

Diagnosis

A presumptive diagnosis of GDV or gastric dilatation can often be made based on signalment, history and physical examination. Clinical signs include restlessness, hypersalivation, and unproductive vomiting or retching. A distended, tympanic abdomen is usually obvious, but may not be apparent in some cases. The dog may be dyspneic due to pain, aspiration, or abdominal distention. Dogs may present in compensatory shock, with tachycardia, tachypnea, pale mucous membranes, prolonged capillary refill time, normal pulses, and cold extremities with normothermia. Endotoxic shock differs from compensatory shock in that the membranes may be injected or "muddy", and fever may be present. Severely affected dogs may be recumbent or comatose. Signs of noncompensatory shock include bradycardia, weak respiration, white or muddy mucous membranes, no capillary refill, poor pulses, cold extremities and hypothermia.

Initial hematology may indicate hemoconcentration (increased packed cell volume and total protein), and a stress or inflammatory leukogram (increased polymorphonuclear leukocytes, increased monocytes, decreased lymphocytes). In cases of decompensation, polymorphonuclear leukocytes are decreased. Thrombocytopenia may be evident on hematology. Changes in activated clotting time, prothrombin time, and partial thromboplastin time may suggest a hypercoagulable state or disseminated intravascular coagulation. Abnormalities of multiple values in the coagulation profile are associated with an increased likelihood of gastric necrosis.[7]

Initial clinical chemistries may show evidence of liver damage (increased alanine transaminase), biliary stasis (increased total bilirubin), and prerenal or renal azotemia (increased blood urea nitrogen and creatinine). There may also be evidence of blood loss or transudation (lower than expected total protein and albumin) and impaired glucose control. There may be electrolyte abnormalities, particularly hypokalemia. Plasma lactate may be elevated due to anaerobic metabolism or endotoxins.[8] Plasma lactate levels are presumably an indication of the degree of systemic hypoperfusion, and higher levels are seen in dogs that are more severely affected clinically.[8] Increased lactate concentration may also be associated with gastric necrosis.[8] However, change in lactate during the treatment period provides more useful information regarding prognosis than the plasma lactate level at a single point in time.[9]

Abdominal radiographs are usually not needed to diagnose gastric dilatation, but may be used to confirm the clinical diagnosis or to distinguish between simple gastric dilatation and GDV. Emergency medical therapy is initiated to stabilize the dog before obtaining radiographs. The right lateral recumbent view is the best single view to determine whether the stomach is rotated.[10] Radiographs of dogs with gastric dilatation reveal a large, uniform gas-filled gastric shadow and possibly excessive gas in the intestines as well. Gastric dilatation-volvulus is suspected if a tissue density separates the gas-filled gastric shadow into two regions. The gas-filled pylorus may be identified dorsal to the fundus of the stomach. Gas within the gastric wall is suggestive of gastric necrosis, but is not a reliable finding.[11] Free gas is present in the abdominal cavity in cases where the stomach has perforated. However, free gas may also be present in those cases where trocarization for gastric deompression was performed prior to obtaining radiographs. Gas in the esophagus may be due to aerophagia and does not necessarily indicate megaesophagus.

Treatment

The initial therapeutic goals are to relieve the gastric distention and treat the cardiovascular compromise. Treatment should begin immediately, and diagnostic tests may be performed as the dog becomes more stable.

Initial Medical Therapy

Aggressive fluid therapy with isotonic crystalloids should be instituted immediately. Several large-bore catheters may need to be placed in order to achieve an adequate rate of fluid administration. The catheters should be in the cephalic or jugular veins, since venous return from the hind limbs may be compromised. The administration rate of crystalloid fluids is 90 ml/kg. A quarter of the total shock dose is administered quickly, and the dog is reassessed. It is preferable to administer crystalloids (10 to 40 ml/kg) in conjunction with high molecular weight fluids (10 to 20 ml/kg hetastarch or 5 ml/kg of 7% hypertonic saline solution in 6% dextran 70 over 5 minutes).[12] After initial fluid administration, crystalloid fluids are continued at approximately 20 ml/kg/hr, depending on the dog's response to therapy. Dopamine or dobutamine (2 to 5 µug/kg/min) may also be indicated to improve splanchnic blood flow or provide positive inotropic effects. If disseminated intravascular coagulation is suspected, plasma and heparin (100 mg/kg SQ TID) therapy may be instituted.

The acid-base status of dogs with GDV is unpredictable, so specific acid-base therapy should not be administered unless a blood gas analysis has been performed. Acid-base imbalances will generally self-correct as effective circulation is restored. However, if the pH is below 7.2, bicarbonate therapy may be indicated. Oxygen therapy (40 to 100% inspired) administered by face mask, nasal catheter, or oxygen cage may be beneficial to offset the effects of impaired ventilation.

Many dogs develop cardiac arrhythmias in association with GDV.[13] The arrhythmias are most commonly ventricular in origin and may include premature ventricular contractions, ventricular tachycardia, or idioventricular tachyarrhythmias. Treatment should be considered if fluid volume has been adequately replaced and the arrhythmia is life threatening or causing poor perfusion. Pain control, and correction of potassium and acid-base abnormalities are important aspects of management prior to specific antiarrythmia therapy. Treatment may be indicated in the presence of R-on-T phenomenon or ventricular tachycardia. Treatment may also be considered if PVCs occur at a rate of more than 20 to

30 per minute, there are runs of PVCs, or PVCs are multifocal in origin. Pulse quality and mucous membrane color should be evaluated and used to guide therapeutic decisions. The initial treatment of choice for ventricular arrhythmias is 2% lidocaine hydrochloride without epinephrine. A slow bolus (1 to 2 mg/kg IV) may be administered until a normal sinus rhythm appears. This may be repeated twice within a 30-minute period if needed, but the entire dose should not exceed 8 mg/kg. If the arrhythmia persists, a continuous intravenous infusion of lidocaine (50 to 100 µug/kg/min) is administered, adjusting the rate based on the dog's response to therapy. Procainamide (10 to 40 µug/kg/min IV or 6 to 8 mg/kg IM q.i.d.) may be used instead of lidocaine in refractory cases. Antiarrhythmic therapy should continue for three to five days after the arrhythmias resolve.

Treatment with corticosteroids and antibiotics are not necessary in uncomplicated cases of GDV. There is no confirmed clinical benefit from corticosteroids when they are administered after the onset of shock. Risks of corticosteroid use include impaired immune function and possible increased rate of gastrointestinal ulceration. If used, they should be given gradually after adequate volume restoration has been initiated to prevent further hypotension.

If gastric ischemia or necrosis is suspected, broad-spectrum antibiotics such as first- or second- generation cephalosporins or ampicillin are used. Drugs such as deferoxamine and allopurinol have been used experimentally to prevent reperfusion injury, but their use has not been supported by clinical trials.[14]

During treatment, parameters such as heart rate, pulse character, mucous membrane color, capillary refill time, urine output, plasma oncotic pressure, and blood pressure are monitored to assess cardiac function and tissue perfusion. In addition packed cell volume, total solids, and plasma lactate levels may be useful measurements to monitor response to fluid therapy. Serum cardiac troponin I and cardiac troponin T may be useful markers of myocardial injury.[4] Elevated myoglobin can be seen and is not specific to myocardial injury, but may be used as one indicator to help estimate prognosis.[5]

Gastric Decompression

Gastric decompression should be performed immediately after intravenous catheters have been placed and volume support has been started. Decompression improves venous return, ventilation, and gastric wall perfusion. However, it can also result in systemic release of endotoxins and metabolic waste products that have accumulated in the areas of vascular stasis and ischemia. This may cause deterioration in clinical signs that necessitate further monitoring and treatment. The stomach is decompressed by orogastric intubation or trocarization. Temporary gastrotomy may be used in rare cases. Esophagostomy or nasogastric intubation may be used to provide continued decompression.

Before attempting orogastric intubation, the distance from the dog's nose to the 13th rib should be measured to estimate the length of tubing needed. A roll of white tape may be placed in the dog's mouth as a speculum. A well-lubricated stomach tube is passed slowly through the tape roll and into the esophagus and stomach. The tube should be passed gently to avoid esophageal or gastric tears. Rotating the tube as it is advanced may facilitate passage. In some cases, elevation of the forequarters may decrease pressure on the gastroesophageal junction and allow the tube to pass. Failure to pass the tube does not necessarily indicate gastric volvulus, nor does easy passage indicate the presence of a simple dilatation. If the orogastric tube cannot be passed, or if the dog strongly resists the procedure, needle trocarization may be performed first.

To trocarize the stomach, two to four large-bore (14- to 16- gauge) over-the-needle catheters are inserted percutaneously through the abdominal and stomach walls in the region of greatest abdominal distention. The skin should be clipped and aseptically prepared prior to catheter insertion. After some gas has been evacuated from the stomach it may be easier to pass an orogastric tube to remove more gas, fluid and ingesta. Complications, such as peritonitis, are rare with trocarization.

If orogastric intubation is unsuccessful and surgery cannot be performed for an extended period, temporary gastrostomy may be considered to maintain gastric decompression. An inverted "L" line block of 2% lidocaine is performed in the right paracostal region. An incision is made in the anesthetized region. The abdominal musculature is separated between the fibers. The stomach is identified and sutured to the skin edges circumferentially with a continuous suture pattern to provide a good seal. An incision is made in the exposed stomach wall to allow decompression. The temporary gastrostomy has several disadvantages. It does not correct gastric rotation and it increases the risk of peritonitis. In addition it may interfere with the permanent gastropexy and must be repaired prior to performing the definitive abdominal surgery. Therefore, this procedure should only be performed if absolutely necessary.

Client Education

The etiology of GDV is not well understood. It is likely that multiple environmental and hereditary factors play a role.[16] Anatomic differences, diet, gastric motility, and gastrointestinal hormones have been studied. Irish setters with an increased thoracic depth to width ratio are at increased risk. Although overeating, pre- or postprandial exercise, large water consumption, and temperament of the dog have been implicated, there is little evidence to support any of these factors as the cause.[1,17,18] Factors associated with an increased risk of GDV that were identified in a prospective study of large breed dogs include increasing age, having a first-degree relative with GDV, faster eating speed (for large breed dogs, but not giant breeds), and eating from a raised food bowl.[17] Feeding a large volume once daily is associated with an increased risk of GDV compared to feeding a smaller volume twice daily.[18] Feeding dry foods containing fats or oils among the first four label ingredients was associated with a significant increased risk of GDV in one retrospective study.[19] Poor body condition and a history of chronic health problems are also associated with an increased risk of GDV, although a causal relationship has not been established.[18] Therefore, it is recommended that large and giant breed dogs be fed more than once

daily using a food bowl that is not elevated. It can also be recommended to avoid breeding dogs that have a first-degree relative that has had GDV. Prophylactic gastropexy may be considered for breeds that have a high risk of developing GDV.[20,21]

Dogs that have had one episode of GDV are more likely to have another, although gastropexy reduces this likelihood. Clients should be educated regarding the potential for recurrence and the clinical signs that should alert them to seek prompt veterinary care. Survival rates for dogs that are treated surgically for GDV are about 85%.[3,13,22-23]

Gastric Dilatation-Volvulus (GDV): Surgical Treatment

Amelia Simpson

The goals of surgery for a dog with a GDV are to de-rotate the stomach and return other organs to their normal anatomic positions, evaluate the viability of stomach and spleen, perform a splenectomy (partial or complete) and/or a partial gastrectomy if indicated, and perform a perform a permanent gastropexy to prevent recurrence of volvulus. Surgery should take place as soon as the patient is stable enough to undergo anesthesia. If signs of shock are minimal, surgery may be performed immediately after gastric decompression and initiation of fluid therapy. Dogs with moderate or severe signs of shock may be stabilized by gastric decompression and fluid therapy for several hours until the vital signs improve. A prolonged period of stabilization, however, is undesirable, since the blood supply to the rotated stomach may remain compromised even after it has been decompressed.[1]

Surgical Technique

A ventral midline celiotomy is performed with the incision extending from the xiphiod process of the sternum to a point midway between the umbilicus and pubis. The use of Balfour

retractors is recommended to maintain adequate exposure of the abdominal cavity. The surgeon should evacuate free blood form the abdomen and any actively bleeding short gastric vessels should be ligated. Most commonly, with the dog in dorsal recumbency, the stomach rotates 180° to 270° clockwise around the long axis of the esophagus. In this position, the ventral leaf of the omentum covers the ventral aspect of the displaced stomach which is readily apparent to the surgeon after the abdomen is opened (See Figure 19-10A-E). A clockwise rotation causes the pylorus and the gastric antrum to become displaced from the right ventral body wall and move ventrally over the gastric fundus and body to become positioned adjacent to the esophagus along the left body wall (See Figure 19-10D and E). The maximum rotation of the stomach in the clockwise rotation is 360°. Counterclockwise rotation, although uncommon, has a maximum rotation of 90°. When counterclockwise rotation occurs, the pylorus and antrum move dorsally along the right body wall to a position adjacent to the esophagus. Counterclockwise rotation direction, causes minimal ventral displacement of the gastric fundus and body and the omentum does not cover the ventral aspect of the displaced stomach.[2] Depending upon the degree of gastric rotation, the spleen can be found in various positions within the cranial abdomen. Occasionally the spleen may undergo torsion around its vascular pedicle.

To de-rotate the stomach for a 180° clockwise rotation, the fundus, which is located near the right abdominal wall, is depressed in a dorsal direction and the pylorus, abnormally located on the dorsal left, abdominal wall is retracted ventrally and from the left to right side of the abdomen. To prevent further trauma to the gastrosplenic vessels, the spleen is placed in its normal position as gastric de-rotation is performed. If significant distension is present, the stomach may be impossible to de-rotate. In this case, gastric decompression is necessary and can be achieved by passage of an orogastric tube, trocharization, or by a combination of these two methods. If an orogastric tube cannot be advanced into the stomach, trocharization of the stomach should be performed. A large bore needle or IV catheter is placed into the gastric lumen through an area of the stomach wall that appears. The needle/catheter can be connected to suction for rapid removal of accumulated gas and fluid and usually, the orogastric tube can then be successfully passed into the stomach. Following successful decompression, the needle/catheter is removed and the stomach is de-rotated as described above. Suturing of the trocharization site is not necessary, unless a tear was created in the gastric wall during needle placement. The surgeon should be certain that the stomach is completely de-rotated and in a normal anatomic location. This can be achieved by visualizing the junction of the intra-abdominal esophagus and cardia of the stomach and noting a lack of tissue folds in the area. After confirming complete de-rotation of the stomach, a complete abdominal exploration is performed.

During the abdominal exploration, particular attention is paid to the viability of the gastric wall and spleen. Initially, the spleen is often enlarged and congested and its viability may appear questionable. Often, after return to its normal anatomic rotation the spleen begins to return to its normal size and color and splenectomy is not required. Thrombosis of the splenic artery and/or vein can be detected by careful palpation and, if identified, requires partial or complete splenectomy. If the spleen has undergone torsion around its vascular pedicle, it should be removed. In order to prevent deleterious toxin release, splenectomy is performed without de-torsing the splenic vasculature. Splenectomy is required in approximately 25% of cases of GDV.

Partial Gastrectomy

Approximately 10% of dogs with GDV have necrosis along the greater curvature of the fundus or body of the stomach.[3] Perforation early in the course of disease due to gastric necrosis is rare. Several methods have been described to evaluate viability of the gastric wall. These include: clinical assessment of serosal

Table 19-2. Partial Gastric Resection

Color of the gastric serosa	Indicative of:	Recommendation
Diffuse petechia/ecchymosis	Vascular damage	Tissue resection usually not necessary.
Diffuse dark red/red-purple hemorrhagic areas	More severe vascular damage	Tissue resection usually not necessary.
Blue-black or black areas	Venous occlusion and intramural-subserosal hemorrhage	These lesions may be reversible. After the stomach is de-rotated small incision is made in the serosa. If arterial blood is not seen, severe hypoxic damage and tissue necrosis are present and the section is resected.
Pale greenish to grayish areas	Ischemia and necrosis	Tissue resection is recommended.

Texture of the stomach wall	Indicative of:	Recommendation
Thickened - often associated with mild to moderate bruising	Congestion with blood and edema	Tissue resection usually not necessary.
Thin/stretched - often associated with a pale greenish to gray color	Devitalized tissue	Tissue resection is recommended.

color and gastric wall texture, the use of intravenous fluroesceine dye, and nuclear scintigraphy. In a study evaluating the use of fluoresceine fluorescence to predict gastric viability, it was found that fluoresceine fluorescence was only 58% accurate.[4] Nuclear scintigraphy, while accurate in assessing stomach wall viability, is impractical in a clinical setting.[5-7] Gastric viability determined by clinical assessment of serosal color and gastric wall texture was accurate in 85% of cases of dogs with GDV in one study.[4] Since clinical assessment of gastric tissue viability is not always accurate, it is possible to remove tissue which may survive as well as to leave tissue behind which may subsequently necrose and lead to gastric perforation hours to days later. General guidelines for partial gastric resection include in Table 19-2.

Ischemic or necrotic gastric tissue can be excised by partial gastrectomy, or it can be invaginated by an inverting or purse-string suture technique and left to be auto-digested within the gastric lumen. I prefer to perform partial gastrectomy and gastric wall closure with staples or suture (Figure 19-11A-C). The stomach is packed off with moistened laparotomy pads to prevent contamination of the abdomen from spillage of gastric contents. Doyen forceps or stay sutures are placed in viable gastric tissue and can be used to help prevent leakage of gastric contents. The necrotic portion of the stomach wall is resected with a scalpel to the point where there is active arterial bleeding at the surgical margin. A monofilament, absorbable or non-absorbable, suture material is used for a two layer closure. A full thickness simple continuous suture pattern followed by an inverting pattern such as a Cushing's oversew is recommended. Alternatively, a thoraco-abdominal stapler can be used followed by a Cushing's oversew using a monofilament, absorbable or non-absorbable suture material. Mortality rates are known to be higher in animals

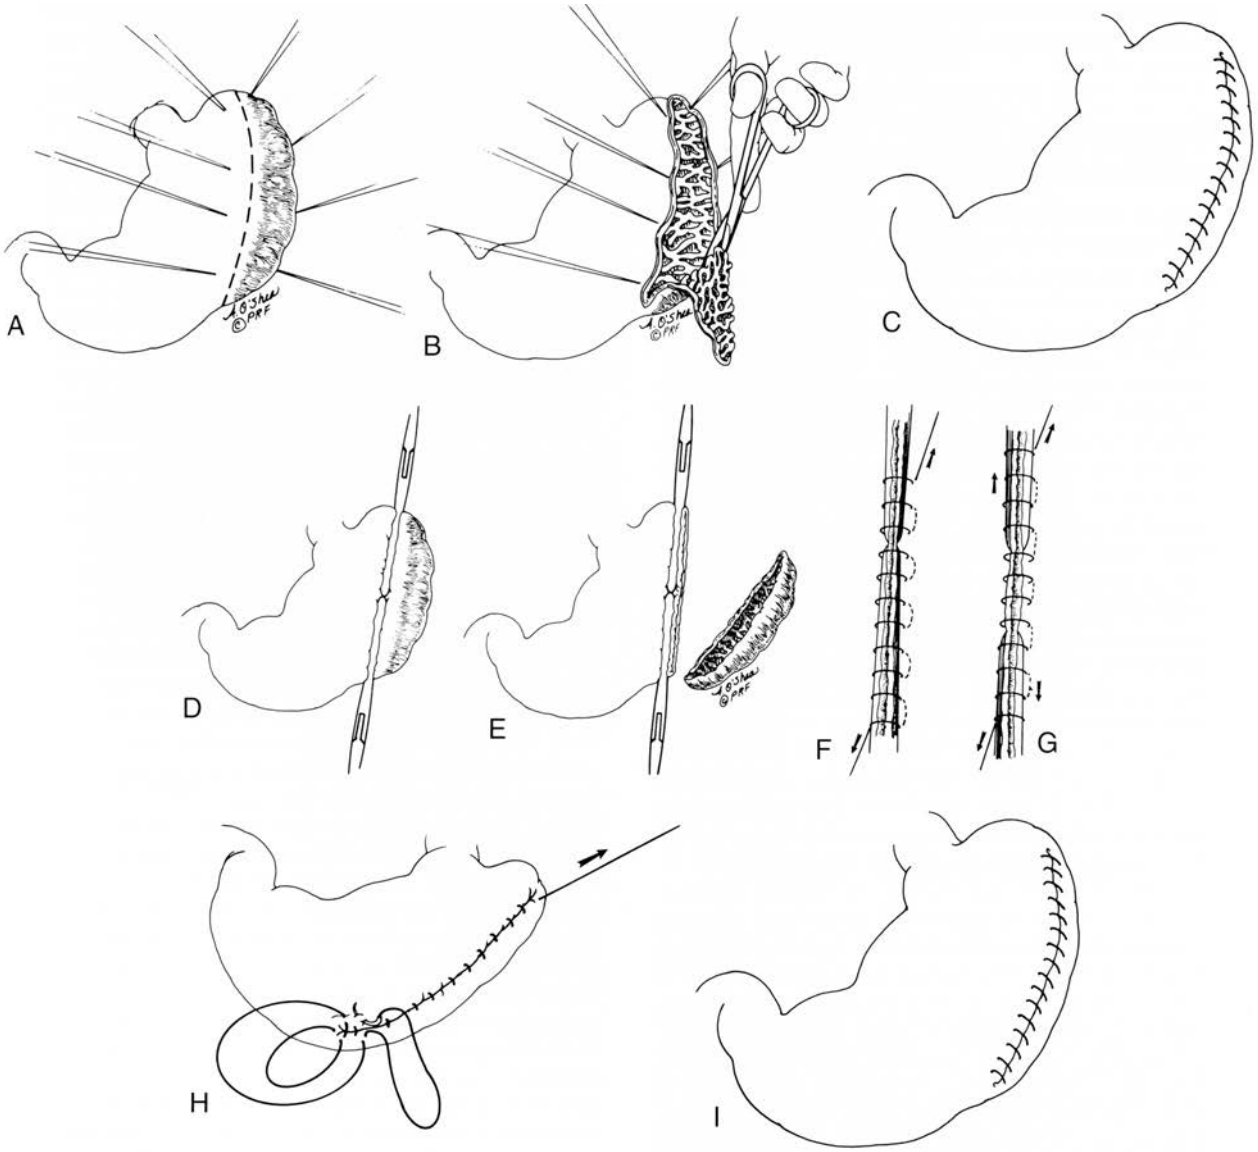

Figure 19-11. Two variations of partial gastrectomy are shown. In **A-C**, stay sutures are placed to elevate the stomach and to minimize leakage. Necrotic tissue is excised with a rim of viable tissue (dotted line). A two-layer inverting closure is used. In **D-I**, atraumatic clamps are placed across viable tissue, and the necrotic tissue is excised. The stomach body is subsequently closed with a Parker-Kerr suture line. The first inverting layer of suture is placed over the clamps. The clamps are subsequently removed as the suture line is pulled tight to invertthe suture line. A second inverting suture line completes the closure. (Redrawn in part from Matthiesen DT. Gastric dilatation-volvulus syndrome. In: Slatter DH, ed. Textbook of small animal surgery. Philadelphia: WB Saunders, 1995:580-593.)

where gastric wall excision is required. The owners should be given a poor prognosis in cases where there is complete gastric necrosis or necrosis of the cardia and abdominal esophagus.

Gastropexy

Mortality rates for dogs with a GDV have been reported to be as high as 23%.[8] Studies have shown that dogs who receive an effective permanent gastropexy at the time of surgery have less than a 5% chance of recurrence of GDV, whereas dogs who do not receive a gastropexy during surgery have a 54.5-80% rate of recurrence within the first year.[8,9] Based on these results, it is strongly recommended that all dogs with a GDV should have a permanent gastropexy performed during surgery for gastric repositioning. Several effective gastropexy techniques have been described including: tube gastropexy, incisional gastropexy, circumcostal gastropexy, belt-loop gastropexy, fundic gastropexy and laparoscopic gastropexy.[10-14] Gastrocolopexy and gastrojejunostomy have also been described, but are rarely performed in a clinical setting and are no longer recommended.[15,16]

I prefer to perform an incisional gastropuexy for prevention of GDV. It is simple to perform, can be completed quickly, has minimal complications, and creates a strong adhesion between the pyloric antrum and the right abdominal wall. The gastropexy is performed only after confirming that the stomach is fully de-rotated and in normal anatomic rotation. The procedure is easier to perform with the surgeon standing on the left side of the dog. A 5-6 cm partial thickness incision is made in the serosal and muscularis layers of the pyloric antrum, midway between the greater and lesser curvature of the stomach, along the long axis of the stomach (Figure 19-12). A corresponding incision is made in the right lateral body wall just caudal to the last rib. The body wall incision should extend through the peritoneum and transverse abdominal muscle. The gastric incision edges are sutured to the corresponding body wall incision edges using a monofilament absorbable (polydioxanone) or non-absorbable suture in a simple continuous pattern (Figure 19-13). The suture should not enter the gastric lumen as this may lead to fistula formation and/or sepsis. Routine abdominal closure is performed after copious lavage.

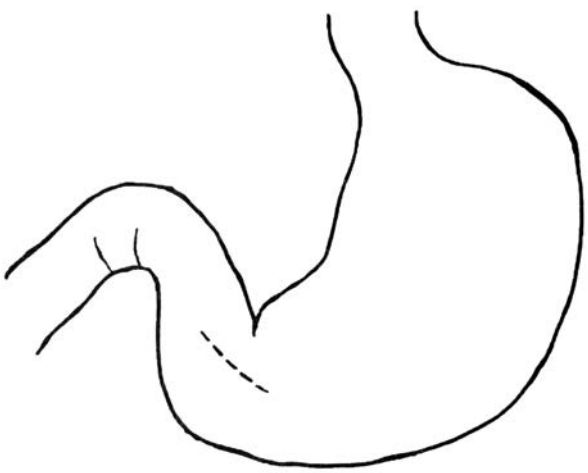

Figure 19-12. The location of the gastropexy site in the area of the pyloric antrum.

Post-Operative Care and Complications

Intensive nursing care should be provided during the postoperative period. Pain control, maintenance of vascular volume, and return to normal alimentation and gastric motility are important. Pain is controlled with injectable hydromorphone (0.05-0.1 mg/kg, SC or IV q4-6hrs) or injectable burenorphine (0.02 mg/kg, SC or IV, q6hrs) for 48-72 hours after surgery. Since these dogs usually have extended hospitaliztion times, they are comfortable by the time of discharge and analgesic medication is not routinely necessary after discharge. If the dog appears painful, Tramadol (1-4 mg/kg, PO, q8hrs) can be prescribed to be administered at home for 3-5 days. Dogs are routinely maintained on intravenous fluids for the first 24-36 hours postoperatively for maintenance and continuing fluid losses, or until they are eating and drinking without vomiting. Food and water are withheld for the first 18-24 hours postoperatively unless the animal is hypoalbuminemic. Ice chips or small quantities of water are offered in small amounts. If there is no vomiting after several hours of starting the patient on water, food is offered in small amounts every 4-6 hours and the patient is gradually returned to normal alimentation over 24-48 hours.

If vomiting occurs, potassium levels should be assessed as hypokalemia is common and may promote ileus. Prokinetic drugs (metoclopramide or cisapride, ranitidine, erythromycin) and gastric acid-inhibitors (cimetidine, ranitidine, famotidine, omeprazole) are beneficial in animals that have vomiting or regurgitation postoperatively.

Antibiotics administered perioperatively are continued in animals that have abdominal contamination during surgery secondary to gastric necrosis and in animals that are suspected of having endotoxic shock initially.

Cardiac Arrhythmias

After surgery, dogs are observed for cardiac arrhythmias with continuous ECG monitoring for 48-72 hours. The most common arrhythmia seen in these patients is ventricular premature contractions (VPCs) although supraventricular arrhythmias such as atrial fibrillation and atrial premature depolarization have also been observed.[17,18] Electrolyte levels should be checked and corrected if abnormal prior to considering therapy for arrythmias. Patients with VPCs occurring at a high rate (200-240+ beats per minute) who appear clinically affected by the arrhythmia (weak pulse quality, poor mucous membrane color, prolonged capillary refill time, and weakness/lethargy) should be treated with antiarrhythmic medication. Most commonly, lidocaine hydrochloride at a dose of 2-4 mg/kg, is administered as an intravenous bolus given slowly to effect. The lidocaine dose can be repeated and, if necessary, it can be continued at a constant rate infusion of 0.05-0.08 mg/kg/min. If the arrhythmia is refractory to lidocaine, procainamide can be used. Procainamide should be administered at a dose of 6mg/kg as an IV bolus over 5 minutes, followed by a 10 to 25 ug/kg/min constant rate infusion. The dog should be placed on oral procainamide at a dose of 10 mg/kg every 8 hours for 15 days. Long-term antiarrhythmic treatment is usually unnecessary as the arrhythmias usually resolve.

Sepsis (Gastric Necrosis/Perforation)

The risk of dehiscence following partial gastrectomy is greatest within the first 72 hours after surgery. Dogs are monitored closely for signs of peritonitis such as lethargy, abdominal pain and/or distension, vomiting, hypotension, hypoglycemia, and hyper- or hypothermia. If dehiscence is suspected, a CBC and abdominocentesis should be performed. The abdominal fluid should be evaluated for the presence of intracellular bacteria. A paired sample of the abdominal fluid and blood should be measured for glucose levels. A glucose level in the abdominal effusion that is more than 20 mg/dl lower than the blood glucose is indicative of septic peritonitis and warrants re-exploration.[19]

Prophylactic Gastropexy

Prophylactic gastropexy is currently recommended for dogs who have had a spontaneous episode of gastric dilatation, in dogs that have a first-degree relative who has had GDV, and in some breeds that are at high risk for the development of GDV such as Great Danes, Irish Setters, and Bloodhounds. Prophylactic gastropexy can be performed at the time of elective neutering in susceptible breeds. Any of the previously mentioned gastropexy techniques can be performed by an open approach. Rawlings and colleagues have performed laparoscopic-assisted prophylactic gastropexy in 23 dogs susceptible to GDV and found that it resulted in a persistent attachment between the stomach and abdominal wall, few complications and no occurrence of GDV within one year of the original surgery.[20] Clinically, laparoscopic assisted gastropexy has proven an easy and effective prophylactic gastropexy technique.[20]

Incisional Gastropexy

Douglas M. MacCoy

Gastric volvulus is a serious, often fatal problem that occurs primarily in large, deep-chested dogs. Gastropexy,[1,2] gastroplasty,[3] tube gastrostomy,[4] and gastrocolopexy[5] have all been used in an attempt to fix the stomach to the body wall permanently and to prevent recurrent volvulus. The incisional gastropexy[1] offers a method of producing a permanent gastropexy without the potential complications and aftercare associated with tube gastrostomy. It may be used as an alternative to a tube gastrostomy when postoperative decompression will be provided by pharyngostomy tube or is not thought necessary, but a permanent gastropexy is still desired.[6] The same low potential for complications also makes it suitable as a prophylactic procedure in high-risk patients.

Surgical Technique

The cranial abdomen is approached by a ventral midline laparotomy. The pyloric antrum is identified and is held in the surgical field by thumb forceps, Babcock forceps, or stay sutures. Using a scalpel, the surgeon makes an incision equal in length to the diameter of the duodenum through the gastric serosa and into but not through the muscularis over the parietal surface of the pyloric antrum equidistant from the attachments of the greater and lesser omenta (See Figure 19-13A). The incision should be at least one duodenal diameter away from the pylorus, to avoid distortion of the pylorus. A second incision of the same length is made through the peritoneum and internal fascia of the rectus abdominis muscle or transversus abdominis muscle of the ventrolateral abdominal wall adjacent to the incision on the pyloric antrum (See Figure 19-13B).

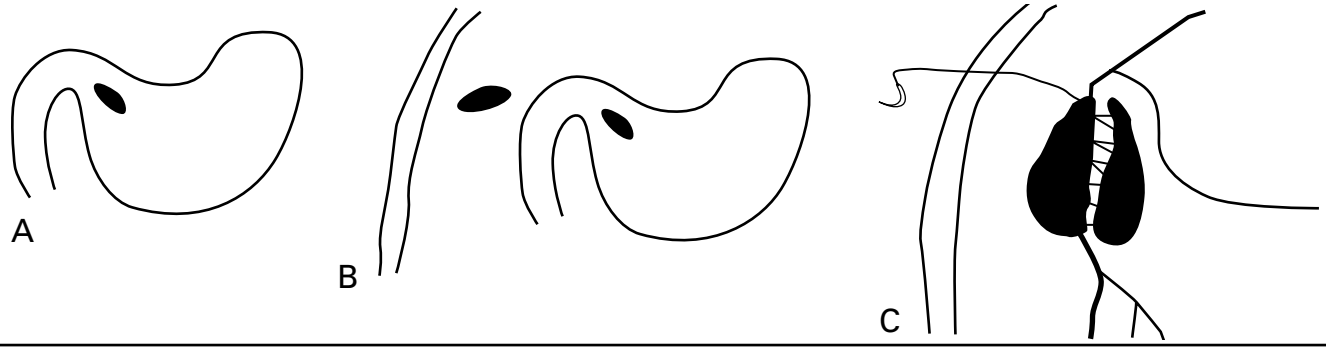

Figure 19-13. A. Initial pyloric antrum incision. **B.** Matching incision on body wall. **C.** Suturing of body wall and pyloric antrum.

The edges of the abdominal wall incision are sutured to the edges of the antral incision using 2-0 or 1-0 monofilament nylon or polypropylene in a simple continuous pattern, creating an imperforate, circular stoma (See Figure 19-13C). The abdominal incision is closed in a routine fashion.

Postoperative Care

Exercise is restricted for a minimum of 3 weeks to allow healing of the abdominal incision. No dietary restrictions are needed.

Editor's Note: Techniques such as gastrocolopexy do not prevent gastric volvulus. I pefer the incisional gastropexy technique described however I make the antral incision 5-6 cm in length. Many surgeons prefer a long-acting absorbable suture such as polydioxanone for gastropexy.

Circumcostal Gastropexy

Gary W. Ellison

The circumcostal gastropexy technique[1] has become popular with many small animal surgeons because it forms a stronger adhesion than the tube gastrostomy or incisional gastropexy technique.[2] Other potential advantages of this technique include a viable muscle flap adhesion and a more proper anatomic placement of the stomach.[1] Potential disadvantages of the circumcostal gastropexy technique include possible rib fracture or creation of pneumothorax when the operation is performed by surgeons who are inexperienced with the technique.[3] This procedure is also reported to be more technically demanding and time-consuming to perform than other gastropexy techniques, but I disagree with this statement.

Surgical Technique

To perform the circumcostal gastropexy, two 1x4 cm partial-thickness gastric flaps are created and are wrapped around either the eleventh or twelfth costal cartilage. Initially, 2-0 polypropylene stay sutures are placed 2 and 8 cm proximal to the pylorus, respectively. A transverse nick incision is then made 3 cm distal to the pylorus with Metzenbaum scissors. A second transverse nick incision is made at the other end 4 cm proximal to the first. To avoid penetrating the gastric lumen when making these incisions, the serosa and muscularis are first grasped between the surgeon's thumb and forefinger. This maneuver separates these layers from the underlying submucosa. The two transverse incisions are then connected with a scalpel or scissors. The seromuscular layer is then separated from the submucosa with scissors on both sides, thereby creating two 1.0x4 cm seromuscular pedicle flaps (Figure 19-14). The chondral portion of the right eleventh or twelfth rib is encircled with towel clamps from the abdominal surface, and the peritoneum and transverse abdominal muscle are incised with a No. 10 blade (Figure 19-15). A tunnel is then made around the medial aspect of the rib using Metzenbaum scissors. If the eleventh or twelfth rib is used, the incision is caudal to all diaphragmatic attachments, and the thoracic cavity is not entered. The caudal arm of each stay suture is then passed through the rib tunnel, and the stomach is pulled up against the right abdominal wall. The caudal muscular flap is passed around the lateral aspect of the rib with a stay suture or grasping forces, and the two stay sutures are tied around the rib (Figure 19-16). The caudal muscular flap is then apposed to the cranial muscular flap with simple interrupted sutures of 2-0 polypropylene (Figure 19-17). A second layer of simple interrupted sutures of 3-0 po lypropylene is used to appose gastric serosa to the incised transversus muscle (Figure 19-18). The ventral midline is then closed routinely. Postoperative care is similar to that for other gastropexy techniques.

Results

In one study, 30 patients with GDV were followed-up for an average of 12.7 months after circumcostal gastropexy with contrast studies or necropsy.[4] Of the animals that survived, just 1 dog (3.3%) suffered

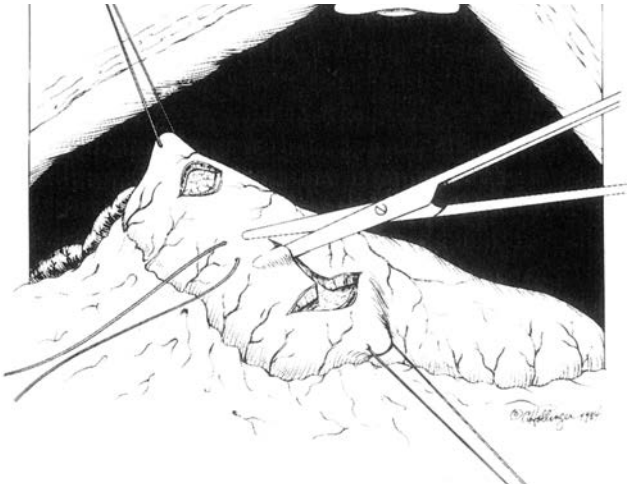

Figure 19-14. After placing stay sutures, two small incisions are made through the seromuscular layer of the pyloric antrum and are connected with scissors. The flaps are undermined for a distance of I cm. (From Ellison GW. Gastric dilatation volvulus: surgical prevention. Vet Clin North Am Small Anim Pract 1993:23:524.)

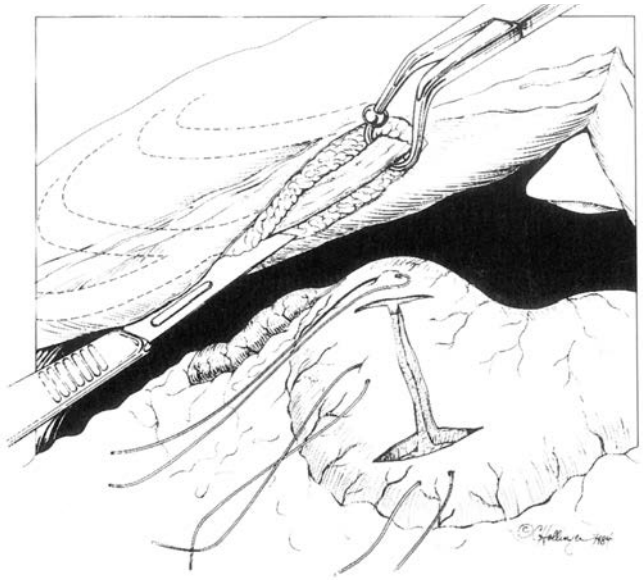

Figure 19-15. The eleventh or twelfth rib is then grasped with towel clamps from the abdominal surface, and the peritoneum and transverse abdominal muscle are incised with a No. 10 blade. (From Ellison GW. Gastric dilatation volvulus: surgical prevention. Vet Clin North Am Small Anim Pract 1993:23:524.)

a clinical recurrence of gastric dilatation. In another study, 34 dogs were followed-up after circumcostal gastropexy, with a mean follow-up of 11.3 months. One patient developed peritonitis as a result of inadvertent penetration of the gastric wall during flap formation. The overall mortality was 8.8%, and suspected recurrence occurred in 2 patients (6.9%) because of a second episode of gastric distension.[5] Neither of these recurrences was documented with radiographs or necropsy as due to gastropexy failure.

Laparoscopic Assisted Gastropexy

Don R. Waldron

Introduction

Creation of a permanent gastropexy is the single most important factor in preventing gastric-dilatation volvulus (GDV) in susceptible dogs. Gastropexy is performed most commonly as part of therapeutic surgery following gastric repositioning for animals with gastric volvulus. Performance of an effective gastropexy includes fixation of the gastric antrum to the right abdominal wall or rib area. Many methods of gastropexy have been described and are effective if performed well technically. Incisional gastropexy is a simple and effective technique that has been widely used and is simple to perform.

Increased knowledge of GDV among veterinarians and owners and identification of known risk factors for dogs susceptible to the condition has resulted in increased numbers of dogs having prophylactic gastropexy to prevent gastric volvulus. Risk factors for development of the disease include first-degree relatives who have been affected (genetic), stress, breed/confirmation (Great Danes, St, Bernards, Weimeraners, Irish Setters, Gordon Setters, Standard Poodles) and diet.[1] It is widely accepted that animals with deep thorax-to-width ratios are especially at risk for the disease. Because of high mortality rates associated with GDV, prophylactic gastropexy should be considered in dogs identified as being at high risk.

Prophylactic gastropexy can be performed by open laparotomy concurrently with elective ovariohysterectomy in the female however the incision required is a substantial one extending from xiphoid caudal to the umbilicus. Laparoscopic gastropexies have been described however a high degree of laparoscopic surgical skill and experience are required.[2] The laparoscopic-assisted gastropexy technique described here was developed and described by Rawlings et al in 2001 and 2002.[3,4] The technique was investigated in the laboratory and has been widely used on client owned dogs with minimal morbidity and a high degree of success in preventing GDV. Two portals are used and the laparoscope is used to identify and grasp the antrum, however, once the antrum is exteriorized the gastropexy is performed as an open technique. Minimal laparoscopic skills are required making the technique relatively easy to perform.

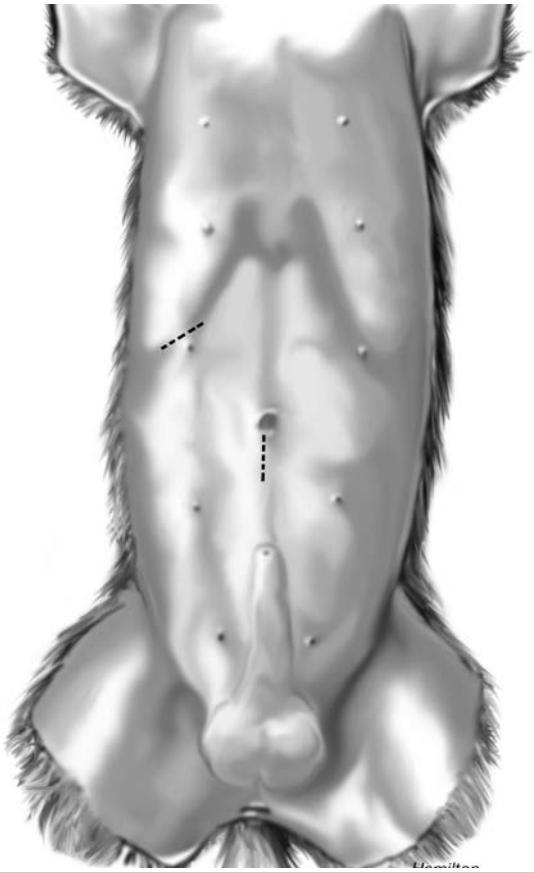

Figure 19-19. The dog is placed in dorsal recumbency and two abdominal incisions are made, midline for the laparoscope and right side caudal to the last rib for the gastropexy.

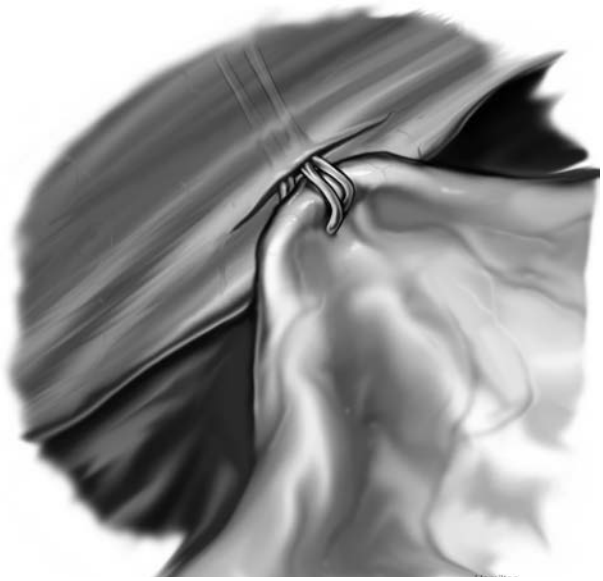

Figure 19-20. The antrum is grasped with tissue forceps midway between the greater and lesser curvatures about 5 to 7 cm orally from the pylorus. The forceps, the right-sided trocar cannula and the antrum are exteriorized through the lengthened cannula incision.

Technique

General anesthesia is induced and positive-pressure ventilation used during laparoscopic surgery. The dog is placed in dorsal recumbency and the complete abdomen prepared for surgery. A trocar cannula is placed 2cm caudal to the umbilicus which accommodates the laparoscope (Figure 19-19). The peritoneal cavity is distended with carbon dioxide and a 0°, 5°, or 10° laparoscope connected to a light source and video camera is inserted through the cannula. A second trocar cannula is placed 3 cm caudal to the last rib and lateral to the rectus abdominis muscle (See Figure 19-18). A 10mm Babcock forcep is placed into the abdomen to grasp the gastric antrum midway between the greater and lesser curvatures approximately 5 to 7 cm proximal to the pylorus. Allis tissue forceps are more traumatic but are useful in grasping the antrum if the stomach slips from the Babcock forceps.

The tissue forceps and antrum are exteriorized by removing the right side cannula and extending the cannula incision to 4cm in length in a direction parallel to the last rib. Care is taken to assure the antrum is not twisted as it is withdrawn from the abdomen (Figure 19-20). Size 0 "stay" sutures are placed 4 to 5 cm apart through the gastric serosa/muscularis to control the gastric wall during gastropexy. A seromuscular longitudinal incision is made in the gastric wall between the stay sutures. The sides of the gastric wall incision are dissected free from the mucosa so that adequate gastric tissue is available for the gastropexy and so that sutures are not placed through the gastric mucosa. A simple continuous pattern of size 0 or 2-0 synthetic monofilament absorbable suture (polydioxanone) is used to appose the seromuscular layer of the stomach to the transversus abdominus muscle (Figure 19-21). A separate suture line is placed on the cranial and caudal aspects of the gastropexy site. The abdominal oblique muscles are closed with interrupted absorbable sutures and the remainder of the incision by surgeon's choice. The completed gastropexy site is viewed intraabdominally (Figure 19-22) to assure that the gastric antrum is not twisted, the midline cannula is removed and the incision is closed.

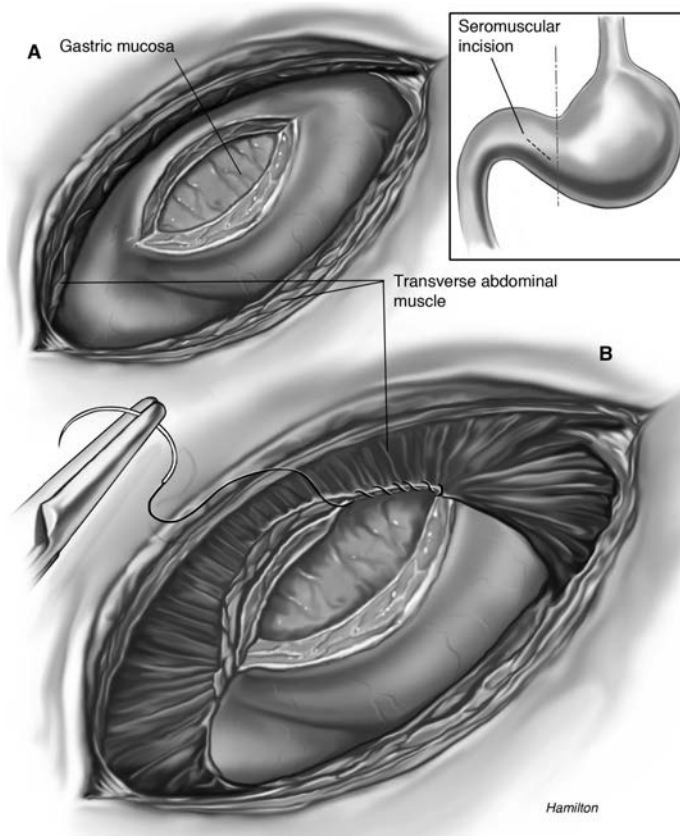

Figure 19-21. A seromuscular incision is made in the gastric wall down to the gastric mucosa and the sides of the incision dissected in both directions from the primary incision. The seromuscular layer is sutured to the transversus abdominis muscle with a continuous pattern of monofilament absorbable suture. SM=seromuscular layer of the stomach; GM=gastric mucosa; TA= transversus abdominis muscle.

Figure 19-22. Laparoscopic view of the completed gastropexy with no evidence of antral twisting.

Chapter 20

Intestines

Enterotomy

Gary W. Ellison

Indications

The most common indication for enterotomy in small animals is to remove intraluminal intestinal foreign bodies that cause obstruction. Foreign bodies can be present in animals of any age, but they are most common in puppies or kittens because of indiscriminate eating habits. Common intestinal foreign bodies in dogs include bones, balls, corncobs, and cellophane wrappers. Cats commonly ingest sharp foreign bodies (e.g., straight pins and needles) and linear foreign bodies (e.g., yarn, tinsel, fishing line, and string meat wrappings). Enterotomy also is performed as a biopsy technique and to examine the intestinal lumen for evidence of mucosal ulceration, strictures, or neoplasia. Superficial ulcerations or intestinal polyps sometimes can be resected via enterotomy, but most intramural lesions require intestinal resection and anastomosis.

Pathophysiology and Preoperative treatment of Intestinal Obstruction

Animals with incomplete intestinal obstruction caused by intraluminal foreign bodies or neoplasia usually vomit sporadically or are anorectic. Surprisingly, sharp foreign bodies such as nails, straight pins, and bones often pass spontaneously through the entire gastrointestinal tract without causing a perforation. Conversely, complete intraluminal obstructions usually cause acute bowel distension and unrelenting clinical signs. With proximal (duodenal) obstructions, vomiting may be projectile. With distal jejunal or ileal obstructions, vomiting may be seen early in the course of the disease, but anorexia and bowel distension follow. After obstruction of the midjejunum in dogs, vomiting often decreases to once a day after 24 to 36 hours, and many dogs can live for several weeks if hydration is maintained.

Most intestinal obstructions are distal to the bile and pancreatic ducts, resulting in loss of highly alkaline duodenal, pancreatic, and biliary secretions. Metabolic acidosis usually occurs from loss of these bicarbonate-rich duodenal contents. Dehydration should be corrected and maintenance fluid needs are usually met with a balanced electrolyte solution such as lactated Ringer's solution. Potassium chloride supplementation of fluids may be indicated, depending on the patient's acid-base status and serum potassium level. With obstructions at the pylorus or proximal duodenum, gastric fluids rich in potassium, sodium, hydrogen ion, and chloride are vomited, and metabolic alkalosis with hypochloremia, hyponatremia, and hypokalemia may result. In those cases, dehydration is corrected with intravenous 0.9% sodium chloride solution supplemented with potassium chloride depending on the patient's preoperative serum potassium level.

Surgical Technique

A ventral midline laparotomy incision is made from the xiphoid to the pubis. The entire intestinal tract should be evaluated to determine the number of foreign bodies and assess the viability of the bowel wall. The affected bowel segment is isolated from the remainder of the viscera with saline-soaked laparotomy sponges. In patients with a complete obstruction, intestinal distension proximal to the obstruction is often profound, and the distended loops of bowel usually take on a congested or cyanotic appearance (Figure 20-1A).

Intestinal viability is best evaluated after decompression of fluid and gas from dilated loops of intestine. Decompression is performed with a 20-gauge needle and suction apparatus or a 60-mL syringe with a three-way stopcock. If intestinal wall ischemia and necrosis are present, resection and anastomosis must be performed (following article). In most cases of simple mechanical obstruction, however, bowel viability is maintained, and the gross appearance of dark, distended loops of bowel improves rapidly after decompression and removal of the obstruction.

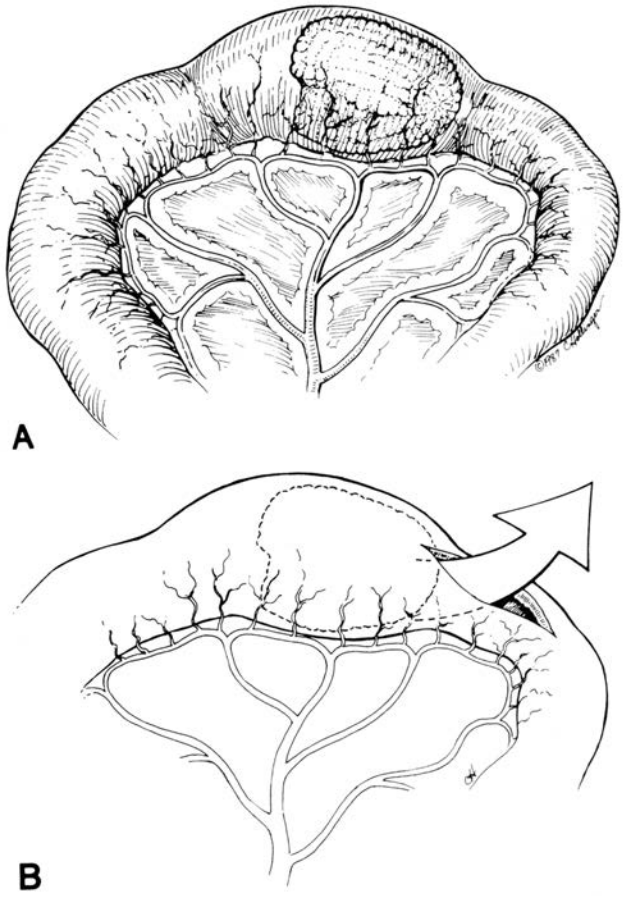

Figure 20-1. A. Complete intestinal obstruction caused by a luminal foreign body such as a corncob causes fluid and gaseous distension. Congestion or cyanotic appearance of the bowel wall occurs proximal to the obstruction. **B.** An enterotomy is made in the antimesenteric surface of viable bowel just distal to the foreign body. The length of the incision approximates the diameter of the foreign body. The foreign body is delivered through the incision with gentle manual pressure.

Intestinal contents are milked 10 cm to either side of the foreign body and the bowel is held between an assistant's fingers or with Doyen intestinal forceps. A No. 15 scalpel blade is used to make a full-thickness longitudinal incision in the antimesenteric border of the intestine in the viable tissue immediately proximal or distal to the foreign body. The length of the enterotomy approximates the diameter of the foreign body. Continuous suction is used to reduce spillage, and the surgeon pushes the foreign body gently through the enterotomy, taking care not to tear the incision margins (Figure 20-1B). The bowel lumen is examined for evidence of perforations or strictures before closure.

Linear foreign bodies such as string, fishing line, meat wrappers, and sewing yarn present a difficult surgical problem. The trailing end of a linear foreign body usually catches over the base of the tongue or in the pyloric antrum and acts as an anchor. Intestinal peristalsis attempts to move the foreign body distally, but because it remains fixed proximally, the bowel plicates itself along the length of the foreign body, which often cuts through the intestinal wall on the mesenteric surface, resulting in local peritonitis.

Linear foreign bodies should be managed by identifying the glossal anchor point initially and releasing it before laparotomy. Commonly, a gastrotomy is also necessary to free wadded string or fishing line from a gastropyloric anchor. The traditional way for linear foreign body removal requires multiple enterotomies to complete removal of the linear body (Figure 20-2). If too few enterotomies are made with too much traction placed on the linear body, the mesenteric border may be perforated in an area that is difficult to explore and suture. Occasionally, the intestinal foreign body perforates at several locations before surgery, and local peritonitis is evident. Sometimes, enough fibrosis has occurred around the foreign body so, even after its removal, the bowel retains its plicated conformation. In these patients, intestinal resection and anastomosis may be necessary.

Linear foreign body removal may often be facilitated using a urinary catheter technique. With this technique only one or two enterotomies are necessary. Once the foreign body is released from its proximal anchor point it is tied or sutured to the tip of an eight to 12 French vinyl urinary catheter (Figure 20-3A). The catheter tip is then pushed distally along the pleated length of bowel. As the catheter is pushed distally, the imbedded linear foreign body disengages from the intestinal wall (Figure 20-3B inset) and the bowel unpleats itself (Figure 20-3B). Once the foreign body is completely disengaged from the bowel wall a second short enterotomy is made distally over the distal tip of the catheter and the remainder of the foreign body is retrieved (Figure 20-3C). Alternatively a longer catheter can be used and pushed down through the colon. The foreign body can then be retrieved from the anus (not shown). The author has found catheter facilitated removal to be a very useful method for linear foreign body retrieval.

Closure of the enterotomy incision usually is performed with a simple interrupted suture pattern in side-to-side longitudinal fashion (Figure 20-4). Single-layer closures are recommended because double-layer closures may cause excessive narrowing of the lumen diameter. Various suture patterns are acceptable, but with all techniques, the vascular and collagen-rich submucosa must be incorporated in the sutures. Single-layer appositional techniques such as the simple interrupted appositional suture pattern is most commonly used. A simple interrupted approximating suture can be used (See Figure 20-10A). Sutures are placed 3 to 4 mm apart and 2 to 3 mm from the cut edge, taking care to incorporate all layers of the intestinal wall. Crushing sutures are tied tightly and cut through the muscularis and engage the submucosa. The author feels they should be avoided since they cause excessive hemorrhage and tissue ischemia (See Figure 20-10B). I prefer a modified Gambee suture, which incorporates the serosa, muscularis and submucosa but excludes the mucosa and is helpful in reducing mucosal eversion (See Figure 20-11).

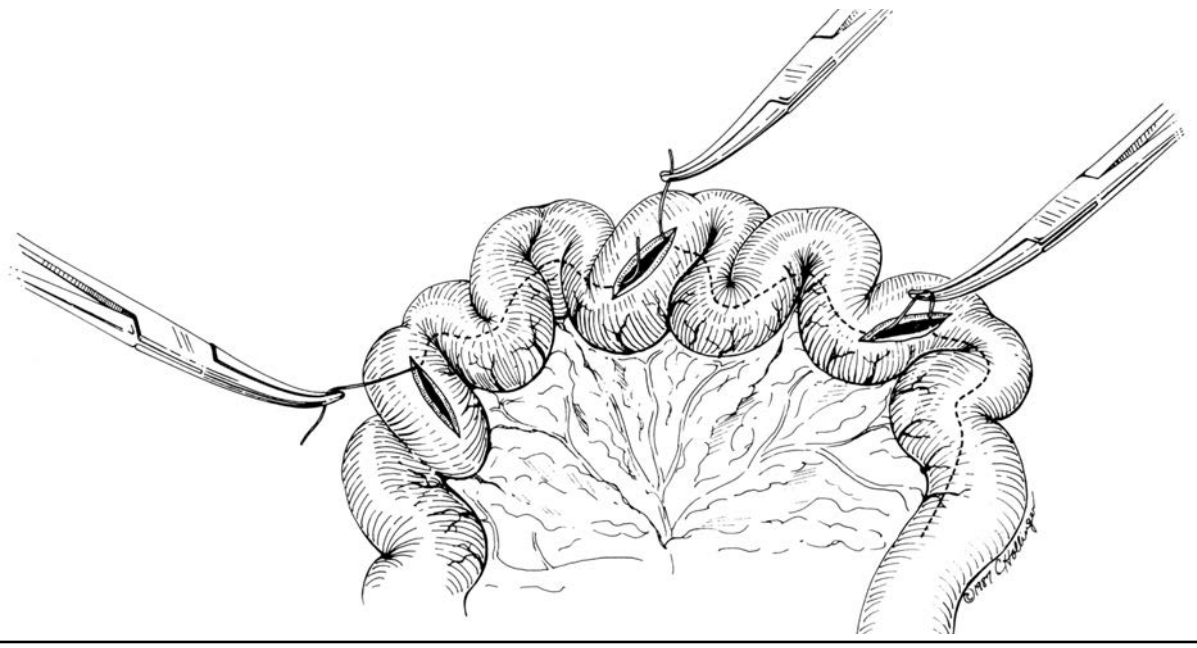

Figure 20-2. With a linear foreign body (e.g., a piece of string), multiple enterotomies usually are required. Mosquito hemostats are used to grasp a loop of the string at each enterotomy site. The string is then sequentially cut and withdrawn through the nearest enterotomy site. See text for details.

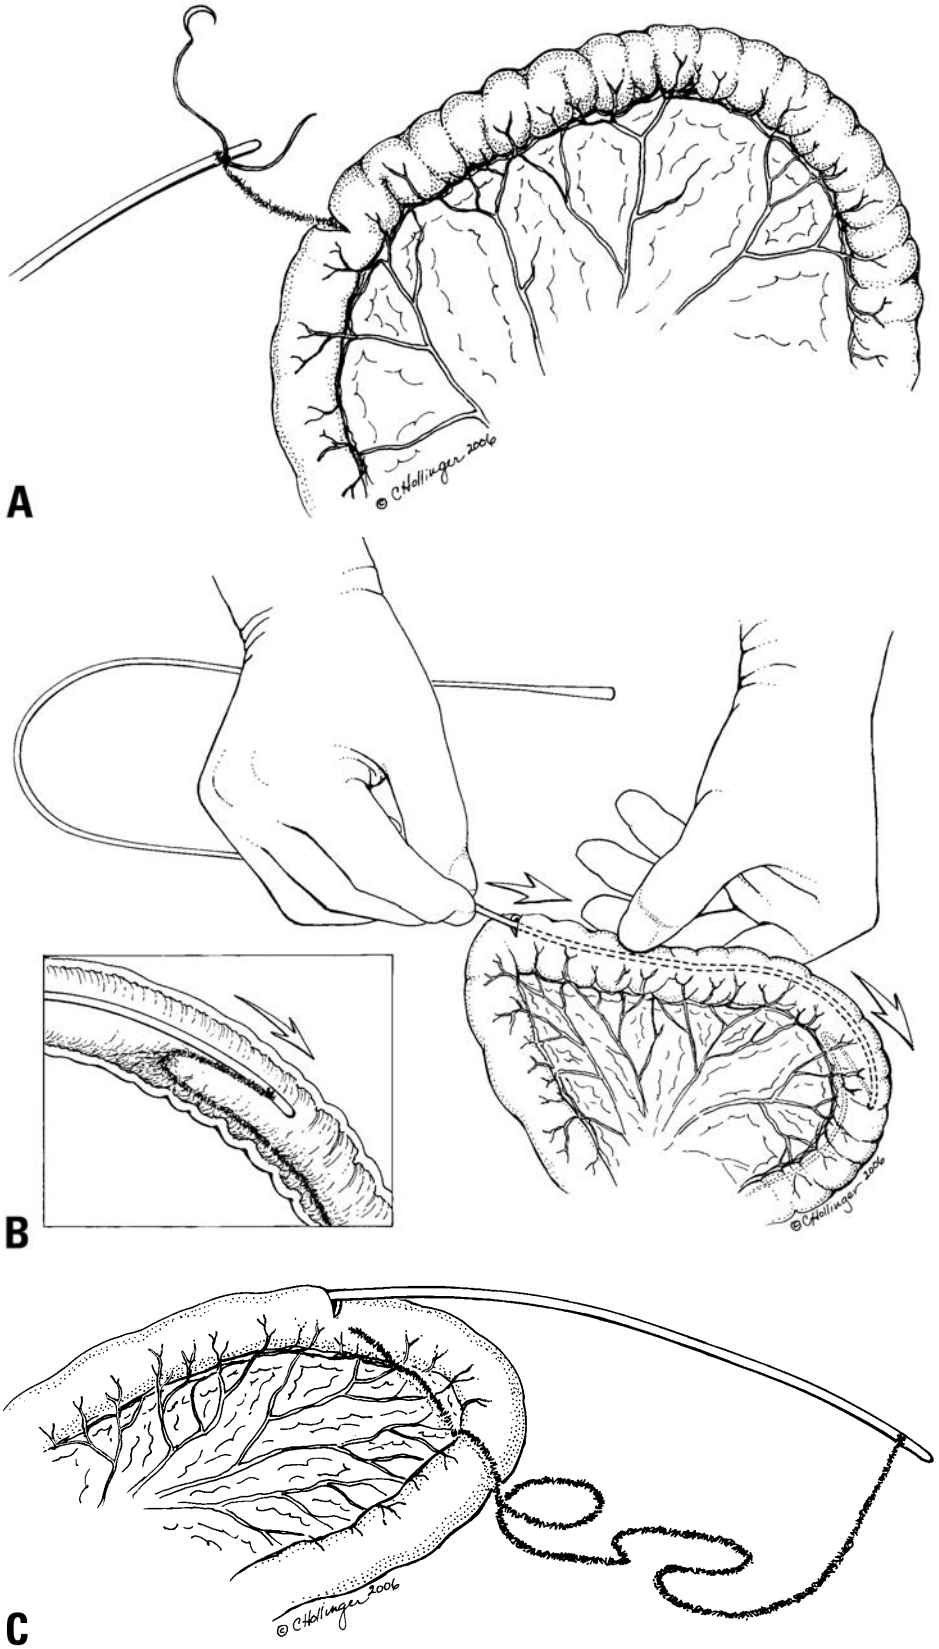

Figure 20-3. Fewer enterotomies are needed if **A.** The linear foreign body is tied or sutured to the tip of a urinary catheter. **B.** The catheter is pushed distally and disengages the foreign body from the intestinal mucosa (inset) as the intestine unpleats itself. **C.** A small enterotomy is made over the tip of the catheter and the foreign body is retrieved. If the catheter is long enough it can be pushed through the colon and out the anus (not shown).

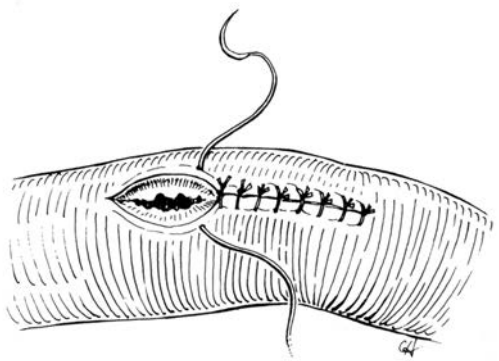

Figure 20-4. An enterotomy usually is closed in side-to-side fashion interrupted suture pattern. Appositional, crushing, or modified Gambee sutures can be used.

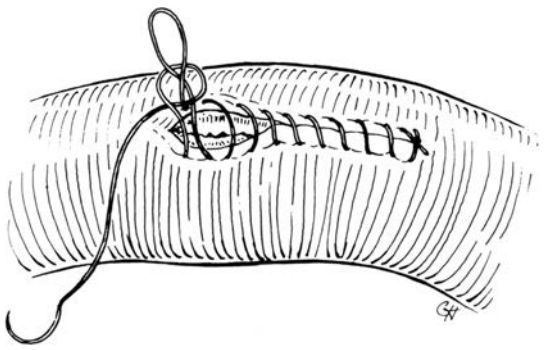

Figure 20-5. An enterotomy also can be closed with a simple continuous appositional pattern.

The enterotomy also can be closed using a simple continuous approximating pattern (Figure 20-5). Suture bites are taken perpendicular to the bowe1 wall 2 to 3 mm from the cut edge and 3 mm apart. The suture line is advanced outside the bowel lumen. Sutures are pulled snugly enough to appose the wound edges gently. Pulling the suture line too tightly may cause strangulation of the wound edge and may lead to dehiscence. Some surgeons tend to close the enterotomy with a Cushing pattern. A continuous inverting Cushing pattern gives good serosa-to-serosa apposition and luminal bursting strengths that exceed those of the interrupted approximating patterns for the first day post operatively. However, lumen diameter is reduced. Suture bites are placed 2 to 3 mm from the wound edge to minimize the amount of inversion (Figure 20-6). The tough submucosal layer is secured with each pass of the needle.

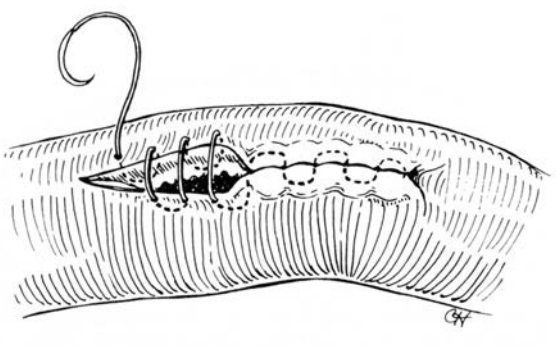

Figure 20-6. A continuous inverting Cushing suture pattern may be chosen for animals lumen who have a higher than normal risk of enterotomy leakage.

A rapid method of closing multiple enterotomies involves the use of a regular dimension skin stapler (AutoSuture multifire premium, United States Surgical, Norwalk, CT). Full thickness traction sutures are placed on both ends of the enterotomy and skin staples are placed every 2-3 mm (Figure 20-7). If the enterotomy is made in a small-diameter loop of bowel, longitudinal closure may cause luminal constriction. To prevent this constriction, the ends of the enterotomy can be closed in transverse fashion. A simple interrupted suture is used to approximate the proximal and distal ends of the longitudinal incision. Additional sutures are then placed 3 to 4 mm apart to appose the remaining bowel wall, resulting in a widened lumen diameter (Figure 20-8). For intestinal biopsies and for enterotomies in small animals I prefer to make a short transverse incision which goes not more than 30 to 40% around the diameter of the enterotomy and then close this wound transversely. I find that making the wound in this direction preserves lumen diameter better than either a longitudinal incision with side to side or transverse closure (Figure 20-9).

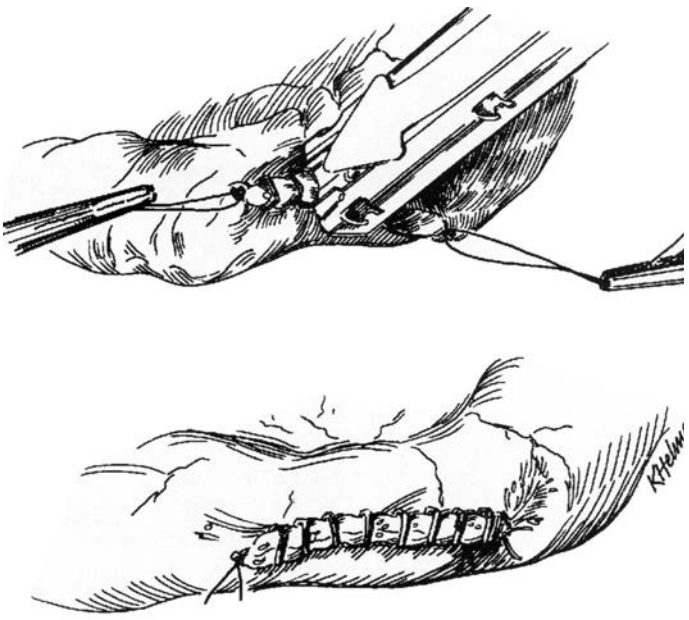

Figure 20-7. Multiple enterotomies can be closed in rapid fashion using a multifire skin stapler. Full thickness stay sutures are placed on the end of the wound and traction applied while staples are applied every 2-3 mm. (From Coolman BR, Ehrhart N, Marretta SM. Use of skin staples for rapid closure of gastrointestinal incisions in the treatment of canine linear foreign bodies. J Am Anim Hosp Assoc 36:542, 2000, with permission).

I prefer to close enterotomies with 3-0 to 4-0 synthetic monofilament suture material. Acceptable materials include polydioxanone (PDS, Ethicon, Inc.), poliglecaprone 25 (Monocryl, Ethicon, Inc.), polyglycomer 631 (Biosyn, United States Surgical) or polyglyconate (Maxon, United Status Surgical) on a narrow-taper, taper-cut, or small reverse-cutting need1e. Due to their rapid absorption time poliglecaprone 25 (Monocryl, Ethicon, Inc.) and polyglycomer 631 (Biosyn, United States Surgical) should be

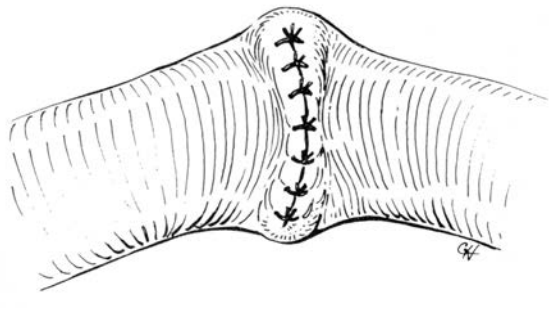

Figure 20-8. In a small-diameter loop of bowel, the longitudinal incision can be closed transversely to prevent luminal stenosis, a simple interrupted pattern is used.

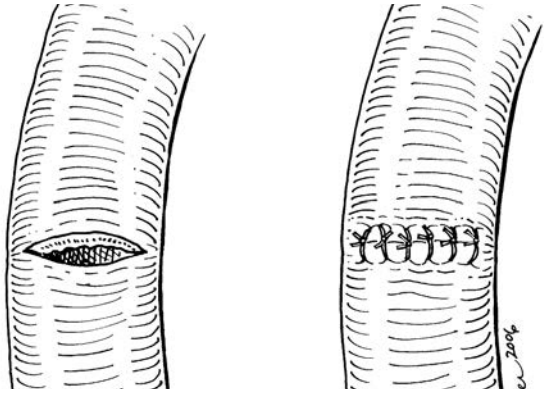

Figure 20-9. For intestinal biopsy make a transverse incision in the bowel wall and close the wound transversely with simple interrupted sutures to preserve lumen diameter.

avoided in colonic surgery (See Chapter 1). Chromic surgical gut has been used with clinical success, but it is not recommended for intestinal closure because it loses tensile strength rapidly in the presence of collagenase and is quickly phagocytized in an infected environment. Nonabsorbable monofilament materials such as nylon (Ethicon, Ethicon, Inc.) or polypropylene (Prolene, Ethicon, Inc.) also may be used but foreign bodies have reportedly become attached to their exposed intraluminal segments. Stainless steel skin staples are reported to migrate into the lumen of the bowel and may be extruded in the feces. After the enterotomy closure is complete, it is rinsed with saline and covered with omentum (See Figure 20-19).

Postoperative Care

The bacterial population of the small intestine is lowest in the proximal duodenum and highest in the distal ileum. Uncomplicated enterotomies of the proximal small bowel may not require postoperative antibiotic therapy. However, when spillage occurs or when an enterotomy is performed on the distal small bowel, parenteral antibiotics are administered prior to or during surgery and are continued for 24 to 48 hours postoperatively. Broad-spectrum bactericidal agents such as intravenous cephazolin, at 10 mg/kg four times daily, in combination with enrofloxacin, 7.5 mg/kg IV twice daily, provide good prophylaxis against most gram positive cocci and gram-negative enteric organisms. Intravenous metronidazole, at 15 mg/kg PO four times daily, is also effective against anaerobic organisms

Replacement intravenous fluids and electrolyte therapy are continued in the postoperative period until dehydration and acid-base and electrolyte abnormalities are resolved. Early introduction of food stimulates bowel contraction, reduces the likelihood of postoperative ileus or adhesion formation, and also serves as a valuable source of fluid and electrolytes. We begin feeding the day after surgery with small amounts of I/D gruel (Hills Pet Nutrition Inc., Topeka, KS). Persistent vomiting, fever, and leukocytosis in the presence of abdominal tenderness may indicate peritonitis resulting from leakage from the enterotomy. Abdominal paracentesis or diagnostic lavage should be performed. If a septic exudate is present, early exploration of the abdomen is indicated, and resection and anastomosis or one of the serosal patching techniques may be performed.

Intestinal Resection and Anastomosis

Gary W. Ellison

Indications

Intestinal resection and anastomosis is performed for various common lesions of the small intestine. Mechanical obstructions, whether luminal, intramural, or extramural commonly require intestinal resection and anastomosis. Lodged intraluminal foreign bodies often cause local bowel wall necrosis or perforation, which may necessitate intestinal resection. Intramural lesions caused by strictures, neoplasms, or fungal granulomas caused by pythiosis must be removed by resection of the affected section of bowel. Occasionally, extramural lesions caused by adhesions secondary to previous surgery, regiona1 peritonitis, or abdominal abscesses require resection of the obstructed segment of intestine.

Strangulated loops of bowel associated with diaphragmatic, ventral, inguinal, perineal, or femoral triangle hernias often require emergency resection and anastomosis. Animals with intestinal or mesenteric volvulus have peracute mesenteric vascular pedicle obstruction and secondary bowel wall ischemia and may require massive resection and anastomosis. With intussusception, the invaginated segment of bowel undergoes early venous congestion and becomes edematous. Intussusceptions then become rapidly irreducible due to outpouring of fibrinous exudate from the invaginated serosal surface. If arterial thrombosis occurs, the invaginated bowel will become ischemic and necrotic. Resection and anastomosis of the affected section of bowel is then necessary.

Determining Intestinal Viability

Non-viable intestine is usually distended, blue, black or grey in appearance and easily discernable from normal bowel. In some cases, determining viability in cyanotic appearing bowel is difficult. The intestine should be decompressed with a needle and suction apparatus to relieve venous congestion. Standard clinical criteria for establishing intestinal viability are color, arterial pulsations, and the presence of peristalsis. Of these three parameters, peristalsis is the most dependable criteria of viability. The "pinch test" should be performed on questionable areas of bowel to determine whether smooth muscle contraction and peristalsis is present. If clinical criteria are inadequate to determine viability, intravenous fluorescein dye or surface oximetry can be used. A 10% fluorescein solution (Fundescein-10, Cooper Laboratories, San Germain, PR) is given at a dosage of 1 mL/5 kg intravenously through any peripheral vein. After 2 minutes, the tissues are examined using long-wave ultraviolet light (Wood's lamp). Areas of bowel are considered viable if they have a bright green glow. Areas of bowel are not viable if they have a patchy density with areas of nonfluorescence exceeding 3 mm, have only perivascular fluorescence, or are completely nonfluorescent. Oxygen saturation may also be a reliable method of determining intestinal wall viability. A sterile probe is placed on the surface of the bowel and an oxygen saturation level reading will occur. According to published reports in rabbits, saturation levels of 81% or above typically mean that the bowel is viable. Values below 76% were consistent with mucosal necrosis and those below 64% indicated transmural intestinal necrosis.

Anastomotic Pattern and Suture Material

Although numerous suture techniques have been used for end-to-end intestinal anastomosis in small animals, approximating patterns are recommended at present. Properly performed approximating techniques create a lumen diameter comparable to normal, result in rapid and precise primary intestinal healing, and minimize the potential for postoperative adhesion formation. Everting techniques (e.g., horizontal mattress pattern) initially create a larger lumen diameter, but ultimately they cause narrowing and stenosis of the lumen. Everting anastomoses are not recommended because they have a greater tendency to leak and because of delayed mucosal healing, prolonged inflammatory response, and increased adhesion formation compared with approximating anastomoses. Inverting anastomoses using Cushing or Connell patterns provide a temporary leak-resistant serosa-to-serosa approximation but they create an internal cuff of tissue, which may cause luminal stenosis. Inflammation is more severe and healing time is slower than with approximating techniques. Despite these dangers, inverting techniques should be considered in patients with a high risk of leakage or for use in colonic resection and anastomosis; in the latter situation, the high bacterial content of feces makes leakage of the anastomosis extremely dangerous.

Approximating end-to-end intestinal anastomoses can be created with various simple interrupted suture patterns or with a simple continuous suture pattern. Interrupted patterns generally are easier to perform, but the simple continuous pattern minimizes mucosal eversion and therefore provides better serosal apposition and primary intestinal healing. Regardless of the suture technique used, proper incorporation of the tough submucosa and reduction of mucosal eversion are vital in performing consistently successful intestinal anastomosis.

A simple interrupted appositional suture incorporates all tissue layers and gently apposes the wound edges (Figure 20-10A). A crushing suture is pulled tightly and cuts through the serosa, muscularis, and mucosa, and engages only the tough submucosal layer of the bowel wall (Figure 20-10B). Crushing sutures create more microhemorrhage and tissue necrosis directly at the anastomosis and the author feels they should be avoided. With both the appositional and crushing techniques, mucosal eversion tends to occur between sutures. I prefer a modified Gambee suture pattern because it reduces mucosal eversion. In this technique, the need1e is passed through the serosa, muscularis, and submucosa, but the mucosal layer is not incorporated in the suture (Figure 20-11). The suture is tied snugly enough to approximate all layers of the intestinal wall gently. The mucosa tends to be pushed into the intestinal lumen and does not evert between sutures.

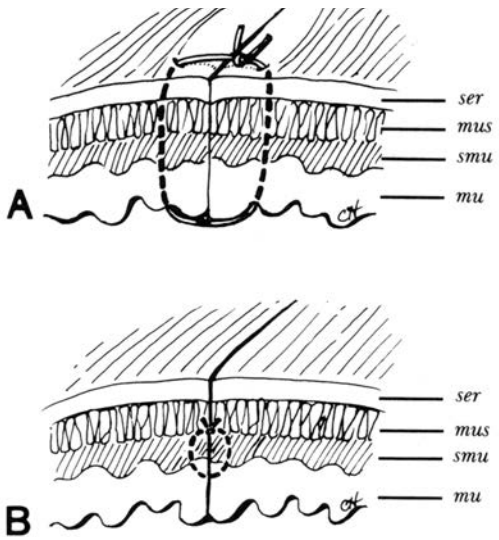

Figure 20-10. A. Simple interrupted appositional suture, the wound edges are gently apposed. mu, mucosa; smu, submucosa; mus, muscularis; ser, serosa. **B.** Crushing suture. The knot is tied tightly cutting through all tissue layers and engaging the submucosa. This suture causes microvascular ischemia and tissue necrosis.

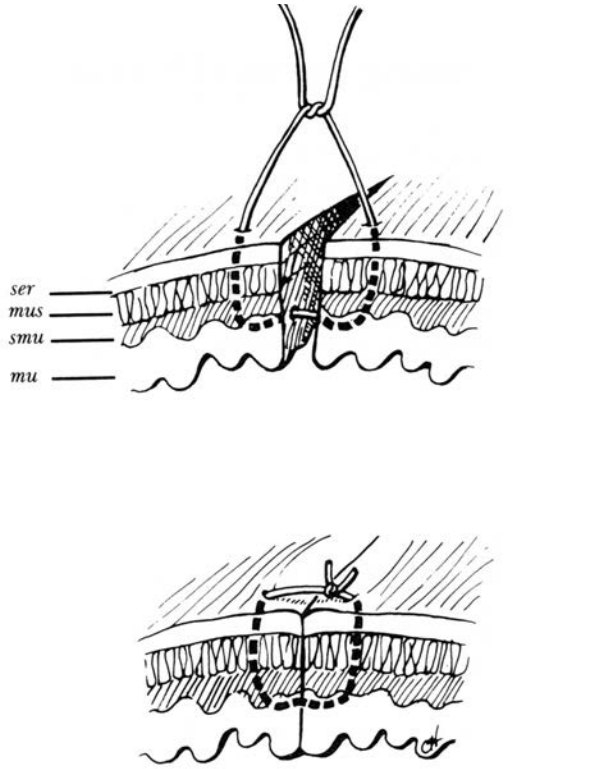

Figure 20-11. Modified Gambee suture. When tied, this suture gently approximates all tissue layers and slightly inverts the mucosa, thereby minimizing mucosal eversion between sutures (bottom). mu, mucosa; smu, submucosa; mus, muscularis; ser, serosa.

A taper-cut, narrow-taper, or small reverse-cutting need1e with 3-0 or 4-0 swaged-on suture material is suitable for most anastomoses. Braided, nonabsorbable materials such as silk or braided polyesters should be avoided. Chromic surgical gut rapidly loses tensile strength due to collagenase and phagocytosis at the wound edge and is not recommended. Synthetic, braided, absorbable suture materials such as polyglactin 910 (Vicryl, Ethicon, Inc., Somerville, NJ) are acceptable, but they have significant tissue drag. I prefer poliglecaprone 25 (Monocryl, Ethicon Inc., Somerville, NJ), glycomer 631 (Biosyn, United States Surgical Corp, Norwalk, CT), polydioxanone (PDS, Ethicon, Inc., Somerville, NJ), and polyglyconate (Maxon, United States Surgical Corp., Norwalk, CT), which are monofilament absorbable sutures with little tissue drag and have all been used successfully for intestinal anastomoses. Nonabsorbable monofilament sutures such as nylon (Ethicon, Ethicon, Inc., Somerville, NJ) or polypropylene (Prolene, Ethicon, Inc., Somerville, NJ) also are acceptable for simple interrupted anastomoses, but they should not be used for simple continuous anastomoses because they do not allow luminal distension. Newer versions of triclosan impregnated polygalactin 910 (Vicryl plus, Ethicon Inc., Somerville, NJ) and poliglecaprone 25 (Monocryl plus, Ethicon Inc., Somerville, NJ) are undergoing investigation in hopes that this bacteriostatic compound will reduce wound infection.

Surgical Technique

A standard midline laparotomy is performed, as well as a thorough examination of the intestinal tract. The area to be resected is packed away from the abdomen with moistened laparotomy sponges. Intestinal contents are milked proximally and distally, and the bowel is held between an assistant's index fingers or with Doyen intestinal forceps 4 to 5 cm from the proposed resection site. A 1- to 2-cm margin of normal viable intestine is included in the proximal and distal boundaries of the area to be resected, which is clamped with Carmalt or Doyen forceps. If luminal disparity is present, the forceps are placed at a 75° to 90° angle on the dilated proximal segment (Figure 20-12A) and at a 45° to 60° angle on the contracted distal segment of bowel (Figure 20-12B). Branches of the mesenteric artery and veins supplying the devitalized bowel are isolated with curved mosquito forceps and are double-ligated. The arcadial vessels located within the mesenteric fat are double-ligated at the area of the proposed resection. A scalpel blade is used to excise the bowel along the outside of the intestinal forceps (See Figure 20-12, dashed lines). With dissecting scissors, the vessels are divided, the mesentery is transected (See Figure 20-10, dotted lines), and the excised bowel is removed from the surgical field. After resection, the small intestinal mucosa has a tendency to evert and can be trimmed back with Metzenbaum scissors (Figure 20-13).

If angling the intestinal incision does not adequately correct for luminal disparity, the smaller stoma can be enlarged by incising the bowel section for a distance of 1 to 2 cm along the antimesenteric surface and then trimming off two triangular flaps (Figure 20-14). This procedure creates an ovoid larger stoma, which can be anastomosed to the larger-diameter section of the bowel.

When the anastomosis is closed with a simple interrupted suture technique, the first suture is placed at the mesenteric border because the presence of fat in this area makes suture placement most difficult, and this is where leakage is most likely to occur. The second suture is placed on the antimesenteric border, and the third and fourth sutures are placed laterally at the 90° quadrants (Figure 20-15A). Depending on bowel diameter, two to four more sutures are placed between each of the quadrant sutures (Figure 20-15B). All sutures are placed 3 to 4 mm apart and 2 to 3 mm from the wound edge. Suture bites on the dilated side of the anastomosis are placed farther apart than on the contracted side of the anastomosis to correct for luminal disparity. Once one side of the anastomosis is sutured, the bowel is flipped over, and the opposite side is completed. From 12 to 20 sutures are used to complete the anastomosis. After the anastomosis has been completed, it is checked for leakage by infusing saline under low pressure into the bowel lumen and massaging the fluid past the anastomosis. The anastomosis can also be checked by gently probing the spaces between sutures with mosquito hemostats for openings. The surgeon then closes the mesenteric defect with a simple continuous pattern, taking care not to include any mesenteric vessels within the suture line (Figure 20-15C).

Occasionally, the small-diameter loop of bowel cannot be enlarged enough to be anastomosed to the larger one. In this case, the large-diameter stoma is reduced by initially angling the cut at 45°. The anti-mesenteric portion of the incision is then apposed with simple interrupted sutures in side-to-side fashion until the remaining opening is an appropriate width to anastomose to the smaller-diameter loop of bowel (Figure 20-16).

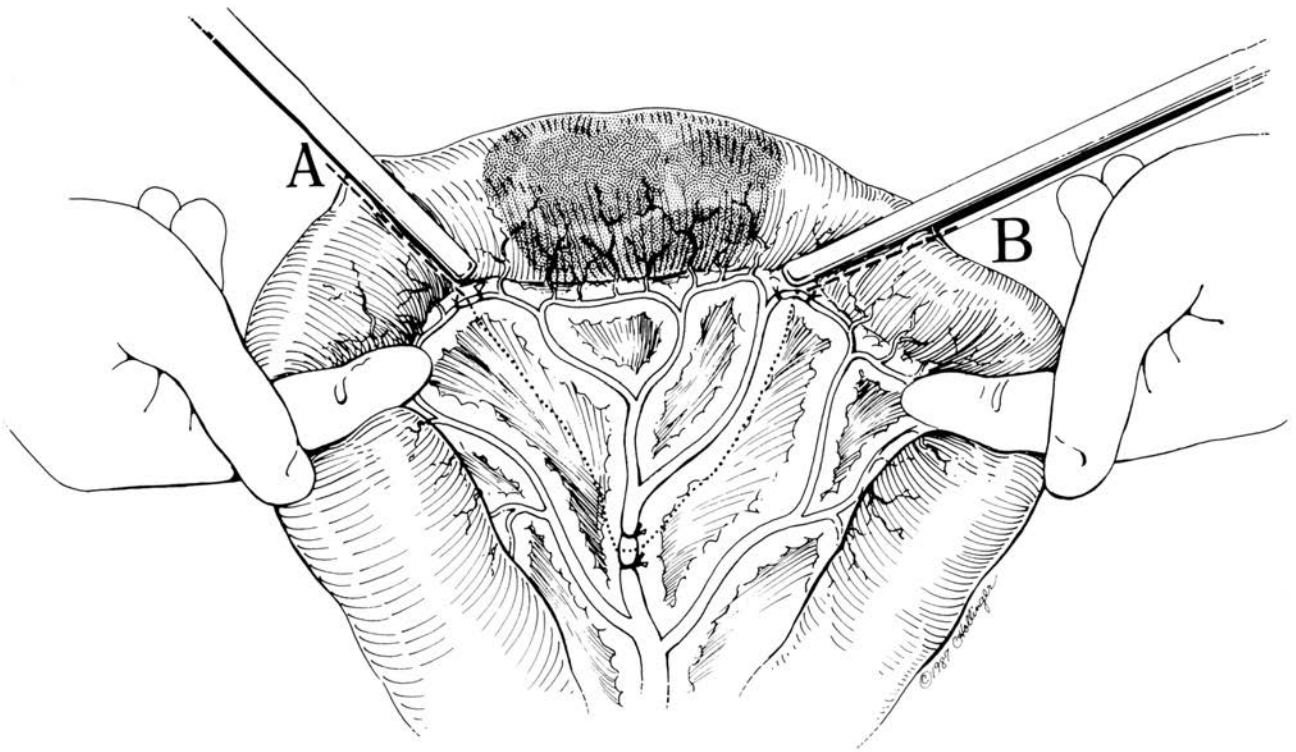

Figure 20-12. Proximal *A.* and distal *B.* forceps are placed at the area to be resected. Mesenteric and arcadial vessels are double-ligated as shown. The bowel is transected with a scalpel blade outside of the clamps (dashed lines), and the mesentery is incised with dissecting scissors (dotted lines). See text for details.

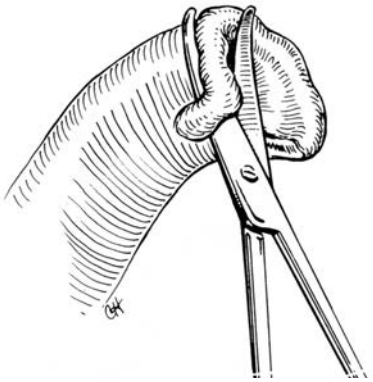

Figure 20-13. Everted mucosa can be trimmed back before the anastomosis is performed.

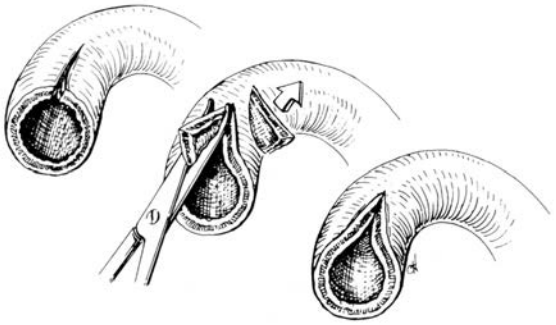

Figure 20-14. Enlargement of bowel section with a smaller diameter may be necessary prior to anastomosis. See text for details.

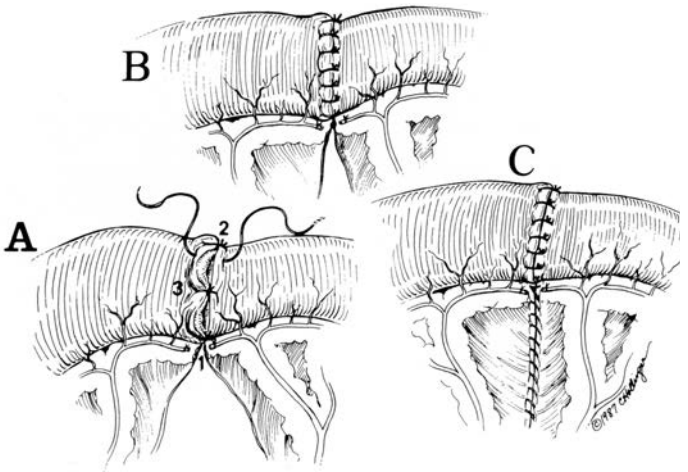

Figure 20-15. Closing anastomosis with simple interrupted suture pattern. **A.** Placement of first (1), second (2), and third (3) sutures; the fourth suture is placed on the lateral bowel wall opposite to the third suture. **B.** Additional sutures are placed between each of the original four. **C.** Final step is closure of the mesenteric defect with simple continuous sutures. See text for details.

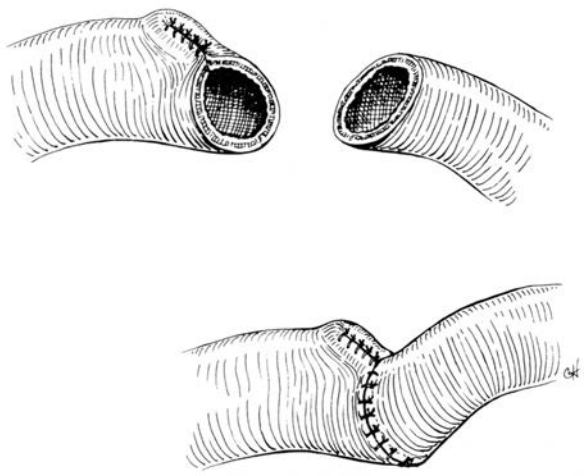

Figure 20-16. Lumen diameter of larger stoma can be reduced to equal that of smaller diameter (top), so anastomosis can be completed (bottom). See text for details.

Alternatively, a simple continuous approximating technique can be used to create the anastomosis. This is performed with two lengths of suture. The first knot is tied at the mesenteric border and the second at the antimesenteric border (Figure 20-17A). The sutures are then advanced around the perimeter approximately 3 mm from the cut edge, with the wound edges gently approximated. The needles are advanced in opposite directions, so one knot is tied to the tag at the antimesenteric border. The final knot is tied to the tag on the mesenteric border (Figure 20-17B and C). If the knot is tied too tightly, a pursestring effect will be produced, and stenosis of the anastomosis may occur. The completed anastomosis is tested for leakage, and the mesenteric defect is closed.

A rapid alterative to sutured anastomosis is the use of stainless steel skin staples. Three stay sutures are used to triangulate the bowel ends and an end-to-end anastomosis is performed with an AutoSuture 35 skin stapler with stainless skin staples (United States Surgical Corp., Norwalk, CT). After triangulating the intestine with three stay sutures, the skin stapler is used to place staples every 2-3 mm around the perimeter of the wound (Figure 20-18). These closures are more rapidly done than handsewn anastomosis and have similar bursting strengths, but some mucosal eversion is created.

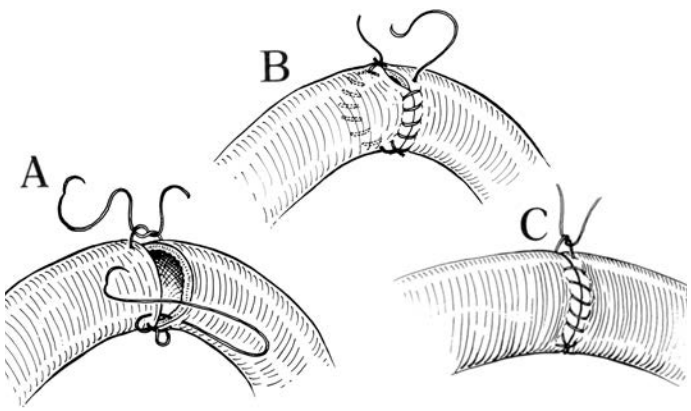

Figure 20-17. Intestinal anastomosis using the simple continuous approximating suture pattern. Two lengths of suture are used. **A.** The first knot is tied at the mesenteric border and the second at the antimesenteric border. **B.** The sutures are advanced in opposite directions around the perimeter of the bowel. **C.** Knots are tied to tags at the mesentery and antimesentery. See text for details.

Leakage of any intestinal anastomosis is most common in animals with pre-existing peritonitis, low serum albumin and in those animals where intestinal foreign bodies have created intestinal ischemia. To help prevent anastomotic leakage, a pedicle of greater omentum is wrapped around the suture line. The omentum is critical to the successful healing of intestinal wounds because it can seal small anastomotic leaks and can prevent peritonitis. Dogs with the greater omentum removed have significant morbidity and mortality associated with intestinal anastomosis, whereas most dogs survive and do well when the omentum is retained. The omentum is tacked to the serosa with two simple interrupted sutures of 3-0 suture material placed on each side of the bowel wall (Figure 20-19).

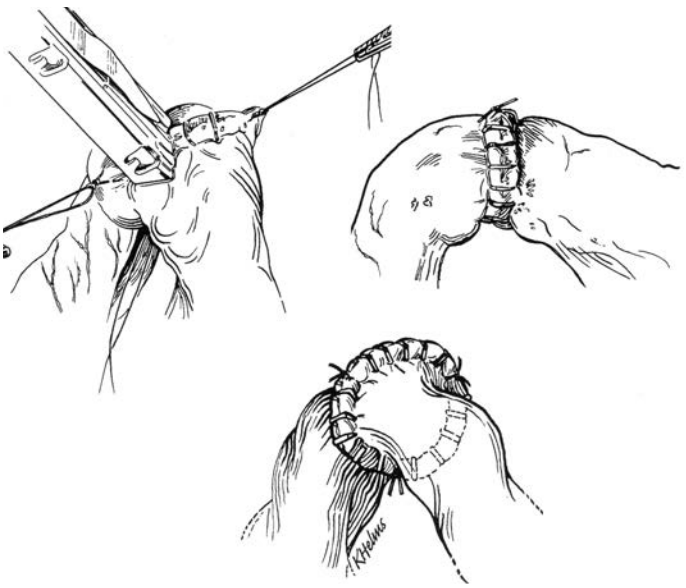

Figure 20-18. Anastomosis can be fashioned using skin staplers by first triangulating the wound ends and then applying staples every 3 mm around the perimeter of the anastomosis. (From Coolman BR, Ehrhart N, Pijanowski G, et al. Comparison of skin staples with sutures for anastomosis of the small intestine of dogs. Vet Surg 29:293, 2000, with permission).

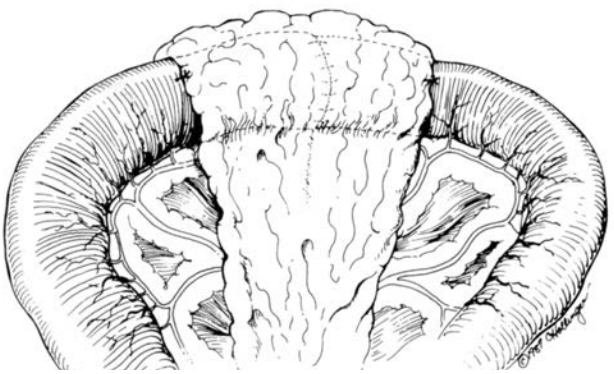

Figure 20-19. To help prevent leakage a pedicle of greater omentum is wrapped around all enterotomies and anastomoses and is tacked to the serosa on both sides with simple interrupted sutures.

Postoperative Care

Fluid and electrolyte deficits are corrected and antibiotic therapy is continued in the postoperative period. The author uses metoclopramide 2.2 mg/kg IV every eight hours to reduce ileus and promote intestinal motility. Feeding a bland diet such as canned I/D gruel (Hills Pet Nutrition Inc., Topeka, KS) is initiated the day following surgery. In uncomplicated cases, reasonable appetite usually resumes within 48 hours. Anorexia or vomiting in the presence of fever, abdominal tenderness, and leukocytosis suggests that anastomotic leakage and peritonitis may have occurred. If degenerate neutrophils with engulfed bacteria or free peritoneal bacteria are present on abdominocentesis, early reexploration of the abdomen is warranted. Further resection and reanastomosis or use of one of the serosal patching techniques described later in this section may be required. Aggressive treatment of generalized peritonitis may be needed to salvage the patient.

Managing Animals with Massive Resection

The propensity for short-bowel syndrome after massive intestinal resection depends on the amount of tissue excised, the location of the resection, and the time allowed for adaptation. Resection of up to 80% of the small intestine in puppies may allow for normal weight gain, whereas resection of 90% produces morbidity and mortality. After resection of large portions of small intestine, maldigestion, malabsorption, diarrhea induced by fatty acids or bile salts, bacterial overgrowth, and gastric hypersecretion may occur. Location of the resection is important. High resection of the duodenum and upper jejunum may decrease pancreatic enzyme secretion because pancreatic-stimulating hormones such as secretin and cholecystokinin are produced in the mucosa of these sections. These reductions in release of pancreatic enzymes contribute to maldigestion. Maldigestion of protein, carbohydrate, and fat leads lo catabolism, negative nitrogen balance, and steatorrhea. Unabsorbed sugars also may cause osmotic diarrhea. If the ileocecal valve is resected, bacteria may ascend, overgrow in the small bowel, and contribute to diarrhea.

After massive resection, the remaining small intestine adapts by increasing lumen diameter, enlarging microvilli size, and increasing mucosal cell number. These compensatory changes may take several weeks; during this period, parenteral fluids, electrolytes, and hyperalimentation may be necessary for the survival of the animal. During this time, the animal ideally will be able to maintain weight even with diarrhea. Medical treatments for unresponsive diarrhea after massive resection include frequent small meals, low-fat diets such as intestinal diet (I/D Hills, Topeka, KS) elemental diet supplements, medium-chain triglyceride oils, pancreatic enzyme supplements, B vitamins, kaolin antidiarrheals, and poorly absorbed oral antibiotics such as neomycin.

Subtotal Colectomy in the Cat and Dog

Ronald M. Bright

Introduction

Megacolon is defined as distension of the large intestine that is usually associated with various degrees of colonic hypomotility. In the cat and dog, this is usually an acquired disorder related to mechanical obstruction of the rectum or colon due to a foreign body, dietary indiscretion, neoplasia (intraluminal/extraluminal), and malformation and stenosis of the pelvis secondary to a healed pelvic fracture. Neurological deficits associated with lumbosacral disease or dysautonomia, a progressive polyneuropathy of the autonomic nervous system of older cats, can also lead to megacolon. Manx cats with partial or complete absence of the sacral and caudal spinal cord may have megacolon with concurrent urinary or fecal incontinence. In cats, megacolon is considered an idiopathic disorder in the majority of cases. Megacolon usually results in impaction of feces resulting in constipation or obstipation.

Dogs and cats can have constipation for several days without clinical signs. If obstruction of the movement of feces is delayed, the stool becomes harder and can form concretions. This

retention of feces, if chronic or prolonged, can result in severe distention of the colon and motility disorders. It can also result in various degrees of mucosal injury that may result in absorption of bacterial toxins contributing to more severe clinical signs. The duration of obstruction that leads to more severe mucosal changes is unknown. One study in cats suggests that if colonic distension is present for 6 months or longer as may be seen with pelvic stenosis secondary to pelvic fractures, degenerative intramural myoneural changes in the colon may not allow return to normal function even if the cause of obstruction is relieved.

When constipation progresses to obstipation, excessively hard feces will prevent defecation. Digital removal of the impaction is usually necessary in these cases. When the condition progresses to obstipation, medical therapy becomes ineffective.

History and Clinical Signs

Regardless of the cause of the constipation, tenesmus with little or no production of feces is the most common complaint. It is not uncommon to have passage of mucus and/or blood associated with obstipation as a result of inflammation of the colonic mucosa. Historically, the owner may describe a possible etiology such as pelvic or lumbosacral trauma or dietary indiscretion.

Systemic signs depend on the duration of the obstipation and degree of injury to the colonic mucosa. These signs can include anorexia, weight loss, lethargy, dehydration, vomiting, and liquid bloody feces. Some cats will eventually become unthrifty and have perineal soiling. Hard concretions within an enlarged colon will often be palpated and some discomfort may be noted. Rectal palpation is done to evaluate for any pelvic canal stenosis, the presence of a perineal hernia, and any intraluminal or extraluminal masses that can result in a mechanical obstruction. In the dog, prostatomegaly or severe lymphadenomegaly of the iliac/sublumbar lymph nodes associated with neoplasia should be considered and carefully evaluated.

Diagnosis

Tenesmus and decreased fecal production should prompt the clinician to consider constipation/obstipation secondary to megacolon. Abdominal and pelvic radiographs will help confirm megacolon and may identify pelvic abnormalities or lumbosacral disease, or other abdominal masses that may be causing colonic or rectal obstruction.

Careful palpation of the abdomen should be performed after feces has been evacuated. Ultrasound examination or colonoscopy can be used to rule out other disease processes such as neoplasia or stricture, especially if there are palpable abnormalites.

Barium enema contrast studies of the rectum and colon may be valuable and can be performed especially in dogs after evacuation of the feces.

Conservative Treatment

Medical management is indicated prior to any surgical intervention. Warm water enemas followed by laxatives and dietary supplements (canned pumpkin) may be helpful. Cisapride, has been used successfully to stimulate colonic motility (0.25 mg/kg or 2.5 mg every 8-12 hours for smaller cats and 5 to 10 mg every 8 to 12 hours in larger cats and dogs). This dose can be safely doubled if lower doses are not effective. Cisapride is no longer commercially available but some pharmacies are able to compound this drug on request. I prefer to use cisapride and lactulose (Lactulose generic, Apotex) concurrently to optimize the effect of keeping the colon evacuated. Some cats aggressively treated in this manner may never require surgical intervention. Other cats, however become less responsive to medical management over time and require surgery.

Surgical Treatment

A subtotal colectomy was once considered a "salvage" procedure. However, a long-term history of success with this technique makes it a very good alternative to medical therapy. Surgery is most often performed in those patients who fail to respond to aggressive medical therapy. However, I have had several owners that opt for surgery on their cat because of their unwillingness or inability to be involved in medical management, which becomes cumbersome or causes behavior problems with the cat. Another group of owners eventually select a surgical option because of the emotional cost that is associated with restraining their cat and giving the appropriate medications.

In cats, a bilateral perineal hernia may be seen concurrently with megacolon. In these cases, performing a subtotal colectomy is usually sufficient to relieve the signs. If not, a bilateral herniorrhaphy may be necessary at a later time.

The standard of surgical treatment for megacolon in the cat is a subtotal colectomy that involves removal of approximately 95% of the colon. I prefer preservation of the ileocolic valve (ICV) in most cats and in all dogs, although numerous reports cite good results when the ICV is removed in cats. I do not remove the ICV except in those cats where a colocolostomy will result in too much tension across the anastomosis.

Before an animal has colectomy performed, it should be carefully evaluated for concurrent problems that may detract from a successful outcome. Loss of anal sphincter tone that is not diagnosed prior to a subtotal colectomy will usually result in an unsatisfactory outcome. Rectal stricture or neoplasia should be ruled out by performing a digital rectal examination prior to surgery.

If the megacolon is the result of an acquired pelvic stenosis that is the result of pelvic fracture malunion and it is less than 6 months from the time of injury, a hemipelvectomy or corrective osteotomy can be tried. The technical demands of the orthopedic procedures make the subtotal colectomy a more viable option.

Enemas should not be administered within 48 hours of surgery to decrease the risk of contamination from liquid intestinal contents at the time of surgery. Applying aseptic surgical principles to colonic surgery, carefully isolating segments of bowel with saline-soaked laparotomy sponges or towels, and employing meticulous and gentle handling of tissues will help ensure success. Perioperative use of an appropriate antimi-

crobial drug is indicated because the surgery results in a "clean contaminated" or "contaminated" wound. A broad-spectrum antibiotic such as a second-generation cephalosporin such as cefoxitin (Mefoxin, Merck and Co.) is preferred because of its effectiveness against most anaerobes as well as the usual gram-negative aerobes. It is preferable to give the drug preoperatively intravenously. Administering the drug 20 to 30 minutes prior to surgery at a dose of 20 mg/kg will result in optimum blood levels of the drug at the operative site. This is repeated 2 to 3 hours later.

Subtotal colectomy is performed through a ventral midline abdominal incision extending from the umbilicus to the pubis. The appropriate colic and caudal mesenteric vessels are ligated and divided. (Figure 20-20) If the ICV is resected, then additional ligatures are necessary for the ileocecocolic artery and vein. I do not find it necessary to ligate the cranial rectal vessels.

In order to optimize exposure of the colon and the planned site of anastomosis, it is helpful to exteriorize the small bowel from the abdomen to the right of the abdominal incision. Moistened laparotomy pads are placed to protect and moisten the small intesine. The urinary bladder is emptied manually or by cystocentesis to ease isolation from the surgical site. Fecal material is massaged toward the middle of the segment of the colon to be removed away from the site of intestinal transection. The colon or ileum is transected proximally and again distally 1-2 cm rostral to the pubis. Straight intestinal clamps (Doyen) are used to hold the segments of the bowel together during the anastomosis. I prefer to perform a single layer anastomosis using simple interrupted appositional sutures of 4/0 polydioxanone or polypropylene (Prolene and PDS, Ethicon, Inc., Somerville, NJ). Some cats have concurrent inflammatory bowel disease and a biopsy of the small bowel may be indicated.

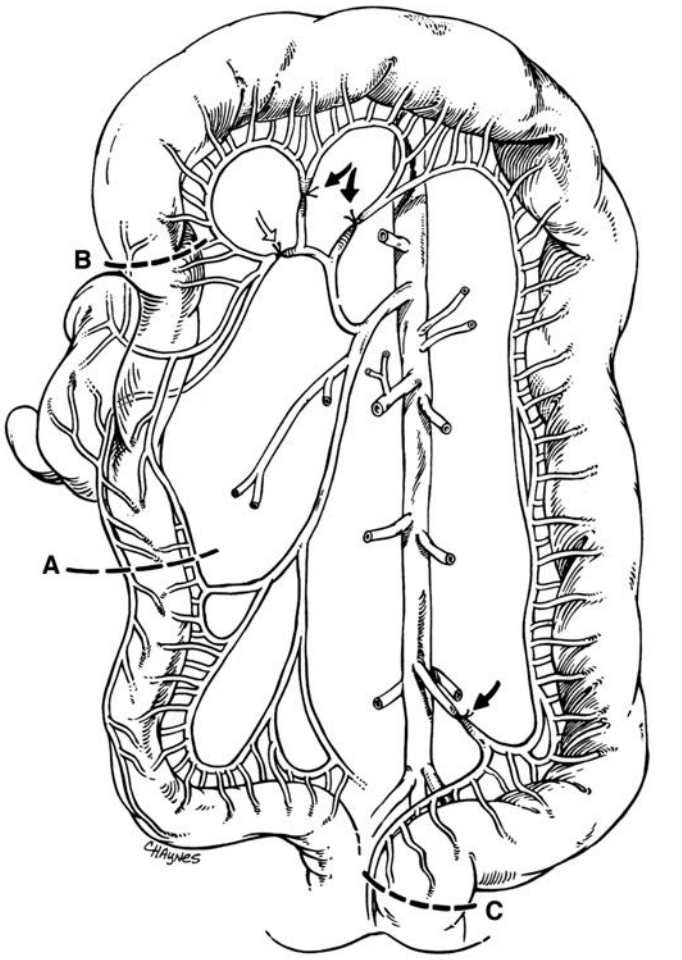

Figure 20-20. The appropriate colic and caudal mesenteric vessels (arrows) are ligated before division of the colon. If the ileocolic valve is removed, the ileocecocolic vessels (open arrow) need to be ligated as well. With the ileocolic valve preserved (my preference), a small length (I to 2 cm) of ascending colon remains after transecting the bowel *A.* Likewise, when transecting the distal colon *B.* a small remnant of colon or cranial rectum is left to anastomose to the proximal segment.

When preserving the ICV, a 2-3 cm segment of the proximal colon is preserved and anastomosed to the 1 to 2 cm segment of remaining distal colon just ahead of the pubic bone (Figure 20-21). Holding these segments together during the suturing process requires intestinal forceps. If there is lumen disparity between the two segments as when the ICV is resected, then the smaller lumen (ileum) can be spatulated to increase its circumference to match that of the opposite larger colonic segment (See Figure 20-14). Alternatively, the larger lumen segment can be oversewn until it matches the diameter of the smaller segment and the anastomosis is completed with a simple interrupted approximating suture pattern using 3 or 4-0 suture size (Figure 20-22). Following the anastomosis, an attempt is made to remove any remaining feces from the rectum by massaging the material distally followed by digital removal through the anus at the conclusion of surgery.

In lieu of the standard suturing technique for the anastomosis, a surgical stapler may be used with the placement via the rectum or transcecally (EEA stapler, U S Surgical). Recently a single-use biofragmentable anastomosis ring, BAR, (Valtrac, US Surgical) has been described and compared to conventional suture technique for restoration of bowel continuity. The BAR is a sutureless inverting anastomosis technique that has compared favorably with standard anastomosis techniques.

Following subtotal colectomy, tenesmus and/or hematochezia may be observed. This usually resolves within 7-10 days. A soft stool will be present indefinitely following this surgery and it appears that the return to a somewhat normal consistency occurs sooner when the ICV is preserved. Frequency of defecation usually increases and rarely is anastomotic stricture a problem postoperatively. Balloon dilation and the use of laxatives have been successful in treating stricture when it has occurred.

Most cats are greatly improved following a subtotal colectomy with normal bowel function. The need for medical management is unlikely. Some cats may continue to have bloody diarrhea and various degrees of discomfort when defecating. This may be related to a stricture at the site of anastomois or inflammatory bowel disease. Endoscopy and biopsy are required to confirm the etiology. Medical therapy is usually successful in improving signs related to inflammatory bowel disease and balloon dilatation and laxatives are usually successful in reversing signs related to stricture.

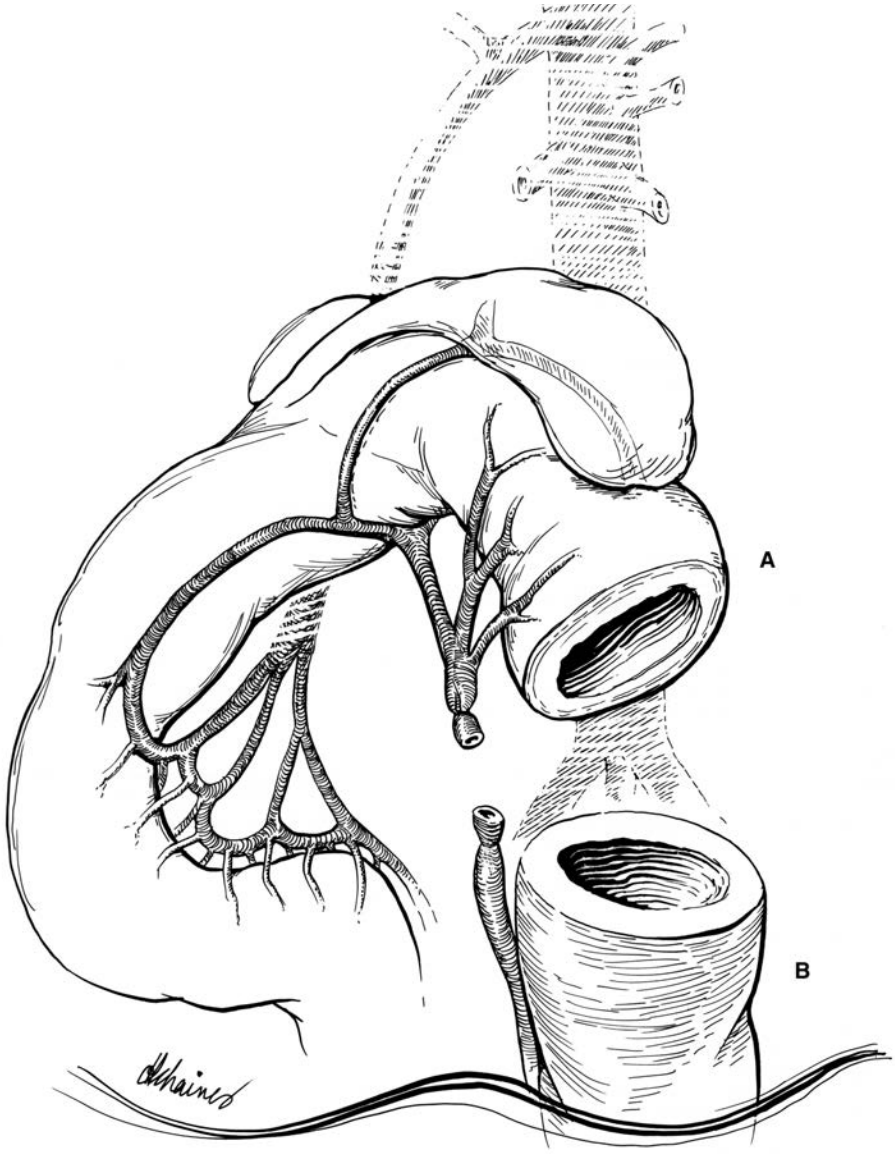

Figure 20-21. The mesenteric sides of the proximal *A.* and distal *B.* bowel segments are aligned before proceeding with the anastomosis.

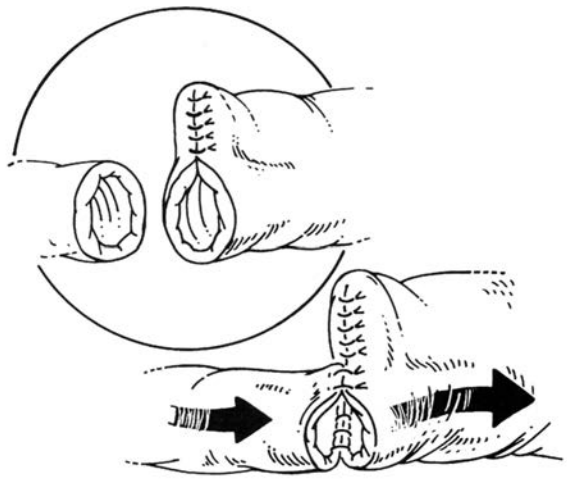

Figure 20-22. When lumen disparity exists between the two segments to be anastomosed, the larger lumen can be sutured closed until the remaining lumen approximates the size of the opposite segment.

I and others have used subtotal colectomy in dogs successfully. The most common indication is for pelvic malformation. Dietary discretion has also been the cause of megacolon in one dog. The prognosis is good in dogs but it appears that preservation of the ICV is much more important in the dog. Their ability to adapt to the absence of the colon and the ICV seems inferior to the cat.

Surgery of the Colon and Rectum

Brian T. Huss

This topic is written based on the available literature through 2010 and does not cover the most current literature on this topic.

Introduction

Colorectal surgery in small animals can be performed with the same surgical success rates as other gastrointestinal surgery with the use of careful tissue handling techniques and modern surgical materials.

The large intestine of the dog and cat is shorter than the small intestine, ranging from approximately 20 to 35 cm in length.[1,2] As a general rule, the large intestine is approximately the length of the trunk in dogs and cats, with the small intestine measuring about four times the length of the trunk. Because of its shorter mesentery, the large intestine does not vary as much in length or position as the small intestine. The large intestine is, however, considerably larger in internal diameter than the small intestine, and has neither the tenia (longitudinal bands) nor haustra (sacculations) seen in other species. Classically, the large intestine has been divided into the cecum, colon (ascending, transverse, and descending), and rectum (Figure 20-23).

Microscopically, the colon is composed of five layers. From the inner luminal surface outward the layers of the colon are 1) mucosa, 2) submucosa, 3) circular muscle layer, 4) longitudinal muscle layer, and 5) serosa. The mucosa consists of columnar epithelial lining cells, mucus secreting goblet cells, and enteroendocrine cells. Intestinal villi are absent in the colonic mucosa; however, intestinal crypts (crypts of Lieberk¸hn) remain. Intestinal crypts are elongated and straight, opening onto the luminal surface of the colon. The submucosa is composed of collagen and elastin fibers arranged in an orderly honeycomb pattern, with submucosal glands and lymphoid tissue dispersed throughout this layer. The submucosa's high collagen and elastin content makes it the important suture holding layer of the intestine. Tunica muscularis is the term commonly given the combined smooth muscle layers of the intestine. Contraction of this group of muscles is responsible for intestinal motility. Finally, the tunica serosa consists of loose connective tissue covered with a layer of squamous mesothelial cells.

The large intestine is anchored to the sublumbar region by the mesocolon, which arises from the left side of the mesentery and is divided into the same parts as the colon that it suspends. The blood supply to the colon and rectum arises from the cranial and caudal mesenteric arteries supported in the mesocolon (See Figure 20-23). The cranial mesenteric artery supplies the cecum, ascending, transverse, and part of the descending colon. The caudal mesenteric artery supplies the remainder of the descending colon as well as the rectum.[1-4] Numerous perpendicular branches (vasa recta) split from the colic arteries, anastomosing with each other along the lesser curvature of the colon. Most of the large intestine is drained by the portal system through the ileocolic and caudal mesenteric veins.[1-4] The caudal rectal vein drains the anal canal and empties directly into the caudal vena cava.[1-4]

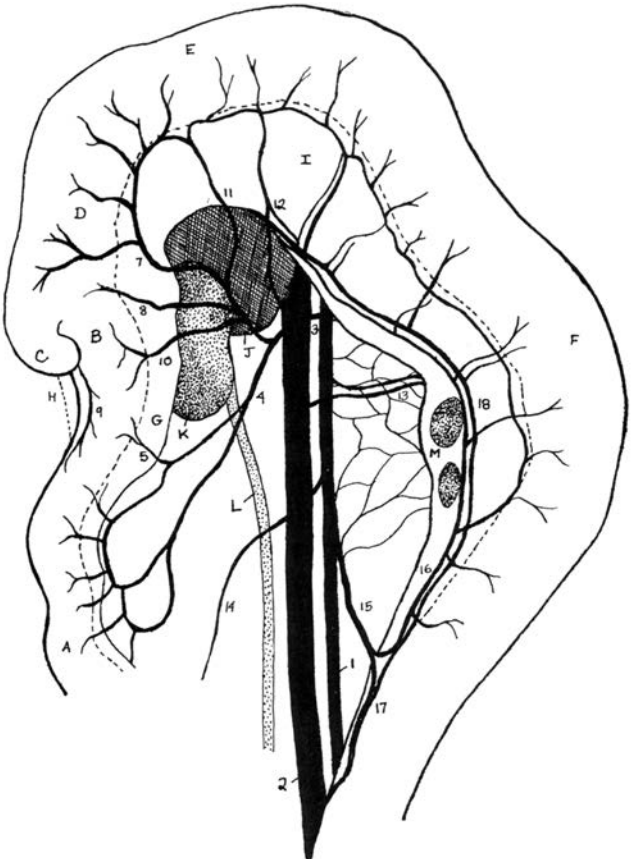

Figure 20-23. Surgical anatomy of the feline large intestine, ventral view. Indications for Surgery

The need for colonic surgery in small animals is not as common as the need for small intestinal surgery. Colonic surgery techniques involve primary closure of traumatic defects, resection and anastomosis, biopsies, and rarely, foreign body removal.

Trauma to the colon can result from intraluminal or extraluminal sources. Intraluminal causes of injury are rare, but such injury

can result from ingested sharp foreign bodies or improper use of transanal instruments. Colonic foreign bodies can often be gently milked through the colon to a point at which they can be grasped by an assistant using a transanal forceps. Rarely, a colotomy must be performed to retrieve a foreign body. Extraluminal sources of trauma are more common and include gunshot and knife wounds, and less commonly, penetrating bone fragments from pelvic fractures. Indirect or blunt trauma to the colon can also result in contusions, vessel thrombosis, colonic torsion, or even avulsions of the colon. Penetrating wounds of the colon require immediate treatment. Primary repair of clean lacerations, debridement and primary closure of more severe wounds, or resection and anastomosis of devitalized segments may be required to close colonic defects. In one study of dogs with rectal tears resulting from pelvic fractures, only dogs with tears repaired within 24 hours of trauma survived.[5]

Neoplasia of the colon is less common than in other parts of the alimentary system. Benign tumors of the colon commonly include leiomyomas, papillary adenomas, and adenomatous polyps. Malignant transformation of adenomatous polyps has been reported to occur in 18% of dogs in one study.[6] Malignant tumors of the colon commonly include lymphosarcomas, carcinomas, and adenocarcinomas. Metastasis of colonic tumors occurs most commonly to the regional lymph nodes and the liver. Intussusception of the large intestine occurs most commonly at the ileocecocolic junction. Intussusception of the body of the colon is rare. Intussusceptions of the large intestine are treated in the same manor as those occurring in the small intestine.

Colectomy, either partial or complete, may be the treatment of choice for patients with unresponsive megacolon, severe unresponsive inflammatory bowel disease, colonic ulcerations, colonic strictures, colonic torsion, and pelvic canal stenosis resulting from pelvic fracture malunion. Removal of the cecocolic valve has been advocated in the case of megacolon caused by pelvic fracture malunion, to create a soft stool. Most surgeons, however, recommend leaving the cecocolic valve in the treatment of other colonic diseases.

Surgical biopsy of the colon may be the diagnostic method of choice in some colonic diseases. Direct visualization of the entire colon, the ability to safely obtain multiple full thickness samples of colonic wall and regional lymph nodes, and commonly available surgical instrumentation make open colonic biopsy a viable diagnostic method.

Diagnostic Methods

Diagnosis of colorectal disease is based upon physical exam findings and various imaging techniques. Colonic masses can often be palpated in the central to caudal aspect of the abdomen. Rectal masses can often be felt upon digital rectal examination. Survey abdominal and pelvic radiographs are recommended in all patients with suspected large intestinal disease. Radiographs can give indications of regional lymph node size, luminal contents, including the degree of colonic filling and overall density of the luminal contents. Radiographs can also help to diagnose intraluminal or extraluminal foreign bodies, or space occupying lesions, and they give a rough estimate of intestinal wall thickness, as well as, plication or intussusceptions of the intestine. However, abdominal ultrasound provides a better view of the intestinal wall and has become the imaging method of choice for diagnosing intussusceptions. Ultrasonography also allows more detailed imaging of intra-abdominal structures when peritonitis is present and for biopsy and staging of patients with neoplasia. Positive-contrast enemas may be helpful diagnostic tools in selected cases; however, they are contraindicated when perforations or weakened intestinal walls are suspected.

Other diagnostic methods that may be of benefit in large intestinal diseases are proctoscopy, computed tomography (CT) scans and magnetic resonance imaging (MRI). Proctoscopy should be performed with care if weakened intestinal walls are suspected and it is contraindicated when large intestinal perforations are suspected. Computed tomography scans and MRI are most useful when staging patients with cancer to determine the extent and spread of disease.

Microscopic analysis of peritoneal fluid can provide a definitive diagnosis in the case of intestinal perforation. Fluid can be obtained via abdominal paracentesis or, ideally, by peritoneal lavage. A large number of neutrophils with intracellular bacteria are diagnostic of bacterial peritonitis. Less definitive are fluid samples with large numbers of degenerative neutrophils, free abdominal bacteria, or debris which would normally be found intraluminally. Inadvertent sampling of the intestinal lumen could account for these findings. A peritoneal lavage is recommended to confirm equivocal results.

Preoperative Preparation

Bacterial populations in the normal gastrointestinal tract increase dramatically from oral to aboral, changing from predominately aerobic to predominately anaerobic. A gram of feces from the colon contains up to 10^{11} organisms.[7] Aerobic bacteria in the large intestine normally include the Gram-positive genera *Streptococcus, Staphylococcus, Bacillus,* and *Corynebacterium* and Gram-negative members of the enterobacter family, especially *Escherichia coli, Enterobacter, Klebsiella, Pseudomonas, Neisseria,* and *Moraxella*.[7] Up to 90% of the bacteria in the large intestine are anaerobes, including members of the Gram-positive genera *Clostridium, Lactobacillus, Propionibacterium,* and *Bifidobacterium*; the Gram-negative anaerobic bacteria include *Bacteroides, Fusobacterium* and *Veillonella*.[7] The importance of anaerobic bacteria as pathogens in small animals, especially Bacteroides fragilis, has been demonstrated.[8,9]

Mechanical cleansing of the bowel when possible, decreases the risk of intraoperative bacterial contamination by decreasing the quantity of feces in the intestine while the lumen is opened. Mechanical cleansing, however, does not decrease the concentration of bacteria per gram of feces, only the quantity of feces present. The current veterinary regimen of choice for mechanical bowel cleansing is the technique used for colonoscopy preparation.[10,11] The lavage solutions Colyte (Reed & Carnick, Piscataway, NJ) or GoLytely (Braintree Labs, Inc, Braintree, MA) at 80 mg/kg are administered orally in two divided doses four

to six hours apart 18 to 24 hours prior to the procedure. These lavage solutions produce an osmotic diarrhea which cleanses the entire gastrointestinal tract. Potential problems with using mechanical cleansing are poor cleansing of the proximal colon when using enemas only, and watery intestinal contents which are more difficult to control once the intestinal tract is open. One human study comparing mechanical preparation alone prior to colorectal surgery demonstrated an over-all postoperative infection rate of up to 45% compared to mechanical preparation with some form of antibiotic solution at 18%.[12] To reduce infection rates to an acceptable level after colorectal surgery, some form of antibiotic prophylaxis is also recommended in human colorectal surgery.

Oral antibiotics used for prophylaxis in colorectal surgery are generally those that are poorly absorbed from the intestinal lumen. The purpose of oral antibiotics is to lower the concentration of bacteria within the intestine. To be effective, oral antibiotics should be active against the organisms most commonly found in the large intestine. Most oral antibiotic regimens include an aminoglycoside, such as neomycin or kanamycin, in combination with an antibiotic effective against anaerobic bacteria, like metronidazole, erythromycin, tetracycline, lincomycin, or clindamycin.[7,12-16] Neomycin used alone has actually been incriminated in higher postoperative infection rates.[16] When combined with mechanical bowel cleansing, oral antibiotic prophylaxis reduces postoperative infection rates to 5% to 18% in human patients undergoing colorectal surgery.[12,14,15] Oral antibiotic regimens should not be administered earlier than 24 hours prior to surgery to prevent possible resistant bacterial overgrowth.

Systemic antibiotics have been used alone or in combination with mechanical or oral antibiotic bowel preparation for surgical prophylaxis.[13,15-17] The rationale for systemic antibiotic prophylaxis is to obtain blood and tissue levels of antibiotic higher than the minimum inhibitory concentration of potential pathogens at the time of maximum tissue contamination. In cases of emergency gastrointestinal surgery, systemic antibiotics are the only feasible method of preoperative prophylaxis.

General recommendations for systemic antibiotic prophylaxis in colorectal surgery include using a drug, or drugs, that are effective against both the aerobic and the anaerobic bacteria found in the large intestine, and that can be administered by a bolus intravenous injection which can rapidly achieve peak serum levels. Bacteriocidal antibiotics with the most narrow effective spectrum, least cost, least toxic side effects, and easiest administration regimen should be used. Drugs should be given preoperatively to obtain effective target-tissue concentrations at the time of potential primary bacterial lodgement; generally they are administered approximately thirty minutes prior to the start of surgery. The pharmacokinetics of the drug should allow it to obtain effective levels against the expected pathogens in the target tissue. Antibiotics should be re-dosed approximately every two half-lives during surgery to maintain effective tissue levels. Finally, prophylactic antibiotics should be discontinued after surgery, with 24 hours being the maximum accepted duration. Continued postoperative antibiotic administration, or administering systemic antibiotics for extended periods prior to surgery, can result in bacterial antibiotic resistance and superinfections.

Systemic antibiotic prophylaxis for colorectal surgery can be broken into combination therapy regimens and monotherapy regimens. The most commonly used combination antibiotic regimens for human colorectal surgery are aminoglycosides, such as gentamicin, kanamycin, amikacin, or tobramycin along with lincomycin, clindamycin, or metronidazole.[14,18] Effective monotherapy drugs used for antimicrobial prophylaxis in colorectal surgery include cefoxitin, several third generation cephalosporins, and ampicillin/sulbactam.[8,14,19] Cefoxitin has been recommended by several authors as the systemic prophylactic antibiotic of choice for colorectal surgery in veterinary medicine.[20-22] The drug is a single agent intravenous antibiotic that has a low toxicity, is relatively inexpensive, and has good bacteriocidal effects against the primary bacterial pathogens. Cefoxitin dosage recommendations in small animals range from 6 to 30 mg/kg IM or IV given every eight hours.[21,23] With a half-life of 41 to 59 minutes, cefoxitin should be redosed every 1.5 to 2 hours as a surgical prophylaxis.

The above protocols are predominately based upon research on human colorectal surgery. While controversial, the author only uses first generation cephalosporins as a single agent systemic antibiotic prophylaxes, with no local oral antibiotics or mechanical cleansing. The author has not noted any increase in morbidity or mortality in dogs and cats using this minimal bowel preparation.

Surgical Techniques

Approaches

The colon and rectum can be approached through a ventral midline celiotomy, through a partial or complete pubic (ischial-pubic) osteotomy, by a dorsal approach, by a lateral perineal approach, by prolapsing the distal rectal mucosa, or by a rectal pull-through (Figure 20-24).

A caudal ventral midline celiotomy from 2 to 3 cm cranial to the umbilicus extending to the pubic rim permits access to the entire colon and the colorectal junction. The patient should be clipped and aseptically prepared from midthorax to beyond the caudal edge of the pubis. Laterally, the skin preparation should extend slightly beyond the flank folds. The prepuce of male dogs should be flushed with a dilute chlorhexadine or betadine solution.

Exposure to the proximal and middle rectum can be made by extending the caudal midline celiotomy through a partial or complete pubic osteotomy, respectively. The skin incision is extended caudally over the pubis. For a partial pubic osteotomy, the aponeurosis of the gracilis and adductor muscles are incised on the midline and reflected laterally (Figure 20-25A).[24] The obturator nerve and vessels lie at the cranial lateral edge of each obturator foramina, and must be protected. Drill holes are made on each side of the osteotomies to facilitate later repair of the defect (Figure 20-25B) and to the drill holes. Guarding the soft tissue, the pubis is then cut on both sides with a sagittal saw,

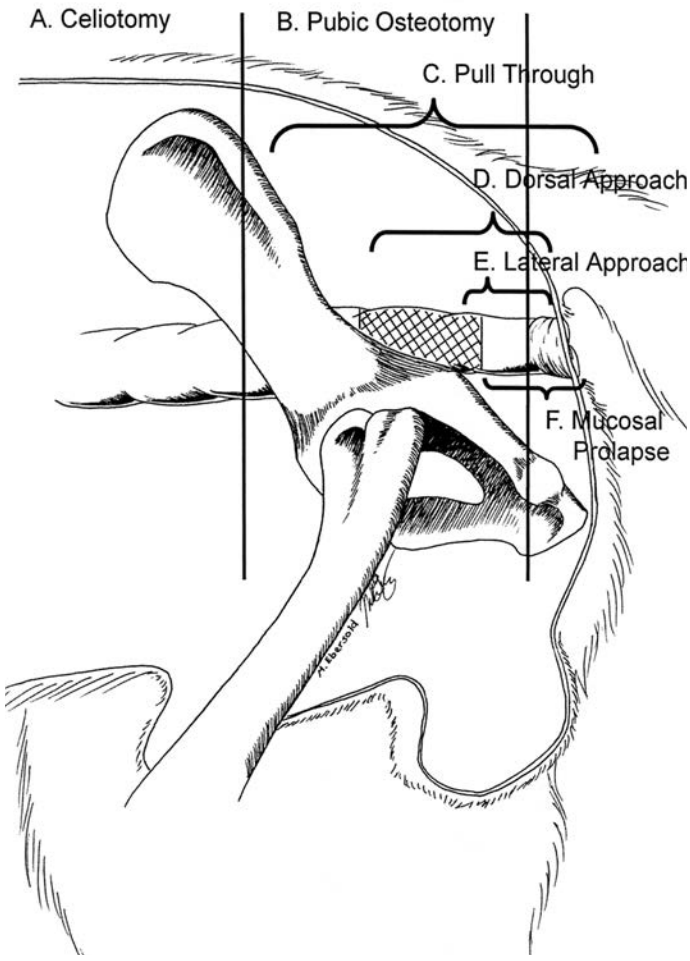

Figure 20-24. Approaches to the colon based on the area of interest (Cross hatched area is the middle 1/3 of the rectum). *A.* Celiotomy for any area of the colon to just cranial to the pubis. *B.* Pubic osteotomy for any area just cranial to and within the pelvic canal. This approach can be combined with a celiotomy. *C.* Rectal pull-through for any lesion caudal to the pelvic reflexion. This procedure will likely result in fecal incontinents. *D.* Dorsal approach for the middle 1/3 of the rectum to just cranial to the anus. *E.* Lateral approach for one side or the other of the distal middle 1/3 of the rectum to just cranial to the anus. *F.* Distal rectal mucosal prolapse for lesions of the distal 1/3 of the rectum and anus.

Gigli wire, osteotome, or bone cutter. The cut should be made 2 to 3 mm medial to the lateral edge of each obturator foramina. Leaving the periosteum and soft tissue attached caudally to the floor of the pelvis, a third osteotomy is made joining the caudal edges of the obturator foramina. The pubis is then hinged caudally as a caudally attached flap (Figure 20-25C). The flap is reattached with two orthopedic wires through the pre-drilled holes. Approach to the rectum through a complete pubic osteotomy is performed in a similar manor; however, the caudal osteotomies are made from the obturator foramina transversely through the caudal ischii.[25] The ischial-pubic flap is then hinged to one side (Figure 20-25D). Before the osteotomies, drill holes are made on each side of each osteotomy to facilitate repair of the flap. Drill holes craniaocaudally along one side of the pubic symphysis have been recommended to aid in reattachment of the muscle aponeuroses. A urinary catheter is used in male dogs to allow easy identification of the urethra so it can be protected.

The dorsal approach to the rectum is an easy one that allows good visualization of the middle and caudal rectum, but not the anal canal. The patient is placed in ventral recumbency with the pelvis elevated and the hindlimbs hanging over the back edge of the surgery table (Figure 20-26). The back edge of the table is padded to prevent pressure on the femoral nerves. The tail is fixed over the back with tape. A curvilinear incision is made dorsal to the anus from just above one ischiatic tuberosity to the other. The subcutaneous fat is dissected to the underlying muscles. The thick paired rectococcygeus muscles are identified dorsally, isolated, and transected (Figure 20-27). Depending on the amount of rectum that needs to be resected, circumferential dissection of the rectum can be performed. The levator ani muscles on either side of the rectum can be partially transected to the level of the caudal rectal nerves to aid in the rectal approach. The external anal sphincter can also be elevated caudally. Stay sutures are placed around the area of the rectum to be excised to keep tissue from retracting into the pelvic canal. Stay sutures can also be used to partially rotate the rectum and gain better exposure to the lateral and ventral surfaces. Full circumferential segments of rectum can be resected, or smaller masses, or lacerated tissue, can be resected with an elliptical incision in the rectum (Figure 20-28). The rectum is closed as previously described using sutures or staples. The transected muscle bellies and skin are closed routinely. Rarely, drains may be necessary in contaminated rectal lacerations, however, the drains should not touch the anastomosis as this may predispose the wound to dehiscence.

The lateral perineal approach is rarely indicated to expose one side or the other of the caudal portion of the rectum. The initial approach is identical to that used for repair of a perineal hernia. The rectum is approached by separating the external anal sphincter and the levator ani muscles.

Distal rectal masses that are small and noninvasive can be approached by prolapsing the caudal rectal tissue through the anus. This can be performed digitally or by placing a stay suture or allis tissue forceps oral to the mass (Figure 20-29). Stay sutures are used to retract the rectum while the affected tissue is resected. The rectum is closed in a single layer with a simple interrupted or a continuous suture pattern. The stay sutures are released to allow the rectum to retract into the pelvic canal.

Approaches to the middle and distal thirds of the rectum can be approached through various pull-through techniques. These techniques can involve prolapsing tissue, extensive tissue dissection, or a combination of the two.

Resection and Anastomosis

Resection and anastomosis of the colon are performed in a manner similar to that of the small intestine. After making an approach to the affected segment of colon, a complete exploration of the area is performed. To determine the extent of the disease process, regional lymph nodes and adjacent organs are carefully examined at surgery. Examination for unrelated, but potentially complicating disease processes should be performed during celiotomy approaches.

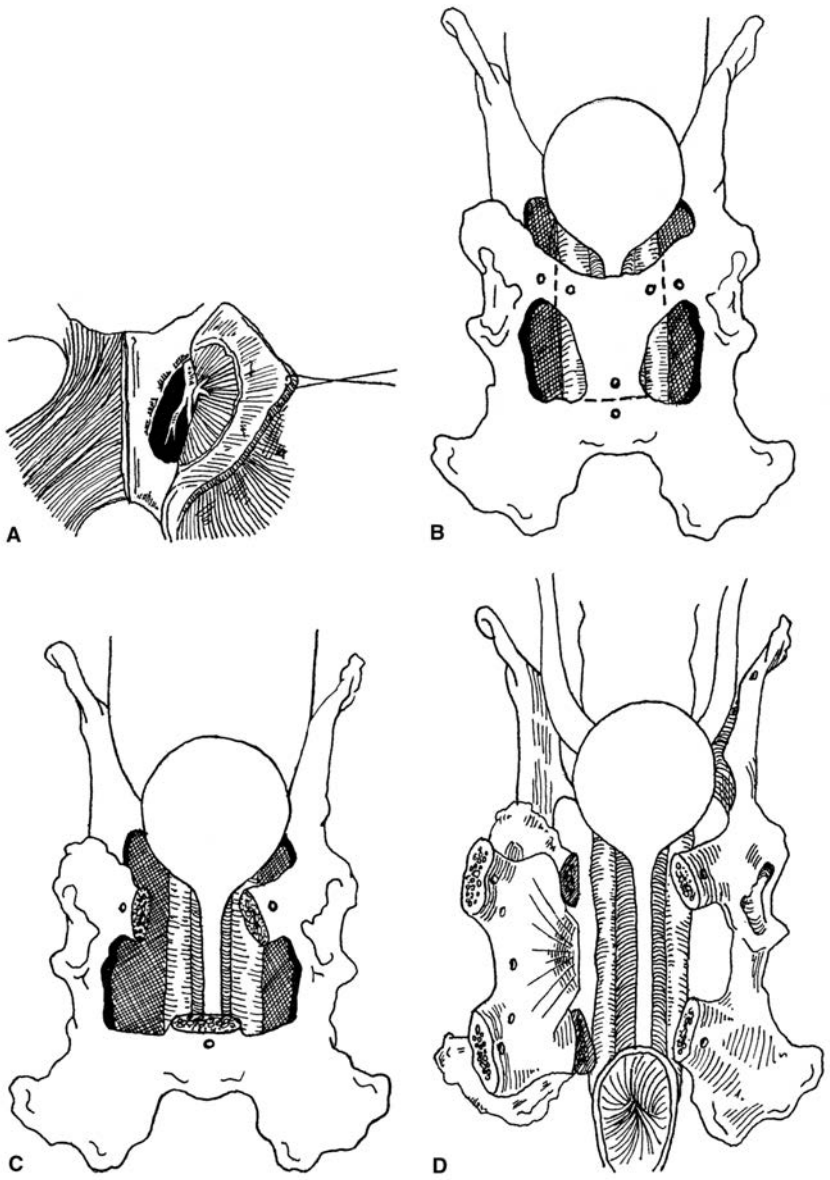

Figure 20-25. Approach to the colon and rectum through a pubic osteotomy. See text for details. **A.** The aponeurosis of the gracili and adductor muscles are incised on the midline and reflected laterally. Note the obturator nerve and vessels at the cranial lateral edge of the obturator foramina. **B.** Osteotomy sites and drill holes for a partial pubic osteotomy. **C.** After reflecting the pubic floor segment caudally, the rectum is visible under the urinary tract. **D.** Reflecting the pubic floor laterally after a complete osteotomy, the entire ventral rectum can be visualized.

The intestinal segment to be resected should be carefully isolated with laparotomy sponges moistened with warm isotonic saline (Figure 20-30A). The exposed tissue should be kept moist at all times to prevent desiccation and trauma. Two to three layers of laparotomy sponges or 4x4 sponges allows for removal of contaminated material with minimal chance for further contamination. Contaminated material should be removed from the sterile field as soon as possible to prevent further spread of contamination. An area for contaminated surgical instruments on the sterile field can be made with a dry lap sponge or drape. As soon as the instruments are no longer needed, they should be removed from the instrument table.

Once the affected colonic segment is isolated, the luminal contents should be milked from the areas that will be incised. The author prefers to remove the luminal contents with the resected intestinal segment or milk the contents aboral of the planned anastomosis site. The blood supply to the affected segment should then be double ligated using 3-0 to 4-0 suture material or ligation clips (Figure 20-30B). For short segments, only the vasa recta perpendicular to the colon need to be ligated, preserving the vessels running parallel to the colon. Resection of longer segments necessitates ligation of the main blood supply running parallel to the colon. Once the blood supply has been ligated, delineation between vascular and avascular segments of colon can be easily observed.

Carmalt forceps can be placed at the edges of the colonic segment to be resected. A minimum of 1 to 2 cm of healthy vascularized tissue should be included within the segment to be resected. Carmalt forceps can be placed perpendicularly across the colon, or they can be placed to back cut on the antimesen-

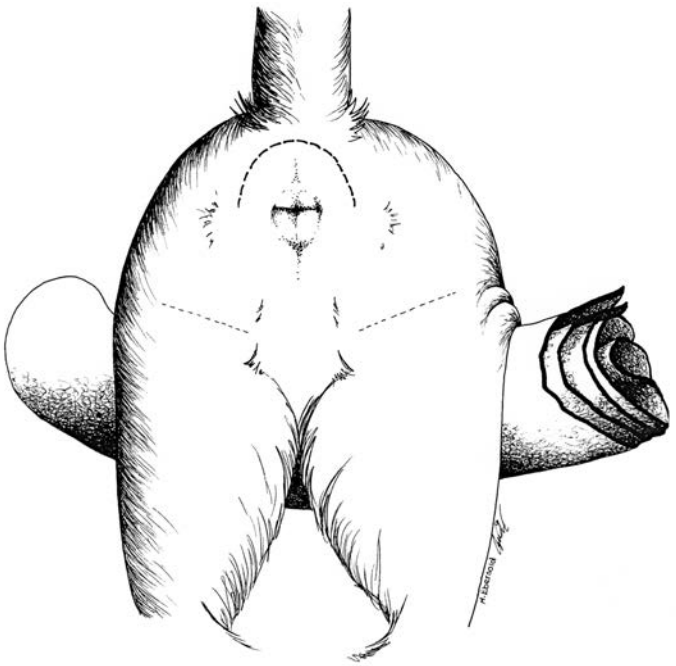

Figure 20-26. Patient positioning for a dorsal approach to the rectum (See text for details). The curved dotted line indicates the location of the incision.

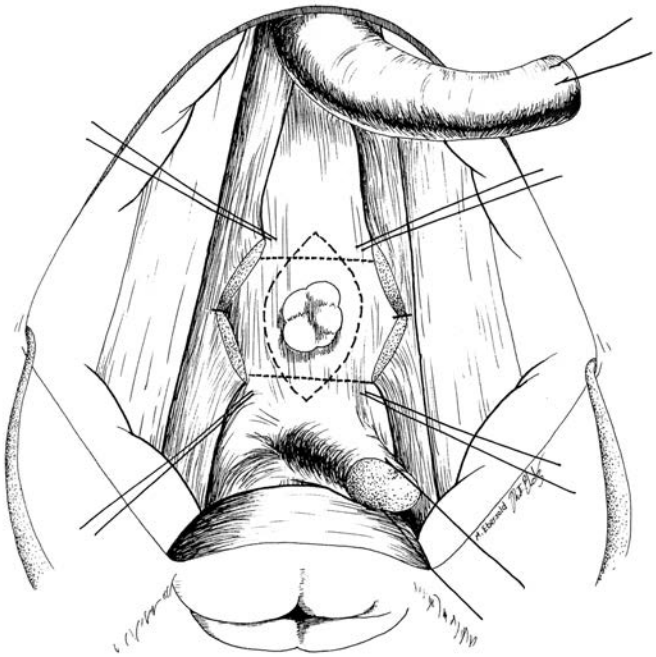

Figure 20-28. After cutting and retracting the rectococcygeus muscles the levator ani muscles on either side of the rectum can also be partially transected to expose the rectal lesion. The rectum can be resected with an elliptical incision or circumferentially as needed to remove the lesion (dotted lines). Make certain to use sufficient stay sutures in normal rectal tissue to keep the cut edges from retracting away from the surgery site.

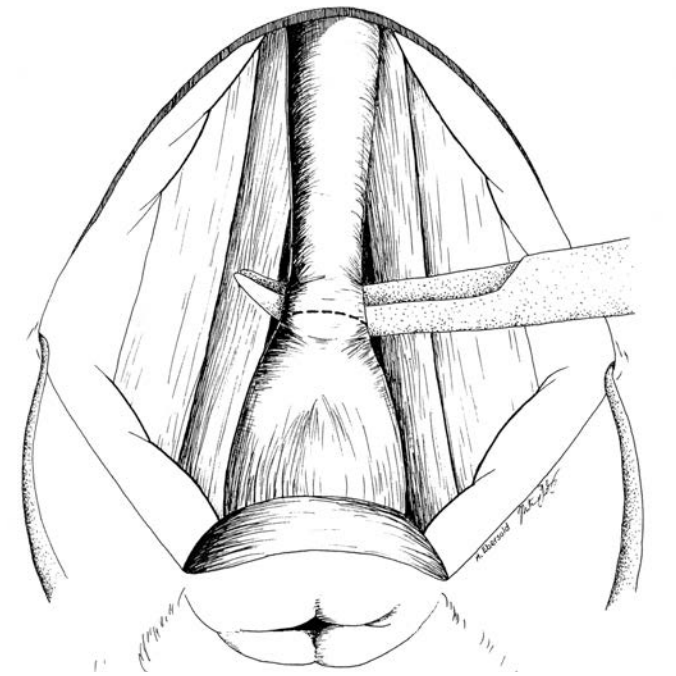

Figure 20-27. The taught thick paired rectococcygeus muscles (under forceps) are easily identified after the incision is made and subcutaneous fat is dissected. The muscles can be cut anywhere along the belly (dotted line) and distracted with stay sutures.

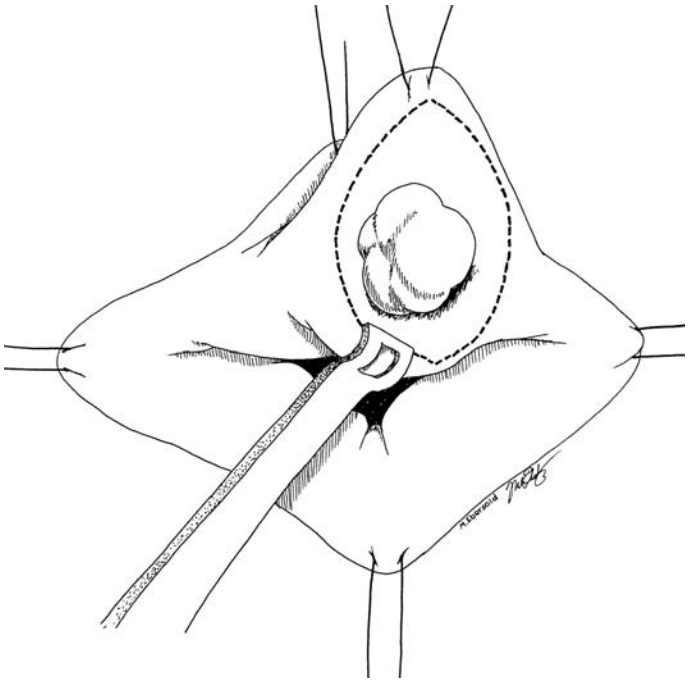

Figure 20-29. Prolapsing caudal rectal mucosa can be done by grasping the mucosa oral to the lesion with atraumatic forceps or stay sutures. Sufficient full thickness stay sutures in normal rectum should be placed to keep the cut edges well defined and prolapsed until the defect is closed.

teric side, creating a larger anastomotic diameter. Atraumatic clamps (Doyen forceps, vascular forceps, bobby pins, or an assistant's finger tips) are placed 4 to 5 cm to the outside of the Carmalt forceps. The atraumatic forceps keep luminal contents from leaking from the cut ends of the colon, as well as assisting in manipulation of the cut ends of the colon. Any remaining mesocolon is then resected as far from any vessels as possible. The affected colon segment can then be resected with a scalpel, using the outside edge of the Carmalt forceps as a guide. Colonic mucosa commonly everts over the cut edge of the intestine. It is easier to anastomose the colon if the mucosa is resected level to the cut edge of the outer colonic wall. This procedure is easily performed using Metzenbaum scissors. The colonic segments can then anastomosed using a variety of techniques listed below.

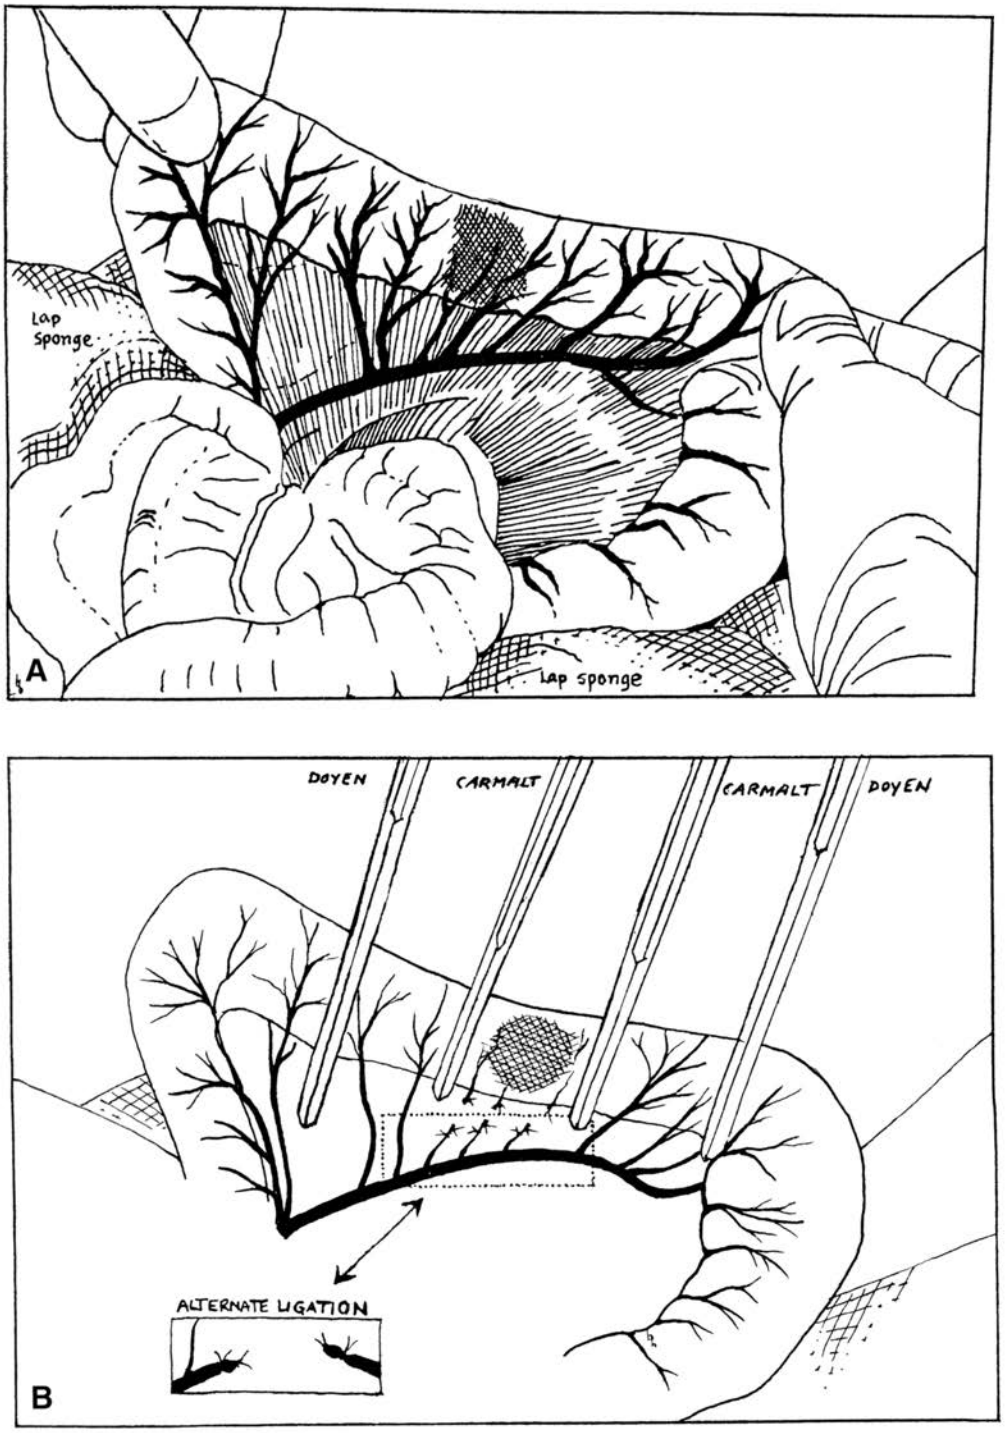

Figure 20-30. Preparation for colonic resection and anastomosis. **A.** Moistened laparotomy sponges are placed under the balfour retractor and wrapped around the base of the mesentery to isolate the affected colonic segment. **B.** The blood supply to the affected segment is double ligated. For short colonic segments, individual vasa recta should be ligated, preserving the longitudinal mesenteric vessels. For longer colonic segments, the longitudinal mesenteric vessels can be ligated. Carmalt forceps are placed oral and aboral to the segment of colon to be resected, making certain to include all of the avascular bowel. Atraumatic forceps are then placed outside the carmalt forceps. The affected colonic segment is now transected using the outside of the carmalt forceps as a guide.

After performing and pressure leak testing the colonic anastomosis, the anastomotic site is flushed with saline. Layers of laparotomy sponges can be removed in between flushing the anastomosis. Surgical gloves, instruments, and other contaminated equipment should be changed at this time. A sterile fenestrated drape can be placed over the surgery site. If there is no obvious contamination of the abdomen, abdominal lavage is not necessary. Otherwise, the abdomen should be lavaged with warm isotonic saline until the effluent is clear. The mesocolon should be closed with a continuous suture pattern of 3-0 or 4-0 absorbable material. Care should be taken so as not to damage the adjacent blood supply to the colon. The surgical approach is then closed in a routine manor.

Methods of Colonic Anastomosis

After intestinal resection, the continuity of the intestinal tract can be reconstructed using three basic anastomotic techniques: end-to-end, side-to-side, and end-to-side. When hand suturing is used, the end-to-end intestinal anastomosis is the easiest and quickest technique to perform and results in a more physiologic reconstruction. Side-to-side and end-to-side anastomosis of the intestine have also been incriminated with formation of blind pouches where bacterial overgrowth and resulting malabsorption can occur.

When a disparity of luminal diameters is present, especially as seen with ileocolic anastomoses, several techniques are available to aid in end-to-end anastomoses. A funneled closure is the simplest anastomosis if minor disparities of luminal diameters exist. Sutures are placed equidistant around the circumference of the lumen ends. This results in stretching of the smaller luminal opening and constricts the larger luminal opening (Figure 20-31A). With larger luminal disparities, the smaller diameter intestine can be cut at an angle, with more tissue removed from the antimesenteric border (Figure 20-31B). If a luminal disparity still exists, the antimesenteric border of the smaller-diameter intestine can be further incised 1 to 2 cm. Two triangular flaps of intestinal wall can then be cut off each side of the incision, leaving an ovoid stoma that can be anastomosed to the larger-diameter intestine (Figure 20-31C). Finally, if the smaller-diameter intestinal lumen cannot be opened widely enough, the larger-diameter intestine can be partially sutured closed until the luminal diameters are equal (Figure 20-31D).

Two-layer anastomotic closures of the colon are no longer advocated. Several studies have demonstrated there is no increase in intestinal dehiscence and actually an increased healing rate, using a single-layer closure versusa two-layer closure.[26,27] In fact, two-layer anastomotic closures have been demonstrated to have significantly greater incidences of dehiscence and stricture formation in the rectum because of avascular necrosis of the tissue incorporated in the inner suture pattern.[26] Leakage at the anastomosis site is not a problem if the omentum is healthy and intact and the patient is not hypoproteinemic. A fibrin seal will form at the anastomosis site within about 3 hours in most patients.[28]

Numerous intestinal anastomosis studies have been performed comparing simple continuous, simple interrupted, inverting, everting, or appositional suture techniques. The anastomosis techniques that are the easiest to perform, with the least leakage, the least adhesion formation, and the best histologic healing, have been the single-layer simple interrupted approximating techniques. In 1968 Poth and Gold described the crushing appositional anastomosis technique in human patients.[29] This technique involved a through-and-through suture, which was then tightened to cut through all the layers of the intestine except the tough submucosa (Figure 20-32A). This technique kept the suture from being exposed to the luminal surface, where it could become infected, and from exposure to the abdominal lumen and serosal surface, where adhesions could form. At about the same time the crushing technique was developed, DeHoff investigated the use of a simple interrupted approximating technique for intestinal anastomosis in dogs (Figure 20-32B).[30] Both appositional techniques maintain luminal diameter, diminish adhesion formation, and allow for rapid primary healing of the intestinal anastomosis. Some eversion commonly occurs with both these appositional techniques, resulting in adhesions and some altered healing.[28] The Gambee suture pattern helps eliminate the slight eversion caused by the simple appositional suture patterns (Figure 20-32C).

Various suture materials are used successfully for intestinal anastomosis, including monofilament and braided sutures of absorbable and nonabsorbable sutures. The monofilament absorbable sutures polydioxanone, polyglyconate, and poliglecaprone 25 are closest to the ideal suture material available for intestinal anastomosis today. Nonabsorbable monofilament suture material such as nylon or polypropylene may be useful in patients that are expected to have delayed tissue healing. The braided absorbable sutures polyglycolic acid and polyglactin 910 are absorbed in a relatively short period of time. These sutures have a constant absorption rate which is not affected by infection, so infected suture tracts and granulomas are of little concern. The biggest problem with the absorbable braided suture is the tissue trauma (drag or chatter) as they are pulled through tissue. The surface characteristics of braided sutures have been shown by electron microscopy to increase trauma to the tissue they have been pulled through, as opposed to smooth surfaced monofilament suture material.[31] In small animal colonic surgery, a size 3-0 to 4-0 suture should have sufficient tensile strength to hold intestinal tissue.

A swaged-on reverse cutting or taper-cut suture needle is recommended for colonic surgery. These suture needles facilitate penetration of the intestine's tough submucosa with the least effort and tissue trauma. Taper-point or narrow-taper needles have been suggested by some surgeons, because less intestinal leakage occurs around the suture tract. The increased trauma of passing the taper needle through the submucosa must be balanced with this minor benefit.

The number of sutures placed to form an anastomosis should be the minimum needed to prevent leakage of the anastomosis. Most intestinal anastomosis techniques describe placing sutures 2 to 4 mm from the cut serosal surface and 3 to 4 mm apart. This averages to approximately 12 to 16 simple interrupted sutures evenly spaced around the anastomosis. The first suture

Notice the suture passes through the mucosa and causes very slight tissue inversion.

is normally placed at the mesenteric border because this is the most difficult to see, and this area has the highest incidence of leakage and dehiscence (Figure 20-33A). The second suture is normally placed at the antimesenteric border, with the remaining sutures filling in the area between the first two sutures (Figure 20-33B). The anastomosis can be tested by filling the segment of intestine with saline under slight pressure, or milking luminal contents across the anastomosis and looking for leaks. Any anastomosis will leak if too much pressure is applied. Too many sutures decrease anastomosis healing by interfering with blood supply to the intestinal edges. Some authors recommend wrapping or even suturing the omentum around the anastomosis site. This is normally not necessary because the omentum naturally moves to cover any leaks in an intestinal anastomosis.

Surgical stapling is another method of intestinal anastomosis that has become increasingly popular. The device commonly used in colonic resection and anastomosis is the circular stapler manufactured by Ethicon (Proximate ILS, Ethicon, Inc., Somerville, NJ) or United States Surgical (CEEA, United States Surgical Corp., Norwalk, CT). The circular stapler inverts the intestinal ends and places two circumferential rows of staggered B-shaped sutures. The device then cuts out a donut-shaped section of the inverted tissue from the ends of the intestine being joined. The circular stapler can be inserted through the anus or through an access incision in the intestine. A modified Furness clamp, or purse string stapler, is used to place a purse string suture around the ends of the intestinal segments to be joined. One intestinal end is then slipped over the cartridge end, and the other intestinal segment is placed over the anvil. The purse string sutures are then tied to the movable central shaft between the cartridge head and anvil. The shaft is shortened, compressing the cartridge to the anvil with the intestinal ends in between. The stapler is then fired, forming the anastomosis and cutting out the purse string along with the tissue in the middle of the lumen (Figure 20-34). The circular stapler forms a true inverting anastomosis. Occasionally, the result is the same problem caused by a hand-sutured inverting anastomosis, that is, luminal strictures. The circular stapler is a technically demanding stapler to use. Improper usage of the stapler, or poor surgical technique, may result in anastomotic stricture or dehiscence. When performed by an experienced surgeon, the stapled anastomosis line has been demonstrated to leak less, to be better aligned, and to heal better than single-layer hand-sutured anastomoses.[32] Ordinary skin staplers have also been found to provide safe anastomoses.[33] Skin staplers are especially helpful in repairing multiple intestinal perforation caused by gunshot wounds. Various other sutureless intestinal anastomosis techniques have been studied through the years, from cyanoacrylate adhesives and fibrin glue, to laser welding and non-absorbable and absorbable anastomosis rings. For various reasons anastomosis techniques other than sutures and staples have not met with wide acceptance.

Colonic Healing

The colon follows the same stages of healing as skin and other soft tissue: inflammation, debridement, repair, and maturation.[34] A unique property of colonic healing, however, involves the balance of collagen synthesis and degradation. During the first 3 to 5 days after wounding, collagen synthesis is competing with collagenolysis.[34-36] This is important, because the collagen content of a wound has been directly correlated with wound strength.[36] There is an especially high turnover rate of collagen in the wounded colon.[34-37] Earlier work suggests that as much as 40% of the rat colon's original collagen content, throughout the entire colon, is lost to collagenolysis during the first 4 to 6 days after wounding.[37] However, early studies have over emphasized the drop in collagen content in colonic wounds. With the use of more advanced techniques in measuring the collagen content of a wound, researchers have found that the drop in collagen content is not as dramatic as originally thought.[38] Rapid gain occurs in colonic tensile strength between the third and seventh days after wounding.[38] Local factors in the colon can, however, shift a wound towards increased collagen lysis. Traumatic handling of colonic

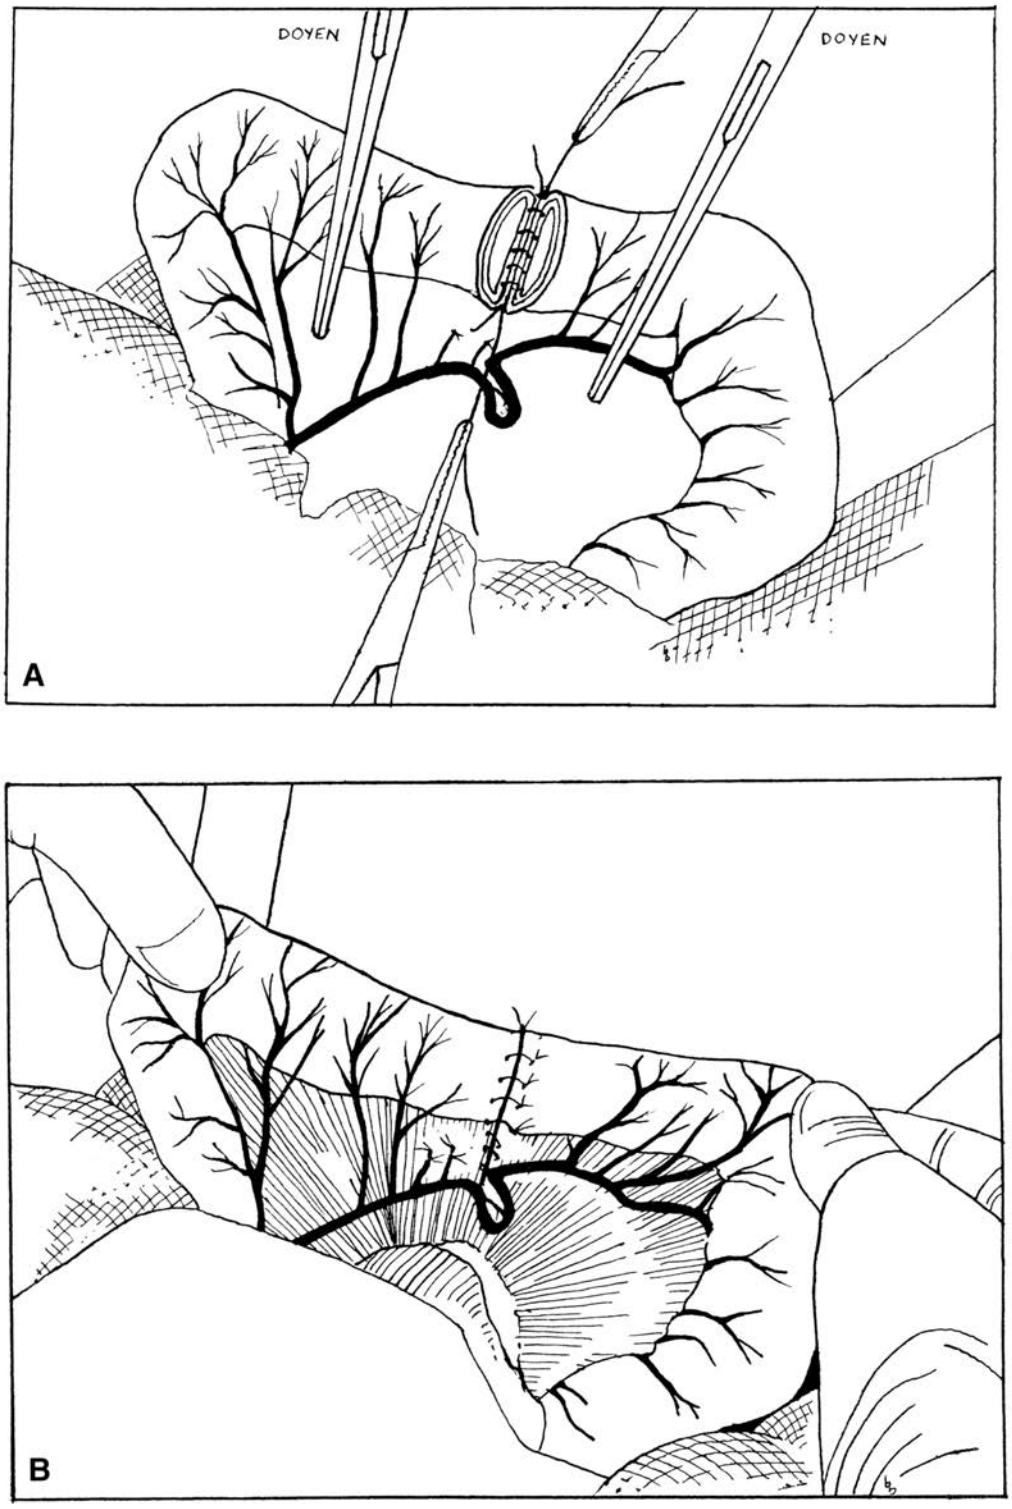

Figure 20-33. Technique for colonic anastomosis. **A.** The two colonic segments are held together with the aid of the atraumatic forceps as a mesenteric and then antimesenteric suture is placed to start the anastomosis. These first 2 sutures can be used as stay sutures to handle the bowel. **B**. The anastomosis is completed with a single layer appositional suture pattern filling in the sutures between the stay sutures. The mesentery is closed with a simple continuous suture pattern.

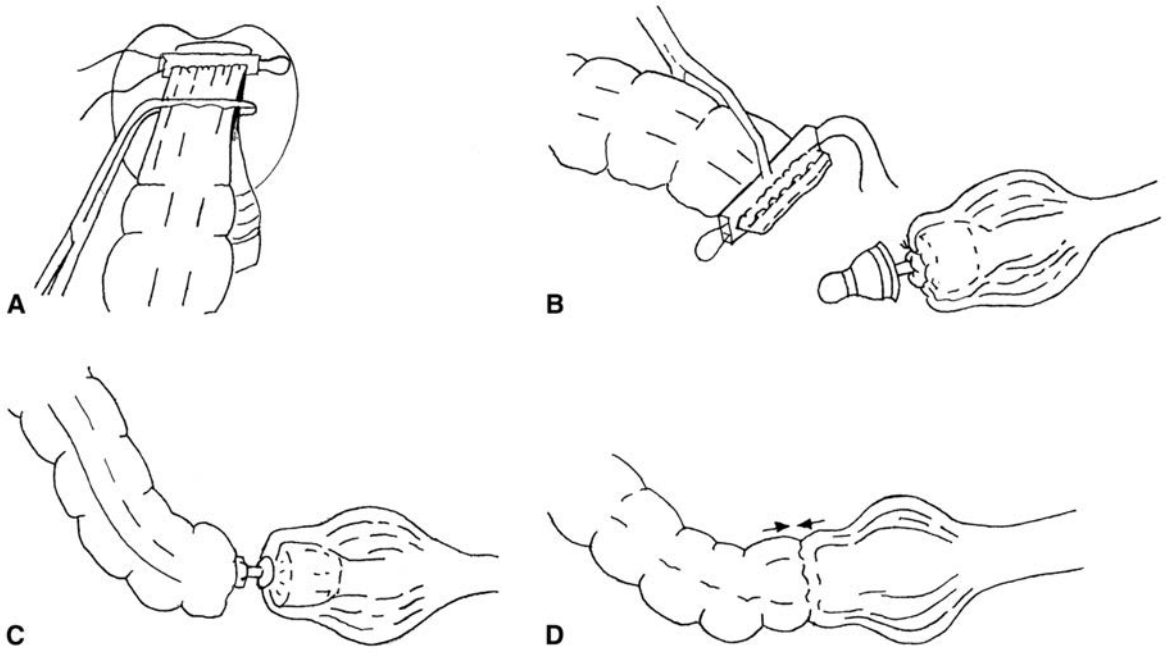

Figure 20-34. Distal colorectal anastomosis with a circular stapler. See text for details. **A.** A modified Furness clamp is used to place a purse string suture on the aboral intestinal segment (top of figure). The affected orad segment is isolated and resected. **B.** A transrectal circular stapler is placed to the level of the aboral purse string suture. The purse string is then tied around the center anvil of the stapler. **C.** A purse string suture around the orad intestinal segment is used to secure the segment to the circular stapler anvil cranial to the aboral segment. **D.** The circular stapler is then compressed and fired to form the anastomosis.

tissue, bacterial contamination, foreign material, and certain suture patterns used for intestinal anastomoses all increase the amount of collagenase produced locally in colonic tissue.

Biopsy

Full-thickness biopsy techniques of the colon are performed similar to those in the small intestine. Luminal contents are milked from the biopsy site, and the site is isolated with a moistened laparotomy sponge. A full-thickness longitudinal incision approximately 1 to 2 cm long is made in the antimesenteric colonic wall. A full-thickness segment approximately 2 to 3 mm wide is cut from the side of the incision. Care should be taken not to crush the sample with forceps. The colonic defect is then closed transversely using simple interrupted sutures (Figure 20-35). Large diameter round dermal punches have also been successfully used for full thickness biopsies. Care must be taken to only cut through one side of the intestine.

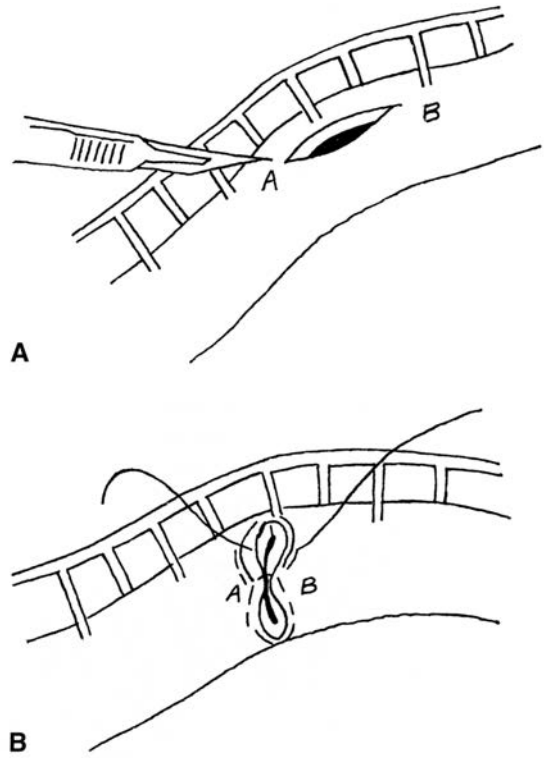

Figure 20-35. A. Longitudinal incisions in bowel can be closed transversely **B.** to prevent reduction of the luminal diameter.

Postoperative Care and Complications

Immediate Postoperative Care

Patients undergoing major colorectal surgery often require significant postoperative care. Intravenous fluids should be continued postoperatively until the patient is taking food and water by mouth and the patient's temperature is below approximately 103.6°F. Rectal thermometers should be used with care. Infrared ear thermometers are preferred in animals that have undergone rectal surgery. Patients should be observed for signs of peritonitis for the first 3 to 5 days after surgery. These signs including fever, depression, anorexia, abdominal pain, vomiting, and shock. Postoperative antibiotics are generally not recom-

mended unless intraoperative signs of established infection are present. Inappropriate use of antibiotics can mask signs of peritonitis and can result in superinfections. The author routinely administers injectable narcotics immediately after endotracheal extubation, with a pain protocol for subsequent doses as needed. Oral or transdermal narcotics and anti-inflamatories are dispensed for 3 to 5 days after surgery. Clinically, patients appear to be comfortable within 12 to 24 hours after surgery. Patients can be offered water once they are fully awake from anesthesia. A low-residue diet can be offered within 12 to 24 hours after surgery. This diet should be continued for the first 2 to 3 weeks, after which the animal's normal diet can be gradually introduced. Stool consistency, color, and presence of blood should be carefully monitored. The patient's first bowel movement commonly contains a large amount of soft to liquid, dark stool whith whole blood. Stool softeners can be administered as necessary to maintain a semifirm consistency. Patients that recover without complications are usually discharged on the second or third postoperative day.

Early Complications

The most serious early postoperative complications of colorectal surgery are infection and fecal incontinence. In a review of intestinal surgery in dogs and cats, patients with peritonitis had a morality rate of 31%.[39] Infection after colorectal surgery can result from preoperative trauma, interoperative contamination of the abdomen, and intestinal dehiscence. While rare, rectal perforations caused by pelvic fractures can be successfully treated if diagnosed before significant contamination of surrounding tissue occurs. In one small study of patients with rectal perforations caused by pelvic fractures, definitive surgical treatment performed within 24 hours of occurrence resulted in no mortality.[5] All patients with delayed diagnosis or treatment had fatal outcomes. Postoperative intestinal dehiscence is one of the most common causes of infection. In one study, dehiscence resulted in a mortality rate of 80%.[39] This same study found no significant difference between small and large intestinal dehiscence rates with an average of 7%. Many factors can result in colorectal dehiscence, including poor surgical technique, traumatic tissue handling, disrupted blood supply, poor suture placement, tension on the anastomosis, improper use of drains, delayed healing, and inappropriate postoperative care. Discriminant analysis in one study demonstrated a sensitivity of 91% with a specificity of 83% using a model where dogs having 2 or more risk factors (preoperative peritonitis, serum albumin concentrations less than or equal to 2.5 g/dL, and intestinal foreign bodies) resulted in intestinal anastomotic leakage.[40]

The clinical signs of peritonitis have been described previously. Diagnostic procedures for postoperative peritonitis and dehiscence may include abdominocentesis or peritoneal lavage, gentle rectal palpation, complete blood count, plain abdominal and pelvic radiographs, and abdominal ultrasonography. Contrast radiographs or proctoscopy are contraindicated and may result in further abdominal contamination.

If signs of peritonitis or intestinal dehiscence are present, the animal should be supported with appropriate intravenous fluids and started on an appropriate therapeutic regimen of antibiotics based on culture and sensitivity testing. The surgeon should not hesitate to perform a "second-look operation" if indicated. Patients with peritonitis do not generally stabilize without adequate abdominal drainage and, if necessary, repair of leaking intestine. Open abdominal drainage is one successful method of surgical drainage that also allows serial evaluation of the affected colorectal segment. For recurrent dehiscence, or areas of questionable vascularity, the use of omental flaps, jejunal patch grafts, and peritoneal muscle flaps have been reported in the veterinary literature. The use of diversional colostomies have been reported in the human and equine literature. This technique has been reported in dogs, and may be a viable treatment option in selected small animal cases.[41,42]

Fecal incontinence, while not in itself fatal, often results in euthanasia of house pets. Fecal incontinence can be divided into reservoir and sphincter incontinence.[43] Patients with reservoir incontinence generally have a conscious, but frequent, need to defecate. This condition is in contrast to unconscious anal dribbling of feces found in patients with sphincter incontinence. Reservoir incontinence can be caused by colorectal irritability, decreased rectal capacity or compliance, increased propulsive motility, and increased fecal volume. One author suggests that fecal continence will be retained if less than 4 cm of rectum is resected, or greater than 1.5 cm of distal rectum is retained in the dog.[44] Treatment for surgically induced reservoir incontinence includes anti-inflammatory drugs, drugs that slow intestinal transit time, dietary manipulation to decrease fecal volume, and surgical techniques that increase rectal capacity. Some animals, over time, may develop ileoanal continence. This is where the ileum distends, taking over the reservoir function of the colon and rectum. The causes of sphincter incontinence are not fully understood, but they include neurologic and muscular trauma or disease. Along with the external anal sphincter, studies have demonstrated muscles of the pelvic girdle, especially the levator ani, play an important role in fecal continence. Treatment for surgically induced sphincter incontinence may include the same medical treatments used for reservoir incontinence. Surgical treatments for sphincter incontinence include reconstruction of the pelvic girdle and external anal sphincter, sphincteroplasty, replacing muscles of continence with muscle flaps or synthetic material, and ileal J-pouch anal anastomoses.

Late Complications

The most common late complication of colorectal surgery is lumenal stricture. Most intestinal anastomoses result in some degree of lumenal stricture. Single-layer and double-layer inverting suture patterns have been reported to result in 39% and 54% lumenal stricture respectively. This was compared with 4% lumenal stricture using an approximating Gambee pattern closure.[45] In another study, colonic anastomoses created with a 25 mm circular stapler where found to result in an average 32% decrease in lumenal diameter at the anastomosis.[46] Too much tissue inversion, suture patterns that restrict the luminal diameter, tension at the anastomosis, and extra lumenal adhesions can result in excessive lumenal stricture. Diagnosis of colorectal stricture include clinical signs, rectal or abdominal palpation,

contrast radiographs, abdominal ultrasound, and proctoscopy. Most commonly, colorectal strictures are treated medically with diet change and stool softeners. Treatment of severe colorectal strictures may require resection and anastomosis of the strictured segment, or, less commonly, mechanical dilation may be attempted. Mechanical dilation can be achieved digitally, by bougienage, or with balloon catheters. Care should be taken not to perforate the intestinal lumen using dilation techniques.

A less common long term complication is associated with the use of nonabsorbable suture material when it is used in a continuous suture pattern.[47] The nonabsorbable suture can be extruded partially into the intestinal lumen where foreign bodies have been reported to attach causing intestinal obstructions. The use of absorbable suture is recommended when making intestinal anastomoses with a continuous suture pattern.

Management of Rectal Prolapse

Mark H. Engen

Although rectal prolapse can occur with any condition that causes prolonged tenesmus, it is most common in heavily parasitized animals that have severe diarrhea and tenesmus. Other causes of straining resulting in rectal prolapse are dystocia, urolithiasis, intestinal neoplasms and foreign bodies, prostatic disease, perineal hernia, constipation congenital defects, and postoperative tenesmus after anal or perineal surgery.

Diagnosis

The diagnosis of rectal prolapse is made by visual observation of a tubelike mass, of varying length, protruding from the anus. If rectal prolapse is diagnosed early, the protruding tissue may be short, and the prolapsed mucosa will appear bright red and nonulcerated. In patients with rectal prolapse of long duration, the protrusion is longer, and the mucosa appears red or black and is either ulcerated or necrotic.

True rectal prolapse must be differentiated from prolapsed intussusception of the intestine or colon. These conditions can be differentiated by passing a probe between the anus and the prolapsed mass. The probe can be passed if an intussusception is present, but it cannot be passed if a rectal prolapse has occurred. To achieve a permanent cure for rectal prolapse, the underlying cause of tenesmus must be diagnosed and treated.

Nonsurgical Treatment

Treatment to correct a rectal prolapse depends on the viability of the exposed tissue and the size of the prolapse. A small prolapse with viable-appearing mucosa usually can be replaced by using a finger or bougie to reposition the bowel. Topical application of hypertonic sugar solution for 20 to 30 minutes may be helpful in relieving edema, so the prolapse can be reduced more easily. When the prolapse has been reduced, an anal pursestring suture is used to prevent recurrence. General anesthesia or epidural analgesia is used in some patients to facilitate reduction of the prolapse and placement of the anal pursestring suture (Figure 20-36).

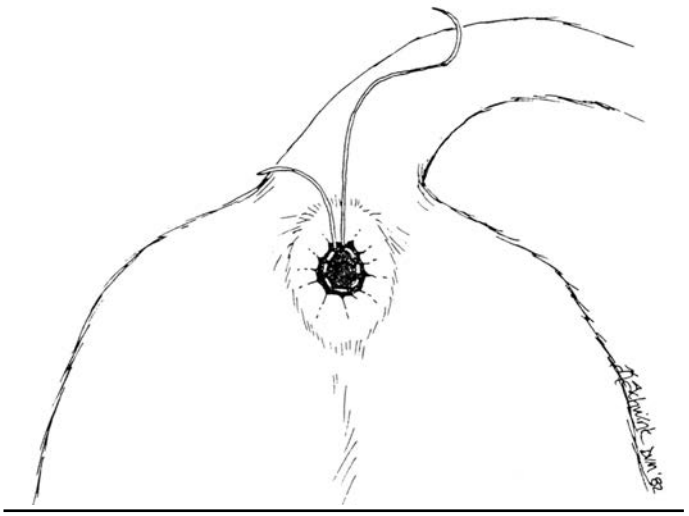

Figure 20-36. Placement of anal pursestring suture after reduction of rectal prolapse by manipulation.

After reduction of the prolapse, epidural analgesia prevents straining for several hours. Periodic rectal application of a local anesthetic ointment (1% dibucaine [Nupercainal ointment, Ciba Pharmaceutical, Ciba-Geigy, Summit, NJ]) may be done initially and after removal of the anal pursestring suture to prevent further straining. The anal pursestring suture is left in place for a minimum of 24 to 48 hours, and the animal is given only fluids orally during this time.

Surgical Treatment

When a rectal prolapse cannot be reduced by manipulation and the lack of tissue viability contraindicates reduction, rectal resection and anastomosis are performed. This procedure is performed under general anesthesia or epidural analgesia. The patient is positioned and draped (Figure 20-37A and B). A test tube or a saline-soaked sponge is placed into the lumen of the bowel to prevent fecal contamination. Three stay sutures are placed through the full thickness of both layers of the prolapse to form a triangle (Figure 20-37C and D). The prolapse is then resected 1 to 2 cm from the anus. The anastomosis is performed with a single-layer closure using a simple interrupted suture pattern (Figure 20-37E). Synthetic absorbable suture (3-0 or 4-0) is preferred. The sutures are placed through the full thickness of the incised ends of the bowel. The sutures must pass through the submucosa to ensure proper holding strength. The stay sutures are then removed, and the anastomosis is reduced manually inside the anus.

When the rectal prolapse cannot be reduced by external manipulation, but the rectal tissue is still viable, a celiotomy is performed, and the prolapse is manually reduced by gentle traction on the colon (Figure 30-38A). A colopexy is performed after reduction of the prolapse to prevent recurrence using

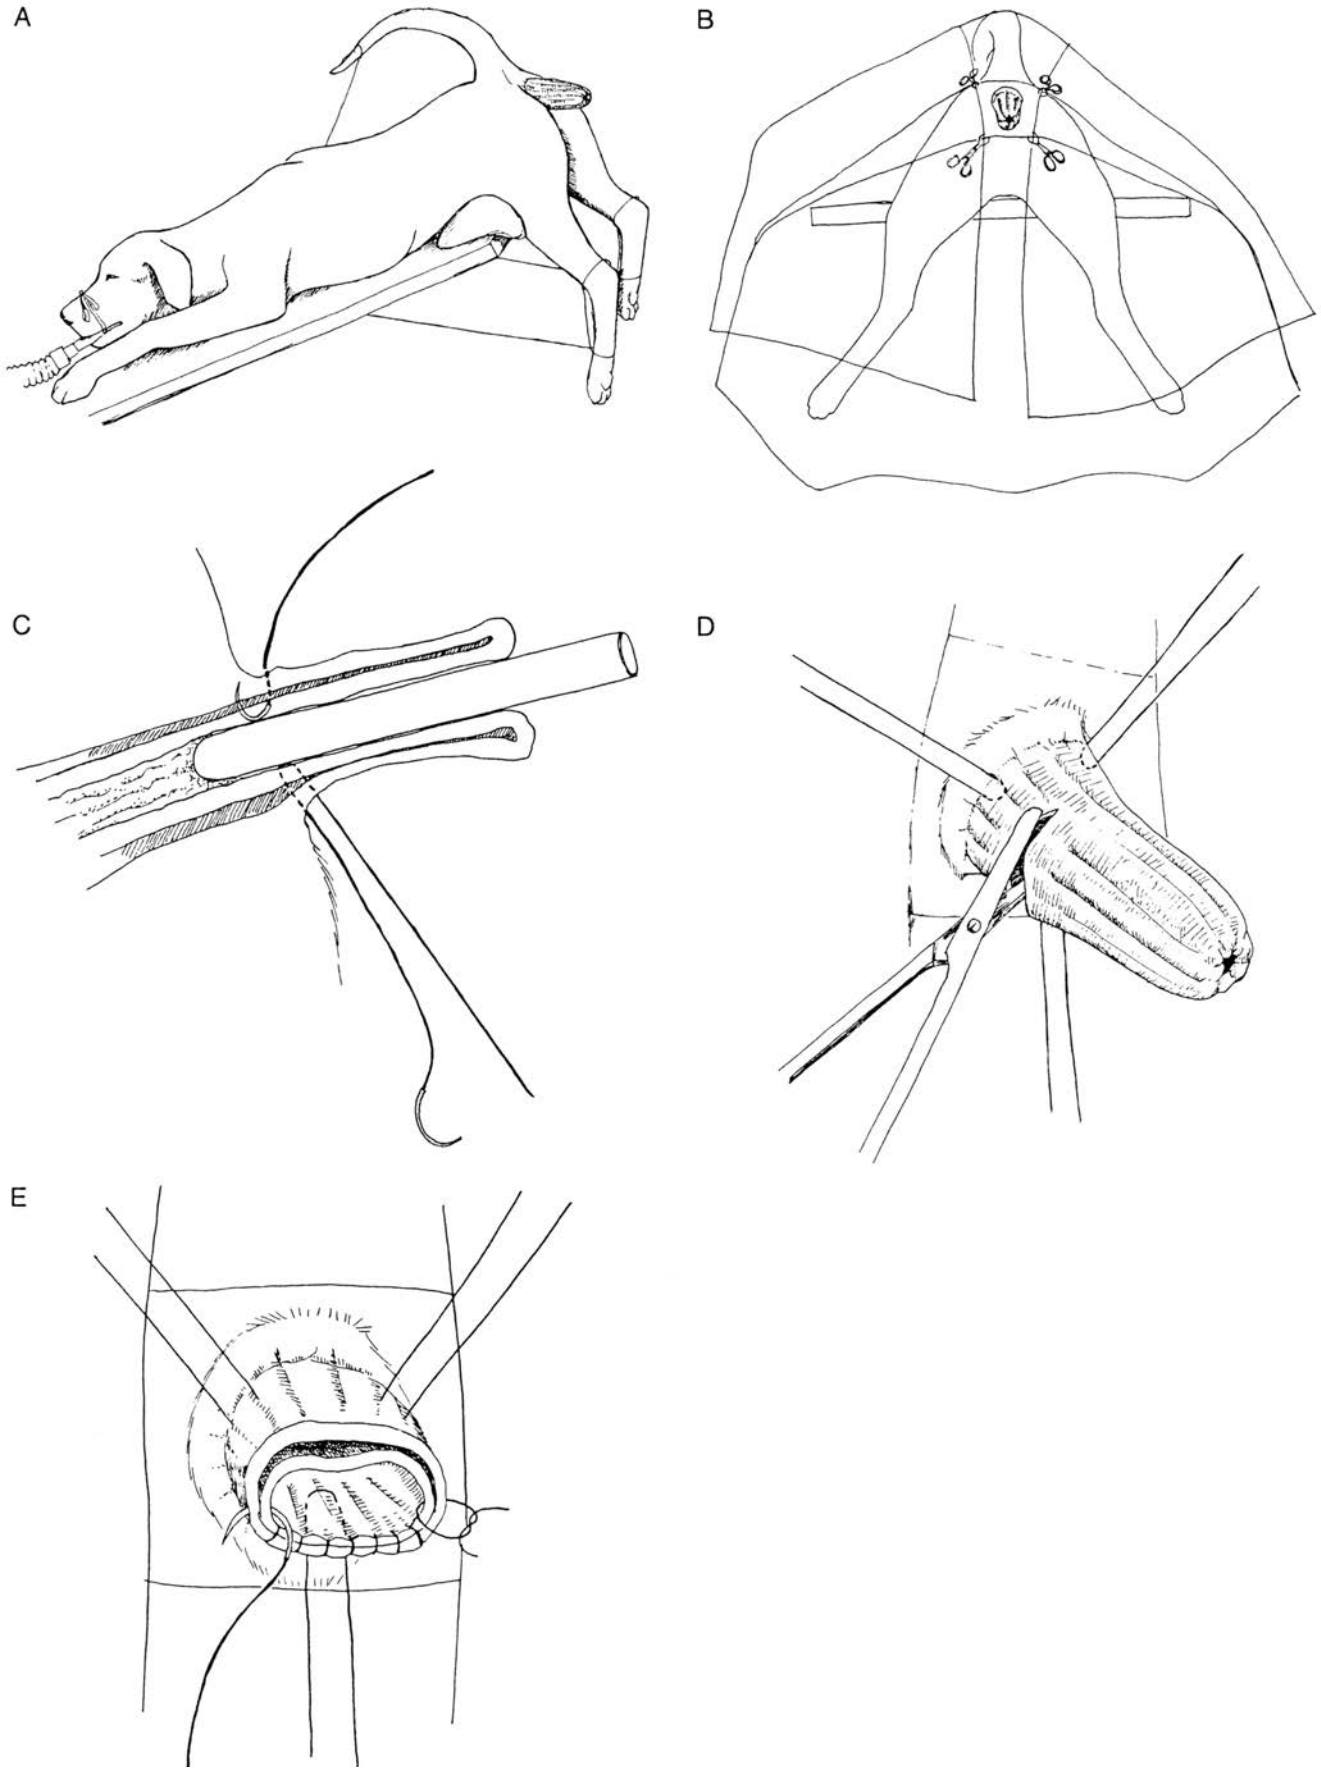

Figure 20-37. Rectal resection and anastomosis to correct prolapse. **A.** Positioning of patient on a perineal stand. **B.** Sterile draping of the prolapse. **C.** Insertion of test tube into rectum and placement of stay sutures. **D.** Excision of the prolapsed mass. **E.** Full-thickness anastomosis of the rectal lumen.

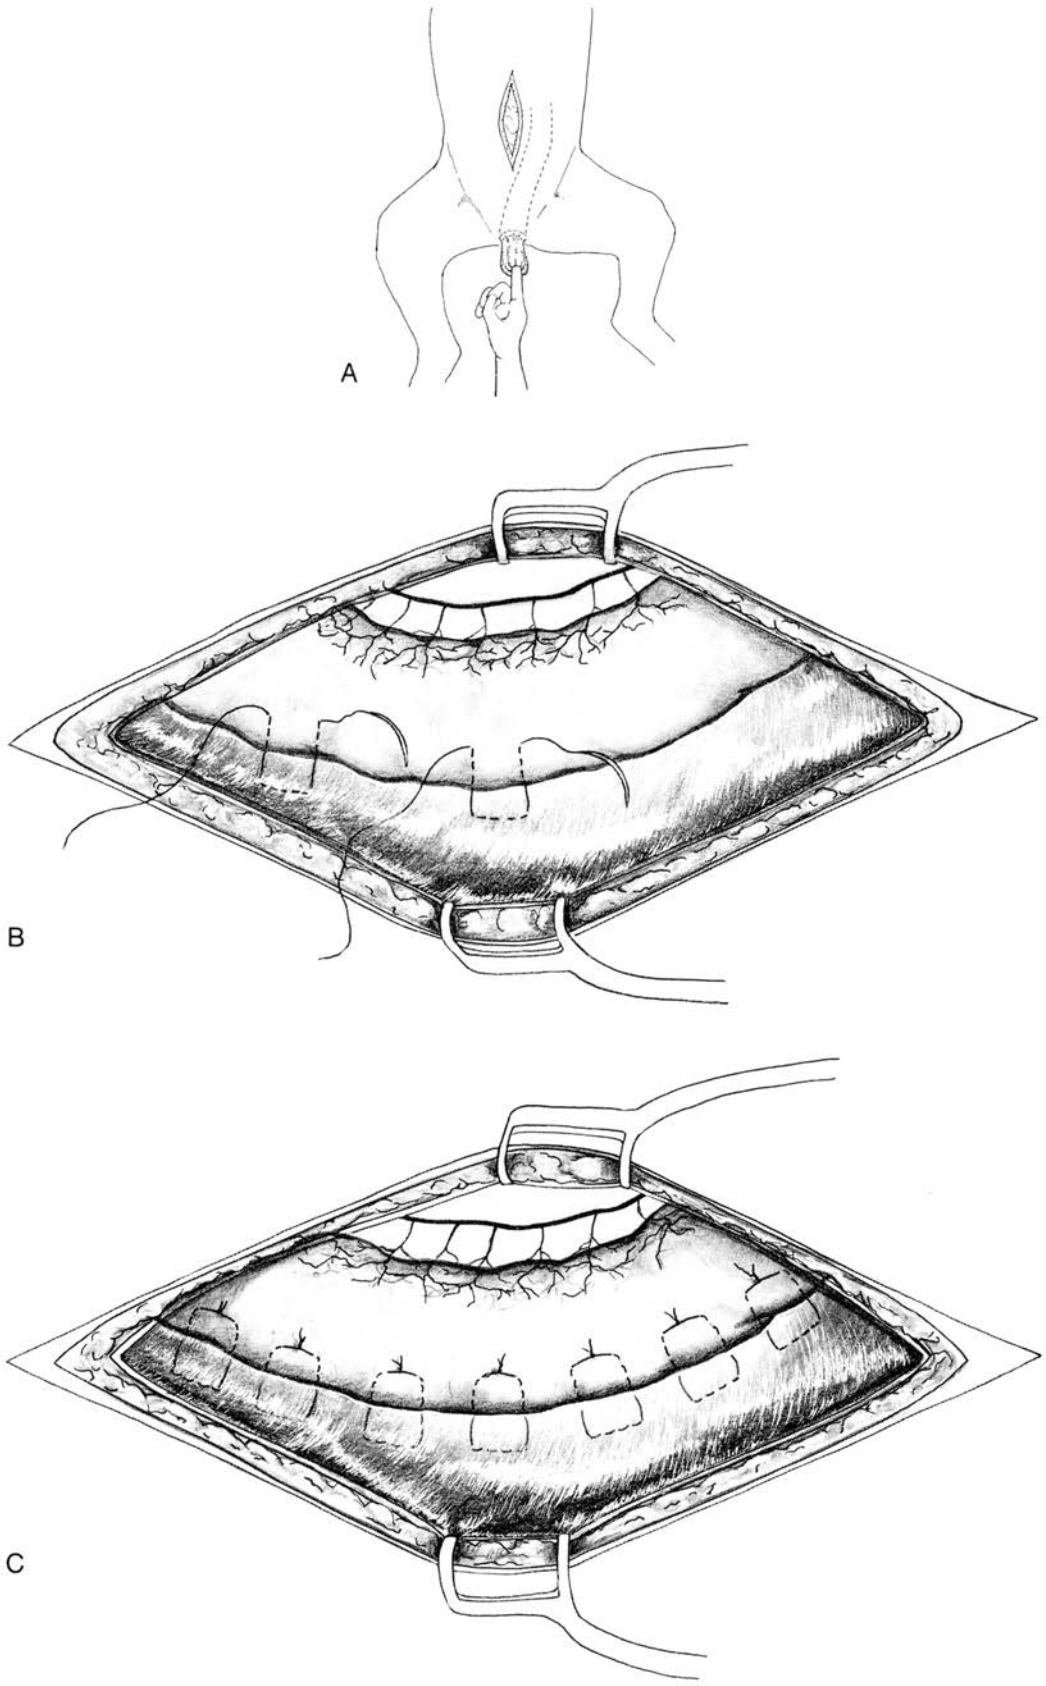

Figure 20-38. Celiotomy and colopexy for treatment of rectal prolapse. **A.** Abdominal incision and digital replacement of the prolapsed tissue. **B.** Placement of colopexy mattress sutures. **C.** Six to eight mattress sutures are placed to complete the colopexy.

synthetic absorbable suture (2-0 or 3-0) (Figure 30-38B and C). A colopexy may also be performed in cases of recurrent rectal prolapse that can be reduced by external manipulation. Such a colopexy is rarely needed, however, if the cause of straining has been diagnosed and eliminated.

Postoperative Care

Topical anesthetic (1% dibucaine) ointment is instilled rectally after correction of any rectal prolapse to prevent further tenesmus. The patient may be fed on the day after the operation. A diet of soft food and a fecal softener (dioctyl sodium sulfosuccinate) also may be administered for 1 week postoperatively. Diarrhea should be treated with neomycin, intestinal coating agents, and anticholinergic drugs. Feces should be examined, and antihelminthic agents should be administered, based on results of fecal examinations for parasitic ova.

In conclusion, once a rectal prolapse has been corrected by surgical or nonsurgical means, recurrence is rare if the cause of the tenesmus has been diagnosed and resolved (e.g., removal of intestinal parasites by worming).

Anal Sac Disease and Removal

Roy F. Barnes and Sandra Manfra Marretta

Introduction

Anal sac disease occurs with an approximate incidence of 12% in the canine, with small breeds being overrepresented compared to large breeds. Cats are infrequently afflicted with anal sac disorders. Conditions which require anal sacculectomy include relief from chronic and recurrent episodes of anal sac impaction or infection, adjunctive treatment of perianal fistulas and local treatment of apocrine gland anal sac adenocarcinoma and other malignant neoplasms.

Anatomy

The anal sacs are cutaneous diverticula ventral and lateral to the anus, between the internal and external anal sphincters. Anal sacs of the dog and cat are composed of large coiled apocrine glands. In addition, the feline anal sac includes a complex series of sebaceous glands. Despite the species difference, all glands will coalesce to form a sac and from the sac, a keratinized epithelial duct arises to carry material to the external environment. In the dog, the anal ducts open into the inner cutaneous zone of the anus while in the cat, the ducts open into a pyramidal prominence 2.5 mm lateral to the anus. Regardless of the duct opening, the anal sacs are typically located at the 4 and 8 o'clock positions with reference to the anus proper.

The blood supply to the anal sac arises from the caudal hemorrodial, perineal and caudal gluteal arteries and veins. The innervation to the anal sac and external anal sphincter is via the pudendal nerve.

Preoperative Care

Prior to anal sacculectomy, patients with anal sac impaction or infection should undergo medical therapy. Failure to resolve any inflammation associated with the anal sac disease prior to surgery may increase the potential for postoperative complications.

Medical therapy consists of expression of the anal sacs and the concurrent instillation of an oil-based antibiotic and corticosteroid-containing ointment into the anal sac. Broad spectrum antibiotics are utilized in animals with severe infection or abscessation of the anal sac. Warm compresses and hydrotherapy are applied to the perineum to improve lymphatic drainage, and cleanse the region. All animals with a suspected neoplasm of the anal sac should undergo appropriate clinical staging with emphasis on determining the potential for local and distant metastasis. Hypercalcemia, if present, should be treated with appropriate medical therapy prior to the induction of general anesthesia. Consideration should also be given to the possibility of postoperative hypocalcemia.

Surgical Technique

Several surgical techniques have been described in the veterinary literature for removal of the anal sacs. Surgeries are divided into open, modified open or closed techniques. The major difference between the techniques is whether or not the anal sac and its duct are incised, thus exposing the lumen. The closed technique is described here. It is imperative that a closed anal sacculectomy be performed for the treatment of apocrine gland anal sac adenocarcinoma or any other malignancy of the anal sac or duct.

Regardless of which surgical technique is performed, the protocol for surgical preparation is similar. The diseased anal sac is expressed to expel its contents with subsequent instillation of a dilute antiseptic, such as chlorhexidine or povidone-iodine solution. Neoplastic conditions of the anal sac may not allow anal sac expression and the instillation of antiseptic solutions. The patient is placed in a padded perineal stand (Figure 20-39). Proper position on the stand will help prevent circulatory compromise, neuropraxia and exacerbation of chronic osteoarthritis of the rear limbs. Several gauze sponges are placed into the patient's rectum. The perineum is clipped and scrubbed according to acceptable standard aseptic techniques. The surgical site is draped routinely to protect the surgical wound.

In preparation for a closed anal sacculectomy some surgeons may elect to fill the anal sac with a groove director, self-hardening gel or resin, string, umbilical tape, plaster of Paris or dental acrylic to assist in the dissection of the anal sac and associated duct (Figure 20-40A). In larger dogs, a #6 Foley urinary catheter can be inserted into the anal sac and the balloon inflated. It should be noted that filling of the anal sac with material can only be performed in non-neoplastic diseases.

Based upon the described anatomy, a vertical skin incision is made over the anal sac, approximately 3 to 4 cm in length and 5 to 10 mm lateral to the mucocutaneous junction (Figure 20-40B and Figure 20-41). The subcutaneous tissue is incised equidistant with the skin. Blunt dissection and digital palpation is used to locate the anal sac. Blunt and sharp dissection using Steven's tenotomy scissors, metzenbaum scissors and cotton-tipped applicators can be used to isolate the anal sac and duct (Figure 20-40C and Figure 20-42). Dissection of the anal sac from the internal and external anal sphincter can be difficult. The caudal rectal branch of the pudendal nerve should be avoided. Hemorrhage can be controlled using judicious use of electrocautery, ligatures and direct digital pressure. Once the anal sac and duct is dissected, the anal duct is ligated close to its termination at the anus and transected (Figure 20-40D). Alternatively, the anal duct can be transected at its termination at the anus (Figure 20-43). The anal mucosa is everted and subsequently closed using absorbable suture material (Figure 20-44).

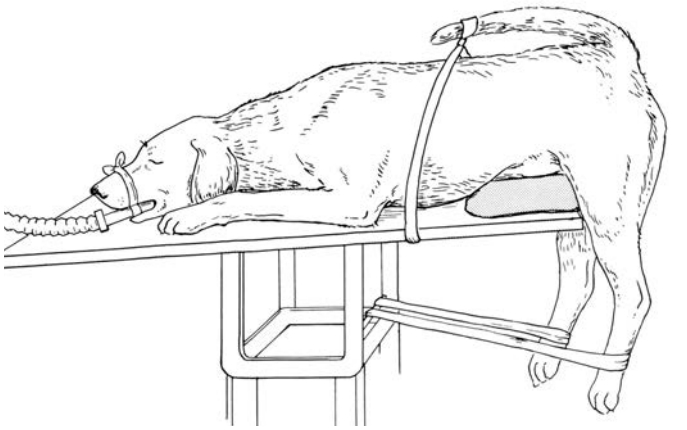

Figure 20-39. A routine perineal stand involves placing the animal in ventral recumbency with the table slightly tilted forward. Adequate padding should be placed beneath the abdomen and at the caudal edge of the surgery table. The animal's legs and tail are loosely tied to the surgery table.

Once transected, all tissue should be submitted for histopathological analysis. The surgical site should be lavaged thoroughly with sterile physiologic saline. The external anal sphincter should be closed using a synthetic, absorbable, monofilament suture, such as PDS or Maxon. The subcutaneous and subcuticular tissues should be apposed in a routine manner. If skin sutures are utilized, trim the ends of the sutures so that irritation to the adjacent anus and perineum will be minimized (Figure 20-40E and

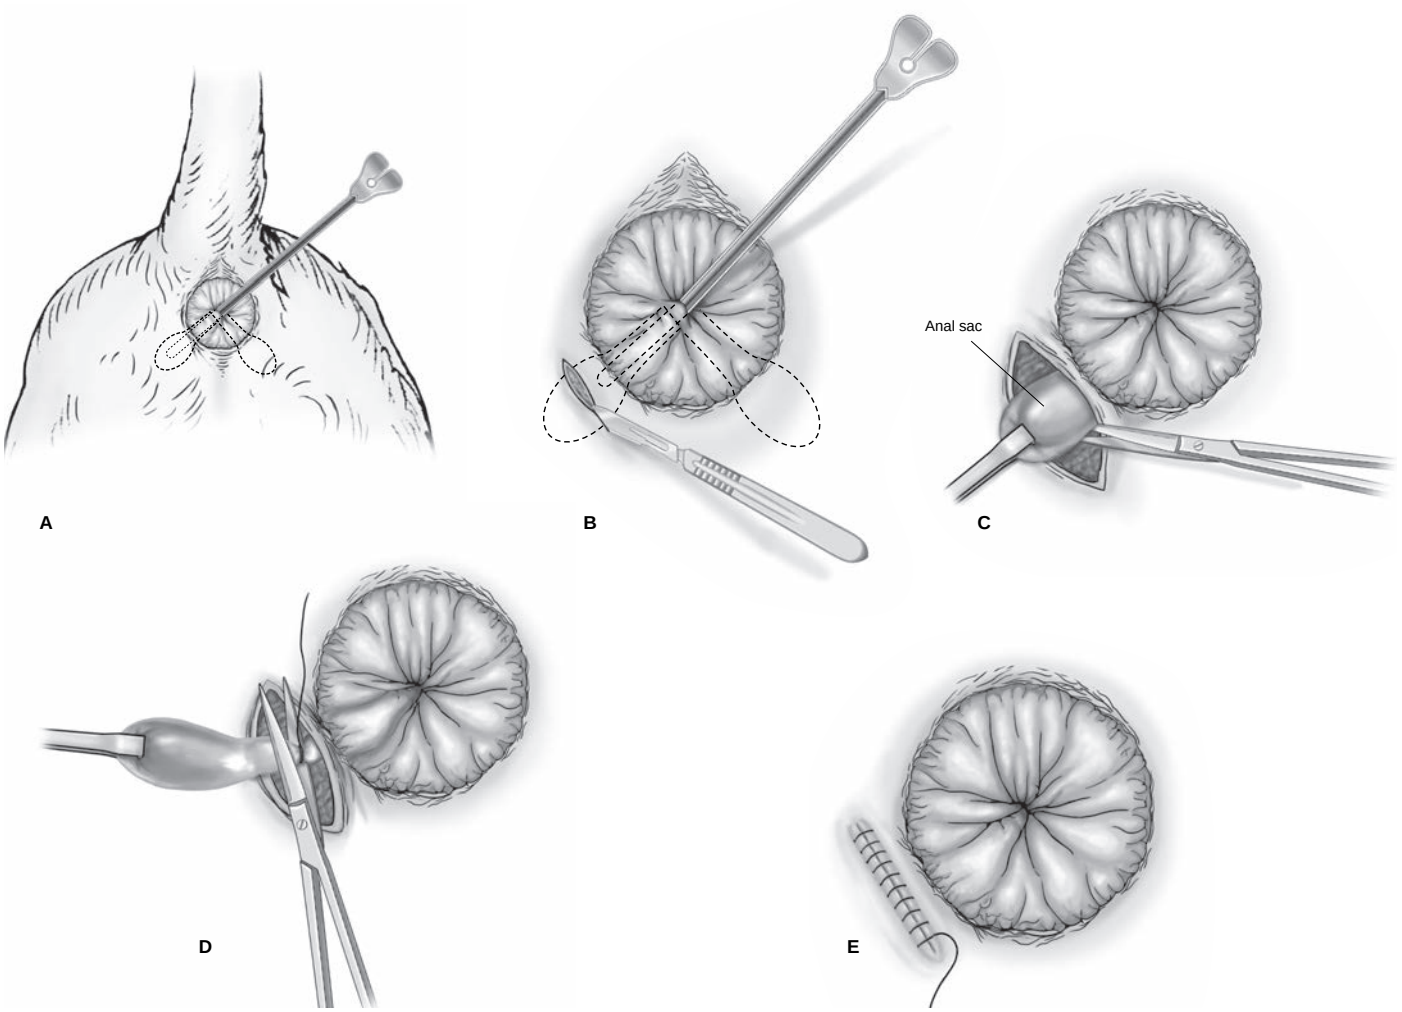

Figure 20-40. Closed technique tor anal sac removal, **A.** A groove director is used to identify the anal sac. The anal sac can be filled to delineate it from surrounding tissues. **B.** An incision is made over the anal sac. **C.** The anal sac is dissected out from surrounding tissues, **D.** The duct is ligated, and the sac is removed, **E.** Routine closure. Figure 20-43. Forceps are depicting the opening of the anal duct at the level of the inner cutaneous zone.

Figure 20-45). After surgery, a rectal exam should be performed. At this time, any defect in the rectal mucosa should be made apparent and if present, repaired appropriately.

Postoperative Care

An Elizabethan collar is recommended to prevent self-mutilation of the surgical site. Broad spectrum antibiotics should be administered immediately preoperatively and for the next 7 to 10 days due to the classification and location of the surgical wound. Cold compresses should be applied three to four times daily to the wound for the first 36 to 48 hours. After discontinuation of cold compresses, warm compresses should be applied two to three times daily until suture removal. Alternatively, hydrotherapy can be administered during the period of warm compresses. Hydrotherapy will not only help with any post-operative swelling, but will help keep the surgical site clean. Skin sutures, if present, are removed in 10 to 14 days.

Analgesics are paramount in the post-operative period. A full

Figure 20-44. Apposition of the anal mucosa after transection of the anal duct.

Figure 20-45. Apposed skin and anal mucosa. Note the short sutures along both apposed incisions.

agonist opioid, such as hydromorphone or oxymorphone, should be utilized for the first 24 to 36 hours. If medically appropriate, a non-steroidal anti-inflammatory drug, such as carprofen or etodolac, can be administered for additional analgesia. A high-fiber diet or stool softeners may be utilized to provide a soft, but formed stool. Either therapy can be useful in the post-operative period to help limit constipation associated with the administration of opioids or to help offset any potential tenesmus.

Preoperative conditions, such as hypercalcemia, should be monitored closely. If the hypercalcemia is secondary to a malignant neoplasm, such as an apocrine gland anal sac adenocarcinoma, the hypercalcemia should resolve if there is no local or distant tumor burden. However, if the hypercalcemia persists in the post-operative period, then either the tumor has metastasized or there is another disease process present. If the persistent hypercalcemia is secondary to a malignant neoplasm, consultation with a medical oncologist is recommended. Regardless of the presence of hypercalcemia, any patient suffering from a neoplasm of the anal sac or duct should be evaluated by a medical oncologist to determine if ancillary therapy is warranted.

Postoperative Complications

Short-term complications (< 14 days) after a closed anal sacculectomy include drainage, seroma formation, inflammation, hemorrhage, infection, and tenesmus or dyschezia. Drainage and seroma can be minimized by meticulous and delicate tissue handling and apposition of incised tissues. Inflammation can be minimized by avoidance of traumatic tissue handling, desiccation of exposed tissues, judicious use of electrocautery and proper identification of anatomy. Hemorrhage can be avoided if subcutaneous, muscular and parenchymal vessels are ligated using appropriate techniques and the use of electrocautery. If mild postoperative hemorrhage is present, a cold compress and sedation with acepromazine may provide relief. If hemorrhage is severe, immediate exploration of the surgical wound is indicated. Infection rates associated with a closed anal sacculectomy are low. However, if infection occurs, it will become apparent within the first 48 to 72 hours after surgery. The treatment of infection consists of removing the ventral sutures in the surgical wound to allow drainage and the application of dilute antiseptic solutions (chlorhexidine or povidone-iodine). Hydrotherapy performed twice daily and the administration of broad spectrum antibiotics (based on proper pharmacokinetics and suspected pathogen) pending results of bacterial culture and sensitivity testing is recommended.

Long-term complications of a closed anal sacculectomy can include fecal incontinence, chronic fistula formation, anal stricture and reoccurrence of local disease. The first three complications can be minimized with careful intraoperative technique and attention to anatomical structures. Fecal incontinence may result from excessive surgical trauma to the external anal sphincter (> 50% of its diameter) or direct damage to the caudal rectal branch of the pudendal nerve. Treatment of fecal incontinence includes dietary changes and the potential for muscle pedicle transpositions. Chronic fistula formation usually appears a few weeks to months after surgery. The cause of fistula formation is incomplete removal of the anal sac or duct. Treatment of the fistula includes surgical exploration of the draining tract and subsequent removal of any remaining secretory tissue. Anal stricture is an infrequent complication of closed anal sacculectomy due to the surgical approach. Clinically, anal strictures will appear weeks to months after surgery and clinical signs usually reveals tenesmus. Treatment of anal strictures includes stool softeners, balloon dilation, and if severe, surgical resection of the stricture. Local disease reoccurrence may occur in the case of anal sac neoplasms. Ancillary therapy, such as radiation therapy for local disease or chemotherapy for distant metastasis may be necessary for neoplasms. Complete staging of the neoplasm coupled with consultation with a medical oncologist is recommended.

Nonsurgical Management of Perianal Fistulae

Dean Fillipowicz

Introduction

Dogs afflicted with anal furunculosis (perianal fistula, fistulae or fistulas; perianal hidradenitis) suffer from painful, malodorous and suppurative ulceration and sinus tract formation of the skin and subcutaneous tissues of the perineum. The etiology of this chronic and progressive inflammatory condition is unknown, but an immune mediated cause is likely. Previously regarded as a surgical disease, medical management is now the primary mode of treatment, with surgery reserved for recalcitrant cases and animals whose lesions are no longer responsive to immunosuppressive therapy. Goals of therapy include eliminating discomfort, ameliorating other associated clinical signs, and preventing recurrence.

Signalment and Clinical Signs

German Shepherd dogs are most commonly affected making up 89%,[1] 85%,[2] 81%,[3] 79%,[4] 96%,[5] 75%,[6] and 100%[7] of recent studies. Other breeds that have been reported include Labrador Retrievers, Irish Setters, Old English Sheep Dogs, Border collies, Bulldogs, Bouvier des Flandres, beagles, various spaniels, and mixed breeds.[5,8-13] The mean age of presentation is between four and seven years old, but reports exist of patients aged between

one and fourteen years old.[12,13] A sex predisposition has not been substantiated; reports exist of increased male prevalence,[4,7,14-18] increased female prevalence,[19] and an equal sex distribution.[3,6,20,21]

Clinical signs most commonly reported include tenesmus, pain, dyschezia, excessive licking of the perineum, and a malodorous, purulent discharge, but self-mutilation, hematochezia, fecal incontinence, constipation or diarrhea, flatulence, and weight loss may also be seen.[1-8,10,15,21]

Patients present with varying degrees of ulceration and sinus tract formation radiating around the anus. In mild cases, the affected region may encompass an arc of 90° or less with focal, erythematous, superficial lesions. More advanced cases may have diffuse, deep, epithelial lined, communicating tracts extending 360° circumferentially with possible involvement of the anal sacs. True anocutaneous and rectocutaneous fistulae have been reported. Fortunately, they are uncommon in the canine species, with most dogs being presented with moderate to severe ulceration and multiple sinuses.[5,10-13] Many dogs have advanced forms of the disease before initial presentation, possibly because the wide tail base and dense, thick hair coverage of many afflicted dogs prevents frequent observation of affected areas by owners.

Pathogenesis

Though the etiology of anal furunculosis is uncertain, several factors have been proposed as contributing to development of the disease: low tail carriage, broad tail base, and dense tail fur resulting in increased perianal humidity and contamination, anal sacculitis with concomitant spread of infection, anal crypt or gland fecalith impaction with subsequent abscessation, perianal trauma, and foreign body reaction. Though it is likely that these conditions may exacerbate inflammation and lesion formation, no strong evidence exists supporting any of these as a primary cause of the disease.[2,9,10,13] Involvement of the anal sacs and subsequent infection, abscessation, and ulceration is common in advanced cases, but appears to be a secondary development rather than a primary cause of the disease.[9,12] A correlation with hypothyroidism has been proposed, but remains unsubstantiated.[17] In the same study, no immunologic abnormalities were found between affected and normal dogs.[17]

A failure in immune modulation is accepted to be the most likely cause of perianal fistulae, and evidence exists supporting this hypothesis. Most notably, anal furunculosis and Crohn's disease in humans have similar clinical appearances and demonstrate similar positive responses to immunomodulatory medications.[2-7,10,12,15,19,20,22] In addition, it has been shown that mRNA expression of those cyctokines associated with TH-1 T-cells is heightened in perianal tissue taken from dogs with anal furunculosis.[23] However, a simple immunological defect, at least in German Shepherds, has not been found.[24]

Diagnosis and Evaluation

The diagnosis of anal furunculosis is based on signalment, history, physical examination findings, and exclusion of differential diagnoses. Severe local pain makes a thorough examination of the perineum difficult in affected animals and can seldom be done without general anesthesia. Prior to anesthesia, it is important to assess anal tone, as incontinence can be seen with advanced disease and as a post-operative complication. Once the patient is anesthetized, the perineal area should be liberally clipped to aid in assessment and subsequent cleaning of diseased tissue. Tracts should be gently probed with a sterile, blunt instrument to assess size, depth, and possible communication with nearby structures. At least one of the anal sacs is often secondarily involved or may become so before a response to therapy is seen. Both structures should be evaluated for involvement, rupture, or abscessation. Palpation, expression of the sacs if un-involved, and flushing with sterile saline to identify previously unobserved tracts is important. If occluded, the anal sac ducts should first be cannulated with a lacrimal duct cannula or small urinary catheter. Fine needle aspiration of grossly enlarged anal sacs may help identify abscessation or neoplasia.

A thorough rectal examination is necessary. The concurrent presence of a perineal hernia, or rectal dilation, or sacculation affects prognosis for both disease processes. Gently probing the fistulous tracts while performing the rectal examination may identify rectocutaneous fistulae. Care should be taken to identify thickening of the external anal sphincter and rectal and anocutaneous tissues, particularly in those patients suffering from tenesmus. Anorectal stenosis or stricture caused by chronic disease will also adversely affect prognosis.

Superficial cytology and culture gives little useful information, though culture and sensitivity of deep sinus tracts will aid in antibiotic selection for those cases responsive to medical management. Sinus tract biopsies can give histological support of a diagnosis of anal furunculosis, but more importantly, may identify neoplastic disease.

An association has been suggested between colitis and perianal fistulae.[16,20] It is therefore further recommended to obtain colonic biopsies as the two disease entities present similarly, and treatment of fistulae is complicated by concurrent large bowel disease.

Additional diagnostics may include complete blood count, chemistry panel, and urinalysis for overall health assessment, fecal floatation to help identify endoparasites, and thoracic radiographs if neoplasia or fungal infection is suspected as contributing to the perianal ulceration. Other perineal disease entities to rule out include anal sac abscessation, fungal infection, pythiosis, lagenidiosis, perianal adenoma, apocrine gland adenocarcinoma, squamous cell carcinoma, caustic injury, and trauma.[10,25]

Medical Management–Systemic

It is important for owners to be aware that therapy is directed at control of the disease and its clinical signs and that a cure is seldom attained. In addition, owners must be well informed about the potential complications of management and should be committed to long-term aftercare.

Previously an exclusively surgically-managed disease, medical management is now the cornerstone of therapy for anal furunculosis. The goals of treatment are initially to eliminate discomfort and pain followed by reduction in lesion volume. Long term therapy is directed at prevention of disease recurrence. Four components make up medical management: regional hygiene, elimination/reduction of secondary infection, immunomodulatory therapy, and dietary modification. Surgery is indicated in recalcitrant cases and in those cases where no further improvement from medical management is noted. However, medical therapy should be be attempted first to reduce lesion severity; subsequent surgery may then be associated with fewer complications such as incontinence, stricture, and disease recurrence.[13,19]

As therapy is initiated, attention to perianal hygiene should only be attempted with the aid of chemical restraint. As lesions and pain diminish, the patient may learn to tolerate disease care without sedation. Frequent clipping is initially necessary to remove debris and allow cleaning and monitoring of the affected area. Later in the course of management, the area should remain clipped and clean to prevent recurrence and allow application of topical medication.

Systemic antibiotics are indicated as most cases have some degree of secondary infection. Bacterial culture and sensitivity results should dictate the antibiotic of choice. However while results are pending, empiric therapy with an antibiotic that affords gram negative and anaerobic coverage such as amoxicillin-clavulanic acid is appropriate. Systemic therapy should continue for five days past the disappearance of gross evidence of infection. Topical antibiotic therapy such as mupirocin ointment (Bactoderm, Pfizer) once every twelve to twenty-four hours can be used once patient compliance allows application. This can be used to prevent and reduce bacterial colonization, and can be used concurrently with systemic antibiotics. Lesion resolution negates the need for continued antibiotic therapy. Hygiene and antibiotic therapy alone are unsuccessful in the management of this disease, and are considered to be palliative at best.[9]

Immunomodulatory therapy is the primary and most important aspect of the medical management of anal furunculosis, and several regimens are available. As discussed later, systemic cyclosporine coupled with ketoconazole followed by topical tacrolimus is the currently preferred method of management. However, reasonable success has been attained with cheaper, more commonplace immunosuppressives such as glucocorticoids, azathioprine, and metronidazole. Table (20-1) summarizes drug regimens recently as offering some success with less expensive drug combinations.

The advantages of glucocorticoid administration are ease and low cost. Unfortunately, side effects with this medication can be severe and include polydypsia, polyuria, polyphagia, decreased resistance to infection, slower wound healing, muscle wasting, and insulin antagonism. In addition, glucocorticoid administration for perianal fistulae may show no, poor, or transient response. Advantages of the metronidazole/azathioprine regimen include low cost, absence of untoward side effects, and reduced risk of post-operative complications previously reported.[19] Though side effects were not seen in the cases of this report, this drug regimen is not innocuous. Azathioprine suppresses both humoral and cell mediated immunity and can result in gastrointestinal upset, pancreatitis, hepatotoxicity, and bone marrow suppression.[26] Metronidazole is an antiprotozoal with immunomodulatory effects but can result in vomiting, anorexia, hepatotoxicity, and central vestibular signs.[27]

Table 20-1. Summary of Drug Regimens for Treatment of Perianal Fistulae

Reference #	Sample size	Medication Regimen	Lesion resolution	Clinical sign resolution	Notes
16	27 GS w/PF & colitis	Pred: 2 mg/kg SID x 2 wks→1 mg/kg SID x 4 wks→1 mg/kg EOD x 8-16 wks	Complete in 1/3 Partial in 1/3	11/16 regardless of lesion resolution	Caution as to GC usage
10		Pred: 3-4 mg/kg SID-BID x 3-6 wks PLUS Azathioprine: 1.5-2.2 mg/kg SID x 2-4 wks OR Metronidazole: 10-15 mg/kg BID	Reasonable success in reducing lesion size and associated pain and inflammation though data is lacking		GCs tapered over weeks to months. Azathioprine tapered to EOD x 4 wks. Caution as to GC and Azath or Metronid usage
19	5 dogs	Metronidazole: 400 mg/dog SID AND Azathioprine: 50 mg/dog SID	Significant improvement with no additional progress after 4-6 wks	Significant improvement in all w/in 2 weeks	Sx at end of regimen followed by addl. 3-6 weeks immunomodulatories. 5/5 dz free 7-10 months post-op

The similarities in clinical appearance between Crohn's disease in humans and canine anal furunculosis led to the discovery that encouraging treatment results can be achieved when affected dogs are treated with the same immunomodulating drug used in human medicine.[2-7,10,14,15,22,28] Cyclosporine acts by reversible inhibition of calcineurin, an enzyme normally partially responsible for cytokine synthesis, among other functions. The end result is inhibition of cell mediated immunity and T-cell (T-helper and T-cytotoxic) activation and proliferation.[10,22] The microemulsion (ME) formulation of this drug (Atopica, Novartis) is given because of improved bioavailability and decreased inter-individual serum levels. Because of delayed absorption when given with food (even with the ME formulation), it is recommended that cyclosporine be administered two hours before or after a meal.[22]

Several reports have shown the benefits of the sole use of cyclosporine in the treatment of anal furunculosis, and several conclusions have been reached: faster remission and higher recovery rates are seen with higher dosages, clinical signs may be more likely to return after cessation of high dose treatment, and longer administration (thirteen weeks) decreases the rate of relapse.[2,4-7,11,14,15,29] Unfortunately, a definitive dosing regimen has not been found. A recent review recommends initially treating at 4 to 8 mg/kg PO q 24h for eight to sixteen weeks until a marked resolution of clinical signs has occurred. At that point, it has been suggested to decrease the dose by 20 to-40% or decrease the frequency of administration to every forty-eight hours with further tapering based on clinical response and lack of recurrence.[10]

Though encouraging results have been obtained with the use of cyclosporine, difficulties still exist as to the appropriate dosage, schedule, and duration of therapy. Initial dose schedules were extrapolated from human medicine where cyclosporine was used to prevent renal allograft rejection. Because of the high doses required to prevent organ rejection and the relatively small margin of safety this drug has in humans (hypertension and nephrotoxicity are not uncommon side effects), dosing adjustments in transplant patients are necessary and are made based on serum trough levels. The treatment of canine anal furunculosis requires lower doses of cyclosporine than is required to prevent organ rejection. In addition, recent studies in dogs with anal furunculosis treated with cyclosporine failed to find a relationship between trough concentrations and treatment efficacy.[5,7] Therefore, though monitoring trough levels in transplant patients assists in fine tuning those treatment regimens, the practice provides no additional information in the treatment of most cases of anal furunculosis in which a favorable clinical response is seen to cyclosporine alone.

Serious side effects are rare with cyclosporine administration in dogs, but long term studies are needed to assess its full effects.[22] Side effects noted in recent clinical reports include hair shedding that may be followed by increased hair growth, gastrointestinal effects (vomiting and diarrhea, inappetance), lethary, and lameness.[2-5,15] The most common side effects, hypertrichosis and vomitting/diarrhea, were mild and resolved spontaneously during treatment or after cyclosporine administration had stopped. Gingival hyperplasia and papillomatosis have also been reported.[28] Though there is an increased risk in humans of developing lymphoma after cyclosporine usage, there are only two case reports in the veterinary literature (one cat after renal transplant surgery and one dog with anal furunculosis) that suggest lymphomagenesis may be associated with cyclosporine administration.[30] There is no evidence that administration of cyclosporine in dogs, or in humans with dermatologic conditions, has been associated with an increased risk of infection.[22]

Unfortunately, cyclosporine is expensive, particularly when treating the large breeds affected by anal furunculosis. By inhibiting the cytochrome P450 system, ketoconazole has been used to decrease the hepatic clearance of cyclosporine resulting in increased serum levels. Lesser amounts of cyclosporine are then needed at a significant cost advantage to the owner. Increases in serum cyclosporine levels are proportional to ketoconazole doses when the latter is dosed between two and twelve mg/kg.[31] Unfortunately, the amount of increase in cyclosporine blood concentration due to hepatic inhibition from ketoconazole is individually variable, necessitating dose adjustments for most patients. This is an indication for measuring cyclosporine serum trough levels. Trough levels can be evaluated by high pressure liquid chromatography (HPLC), fluorescent polarization immunoassay (FPIA) or radioimmunoassay (RIA). These last two assays, though faster and cheaper, use antibodies that cross react with cyclosporine metabolites, and can overestimate the cyclosporine blood concentration. In fact, cyclosporine blood concentrations when measured with FPIA are nearly twice those measured with HPLC. This latter assay is more expensive and less widely available, but more accurate.[22]

A previous review suggests an initial starting dose of ketoconazole at 5-10 mg/kg PO q 24h in conjunction with a moderate starting dose of cyclosporine at 5mg/kg PO q 24h.[10] With resolution of lesions and other clinical signs, the cyclosporine dose is tapered starting six to ten weeks after initiation of therapy. Higher doses may be required in some recalcitrant cases or in more severe, chronic cases. The goal of therapy is the lowest dose and frequency of both drugs that will prevent recurrence of lesions or clinical signs. Some animals may only require topical medication (described below) as maintenance therapy, while others will require life long cyclosporine treatment with or without topical therapy. Trough cyclosporine levels, measured ideally with HPLC, should be assessed if the patient is not or is no longer responding to treatment. Dosing should be increased in these cases if trough levels below 400 ng/ml are found. Serum trough levels to monitor dose reductions are also necessary when signs of cyclosporine toxicosis are noted.

Because large variations (10 to 60%)[4,7] in blood cyclosporine concentrations exist between dogs on the same dose of cyclosporine given both cyclosporine and ketoconazole for the treatment of anal furunculosis, definitive dosing regimens are unavailable, and the above is given as a starting point. However, encouraging results have been reported with the use of this drug combination (Table 20-2).

Side effects noted in clinical reports of combination therapy included vomiting, diarrhea, inappetance, weight loss, hypertrichiasis, hypoalbuminemia, lameness, and gingival hyperplasia. Most effects were transient during initial treatment and resolved spontaneously or with minimal intervention. Those side effects

TABLE 20-2. Results using Cyclosporinte and Ketoconazole for Treatment of Perianal Fistulae

Ref #	Sample Size	Medication Regimen	Response	Long Term	Notes
7	16	CSA 1mg/kg BID Ketoconazole 10mg/kg SID	50% sinus depth reduction and area of ulceration w/in 2 weeks	93% in full remission @ 14 weeks 50% disease free @ 1 year	Dosages decreased to maintain 200 ng/ml trough levels by HPLC. Suggested that starting CSA @ 0.5 mg/kg BID may allow fewer dosage adjustments but still therapeutic serum levels and steady maintenance level
6	12	8K9: CSA 2.5 mg/kg BID Keto 8 mg/kg SID 4K9: CSA 4 mg/kg SID Keto 8 mg/kg SID	100% full resolution of clinical signs in 9 weeks	Full remission in 8/12. 5/8 suffered recurrence @ mean of 12.4 weeks past cessation of tx. 5/5 complete resolution of clinical signs with same tx. Significant improvement in severity of lesions in 4/12 but persistent lesions	CSA dosages adjusted to maintain 400-600 ng/mL (checked monthly). B/c of keto involvement, CSA dose reductions of 50-75% appreciated resulting in savings of 36-71%. Those w/ relapse more likely to have suffered clinical signs longer hinting @ more severe dysregulation of immune system.
4	19	CSA @ 0.5, 0.75, 1, or 2 mg/kg Keto 5.3-8.9 mg/kg BID	Resolution in all within 3-10 weeks	12/19 remained in remission. 4/4 of those with recurrence achieved full resolution after 2 nd course of therapy.	Radioimmune assays weekly w/adjustments to achieve 400-600 ng/mL. Dogs on higher 2 dosages had trough levels persistently above target range indicating that dosages of 0.5-0.75 mg/kg BID may be sufficient. Savings of up to 70% realized compared to earlier study.

which were more recalcitrant resolved with cessation or reduction of administration and were not intolerable.[4,6,7,32] Hepatotoxicity is a suggested side effect of ketoconazole and may be idiosyncratic or dose dependent, though none of the previous reports describe this complication.[33]

Medical Management–Topical

In 2000, Misseghers et al.reported on once to twice daily topical application of tacrolimus (0.1%) to treat canine anal furunculosis in ten dogs.[34] Like cyclosporine, this drug is used to inhibit T-cell activation through inhibition of calcineurin. Tacrolimus is ten to one hundred times more potent than cyclosporine, is absorbed topically better than cyclosporine, and doesn't require systemic levels to be effective. Side effects are typically reported at the same frequency as those of cyclosporine. However none of the animals described in the initial study showed untoward side effects. Five of the ten dogs (50%) achieved full remission of between one and eight months duration after cessation of treatment, and nine of ten (90%) dogs showed complete resolution of clinical signs with at least a 50% reduction in lesion volume. This report suggested that once daily administration of tacrolimus should be considered a low cost alternative to cyclosporine in mild to moderate cases of anal furunculosis or as maintenance therapy after cyclosporine induced remission of disease.

There is little in the literature that describes the concurrent use of both calcineurin inhibitors, but combination therapy should have a role in treatment. One group has reported good results in "normal" cases of anal furunculosis with twice daily application of tacrolimus that was started once tapering of cyclosporine has begun.[10] Anecdotally, the tacrolimus seems to speed cyclosporine tapering. This paper suggests that some patients can be weaned entirely off systemic cyclosporine/ketoconazole and be managed with tacrolimus applied topically every 24 to-72 hours. In very mild cases of disease, tacrolimus alone may be sufficient. Whether topical medication may be required for life long management[10] or should only be continued for four weeks past resolution of clinical signs[34] in these cases is uncertain. If tacrolimus is not used because of client or patient concerns, the lowest dose and frequency of cyclosporine and ketoconazole (or other immunomodulator combination) that controls clinical signs is recommended.

Dietary Management

To my knowledge, there have been no prospective studies which show a definitive response to restrictive diets. However, anecdotally, many authors agree that the introduction of a novel antigen diet is a component of treatment.[10,16,20,25] An association between colitis and anal furunculosis has been suggested.[16] Thirty-three percent (9/27) of dogs with perianal fistulas in a study of 27 German Shepherd dogs with a concurrent diagnosis of colitis experienced complete lesion resolution, 33% experienced an improvement in lesion severity, and the remainder were unchanged[16] when treated with corticosteroids and a novel protein diet. In another study, 50% (9/18) of dogs had histological diagnoses of colitis when they were presented for perianal fistulae. Several theories have been proposed for this association, but our lack of understanding of either disease precludes a definitive etiology without further study.

Summary

Life long medical management can reduce the severity of or prevent the recurrence of clinical signs. Systemic and/or topical medication have shown good results in decreasing the severity of disease. The importance of recheck evaluations should be stressed to owners. Rectal examinations should be performed biannually unless there are clinical problems that recur sooner. Adjunctive surgical intervention should only be attempted after medical options have been explored and owners have been advised of possible surgical complications.

Anal furunculosis has historically been a surgically managed disease. Surgery is still indicated in those rare cases that are completely unresponsive to immunomodulators and in those in which no further response is appreciated despite appropriate drug dosing adjustments. The trend away from surgical therapy has been a result of the high rates of fistulae recurrence and potential serious surgical complications regardless of the technique employed.

Excisional Techniques for Perianal Fistulas

Gary W. Ellison

Introduction

Since the last edition of this text was published, dramatic improvements have been made in the medical management of perianal fistulas to the point that surgical therapy is currently considered a secondary treatment for this confounding disease. Current theory is that the disease may be immune mediated resembling Crohns disease in people. The term "immune mediated proctitis" may be a better term for this syndrome than perianal fistulas. The presence of concomitant inflammatory bowel disease and recent reported success of immunosuppressive therapy with drugs such as oral prednisone, oral cyclosporine, combination oral cyclosporine and ketoconizole, combination oral azathioprine with metronidazole and topical tacrolimus lend further support to this hypothesis. Early infiltration of the circumanal glands with lymphocytes and plasma cells may occur prior to the more traditional secondary histologic changes which include inflammation and necrosis of the apocrine glands, infection of circumanal glands or hair follicles, impaction and infection of the anal sinuses or anal crypts and anal sac infection or abscessation. Ultimately the normal regional anatomy is permanently disrupted and gross lesions include fistulas of the anal sinuses, submucosal fistulas and ruptured anal sacs in addition to cutaneous perianal fistulas. In these advanced cases medical therapy is more likely to fail and surgery is indicated.

Indications for Surgery

Although an estimated 85% to 90% of perianal fistulas show improvement or complete resolution after eight to twelve weeks of immunosuppressive therapy, those lesions associated with anal sac rupture or disruption of the anal sac ducts often will not completely respond, or are subject to recurrence after cessation of appropriate medical therapy. Recurrence rates of 40 to 60% are reported especially in those cases where anal sac drainage is impaired. In the authors experience, residual or recurrent lesions are most often located ventral and lateral to the anus. Surgical excision of fistulas with concurrent anal sacculectomy is indicated in these cases as well as those where large areas of the anal circumference are involved and continued tenesmus or dyschezia with obstipation is caused by anal stenosis. Potential limitations of excision include the inability to remove all of the tracts if they extend too far peripherally and the danger of creating fecal incontinence if the tracts deeply invade the external anal sphincter. However, if an anal stricture is present due to a deep-seated invasion of the external anal sphincter by the fistulas, or if extensive fibrosis has occurred, then incision or excision of the areas of fibrosis is usually necessary for release of the constriction and for relief of painful defecation.

Preoperative Medical Treatment

For recurrent fistulas I prefer to treat the patient for two to four weeks preoperatively with 2 to 3 mg/kg of cyclosporine (Neoral, Novartis NA, East Hanover, NJ) PO every 12 hours or with a combination of 0.25 to 0.5 mg/kg cyclosporine and 10 mg/kg of ketaconazole (Nizoral, Janssen, Titusville, NJ) PO once daily. Pre-treatment CBC and blood chemistries should be drawn to establish baseline values for liver and renal function. Cyclosporine dosages often need to be adjusted to achieve a target range concentration of 200 ng/L on a 12 hour trough serum sample. The goal of presurgical therapy is to reduce existing fistulas to a negligible size and therefore reduce the volume of diseased tissue that needs to be excised. Reduction in diseased tissue will also allow the surgeon to better visualize the involved anal sacs and aid in their complete removal. If perianal fistula disease is chronic in a dog, abdominal radiographs should be taken to rule out the presence of secondary megacolon. Biopsies may be indicated in some cases to rule out neoplastic disease before extensive surgical therapy is performed.

Surgical Technique

The perianal area and tail base are clipped extensively after the animal has been placed under general anesthesia. A thorough digital rectal examination should be performed to determine how much of the rectal circumference is diseased, to identify the severity of anal sphincter stenosis and to determine how far the fistulas extend peripherally. The fecal contents of the rectum are evacuated digitally. Enemas are usually not administered prior to surgery unless significant fecal impaction is present. Culture of the fistulous tracts usually is not warranted since a mixed culture of gram positive cocci and gram negative coliform bacteria are usually isolated. The animal can be positioned in ventral or dorsal recumbency with the tail pulled over the back or below the table, respectively. The rectum is packed with chlorhexidine soaked tampons and routine surgical preparation of the perianal region is performed.

The fistulas and anal sacs are carefully probed with a groove director to determine their extent and depth. When the anal sacs are not diseased, they are removed prior to fistulectomy. More commonly, the anal sacs are ruptured or abscessed, and are best excised concurrently with the fistulous tracts. A circular incision is made around the periphery of the fistulas using a #10 blade, needle tipped electrosurgical unit or surgical laser (Figure 20-46). A plane is established deep to the fistulas and dissection is carried medially toward the anal canal. The dissection plane must stay as close to the fistulas as possible to preserve the external anal sphincter but it is important to dissect deep to the fibrous tracts (Figure 20-47). Hemorrhage is moderate and is controlled with electrocoagulation or laser ablation. Any remaining anal sac lining is carefully dissected from the surrounding fibers of the external anal sphincter with mosquito hemostats or fine dissection scissors (See Figure 20-47 inset). The entire secretory lining of the anal sac must

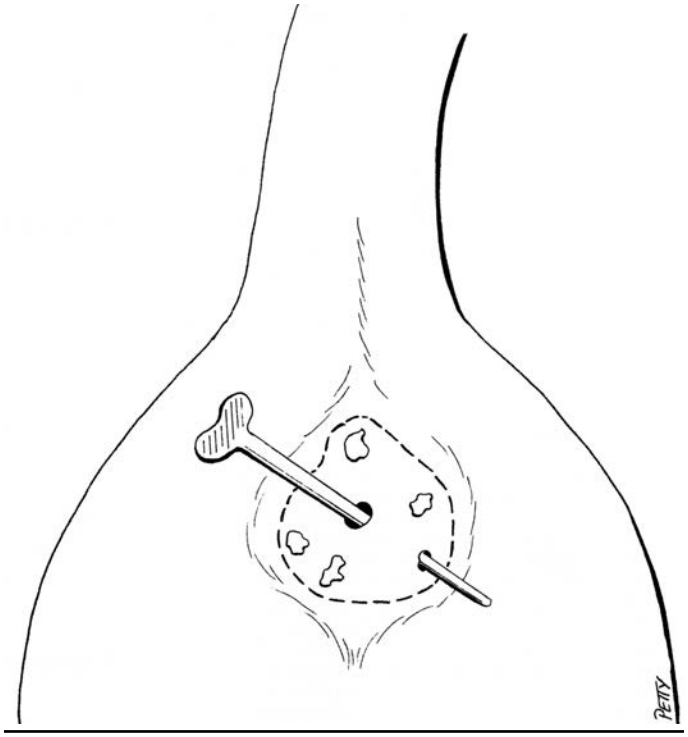

Figure 20-46. A groove director is used to probe the fistulous tracts and also check for patency of the anal sacs. An incision is made around the perimeter of the tracts with a #10 scalpel, needle tipped electrosurgical unit or laser unit.

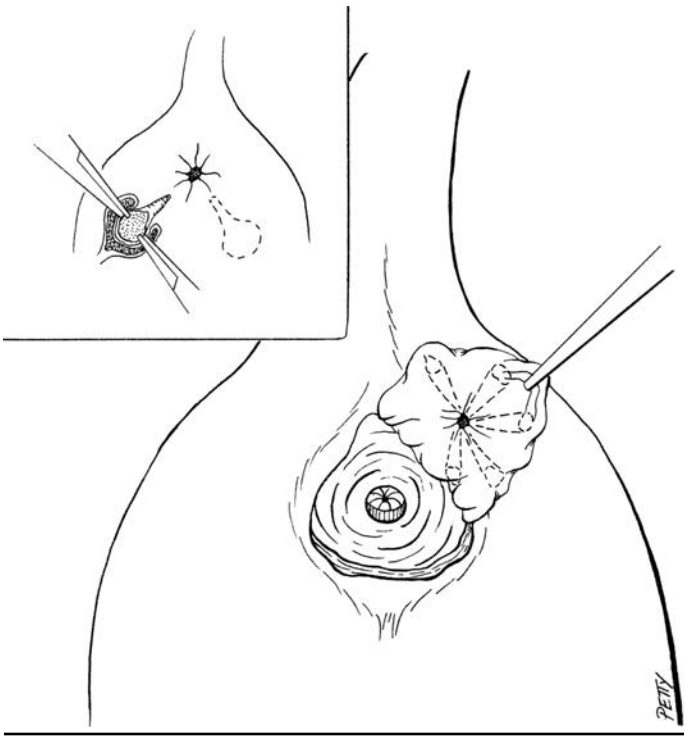

Figure 20-47. The dissection is continued deep to the tracts with efforts at preserving as much of the anal sphincter. Residual anal sacs lining should be removed by blunt dissection using mosquito hemostats or fine tipped scissors (inset).

be removed or sinus tracts may develop postoperatively. The dissection is carried medially to the anal canal and a circular incision is made in healthy rectal mucosa cranial to any rectal or anal sinuses (Figure 20-48). The excised fistulous tracts and a portion of rectal mucosa should be submitted for histopathology to rule out neoplasia and to check for evidence of inflammatory bowel disease. Eight to ten simple interrupted sutures of 3-0 synthetic monofilament absorbable sutures are used to appose the rectal submucosa to the subcutis. The rectal mucosa is then sutured to the skin with simple interrupted 3-0 monofilament nylon or polypropylene sutures (Figure 20-49 and inset). Often there are areas where the fistulas extend so far peripherally that direct skin to mucosal apposition is not possible. In these cases the adjacent areas of skin can be apposed or the wound can be left open to heal by second intention.

Laser excision–A Nd:YAG contact-tip laser has been used to successfully treat perianal fistulas. A frosted, synthetic sapphire tip and a continuous impulse of 13 to 15 watts was used to excise the fistulas, and the wound was closed primarily. Anal tone was reduced, flatulence was increased in 60% of the dogs, and 20% developed fecal incontinence. However, fecal incontinence when present was effectively managed by means of diet modification. The overall success rate for resolution of fistulas was 95% during a mean follow-up time of 22.9 months. Surgical treatment by laser excision of fistulas was particularly effective in relieving pain in those dogs with preexisting anal stenosis. Other authors have successfully used the CO_2 laser for fistulectomy.

Postoperative Care and Complications

Dogs may experience significant postoperative pain the day of surgery and injectable morphine, hydromorphone or bupivacaine or morphine epidural analgesia is often prescribed in addition to injectable NSAIDS (See Chapter 9). NSAIDS should not be administered to patients that have recently received prednisone. Pain

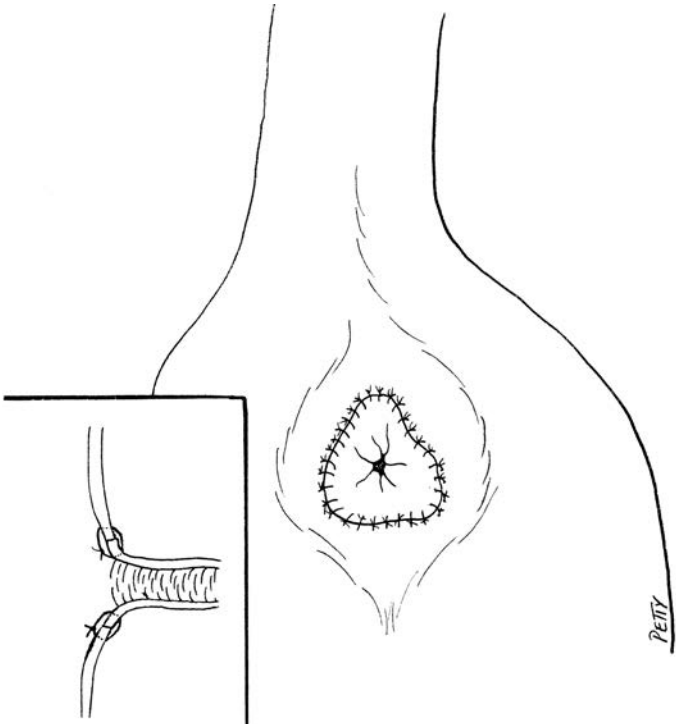

Figure 20-49. After apposing the deep subcutaneous tissues with simple interrupted sutures the rectal mucosa is apposed to the skin with simple interrupted sutures. It is important to closely approximate the rectal mucosa with the skin *(inset)*.

usually resolves rapidly and often within 48 hours animals are less painful than they were preoperatively. Drainage of serosanguineous fluid from the wound edge is expected for several days. Perioperative antibiotics may be indicated since fecal contamination may occur during surgery. Intravenous cefazolin (22 mg/kg IV every 8 hours) in combination with metronidazole (15 mg/kg IV every 8 hours) is initiated prior to surgery and continued for 24 hours. Oral cephalexin (10 mg/kg every 12 hours) and metronidazole (15 mg/kg every 12 hours) is then continued for five days postoperatively. The area is gently cleaned twice daily and sutures are removed in 10 days. Partial wound dehiscence is not uncommon. If wound dehiscence occurs, it is managed by local wound flushes and parenteral antibiotics as needed. Most open wounds heal by second intention in two to three weeks. Stool softeners are only used if preoperative constipation was present. Various degrees of fecal incontinence or flatulence may occur after the procedure. Fecal incontinence is usually less common with first time surgical procedures, but tends to occur more commonly when multiple procedures have been performed. When present, fecal incontinence is often successfully managed by feeding diets with high digestibility. The reported long-term success rates of excision techniques varies from 46 to 95%. However, many animals undergoing surgery have had other procedures performed prior to the excision technique. Postoperative anal strictures are rare with this technique. Periodic clipping and daily cleaning of the perianal region should be performed by the owners during the remainder of the dog's life. All dogs should undergo reexamination every two months to look for early signs of recurrence. Recurrent superficial ulcerations when treated early, usually respond to two to four weeks of cyclosporine therapy without further surgery.

Liver, Biliary System, Pancreas

Hepatobiliary Surgery

Robert Martin and Mike King

Liver Surgery

Anatomy

The liver is the largest glandular organ in the body, consisting of between 3% and 5% of bodyweight in dogs and cats. Blood draining from the gastrointestinal tract passes through hepatic cells prior to returning to the general circulation of the body.

Positioned in the cranial abdomen, the canine liver is bound by the diaphragm cranially, and the stomach, intestines and spleen caudally, and lies transversely within the abdomen, with a slight majority of its mass located on the right of midline. The organ is divided into 6 lobes: left lateral, left medial, quadrate, caudate, right medial and right lateral (Figure 21-1A). The caudate lobe is further divided into caudate and papillary processes and is positioned transversely across the abdomen. The papillary process extends to the left where it lies in the lesser curvature of the stomach and the caudate process to the right where it contacts the cranial aspect of the right kidney. The portal vein lies ventrally and the vena cava dorsally to the caudate lobe. The quadrate lobe is situated between the right medial and left medial lobes, with the gallbladder located in a fossa formed between the quadrate and right medial lobes.[1,2]

The cranial surface of the liver follows the curve of the diaphragm, and the right and left coronary ligaments attach it to the diaphragm caudolateral to the vena cava. The right and left triangular ligaments extend from their respective crus of the diaphragm, attaching to the adjacent lateral lobes. The visceral surface consists of several visceral impressions; the most prominent is to the left of midline, formed by the stomach. The dorsal border extends more caudally than the ventral border, with the cranial pole of the right kidney located within a renal impression formed on the caudate process of the caudate lobe. The normal liver does not usually extend caudal to the costal arch.[1,2]

Blood supply to the liver arises from both the hepatic artery (a branch of the celiac), and the portal vein (formed from tributaries that drain the gastrointestinal tract, pancreas, and spleen). Branches of both these vessels supply the connective tissue of the liver as they divide and course through the parenchyma ending at the hepatic sinusoids. Blood is carried away from the liver first via central veins of the hepatic lobules which then form hepatic veins that finally empty into the vena cava. Innervation of the liver is maintained by both periarterial plexuses (sympathetic) and the vagal trunks (parasympathetic).

Bile is secreted by the hepatocytes into canaliculi within hepatic lobules. Canaliculi drain into interlobular ducts which unite to form lobar ducts that exit from each liver lobe as extrahepatic bile passages termed hepatic ducts. Hepatic ducts may vary in number and terminate in the bile duct (Figure 21-1B).

In addition to the production of bile the liver has other functions, including metabolism of protein, fat, carbohydrates, as well as many drugs. Patients with liver disease may suffer from hypoproteinemia, hypoglycemia, and decreased levels of clotting factors. Patients with liver disease to be treated surgically are less than ideal anesthetic candidates, as hypotension, increased risk of hemorrhage, and more profound reaction to many anesthetic agents may be seen. Preoperative hemogram, serum chemistries, strict attention to intravenous fluid support (often with

colloids to maintain osmotic pressure in a hypoalbuminemic patient) and careful attention to hemostasis are essential as is formulation of an appropriate anesthetic protocol.

Biopsy Techniques

Cytological evaluation of samples obtained by fine needle aspiration can be useful in diagnosis of some diffuse diseases. Care should be taken in the interpretation of such samples because the accuracy of liver cytology is markedly less than that of histopathological evaluation, especially in inflammatory hepatic disease.[3-5]

Ultrasound-guided needle biopsy is a commonly used technique for percutaneous liver biopsy (Tru-cut biopsy instrument).[6,7] This allows the clinician to obtain multiple samples for histopathological assessment with low risk of complications such as excessive hemorrhage.[8] Needle biopsy samples are not as accurate in yielding a diagnosis as larger wedge biopsies and laparoscopic liver biopsy is currently the best percutaneous technique.[9] Laparoscopic biopsy allows direct visualization of the liver, especially when the disease is not generalized, and provides for a larger sized tissue sample.[7] General anesthesia, specific equipment and expertise is required for the procedure.

A variety of techniques have been described for obtaining a liver biopsy during celiotomy. In cases of generalized disease or where a lesion exists at the apex of a lobe, the guillotine method is useful.[6,7] A single loop of absorbable suture material is placed around the tip of a lobe and tightened (Figure 21-2A and B). The suture cuts through the parenchyma and tightens around the resulting pedicle of tissue which contains any vessels large enough to require ligation. A scalpel or dissecting scissors are used to transect the liver tissue distal to the ligature, producing the biopsy sample. A 2 to 3 mm tag of tissue should remain distal to the suture to avoid it loosening and becoming dislodged when the biopsy sample is excised. The edge of the lobe at the transection site should be examined for excessive hemorrhage. Hemorrhage can be controlled with direct electrocoagulation or placement of additional ligatures. For a larger biopsy sample along a lobe margin, a series of multiple interlocking sutures or a mattress suture pattern can be used. These can provide greater hemostasis than a single encircling ligature.[6] The sutures should be pre-placed across the lobe or around the lesion and tightened before removing the biopsy sample.

In cases where a biopsy of a specific region or lesion is required, or when the disease process is not located at the margin of a lobe, a punch biopsy may be useful.[6,7] Once the region of interest has been identified on the convex (ventral) surface, a 6 mm cutaneous biopsy punch is directed into the lesion, taking care to not penetrate more than 50% of the thickness of the lobe. This avoids larger hepatic veins situated near the concave surface of the lobe. To complete the biopsy the punch is positioned at a slight oblique angle to the direction it was first inserted and then driven a short distance further. The resulting defect in the liver defect can be filled with absorbable gelatin foam (Gelfoam, VetSpong) or omentum to contain hemorrhage. Placement of a mattress suture around the defect can also provide hemostasis, if necessary.

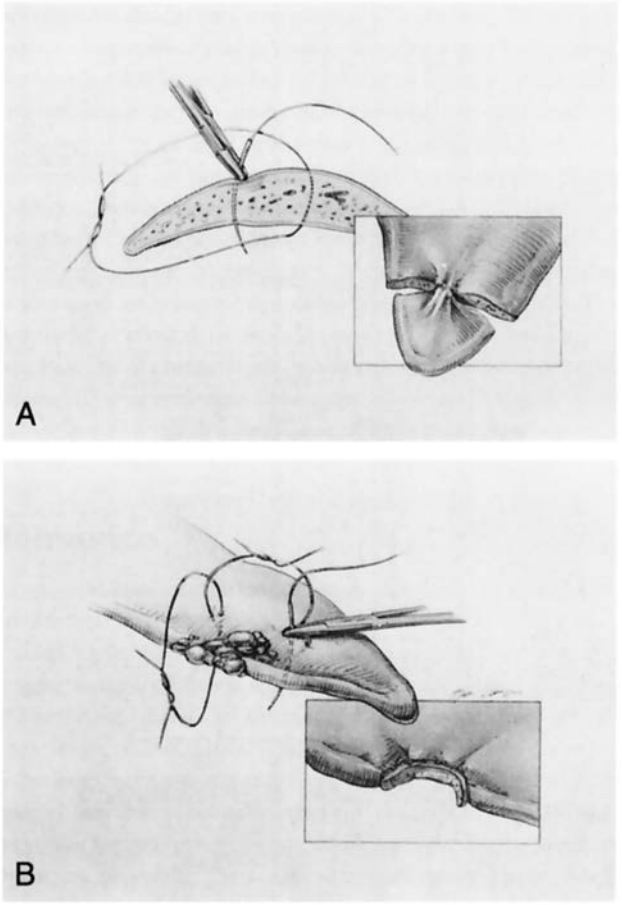

Figure 21-2. Interlocking sutures of an absorbable material are pre-placed to isolate the proposed biopsy site. Although two sutures are often adequate for biopsies obtained from the tip of the liver lobe **A.** multiple sutures may be needed for other areas **B.** The sutures are tightened and tied, and the biopsy sample is removed by sharply incising the tissue a few millimeters from the suture line.

Regardless of technique employed, care is taken to avoid crushing the sample with tissue forceps or other instruments since this can cause histological alterations, possibly affecting the diagnosis.

Liver Lobectomy

Complete or partial liver lobectomy is indicated in a variety of clinical situations such as hepatic abscess, neoplasia, lobe torsion, and vascular alterations.[6,7,10,11]

For partial lobectomy the liver capsule is sharply incised along the planned point of resection. The parenchyma is bluntly dissected using a Bard scalpel handle, Doyen clamp, or digital pressure, leaving isolated vascular structures intact.[6,7] Small structures can then be occluded by electrocoagulation while larger vessels (> 2 mm in diameter) should be ligated with suture or vascular occluding staples before transection.[7] Surgical suction is useful in maintaining a hemorrhage-free field during dissection, allowing better visualization of vessels that require ligation. More pronounced hemorrhage can be controlled by temporary

vascular inflow occlusion using the Pringle maneuver.[12] A finger is passed around the free edge of the lesser omentum into the epiploic foramen where the hepatic artery, portal vein, and bile duct can be compressed between the thumb and forefinger. Occlusion of the hepatic artery and portal vein can be maintained safely in this manner for up to 15 minutes while the hemorrhage is controlled.[12] A bulldog vascular clamp can be used to occlude these vessels, providing less interference to surgical exposure of the liver. Upon completion of a partial lobectomy the exposed parenchyma should be free of hemorrhage. Omentum can be sutured over the raw hepatic surface, though this is not necessary as omental adhesions will form spontaneously.[7]

Partial liver lobectomy can also be performed with specialized surgical stapling equipment, though this is dependent on lobe thickness and width.[7,13,14] The Thoracoabdominal (TA™) series of stapling instruments were designed for use in pulmonary and gastrointestinal surgery and are also effective for hepatic surgery.[7,13] Stapling devices are faster, provide more complete hemostasis, and are thought to cause less tissue inflammation than dissection and ligation techniques.[13] The TA stapling instruments use preloaded disposable cartridges that produce a staggered double row of staples 30, 55, or 90 mm in length.[14] The appropriate size instrument is selected based on lobe width at the desired point of transection. The liver capsule is incised, and the stapler is used to crush the parenchyma, compressing vessels and bile ducts between the jaws of the instrument. The staples are discharged and the parenchyma excised distal to the staple line.[7,14] Application of the TA stapler can be simplified by crushing the liver parenchyma digitally or with a crushing instrument (Carmalt or Doyen intestinal forceps), leaving the vascular pedicle intact for stapling.

Complete liver lobectomy can be a challenging procedure. For complete lobectomy of the left liver lobes, the triangular ligament is transected, allowing surgical access to the hilus. In small dogs and cats the tissue around the hilum can be crushed using digital pressure, and a single encircling ligature placed, prior to transection of the lobe distal to the suture.[6,7] Mass ligatures are not recommended for use in central or right division lobectomy or in larger dogs for left liver lobectomy as severe hemorrhage can occur should the ligature become dislodged.[6,7] Complete lobectomy of central or right division lobes requires dissection of hepatic parenchyma from the caudal vena cava. Care must be taken to not damage this structure. The lobe must be freed from attachments to surrounding tissues or organs, and any parenchyma remaining at the hilus is crushed. If the right medial and/or quadrate lobes are to be removed, the gallbladder has to be preserved.[7,14] Once the vascular supply and biliary duct(s) of the lobe to be removed have been identified, they should be isolated and individually ligated. The lobe is then transected distal to these ligatures and removed. The hilus is examined for any signs of persistent hemorrhage and additional ligatures placed, if necessary.

Use of surgical stapling devices can avoid the need for individual dissection and ligation of hilar vessels. Once the lobe has been freed from its attachments the instrument can be applied at the hilus and the staples deployed. After the lobe has been excised and the stapler removed, the hilus should be assessed for any persistent hemorrhage which may require additional attention with suture or large vascular clips.[7,13,14]

Extrahepatic Biliary Tract Surgery

Anatomy of the Extrahepatic Biliary System

The gallbladder, a pear-shaped structure located between the quadrate and right medial liver lobes, varies in size depending on the size of the dog. Cats have a relatively consistent gallbladder size but are more prone to anatomic variations. In a beagle-sized dog, the gallbladder measures 5 cm long and 1.5 cm wide at its widest area with an approximate 15 ml volume storage capacity of bile.[15] Anatomic regions of the gall bladder include a fundus, body, and a neck that continues as a cystic duct, the first structure of the biliary duct system (Figure 21-3).[15] The bile duct is the main excretory channel to the duodenum that begins where the cystic duct joins with the first biliary tributary (hepatic duct) from the liver.[15] Four hepatic ducts drain functional divisions of the liver and empty into the bile duct along its free portion (5 or more cm) as it courses to the duodenum through the hepatoduodenal ligament and lesser omentum (Figure 21-4).[7,15] The central liver division (right medial and quadrate lobes) usually contribute 2 hepatic ducts that empty into the origin of the bile duct along with the cystic duct. The left division (left lateral and medial lobes, papillary process of the caudate lobe) usually gives rise to a single hepatic duct that enters midway along the free portion of the bile duct. The right division (right lateral and caudate lobes) usually gives rise to a single duct that is the last hepatic duct to enter the bile duct before it enters the duodenal wall where it courses for about 2 cm through the duodenal wall as the intramural portion of the bile duct. The intramural bile duct is surrounded by a double layer of smooth muscle as it passes terminally into the major duodenal papilla through a smooth muscle funnel. Bile is discharged into the duodenal lumen primarily as a result of duodenal motility with digestion but also by a coordinated active gallbladder contractile process.[7,15] Variations in hepatic duct number (usually 3 to 5), liver division drainage, and hepatic duct entry into the bile duct can occur.

The frequent use of abdominal ultrasound (U/S) examination in dogs and cats has led to identification of asymptomatic biliary conditions such as gallbladder sludge (up to 50%), choleliths (about 5%), mucocoele (1 to 2%), and gallbladder wall thickening (1 to 2%) as incidental findings in dogs that do not have clinical signs of biliary tract disease.[a] Abnormal ultrasound findings can be significant if accompanying clinical signs and laboratory abnormalities (hemogram, serum chemistries) support a diagnosis of biliary tract obstruction. Only when ultrasonographic evidence of biliary obstruction (dilatation of the extrahepatic biliary system) is seen in a clinically ill patient does the role of infection become a likely contributor to biliary tract disease.

Surgical manipulation of the extrahepatic biliary tract is only part of the overall management of patients with clinical evidence of an extrahepatic biliary tract disease. The decision for surgical exploration should be made cautiously in clinically ill patients where morbidity has been induced by a biliary obstructive process (cholecystitis, inspissated bile, cholelithiasis, mucocoele,

[a] Personal Communication, Dr. Martha M. Larson and Dr. Colin C. Carrig

neoplasia, fibrosing pancreatitis, other).[7,16] The selection of a surgical procedure and timing of intervention become critical factors that often affect patient survival. Stress of disease, anesthesia and prolonged surgery in these patients frequently results in death. **Cholecystocentesis** with U/S guidance is a minimally invasive procedure that can provide temporary biliary decompression for management of biliary obstructive disease in a sick patient.[17] If patient stabilization can be achieved by fluid and electrolyte replacement, appropriate antibiotic administration, and nutritional support, then definitive surgical management can be undertaken with a better prognosis. In diseases such as cholecystitis with gallbladder necrosis and septic peritonitis, the surgeon may have little choice but to operate on an unstable patient. Even these patients could possibly be better managed by ingress/egress abdominal infusion of warm balanced electrolyte fluids after placement of a multifenestrated catheter for fluid retrieval. These patients have a guarded prognosis with immediate surgical intervention whereas stabilization over a period of hours or days prior to surgery might improve survival. In stable patients that show only mild to moderate clinical signs of biliary tract disease, surgery can be performed before the patient status deteriorates.

Surgical diseases of the extrahepatic biliary system can be divided into traumatic or obstructive processes. While sharp or missile-penetrating trauma can lacerate the biliary system, blunt force trauma (automobile, kick) is the most frequent cause of traumatic disruption. A delay of days to weeks between blunt trauma and recognition of bile peritonitis is a common occurrence.[7] Animals are either presented in a stable state with abdominal effusion (chemical peritonitis only) or with varying degrees of illness and abdominal effusion (mixed chemical/bacterial peritonitis likely). Abdominocentesis is most often diagnostic when bilious fluid (green-tinged) is aspirated. The Ictotest® (Bayer HealthCare, Elkhart, IN) reagent tablets for detection of bilirubin in urine can be used to confirm the presence of bile in an abdominal fluid aspirate as can the less sensitive Multistix® 9 and Bili-Labstix® reagent strips (Bayer HealthCare, Elkhart, IN) used for standard urinalysis screening of bilirubin. Direct measurement of the bilirubin level may also be performed; if the bilirubin concentration of the

effusion is at least twice that of peripheral blood, a diagnosis of biliary disruption is confirmed.[7] Surgical exploration is indicated either immediately in a stable patient or should be delayed (hours) while steps are taken to improve the unstable patient's surgical status. Most frequently, omentum will have formed adhesions in the vicinity of the biliary rupture that must be broken down to identify the site of rupture to determine what appropriate surgical steps should be taken.[16]

Bile peritonitis can also occur following gallbladder rupture from obstruction or infarction.[7,18] These patients are often very ill and have a high mortality rate as a result. Surgical timing should coincide with an initial delay while attempts are made to improve patient stability over a period of hours, not days. A delay in owner recognition and subsequent presentation of a pet becoming ill from a biliary obstruction with bile peritonitis usually exists and time becomes a critical factor for patient survival in making the diagnosis and electing surgical intervention.[18]

Extrahepatic biliary obstruction occurs when disease processes interfere with the normal flow of bile from the liver and gallbladder into the duodenum. Biliary obstruction without rupture can occur from benign or neoplastic causes (benign – pancreatitis with periductal fibrosis[7,8] edema, and/or abscess obstructing the bile duct, sludge, mucocoele, choleliths/choledocholiths, cysts, parasitic [flukes in cats in tropical zones], congenital cysts or atresia, and granulomas; inspissated bile, suppurative cholangitis; neoplastic–gastric, pancreatic, duodenal, biliary, and hepatic).[7,16] Obstruction may be partial or complete, and intermittent or continuous. Consequences of extrahepatic biliary tract obstruction include impaired function of the reticuloendothelial system, increased absorption of endotoxins into the portal and peripheral circulations, depletion of coagulation factors, acquired platelet dysfunction, and an increased incidence of postoperative renal failure.[17] Bile salts enhance absorption of the fat-soluable vitamins (A, D, E, and K) and chronic biliary obstruction can result in prolongation of coagulation related to vitamin K-dependent coagulation factor deficiencies (Factors II, VII, IX, and X).[7,17] However, obstruction-related coagulopathy is unlikely in most cases of biliary obstruction in dogs and cats.[7] Parenteral vitamin K administration should be considered for 8 to 12 hours prior to surgery when PT and PTT are prolonged.[7,17,19] If coagulation is abnormal at the time of surgery, fresh whole blood (cross-matched) or fresh frozen plasma should be administered.[7] Clinical signs include icterus, abdominal pain, vomiting, anorexia, depression, fever, dehydration, acholic feces, and weight loss.[17] Most patients are debilitated on presentation from a chronic obstructive process.[7,16,17] In general, diseases involving the gallbladder should be treated with cholecystectomy rather than cholecystotomy with content evacuation unless the gallbladder wall is healthy and it is required for construction of a bile flow diversion procedure.

Primary obstructive diseases of the bile duct can be treated primarily (choledochotomy or cholecystotomy for stone removal, with anthelmintics for flukes in cats, using stents for temporary obstructions and primary repair) or by bile flow diversion (neoplasia, traumatic avulsion, fibrosing pancreatitis and granulomas). Either stents or bile flow diversion procedures can be used for both palliative and curative intent. A bile sample is always taken for routine culture and antibiotic sensitivity testing and a liver biopsy is standard for biliary tract surgery. Moist laparotomy sponges are routinely used to pack around the surgical site to contain bile spillage. Gauze sponges with a radiopaque marker (Vistec X-ray Detectable Sponges, Tyco Healthcare/Kendall, Mansfield, MA) are counted immediately prior to a celiotomy and immediately prior to closure to prevent leaving a sponge in the abdomen. Abdominal lavage with warm physiologic fluid is a standard part of surgical management of extrahepatic biliary tract disease prior to celiotomy closure. The surgeon should consider use of supplemental feeding techniques postoperatively (esophageal feeding tube, gastrostomy tube, jejunostomy tube; jugular catheter for total parenteral nutrition) to promote nutritional health. Laparoscopic equipment, if available, can be used efficiently to visualize the extrahepatic biliary system and assist in performing temporary decompression procedures, liver biopsy, or cholecystectomy.

Ultrasound-guided Percutaneous Cholecystocentesis

Goals of percutaneous cholecystocentesis are to provide rapid preoperative relief of jaundice, to allow control of biliary sepsis, and to allow time to improve the nutritional status of the patient before definitive surgery, especially in severely ill patients.[17] Evidence of a ruptured gallbladder is a contraindication for percutaneous cholecystocentesis. Recent reports of percutaneous cholecystocentesis have demonstrated the value of temporary decompression in patients until stabilized by fluid, electrolyte, antimicrobial, and nutritional management, resulting in a more favorable risk/benefit ratio for a successful surgical outcome.[19] Repeated cystocentesis can eliminate the need for definitive surgery in acute, temporary obstructions (e.g. acute pancreatitis) that resolve after intermittent biliary decompression.[17,19] An 18- or 20-gauge, 3.5 inch spinal needle (Becton Dickinson, Franklin Lakes, NJ), is easily inserted into a dilated gallbladder under U/S guidance and usually has a large enough internal diameter to allow aspiration of tenacious bile without leaving a large hole that results in excessive bile leakage once the biliary tract is decompressed and the needle is removed. Leakage always occurs to some degree and resulting morbidity is partially dependent upon patient status, amount of bile leakage, and bile sepsis. Daily or even twice daily cholecystocentesis should be employed over 3 or more days in sick patients with biochemical and ultrasonographic evidence of obstructive biliary tract disease until patient stability can be achieved to improve the prognosis for surgical intervention.

A Cook™ spiral catheter is attractive as a temporary percutaneous implantable catheter for use over several days in selected patients to minimize the necessity of multiple sedations and percutaneous needle placements but its use for percutaneous cholecystocentesis has not been reported. Accordion-type catheters have been described for use as an indwelling catheter after percutaneous placement.[17] An esophageal feeding tube should also be considered for nutritional support in the initial preoperative management of these patients.

Hepatic Duct Ligation

Avulsion of a single hepatic duct can occur following blunt abdominal trauma. Bile peritonitis results and a significant delay (10 to 20 days) between the time of trauma and onset of clinical signs is common.[7,16] Surgical management usually involves ligation of the avulsed duct.[7] Marked elevation in serum alkaline phosphatase will result (usually present with bile peritonitis), peaking at 10 to 14 days, and declining subsequently.[20] In some cases, an auxiliary retroportal network of bile ducts will develop to drain bile from the affected liver lobe (s) whereas, in other cases, diffuse microscopic biliary cirrhosis results.[7,16,20] If the avulsion is directly off the bile duct (often), either the bile duct tear is oversewn with 6/0 monofilament suture with or without a stent or the bile duct is ligated and a bile flow diversion procedure is performed.[7,16]

Tube Cholecystostomy

In situations where the clinician does not have the capability of providing frequent cholecystocentesis, tube cholecystostomy can be employed as a percutaneous placement or by relatively quick surgical intervention to achieve biliary decompression without performing a prolonged definitive corrective procedure (Figure 21-5).[16,17,20] Because surgical time can be a critical factor in a patient's survival, tube cholecystostomy should be selected only as a temporary procedure for rapid surgical biliary decompression until patient stabilization permits a definitive correction of extrahepatic biliary tract obstruction. The Hawkins needle-guide system (22-ga cannulated needle with stylet and guidewire; Cook, Inc., Bloomington, IN) and a 6.5-Fr polytetrafluoroethylene self-retaining accordion catheter with side holes has been described for percutaneous placement through the right abdominal wall caudal to the costal arch.[17] The catheter is secured to a Tuohy-Borst fitting and functions as a self-retaining catheter.[17]

A right paracostal celiotomy provides direct access to the gallbladder but ventral midline celiotomy is the more common approach for biliary surgery. Following creation of a cranial midline celiotomy, the falciform ligament is separated but not removed to minimize surgical time and blood loss. A self-retaining retractor (Gelpi for small dogs and cats; Balfour [pediatric and standard]) is used most efficiently to maintain body wall retraction for access to the gallbladder. A cutaneous incision is made ventral to the tip of the 13th rib on the right lateral body wall and a hemostatic forceps (Crile, Kelly, mosquito) is pushed with its tip from intraabdominal toward the skin incision. A Bard scalpel blade is used to sharply incise over only the tip of the forceps until its jaws pass completely through the body wall at that site. The tip of a 7- to 14-Fr balloon catheter (Foley catheter, Tyco Healthcare/Kendall, Mansfield, MA) or mushroom-tipped catheter (Bard Urological Catheter, CR Bard, Inc, Covington, GA; excise the tip of the mushroom catheter to improve bile drainage) is grasped with the forceps and pulled through the body wall and into the abdomen. The catheter is then passed through a layer of omentum.[7,16,17] Avoid bunching omentum such that it impairs surgical manipulation of the gallbladder. Using 3/0 monofilament absorbable suture material, a pursestring suture is placed in the

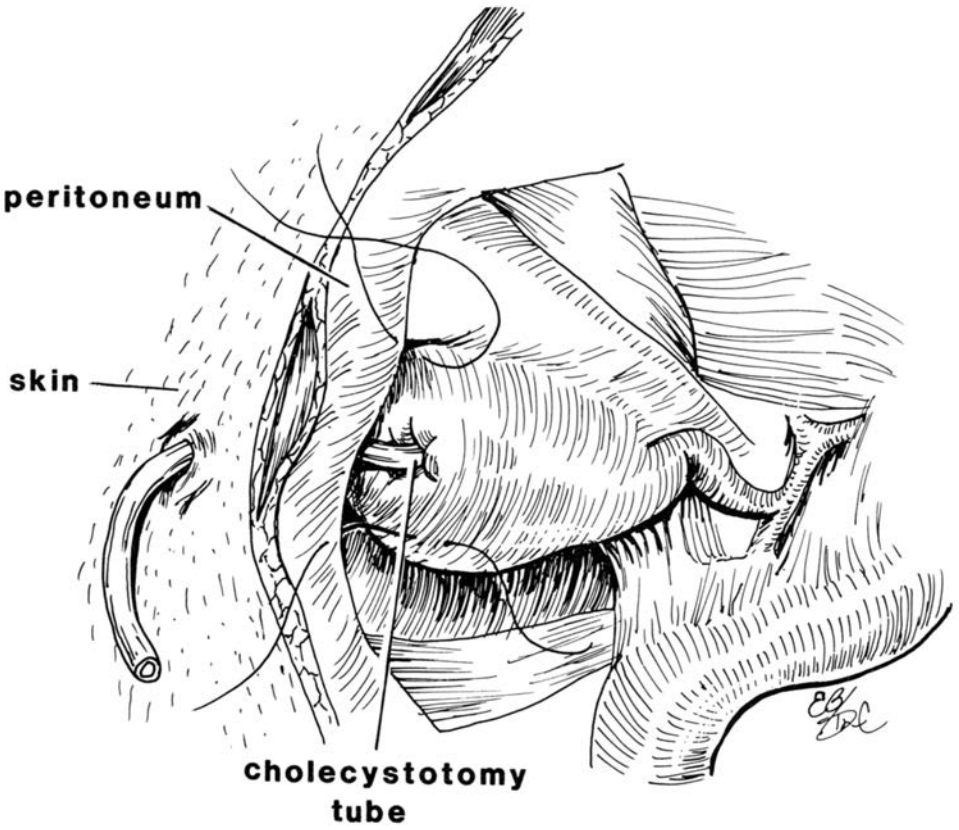

Figure 21-5. A cholecystostomy tube is maintained in the gallbladder with a pursestring suture. Two (of five or six) chromic catgut sutures are placed through the serosa of the gallbladder and peritoneum at the place of exit through the skin.

fundus of the gallbladder. The gallbladder is not dissected from its hepatic fossa[7,16] nor is it necessary to pexy the gallbladder fundus to the body wall at the site of tube entry into the abdomen.[7] Once the pursestring suture is placed, a stab incision (caution to avoid cutting the pursestring suture) is made with an 11 Bard blade into the center of the pursestring suture and bile is aspirated using suction. Alternatively, a large bore needle (14 gauge or teat cannula) connected to a 35 ml syringe can be introduced into the gallbladder from inside the pursestring suture to aspirate bile sufficiently to avoid leakage when the cholecystotomy is made for catheter tip introduction. Insert the catheter tip, inflate the balloon with sterile saline if a Foley® catheter is used, and tie the pursestring suture securely. Using a 4mm skin biopsy punch, take a liver biopsy from the ventral surface of a liver lobe, place a gelatin foam hemostatic sponge (Gelfoam®, Upjohn Company, Kalamazoo, MI; VETSPON®, Ferrosan A/S, Soeborg, Denmark) plug in the biopsy site to control hemorrhage, and close the celiotomy wound with an appropriate size absorbable monofilament suture material in a simple continuous pattern. The tube is secured to the skin at the exit site using 2/0 nylon in a finger-trap suture pattern. Avoid placing excessive external tension on the tube. The tube is occluded (use a 3 ml syringe placed into the tube end) and bandaged to the dorsal aspect of the patient for easy access for intermittent drainage multiple times daily. Gravity flow into a sterile collection system can also be used. The wound at the tube exit site is cleaned daily. The procedure should be accomplished in about 15 minutes in an attempt to minimize patient morbidity.

If the bile is not septic and the patient is eating or being fed through a tube (esophagostomy, gastrostomy), collected bile can be returned to the patient in gelatin capsules or directly into the tube to support digestion of dietary fats if prolonged drainage is anticipated.[7,16,20] In cases of temporary bile duct obstruction, biliary tract patency can be determined with cholangiography by injecting radiographic contrast media (**Conray® 400**) through the tube and into the gallbladder, taking a radiograph immediately after injection. If biliary patency is confirmed, the patient is sedated and the tube removed by firm traction five or more days postoperative without concern for bile leakage into the abdomen.[7,16] If at the time of tube placement the surgeon anticipates tube removal without further definitive biliary tract surgery, a balloon-tipped catheter (Foley catheter, Tyco Healthcare/Kendall, Mansfield, MA) is preferred since it can be deflated and more easily removed by traction than a mushroom-tipped catheter. The omentum forms a fibrous tract around the tube that collapses and seals off the gallbladder stoma after the tube is extracted. The cutaneous stoma is cleaned daily and allowed to heal by second intention.

After stabilization of a patient requiring definitive biliary surgery, the tube is removed under direct visualization following a second celiotomy. Tube cholecystostomy does not hinder subsequent cholecystectomy or biliary diversion using the gallbladder for a cholecystoenterostomy. In either procedure the tube should be cut several cm distal to the pursestring suture site to extract it externally from the body wall. The tube stump can be used to apply traction while the surgeon dissects the gallbladder from its hepatic fossa.

Choledochal Tube Stenting

Use of a choledochal tube stent has been previously described in individual case reports in the veterinary literature and in experimental studies however only recently has its use in a series of dogs with clinical biliary tract obstruction been reported, including long-term outcome.[7,21] Indications include short-term stenting for reversible disease processes (acute pancreatitis with temporary obstruction), internal support after primary repair of bile duct trauma, palliation of bile duct obstructing malignancy, and drainage of an obstructed bile duct prior to definitive surgical management in the severely compromised patient.[21] We prefer tube cholecystostomy over choledochal tube stenting for temporary decompression of biliary obstruction in the severely compromised patient because tube cholecystostomy is a more rapid surgical technique that does not require an enterotomy. Advantages of choledochal tube stenting include decompression for temporary obstructive diseases (pancreatic inflammation, edema, or abscesses) without altering the normal anatomic features of the biliary tract, support for primary repair of a bile duct tear, and possibly preventing stricture during the early phases of healing (controversial).[7,21]

An antimesenteric duodenotomy is made 3 to 6 cm distal (aborad) to the pylorus over the major duodenal papilla. A red rubber catheter (Feeding tube, Tyco Healthcare/Kendall, Mansfield, MA) is used because of its availability in a variety of sizes to accommodate variable diameters of a bile duct opening.[21] An appropriate diameter catheter is selected and passed retrograde from the bile duct opening at the major duodenal papilla. The biliary tract is flushed with a balanced electrolyte solution or sterile saline (0.9% NaCl) solution. If patency can be established, either by flushing through the stent only or by concurrent removal of choledocholiths/cholecystoliths through a choledochotomy, cholecystotomy or cholecystectomy, the stent is left with its tip midway in the free portion of the bile duct. The remaining tube is cut to leave 3 to 5 cm of stent extending through the major duodenal papilla and into the duodenal lumen. The stent is secured in place by passing a monofilament absorbable suture through the stent wall and through the submucosa of the duodenal wall just distal (aborad) to the major duodenal papilla and tying the suture routinely.[21] A monofilament nonabsorbable suture material should be used when a stent is placed for palliation of malignancy. Because of likelihood for stent occlusion to occur postoperatively, removal of the tip of the red rubber catheter while preserving the side openings should be considered even though bile can be expected to flow freely around the stent and into the duodenum.[21] The duodenotomy is closed routinely. The stent can be expected to pass through the feces months later or it can be electively removed by endoscopic retrieval 3 to 6 months later after clinical and biochemical evidence of biliary tract obstruction has resolved.

An alternate placement of a red rubber catheter stent is by direct introduction through the body wall and duodenum and through the major duodenal papilla into the bile duct. A large bore needle is passed from within the abdominal cavity through the right body wall at a point equidistant between the tip of the last rib and ventral midline. The tip of an appropriate size red rubber catheter is passed from outside into the needle lumen and into

the abdomen. The needle is removed from the body wall and catheter and it is next passed from the lumen of the duodenum 5 to 10 centimeters distal (aborad) to the major duodenal papilla (at a point in the descending duodenum that can be easily approximated to the right body wall) through the bowel wall on the antimesenteric surface of the duodenum. The tip of the red rubber catheter is again passed through the needle lumen and into the duodenal lumen. The needle is withdrawn and the catheter is passed into the bile duct through the major duodenal papilla to the midpoint in the free portion of the bile duct proximal to the level of obstruction or tear. The duodenotomy is closed routinely. The descending duodenum is sutured to the right body wall to fix the points of tube entry and prevent potential leakage. The red rubber feeding tube (Tyco Healthcare/Kendall, Mansfield, MA) is fixed to the skin by a finger-trap suture pattern with 3/0 nylon suture material. Bile can be drained passively from the tube externally or aspirated intermittently and returned to the animal through feeding as described above, if appropriate. Once serum bilirubin concentrations return to a normal level, a cholangiogram is performed by injecting contrast material (**Conray 400®**) through the stent and into the biliary system. If contrast can be seen flowing around the stent and into the duodenum, then the tube can be removed by cutting the fingertrap suture and placing gentle traction on the catheter.

Choledochal stenting may provide a less invasive and less time-consuming option for palliation of malignancies, compared with rerouting procedures.[21] Duodenobiliary reflux with subsequent cholangiohepatitis does not seem to be a consequence of stenting.[21]

Cholecystotomy

Cholecystotomy has limited indications in biliary surgery (removal of inspissated bile or biliary sludge, gelatinous bile, cholecystoliths/choledocholiths, and possibly to cannulate the bile duct to confirm its patency).[7,16] A bile sample for culture analysis can be obtained as an attempt is made to aspirate bile (20 to 35 ml syringe, 14- or 16-ga needle) before cholecystotomy is performed.[7] The bile duct is difficult to catheterize through a cholecystotomy because of the acute angle formed by the cystic duct as it joins the bile duct. An angiographic flexible-tipped guidewire is usually necessary to first pass around the sharp angle, followed by catheter passage over the guidewire to explore and flush the bile duct and its branches from this approach.[16] Diseases of the gallbladder are usually best managed by cholecystectomy and not just evacuation of gallbladder contents (stones, mucocoele, and sludge) although stones can be successfully removed via cholecystotomy.[7] It is imperative to insure that the bile duct is patent and a biopsy of the gallbladder wall is taken before a cholecystotomy is closed.[7] Closure is best achieved by using small-gauge monofilament absorbable sutures in a simple interrupted or continuous, inverting suture pattern (Lembert or Cushing). A two-layer closure is not necessary or recommended.[7] The primary indication for a controlled surgical opening of the gallbladder is in preparation for tube cholecystostomy or cholecystoenterostomy.

Cholecystectomy

Gallbladder removal is the treatment of choice for diseases of the gallbladder.[7] Secondary changes of inflammation, fibrosis or necrosis of the gallbladder wall are common. Removing the gallbladder eliminates a potential source of disease and a reservoir for subsequent stone formation.[7] An intact distended gallbladder is more easily dissected from its hepatic fossa than a flaccid one and stay sutures or tissue clamp become useful in manipulating the structure (Figure 21-6).[16] With gallbladder necrosis and/or rupture, cholecystectomy becomes more difficult to perform because stay sutures are no longer useful.

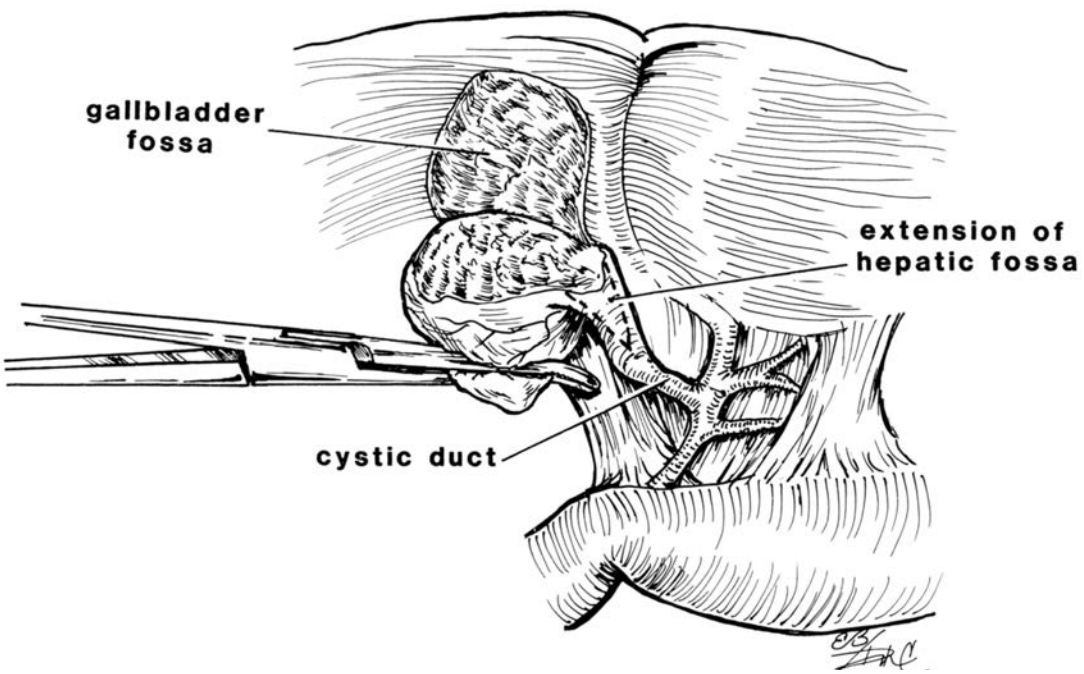

Figure 21-6. Tissue clamp is placed on the fundus of the gallbladder, and dissection from fundus to neck begins. (Redrawn from Nora PF, ed. Operative surgery. Philadelphia: Lea & Febiger, 1972.)

Omental, liver lobe, and diaphragmatic adhesions often require dissection to expose the gallbladder.[7] Traumatic rupture of the gallbladder is uncommon, and by the time of diagnosis, omental adhesions have usually formed so that primary closure is a less likely consideration, necessitating cholecystectomy.[7]

The gallbladder is covered by a layer of visceral peritoneum over its free (abdominal) surface that is confluent with the liver surface (tunica serosa or Glisson's capsule). This layer requires sharp dissection along the complete margin of the gallbladder and hepatic fossa. Some surgeons inject fluid beneath this layer to make it more distinct and to improve ease of dissection (Figure 21-7).[7,16] Once this layer of peritoneal reflection is partially disrupted, the gallbladder can be sequentially removed from its intimate attachment with hepatic parenchyma in the hepatic fossa, either by precise blunt scissor dissection or by more crude but rapid finger dissection. As this separation progresses, the peritoneal reflection can be continued sharply until the gallbladder is completely freed from its hepatic fossa, down to the junction of the cystic duct and the bile duct. With precise dissection, the hepatic fossa is minimally disturbed so that hemorrhage from a raw liver surface is minimal. With finger dissection, increased hepatic hemorrhage can be expected.[7] Because hemorrhage is not usually a major concern, blunt finger dissection of the gallbladder from the liver after peritoneal incision is a rapid method of mobilizing the gallbladder.[7] Any hepatic hemorrhage is controlled with pressure by packing with a moist laparotomy sponge.[7] In the normal dog, the cystic artery can be identified and ligated or coagulated directly. In clinical obstructive disease this structure can be ligated or coagulated when it is encountered. After gallbladder dissection is complete, the cystic duct can be cross-clamped and severed between the clamps (Figure 21-8). Our preference is to place a single clamp midway on the cystic duct to prevent spillage of gallbladder contents while leaving a sufficient stump (5 to 10 mm) attached to the bile duct to manipulate with Debakey tissue forceps for cannulation with an appropriate size catheter (5- to 8-Fr red rubber feeding tube, Tyco Healthcare/Kendall, Mansfield, MA). Once patency of the bile duct is confirmed by flushing and passing a catheter through the bile duct, a circumferential ligature is placed on the stump with 3/0 monofilament absorbable suture material or a hemoclip is applied. Double ligation or transfixation is not necessary when an adequate cystic duct stump is preserved although either can be employed, based on a surgeons' discretion. With a very short stump or with friable tissue, transfixation becomes more important to avoid suture slippage or tissue tearing and subsequent bile leakage. Because bile is soluble in saline or balanced electrolyte solutions, any spillage not contained by laparotomy sponges during the cholecystectomy can be removed during abdominal lavage. Sponges are removed from the hepatic fossa at completion of the procedure. Omentum can be placed in contact with the raw liver surface if leakage is a concern.

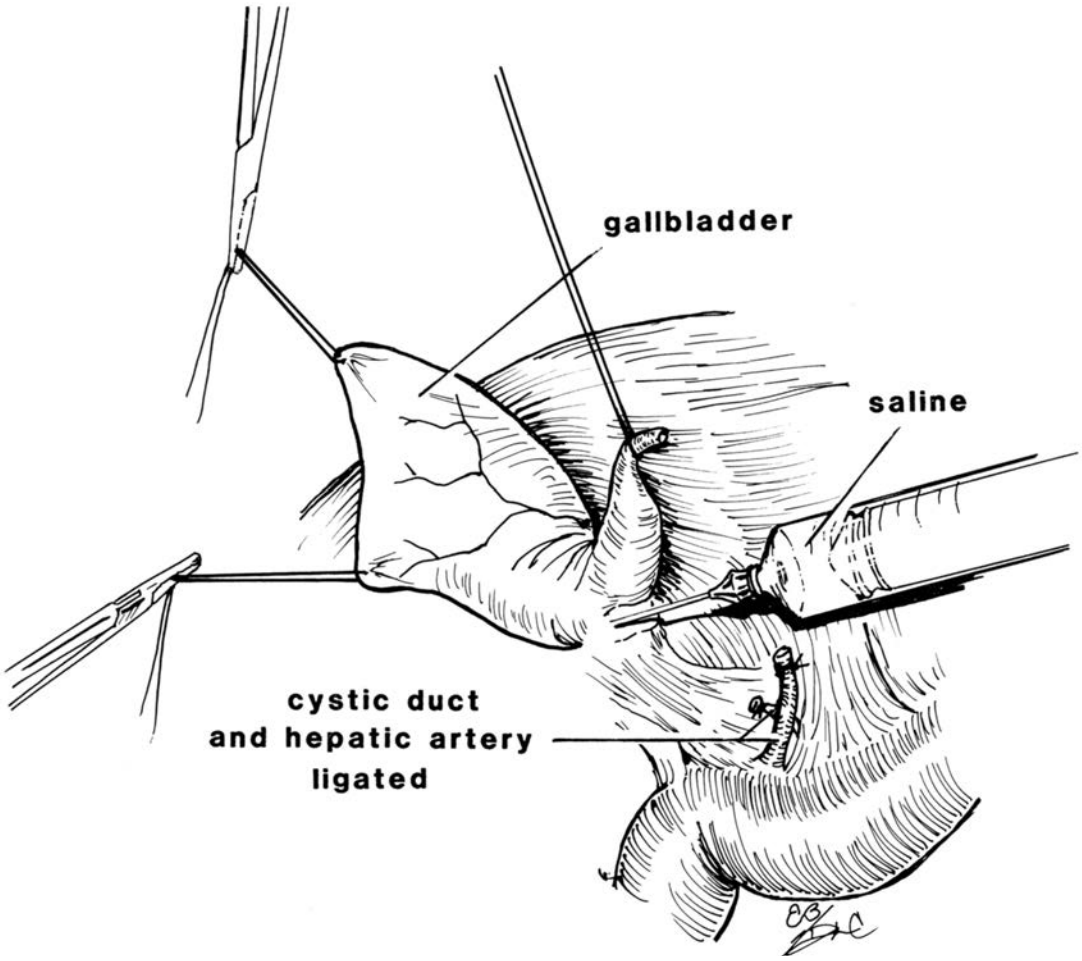

Figure 21-7. Saline solution injected subserosally, where the gallbladder adheres to the liver, aids in dissection during cholecystectomy. (Redrawn from Nora PF, ed. Operative surgery. Philadelphia: Lea & Febiger, 1972.)

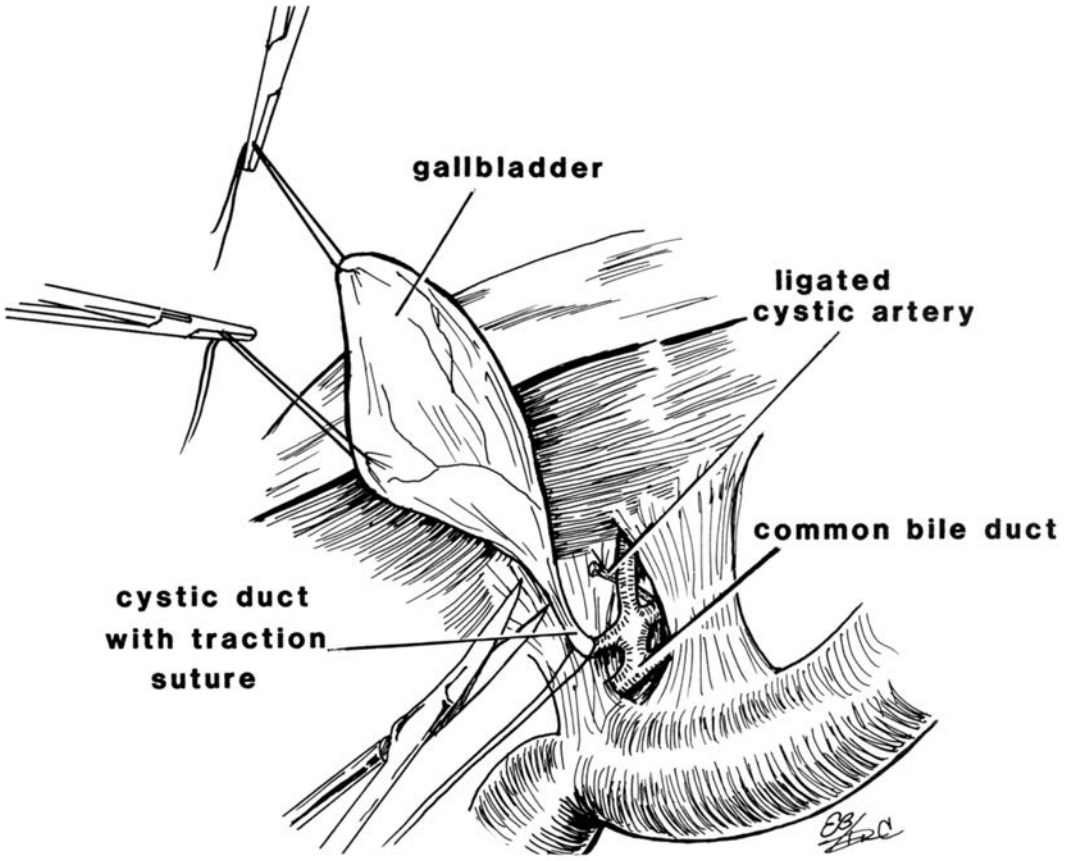

Figure 21-8. Sharp and blunt dissection isolates the cystic duct with traction sutures; the cystic artery is doubly ligated and transected between ligatures. (Redrawn from Nora PF, ed. Operative surgery. Philadelphia: Lea & Febiger, 1972.)

Drainage of the area is unnecessary. The bile duct will dilate 2 to 3 times its normal diameter and remain dilated after cholecystectomy.[7] Cholecystectomy performed by beginning the dissection at the cystic duct has been described.[16]

Choledochotomy

The normal bile duct in dogs and cats is usually too small (2.5 mm in diameter[15]) to consider an elective choledochotomy because of risk of either stricture and/or leakage after closure. However, in cases of bile duct obstruction in the distal free portion or in the intramural portion, dilation can result in a duct of sufficient size to make choledochotomy practical if needed to remove an intraluminal obstruction such as a choledocholith.[7] Biliary flushing and tube exploration in both directions is achieved through the choledochotomy.

Solitary choledocholiths located in the free portion of the bile duct can occasionally be removed via a linear choledochotomy directly over the stone. Bile duct patency is confirmed using a catheter inserted through the choledochotomy site with flushing of the bile duct in both directions. Primary closure with small-gauge (5/0 or 6/0) monofilament absorbable suture in a simple interrupted or continuous pattern is used to close the incision. A continuous cruciate pattern is leak proof when the bile duct is of sufficient diameter and thickness to employ the suture pattern.

Traumatic tears of the bile duct may be amenable to primary repair followed by placement of a stent tube[21] or a cholecystoenterostomy can be performed after ligation of the bile duct proximal to the tear. Primary closure of a choledochotomy or laceration by application of collagen biomaterial (fibrin-glued, sutured collagen patch) has been described; fibrin sealant alone was not reported to be effective.[7]

The bile duct is used in humans to bypass distal benign obstructions, usually stones, by creating a choledochoenterostomy (duodenal or jejunal). The procedure is described as a viable option in dogs and cats (Figure 21-9) when the duct is of sufficient size and the obstruction is distal.[16] There is little indication for this procedure electively in dogs and cats. Choledochoduodenostomy is not recommended unless the gallbladder must be removed, the bile duct is dilated to at least 1 cm in diameter, and a stoma of at least 2.5 cm can be created.[7]

Sphincterotomy/Sphincteroplasty

When the intramural portion of the bile duct contains an intraluminal obstruction (choledocholith), antimesenteric duodenotomy is used to access the major duodenal papilla where a blade of a blunt-tipped iris scissors or 60° Potts scissors can be introduced across the sphincter of Oddi to incise the intramural bile duct and duodenal mucosa sufficiently to remove the obstruction.[7] Because of its small size, creation of a sphincteroplasty (suturing bile duct mucosa to duodenal mucosa; (Figure 21-10) to permanently enlarge the opening of the intramural bile duct is not usually practical in the dog or cat. Following a sphincterotomy, the biliary system is catheterized and flushed but no further manipu-

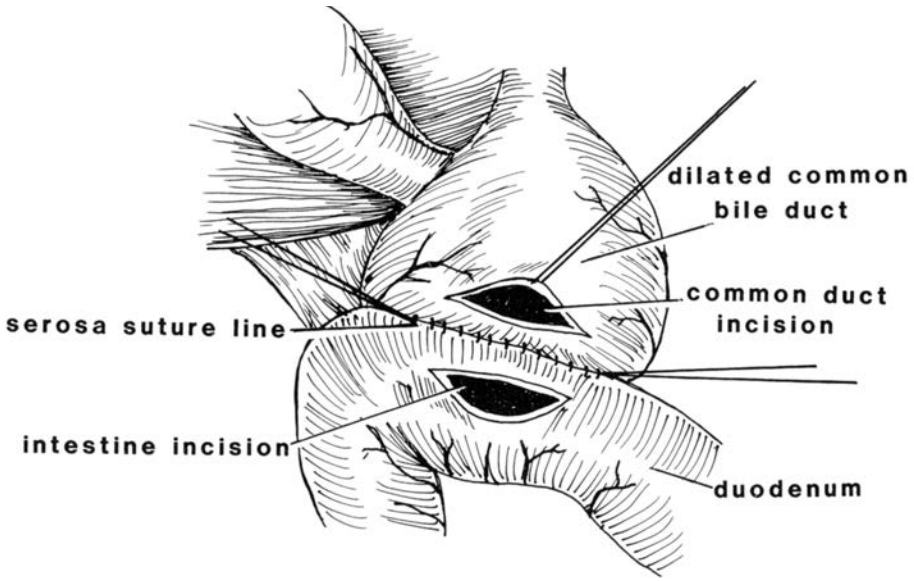

Figure 21-9. The dilated common bile duct is united by a simple interrupted serosal suture line to the intestine, and a gallbladder incision and enterotomy are made close to the serosal suture line. (Redrawn from Nora PF, ed. Operative surgery. Philadelphia: Lea & Febiger, 1972.)

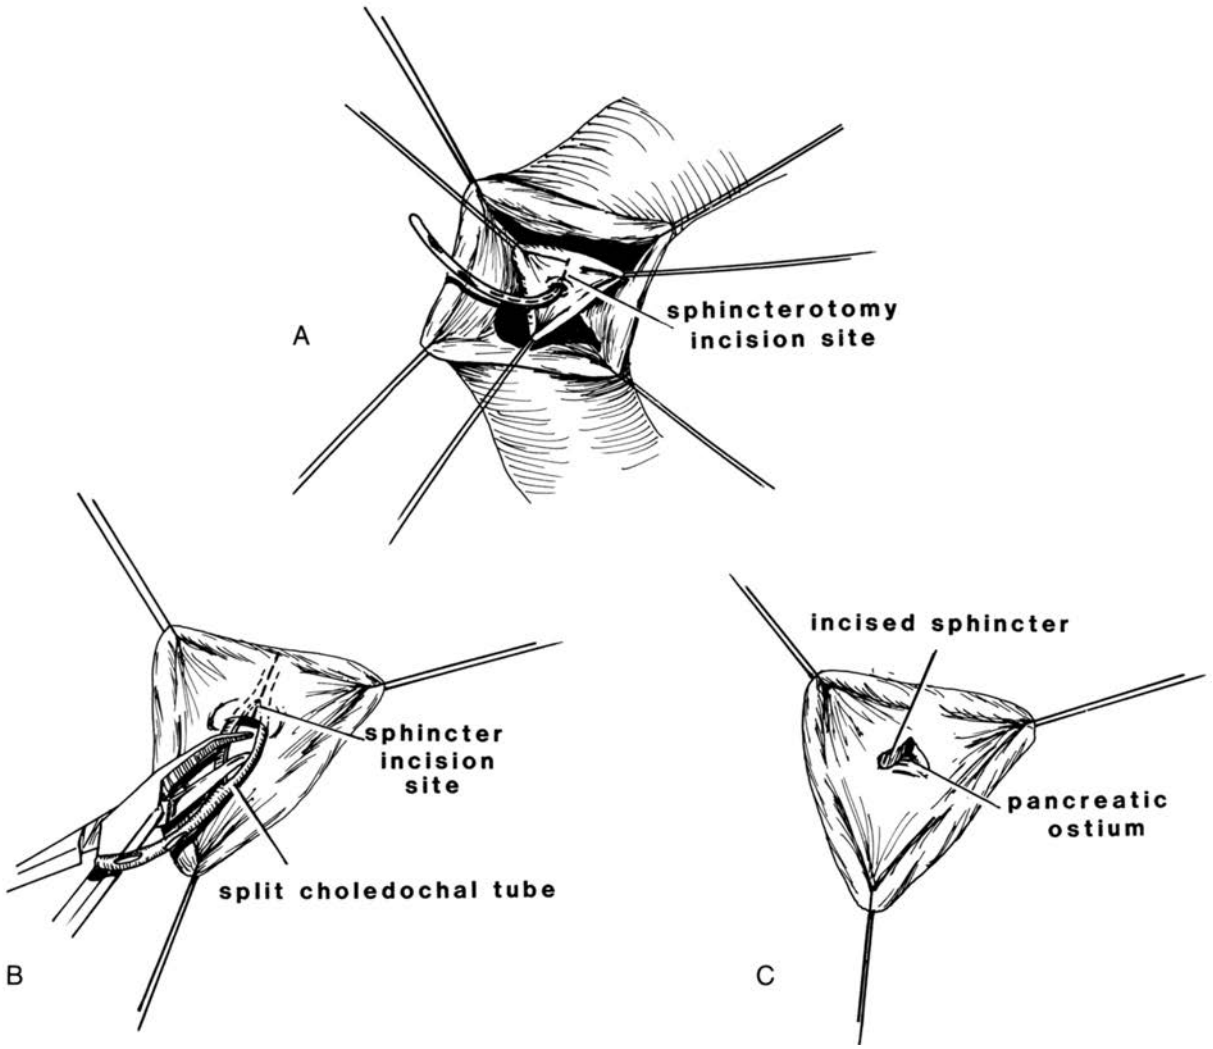

Figure 21-10. A. The duodenal incision is maintained open with four traction sutures. Three additional traction sutures elevate the bile duct hillock containing a choledochal tube in the bile duct orifice. Dashed lines on the hillock and tube indicate incision lines. **B.** The choledochal tube is split and retracted into the common bile duct. Mosquito forceps spread the split tube in and out of the common duct. Sphincterotomy can be easily performed along the split tube (dashed line). **C.** Sphincterotomy is complete. The ventral pancreatic duct may be present within the common bile duct hillock.

lation of the intramural bile duct is required. The duodenotomy is closed routinely with 3/0 monofilament absorbable suture in a simple continuous pattern that captures the submucosal layer of the bowel wall. The major pancreatic duct empties into the duodenal hillock with the bile duct in approximately 50% of dogs and in nearly all cats yet iatrogenic pancreatic insufficiency has not been reported.[16]

Rarely, a pancreatic abscess[22] or carcinoma of the intramural bile duct or major duodenal papilla can cause biliary obstruction. Drainage and stent management of a pancreatic abscess has been described in a dog.[21] Duodenal resection and anastomosis with biliary diversion using a cholecystoenterostomy is required for definitive treatment of a neoplasm in this location. The first author (RAM) has seen one case of obstruction caused by a solitary tumor of the major duodenal papilla. A stent could be considered for palliative management of neoplastic obstruction of the intramural portion of the bile duct if it can be introduced into the bile duct successfully.[21]

Biliary-enteric Anastomosis for Bile Flow Diversion

Rerouting the flow of bile is necessary when its normal course is disrupted, either by traumatic rupture or benign or malignant obstruction. Obstruction of the distal part of the free portion of the bile duct that cannot be relieved by other means becomes the most common reason to reroute bile through an anastomosis surgically created between the gallbladder and duodenum or jejunum. Occasionally, traumatic rupture of the bile duct by avulsion of its free portion from its intramural junction or a tear in its free portion occurs and is managed by bile flow diversion. Normally, the anatomic arrangement of smooth muscle layers around the intramural portion of the bile duct and around its terminal opening at the major duodenal papilla prevents reflux of duodenal contents into the biliary system.[15] However, reflux of intestinal contents (chyme and bacteria) into the biliary system occurs when the gallbladder is anastomosed to the small bowel. While long-term hepatic enzyme values (SAP, SGPT) and histological changes reflect subclinical reflux cholangitis, clinical signs of cholecystitis/cholangiohepatitis (fever, vomiting, anorexia, depression, abdominal pain and icterus) do not occur as long as the anastomosis remains sufficiently patent for ingress of contents to egress with the flow of bile.

Cholecystoduodenostomy is the most common bile flow diversion procedure used in veterinary medicine.[7,16] Cholecystojejunostomy has been reported in dogs and cats as a viable technique for bile flow diversion but postoperative complications are more common. Increased alkaline phosphatase and alanine aminotransferase hepatic enzymes and subclinical periportal inflammation and fibrosis result following biliary enteric anastomosis in normal and clinical dogs but these changes may already exist with bile duct obstruction in most clinical patients. Serum hepatic enzyme levels remain elevated for at least 6 months after cholecystoduodenostomy but may return to normal within 1 to 2 years.[7]

Cholecystoduodenostomy

The gallbladder is dissected from its hepatic fossa down to the junction of the cystic duct and the bile duct, as for cholecystectomy. Partial dissection of the gallbladder from the hepatic fossa has been described to minimize trauma to the cystic artery nourishing the gallbladder and to prevent cystic duct torsion.[7,16] Decreased tension on the anastomosis is achieved by complete dissection of the gallbladder from the hepatic fossa without loss of its viability. Use of two full-thickness stay sutures, one in the fundus and the other in the neck on the free surface, prevent iatrogenic gallbladder torsion. These retraction sutures are then used to stabilize the gallbladder for anastomosis to the antimesenteric border of the duodenum at its most tension-free location, typically 3 to 6 cm distal to the pylorus, depending on patient size (Figure 21-11). Similarly, two full-thickness stay sutures are placed in antimesenteric surfaces of the duodenum to stabilize this portion of small intestine. Doyen intestinal forceps can be used across the gastric antrum and distal to the right limb of the pancreas after the descending duodenum has been manually "milked" to empty lumen contents in an aborad direction to prevent leakage of fluid into the abdomen following duodenotomy. This step is usually not necessary. Packing clean, moist laparotomy pads dorsal to the gallbladder and duodenum also helps contain any bile or gastrointestinal fluid spillage in the region of the anastomosis.

The gallbladder is opened sharply from its fundus toward its neck for 4 cm or to the level of the neck in smaller gall bladders in order to create a stoma that will remain patent after it contracts up to 50% as it heals.[7] An incision of this length permits the maximum stoma size in small patients and an adequate stoma size in all patients. Using 3/0 monofilament absorbable suture on a tapered needle, a U-suture is placed between the proximal (orad) apex of the duodenotomy and the opposing apex at the neck of the cholecystotomy. A second U-suture is placed at the distal (aborad) apices of each structure. A single square knot is used to secure each U-suture to avoid a "daisy chain" effect created by multiple knots that potentially could leave enough space to allow for anastomosis leakage. The needle and suture of the proximally placed U-suture are brought back through the gallbladder wall and into its lumen immediately adjacent to the U-suture knot. A continuous suture pattern is employed to appose the dorsal (deep) margins of the stoma in a distal direction toward the second U-suture. When the suture line reaches the distal apices and U-suture, the needle and suture are brought through the gallbladder wall adjacent to that U-suture knot and the suture is tied securely to the free tag of that U-suture. At this point, the deep margin of the stoma is complete as a single-layer, simple continuous suture anastomosis that should be leak-proof if suture bites are placed appropriately (2 to 3 mm apart). The needle limb of the distal U-suture is now used to place a full-thickness simple continuous suture line through the ventral (superficial) margins of the gallbladder and duodenum, ending this suture pattern by tying to the free limb of the first U-suture on the external surface of the completed anastomosis. The deep stoma margin is inverted since it was created by suturing from within the lumen of the stoma whereas the superficial margin with be everted since it was created by suturing from the external surface of the stoma. The surgeon can digitally palpate

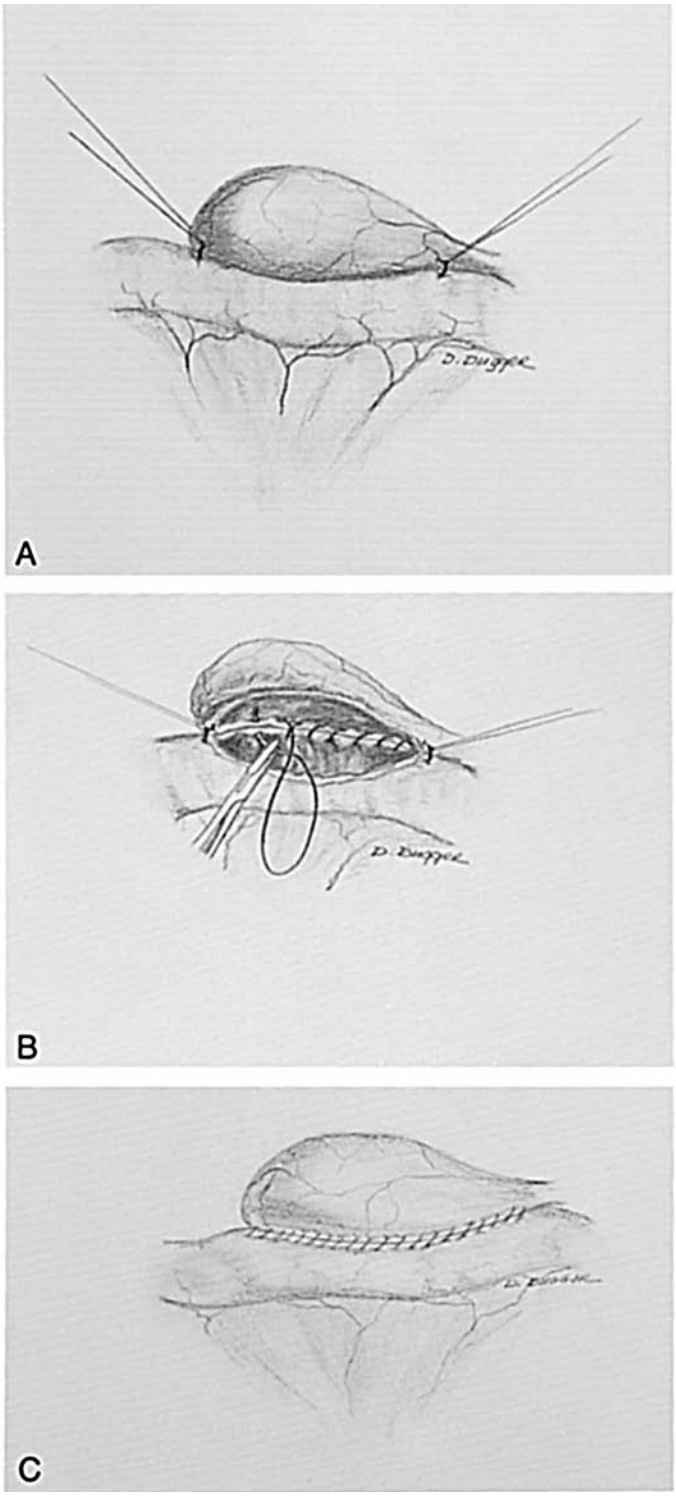

Figure 21-11. A. The gallbladder is approximated to the duodenum with one or two stay sutures. One stay suture should be placed close to the cystic duct to allow a 2.5 to 4 cm incision in the gallbladder. **B.** The gallbladder mucosa is sutured to the duodenal mucosa using a simple continuous pattern. **C.** The serosal surfaces surrounding the anastomosis are approximated with a simple continuous or Lembert pattern.

the stoma through the walls of the gallbladder and duodenum to assess the opening created. The anastomosis is lavaged locally, followed by complete abdominal lavage prior to body wall closure.

Cholecystojejunostomy

This technique is employed when a surgeon either elects to perform the procedure or circumstances (gastric, duodenal, pancreatic, or biliary masses) require its performance. When bile is diverted from the proximal duodenum, normal physiology of gastric acid production and fat digestion is altered. Bile is required in the proximal duodenum to activate duodenal mechanisms responsible for inhibition of gastric acid secretion. Excessive gastric acid production can lead to peptic ulceration of the pyloric antrum and/or, more commonly, the proximal duodenum.[7] Fat digestion is also disrupted since bile salts enhance both the hydrolysis and absorption of fats. Weight loss can result. No long-term reports exist on outcomes of cholecystojejunostomy in a series of dogs or cats to recommend the procedure.

Two techniques can be employed. A loop cholecystojejunostomy between the gallbladder and proximal jejunum is the simpler technique to perform. Noncrushing intestinal forceps (pediatric Doyen) should be applied proximal and distal to the selected jejunotomy site to minimize intestinal fluid spillage. Without dissecting the gallbladder from its hepatic fossa, a cholecystotomy is created in the free portion of the gallbladder from its fundus toward the neck and a loop of proximal jejunum is brought into proximity. An antimesenteric jejunotomy of equal length to the cholecystotomy is created and the two structures are anastomosed in a side-to-side fashion, using a continuous suture pattern with U-sutures as described for cholecystoduodenostomy. Stoma size should be either 4 cm in length or as long as the cholecystotomy will accommodate in patients too small to achieve this length. Reflux of jejunal contents will occur.

An alternate technique requires construction of an isoperistaltic antireflux limb of jejunum 40 to 50 cm long, according to the Roux-en-Y principle. The proximal jejunum is divided transversely, and the distal (aborad) segment is advanced to the gallbladder and anastomosed end to end with the gallbladder fundus. The proximal (orad) jejunal segment is anastomosed in an end-to-side manner 40 to 50 cm distal (aborad) in the distal (aborad) jejunal segment. This distance, considered necessary to prevent reflux of chyme into the gallbladder, is greater than half the length of the jejunoileum in all cats and most small dogs. A short bowel syndrome (maldigestion due to lack of small intestinal mucosal surface area) or stagnant bowel syndrome (overgrowth of bacteria in refluxed intestinal contents that stagnate in the limb) could result. This technique has only been reported in dogs experimentally where reflux occurred in all dogs having only a 15 cm Roux-en-Y jejunal limb.[7]

Congenital Portosystemic Shunts in Dogs and Cats

Karen M. Tobias

Introduction

Portosystemic shunts (PSS) are abnormal vessels that divert blood from the abdominal viscera to the heart, bypassing the hepatic sinusoids and carrying intestinal absorption products directly to the systemic circulation.[1] Portosystemic shunts can occur as congenital anomalies, or may develop secondary to liver disease and portal hypertension. Congenital PSS usually occur as single large vessels, while acquired shunts are numerous and often small in size. Common types of single congenital portovascular anomalies include intrahepatic portocaval shunts, such as patent ductus venosus, and extrahepatic portocaval or portal-azygos shunts. Shunts may connect the portal vein with the caudal vena cava directly, or may originate from a portal tributary, such as the left gastric vein, and terminate on a caval tributary, such as a phrenic or hepatic vein. In a small percentage of dogs, the prehepatic portal vein is also congenitally absent.[1,2]

Signalment, History, and Clinical Signs

Congenital intrahepatic and extrahepatic PSS are usually diagnosed in immature animals. No sex predilection is evident. Intrahepatic PSS are found primarily in large breed dogs such as Irish Wolfhounds, Bernese Mountain dogs, Old English sheepdogs, Golden and Labrador Retrievers, and Samoyeds, and in medium-sized breeds such as Australian shepherds and Australian Cattle dogs.[1,3] Extrahepatic PSS occur primarily in small breed dogs such as Yorkshire terrier, Maltese, pug, Schnauzer, Cairn terrier, Shih Tzu, and dachshund.[3] In cats, PSS are most often extrahepatic. Congenital shunts are hereditary in Irish Wolfhounds, Yorkshire Terriers, Cairn Terriers, and several other breeds.[3-6]

Clinical signs associated with portosystemic shunts commonly involve the nervous system, gastrointestinal tract, and urinary tract.[1] General clinical signs include poor growth rate, weight loss, fever, and anesthetic or tranquilizer intolerance. Neurologic dysfunction is seen in most animals with PSS and includes lethargy and depression, ataxia, behavioral changes, and blindness (especially cats).[1,7,8] Animals with severe hepatic encephalopathy may develop head pressing, circling, dementia, stupor, muscle tremors, motor abnormalities, focal and generalized seizures, or coma. Hepatic encephalopathy may be precipitated by drugs (i.e.diuretics or sedatives), protein overload, hypokalemia, alkalosis, transfusion of stored red cells, hypoxia, hypovolemia, gastrointestinal hemorrhage, infection, and constipation.[1,9,10] Gastrointestinal clinical abnormalities in animals with PSS include anorexia, vomiting, and diarrhea. Some dogs have no apparent clinical signs or are presented only with signs of cystitis or urinary tract obstruction. Seizures and hypersalivation are the most common clinical sign in cats, and some have unusual copper colored irises.[7,8]

Diagnostic Tests

The most common abnormality found on hemograms of animals with PSS is microcytosis.[1,11] Up to half of dogs with congenital PSS have prolonged PTTs;[12] however, this does not usually result in clinically significant hemorrhage. Biochemical abnormalities in dogs with PSS include decreases in blood urea nitrogen, protein, albumin, glucose, and cholesterol; and increases in serum alanine aminotransferase and alkaline phosphatase.[1] An increase in alkaline phosphatase is most likely from bone growth, since cholestasis is not usually a problem in animals with PSS. Cats with PSS often have increased liver enzymes but may have normal albumin and cholesterol concentrations.[7,8] Urine abnormalities may include low urine specific gravity and ammonium biurate crystalluria, and inflammatory urine sediment in animals with cystitis or urolithiasis.

Animals with portosystemic shunting will have decreased protein C activity and increases in fasting and 2-hour postprandial bile acids and in ammonia after an ammonia challenge (ammonia tolerance test). These tests are not specific for shunting, since they can occur with many liver diseases.

Hepatic histologic changes in animals with PSS include generalized congestion of central veins and sinusoids, lobular collapse, bile duct proliferation, hypoplasia of intrahepatic portal tributaries, proliferation of small vessels and lymphatics, diffuse fatty infiltration, hepatocellular atrophy, and cytoplasmic vacuolization.[1,11,13] These pathologic changes are often termed "hepatic microvascular dysplasia" and can also be seen in dogs with congenital portal vein hypoplasia (without macroscopic shunting) or noncirrhotic portal hypertension. Pathologic changes may be present in the central nervous system, especially in encephalopathic animals with shunts.

On plain radiographs, microhepatica and renomegaly may be present. Urate calculi normally are radiolucent but occasionally will be seen in the renal pelvis, ureter, or bladder on survey films when combined with struvite or other radioopaque material. Portosystemic shunts may be definitive diagnosed with angiography, ultrasonography, scintigraphy, computed tomography, or magnetic resonance angiography.[1] Mesenteric portography provides excellent visualization of the portal system but usually requires an abdominal incision. Water-soluble,sterile, iodinated contrast medium is injected into a catheterized jejunal or splenic vein (Figure 21-12), and one or more radiographs are taken during completion of the injection. Sensitivity of the test is greatest when performed with the animal in left lateral recumbancy.[14]

Differential Diagnoses

Single congenital portosystemic shunts must be differentiated from multiple acquired shunts secondary to portal hypertension, and from congenital portal vein hypoplasia (PVH); previously known as hepatic microvascular dysplasia or MVD). Congenital portal hypoplasia signifies a disorganization of the liver's microscopic architecture that is similar to that of dogs with single congenital shunts.[11,13] Congenital portal hypoplasia has been reported primarily in small breed dogs such as the Yorkshire terrier, Cairn terrier, Maltese, Cocker spaniel, and papillon. Dogs

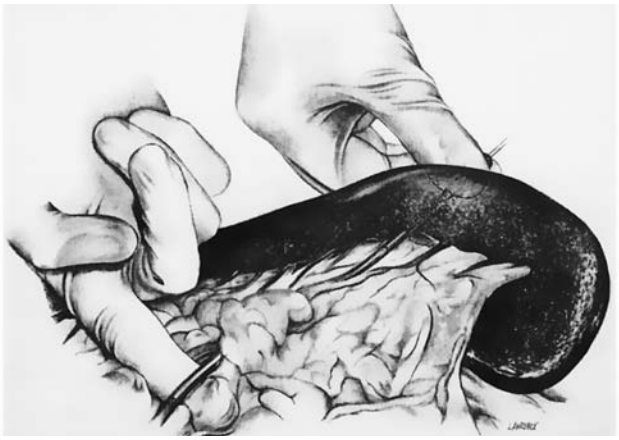

Figure 21-12. A transplenic through-the-needle catheter has been placed through the parenchyma and into splenic vein. The catheter may be used for portography or portal pressure measurements. (From Schultz KS, Marin RA, Henderson RA. Transsplenic portal catheterization: surgical technique and use in two dogs with portosystemic shunts. Vet Surg 1993;22:365)

with PVH display biochemical, hematologic, and clinical changes consistent with portosystemic shunting but lack a macroscopic portosystemic shunt. Therefore, in dogs with PVH, portograms and scintigrams are normal. Signs of PVH are managed with a protein restricted diet. Lactulose is added if clinical signs are not controlled with diet alone. Some clinicians may administer nutriceuticals (milk thistle, denosyl) to improve hepatic function.

Medical Management of PSS

Medical management of animals with PSS includes correction of fluid, electrolyte, and glucose imbalances and prevention of hepatic encephalopathy by controlling precipitating factors.[1] Dietary protein is restricted (protein content 18-22% in dogs; 30-35% in cats) to reduce substrates for ammonia formation by colonic bacteria, and any sources of gastrointestinal bleeding must be treated. Antibiotics that are effective against urease producing bacteria, such as neomycin or metronidazole, can be administered to decrease intestinal bacterial populations. Enemas and cathartics may be used to reduce colonic bacteria and substrates and are especially important in animals with hepatic encephalopathy. Lactulose is administered to reduce ammonia absorption and production. Cystitis is treated with an appropriate antibiotic based on urine culture and sensitivity; response may be poor if uroliths are present. Urate uroliths may respond to low protein diets; renal calculi have reportedly dissolved after shunt ligation.

With proper medical management, weight and quality of life stabilize or improve with treatment in most animals. In one study,[15] one third of dogs did well with medical management as the sole method of treatment, with many living to 7 years of age or older. Duration of survival with medical management alone was correlated to age at initial onset of clinical signs and with BUN concentration: dogs with extrahepatic PSS that were older at presentation or had a higher BUN lived longer. Over half of dogs treated with medical management alone were euthanized, usually within 10 months of diagnosis, because of uncontrollable neurologic signs and, in some cases, progressive hepatic fibrosis

and subsequent portal hypertension.[15] In another study[16] long term survival rate was 88% for dogs that underwent surgical treatment and 51% for dogs that were managed medically. In that study, age was not correlated with length of survival.[16] To the author's knowledge, no studies have evaluated survival of cats treated with only medical management. Of 4 cats managed medically by the author, 3 died or were euthanized less than 3 years after diagnosis because of neurologic disease or recurrent urinary tract obstruction. For animals with congenital PSS, particularly those that are symptomatic, surgery is considered the treatment of choice; however, surgery should be delayed until the animals are clinically stable.

Surgical Management

Most patients are premedicated with an opioid and a sedative. Low dose acepromazine (0.1 to 0.25 mg total dose) can be used for sedation before or after surgery since it does not increase the risk of seizures in these patients.[1] Animals can be induced with intravenous propofol or by mask induction with isoflurane or sevoflurane in oxygen.

Definitive diagnosis of extrahepatic PSS can usually be made during exploratory laparotomy if the veterinarian is thoroughly familiar with the vascular anatomy of the abdomen.[17,18] In a normal dog, there are no large vessels entering the caudal vena cava between the renal and hepatic veins. Many extrahepatic PSS terminate on the caudal vena cava cranial to the renal veins at the level of the epiploic foramen. The caudal vena cava will appear dilated and contain turbulent flow at the level of the shunt terminus. Portocaval shunts entering near the epiploic foramen may be difficult to see if the terminus of the PSS is obscured by an overlying artery, liver lobe, or the pancreas. Occasionally, portocaval shunts will traverse along the lesser curvature of the stomach and the ventral surface of the distal esophagus before joining the left phrenic vein. Portoazygos shunts traverse the diaphragm at the level of the crura or aortic hiatus and are obscured by overlying viscera.[17] To improve detection of and access to these shunts, it may be necessary to open the omental bursa (Figure 21-13) by tearing a hole in the superficial, ventral leaf of the greater omentum and retracting the stomach cranially and intestines caudally. Any vein of significant size that visibly penetrates the diaphragm at its lumbar attachments is likely to be a portoazygos shunt. Shunts that traverse the diaphragm through the esophageal hiatus may be easier to approach outside of the omental bursa by retracting the liver and stomach to the dog's right so that the cardia and esophagus are visible. Thorough exploration is warranted in all dogs with single congenital PSS because of the possibility, though rare, of a second shunt.

Intrahepatic PSS are more difficult to detect and treat. Experienced surgeons will note enlargement of the portal vein branch to, or hepatic vein draining, the lobe containing the shunt.[18] The liver lobe containing the intrahepatic shunt may have a visible, aneurysmal dilation of the shunt near the diaphragmatic surface of the parenchyma or may be palpably softer than the other lobes. When the shunt is a patent ductus venosus, it can occasionally be seen as it traverses between the left lateral and medial lobes. Because intrahepatic shunts are difficult to find and treat, preoperative dual phase contrast computed tomography is recommended in all large breed dogs and any other dog in which an intrahepatic shunt is suspected. Intrahepatic shunts can be occluded with interventional techniques (placement of a caval stent, followed by coils within the shunt); facilities that perform this procedure will utilize fluoroscopic and computed tomographic imaging as part of their diagnostic and therapeutic planning.

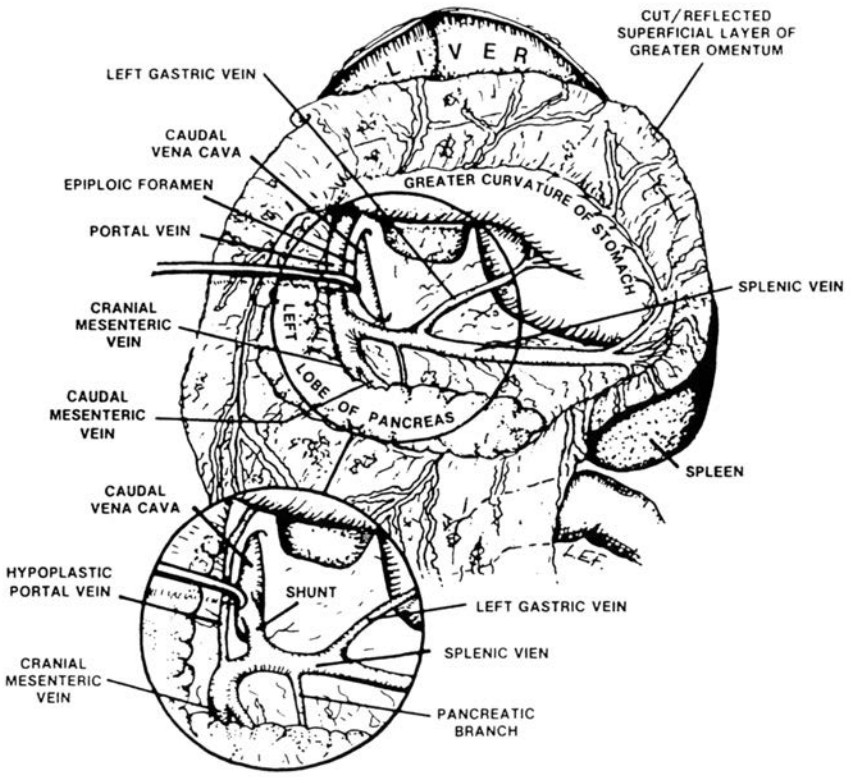

Figure 21-13. Ventral view into the omental bursa. Note the normal topographic relationships between the splenic, left gastric, and portal vein and compare with a typical single extrahepatic portocaval shunt diagram (inset). (From Martin RA. Identification and surgical management of portosystemic shunts in the dog and cat. Semin Vet Med Surg (Small Anim) 1987;2:304).

When a shunt is not found, the surgeon should obtain a liver biopsy to rule out other hepatic diseases such as PVH and perform intraoperative mesenteric or splenic portography to definitively rule out a PSS.

Porsostystemic Shunt Occlusion

Once the PSS is identified and presence of a prehepatic portal vein is verified, shunt occlusion can be attempted. It is critical to attenuate the shunt as close to its insertion site as possible so that all tributaries of the shunt are upstream from the occlusion. Portocaval shunts should be occluded at their terminus on the caudal vena cava. Portoazygos shunts can be occluded on the abdominal side of the diaphragm. Thorough examination is warranted before ligature placement as portoazygos and portophrenic shunts frequently have small branches from gastric veins that enter the PSS just before it traverses the diaphragm. The diaphragm may be opened if more exposure is needed.

Shunts can be occluded with suture or constricting devices. Most surgeons prefer to use devices that result in gradual occlusion of the shunt (e.g. ameroid constrictors or cellophane bands) or that are less invasive than open abdominal surgery (e.g., coiling of intrahepatic shunts). Suture attenuation is occasionally necessary when occlusive devices are not available. It is critical for veterinarians undertaking shunt ligation to understand that over half of animals with congenital shunts will die if the shunt is acutely ligated; therefore, partial ligation is necessary in most animals that undergo suture attenuation. If suture is to be used to ligate the shunt, then a small opening is made through the fascia around the shunt by dissecting adjacent to the PSS at its terminus. Silk suture (2-0) is frequently used in dogs because of ease of handling and knot security; however, a nonabsorbable monofilament suture is recommended in cats. The shunt should be temporarily occluded for 5 to 10 minutes while the surgeon evaluates the viscera for evidence of portal hypertension, including pallor or cyanosis of the intestines, increased intestinal peristalsis, cyanosis or edema of the pancreas, and increased mesenteric vascular pulsations.[19] Additionally, the surgeon can measure portal and central venous pressures.[18,20] To measure portal pressure, a catheter is placed directly into a jejunal vein or through the splenic parenchyma and into a splenic vein (See Figure 21-13).[21] The catheter is secured in place with gut suture and is attached to an extension set, 3-way stopcock, and syringe. A water manometer is attached to the 3-way stopcock, which is rested on the inguinal region of the patient to provide consistent readings during portal pressure measurements.

Recommendations for postligation pressures are to limit the maximum portal pressure to 17 to 24 cm H_2O, maximal change in portal pressure to 9 to 10 cm H_2O, and maximal decrease in central venous pressure to 1 cm H_2O.[1,17,18,20] Partial ligation should be performed if evidence of portal hypertension is noticed during surgery. Objective pressure measurements should not be used as the sole criteria for degree of shunt attenuation, since blood pressures can vary with depth of anesthesia, hydration status, phase of respiration, degree of splanchnic compliance, and other systemic factors. To perform partial ligation, choose a cylinder (a piece of tubing, steel pin, or rod) that is the approximate diameter that you wish to achieve during shunt occlusion.[22] Place the cylinder next to the shunt and wrap the ligature around the shunt and the cylinder. Tie the ligature and remove the cylinder, then recheck portal pressures and evaluate the color of the viscera.

Abrupt occlusion and partial ligation of PSS have been associated with serious postoperative complications, including perioperative death in 14 to 22%, seizures in 7.5 to 11%, recurrence of clinical signs in 40 to 41%, and development of multiple PSS in 7%.[1,17,22,23] Therefore, many surgeons prefer gradual, complete shunt ligation with devices such as ameroid constrictors, cellophane bands, or hydraulic occluders.[1,24-27] An ameroid constrictor (Research Instruments N.W., INC, Lebanon Oregon, 97355; researchinstrumentsnw.com) is an inner ring of casein that is surrounded by a stainless steel sheath. Casein is a hygroscopic substance that swells as it slowly absorbs body fluid; the stainless steel sheath forces the casein to swell inwardly, partially compressing the shunt. Ameroid constrictors cause shunt occlusion over 2-3 weeks by direct pressure and by stimulation of a fibrous tissue reaction. Ameroid constrictors are gas sterilized and therefore should not be used until 12 to 24 hours after sterilization to allow residual ethylene oxide to be released from the casein.

Ameroid constrictors with a 5 mm internal diameter are most frequently used for extrahepatic PSS ligation. The choice of ameroid constrictor size for PSS occlusion is based on shunt diameter; therefore, the surgeon should have a selection of sizes available at each surgery. To avoid postoperative portal hypertension, choose a constrictor that does not compress the shunt vessel during initial placement.[1,17] In cases where larger constrictors are not available, portal pressures can be measured during partial shunt occlusion and viscera can be evaluated subjectively for signs of portal hypertension to determine whether a smaller constrictor could be used.

Before constrictor placement, the "key", a small column of stainless steel that completes the constrictor ring, is removed from the ameroid constrictor and set aside. The ameroid constrictor is held securely by a pair of Allis tissue forceps, which prevent rotation of the casein inside of the stainless steel ring. Dissection of the supporting fascia around the PSS should be kept to a minimum when placing an ameroid constrictor to prevent postoperative movement of the ring and acute obstruction of the shunt (Figure 21-14). Once an opening has been made through the fascia around the PSS, the shunt is flattened by elevating it with open right angle forceps or two silk sutures. The constrictor ring is slipped over the shunt and, with a hemostat, the key is replaced within the constrictor to complete the circle (Figure 21-15). Anti-inflammatory doses of steroids should not be administered for 1 month after ameroid constrictor placement since they reduce the amount of tissue reaction and may prevent shunt closure. Complication and mortality rates after ameroid constrictor occlusion of extrahepatic PSS were 10% and 7%, respectively, in one study.[25] Excellent outcomes were seen in 80% to 85% of patients, although persistent shunting on scintigraphy was seen on recheck scintigraphy in 17 to 21% of animals in earlier studies.[1,17,24,25] Causes of persistent shunting include development of multiple acquired shunts, presence of a second

Figure 21-14. The fascia around the shunt is dissected as close to its terminus as possible, and the open constrictor is slipped over the flattened vessel.

shunt, inadequate fibrosis of the original shunt, or inappropriate location of the constrictor. Multiple acquired shunts are less common when shunt diameter is smaller than the constrictor ring internal diameter at the time of surgical placement.

Gas sterilized strips of cellophane have been used to provide partial occlusion of shunts in dogs.[26] Because the strips are flexible, they are easier to place around intrahepatic shunts than ameroid constrictors. The strips are wrapped once around the shunt and an adjacent stainless steel pin, and the ends of the band are held together with 4 alternating 11.5 mm surgical clips. Portal pressures are measured for several minutes after banding, and the viscera are evaluated for subjective signs of portal hypertension. Originally, animals required placement of bands with a final internal diameter of < 3 mm in diameter in animals to induce complete shunt closure.[26] In more recent studies, however, PSS closure occurred after bands were placed without intraoperative shunt attenuation.[27] Inflammation caused by the cellophane results in complete occlusion of most shunts in dogs in less than 4 to 6 weeks.[24,26] Mortality rates are 6% to 9% after cellophane banding, and persistent hepatic dysfunction was evident on bloodwork in 16% of animals.[26,27]

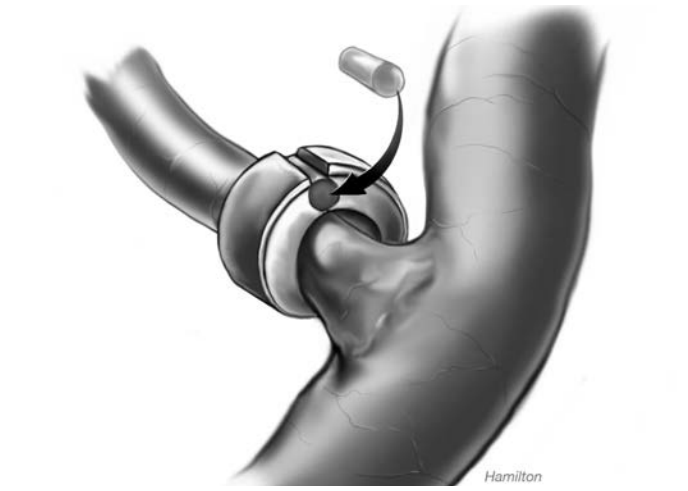

Figure 21-15. After application of the ameroid constrictor to the portosystemic shunt, the ring is locked with a cylindrical key to prevent dislodgement. The ameroid gradual swells, compressing the shunt, which subsequently closes by fibrosis or thrombosis.

Hydraulic occluders have been used for gradual extravascular occlusion of intrahepatic portosystemic shunts.[24,28] The silicone and polyester cuff of the occluder is placed around the shunt, and the attached access port is inserted under the skin. The cuff is gradually inflated postoperatively by intermittent injections of a solution into the subcutaneous port until the shunt is closed.

Blood flow through intrahepatic PSS may be reduced by occluding the portal vein branches leading to, or hepatic veins draining, the shunt using the above described extravascular techniques.[1,18] Alternatively, the shunt can be approached intravascularly during inflow occlusion. Most surgeons prefer minimally invasive extravascular techniques when possible to reduce the risk of complications.

Minimally invasive techniques for shunt occlusion are showing great promise for treatment of intrahepatic PSS. Thrombogenic coils have been placed via catheter access into the shunt to gradually obstruct PSS.[24,29,30] Coil migration is prevented by placement of a caval wall stent.[24] Under fluoroscopic guidance, a catheter is inserted through the mesh wall of the stent and into the shunt, and coils are placed via the catheter until portal pressure increases. Initially, complication rates were high with this technique; however, complication rates have been reduced to < 5% since initiating lifelong antacid therapy in dogs undergoing this procedure.[29]

Postoperative Management

After surgery, animals are monitored closely for seizures, hypothermia, hypoglycemia, and signs of portal hypertension, including shock, pain, and abdominal distension.[1,9] Most animals will need analgesics; opioids are used most frequently. Carprofen and meloxicam have been used safely in dogs with extrahepatic shunts but, in rare instances, may precipitate gastrointestinal ulcerations. Antacid therapy is recommended in all dogs with intrahepatic shunts. Sedation with a low dose (0.1 to 0.25 mg total dose) of acepromazine or dexmedetomidine 1-3 mcg/kg IV may be necessary if dogs are vocalizing or abdominal pressing, since these activities will increase portal pressure. Dogs with ameroid constrictor occlusion usually experience minimal discomfort.

A protein restricted diet and lactulose are continued after surgery until liver function improves. Frequently the animals can be gradually weaned off of the lactulose 4 to 6 weeks after the surgery. Bile acids and albumin are evaluated 3, 6, and 12 months after the surgery or until liver function is improved. Protein in the diet can be gradually increased once bile acids are improved. In dogs with mildly elevated bile acids and normal albumin, it may be necessary to monitor clinical response to diet change to determine whether dietary protein content can be gradually increased, since many dogs with PSS also have PVH and, therefore, will always have mildly increased bile acids.

Treatment of postoperative portal hypertension includes intravenous fluid administration for hypovolemic shock, systemic antibiotics, and immediate surgery to remove the constrictor

or ligature.[1,9] Factors that may increase portal pressure postoperatively include excessive intraoperative fluid administration, increased systemic blood pressure from anesthetic recovery, and increased intra-abdominal pressure from bandages, pain, or vocalization.

Between 0 and 18% of small breed dogs develop seizures after shunt ligation.[1,25,26,30,31,32] The etiology is unknown, and affected animals usually do not respond to fluids, dextrose, or enemas. Seizures are treated with an IV bolus of diazepam to effect or propofol to induce anesthesia and blood glucose is measured and corrected if low. The patient is started on intravenous levetiracetam and switched to an oral form once the animal is able to swallow. If the animal continues to seizure, the animal is placed on a continuous intravenous infusion of propofol to maintain light anesthesia and treated with IV mannitol and phenobarbital. Levetiracetam is continued, and intensive nursing care is provided. Propofol is discontinued after 12 hours; sedation with dexmedetomidine or acepromazine may be required during propofol recovery. If seizures occur after anesthetic recovery, the CRI is reinstated for another 12 hours. Prognosis is poor for animals with postoperative seizures, and those that survive usually continue to have neurologic problems.

Animals with persistently elevated bile acids should be re-evaluated by ultrasound, scintigraphy, or portography. Persistent shunting is usually from development of multiple acquired shunts but can occur with lack of closure of the shunt within the constricting device, or because of presence of a second shunt. If no shunting is detected, a liver biopsy is performed to determine the underlying pathology.

Prognosis

The prognosis for successful surgical treatment is best for dogs with extrahepatic shunts, for animals that undergo complete suture ligation or gradual occlusion with ameroid constrictors or cellophane bands, and for those animals that are presented with urinary tract signs and no hepatic encephalopathy.[1,25,33-35] Mortality rates after surgery are higher in animals with low albumin, high white blood cell counts, seizures, or intrahepatic shunts and in those that undergo acute partial shunt ligation.[1,25,26]

Half of dogs that undergo partial shunt ligation with suture develop clinical signs of portosystemic shunting within 2 years after ligation.[34] Some of these animals will respond to further ligation, while others have developed multiple acquired shunts or cannot tolerate further PSS occlusion. Clinical signs in these patients are controlled with lactulose and a protein restricted diet.

Cats commonly develop neurologic signs after surgery and may require continued treatment with phenobarbital. The prognosis is variable depending on the severity of preoperative clinical signs. After ameroid constrictor placement, acute complications occur in 25% to 75% of cats and excellent long term outcome is seen in 33% to 77%.[7,8] The mortality rate was 20% and recurrence of hepatic encephalopathy was noted in 30% to 40% of cats after acute suture ligation.[22]

Cellophane Banding of Portosystemic Shunts

Geraldine B. Hunt

Background

Most congenital portosystemic shunts cannot be completely ligated at the time of surgery because of the risk of inducing life-threatening portal hypertension. Placement of devices to produce gradual progressive occlusion is now considered by most surgeons to be the treatment of choice. A variety of methods of gradual occlusion have been evaluated clinically and experimentally, including cellophane bands,[1-3] ameroid constrictors,[4-9] thrombogenic coils[2,10] and hydraulic occluders.[11]

Cellophane is a transparent flexible cellulose sheeting widely used in the packaging industry. It creates a foreign body reaction when implanted into the body of dogs. When placed around a blood vessel, cellophane promotes gradual progressive occlusion of the vessel by direct pressure of the developing fibrous tissue. Cellophane has been used for vessel occlusion in experimental animals for many years[12] and had a role in human surgery at one stage, as a means of supporting vascular aneurysms and as a non-permeable barrier to discourage adhesions around joints.[13] Cellophane was first reported for attenuation of a congenital portosystemic shunt in a dog in 1990[14] and its use has been reported subsequently in larger case series.[1,3] Studies by Youmans and Hunt showed progressive reduction in diameter of the femoral vein from 5 mm to 2 mm in dogs after application of cellophane bands.[2] For this reason, cellophane band diameters of no more than 3 mm are usually applied to the target vessel. However, a previous report,[15] anecdotal observations and the author's own experiences indicate that larger bands are capable of promoting complete vessel occlusion in some animals.

Equipment

Cellophane is acquired in sheet form from a stationer or paper company. It should be strong enough to withstand handling, but not sufficiently thick to cause kinking of the fragile shunt vessel. Recent work has shown that the clear films reported for portosystemic shunt attenuation are not always cellophane.[18] Nevertheless, polypropylene and polyethylene have yielded similar results, possibly due to the irritant effect of chemicals used during processing. Prior to implantation, the surgeon should check which particular clear film they are using. Cellophane strips should be cut parallel to the fiber orientation to preserve its breaking strength. Cellophane should be sterilized by autoclave, as this best preserves its strength once the band becomes wet with saline or body fluids. The best method of sterilization for synthetic polymers has yet to be determined. Gauging devices of various diameters are fashioned from surgical pins or connecting bars, bent at right angles and with their ends filed to a blunt tip if necessary. In most cases, a range between 2 mm and 1 cm is satisfactory. Medium-sized titanium surgical ligating clips are used to secure the cellophane band around the shunt. A water manometer is used to monitor changes in portal pressure during cellophane application in dogs weighing more than 10 kg. Right angled dissecting forceps (Debakey bile duct forceps) and Adson tissue foceps assist mobilization of the shunt and passage of materials around it.

Surgical Technique

Surgery is performed through a ventral midline celiotomy incision. The incision extends ventral to the xiphoid process of the sternum and the linea alba is divided to expose the xiphoid at the level of its cranial connection to the pectoral muscles. Care is taken when dividing the falciform ligament as shunts have occasionally been encountered in this location.

Initially, the abdominal viscera is retracted to the right using the mesocolon and the paravertebral gutter and left kidney are examined to rule out the presence of multiple acquired shunts that result from portal hypertension. The crura of the diaphragm is examined to determine whether a portoazygous shunt is present.

The abdominal viscera is then retracted to the left using the mesoduodenum and the caudal vena cava examined for the presence of abnormal veins emptying into it. The cava should be visualized from its origin at the confluence of the common iliac veins to the area cranially where it deviates to pass dorsad to the liver. The right and left renal veins, gonadal veins and phrenicoabdominal veins should be the only vessels entering the caudal vena cava within the cranial abdominal cavity. Any vessel terminating in the vena cava cranial to the phrenicoabdominal veins is abnormal. Dilation and obvious turbulence visualized through the thin wall of the cava may be indicative of an abnormal vessel. However, turbulence can occur as a normal finding at the point of entry of the renal veins in some animals. The caudal vena cava should be inspected as it crosses the liver to ensure that it does not continue forward as the azygous vein.

Particular attention is directed to the area of the epiploic foramen. The epiploic foramen is dorsal to the duodenum and is created by the fold of tissue containing the hepatic artery and portal vein ventrally and bounded by the vena cava dorsally. A small, flat-bladed retractor is placed dorsal to the hepatic artery into the foramen and elevated to visualize the left side of the vena cava. Extrahepatic portosystemic shunts are commonly detected entering the vena cava in this location.

The hepatic portal vein should be examined as it courses adjacent and ventral to the hepatic artery to arborize at the porta hepatis of the liver. Portal vein branches can be identified that supply the right lateral, right medial and left liver lobes. Dilation of one of these branches may indicate the presence of an intrahepatic shunt. *Dilatation of all portal vessels simultaneously may signify portal hypertension, rather than increased portal flow.*

If a shunt has not been identified within the epiploic foramen, the abdominal viscera are returned to their normal position and an opening created in the ventral leaf of the omentum to visualize the omental bursa. The stomach is retracted cranially to inspect the left gastric, splenic and pancreaticoduodenal veins. Dilation of one of these vessels usually indicates the presence of an extrahepatic shunt. Identify the portal branch giving rise to the dilated vessel and follow it to its point of entry into the systemic circulation.

If it is not possible to confidently identify an extrahepatic shunt, consider the likelihood of an intrahepatic shunt, or microvascular dysplasia. If a portoazygous shunt is suspected, the crura of the diaphragm may be divided to allow visualization of the caudal mediastinum.

Once the shunt has been identified, the viscera should be retracted so as to provide maximum access for dissection and attenuation of the vessel. Exposure of the shunt varies according to specific shunt anatomy but in most cases, portocaval shunt dissection is easiest when performed through the epiploic foramen. For portoazygous shunts, dissection is usually easiest from a left approach with the viscera retracted to the right. Attenuation of any shunt should take place as close as possible to the systemic vascular system so as to ensure that small portal branches do not enter distal to the attenuation point.

Determining Cellophane Band Diameter

The shunt vessel should be dissected free from surrounding fat and connective tissue. A suture of 2-0 or 0 polypropylene is passed around the vessel to facilitate further attenuation at a later date should the cellophane band not promote complete shunt occlusion. Baseline physiologic parameters are measured including heart rate, direct or indirect systolic arterial pressure and central venous pressure. The color of the pancreas and intestines, and intestinal motility are assessed prior to placement of the cellophane band. In dogs heavier than 10 kg, and those with intrahepatic shunts, a jejunal vein is catheterized to permit measurement of portal pressure using a water manometer during band placement and tightening.

The polypropylene suture is tightened so as to occlude the shunt completely and measurement of the previously described physiologic parameters repeated. Elevation of the heart rate by more than 20 beats per minute, a fall in systolic arterial pressure of more than 10 mm Hg, a fall in central venous pressure of more than 1 mm Hg, or a rise in portal pressure of more than 10 cm H_20 (to a maximum of 20 cm H_20) all signify inability to completely occlude the shunt.

Congestion and cyanosis of the pancreas and intestines, and a substantial increase in intestinal motility are also considered indications of unacceptable portal hypertension.

In animals weighing 10 kg or less, cellophane bands between 2 and 3 mm diameter are usually placed around the shunt. A 3 mm band is placed if the shunt is not amenable to total occlusion. If mild to moderate changes in baseline hemodynamic parameters and intestinal color and motility are observed, a 2.5 mm band is placed. If no change is observed, a 2 mm band is applied. In dogs weighing 10 kg or more, the band diameter is dictated by changes in portal pressure, as for other forms of attenuation. Cellophane bands between 2 and 3 mm diameter result in substantial shunt attenuation, however, life-threatening portal hypertension necessitating removal of the cellophane band has only been seen in one small dog (a Bichon Frise in which a small thrombus embolized to the attenuation site 3 days after surgery). Wider cellophane bands may also cause complete eventual occlusion, but this has not been proven in an experimental setting.

Preparation and Placement of the Cellophane Band

Following identification and mobilization of the shunt, a strip of cellophane 1.2 cm wide and about 15 cm long is folded lengthwise to produce a 3-layered band 4 mm in width and 15 cm in length. The end of the cellophane is cut obliquely to facilitate passage around the shunt.

The cellophane band is passed gently around the shunt, incorporating as little perivascular tissue as possible (Figure 21-16A). The cellophane is easily torn when wet, so manipulation of the band should be minimized once it is in place around the vessel.

The surgeon should hold both ends of the band between thumb and forefinger and insert a stainless steel pin of appropriate diameter inside the band, next to the shunt vessel (Figure 21-16B). Hemostatic clips are then applied while the cellophane band is held tight around both the pin and the shunt (Figure 21-16C). Recent work has shown that the resistance to tensile forces of the clip-cellophane configuration increases when multiple clips are alternately applied from opposing directions.[19] In practice, the forces applied to the cellophane band following implantation are low, and placement of two clips with opposing orientations should be sufficient. This results in creation of a cellophane band of the required diameter. The stainless steel pin is withdrawn, allowing the shunt to expand inside the cellophane band to the predetermined diameter (Figure 21-16D). One of the original research studies[4] showed that the diameter tended not

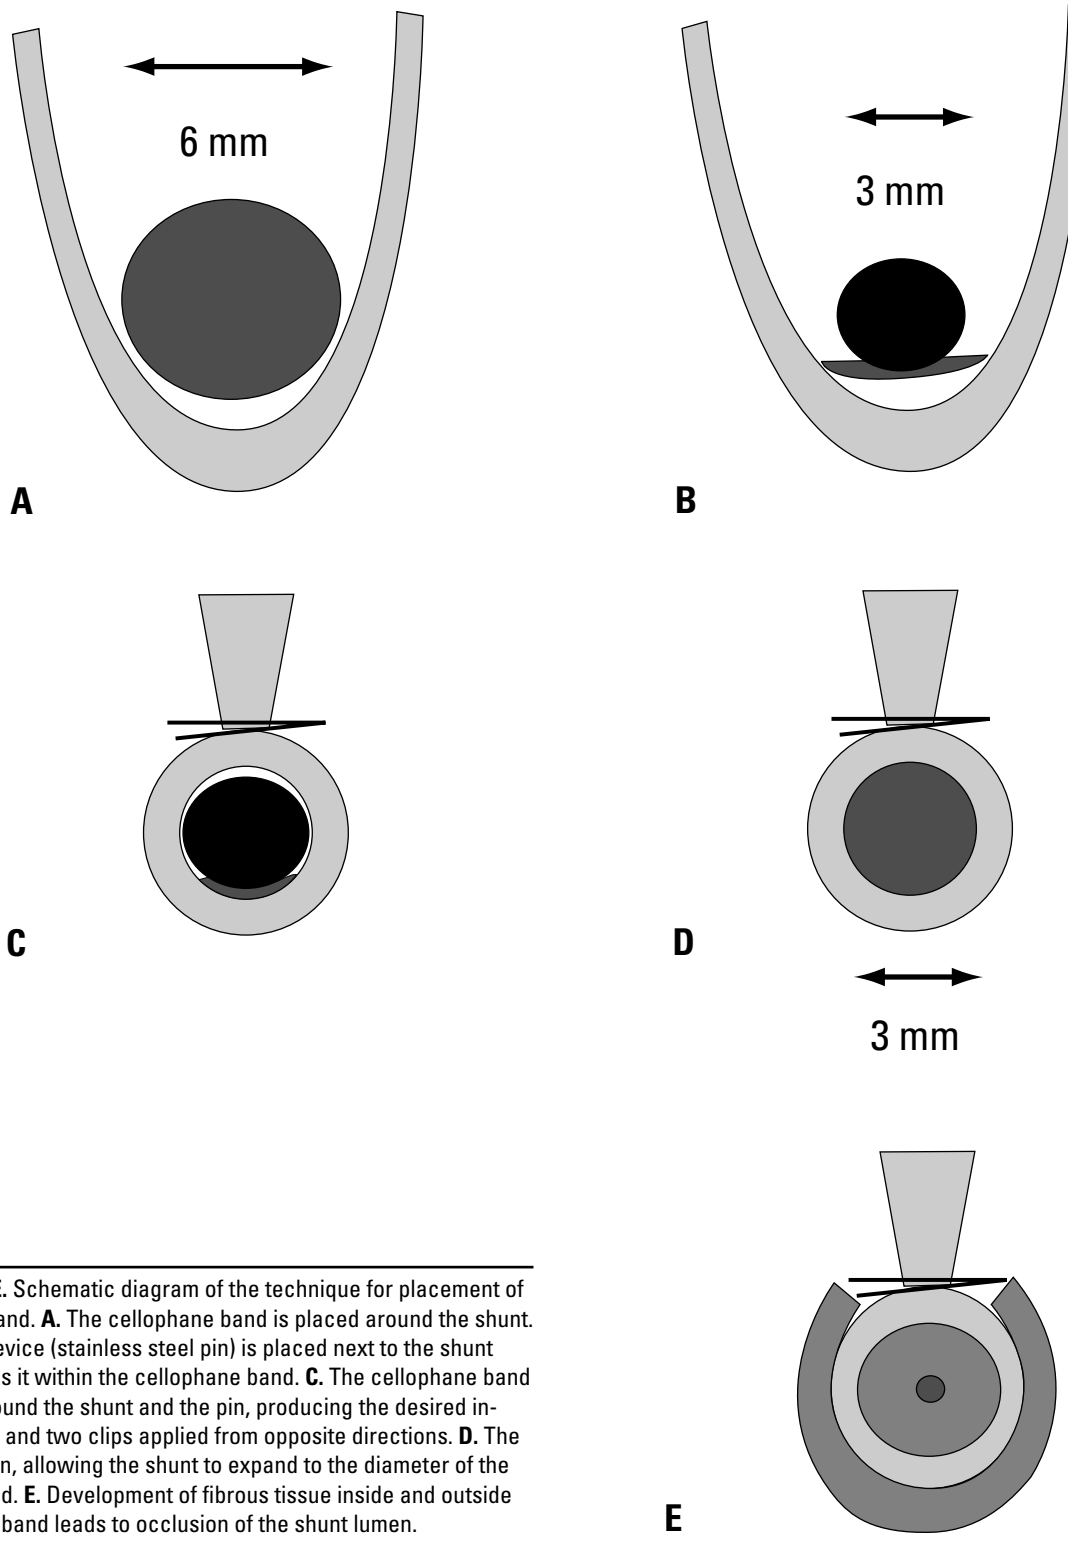

Figure 21-16A-E. Schematic diagram of the technique for placement of a cellophane band. **A.** The cellophane band is placed around the shunt. **B.** A gauging device (stainless steel pin) is placed next to the shunt and compresses it within the cellophane band. **C.** The cellophane band is tightened around the shunt and the pin, producing the desired internal diameter and two clips applied from opposite directions. **D.** The pin is withdrawn, allowing the shunt to expand to the diameter of the cellophane band. **E.** Development of fibrous tissue inside and outside the cellophane band leads to occlusion of the shunt lumen.

to decrease by more than 3 mm following cellophane band application, and hence it is recommended that this diameter not be exceeded in smaller patients. However, other researchers[6] have shown that placement of loose bands that do not constrict the shunt may be preferable in larger patients. It should be noted, however, that the clear film used in these other reports was not cellophane, and may therefore behave differently to cellophane in clinical patients.

Haemodynamic measurements are repeated and the intestine and pancreas inspected to ensure that safe portal pressures have not been exceeded. The ends of the cellophane are cut, so as to leave 1 mm protruding beyond the surgical clip. The cellophane band is gently rotated to ensure it does not kink the shunt or adjacent vessels. The polypropylene suture is tied loosely and cut to leave 4 cm ends. This enables identification of the shunt if subsequent surgery is required due to persistent signs of hepatic dysfunction or portosystemic shunting. The polypropylene suture may be pulled tight during later surgery to check whether the original shunt is closed or patent, thus avoiding the necessity of dissecting through fibrous tissue. The polypropylene suture may be tightened if necessary without having to disturb the shunt itself. The need for a second surgery is rare following cellophane banding of portosystemic shunts.

Postoperative Care

The abdomen is lavaged with warm saline and the celiotomy wound closed routinely. Animals are monitored intensively for the first 72 hours after surgery, which is considered the high risk period for seizures and portal hypertension. A broad spectrum antibiotic is administered perioperatively. Phenobarbital is given as a premedication 30 minutes before surgery (10 mg/kg intramuscularly) and continued for 72 hours postoperatively (2 to 5 mg/kg twice daily by injection or *per os*). If the animal experienced generalized motor seizures before surgery, phenobarbital is continued for approximately four weeks postoperatively and the dose then tapered. Animals are maintained on a commercially available restricted protein diet (Hills L/D) for the first 4 weeks after surgery. No other medical management is used unless animals show signs of hepatic encephalopathy (rare). If the patient is clinically normal four weeks after surgery, the owners are instructed to gradually return them to the original diet they were eating before they experienced clinical signs. If the patient shows signs of hepatic encephalopathy, medical management with restricted protein diet, lactulose syrup (0.5 ml/kg twice daily) and antibiotics is resumed. Analysis of liver function using ammonia tolerance testing, serum bile acid determination or scintigraphy is recommended two months after surgical attenuation of the shunt. Follow up of patients demonstrating continued liver dysfunction should include some form of imaging (ideally contrast-enhanced computer tomography) to differentiate the cause of persistent shunting and determine the best management plan.

Summary

Results of cellophane banding have been reported by several authors.[5-8] The mortality rate is up to 5.5%, largely resulting from portal hypertension and post ligation neurological dysfunction. Liver function returned to normal postoperatively in 85% of dogs and 60% of cats. Reasons for continued liver dysfunction include failure of the shunt to close, inappropriate placement of the cellophane band, and development of acquired shunts.[7,9] This was similar to reported results for a series of 127 dogs that underwent placement of ameroid constrictors in dogs[7] and cats.[10,11] The survival rate and resolution of hepatic dysfunction were lower in dogs with intrahepatic shunts versus those with extrahepatic shunts. Follow up of an additional 33 dogs subsequent to the cases reported above[3] confirms the low mortality rate (1 dog, 3%). This dog (a Bichon Frise) was the only animal that experienced post ligation neurological disorder and was euthanized as a result of uncontrollable seizures that commenced 70 hours after shunt attenuation. No instances of life-threatening portal hypertension were encountered. Cellophane banding continues to yield poorer results in cats than in dogs, for reasons that are not entirely clear.[8]

Pancreatic Surgery

Elizabeth Hardie

Introduction

In general, surgeons prefer to avoid the pancreas, because manipulation may incite inflammation and pancreatitis. The blood supply of the pancreas is intimately connected to that of the duodenum, which makes pancreatic resection technically challenging. However, there are some indications for surgery on the pancreas.[1,2] Pancreatic biopsy is used to confirm pancreatic disease. Nodule removal or partial pancreatectomy is used to treat insulinoma, other endocrine tumors, and pancreatic carcinoma. Complete pancreatectomy has been used mainly as a research surgery to create diabetic models, but may be performed in animals with intractable chronic pancreatitis. Acute pancreatitis is not treated surgically, but may require placement of a jejunostomy tube for enteral feeding. The intimate relationship of the pancreatic duct and the bile duct as they enter the duodenum means that inflammation or scarring of pancreatic tissue may compress the bile duct, and stenting or diversion of the biliary tract may be needed in animals with pancreatitis. The pancreas can develop cysts or abscesses, and drainage or resection may be needed to resolve clinical signs related to these fluid accumulations.

Pancreatic Anatomy

The pancreas is a bilobed organ that sits in the angle between the duodenum and the greater curvature of the stomach. The portion of the gland lying along the duodenum is termed the right lobe, while the portion lying adjacent to the stomach is the left lobe. The portion where the two lobes join is the body. The right lobe lies within the duodenal mesentery. The more distal aspect of the right lobe can be separated from the duodenum, but the gland is tightly adherent to the duodenum in the region of the body. The left lobe lies within the dorsal sheet of the greater omentum. Accessory pancreatic tissue may occur in the region of the gall bladder or mesentery in the dog.[3]

Exocrine secretions from pancreatic tissue are carried by ducts that run along the center of each pancreatic lobe (Figure 21-17).

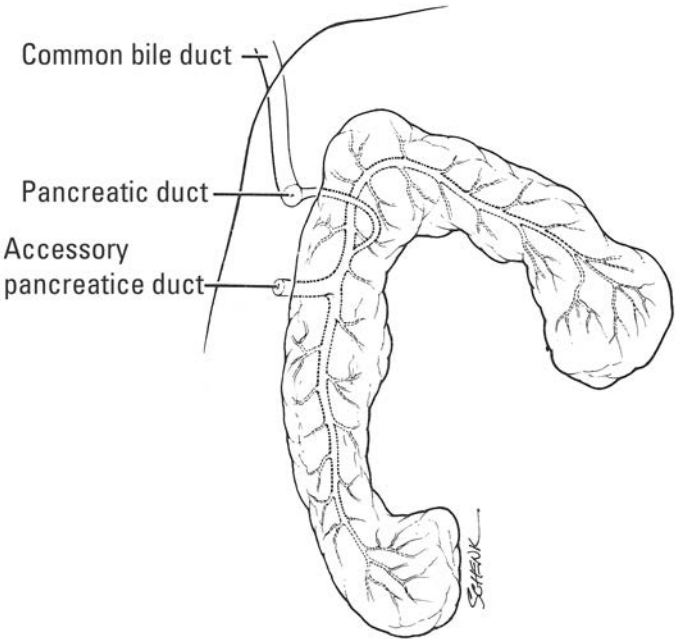

Figure 21-17. The pancreatic excretory ducts.

There is significant anatomic variation between individuals and between species in the number and location of the principal pancreatic ducts that carry pancreatic secretions to the duodenum.[1,3] In most dogs, there are two ducts entering the duodenum. The pancreatic duct is in the body of the pancreas and enters the duodenum, along with the bile duct, at the major duodenal papilla. The second duct, the accessory pancreatic duct, is further distal in the right pancreatic lobe and enters the duodenum at the minor duodenal papilla. In most dogs, the accessory pancreatic duct is the larger duct and drains both lobes of the pancreas, while the pancreatic duct is small and only carries a small amount of secretions. Variations include the presence of three ducts (two opening at the minor papilla and one at the major papilla) and completely separate ducts for the right and left lobes. In the cat, the pancreatic duct is the larger duct, joining the bile duct and entering the duodenum at the major duodenal papilla. Eighty percent of cats do not have an accessory pancreatic duct or a minor duodenal papilla. Ferrets are similar to cats, but the accessory pancreatic duct is present more often.[4] Pancreatic bladders, which are dilations off the pancreatic duct, have been reported in cats.[3]

The blood supply to the right lobe of the pancreas comes from the cranial and caudal pancreaticoduodenal arteries, which anastomose in the right lobe (Figure 21-18). The cranial pancreaticoduodenal artery is a branch of the gastroduodenal artery, while the caudal pancreaticoduodenal artery is a branch of the cranial mesenteric artery. The left lobe of the pancreas is supplied by the splenic artery and small branches off the hepatic artery. Venous blood drains to the portal vein through the pancreaticoduodenal veins and the splenic vein. Lymphatic drainage goes to the pancreaticoduodenal, hepatic, jejunal and splenic lymph nodes.[3]

Pancreatic Biopsy

Pancreatic biopsy is performed to diagnose or confirm pancreatic disease.[1,5] Chronic low-grade pancreatitis must be differentiated

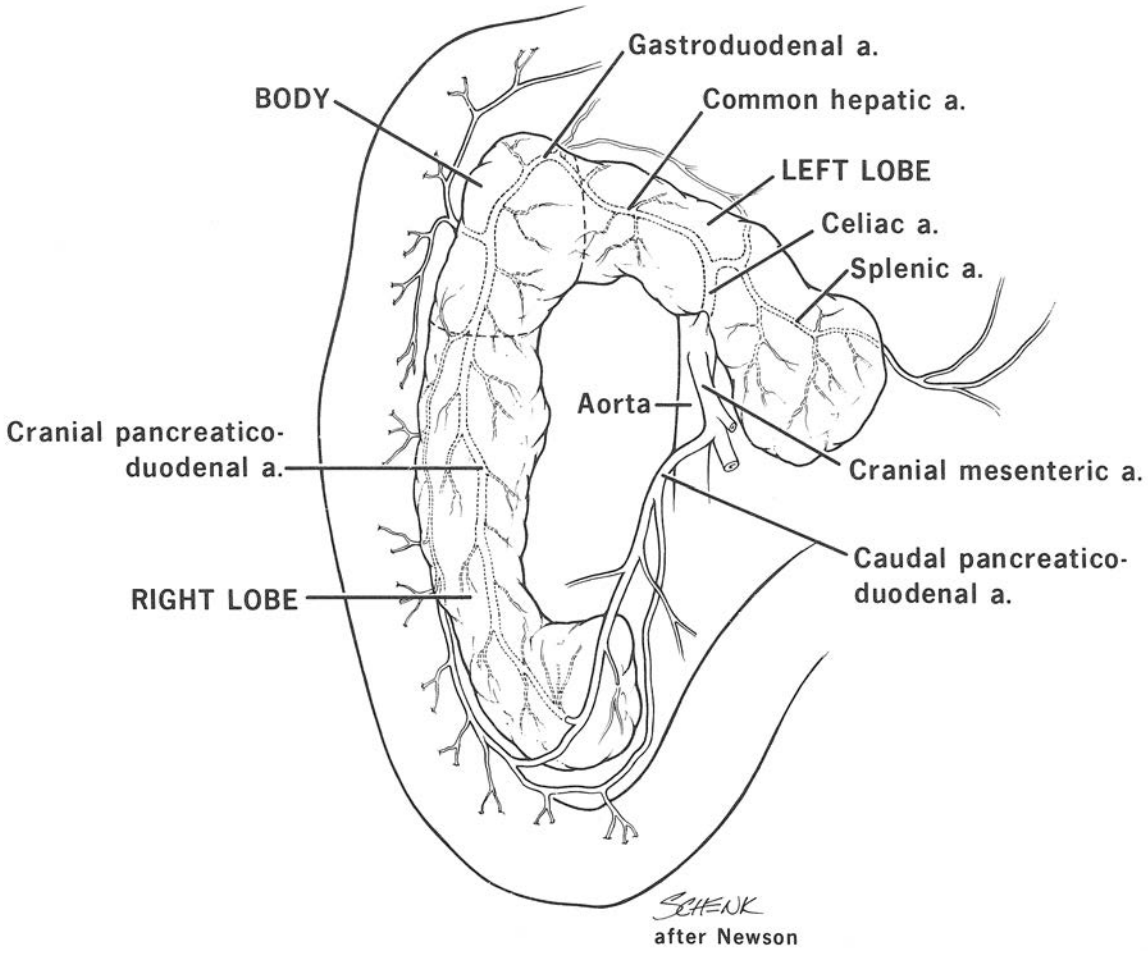

Figure 21-18. The pancreatic arterial supply.[5]

from other causes of chronic gastrointestinal disease. Chronic pancreatitis may only be apparent microscopically and may be multifocal rather than diffuse, requiring several small biopsies to confirm or deny a diagnosis.[6] In animals with macroscopic disease of the pancreas, biopsy is used to differentiate between diseases such as chronic pancreatitis, pancreatic carcinoma, and pythiosis. Leiomyosarcoma of the duodenal wall may invade the pancreas through the shared blood supply.

If the biopsy is being obtained from a grossly normal pancreas, it is usually taken at the distal aspect of the right lobe of the pancreas because of the ease of exposure and low risk of inciting pancreatitis. If the biopsy is obtained laparoscopically, a small piece of tissue is removed using cup biopsy forceps.[7] If needed, hemorrhage is controlled with gentle pressure or a piece of Gelfoam. When the biopsy is taken as part of an exploratory laparotomy, an encircling ligature of a monofilament suture is placed around a portion of the distal lobe. The ligature is tightened and the tissue is removed. If multiple small samples of pancreatic tissue are needed, hemostatic clips can be used to occlude the vessels supplying the tissue which is then excised distal to the clip. The mutilobular nature of pancreatic tissue makes this a relatively easy procedure, but small delicate instruments and magnification are helpful when isolating a lobule. The major ducts and vessels should be avoided, thus biopsies are most safely taken at the edges of the gland opposite the duodenum and the stomach. The mesentery or omentum overlying the portion of the pancreas to be biopsied must be incised to expose the tissue.

Partial Pancreatectomy and Nodule Removal

Partial pancreatectomy is most commonly used to treat insulin secreting beta cell tumor (insulinoma), but there is confusion in the veterinary literature over the term partial pancreatectomy.[2,8] The term has been used to describe neoplastic nodule removal (enucleation), nodule removal with removal of a border of normal pancreatic tissue, and removal of most of one lobe of the pancreas. The term should probably be reserved for removal of most of one lobe. In general, pancreatic neoplastic nodules should be removed with a border of normal tissue, which is most easily accomplished by removing the nodule and the lobe of the pancreas distal to the nodule. In ferrets, it has been shown that animals with beta-cell tumors treated with partial pancreatectomy survive longer than animals treated with enucleation.[8] Enucleation should be reserved for animals with nodules in the body of the pancreas. If the nodule in the body is large or is in a difficult location, it may be preferable to biopsy the nodule using a needle biopsy technique and forego nodule removal in favor of medical therapy (frequent feeding, corticosteroids, diazoxide, octreotide, streptozocin).[2,9,10] The risk of pancreatitis is higher when extensive or prolonged dissection of the body is performed.

The technique for partial pancreatectomy differs for the two

lobes of the pancreas. For the right lobe, dissection is begun at the distal aspect of the lobe, where the pancreaticoduodenal vessels are most easily visualized. The mesentery is incised and the distal pancreas is grasped. The dissection proceeds towards the pylorus, and care is taken to protect the pancreaticoduodenal vessels. Hemoclips or bipolar cautery are used to control bleeding from small branches of the pancreaticoduodenal vessels entering the pancreas. The pancreas becomes more tightly associated with the duodenum as the dissection proceeds proximally, making isolation of the pancreaticoduodenal vessels more difficult. Blunt dissection using moistened cotton swabs or fine hemostats is used to separate the lobules from the vessels (Figure 21-19). In the dog, the right lobe can only be removed to the level of the accessory pancreatic duct, while in the ferret or the cat, the lobe can be removed to the level of the pancreatic duct. Once the desired portion of the pancreas is dissected free from its attachments, one of several techniques may be used to occlude the ducts. An encircling ligature can be placed around the organ, a stapling device can be used to compress the tissue, or fine hemostats can be used to bluntly remove glandular tissue from the vessels and ducts, which are then individually occluded with vascular clips or ligated. The distal portion of the gland is then removed. Any complete rent in the mesentery created by removal of the gland is directly repaired or is covered with an omental patch.

To gain exposure to the left lobe, the ventral leaf of the omentum is opened. The distal portion of the lobe is grasped and the relationship of the pancreas to the splenic and left gastroepiploic vessels is identified. The pancreatic arteries supplying the distal left lobe are branches off the splenic artery. The venous drainage of the left lobe of the pancreas is through two branches that enter the splenic vein. The various pancreatic vascular branches are occluded with vascular clips or ligated, while preserving the splenic vessels. If there is doubt about the integrity of the splenic vessels, splenectomy is performed. As the dissection proceeds towards the body, the branches of the hepatic artery that supply the pancreas must be ligated. Care is taken to preserve the celiac, left gastric, hepatic and gastroduodenal arteries. Once the vasculature is clipped or ligated, the pancreatic tissue is removed in a similar fashion to the right lobe.

Nodule removal is performed by bluntly dissecting the nodule from the surrounding tissue using cotton swabs or a fine hemostat. Hemorrhage from small vessels may be controlled using pressure or small vascular clips. Care is taken to preserve the major intestinal and pancreatic vessels and ducts. Ideally, a border of normal pancreatic tissue should be removed with the nodule.

If multiple pancreatic nodules are found, it may be necessary to use a combination of techniques to remove the nodules. If no nodules are found, intraoperative ultrasound may aid in identification. In dogs, injection of methylene blue has been used to help identify nodules, but the technique carries the risk of causing acute renal failure and is falling out of favor. Finally, if no nodules can be identified , pancreatic biopsy should be performed to rule out diffuse pancreatic beta cell tumor, a condition that occurs in < 5% of dogs with insulinoma.[2]

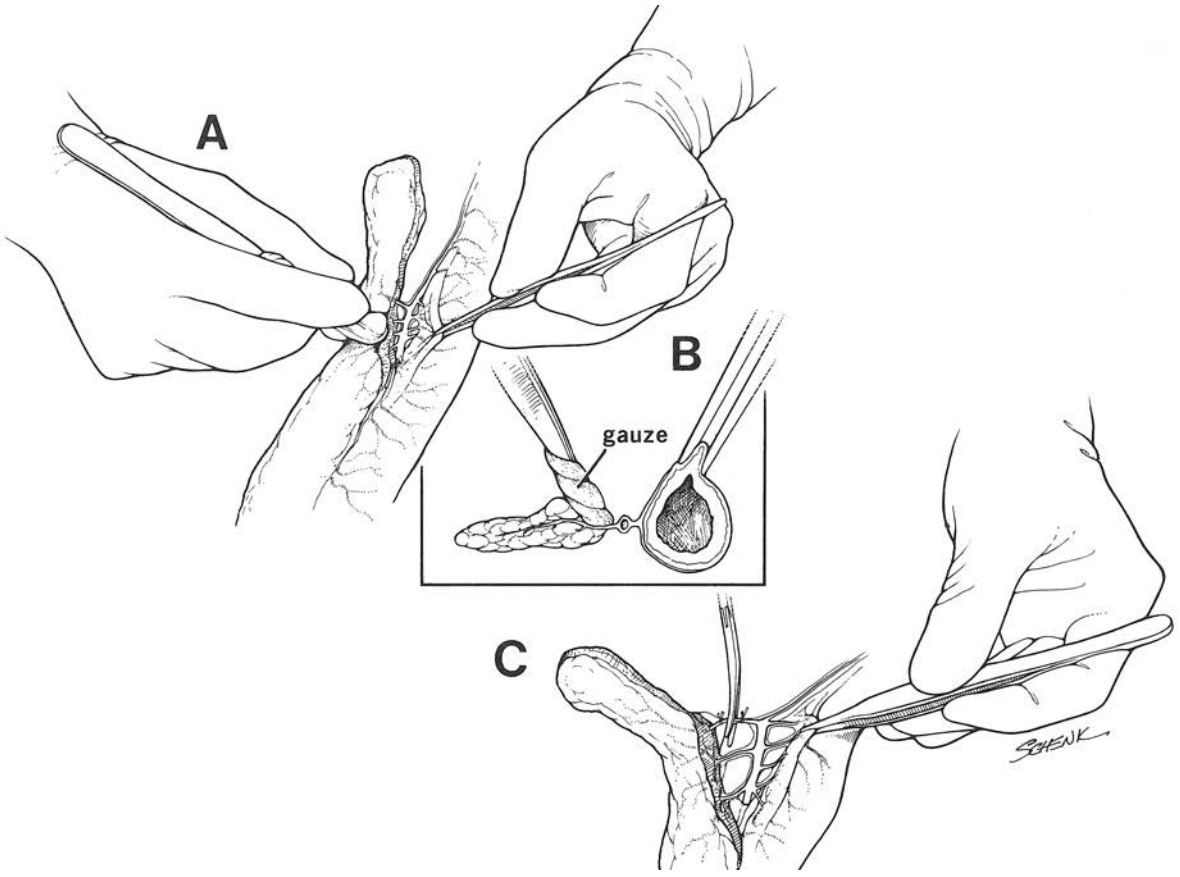

Figure 21-19. Pancreatectomy technique: separation of the pancreas from the duodenum.[5]

Most animals with insulinoma have microscopic or gross metastatic lesions present at the time of initial diagnosis. Metastasis is seen most commonly in regional lymph nodes and the liver. Since metastases are functional tumors it is important to identify and remove as many of the lesions as possible. It would be ideal if metatstatic lesions were identified before surgery, but surgical exploration is currently the most accurate method for identifying these lesions. Ultrasound, computed tomography and single photon emission computed tomography have all been used to identify primary and metastatic lesions, but no technique is superior to surgery.[11] The pancreaticoduodenal, hepatic, jejunal and splenic lymph nodes are carefully examined for enlargement. Precise, careful dissection using fine vascular instruments and magnification is often needed to remove an enlarged lymph node while preserving the vasculature to the intestines. Nodules within the liver can be removed with partial hepatectomy. If removal of the metastatic lesions is likely to endanger the life of the animal, it may be preferable to treat with medical therapy.

Pancreatic tumors other than insulinomas are rare. Endocrine tumors include gastrinomas, glucagonomas and other neuroendocrine cell tumors. Surgical treatment of these tumors is similar to that of insulinoma. Pancreatic carcinomas are often extensive at the time of diagnosis and are highly metastatic. Partial pancreatectomy can provide a period of remission from clinical signs if the primary tumor is localized to one lobe.[12]

Complete Pancreatectomy

Complete pancreatectomy is a formidable procedure and is rarely indicated. Removal of the entire pancreas produces an animal that is diabetic and has pancreatic exocrine insufficiency. Management of these patients requires an intelligent, dedicated owner, who can follow a detailed feeding, medication and glucose monitoring regime. The technique is similar to the technique for partial pancreatectomy, except that the dissection is carried around the body of the pancreas. The dissection is most commonly performed from the left to the right side. The pancreatic branches from the hepatic and gastroduodenal arteries are ligated. Blunt dissection is used to expose and preserve the pancreaticoduodenal vessels and the branches entering the pancreas are clipped or ligated. The pancreatic ducts are transected without ligation. After removal of the pancreas, the rent in the duodenal mesentery is closed.

Surgical Treatment of Pancreatitis

A recent consensus conference on the treatment of acute pancreatitis in people confirmed that surgical treatment of acute pancreatitis is not indicated unless confirmed bacterial abscess formation is present.[13] Studies in dogs have shown that animals treated with early enteral feeding rather than intravenous feeding during pancreatitis have reduced plasma endotoxin levels, decreased bacterial translocation to the portal and systemic blood, and improved measures of bowel wall health.[14] Jejunal feeding tubes can be placed during celiotomy or using minimally invasive surgery techniques. Acute pancreatitis can also lead to obstruction of the bile duct secondary to inflammation. Temporary choledochal stenting (See Hepatobiliary Surgery) is used to maintain biliary tract patency.[15] Animals with chronic pancreatitis can have obstruction of the bile duct secondary to scar formation and may need to be treated with a biliary diversion procedure.

Surgical Treatment of Pancreatic Cysts and Abscesses

Cystic fluid accumulations and abscesses can occur in pancreatic tissue, mainly in association with pancreatitis. Sterile abscesses may be the result of tissue necrosis. When a pancreatic fluid accumulation is observed on ultrasonic examination, needle aspiration is used to identify the fluid and may also be used to drain the accumulation. Cysts and sterile abscesses are not usually treated surgically, unless they are causing obstruction. Infected abscesses require surgical debridement and drainage.

The pancreatic region is carefully explored and the fluid accumulation is located. The wall of the cyst or abscess is removed. The region is flushed and debrided, if indicated. If available, omentum can be placed in the cavity to aid in drainage.[16] A silicone closed suction wound drain or a sump drain is placed to further drain the region.

Perioperative Care

Glucose control is an important part of perioperative management of an insulinoma patient. At the time of food withdrawal, an intravenous infusion of a balanced electrolyte solution containing 2.5-5% dextrose is begun. Infusion is continued through surgery and into the postoperative period. Large doses of dextrose may cause an exaggerated insulin response and should be avoided. After surgery, glucose must be monitored closely because hyperglycemia (8-35% of canine patients) and hypoglycemia (15-26% of canine patients) have been reported. The goal is to maintain a blood glucose between 40-200 mg/dL. If hyperglycemia persists after 48-72 hrs, insulin therapy may be needed.[2]

Animals should be kept well hydrated to help prevent the development of pancreatitis. Oral feeding may be delayed for 24-72 hours after surgery, depending on the extent of pancreatic manipulation. When food is reintroduced, small bland meals are fed. The animal is monitored closely for the development of nausea, vomiting, cranial abdominal pain or systemic inflammatory syndrome. Postoperative pancreatitis has been reported in 10-43% of canine patients undergoing nodule removal or partial pancreatectomy.[2] It is rare in ferrets.[8] If extensive dissection in the body of the pancreas is performed, a jejeunostomy tube should be placed prophylactically to allow early enteral feeding after surgery. Placement of a closed silicone abdominal drain in the region of the pancreas at the conclusion of surgery allows for rapid diagnosis of postoperative pancreatitis and aids in the management of abdominal effusion associated with pancreatitis.

Surgery of Pancreatic Neoplasia

James M. Fingeroth

Introduction

Many veterinarians are reluctant to touch, palpate, or operate on the pancreas because of concern for inducing pancreatitis. Leakage and activation of pancreatic enzymes caused by pancreatic trauma or surgery is possible and caution is indicated but it should not inhibit pancreatic manipulation in an appropriate manner when indicated. Pancreatic palpation, biopsy, and resection can all be performed safely, and proper post-operative patient management will minimize complications postoperatively.

Pancreatic examination should be part of every routine exploratory celiotomy. The right limb of the pancreas is easily visualized by identification and elevation of the descending duodenum toward the ventral midline from right to left during ventral midline celiotomy. The left limb can then be identified by tracing the right limb towards the angle (body), and retraction of the spleen. It can be helpful to perforate the greater omentum to better visualize and palpate the left limb of the pancreas as it courses dorsally along the greater curvature of the stomach. In the area of the angle and left limb of the pancreas the surgeon should also examine the regional lymph nodes since these may be affected by metastasis in cases of pancreatic neoplasia (Figure 21-20).

Because of the lobulated nature of the pancreatic parenchyma, and the tendency for the organ to sometimes fold on itself, examination of the pancreas should be both *visual* and *tactile* (See Figure 21-20). The latter requires the surgeon to gently palpate the organ between his or her fingers along its entire course. Small, but potentially significant lesions (e.g., islet cell tumors) may be missed if the pancreas is not palpated in addition to visual inspection.

On occasion the pancreas will be explored because a large mass has been identified on pre-operative imaging, or because of medically unresponsive pancreatitis. Surgeons should be familiar with the appearance of such lesions as pancreatic pseudocysts and abscesses when examining the pancreas at the operating table. Surgeons should especially be aware that inflammatory disease of the pancreas may appear aggressive and invasive. The organ may be diffusely enlarged, irregular, have varying color, and appear to invade into surrounding omental fat. This appearance may suggest a gross diagnosis of "extensive and unresectable malignant neoplasia", and may even prompt the surgeon to recommend immediate euthanasia. However, it is not uncommon for biopsies of aggressive appearing pancreatic lesions to reveal no evidence of neoplasia, and instead necrotizing/hemorrhagic inflammation along with local steatitis, adhesions, and fat saponification. While the diagnosis of necrotizing/hemorrhagic pancreatitis may prove to be a serious and potentially fatal diagnosis, it may still be manageable with appropriate therapy. The surgeon should not conclude that neoplasia is the diagnosis on the basis of appearance alone.

Similarly, it is common to see multifocal or diffuse small white spots in the pancreas, during exploratory celiotomy especially in older animals. These are usually not neoplastic or of any clinical significance. They usually represent areas of fibrosis. However, I have seen cases of lymphoma affecting the pancreas (albeit there are usually lesions beyond the pancreas as well in such cases), so any doubt or concern should be resolved with pancreatic biopsy.

Surgical Anatomy

The pancreas is coarsely lobulated with color that varies between a creamy white, to pink, to occasionally brownish-red (dependent on the amount of blood in the organ).[1] The right limb is molded to the duodenum with which it shares its blood supply (cranial and caudal pancreaticoduodenal artery; caudal pancreaticoduodenal vein). The "tightness" of this fit between the pancreas and duodenum varies from patient to patient. In some animals there is quite a bit of mesenteric tissue between

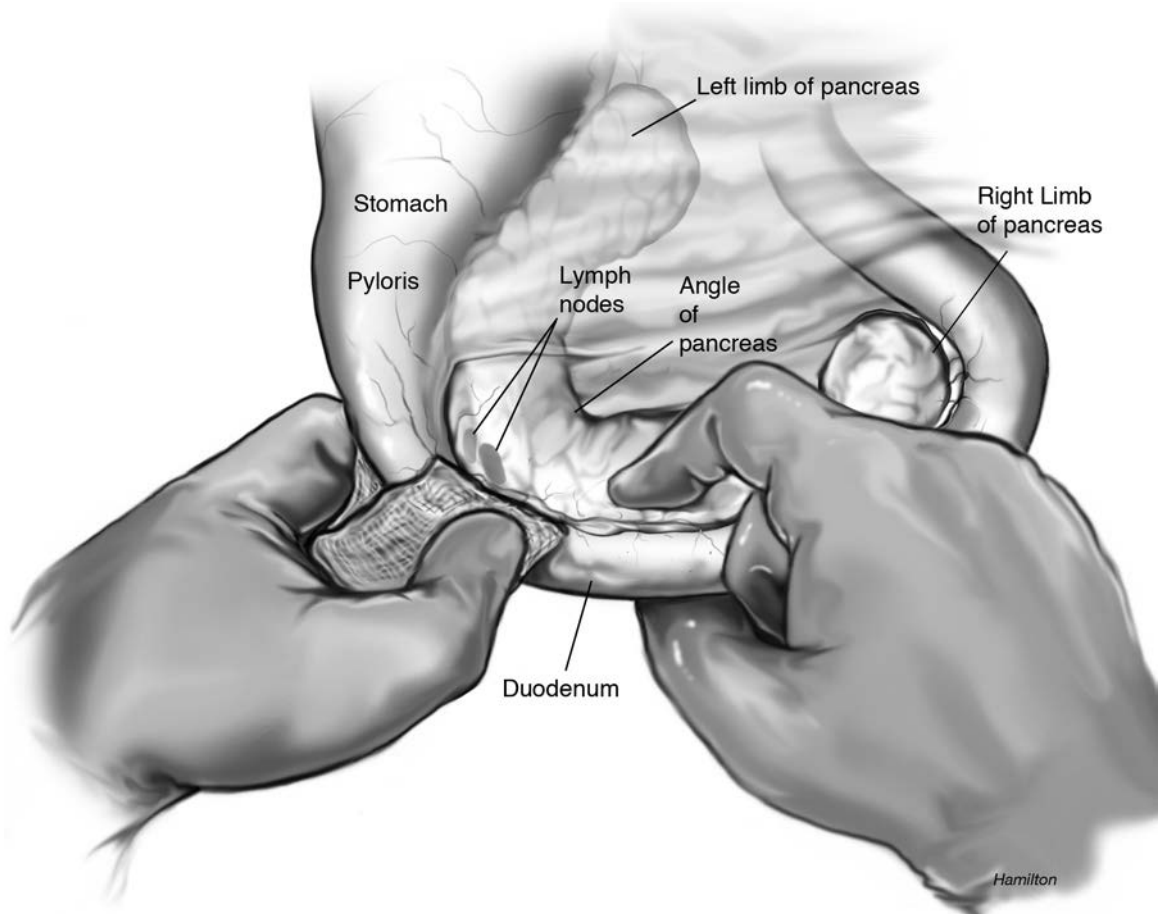

Figure 21-20. Pertinent anatomy for exploration of the pancreas. Arrows depict the right limb, left limb, angle, and approximate location of the pyloric lymph nodes. The pancreas may be gently palpated as shown to detect small masses that may be otherwise visually obscured. The entire organ should be examined, including the left limb which is located in the omental tissues caudal to the stomach and cranial to the spleen. Note the relationship between the right limb and the duodenum, including their shared blood supply.

the two organs, but even then they usually become more closely apposed at the cranial aspect of the right limb near the angle. The arteries course longitudinally between the two organs and are almost completely obscured by pancreatic parenchyma on both sides. The cranial and caudal pancreaticoduodenal arteries (the former a branch of the celiac via the hepatic; the latter a branch from the cranial mesenteric) anastomose within the organ. The left limb of the pancreas is contained within the deep leaf of the greater omentum. Its main blood supply is from the pancreatic branches of the splenic and hepatic arteries (branches of the celiac), with some contribution by the gastroduodenal artery. Thus, the blood supply to the left limb is more segmental than the right. The left and right limbs are joined at a V-shaped angle called the body. This portion of the pancreas resides caudal to the pylorus and antral region of the stomach, and is where the exocrine ducts of the pancreas enter into the duodenum.

The location of the right limb of the pancreas brings it into proximity with other abdominal structures including the right body wall/flank, sublumbar fat containing the right ureter and kidney, the caudate process of the liver, the ascending colon and cecum, and loops of jejunum. The left limb may be in contact with the caudate process of the liver, the portal vein, caudal vena cava, aorta, left adrenal gland, transverse colon, and cranial pole of the left kidney.[2] These relationships may have implications for the surgeon when examining or operating on the pancreas.

The pancreas has lymphatics that drain into the mesenteric, hepatic, and splenic lymph nodes, and these nodes (along with the pyloric nodes) should be examined for metastatic disease when pancreatic neoplasia is suspected. The pancreas receives some sympathetic innervation from the nerves that emerge from the celiac plexus, while parasympathetic nerve fibers from the vagus course to the gland with the celiac and cranial mesenteric vessels. Venous drainage from the pancreas (caudal pancreaticoduodenal vein from the right limb and splenic vein from the left) empties into the portal vein.

The exocrine ducts were named based on the description in humans (pancreatic vs. accessory pancreatic) and this leads to some confusion. Although variation in ductal anatomy has been well described in dogs, the vast majority of dogs have most of their pancreatic exocrine flow into the duodenum via the *accessory duct* and the *minor duodenal papilla*. Since, with few exceptions, the left and right ducts anastomose within the body, the accessory duct carries secretion from both limbs. The smaller (in dogs) pancreatic duct enters the duodenum at the major papilla directly, or by opening into the bile duct as it joins the intestine. In **cats**, the ducts from left and right join to empty almost exclusively via the pancreatic duct into the bile duct at the major duodenal papilla.[3]

Indications for Pancreatic Surgery

Exocrine Pancreatic Disease

The pancreas may be explored because of a clinical diagnosis of exocrine pancreatic insufficiency (EPI). Dogs with EPI are expected to have a significantly reduced volume of pancreatic parenchyma compared with normal individuals. A confirmatory biopsy may be performed as described below. Assuming the entire organ is diffusely affected, the easiest and safest location to biopsy is the distal aspect of the right limb. Dogs with EPI, especially German shepherds, have a reported higher risk for mesenteric volvulus, and may also be at higher risk for gastric volvulus.[4] Therefore, a dog with suspected EPI should have a prophylactic gastropexy performed as part of the surgical procedure (See Chapter 19).

Pancreatitis is treated with intense medical management and is rarely an indication for exploration of the pancreas surgically. However, if imaging studies suggest the presence of an *abscess* or *pseudocyst* then there may be benefit to surgical intervention. The goal should be to obtain appropriate samples for histopathology and culture, and to establish drainage. Drainage techniques will be dependent on the location, size, and mobility of any cavitary lesion identified. Marsupialization is probably the least practical or desirable technique. Drainage tubes may be chosen, and of these a fenestrated silastic drain attached to a closed-suction type device exited through the body wall would be best. Another excellent option to consider is omentalization. This has been described for use with a variety of intra-abdominal abscesses and involves placing a pedicle of vascularized omentum into and/or through the abscess or cystic cavity and securing it with sutures. The omentum brings a blood supply as well as lymphaticovenous drainage to the site of disease.[5-12]

Pancreatitis may be associated causally with or as a result of **biliary disease**.[13,14] Because of the close anatomic association of the pancreatic and accessory pancreatic ducts with the bile duct in the proximal duodenum it is possible for disease in one system to spread to the other. Sludging of bile with extrahepatic biliary obstruction has been reported in dogs with previous episodes of acute pancreatitis.[13,14] Similarly, but less commonly, a primary cholangitis/cholangiohepatitis might result in spread of micro-organisms from the biliary tree into the pancreatic ducts, inducing pancreatitis. Thus, whenever examining the pancreas in instances of exocrine disease the surgeon should also evaluate the biliary tree and liver.

Exocrine tumors of the pancreas (pancreatic adenocarcinoma) are infrequently diagnosed in the canine and feline. Clinical signs of vomiting and anorexia are non-specific, however cats may develop a cutaneous syndrome that includes lameness due to foot pad ulceration and sloughing.[15-17] Clinical signs of exocrine pancreatic neoplasia may be due to the mass effect on neighboring organs if the tumor is large enough, or due to the effects of metastatic disease and/or carcinomatosis. Dogs with pancreatic adenocarcinoma usually do not have signs of either EPI or of pancreatitis. Surgical resection may be attempted depending on the extent of disease, but the prognosis is usually grim. Malignant pancreatic tumors are aggressive cancers and the absence of specific clinical signs usually results in a delay in diagnosis until late in the biological course of disease.

Endocrine Pancreatic Disease

The most common endocrine disease of the pancreas is diabetes mellitus. This disease is usually not an indication for pancreatic surgery. There are important considerations with respect to properly managing diabetic patients undergoing anesthesia and surgery for other disease processes that are addressed elsewhere.[18]

The most common indication for pancreatic surgery due to endocrine disease is the suspicion that the patient has a functional endocrine tumor. Several types of endocrine pancreatic neoplasia have been documented in small animals. The endocrine functions of the pancreas are located in the islet cells (of Langerhans), which are distributed randomly throughout all portions of the pancreas. These mostly neural crest-derived APUD (*A*mine *P*recursor *U*ptake and *D*ecarboxylation) cells migrate into the pancreas during embryonic development. This migration can be imperfect, and as a result functional neuroendocrine cells normally associated with the pancreatic islets may be located in extra-pancreatic locations, including the gastric wall, duodenum, and elsewhere. This in turn implies that functional "pancreatic" tumors may arise ectopically, and this must be borne in mind when exploring a patient's abdomen for a suspected endocrine tumor, especially if a primary lesion is not found in the pancreas itself.

Endocrine pancreatic neoplasia is usually named based on the predominant hormone produced by the tumor. The most common of these tumors is the insulinoma, derived chiefly from a clone of neoplastic beta cells in an islet. In older veterinary literature and in the parlance of the human literature a distinction is made between "insulinoma" (a benign proliferation of beta cells) and "functional islet cell adenocarcinoma" (the malignant variety most commonly diagnosed in dogs). However, in current veterinary clinical and pathology literature the two terms tend to be used interchangeably, so that the term "insulinoma" can describe either benign or malignant neoplasia. Other reported neuroendocrine tumors include gastrinomas (Zollinger-Ellison syndrome) arising mostly from non-pancreatic sites, but occasionally in the pancreas (putatively from delta cells), glucagonomas (alpha cells), non-specific polypeptidinomas, and somatostatinomas (delta cells). In dogs these tumors are usually malignant, and spread to local lymph nodes (Stage II disease) or liver (Stage III disease) is commonly found at the time of initial surgery. The implications for prognosis (disease-free interval and survival time) have been reported as has the use of adjuvant medical therapy.[18-23] This discussion will be limited to patient management during surgery and the immediate postoperative period. The reader is directed elsewhere for a review of criteria for confirming the diagnosis of specific endocrine tumors of the pancreas.[18]

Pancreatic Biopsy and Partial Pancreatectomy

Incisions into the pancreas have the potential for inducing pancreatitis as a consequence of enzymatic leakage and activation of zymogens. Even gentle tissue handling may cause enzymatic

activation. The safest course of action, in my opinion, is to assume that some leakage has occurred. I recommend withholding food and water for a minimum of 36 hours after pancreatic incision. Serum enzymes such as lipase and amylase may be monitored as desired, but these enzymes are notoriously insensitive and non-specific markers for acute pancreatitis. A better indication of when to resume oral intake is the clinical appearance of the patient, including such signs as rectal temperature and emesis. If the patient has not vomited for 36 hours or more, there is no fever, and there is no unusual abdominal tenderness on palpation, oral consumption of small amounts of water, followed by small amounts of bland food every few hours can be attempted, with a gradual return to normal alimentation. Oral consumption should be discontinued or delayed if the animal has signs suggestive of pancreatitis. If extensive pancreatic manipulation is required a **jejunostomy feeding** tube should be placed at the time of surgery (See Chapter 6). The jejunostomy tube will permit feeding the animal without stimulation of pancreatic exocrine secretion.

A generous cranial ventral midline incision is made to expose the cranial abdomen. Exposure of the pancreas is facilitated by appropriate use of retractors and moistened laparotomy pads. Self-retaining retractors such as Balfours placed on the abdominal wall and a surgical assistant using malleable ribbon retractors to retract viscera are beneficial for exposure. Warmed irrigation solution is indicated for local lavage after pancreatic surgery is completed, and suction is helpful to aspirate blood and lavage fluid.

When lesions are confined to the caudal aspect of the right limb of the pancreas, or a random biopsy is intended, the easiest method is excision of the caudal aspect of the right pancreatic limb. This can be performed with sutures, surgical stapling equipment, or the use of a hemostatic sealing device (eg. Liga Sure™). For those animals with a small pancreas it may be suitable to mass ligate the isolated portion with suture (suture-fracture technique) after dissection of the pancreas from the mesoduodenum. I recommend the use of 2-0 or 3-0 monofilament non-absorbable suture such as polypropylene. Alternatively, the duodenal serosa can be gently grasped and dissected off the pancreatic lobules; the lobules are then separated (sterile cotton swabs are useful) from the midline of the gland to expose the vessels and ducts. The vasculature and ducts can then be ligated with suture (3-0 or 4-0) or hemostatic clips and the pancreas resected distal to the ligations. Thoracoabdominal staplers are effective for single-stage ligation and resection. In most dogs the TA-30 size will be suitable, and small vascular staple cartridges (V3) are most effective (Figure 21-21) Stapling can also be performed by laparoscopy. Although the suture-fracture and stapling techniques induce some parenchymal crushing as the suture is tightened or staples are fired, no differences in complication rates have been found.[24] Ligation of a pancreatic duct does not induce pancreatitis but will induce acinar atrophy in any residual pancreas distal to the ligation.

If biopsy or excision of a lesion nearer the body or in the left limb is required, surgical options include partial pancreatectomy as described above (for the left side this requires dissection of the deep leaf of the omentum for exposure), enucleation of the mass, or incisional or needle biopsy. The latter may be performed with a Tru-cut device or other biopsy needle such as Vim-Silverman needle. Enucleation refers to a local dissection of pancreatic lobules while leaving the pancreas distal to the biopsy site intact. Lobules of parenchyma are teased away from the tissue to be removed using fine hemostats and sterile cotton swabs. Hemostasis can be achieved with gentle direct pressure, fine suture (4-0 or 5-0) or fine-tipped bipolar electrocautery. However, if extensive damage to the ducts or vessels is required (depending on the size and location of the lesion), partial pancreatectomy is considered and is preferred rather than enucleation. Incisional biopsy is performed using a #15 scalpel blade to take a small wedge of tissue and a single absorbable suture is used to close the defect.

When pancreatic disease is identified during surgery, the surgeon must determine whether and how to employ the above techniques for successful excision if possible. The most difficult anatomic location to excise a lesion is in the body of the pancreas since there is a risk of disrupting both the pancreatic and accessory pancreatic ducts. There are techniques for attempting to directly anastomose the remaining pancreas and duct to the intestine, but this is technically difficult and rarely performed in veterinary clinical cases.[25] In this situation, or in other situations that might call for total pancreatectomy (such as lesions causing complete obstruction to exocrine flow already, as might be seen with chronic pancreatitis or neoplasia), the surgeon must give careful consideration to the merits of attempting to resect all disease relative to the impact on the animal's (and client's) quality of life following surgery.

Total Pancreatectomy

There are no indications for total removal of the pancreas in dogs other than in the research laboratory. The clinical diagnosis where total pancreatectomy might be indicated is extensive pancreatic neoplasia, but it would be unlikely to have disease confined to the pancreas in such a case. The presence of local infiltration and distant metastasis make such surgical treatment a short term palliative procedure at best. Because of the shared blood supply between duodenum and pancreas, total pancreatectomy will require duodenectomy, splenectomy, and biliary diversion. As a result of surgery the patient will be diabetic and have EPI post-operatively. To my knowledge, there are, at present, no reports of total pancreatectomy for treatment of naturally-occurring disease in dogs or cats.

Surgical Technique for Treating Pancreatic Endocrine Neoplasia

The most common indication for pancreatic exploration and partial pancreatectomy is the suspicion of a functional beta-cell tumor (insulinoma). In most cases the veterinarian should have make a diagnosis of insulinoma by demonstrating that the patient has persistent hypoglycemia not due to laboratory error, and a high level of serum insulin when the serum glucose is well below normal ranges. These findings are not exclusive to insulinoma however. There may be other causes for hyperinsulinism such as hepatic disease (usually neoplasia) that disrupts normal

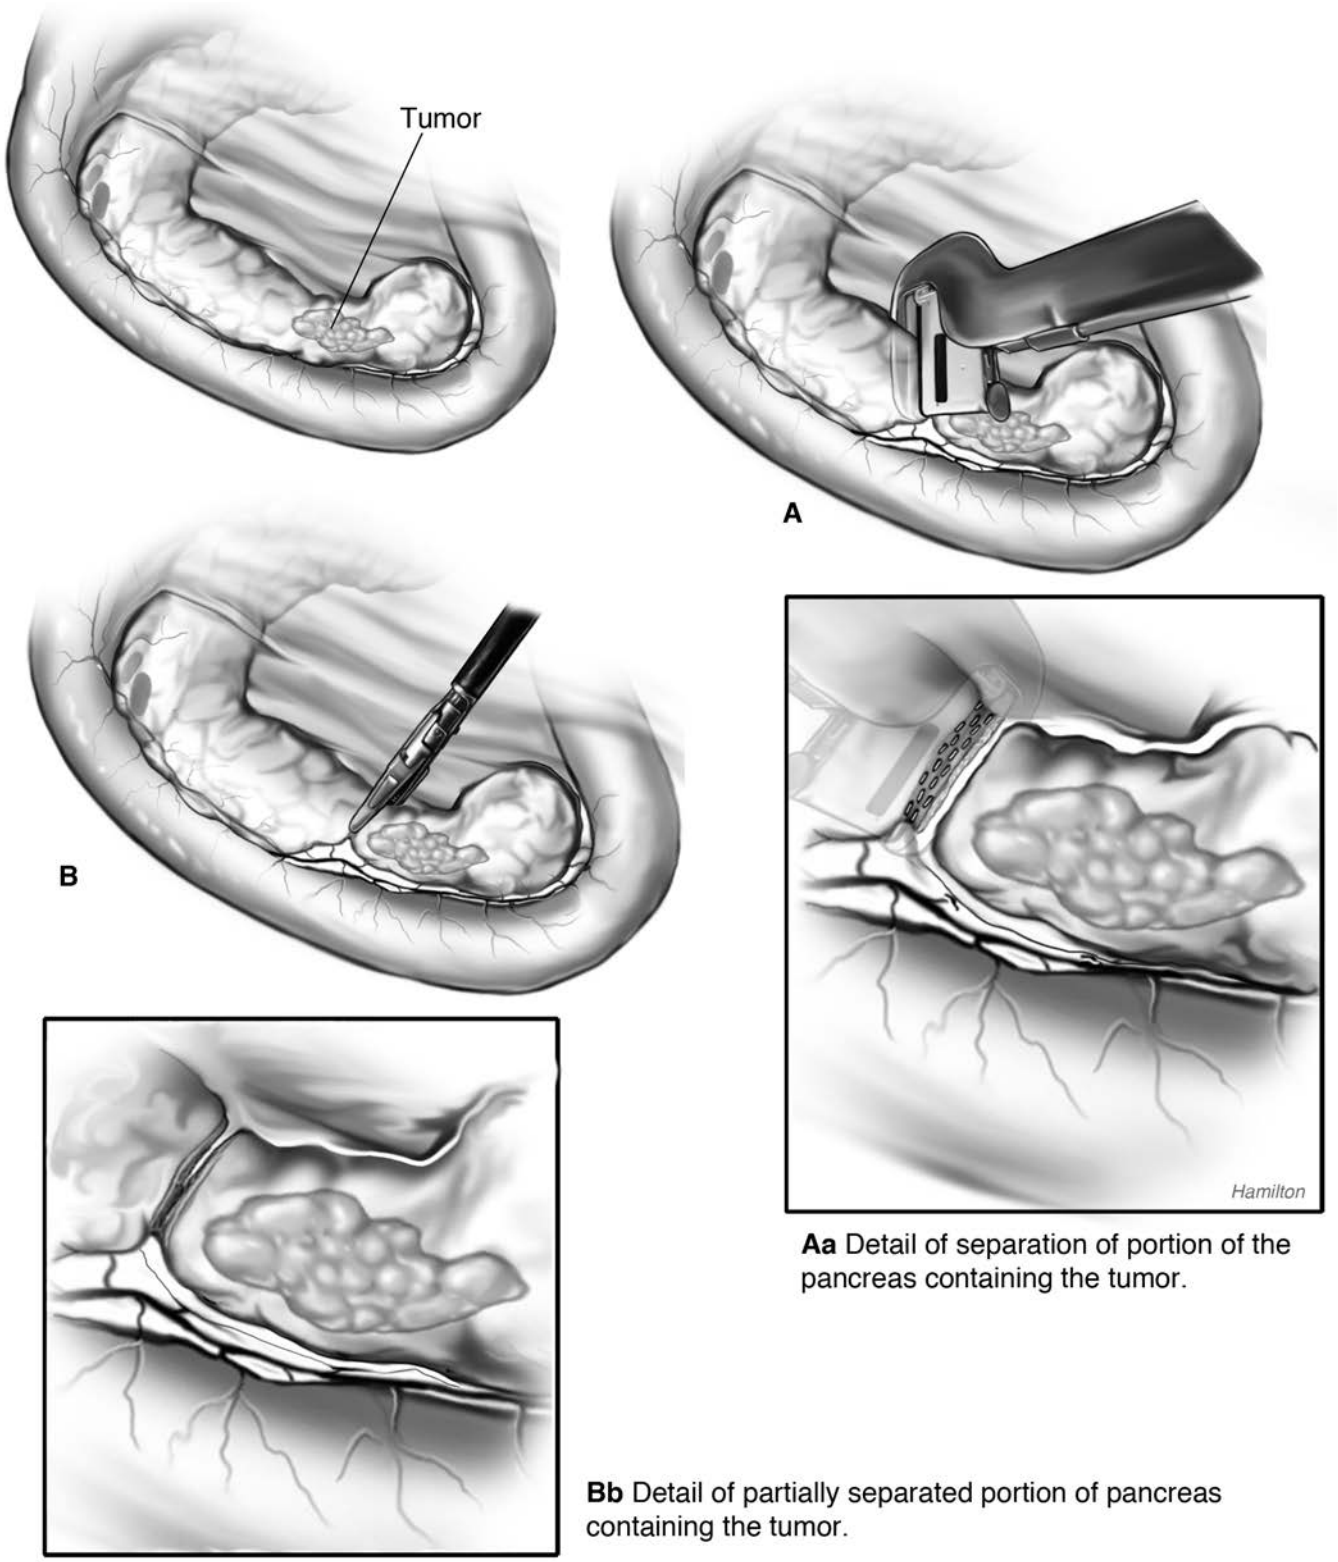

Figure 21-21. Partial pancreatectomy. Depending on patient size, it may be possible to mass ligate the distal aspect of the pancreas for excision of a tumor. For most patients, however, surgical tools designed for achieving hemostasis without inducing pancreatic injury that might activate zymogens (and cause pancreatitis) are preferred. Two of these instruments are depicted here. **A.** is application of a thoracoabdominal *(TA)* stapling device. For most patients a 30 mm instrument is appropriate, and a cartridge with small vascular staples in a triple staggered row achieves both hemostasis and closure of the ducts. *(Aa)* The specimen distal to the stapler, containing the tumor, is then sharply incised using the stapler as a cutting guide, and the specimen is removed. Alternatively, a vessel sealing device may be used as depicted in **B.** The jaws of the instrument are closed around the pancreas and the instrument activated to seal the vessels and ducts. An audible feedback is provided by the instrument to alert the surgeon whether successful sealing has occurred. *(Bb)* The device contains a cutting blade that then divides the tissues contained in the jaws, and the instrument is then advanced sequentially until the entire specimen has been dissected and can be removed. With the vessel sealing device, a portion of the pancreas distal to the area containing the tumor may be preserved. However, the ducts may not be patent and acinar atrophy might result.

insulin degradative metabolism and which may also consume glucose prodigiously. Appropriate imaging studies (ultrasound, computed tomography, magnetic resonance imaging) should be able to distinguish those patients with a primary hepatic lesion. With the possible exception of CT or MRI, however, imaging studies (particularly ultrasound) are often *not* able to confirm the presence of a primary insulinoma in the pancreas. Thus, in most cases animals undergo celiotomy for diagnostic confirmation as well as for disease staging and treatment.

The goal of pre-operative and intra-operative patient management should be to stabilize the blood glucose in an acceptable range, ideally in the low normal range if possible. Anesthetized patients and those with a history of hypoglycemia-induced seizures are particularly vulnerable to the effects of neuroglycopenia which can cause cortical laminar necrosis and permanent brain damage. To some degree, the central nervous system (CNS) has adaptive mechanisms that permit function even at low levels of blood glucose, but the neurons are at a threshold and are intolerant of any further (especially sudden) decrease in glucose levels. Achieving and keeping blood glucose normalized and stabilized is challenging since insulinomas, although not responsive to normal negative feedback mechanisms, may still have intact *positive* feedback. Administering exogenous dextrose especially in high concentrations may stimulate further secretion of insulin. This may fail to raise the blood glucose level by stimulating excess insulin secretion and may cause wide variations in glucose levels. These variations, especially sudden decreases in glucose may induce more severe signs of CNS dysfunction than persistently low blood glucose, at least in conscious patients. The use of 10% to 20% glucose solutions is indicated for management of patients with persistent hypoglycemia. Hypertonic dextrose solutions are best adminstereed through a jugular catheter. A second peripheral catheter can be used for blood sampling and monitoring. In addition to dextrose, other techniques for raising and stabilizing blood glucose include constant rate infusions of glucagon,[26] administration of corticosteroids, beta-blockers, and specific drugs that inhibit secretion of insulin from beta cells such as diazoxide.[18-23] Blood glucose should be monitored regularly during anesthesia and modifications in treatment made as necessary to stabilize levels in the appropriate range.

Anesthetic protocols, other than for glucose homeostasis, are routine and at the discretion of the surgeon or anesthesiologist. I administer prophylactic antibiotics, typically cefazolin (22mg/kg IV, q2h) starting at induction, and pre-emptive use of analgesics should be standard. Drugs that cause blood pooling in the spleen (barbiturates, phenothiazines, certain opioids) should be avoided since retraction of an enlarged spleen may make surgical visualization and manipulation of the left limb of the pancreas more difficult.

Exploratory surgery of the pancreas for an insulinoma is preceded by complete abdominal exploration to identify related or unrelated disease. Special attention and examination for metastasis is focused on the liver and local lymph nodes. I usually reserve examination of the pancreas for last so as to not miss other lesions. The entire pancreas should be exposed, then examined visually and thoroughly palpated. Most islet cell tumors will appear as discrete, raised, firm, lobulated nodules. They range from light brown to almost violet in color. Size can range from a few millimeters in diameter to several centimeters. There is no proven site predilection within the pancreas and tumors have been reported with equal distribution in both limbs and the body of the organ. There is also no correlation between the severity/refractoriness of pre-operative hypoglycemia and the size of the primary tumor. Tumors are usually solitary but the entire pancreas should be examined to ensure that no additional tumors are present. Once the tumor is identified the surgeon will need to determine which of the techniques for partial pancreatectomy is appropriate. In all cases, whether there are gross lesions or not, one or more regional lymph nodes should be resected and at least one liver biopsy obtained for staging purposes. Partial pancreatectomy is desirable when possible since recurrence rates may be lower with this technique compared to enucleation of the mass. All apparent neoplastic tissue including metastatic disease is resected when possible. Persisitent hypoglycemia may result if gross neoplastic disease cannot be resected.[27] The local area should be lavaged with warm saline to remove bacterial contamination or pancreatic enzymes that might have leaked, and the abdominal incision closed routinely.

In rare instances, examination of the pancreas will fail to identify the tumor. This could be the consequence of missing a tumor that's present (eg., a small tumor enveloped within surrounding exocrine parenchyma), an ectopic (extra-pancreatic) tumor, or a misdiagnosis. The first two are most likely. In this case, it can be helpful to utilize *intra-operative vital staining with methylene blue, USP*. Methylene blue concentrates in specific endocrine cells, notably pancreatic islet cells and parathyroid chief cells. The degree of cellular uptake (and therefore intensity of tissue staining) is correlated with the degree of function (secretion) of these cells. Thus islet cell tumors and parathyroid gland tumors will selectively stain more intensively than normal cells.[28,29]

Methylene blue, USP (**MB**) is provided in 10 ml ampules as a 1% solution. It is approved for *in vivo*, intravenous administration. **IT IS NOT THE SAME AS** *NEW* **METHYLENE BLUE** (NMB)**!** The latter is a laboratory reagent, and other than for the unfortunate similarity in common names, the two products are entirely different chemically. If you choose to use this technique be certain you use the correct product. *Do **not** use New* Methylene Blue!

The recommended protocol is to calculate a dose of 3mg/kg methylene blue and dissolve this quantity in 250 to 500 ml of 0.9% saline. This fluid can then be infused intravenously at a maintenance fluid rate of 10ml/kg/hr. Visualization of tissue staining will usually occur 15 to 20 minutes after starting the infusion, with the pancreas taking on a dusky pale blue hue. An islet cell tumor will stain a more intense blue or purplish color. Once the tumor is visualized the MB infusion can be discontinued.[28,29]

In addition to identifying an occult primary tumor or ectopic disease MB infusion can help determine if a lesion seen beyond the pancreas is a metastatic nodule, and help determine if it should be resected.[30]

Using MB infusion routinely during pancreatic exploration for endocrine tumors is not recommended because of potential negative effects. The patient may develop a pseudocyanosis that has the potential for interfering with monitoring of patient oxygenation during anesthesia. More significantly, MB can induce a Heinz-body anemia that will cause the hematocrit to decrease 1 to 2 days after MB administration. In experimental cases and limited clinical use the anemia has not required transfusion however the potential exists, especially if the patient has sustained acute blood loss from the operation. There have been reports of acute renal failure after MB infusion. I am not convinced this was a toxic effect of MB as the reported cases did not provide adequate descriptions of either the pre-operative renal status or of the use of intra-operative fluid therapy. However, caution dictates that this potentially serious adverse effect should be considered especially if the animal has preexisting renal disease. Finally, MB is excreted in the urine. This will make the urine green, and has the potential of staining flooring surfaces that urine may come in contact with.[28]

After the primary insulinoma has been resected the surgeon can expect a rapid rise in blood glucose levels. Fluid therapy should be modified as glucose levels change. In most dogs, the blood glucose will return to and remain in the normal range after administration of dextrose and other pro-glycemic agents has been stopped. However, in some instances the dog will become hyperglycemic and have at least a transient diabetes mellitus. This is largely explained by down-regulation of receptors on the normal beta cells. Persistent hyperglycemia may require exogenous insulin for treatment. Less commonly, but especially if incompletely excised metastatic disease in lymph nodes or liver is present, hypoglycemia may persist after removal of the primary tumor. Further surgical resection of gross disease is possible however most animals are managed with combinations of euglycemic agents such as corticosteroids, diazoxide, and dietary modification. Because almost all insulinomas in dogs are malignant, metastatic disease, even if not grossly apparent at the time of surgery, is likely to develop. Development of metastatic disease may result in illness caused by the effects of the tumor in the organ involved, or more likely, due to the recurrence of hyperinsulinism and resultant hypoglycemia. In some cases a second (or more) operation can be used to effectively debulk metastatic disease and prolong the disease-free interval and survival time.

In addition to medical therapy that specifically promotes euglycemia, cytotoxic chemotherapy can be used as adjunctive treatment. The current drug of choice is streptozotocin. This drug acts specifically to cause death of islet cells, but is also extremely nephrotoxic. Historically, the drug was not used clinically because of its nephrotoxic effects which were reported to be lethal. Interestingly, this conclusion was reached based on a report of *four* dogs in the literature. More recently, streptozotocin has been used with success in treating islet cell tumors when administered with an intensive diuresis protocol.[31]

Other Pancreatic Islet Cell Tumors

Less common than insulinoma are the other islet cell tumors of the pancreas. The principles of surgical exploration, disease staging, and partial pancreatectomy are similar to that described for insulinomas. Management of the medical syndrome induced by the specific hormome excess is dictated by the effects of that syndrome. *Gastrinomas* are usually associated with the *Zollinger-Ellison syndrome*. These tumors produce hypergastrinemia that cause pyloric mucosal hypertrophy and possible gastric outflow obstruction. Gastrin also acts synergistically with histamine and acetylcholine to increase production of hydrochloric acid by parietal cells in the stomach, this may cause gastric ulceration. Antacids such as proton-pump inhibitors, as well as H2-receptor antagonists are part of the medical management for this neuroendocrine tumor. Definitive therapy is removal of the primary tumor, however gastrinomas may be occult, ectopic, or diffuse, making identification and complete removal difficult. Although gastrin is produced by fetal islet cells (some gastrinomas have a primary pancreatic location), in adults most gastrin is derived from extra-pancreatic sites. One of the treatments for this disease is to remove the target for gastrin, ie, to perform a partial gastrectomy with gastroduodenostomy (Bilroth I) or gastrojejunostomy (Bilroth II).

Too few glucagonomas, VIPomas, pancreatic polypeptidomas or somatostatinomas have been reported in animals to reach meaningful conclusions about their biological behavior or treatment, but the principles with respect to pancreatic surgery should be similar. Glucagonomas in dogs have been associated with superficial necrolytic dermatitis and diabetes mellitus, but these conditions can arise independently of a glucagonoma, and need not occur in confirmed cases of glucagonoma.[32-34]

Chapter 22

Diaphragm

Traumatic Diaphragmatic Hernia

Jamie R. Bellah

Introduction

In small animals, diaphragmatic injury may occur by direct or indirect trauma.[1,2] Indirect injury to the diaphragm is the most common cause of diaphragmatic hernia and originates from blunt trauma to the abdominal cavity.[1] Pleuroperitoneal pressure gradients vary from 7 to 20 cm H_2O during quiet inspiration and can increase to over 100 cm H_2O during maximal inspiration.[3] Blunt trauma results in a sudden increase in abdominal pressure, and if it is concomitant with an open glottis, the resultant pleuroperitoneal pressure gradient increases dramatically and domes and tears the diaphragm.[1,2] Prolapse of abdominal viscera is expected to occur simultaneously with the tear. Direct injury to the diaphragm is rare, but it may be inflicted by gunshot, bite, or stab wounds.[4,5] Iatrogenic injury to the diaphragm may occur by inappropriate abdominal incision cranial to the xiphoid process or inappropriate placement of a chest drain.[5]

Loss of continuity of the diaphragm does not necessarily result in severe respiratory distress.[6] The cause of respiratory impairment associated with diaphragmatic hernia is multifactorial.[6] Hypovolemic shock, chest wall trauma, pleural fluid or air, pulmonary contusions, and cardiac dysfunction all contribute to hypoventilation.[6] Rib fractures and an associated flail chest cause mechanical dysfunction. Pulmonary compliance is decreased by pleural fluid, by the presence of abdominal organs in the thorax, or by pneumothorax. Pulmonary hemorrhage, edema, and atelectasis reduce total lung capacity, vital capacity, and functional residual capacity. Myocardial contusion may decrease cardiac output and in conjunction with impaired ventilation, may result in tissue hypoxia. Pain resulting from chest and abdominal contusion and accompanying injuries causes voluntary restriction of motion (thoracic excursion).[6]

Diagnosis

Thoracic injury occurs in 39% of small animals with musculoskeletal trauma, and 2% have diaphragmatic hernia.[7] Therefore, animals examined for blunt traumatic injury must be evaluated for diaphragmatic injury. The average length of time between traumatic injury and the diagnosis of diaphragmatic hernia is several weeks, but it ranges from hours to 6 years.[8,10] Young male dogs have the highest incidence of diaphragmatic hernia.[8,10] Clinical signs of diaphragmatic hernia vary from no overt signs to severe respiratory compromise and shock.[8,11,13] Dyspnea is the most common clinical sign and relates multifactorily to the presence of shock, chest *wall* dysfunction, the presence of air, fluid, or viscera in the pleural space, decreased pulmonary compliance, edema, and cardiovascular dysfunction.[8,11,13] Cardiac

arrhythmias are present in 12% of small animals with diaphragmatic hernia.[8] Other common clinical signs include muffled heart and lung sounds, thoracic borborygmi, a strong apex beat ausculted on one side of the chest because of shifting of the apex to one side, and an asymmetric decreased caudoventral resonance when the thoracic cavity is percussed.[5] A "tucked up" abdomen is a rare finding.[5,14]

Lateral radiographs of the thorax show an incomplete diaphragmatic silhouette in 97% of animals with a diaphragm tear.[15] In 61% of these animals, airfilled small intestinal loops are identified on the thoracic side of the diaphragm.[15] Hydrothorax, which may be pleural effusion or hemothorax depending on the chronicity of the hernia, may be identified and may obscure the diaphragm. Repeated radiography after thoracocentesis is advisable, but it may not show a diaphragmatic hernia definitively.[15] Ultrasonographic evaluation is useful to identify abdominal viscera on the thoracic side of the diaphragm, especially in the presence of pleural fluid because it enhances sonographic evaluation.[16] Ultrasound can show abdominal organs, can differentiate organs such as the spleen or liver from pleural fluid, and can sometimes demonstrate the defect in the diaphragm.[16] Cytologic evaluation of pleural fluid in patients with acute hernias usually reveals hemorrhage, whereas in a chronic diaphragmatic hernia, a modified serosanguinous transudate is identified.[5]

Alternative techniques to attempt to confirm the presence or absence of a diaphragmatic hernia include barium administration (1.0 mL 1kg) to verify herniation of a portion of the gastrointestinal tract, pneumoperitoneography, and positive contrast peritoneography (using 1 to 2 mL/kg of an aqueous tri iodidinated contrast agent).[17,18] These techniques are done only if, in the clinician's judgment, the patient can tolerate the stress of such a procedure and if plain radiographs and ultrasonography are nondiagnostic.[15] Moreover, when viscera or omentum plugs the diaphragm defect, a false negative evaluation is made.[19,20]

Ventilation can be evaluated by arterial blood gas analysis and noninvasive pulse oximetry.[21,22] These techniques may identify ventilation perfusion inequalities (alveolar arterial oxygen difference)[14] and physiologic shunting (estimated shunt equation).[14] Impaired ventilation (hemoglobin saturation) can be determined using pulse oximeter probes attached to the lip in the awake dog.[23] The ear, tail, and toe may also be used effectively in awake dogs if good contact is maintained across the vascular beds.[23]

Timing of Surgical Intervention

The timing of anesthesia and surgical correction of diaphragmatic injury has a profound effect on the outcome of treatment.[5,14] Approximately 15% of small animals with diaphragmatic hernia die before surgery.[5] Animals with diaphragmatic herniorrhaphy performed within the first 24 hours after injury have the highest mortality rate (33%).[8] When surgery must be done depends on the extent of the initial cardiopulmonary dysfunction, the presence or absence of organ entrapment, and the degree of compromised pulmonary function.[14] Diaphragmatic herniorrhaphy may become an emergency procedure if aggressive supportive care cannot stabilize respiratory function.[9] Acute dilatation of a herniated stomach and strangulated bowel are situations in which emergency surgery may be indicated.[9] Gastric outflow obstruction, metabolic alkalosis, and hypokalemia have been reported in a dog with diaphragmatic hernia.[24]

A herniated stomach can rapidly distend from aerophagia, decreasing pulmonary compliance and can compress the caudal vena cava, decreasing venous return resulting in a vicious cycle that can be rapidly fatal.[5]

A herniated parenchymal organ such as the spleen may tear as it passes through the diaphragm; the result may be acute hemothorax and a patient that may deteriorate rapidly after an initial response to shock therapy. Most small animals with diaphragmatic hernia can be stabilized over 24 to 72 hours because the mere presence of a diaphragmatic hernia is not an indication for emergency surgery.[8] For example, thoracic injuries such as pulmonary contusion improve dramatically in 24 to 48 hours, and pneumothorax may be managed by thoracostomy tube insertion. The goal of initial management is to improve the cardiorespiratory status of the patient, thus improving the patient's capability of tolerating the stress of anesthesia and surgery.

Anesthesia

Anesthesia in the patient with diaphragmatic hernia is induced with as little stress as possible. Intravenous catheterization, appropriate intravenous fluid adminstration (crystalloid or colloid), and cardiorespiratory monitoring are important. Premedication with a phenothiazine or a narcoleptic combination may relieve apprehension, but care is taken not to use cardiorespiratory depressing drugs when possible if decompensation of the patient's status is predictable.[8] Mask induction of anesthesia is avoided because it's stressful and does not allow control of respiration or provide the ability to assist ventilation.[8] An ultra short acting barbiturate or propofol is used because it allows rapid induction of anesthesia, quick intubation and near immediate control of ventilation with assitance or by a mechanical ventilator.[25] Isoflurane is preferred for maintenance of anesthesia because a surgical plane of anesthesia is attained more quickly, it is associated with decreased recovery time, it subjects the patient to less cardiac depression, and it does not sensitize the myocardium to arrhythmias.[8]

Ventilation assistance is important as soon as anesthesia is induced because of decreased pulmonary compliance secondary to the presence of air, fluid, or abdominal viscera within the pleural space.[5,14] Assisted ventilation should not exceed 20 cm H_2O, to limit potential barotrauma from pulmonary hyperinflation.[8] Overinflation of the lungs during surgery may result in rupture of pulmonary parenchyma, intrapulmonary hemorrhage, plumonary edema, and, rarely, pneumothorax.[26] Intraoperative elimination of atelectic areas subjects chronically atelectic lungs to mechanical and reperfusion injury.[8,26] In this situation, reperfusion of these collapsed vascular channels disrupts capillary integrity and causes fluid to leak into the interstitium; reexpansion pulmonary edema may result within several hours after surgery.[5,8,27] Atelectic areas that do not inflate with 20 cm H_2O gradually reexpand over several hours with a

continual negative pleural pressure of 10 cm H_2O.[28] Preoperative treatment with glucocorticoids and antihistamines has been recommended (based on experimental evidence) to inhibit the effects of mediators of pulmonary vascular permeability that are activated by lung injury in patients with chronic diaphragmatic hernia, but care is advised because antihistamines may potentiate hypotension.[6,8]

Surgical Approach

A ventral midline celiotomy extending from the xiphoid process to a point caudal to the umbilicus is used to provide initial exposure for diaphragmatic herniorrhaphy. The incision should be large enough to allow exploration of the abdominal cavity. This exposure allows access to all regions of the diaphragm. Most diaphragmatic tears are muscular and are located ventrally and may favor either the right[12] or left side.[10,29] The liver, small intestine, and pancreas are most commonly prolapsed into the thoracic cavity when the diaphragm defect is on the right side, whereas the stomach, spleen, and small intestine prolapse on the left side.[5] The surgeon must examine the entire diaphragm because more than one tear may occur.[14] Exploration of the abdominal cavity is indicated because injury to other abdominal organs may be present and are potentially treated concomitantly. Should additional exposure be required to retrieve abdominal viscera adhered to structures within the thoracic cavity, surgical exposure can be improved by enlargement of the rent in the diaphragm, by paracostal extension of the celiotomy, or by caudal midline sternotomy (Figure 22-1). Lateral thoracotomy is not a practical or appropriate method to expose a diaphragmatic tear because it requires preoperative knowledge of the extent and side of the hernia, and the approach does not allow exploration of the abdomen.[8,14] Lateral thoracostomy also decreases thoracic compliance from pain and thus may contribute to hypoventilation.[8]

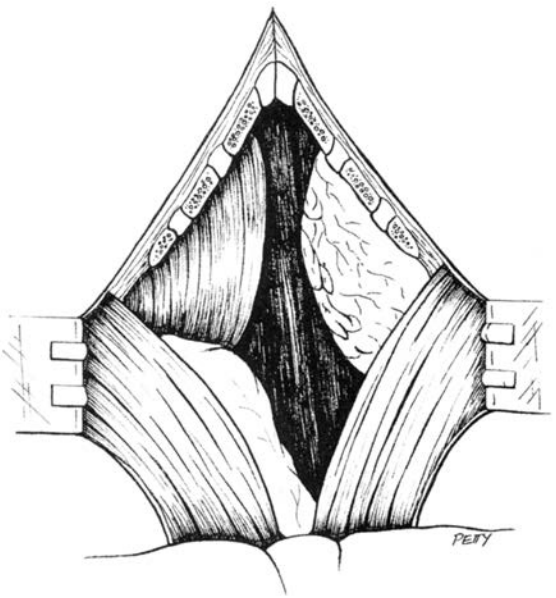

Figure 22-1. In this view, the midline celiotomy has been extended to expose the caudal thorax by caudal midline sternotomy. The diaphragm is incised to the hernia defect to allow blunt and sharp dissection to release abdominal viscera from restrictive thoracic adhesions.

Strangulated viscera found within the thoracic cavity should be resected in situ without reestablishing circulation if possible.[8] By doing so, prevention of toxemia from bacterial endotoxins and exotoxins and the by products of tissue autolysis is possible.[8] Viscera may be incarcerated, strangulated, or obstructed after passing through a diaphragmatic hernia and the systemic effects such as gastrointestinal obstruction or extrahepatic bile duct obstruction may occur acutely or chronically.[5,14,30] Chronic strangulation of a liver lobe results in a modified serosanguinous transudate approximately 30% of the time.[5] Before closing the diaphragm defect, a chest drain is placed from a paramedian stab incision, it is tunneled subcutaneously, and it is inserted intercostally into the pleural space (Figure 22-2). The advantages of placing the chest drain early are that the drain can be placed accurately with direct visualization and, after herniorrhaphy, control of the pleural space is obtained for the duration necessary. The diaphragm closure need not be airtight because the chest drain provides control. Should an inadvertent tear in the lung parenchyma occur during herniorrhaphy, the presence of the tube will detect it and allow simple management. The chest drain is managed for a short time, usually 8 to 12 hours, or until the volume of air or fluid is 2 to 3 mL/kg per day or less. Air can be aspirated from the pleural space as the last suture is tied, but if a parenchymal tear is leaking air or if the herniorrhaphy is not airtight, hypoventilation may result.

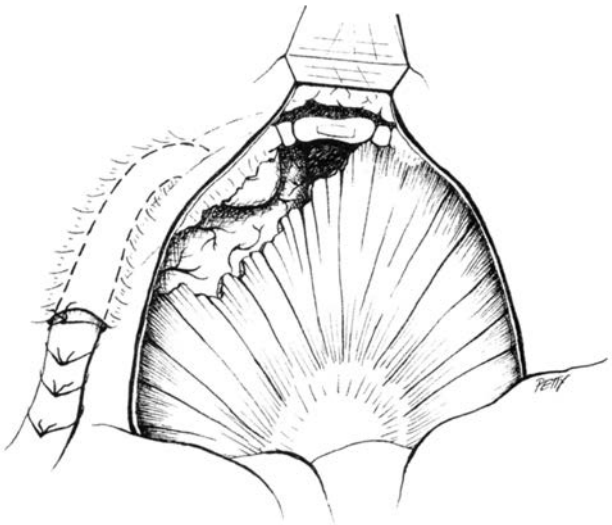

Figure 22-2. In this view, a chest drain has been inserted from a paramedian incision, tunneled over the costal arch, and placed within the pleural space under direct visualization before closing the diaphragmatic hernia.

Assessment of the wound margin of the diaphragm is important after viscera have been replaced into the abdominal cavity. Debridement of the wound margins is usually not necessary, but sutures should be placed through portions of the torn edge of the diaphragm that has an intact fascial surface to afford good suture holding strength. Chronic hernias that have produced scar tissue and collagen at the wound margins have good suture holding strength, but the scar restricts the normal elasticity of the diaphragm. Paracostal incisions are usually sufficient to release the maturing scar tissue and to allow the elastic portions of the diaphragm to be advanced to close the defect.

The suture material and pattern used to appose the diaphragm depend largely on the surgeon's preference. Radial tears are apposed with simple continuous patterns or a combination of a horizontal mattress pattern oversewn with a simple continuous pattern. A single layer simple continuous pattern is quickly completed, but it is susceptible to reherniation should the implant break. The surgeon should suture from the deepest portion of the tear toward the more superficial regions. Large tears or combined radial and paracostal tears may be apposed with several interrupted sutures to arrange apposition of the wound margins to minimize tension. Closure follows, using a simple continuous pattern (Figure 22-3). Polypropylene, monofilament nylon, poliglecaprone, (Monocryl, Ethicon, Inc., Somerville, NJ), polydioxanone, and polyglyconate are sutures materials acceptable for herniorrhaphy. Paracostal tears are sutured using simple continuous patterns by suturing the diaphragmatic wound edge to paracostal fascia or encircling the ribs. Mattress patterns that encircle the costal arch or paracostal muscle fascia may also be used. Preplacing sutures sometimes facilitates closure of chronic diaphragmatic defects. Use of 3-0 and 2 0 suture for small cats and dogs and 2 O and 1 0 for larger dogs is recommended. Larger sizes are appropriate for giant breeds.

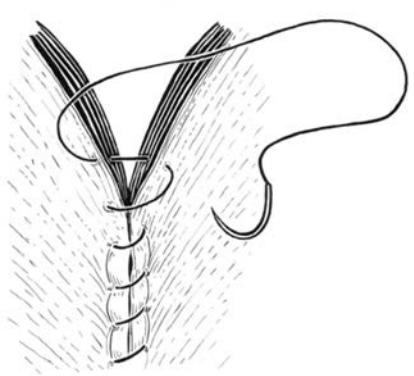

Figure 22-3. A simple continuous pattern may be used to appose the edges of the diaphragm. A fascial layer is included to ensure that encircling tissue is strong enough to hold sutures.

Closure of large diaphragm defects sometimes requires mobilization of the diaphragm or other tissues.[5,9,14] Paracostal incisions may be made to release the diaphragm from restrictive scar tissue, and the diaphragm may be advanced cranially to allow apposition ventrally (Figure 22-4).[5,14] Muscle flaps originating from the transversus abdominis muscle can be used to close diaphragm defects.[31,32] In chronic hernias, the liver capsule may be thickened in response to incarceration, and if the liver lobe is viable and can be oriented to cover the defect in the diaphragm partially without tension, it can be used to close or partially dose the defect.[33] Autologous fascia and omentum has also been used to close large diaphragm defects or small defects that remain after mobilization of the diaphragm.[34,35] Synthetic materials, such as polypropylene mesh or silicone rubber may also be used.[32,36,37] If a rough material such as polypropylene mesh is used, it is advisable to mobilize omentum to create an "omental envelope" that provides angiogenesis to aid incorporation of the prosthetic material and to protect the adjacent soft tissues from the mesh surfaces (Figure 22-5). Sometimes, the time and trauma required to mobilize muscular pedicles, especially in small kittens and puppies, result in significant hemorrhage. and can jeopardize the life of the patient. Prosthetic materials may be a better option if the potential to use autologous tissue may injure the patient.

Abdominal closure is accomplished routinely in patients with acute hernias. In those with chronic hernias, accommodation of the viscera within the peritoneal cavity may be difficult because of the contracted abdominal musculature. The abdominal musculature relaxes over time.[14] Increased intraperitoneal pressure may occur. If intra abdominal pressure increases over 13 cm H_2O, hepatic and portal venous flow may decrease.[39] Intra abdominal pressure (30 cm H_2O) in one dog necessitated surgical decompression.[39]

Postoperative Care

Evacuation of air from the pleural space should be done carefully in patients with atelectasis that does not reinflate with inflation pressures of 20 cm H_2O, such as may occur with chronic hernias. Air may be evacuated in these patients slowly over a 12 hour period by using periodic evacuations or by using a Pleurivac (water seal) with no greater than a negative pleural pressure of 10 cm H_2O.

Oxygen supplementation can be administered during recovery by mask, nasal insufflation or by placing the patient in an oxygen cage (40% oxygen).[8] Nasal insufflation allows the same degree of oxygen supplementation, but it offers the advantage of allowing frequent and close access to the patient should it be required. Heart rate, capillary refill time, mucous membrane color, pulse strength and character, and respiratory rate should be monitored. Direct or indirect blood pressure monitoring, blood gas analysis, and pulse oximetry may also be done.

Analgesics are administered to comfort the patient and to ease apprehension during recovery. Morphine, 0.1 to 0.2 mg/kg, may be used subcutaneously without significant respiratory depression.[5] If a caudal median sternotomy is performed, intrapleural bupivicane may be administered for short term local analgesia.

Prognosis

Death from diaphragmatic hernia is usually attributed to hypoventilation resulting from lung compression, shock, cardiac dysrrhythmias, and multiorgan failure.[5] The survival rate in dogs varies from 52 to 88%.[8,10,40,41] Approximately 1 in 3 dogs undergoing repair within the first 24 hours after trauma dies, as opposed to 1 in 10 dogs in which repair is delayed for 1 to 3 weeks.[5] In dogs that had chronic diaphragmatic hernias repaired more than 1 year after trauma, 73% of the deaths were attributed to a problem unrelated to the hernia.[5]

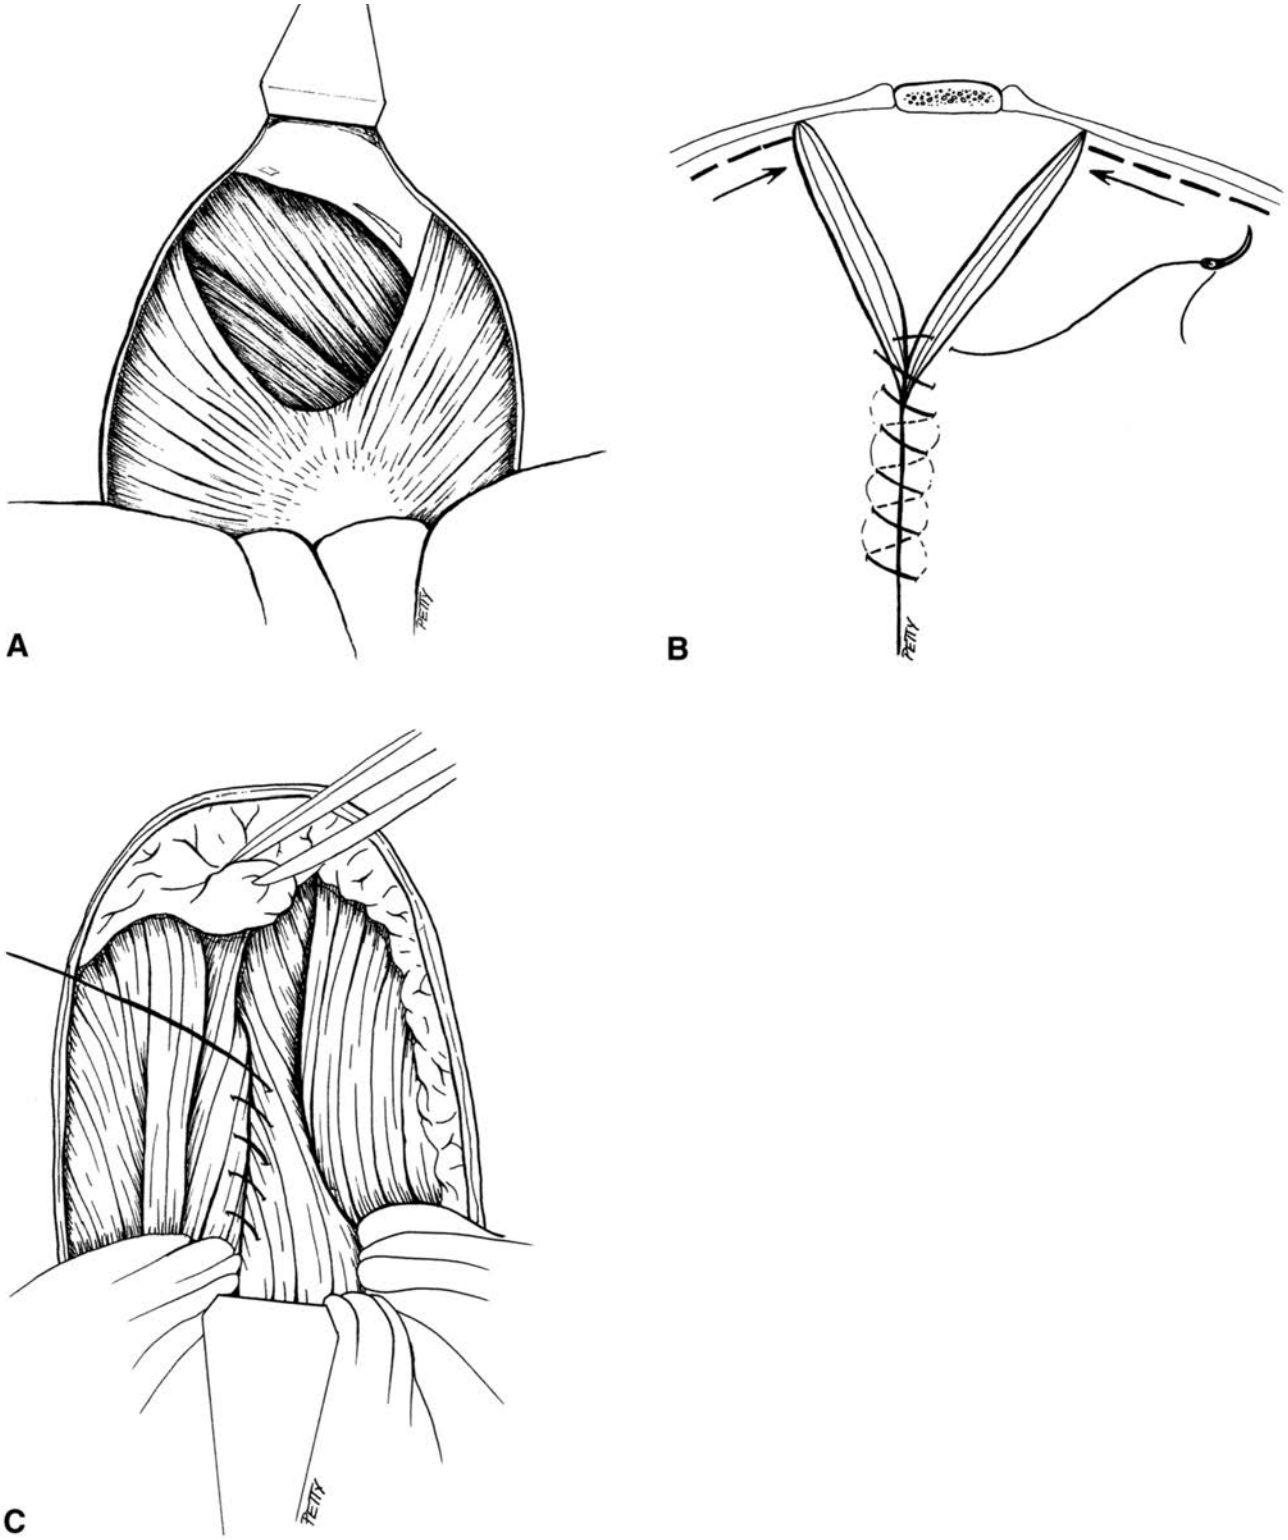

Figure 22-4. A. A large defect in the diaphragm is shown. **B.** Paracostal incisions are made to release the diaphragm from restrictive scar. **C.** The margins of the diaphragm are apposed using a simple continuous pattern. The paracostal margins may be apposed using interrupted mattress sutures or sutures that encircle the costal arch.

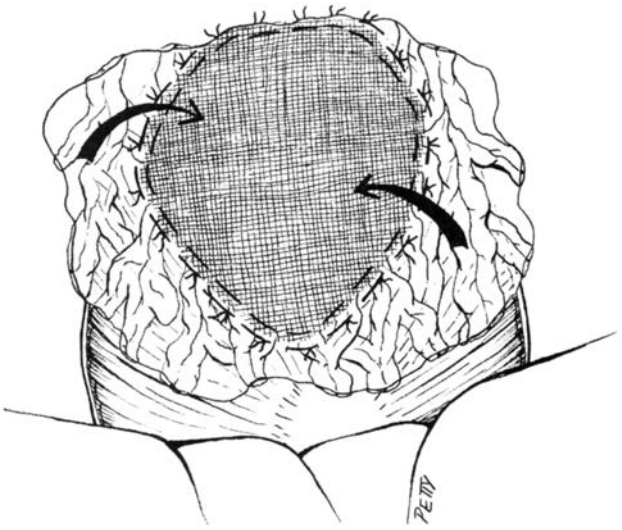

Figure 22-5. In this view, a large defect in the diaphragm is covered with an omental flap intitially. Polypropylene mesh is placed over the omentum and is secured to the margins of the diaphragm defect with mattress sutures. The remainder of the omental pedicle is sutured over the abdominal side of the mesh.

Congenital Diaphragmatic Hernia

Jamie R. Bellah

Introduction

About 5% to 10% of diaphragmatic hernias are congenital.[1-3] Congenital pleuroperitoneal hernia[4-8] and congenital peritoneopericardial diaphragmatic hernia[8-14] have been reported in puppies and kittens. Pleuroperitoneal hernias are thought to develop when the pleuroperitoneal membrane fails to fuse with the pleuroperitoneal canal during development of the diaphragm. This defect is proposed to be heritable by an autosomal recessive mechanism.[6,16,17] Congenital peritoneopericardial diaphragmatic hernias are thought to be the result of a uterine accident during embryogenesis and are not heritable.[12,18,19] The ventral diaphragmatic defect is believed to result from faulty development of the septum transversum.[18] Because congenital peritoneopericardial diaphragmatic hernia may or may not be associated with craniventral abdominal defects, some of these hernias are not easily identified at birth and some are obvious.[12]

Clinical Signs

Clinical signs of congenital diaphragmatic hernia may be identified at any age. Multiple breeds of dogs have been affected and in cats the domestic longhair and Himalayan breeds are over represented.[20] Overt structural defects such as cranioventral abdominal hernia result in an earlier diagnosis, often before 2 years of age. The diagnosis may be incidentally noted while radiographing the thorax for another reason, or it may be found at necropsy.[11,12,14] Respiratory signs including dyspnea, tachypnea, coughing, and wheezing are common, but many nonspecific signs such as vomiting and diarrhea may be identified.[21] Respiratory signs may worsen after eating.[17] Auscultation of the thorax may reveal muffled heart sounds, a heart murmur, and abnormal position of the apex beat.[12,21,20] An electrocardiogram

may reveal electrical alternans or may be normal.[21] Radiographs of the thorax usually reveal an ovoid cardiac silhouette that joins the ventral diaphragm ventrally. Gas-filled loops of bowel may be seen over the cardiac silhouette.[14,21] Congenital peritoneopericardial hernias are often symmetrical in appearance on radiographs whereas thoracic abnormalities in pleuroperitoneal hernias may be assymetrical.[8] Pectus excavatum and sternal abnormalities may be seen with congenital diaphragmatic hernias in cats.[20] Other diagnostic procedures that may be used include administration of contrast material into the upper gastrointestinal tract, pneumoperitoneography or contrast peritoneography, and ultrasonography.[10] Pneumoperitoneogrpahy may induce pneumothorax and therefore may risk decompensation so use of aqueous contrast is preferred.[8] Ultrasonography from the right fifth intercostal space may reveal cardiac tamponade if liver lobes herniate into the pericardial sac and produce an effusion.[10,21] In general, ultrasonagraphic diagnosis of diaphragmatic hernia is difficult.[22] Thoracoscopy can be used to directly observe the abdominal structure but careful inflation pressures are necessary to avoid compromising ventilation.[22]

Congenital Diaphragmatic Hernia with Cranioventral Abdominal Defects

Congenital cranioventral abdominal wall defects in puppies occur cranial to the umbilicus, but they may extend caudally toward and to the umbilicus. (Figure 22-6). The cranial extent of the defect is often in the area of the commonly absent xiphoid process. Although cranioventral abdominal hernias are not frequently encountered in small animal practice, the clinician must recognize that the abnormality differs from the much more common umbilical hernia. Cranioventral abdominal hernias are commonly associated with four other defects, which are recognized as a syndrome in humans and which have been reported in dogs.[12,13] Cranioventral abdominal hernia, failure of caudal sternal fusion, intracardiac defects (most commonly ventricular septal defect) and caudoventral pericardial defect may commonly accompany a congenital diaphragmatic hernia.[12,13] These defects may occur in varying degrees, depending on the individual dog and they do not always appear together. Commonly, the heart has no apparent abnormality. This pentalogy of defects has been noted in several breeds, including cocker spaniels, Weimaraners dachshunds, and collies, and I have seen it in two kittens. This syndrome is similar in some respects to thoracoabdominal ectopia cordis in human infants and has been termed peritoneopericardial diaphragmatic hernia in small animals.[14,18] A recent report did not find abnormalities identical to the pentalogy found in puppies but skeletal and nonskeletal abnormalities did occur in 8 of 67 cats.[20] Peritoneopericardial diaphragmatic hernias are not always associated with cranioventral abdominal wall defects or intracardiac defects, and they are often difficult to detect unless clinical signs are obvious (usually exercise intolerance or a restrictive breathing pattern).

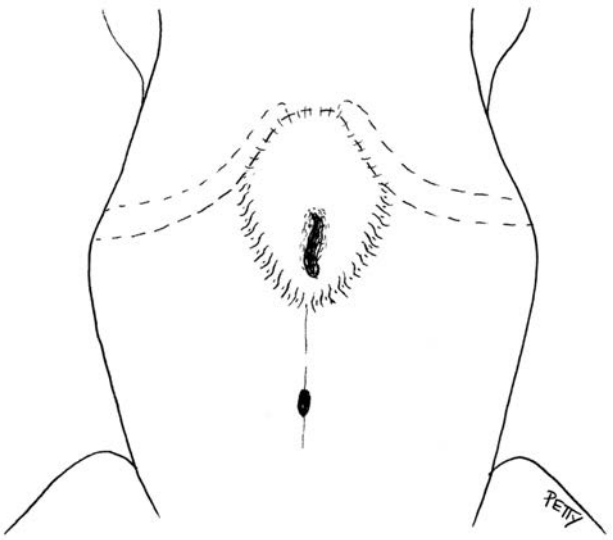

Figure 22-6. Drawing of the cranial abdominal region of a male puppy with a cranioventral abdominal hernia. The position of the hernia is cranial to the umbilicus and is centered in the region of the xiphoid process.

The sternum normally fuses from cranial to caudal in dogs, and the abdominal wall fuses from caudal to cranial. The ventral portion of the diaphragm is thought to originate from the septum transversum, which develops at the same time as cardiac septation; therefore, it seems reasonable that disruption of fetal development at this particular time could cause defects in both regions. Dogs do not have a communication between the pericardial cavity and the peritoneal cavity so if such a communication is present congenitally, it is due to a defect in development. The pericardium normally attaches to the ventral diaphragm by the sternopericardial ligament and visceral mediastinum. Communication of the peritoneal and pericardial cavities is not always obvious in this defect.

In human beings, these defects are attributed to a uterine accident and are not considered heritable. Parents with children affected with thoracoabdominal ectopia cordis have gone on to have anatomically normal children thereafter. No data support heritability of the pentalogy of defects in dogs or cats.

Surgical Correction

Surgical repair of the cranioventral abdominal defect and the diaphragmatic defect can be done early (I have performed such operations on animals as young as 7 weeks of age), usually between 8 and 12 weeks of age. The puppies are usually masked with isoflurane to induce and maintain general anesthesia unless they have significant respiratory restriction. In the latter example, anesthesia may be induced with propofol with prompt intubation, so ventilation may be carefully assisted. All puppies with these defects benefit from assisted ventilation because of the space-occupying abdominal viscera within their caudal mediastinum and/or pericardial sac.[13,23] Liver lobes, gall bladder, omentum and small intestine are commonly found in the caudal mediastinum or pericardial sac, and this appears to be similar in cats with congenital diaphragmatic hernias.[20]

Surgical correction of the defects follows a midline abdominal incision that allows identification of the triangular diaphragmatic defect, the pericardial defect, and the flared, unfused caudal sternebrae (Figures 22-7 to 22-10). In most puppies, the diaphragm

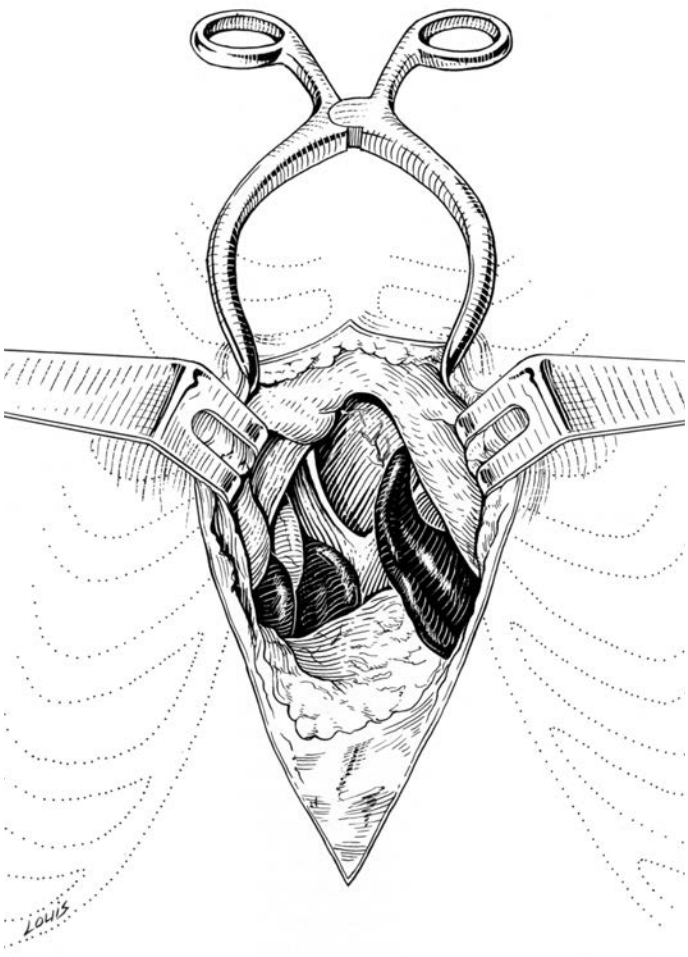

Figure 22-7. Drawing of the surgeon's view of a congenital diaphragmatic hernia before surgical correction. Notice the flared costal arches, absence of a xiphoid process, and a smooth-bordered V-shaped diaphragmatic defect. (From Bellah JR, Whitton DL, Ellison GW, et at. Surgical correction of concomitant cranioventral abdominal wall, caudal sternal, diaphragmatic, and pericardial defects in young dogs. Am Vet Med Assoc 1989; 195:1722.

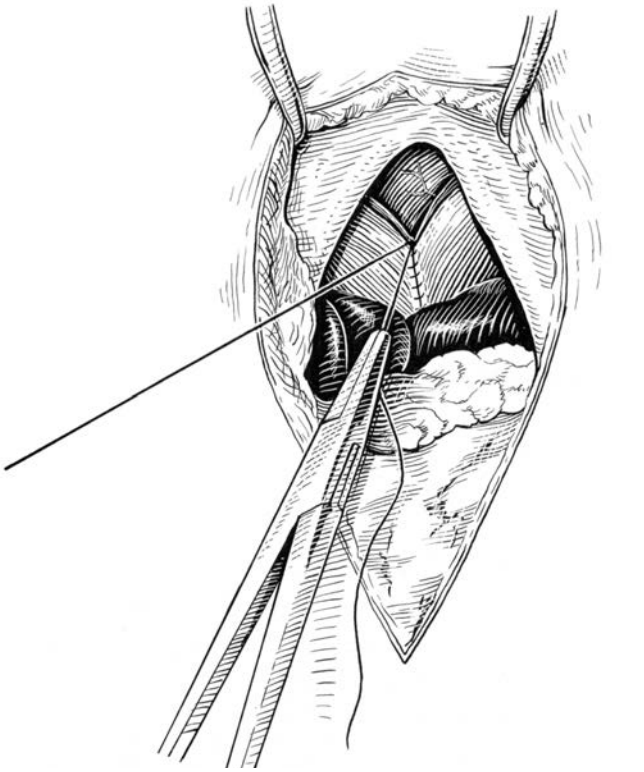

Figure 22-8. After incising the fascia on the abdominal side of the diaphragmatic defect, a simple continuous suture pattern of 3-0 polypropylene is used to appose the crura of the diaphragm. (From Bellah JR, Whitton DL, Ellison GW, et al. Surgical correction of concomitant cranioventral abdominal wall, caudal sternal, diaphragmatic, and pericardial defects in young dogs. J Am Vet Med.

defect can be closed by using a simple continuous pattern from the dorsalmost aspect of the defect and continuing in a ventral direction (toward the sternal defect). When the diaphragm apposition becomes tense, the suture can be tied, and mattress sutures can be preplaced from the diaphragm to the costal arch to complete the separation of the thoracic and abdominal cavities. The pleural cavity does not have to be invaded or opened when this defect is closed. Accidental opening of the pleural cavity by dissection or by needle penetration is possible while suturing. After the mattress sutures are tied, the abdominal defect can usually be apposed with simple interrupted nonabsorbable suture, followed by routine subcutaneous and skin apposition. When closure of the defects as described is routine, young puppies and kittens recover quickly and often do not require specialized postoperative care, other than that appropriate for pediatric patients. Sometimes, the diaphragmatic defect is too wide to appose without excessive tension. Three methods can be used to alleviate this problem. First, the caudal sternal costal arch can be apposed by encircling with nonabsorbable suture. This can effectively decrease the distance between the right and left edges of the diaphragm and therefore can reduce the tension on the closure. The pliability of the unfused costal arch in the young puppies and kittens makes this maneuver possible. If caudal sternal apposition does not narrow the defect to a size that can be apposed without tension, the pericardium can be incised cranial to the diaphragm and flaps can be created to close the defect.[24] A free graft of pericardium may also be used to close the defect.[24] The third method is insertion of polypropylene mesh to separate the body cavities. Omentum can be mobilized and sutured to each side of the implant to cover its surface. Other synthetic implants, such as lyophilized collagen sheeting (derived from porcine submucosa) have been used successfully.[17]

Congenital diaphragmatic hernias that are not associated with ventral abdominal wall defects and that lack obvious clinical signs may not be diagnosed until much later in the pet's life, often when the animal is radiographed for another reason. Correction of all congenital diaphragmatic hernias may not be necessary, especially hernias diagnosed in old animals with no clinical signs of abdominal viscera (usually omentum) in the caudal mediastinum or the pericardial sac. However, dogs or cats with clinical signs of congenital diaphragmatic hernia that are adults when the diagnosis is made are much more likely to have intrathoracic adhesions that prevent simple replacement of abdominal viscera into the abdominal cavity. These adhesions may require extension of the diaphragmatic defect or a caudal midline sternotomy to provide enough exposure for safe dissection within the caudal thorax. Closure of the diaphragmatic defect often requires releasing incisions from the paracostal

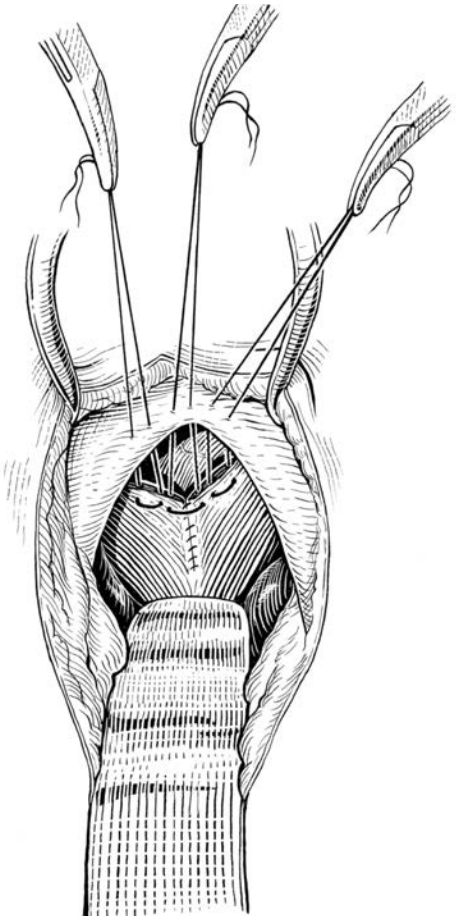

Figure 22-9. When placement of the continuous suture is complete, three horizontal mattress sutures are placed to close the remaining defect between the diaphragm and the costal arch. (From Bellah JR, Whitton DL, Ellison GW, et al. Surgical correction of concomitant cranioventral abdominal wall, caudal sternal, diaphragmatic, and pericardial defects in young dogs. J Am Vet Med Assoc 1989; 195:1722.)

arch using the inherent elasticity of the diaphragm to facilitate apposition. Entrance into the pleural space is inevitable in most situations and requires assisted ventilation during surgery, chest drain insertion, and intensive postoperative management for 24 to 48 hours.

Postoperative management of pain in dogs that have undergone diaphragmatic herniorrhaphy and especially those that have exposure extended by caudal midline sternotomy require analgesia.[25] Use of opioids in combination with non-steroidal antiinflammatory drugs will provide sufficient analgesia. Chest drains, when necessary, are usually removed 12 to 24 hours postoperatively.

Chapter 23

Peritoneum and Abdominal Wall

Closure of Abdominal Incisions

Eberhard Rosin

The most common surgical procedure in small animal practice is incision and closure of the abdominal cavity. Although use of simple interrupted sutures to appose the peritoneum and all fascial layers is the traditional method to close an abdominal incision, a simple continuous suture pattern for a single-layer closure of the rectus fascia, without concern for the peritoneum, is a faster and safe alternative. In paralumbar grid incisions, a layered simple continuous closure is used if the patient's musculature is well developed.

Surgical Anatomy

The external leaf of the rectus sheath is composed of the aponeurosis of the external abdominal oblique muscle, most of the aponeurosis of the internal abdominal oblique muscle, and, near the pubis, a portion of the aponeurosis of the transversus abdominis muscle. The internal leaf of the rectus sheath consists of a portion of the aponeurosis of the internal abdominal oblique muscle, the aponeurosis of the transversus abdominis muscle, and the transversalis fascia. In the caudal third of the abdominal wall the internal leaf disappears. The aponeurosis of the internal abdominal oblique muscle joins the external leaf, and the rectus abdominis muscle is covered only by a thin continuation of the transversalis fascia and peritoneum (Figure 23-1).[1]

Healing of the Peritoneum

The peritoneum is a layer of flat cells, cemented edge to edge at their intercellular margins. This mesothelial layer is supported by an underlying layer of areolar tissue that blends with the connective tissue of the transversalis fascia. Within the peritoneal cavity, a small amount of serous fluid contains freely floating cells including macrophages, desquamated mesothelial cells, and small lymphocytes.[2]

During the first 2 days after wounding, the peritoneal defect is red, with a glistening, slightly irregular surface. During the next 5 or 6 days, the color fades gradually, the surface becomes smoother, and the defect develops a homogeneous, transparent gray sheen. Abdominal tissues slide readily over the defect. Gradually, this gray sheen becomes more opaque until, after 2 or 3 weeks, the area usually is indistinguishable from normal peritoneum. Milky streaks beneath the wound area, apparently resulting from scar formation, may remain. These changes occur simultaneously throughout the entire defect. Large wounds heal as rapidly as small wounds.[2-4]

Microscopically, defects in the peritoneum are covered rapidly by macrophages, which are present in large number in the

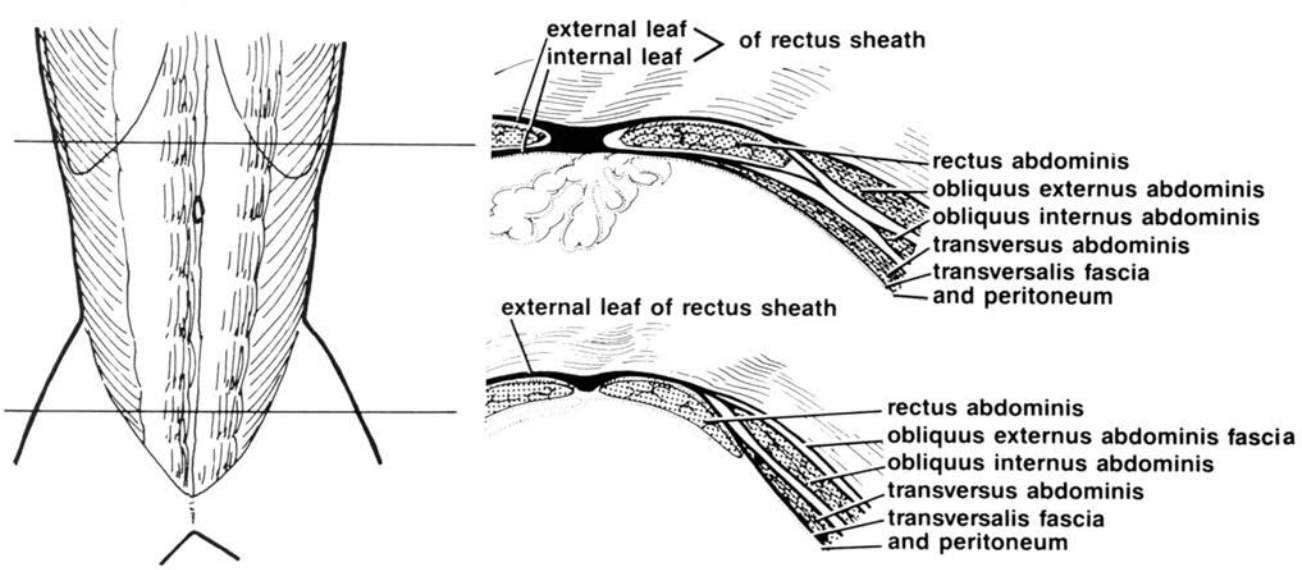

Figure 23-1. Cross sections showing the anatomy of the sheath of the rectus abdominis muscle in the cranial and caudal portions of the abdominal wall.

peritoneal fluid bathing the wound surface. The wound also is invaded by monocytes and histiocytes from blood and underlying exposed tissues. Cells from peritoneal fluid, blood, or underlying tissues differentiate to form fibroblasts, and the superficially located cells undergo metaplasia, gradually forming mesothelial cells. At the same time, intact mesothelial cells at the perimeter of the wound help in the repair by proliferation and migration. Small defects in the peritoneum are healed by proliferation of adjacent mesothelial cells, whereas large defects are covered by undifferentiated cells that then become mesothelial cells.[2-4]

Peritoneal defects that are sutured have a higher incidence of adhesions than defects that are left open to heal. The stimulus for adhesion formation is not the peritoneal defect itself, but rather the ischemic tissue that results when edges of the defect are brought together by sutures.

No evidence, experimental or clinical, supports the contention that closure of the peritoneum is necessary for wound strength, to minimize postoperative dehiscence or hernia formation, or to minimize the development of adhesions. On the contrary, experimental and clinical studies in dogs, horses, and human patients indicate that suturing the peritoneum should be avoided to minimize the incidence of postoperative intra-abdominal adhesions.[3-7]

Closure Alternatives

Closure of the Internal and External Leaves of the Rectus Sheath Versus Closure of the External Leaf Only

Closure of the paramedian abdominal incision by apposition of the internal and external leaves of the rectus sheath is traditional and has proved successful for years of clinical experience. However, closure of the internal leaf takes time and requires that the abdominal wall be manipulated to expose the internal leaf, which frequently retracts after incision. Studies have refuted the admonition that closing only the external leaf of the rectus sheath provides insufficient strength to the incision. In a biomechanical study of healing abdominal incisions in the dog, the strength of incisions closed by suturing the internal and external leaves of the rectus sheath and the strength of incisions closed by suturing the external leaf only were similar.[8]

Simple Interrupted Versus Simple Continuous Suture Pattern

The traditional method to close an abdominal incision is simple interrupted sutures. The same incision can be closed more quickly using a simple continuous pattern, with no difference in wound healing. In a randomized prospective trial of 3135 human patients comparing continuous and interrupted abdominal midline incision closure, no difference was found in the incidence of wound dehiscence.[9] In clinical use of simple continuous closure of abdominal incisions in over 5000 dogs and cats, the incidence of dehiscence is negligible.

Closure Techniques

Midline Incision

With an incision through the linea alba in the cranial two-thirds of the abdominal hall, fibers of the rectus abdominis muscle are not exposed, and the linea alba, including the peritoneum, can be apposed accurately by full-thickness sutures. An adequate portion of fascia must be included with each suture, and the falciform ligament must not be interspersed between the edges of the linea alba (Figure 23-2). Although the traditional suture pattern is simple interrupted, a simple continuous pattern is a safe and faster alternative.

In the caudal third of the abdominal wall, the width of the linea alba decreases. An incision here frequently exposes the rectus abdominis muscle. Because fibers of the rectus abdominis muscle have little holding power, sutures are not full thickness. Instead, sutures are placed to include an adequate portion of the

external leaf of the rectus sheath on each side of the incision and to appose this fascia accurately without interspersion of rectus abdominis muscle (Figure 23-3). The transversalis fascia and the peritoneum are not included in the sutures. Sutures traditionally are simple interrupted, but a simple continuous pattern is a satisfactory alternative.

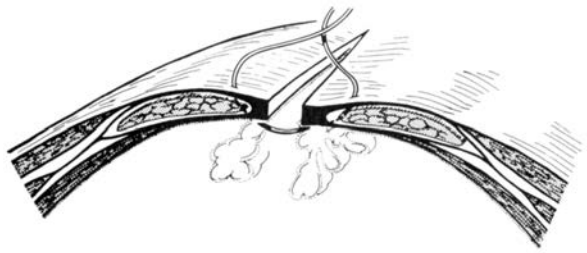

Figure 23-2. Linea alba incision in the cranial two-thirds of the abdominal wall closed by a full-thickness suture placed carefully to avoid the falciform ligament.

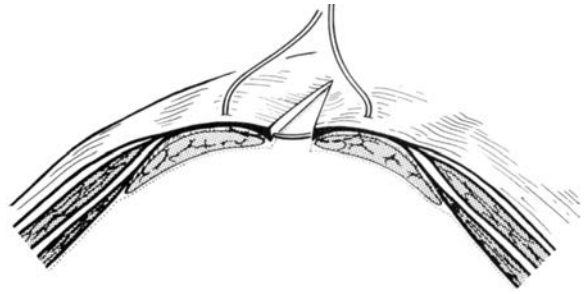

Figure 23-3. Midline incision in the caudal third of the abdominal wall closed by a suture placed to appose the external leaf of the rectus sheath accurately.

Paramedian Incision

If the incision is paramedian in the cranial two-thirds of the abdominal wall, the linea alba will be on one side and the external and internal leaves of the rectus sheath and rectus abdominis muscle will be exposed on the other side, or on both sides of the incision, the internal and external leaves of the rectus sheath and rectus abdominis muscle will be exposed. The external leaf of rectus sheath is closed with a simple interrupted or continuous pattern. The internal leaf of the rectus sheath and the peritoneum are left unsutured (Figure 23-4).

Figure 23-4. Single-layer closure of only the external leaf of the rectus sheath. Care is taken to avoid interspersing rectus muscle between the edges of the rectus sheath.

A paramedian incision in the caudal third of the abdominal cavity is closed by suturing the rectus fascia in a simple interrupted or continuous pattern. The transversalis fascia and peritoneum have little strength and are not sutured.

Simple Continuous Suture Technique

Acceptable suture materials include polyglycolic acid, polyglactin 910, polydioxanone, polyglyconate, polypropylene, and nylon. Surgical gut, stainless wire, and multifilament nonabsorbable suture materials should not be used. Suture size is based on patient size: 3-0 suture material should be used for cats and small breed dogs, 2-0 for medium-sized dogs, 0 for large dogs, and 1 for giant breed dogs.

For a simple continuous suture pattern used in long incisions, more than one strand of suture material is used. Sutures are placed through the linea alba or through the external leaf of the rectus sheath, depending on patient size, and, include a 3- to 10-mm width of fascia on each side of the incision. Sutures are placed 5 to 10 mm apart, depending on the size of the animal. Care is taken to ensure edge-to-edge apposition of the fascia without interspersion of muscle. The internal leaf of the rectus sheath and the peritoneum are not included in the suture pattern.

All knots are placed with care. The first throw is tied with appositional tension only to ensure that tissue is not strangulated. Five additional square, flat throws are placed.[10] After each throw is made, the ends of the suture are pulled tight to make the knot secure. The ends of the suture are cut 4 mm from the knot. As the continuous suture is placed, the rectus fascia must be loosely approximated, not apposed with tension. Wound strength is adversely affected if fascia is closed tightly.[11]

Subcutaneous tissues are closed with the same suture materials, usually a smaller size, placed in simple continuous pattern. Care is taken to avoid cutting the rectus fascia suture during closure of the subcutaneous tissue. Skin is closed with 3-0 nonabsorbable suture placed in a simple interrupted or cruciate pattern, or skin staples are used.

Closed Peritoneal Drainage

Giselle Hosgood

Indications

The use of drains to remove fluid, pus, or contaminated material from the closed peritoneal cavity is hereby referred to as closed peritoneal drainage. The use of drains in the peritoneal cavity is primarily indicated in the management of peritonitis although there is some evidence to show that appropriate surgical and medical management without drainage is equally effective.[1-4] Other indications for peritoneal drainage include diagnostic peritoneal lavage, peritoneal dialysis and administration of peritoneal chemotherapy.[5] Placement of drains after routine abdominal procedures is discouraged, and the use of drains should not replace meticulous surgical technique. The use of drains can be associated with multiple complications, and peritoneal drainage is not a reliable indicator of wound or body cavity events; the absence of drainage does not always imply the absence of fluid and fluid production can be induced by the presence of the drain alone.[1]

Closed-collection systems

Connecting a drain to a collection system has several advantages, and is strongly recommended. A collection system, whether by passive or active drainage, reduces the risk of ascending infection through the lumen of the drain. Ascending infection is one of the most common complications of peritoneal drainage, a function of both bacterial load migrating up the drain and decreased local tissue resistance because of the presence of the drain.[6] Although bacteria can also migrate along the outside of the drain,[7] a closed system greatly reduces the bacterial load. Protection of the drain by a sterile bandage can reduce bacterial migration along the outside of the wound. Collection systems also eliminate the chance of saturating the bandage covering an open drain. A wet bandage over a freely draining passive drain provides an additional source of contamination by bacterial strike-through from the environment. Collection systems also allow accurate assessment of fluid character and volume.

Passive Drainage

The abdomen can be compared with a fluid-filled, flexible container with two separate pressure zones. Positive atmospheric pressure exists within the gastrointestinal tract, whereas the peritoneal cavity has an extraluminal subatmospheric pressure between -5 and -8 cm water; the pressure is most negative in the cranial abdomen near the diaphragm.[8] Passive drainage of fluid from the peritoneal cavity requires an air vent to break the vacuum and to create a positive atmospheric pressure within the peritoneal cavity.[8] Positive pressure occurs after celiotomy or after a stab incision into the abdomen for drain placement. Passive peritoneal drainage relies on a pressure differential between the peritoneal cavity and the environment and functions primarily by overflow. Passive drainage is gravity dependent, and the drain provides a tract of least resistance along which excess fluid flows.[2,8] An inexpensive and easily accessible passive collection system is through a sterile intravenous administration set into a sterile bag. Sterile urine collection systems can also be used. Although passive drains are gravity dependent,[1] the resting level of the drain and the collection bag proportionally affect the gravitational force and the rate of drainage. Increasing this distance excessively may promote obstruction of the drain by omentum or intestinal loops; for instance, having a dog in a high cage with the collection bag on the floor.

Active Drainage

Active drainage requires an external vacuum to create negative pressure within the peritoneal cavity. This allows drainage to occur independent of gravity. The vacuum is achieved by connection of the drain to a compressible container or a constant, low-pressure, suction device (Figure 23-5).[1,2] Some commercial collection systems have one-way valves to prevent fluid reflux from the collection system into the peritoneal cavity. Suction should be applied to the drain before complete abdominal closure to prevent occlusion of the drain by intraluminal blood clot formation or tissue debris. The optimal level of suction is unclear. Low-level suction is effective, but higher levels are not always harmful and may remove more fluid. Suction levels between -9 mm Hg (-12 cm water)[9] and -15 mm Hg (-20 cm water)[10] are typically used in wound drainage in people, although higher levels of suction, -80 mm Hg (-112 cm water)[11] and -150 mm Hg (-200 cm water),[12] have been used successfully. Closed active drains are effective in removing large volumes of fluid; however, as the volume of intraperitoneal fluid decreases, active drainage causes suction of tissue, viscera, omentum, or abdominal wall toward the drain, resulting in occlusion.[1,13] Tissue debris may also occlude the lumen. High-level suction may promote obstruction.

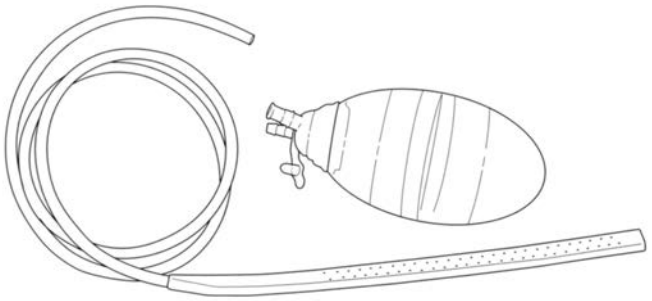

Figure 23-5. A silicone wound drain and compressible collection canister that can be connected together and used for active peritoneal drainage. Note the one-way valve on the canister. Alternately, the drain can be connected to a passive collection system.

Drains Suitable for Peritoneal Drainage

The most suitable drain for use in the peritoneal cavity is a simple tube drain with multiple fenestrations. Variations include channel drains and multilumen drains with channels (Figure 23-6).These tube drains can be connected to an active or passive collection system. Alternate techniques of open peritoneal drainage for the management of pancreatic masses[5] and peritonitis[3] are also reported.

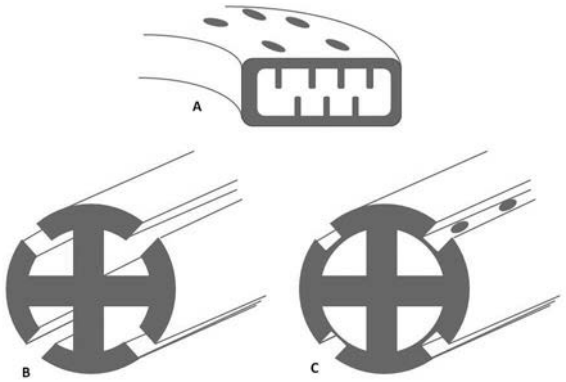

Figure 23-6. Cross-sectional images of multifenestrated silicone wound drain **A**., Channel drain **B**. and multilumen drain with channels **C**.

Simple Tube Drain

The simple tube drain is a single lumen drain that acts primarily by gravity-dependent intraluminal flow. Because most of the drainage is intraluminal, fenestration improves drainage efficiency.[14] However, fenestration reduces the tensile strength of the drain and may predispose to tearing on removal.[15] Channel drains function by extraluminal capillary flow along the channels of the drain. The channelling increases the surface area of the drain, thereby increasing the efficiency. Multilumen drains with channels function by both intra and extraluminal flow whereby channels empty into the lumens via multifenestrations along the length of the drain. Presumably, channelling reduces tissue occlusion against fenestration of the simple tube drains. Pre-fenestrated commercial drains are preferred but fenestrations can be made by hand in a solid drain. Fenestrations should be oval and less than one-third the diameter of the drain, to prevent kinking and tearing.[6] Fenestration using oval-tipped bone rongeurs rather than scissors may give a more precise, controlled cut with easy and safe removal of the fragment in the instrument's jaws.[16] Channel drains can only be purchased. Silicone drains are preferred over plastic (polyvinyl chloride) or rubber drains because silicone is relatively inert (red rubber tubes are the most irritating) and the silicone is soft and pliable. However, silicone drains have less tensile strength than polyvinyl chloride drains, and care is required on removal to prevent tearing.[15] Silicone wound drains are readily available (Cardinal Health Fluid Management Products, 1500 Waukegan Road McGaw Park, IL 60085)

Peritoneal Dialysis Catheter

A modification of the simple tube drain is the multi-fenestrated peritoneal dialysis catheter (Quinton Tenckhoff Peritoneal Catheter, Kendal Healthcare, Covidien, Mansfield, Massachusetts; Figure 23-7).

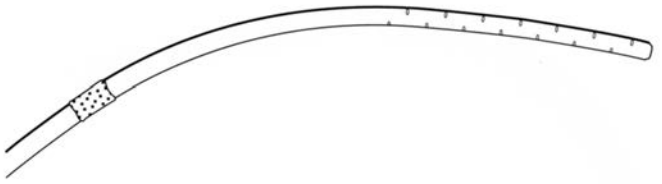

Figure 23-7. A commercial, multifenestrated, peritoneal dialysis catheter. Note the Dacron cuff toward the end of the drain and the radiopaque ridge on top of the drain.

Most peritoneal dialysis catheters are now made of silicone. Some peritoneal dialysis catheters have one or two Dacron cuffs around the tubing that is sutured to the body wall and subcutaneous tissue to stimulate a fibroblastic reaction and to prevent subcutaneous fluid leakage. These catheters are also used for intraperitoneal chemotherapy. Some peritoneal dialysis catheters come with an introducer or trochar which allows for easy percutaneous insertion into the peritoneal cavity. These types of peritoneal catheter are particularly useful for diagnostic peritoneal lavage or intraperitoneal administration of drugs because they can be inserted through a small abdominal incision using local anesthesia in a sedated animal.[5]

Drain Placement

Efficient peritoneal drainage is difficult because of the convoluted nature of the peritoneal cavity, the sometimes intense fibrinous and fibrous reactions encountered during peritonitis, and the ability of the omentum to isolate the drain from the peritoneal cavity. Normal forces associated with movement of the diaphragm, abdominal wall, and intestine affect the intraperitoneal circulation of fluid and cause fluid to pool beneath the diaphragm[16] and in the peritoneal reflections near the distal colon. In addition to normal forces, fluid can become isolated by peritoneal adhesions.[9] Drain placement is extremely important to maximize drainage. Drains are usually placed during celiotomy. Alternately, in acute situations such as diagnostic peritoneal lavage, emergency drainage of fluid from the abdomen (uroabdomen), or for establishment of peritoneal dialysis, a stab incision in the skin of the ventral midline is made, and the drain is "punched" through the body wall. Commercial, simple, peritoneal dialysis catheters and some tube drains come with a stylet-trocar for this purpose. Insertion of these drains in an emergency can often be performed under local anesthesia and sedation.

To drain the peritoneal cavity effectively, two tubular drains may be required, one directed cranially along the ventral abdominal wall toward the diaphragm and the other caudally along the ventral abdominal wall to the peritoneal reflections near the distal colon.[9] Alternately, commercial drains are available that "split", allowing the two sections of the drain to be placed in different directions with the advantage of only having a single collection tube and exit point. The drains should exit close to the midline, in a dependent position, usually between the umbilicus and the xiphoid. The exit incision through the abdominal wall and skin should be only as large as the diameter of the drain.

A small exit incision reduces subcutaneous fluid leakage and subsequent cellulitis and possible incisional herniation. The exit incision should not be so small as to obstruct the drain. The epigastric vessels, which run through the middle of the mammary chains, should be avoided. If the exit incision is small, it can be made between the epigastric vessel and the midline (incision) without weakening the midline celiotomy incision. Exiting lateral to the epigastric vessels moves away from a dependent exit site and may promote subcutaneous fluid leakage and cellulitis. If celiotomy is performed, tacking the omentum to the stomach may help to prevent it from enveloping the drains. The omentum can be excised if it is obviously compromised or heavily contaminated. Excising the falciform fat may help to reduce tissue obstruction of the drains.

The exit tubing can be connected to a collection system, to function by passive drainage or low-pressure suction (40 to 60 mm Hg). All drains should be sutured to the skin using a secure suture such as the Chinese finger trap suture.[18] Suction is applied as soon as the drain is placed, to prevent intraoperative obstruction of the drain with blood clots or tissue debris. All drain exit points should be covered with a sterile bandage on completion of the surgical procedure. If for some reason a closed system is not used, multilayered, thick, absorbent bandage material is indicated to cover the drain, noting that the contact layer must be sterile. Sterile cloth towels and sterile disposable diapers (sterilized with ethylene oxide) make useful absorbent bandage layers.

Postoperative Management

The bandage should be changed as often as required to prevent complete soaking by exudate and possible strikethrough of bacteria from the environment. The frequency of bandage changes is considerably reduced for drains using a collection system, but some leakage can occur through the exit site around the drain. Contamination of the bandage from the environment (urine, feces) can also occur. Use of an indwelling urinary catheter, particularly in male dogs, may help to prevent urine contamination. This is especially useful if the animal is recumbent. Bandaging also helps to prevent self-mutilation of the drainage area and premature removal or damage to the drain by the animal. The volume and nature of the fluid should be monitored closely, at least three to four times a day or more if profuse. The collection system should be changed using sterile technique when it is full or the vacuum has been lost. The vacuum may be lost before the collection system is completely full. Without vacuum and fluid flow, the risk of obstruction of the drain by tissue debris or fibrin and blood clots is increased. In addition, fluid that remains in the collection system for a prolonged period may promote bacterial growth. The drain is removed once the volume of fluid becomes significantly reduced and the fluid becomes serosanguineous. Drainage beyond 2 to 3 days is rarely necessary and persistent fluid production may indicate non-resolving peritonitis or other problems with response to management. The presence of a drain incites an inflammatory reaction and some fluid production (2 to 4 mls/kg/day), hence drainage usually does not cease completely. If drainage ceases suddenly, it may represent drain obstruction rather than resolution of the disease. Fluid may continue to drain for 1 to 2 days after drain removal, and a bandage should remain in place over the exit point to collect drainage and to prevent contamination of the exit site until it is sealed.

Complications

The most common complications of abdominal drains are obstruction and ascending infection. Nosocomial bacterial contamination of the drain and drainage site is a common complication of any drain placement. Retraction of the drain may occur once the animal begins to move and stand. This tends to occur with drains that are not connected to a collection system and that are cut short at the exit site. Suturing the drain securely, at several sites, is also important. Exit site and drain tract cellulitis is not uncommon. This complication is not serious and usually resolves once the drain is removed.

Subcutaneous fluid leakage is more common when peritoneal lavage is used and is particularly noted in the first few hours after surgery. Subcutaneous fluid leakage and cellulitis can be reduced by using a short subcutaneous tunnel between the skin and the abdominal wall exit site for the drain and by having the exit site in a dependent position. The Dacron cuffs on the peritoneal dialysis catheter and disc catheter also help to reduce this complication. Applying a water-repellent ointment to the skin around the exit site (petroleum jelly) may help to prevent skin irritation from drainage fluid. Hypoproteinemia and hypoalbuminemia are significant complications of peritonitis and drainage, but are not complications of drainage per se. Close monitoring of plasma protein concentrations in animals with peritonitis is imperative, and intravenous plasma or colloid infusion may be required.

Negative Pressure Wound Therapy – Modified Closed Drainage

A modified application of suction drainage for septic peritonitis is the use of negative pressure wound therapy.[19,20] The septic abdomen is essentially treated as an open wound with removal of exudate through the application of a sealed, absorbant dressing over the open abdomen which is connected to a commercial, portable suction apparatus. The suction apparatus provides continuous subatmospheric pressure at -80 mmHg to -125mmHg. While the abdomen is open, the drainage system is a closed system, isolated from the environment. Once infection is controlled, delayed abdominal closure is then performed.

Omentum as a Surgical Tool

Giselle Hosgood

Introduction

The omentum is a mesothelial membrane with a unique vascular and lymphatic network that supports its use in various abdominal and extraabdominal surgical procedures. In any surgical procedure where there is a need for increased vasculature, lymphatics, or tissue bulk, the omentum may prove useful.[1]

Anatomy and Physiology[2]

The peritoneum is a mesothelial membrane that lines the abdominal cavity and covers the the abdominal organs. The peritoneal folds which leave the greater and lesser curvatures of the stomach are known as the greater and lesser omentum, respectively. The lesser omentum is derived from the ventral mesogastrium and extends between the lesser curvature of the stomach and the initial part of the duodenum to the liver hilus. The greater omentum is derived from the dorsal mesogastrium and comprises the large bursal portion and the smaller splenic and veil portions. Both omenta are composed of a double peritoneal leaf that is transparent, except for the lacey appearance of fat around the blood vessels that run through it.

The bursal portion of the greater omentum is of most clinical and surgical significance and is hereafter referred to as the omentum. The bursal portion is attached cranioventrally to the greater curvature of the stomach and extends caudally to the urinary bladder. The omentum reflects on itself forming a double layer (visceral and parietal layer) that covers the intestines (Figure 23-8). The potential cavity between the layers is the omental bursa (lesser peritoneal cavity). The only natural opening of the omental bursa is the epiploic foramen.

Important anatomical features of the omentum in the dog, which differ from that of people, may affect the surgical extension procedures that are sometimes performed depending upon its surgical use. In the dog, the spleen is attached to the parietal layer of the omentum. There is no colonic attachment of the omentum in the dog.[1] The primary omental blood supply comes from right and left border vessels that arise from the right gastroepiploic and splenic arteries, respectively.[3] Approximately nine smaller vessels originate from the gastroepiploic arcade along the greater curvature of the stomach.[1] The gastroepiploic arcade does not require mobilization in the dog.[1] The omentum is one of the major fat repositories in obese animals. Lymphatic drainage occurs by blind, bulbous capillaries present in the milk spots on the surface of the omentum. The mesothelial membrane is discontinuous over the milk spots, allowing material access to the lymphatics.[4] Lymphatics follow the vascular paths and anastomose with lymphatics of the stomach and spleen which drain by regional and celiac lymph nodes into the thoracic duct.[4] Drainage into the lacunae on the visceral surface of the diaphragm also occurs.[2] Milk spots are collections of cells of lymphoid and myeloid origin, mainly T and B lymphoctes, monocytes and macrophages. These sites may provide cells that have roles in inflammation, angiogenesis and immune responses.

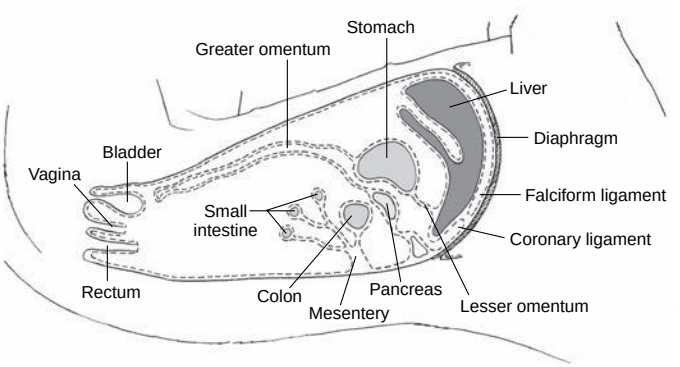

Figure 23-8. Peritoneal reflections of the dog in sagittal section. The dog is on its back, head to the right. (From Evans HE. The abdomen. Miller's Anatomy of the Dog. Philadelphia: W.B. Saunders Co; 1993:434).

Surgical Techniques

Mobilization of the Omentum

For use in local abdominal recipient sites, the free edge of the folded greater omentum can simply be moved to the recipient site. If movement of the omentum to a distant recipient site is needed, the length of the omentum can be extended by "unfolding" the

double layer after freeing the dorsal layer.[1] The omentum and spleen are exteriorized and the dorsal omental layer is reflected ventrally and cranially to identify the pancreatic attachments (Figure 23-9). The dorsal layer is freed from the pancreas using sharp dissection proceeding from right to left. As the dissection approaches the tail of the left lobe of the pancreas, vessels entering the spleen are encountered. Several omental vessels originating from the splenic artery may be encountered and are ligated close to the spleen. Hemorrhage is controlled with ligation, radiosurgery or ligature clips. Care must be taken to avoid hematoma formation which will compromise the vascularity of the omentum.[1] The omentum is now unfolded and extended caudally (Figure 23-10). The extension procedure provides considerable mobility and length with the free edge of the omentum reaching as far as the thoracic inlet cranially and the stifle caudally.[1]

Full extension of the omentum is achieved by making an inverted "L-shaped" incision through the dorsal extension and creating an omental pedicle (Figure 23-11). Beginning on the left side just caudal to the gastrosplenic ligament, the omental vessels are transected across one-half to two-thirds of the width. This makes the foot of the L incision. The incision should only be extended as far as necessary to preserve the width of the pedicle and subsequently the number of longitudinal omental vessels supplying the pedicle. The incision is then extended caudally and parallel to the remaining omental vessels. This incision forms the vertical limb of the L. The vertical incision can be extended as far as necessary, up to two-thirds of the length of the dorsal extension.

Hemorrhage is controlled with ligation, radiosurgery or ligature clips. The completed L-incision provides maximum extension of the omentum, reaching the muzzle cranially and the toes of the hindlimbs caudally.[1]

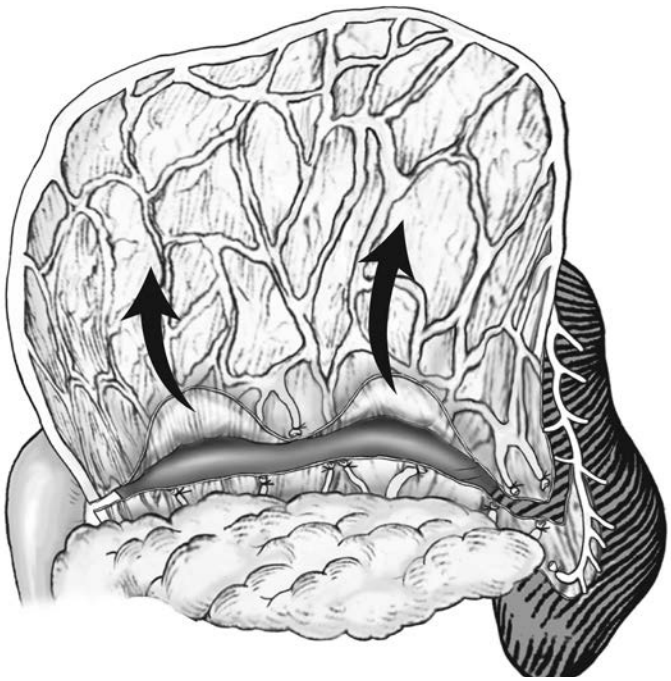

Figure 23-9. Dorsal extension of the omentum. The omentum and spleen are exteriorized, the dorsal leaf of the omentum is retracted ventrally and cranially and the omentum is freed from its pancreatic attachments. One or two vessels originating from the splenic artery are transected. (From Ross WE, Pardo AD. Evaluation of an omental pedicle extension technique in the dog. *Vet Surg* 1993;22:37-43.)

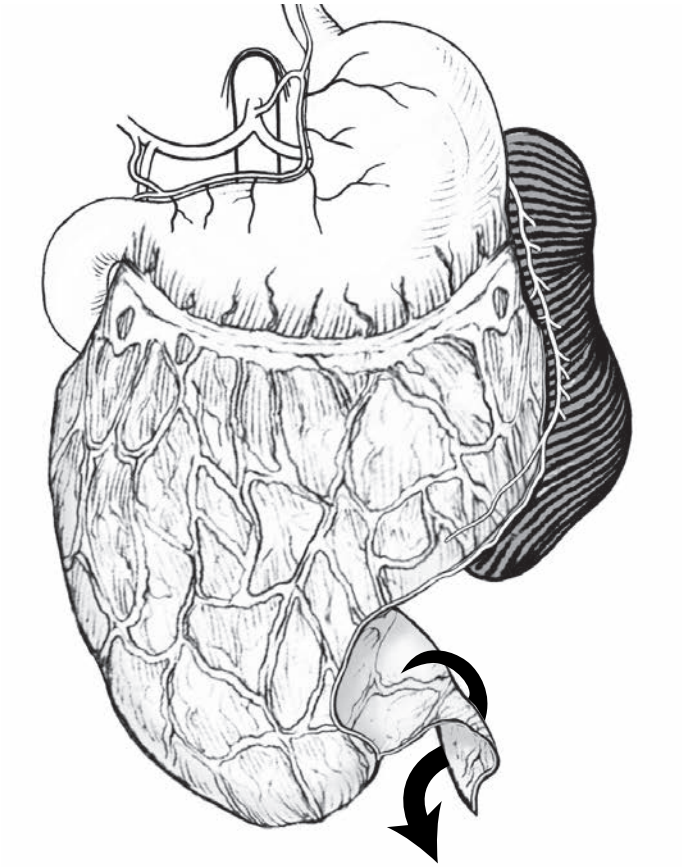

Figure 23-10. The dorsal leaf of the omentum is extended caudally. (From Ross WE, Pardo AD. Evaluation of an omental pedicle extension technique in the dog. *Vet Surg* 1993;22:37-43.)

Microvascular transfer of a free omental graft is used frequently in people since extension of the omentum is restricted by the vascular pattern. Microvascular transfer of an omental graft to the distal extremity in dogs has been reported however ischemia and failure of the grafts occurred in three of the five dogs.[5] Based on the success of omental extension described above, free transfer of the omentum is unlikely to be required in the dog or cat.

Extrabdominal Translocation of the Omentum

The omentum is most effectively translocated to the thoracic cavity by an incision in the diaphragm. Alternately, the omentum can be brought through the body wall, tunneled subcutaneously and then placed into the thoracic cavity through a lateral thoracic incision.

For other extrabdominal sites, the omentum is passed through an incision in the body wall, usually paracostal, and tunneled subcutaneously to the recipient site. Care must be taken to preserve the integrity of the omentum as it is grasped and tunneled through the subcutaneous tissue. Small tunnels that might constrict the omentum should be avoided.

Alternatively, the skin can be incised along the length of the tunnel and sutured over the length of the extrabdominal extension.

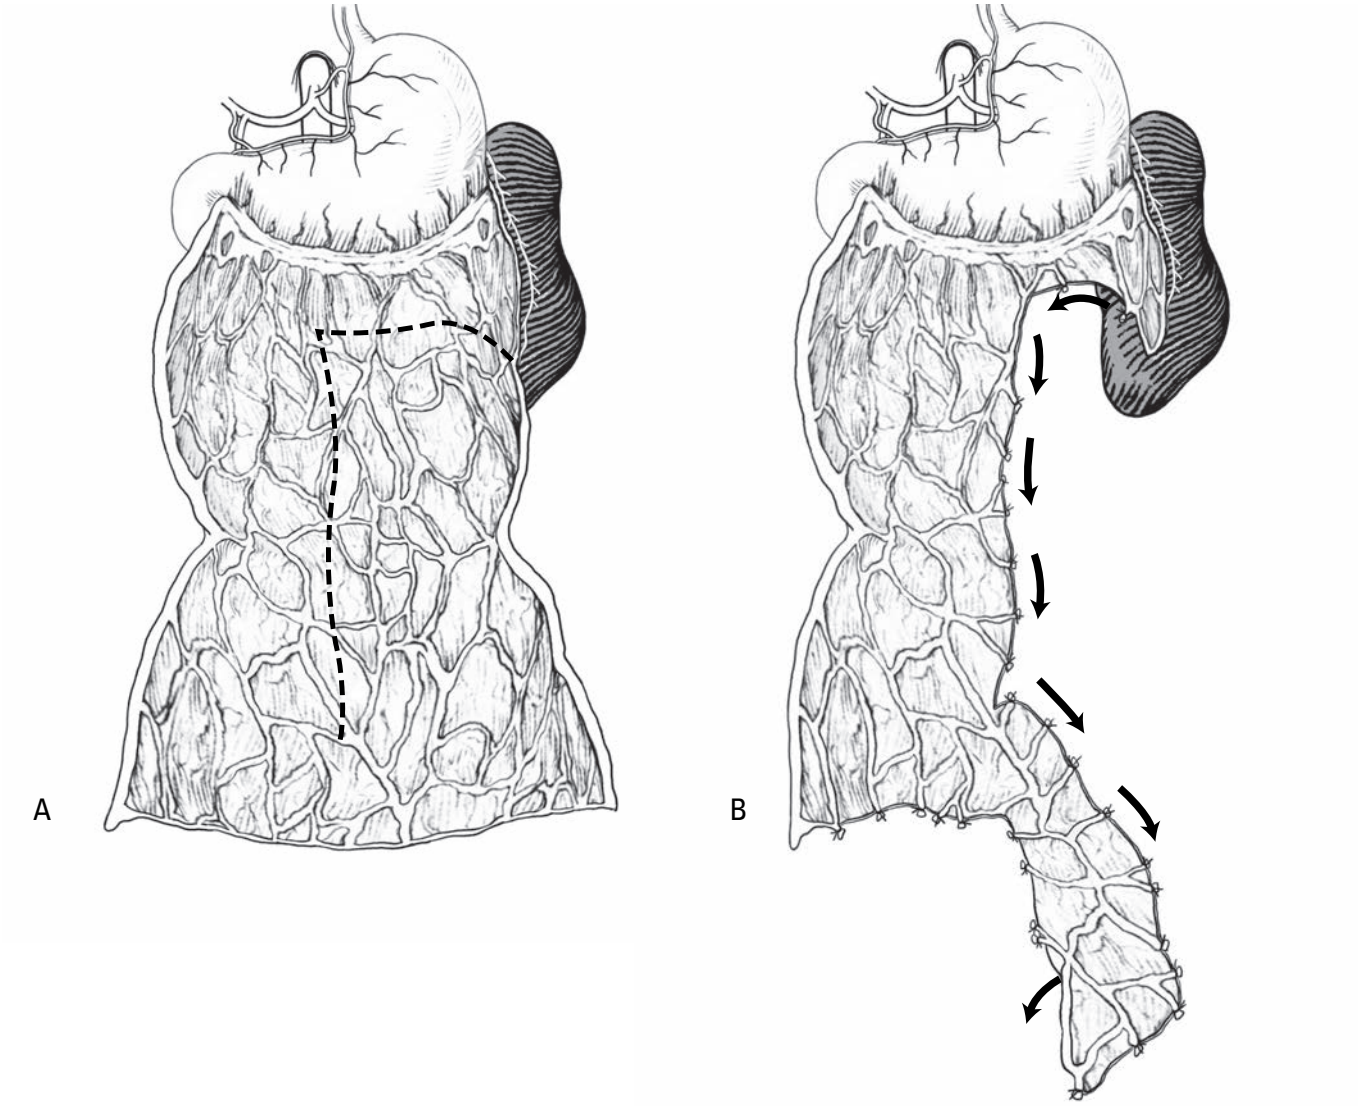

Figure 23-11. Creation of the omental pedicle. The inverted L-shaped incision is begun just caudal to the gastrosplenic ligament **(A)** and extended caudally for full extension **(B)**. (From Ross WE, Pardo AD. Evaluation of an omental pedicle extension technique in the dog. *Vet Surg* 1993;22:37-43.)

Specific Applications using the Omentum

Omentalization of Cystic Organs and Abscesses

The technique for using the omentum in the management of cysts and abscesses of abdominal organs is the same, regardless of the organ affected by disease. Extension of the omentum is usually not necessary for intraabdominal use. Omentalization of prostatic abscesses and cysts, pancreatic cysts and abscesses, uterine stump abscess, perinephric cysts, liver cysts and sublumbar lymph nodes has been reported.[6-12] The technique requires the cyst to be partially or almost completely removed. The omentum is then packed into the remaining shell of the cyst and loosely sutured in place with monofilament, absorbable suture material. Abscess cavities are first cultured and drained and as much of the outer surface wall is removed as possible. Omentum is packed into the remaining abscess cavity and sutured in place.

Chylothorax

Translocation of the omentum into the thorax of a 6 year-old Rhodesian ridgeback[15] and a 6-year-old Himalayan cat[16] with chylothorax have been reported. The omentum was brought through an incision in the muscle of the diaphragm, spread out in the thorax and sutured in the region of the mediastinum. The basis for the use of the omentum in the treatment of chylothorax is to take advantage of the considerable lymphatic drainage provided by the omentum. Both animals were free of disease 16 and 13 months after surgery, respectively. Since the omental lymphatics drain into the cysterna chyli, the rationale for treatment of chylothorax with omental transposition has been questioned.[17]

In theory, non-chylous effusion that may occur following correction of chylothorax may be reduced following omentalization.

Chronic Wounds

Extraabdominal translocation of the omentum to sites of non-healing wounds has been reported in the dog and the cat.[15-17] The omentum provides a vascular bed for free skin grafting or for random cutaneous or axial pattern skin flap reconstruction. The omentum is first extended and an omental pedicle is created if necessary. The omentum is then passed through a paracostal incision in the abdominal wall and tunneled subcutaneously to

the wound bed. The skin is reconstructed over the omentum. Wound drainage with a closed, active drain may be required.

Thoracic and Abdominal Wall and Diaphragm Reconstruction

The omentum has been used in conjunction with mesh reconstruction of thoracic and abdominal wall defects.[23,24] The omentum is first extended and an omental pedicle is created if necessary. The omentum is then passed through a paracostal incision in the abdominal wall and tunneled subcutaneously to the defect and placed on top of the mesh.

The omentum fills the soft tissue defect and also brings vascularity and lymphatic drainage to the wound site. The skin is reconstructed over the omentum. Wound drainage with a closed, active drain may be required.

The omentum has been used to cover experimentally created defects in the diaphragm in the dog. The omentum was folded over on itself and sutured to the edges of defect. After three weeks, the omentum remained viable with evidence of fibrometaplaisa with fibrosis to the diaphragm edges. Despite promising experimental results, reconstruction of the diaphragm is rarely required in dogs and cats. Primary closure of tears in the diaphragm is usually possible, even in chronic cases.

Other Applications

Application of the omentum to other surgical situations is possible, based on the ability of the omentum to enhance vascularity, lymphatic drainage and immune response at a recipient site. Use of the omentum to pack traumatic fractures in parenchymatous organs such as the liver, kidney and spleen is reported in humans. Support of gastrointestinal anastomotic sites is possible and widely used. Autgenous omental grafts, as free non-vascularized grafts, have been used to enhance bone healing in experimental non-union models in dogs.[25,26] Radial osteotomies treated with free autogenous omentum had union by 16 weeks while untreated osteotomies remained as a non-union.[25] In a second study using a similar non-union model in dogs, the effect of the omental graft was potentiated by the inclusion of adipose-derived stem cells.[26] The surgical applications for use of the omentum are numerous and varied however, the use of omentum should be viewed as an adjunct to sound surgical practice and not as a substitute for good surgical technique.

Chapter 24

Nasal Cavity

Resection of the Nasal Planum

Rodney C. Straw

Cats with unpigmented skin of the nasal planum may, over several years, develop squamous cell carcinoma with prolonged exposure to ultraviolet (UV-B) irradiation.[1] One paper suggests a papillomavirus may be involved in the etiology of feline squamous cell carcinoma. Older, white cats or those with lightly pigmented noses and that live in sunny climates are at risk. Lesions progress slowly through early solar damage with crusting and erythema to carcinoma in situ to invasive squamous cell carcinoma.[3] Invasive squamous cell carcinoma initially is confined to the nasal planum, but it slowly becomes more extensive, affecting deep and adjacent tissues late in the course of the disease. Lymph node or lung metastases are rare.[3] Cutaneous hemangiosarcoma of the nasal planum also occurs and is also thought to be associated with solar irradiation.[4,5] Basal cell tumor has been reported to occur on the nose of cats.[6] Cancer involving the nasal planum or premaxilla is uncommon in dogs, but such tumors include squamous cell carcinoma, fibrosarcoma, melanoma, mast cell tumor, and osteosarcoma.[7] Biopsy with histopathologic examination is necessary to diagnose cancer of the nasal planum and is important to rule out nonneoplastic causes of nasal ulceration.

Indications

Various methods have been described to treat cats with squamous cell carcinoma of the nasal planum including radiation therapy, hyperthermia, intratumoral administration of carboplatin, cryosurgery, conservative (marginal or intralesional) surgery, and photodynamic therapy.[8-13] Unfortunately, with most of these treatments, the tumor margins cannot be evaluated to ensure that an adequate volume of tissue is treated. Each of these modes of therapy has other disadvantages, including the need for special equipment and facilities for some techniques, high rates of tumor recurrence, and reported control rates for deeply infiltrating lesions of up to 55% at 1 year. Most of these techniques may work for early, small lesions or carcinoma in situ, but the most cost-effective, reliable treatment for selected patients with invasive squamous cell carcinoma is nasal planum resection. Fifteen of 20 cats with invasive squamous cell carcinoma treated with nasal planum resection were free of recurrent disease at 1 year.[6] Nasal planum resection can also be effectively used to treat other invasive neoplasms in dogs and cats. Although the cosmetic results in cats are generally good and acceptable to most owners, dogs are more noticeably deformed by the surgery. Function is usually excellent.

Nasal Planum Resection

The animal is maintained under general anesthesia and intubated with a cuffed endotracheal tube. A maxillary nerve block is performed and the cat is anesthetized and positioned in sternal recumbency with the head slightly elevated. The surgical area is carefully palpated to try to estimate tumor extension into adjacent tissue. A small area of hair is clipped, but the tactile vibrissae are avoided, and the site is prepared for aseptic surgery. A drape with a circular hole is placed over the prepared site. The nasal planum is completely removed with a 360° skin incision made with a No. 15 scalpel blade (Figure 24-1). The incision is made so it transects the underlying turbinates. If the tumor does not extend to the lip margin, then a thin strip of skin and buccal mucous membrane is preserved at the rostral lip margins on the midline. If tumor has extended into this region, then the lip margin must be removed, resulting in a closure involving rostral advancement of the lips. This may leave the incisor teeth slightly exposed. The cartilage of the nasal planum and the turbinates are cut with an incision angled at about 45° to the hard palate (Figure 24-2). Bleeding is usually brisk. Hemorrhage is controlled by direct pressure with a sponge. Electrocautery should only be used sparingly to avoid thermal necrosis, which delays healing.

Once the nasal planum is removed, the skin edges retract and the nasal conchae are exposed. A pursestring suture of 3-0 monofilament nonabsorbable suture material is placed through the skin around the incision. The surgeon does not need to place any deep sutures into the cartilage or nasal mucosa. It is only

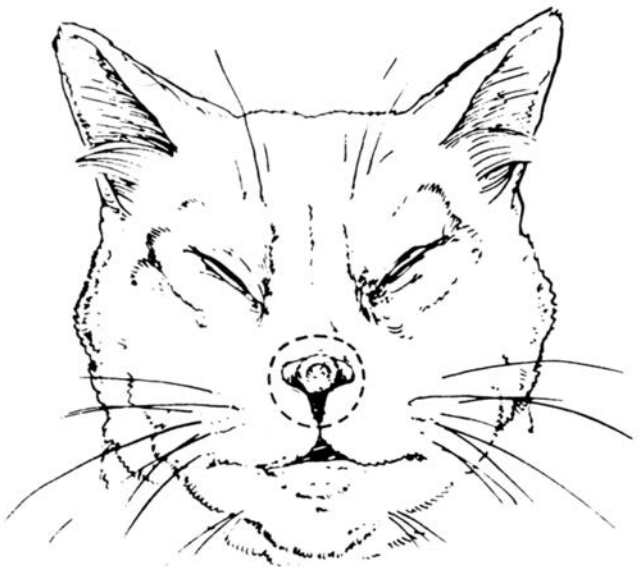

Figure 24-1. The 360° incision around the nasal planum is indicated by the dotted line. If possible, a strip of skin is left ventrally so the lips are left attached at the midline. (From Withrow SJ, Straw RC. Resection of the nasal planum in nine cats and five dogs. J Am Anim Hosp Assoc 1990;26:219-222.)

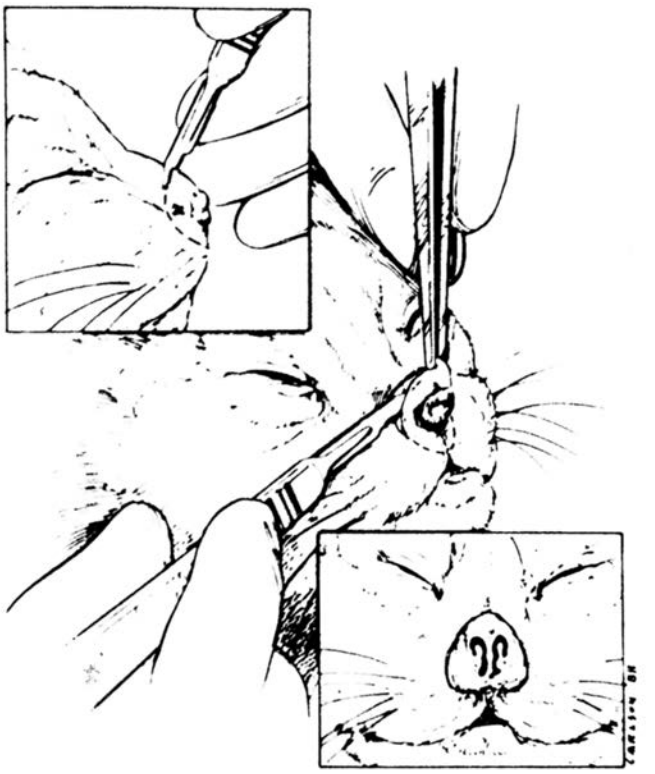

Figure 24-2. The angle of the deep incision as seen from the lateral side is angled at approximately 45°. The turbinates are sharply divided. Skin retracts after removal of the nasal planum, exposing the nasal cavity. (From Withrow SJ, Straw RC. Resection of the nasal planum in nine cats and five dogs. J Am Anim Hosp Assoc 1990;26:219-222.)

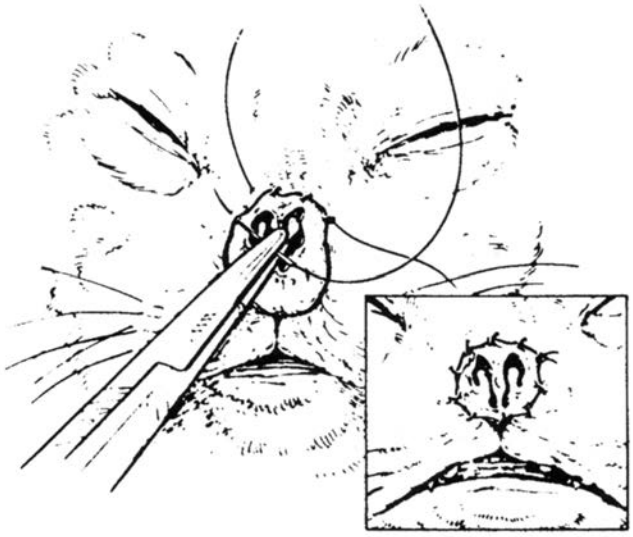

Figure 24-3. A continuous pursestring suture is used to reduce the nasal orifice to about I cm diameter. No sutures are placed in cartilage. (From Withrow SJ, Straw RC. Resection of the nasal planum in nine cats and five dogs. J Am Anim Hosp Assoc 1990;26:219-222.)

necessary to tighten the pursestring suture lightly; for cats, the new nasal orifice is closed to approximately 1 cm in diameter (Figure 24-3). The entire excised nasal planum is submitted for histopathologic examination, with a request for the pathologist to examine the surgical margins carefully. India ink or other tissue marking ink may be painted on the cut edges of the specimen to delineate the surgical margins. Analgesics are used, and patients are usually sent home within 24 hours. Owners are advised not to try to clean the surgical site and are warned that the patient may sneeze blood for several days. Patients should be tempted with favored food, but they may be reluctant to eat for a few days after surgery. Older animals with compromised renal function need fluid support until water intake becomes adequate. Elizabethan collars are usually not necessary. Sutures are removed approximately 10 days after surgery, and sedation or a short course of anesthesia may be required.

Combined Resection of the Nasal Planum and Premaxilla

For extensive neoplasms of the nasal planum and premaxilla, nasal planum resection or premaxillectomy alone may be inadequate. Wide surgical margins can be attained using combined resection of the nasal planum and premaxilla.[7] This technique offers a surgical treatment for large tumors in dogs that obviates

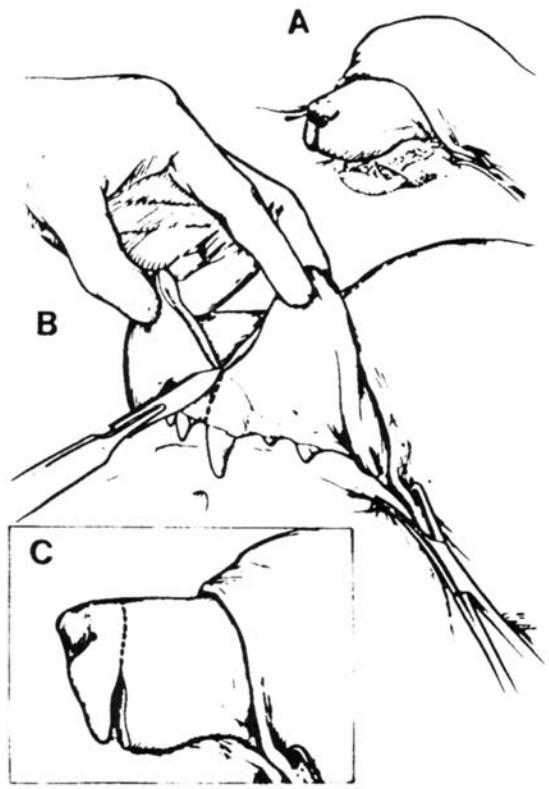

Figure 24-4. A. The dog is placed in sternal recumbency and is draped after preparation for aseptic surgery. The mouth is open, and the lower drape is within the mouth. **B.** The upper lip is incised full thickness on each side of the nasal planum. **C.** The two incisions are united on the dorsal midline of the nose caudal to the nasal planum. (From Kirpensteijn J, Withrow SJ, Straw RC. Combined resection of the nasal planum and premaxilla in three dogs. Vet Surg 1994;23:341-346.)

the need for adjuvant or primary radiation therapy. Cosmetic results are considered acceptable by most owners.

The dog, maintained under general anesthesia and intubated with a cuffed endotracheal tube, is positioned in sternal recumbency with the mouth slightly open. The skin overlying the maxilla and upper lip is clipped and prepared for aseptic surgery. The oral mucosa of the lips and hard palate is prepared with a disinfectant such as a dilute povidone-iodine solution. The area is draped, allowing access to the oral cavity (Figure 24-4A). The upper lip is incised from the skin through the mucosa on each side of the nasal planum (Figure 24-4B). The two incisions are connected at the dorsal midline of the nose caudal to the nasal planum (Figure 24-4C). The nasal cartilages are incised to the palatal region of the maxillary bone. At the level just either rostral to or caudal to the canine teeth, depending on the extent of invasion of the tumor, the mucosa of the hard palate is incised transversely with a scalpel blade down to bone. An oscillating saw is used to cut the palatal and maxillary or incisive bone (Figure 24-5). The excised specimen is submitted for histopathologic examination, with emphasis on evaluation of margins for completeness of resection. Hemorrhage is controlled by a combination of direct pressure, electrocautery, and vessel ligation. Four or five small holes are drilled 2 to 3 mm from the cut edge of the hard palate. The submucosa of the incised lip is sutured through the holes in the hard palate with 2-0 monofilament absorbable suture material. The lip is joined on the midline of the palate with sutures that are placed approximately in the middle of each lip incision (Figure 24-6A). The mucous membrane of the lip is sutured to the mucous membrane of the hard palate, and the contralateral lip is sutured with 3-0 monofilament absorbable suture material in a continuous or interrupted pattern. This technique results in closure of the oral cavity in the form of a "T" (Figure 24-6B). The skin of the lips is closed on the midline with 2-0 or 3-0 monofilament nonabsorbable suture material. As with closure after nasal planum resection alone, the diameter of the nasal opening is reduced using a pursestring suture of monofilament nonabsorbable suture material (Figure 24-6C). The nasal opening

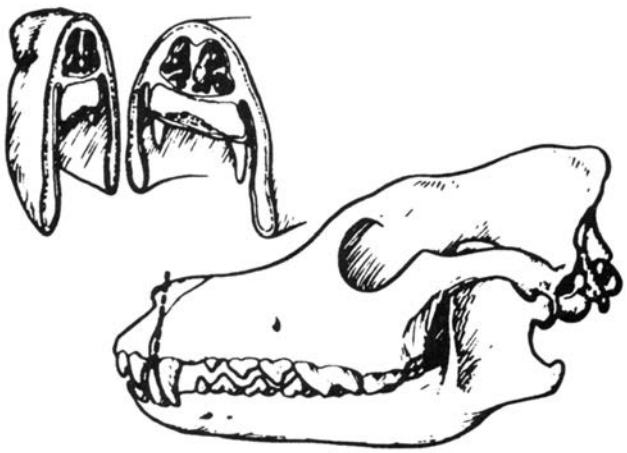

Figure 24-5. The nasal cartilages are incised perpendicular to the long axis of the skull down to the floor of the nasal cavity. The mucosa of the hard palate is transversely incised at a level just rostral to the canine teeth (or caudal to the canine teeth, depending on the extent of tumor invasion) down to bone. An oscillating saw is used to cut the bone of the hard palate and lateral bodies of the maxilla. (From Kirpensteijn J, Withrow SJ, Straw RC. Combined resection of the nasal planum and premaxilla in three dogs. Vet Surg 1994;23:341-346.)

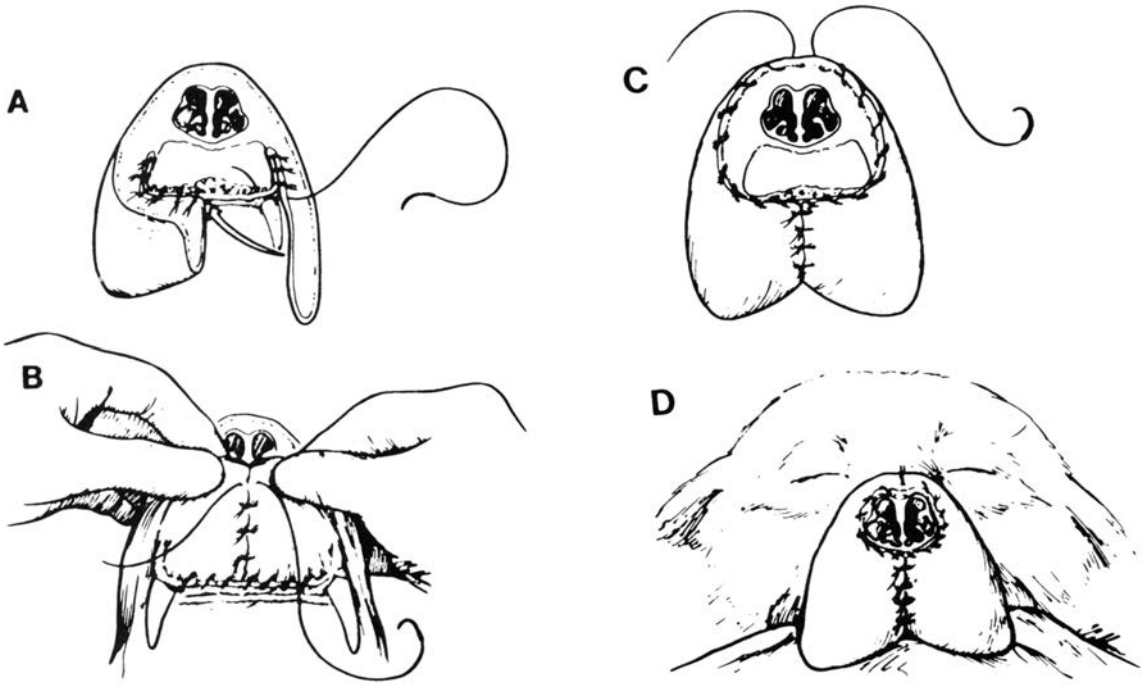

Figure 24-6. A. The submucosa and mucosa of the lip is sutured through drill holes in the hard palate and to the contralateral lip. **B.** This results in closure of the oral cavity from the nasal cavity in the form of a "T." **C.** The nasal orifice is reduced in diameter by placing a simple continuous pursestring suture. **D.** View from the front of the dog after surgery. The new nasal orifice is approximately the diameter of the resected nasal planum. (From Kirpensteijn J, Withrow SJ, Straw RC. Combined resection of the nasal planum and premaxilla in three dogs. Vet Surg 1994;23:341-346.)

is reduced to a size corresponding to the diameter of the nasal planum removed (Figure 24-6D).

Analgesia is provided using narcotics as necessary. An Elizabethan collar may be needed to prevent mutilation of the wounds. Dogs are allowed to drink water on recovery and are offered food 24 hours after surgery. Antibiotics can be given during the immediate perioperative period, but they are usually not necessary. Dogs are sent home within 2 to 3 days, and sutures are removed 10 days postoperatively.

Mild postoperative bleeding may occur and resolves within a day or so. Lip dehiscence can be avoided if the closure is tension free. Stenosis of the new nares can occur if the pursestring suture is too tight. Crusting of the nasal orifice is possible and resolves after suture removal; however, serous nasal discharge can persist.

Combined Resection of the Nasal Planum and Rostral Maxilla

For animals with malignant rostral maxillary tumors a technique has been described where the maxilla and nasal planum can be resected between PM2 and PM3.[14] The postoperative appearance was acceptable to owners and there was a low risk of local recurrence which can produce long term survival for animals with certain malignancies. A preoperative biopsy is performed with appropriate tumor staging before definitive resection with this aggressive rostral maxillectomy procedure. Computed tomography (CT) is excellent for tumor staging and surgical planning.

The animal is positioned in ventral recumbency and anesthesia, analgesia and surgical preparation are similar to previously described procedures in this chapter. The mouth is held slightly open with a mouth gag or similar device and care is taken to pack the pharynx with moistened gauze swabs adjacent to a cuffed or snug fitting endotracheal tube to avoid aspiration of blood and fluid during surgery. The commissures of the lips need to remain mobile after draping to allow for labial advancement during reconstruction. The preoperative CT scan defines the extent of tissue infiltrated with tumor, and its relation to the dentition. The teeth are used as landmarks to allow the approximate edges of the tumor to be marked using a sterile marker pen. A sterile ruler is used to mark 1 or 1.5 cm beyond the borders of the tumor so that a line of "planned complete resection" can be drawn. The line of bone excision is level with or slightly caudal to the caudal-most aspect of the soft-tissue resection. This results in sufficient soft tissues to reconstruct a lip rostrally and cover the exposed maxilla. Full-thickness, labial incisions are made perpendicular to the labial margin. The incisions are continued perpendicular from the labial margin for a minimum of 1 to 2 cm and then curved to meet on the midline of the maxilla. Once the skin is scribed with a scalpel, electrocautery is used for most of the tissue division, and hemostasis is maintained by a combination of cautery and vascular clips or ligatures. The incisions are continued deeper through the subcutis and nasolabial muscles and fascia to the maxillary bone at predetermined resection levels. If this is the rostral zygomatic arch, the infraorbital neurovascular bundles will need to be divided between ligatures. If this is near the canine tooth the skin, subcutis, nasolabial muscle, and labium are reflected while preserving their vascular support from the infraorbital neurovascular bundle. These soft tissues and labium are reflected to the rostral zygomatic arch, exposing the maxilla. Once exposed, the rostral maxilla, nasal turbinates, and bony palate are amputated with a reciprocating saw. The transection is perpendicular to the maxillary axis. The rostral maxilla can then be removed following transection of the palatine mucosa parallel to and at the level of the hard palate. The palatine and sphenopalatine arteries are ligated.

Labial reconstruction is performed by transposing either a unilateral labial flap or bilateral labial flaps depending on the amount resected and the conformation of the animal. Regardless of whether a unilateral or bilateral flap is used, the lip and palate are united first. Dehiscence may be less likely when bilateral flaps are used. It may be necessary to relieve tension by incising the labiogingival reflection to mobilize the labial flap. The mucosa of the labial flap is removed except for a 0.5- to 1.0-cm width adjacent to the labial margin. This distance is determined by bringing the tissues together and identifying the contact point of the palatine mucosa and labium, and then assessing how much "new lip" there would be projecting ventrally from the palatine mucosa. Avoid making this margin overly large which may result in prehension problems after surgery. Once the mucosa is excised, the remaining mucosal margin is sutured to the palatine mucosa with interrupted 4-0 absorbable sutures, thus providing strong support and preventing mucosal inversion.

Bilateral advancement flaps are also prepared by incision of the labiogingival borders as necessary to permit tension-free advancement of the flaps on the approximate midline. The labial mucosa is once again débrided leaving only a 0.75- to 1.0-cm margin of labial mucosa to be sutured to the palatal incision as a palatobuccal recess. This length of recess is chosen to ensure the margin will not be trapped between the teeth during chewing or interfere with food transfer into the mouth. Prior to suturing, the left and right lips are aligned toward the midline using temporary sutures. As the palatolabial suturing progresses from lateral to medial, the labial margins are drawn into apposition. As with the unilateral flap the labial submucosa can be first sutured to the edge of the incised palatine bone using small holes drilled in the palatine bone with a 0.0625-inch Kirschner wire. The remaining lip union is reconstructed beginning along the ventral aspect, aligning the labial margin with a nonrolling figure-of-eight suture. Suturing progresses using the same suture pattern in the submucosa, muscle, subcutaneous, and dermal layers.

The dorsal and rostral portions of the incision are left open forming the nasal orifice. And it is advisable to create an orifice approximately twice the desired final size to compensate for the expected contraction during healing. The nasal orifice size can be controlled using a purse-string type pattern of suture as with simple nasal planectomy.

Analgesic protocols are aggressive and include premedication with an opioid (i.e., oxymorphone at 0.2 to 0.5 mg/kg intramuscularly [IM] or morphine at 0.2 to 0.6 mg/kg IM) and infraorbital nerve

blocks performed bilaterally prior to surgery using bupivacaine (0.5 to 1.0 mL of a 0.75% solution used per site). During general anesthesia, constant-rate infusions of fentanyl (0.01 mg/kg per hour) may be administered. At the time of extubation, the opioid administered preoperatively is repeated, and a postoperative analgesic opioid protocol is instituted. This can be buprenorphine (0.07 mg IM q 6 hours) which can be continued for up to 60 hours. Following a loading dose of the appropriate opioid (i.e., morphine 0.5 mg/kg intravenously [IV]; oxymorphone 0.2 mg/kg IV; or fentanyl 0.002 mg/kg IV), dogs can receive constant-rate infusions of morphine (0.05 mg/kg per hour), oxymorphone (0.13 mg/kg per hour), or fentanyl (0.002 to 0.006 mg/kg per hour) for 24 hours to provide a constant level of analgesic drug. Carprofen (2.0 mg/kg per os [PO] q 12 hours) may be initiated 12 hours after surgery and continued postoperatively as necessary.

An Elizabethan collar is often used until healing is complete and it may be necessary for oronasal suction to be instituted as needed to keep the nasal passages clear, using a pediatric suction device. Some animals do not eat readily, and feeding can be supplemented with a food gruel administered through a pharyngostomy tube for a short term up to 7 days. Topical petrolatum-based antibiotic ointment can be placed around the nasal orifice wounds to reduce wound crusting and debris. Additionally, topical misting of physiological saline can be delivered via a conventional spray bottle to humidify and cleanse the nasal turbinates. Some animals are able to eat soft food offered on a plate between 12 and 30 hours after surgery and may be discharged to their owners once eating on their own. Owners may be advised to keep the new rostral orifice patent and clean using saline-soaked cotton balls for 1 month postoperatively. Antibiotics such as cefazolin 20 mg/kg IV are given immediately preoperatively and every 90 minutes during surgery and postoperative antibiotics are generally not necessary.

Although this technique is very similar to the combined resection of the nasal planum and premaxilla it is more extensive allowing wide resection of larger tumors. The advantage of such a technique is that it has the potential to increase the number of animals in which "complete" resections can be performed. However, the disadvantage of such a surgery is the possibility of interfering with the animal's ability to eat and drink making oral spillage of both food and water possible. The technique does offer the opportunity for prolonged tumor-free remission times for animals with certain neoplasms that involve the rostral maxilla, if tumor-free margins can be obtained.

Rhinotomy Techniques

Cheryl S. Hedlund

Introduction

Dogs and cats with chronic nasal and paranasal sinus disease are usually diagnosed and treated without the need for rhinotomy (surgical exploration of the nasal cavity). Rhinotomy is only indicated if other diagnostic techniques fail to provide a definitive diagnosis or if required as part of a therapeutic protocol. Potential candidates for rhinotomy have symptoms that may include: nasal discharge, epistaxis, sneezing, gagging, stertorous breathing, dyspnea, fetid breath, nasal discomfort, or nasal deformity. Causes of diseases of the nasal cavity and paranasal sinus can be difficult to identify, but are commonly of infectious (fungal, bacterial, or viral) or neoplastic origin. Other inciting causes include foreign bodies, trauma, parasites (Pneumonyssus caninum, Linguatula serrata), dental disease, congenital anomalies, and lymphocytic plasmacytic inflammation.[1]

Diagnostic Procedures

A standard protocol for evaluation should be used for all dogs and cats presenting with chronic nasal disease. The protocol should include a thorough history and physical examination. In addition, a complete blood count, serum chemistry profile, coagulation profile, radiographs, computed tomography (CT scan), magnetic resonance imaging (MRI), serology, cytology, culture, rhinoscopy, and nasal biopsy may be required for

accurate diagnosis and prognosis.[2-6] The clinical history provides important diagnostic clues. A destructive process is suspected if the discharge changes from unilateral to bilateral. Sneezing suggests involvement of the rostral or middle nasal chambers and gagging suggests nasopharyngeal involvement. A history of trauma or dental disease might suggest an oronasal fistula.

Physical examination findings are as follows: Epistaxis may indicate a systemic disease, an acute nasal disease, or an ulcerative, destructive disease. A mucopurulent discharge with or without epistaxis suggests chronic rhinitis. Obstruction of nasal airflow through one or both nostrils suggests a unilateral or bilateral condition. Facial or palatal deformity suggests neoplasia. Mouth breathing may indicate nasopharyngeal obstruction. Labored breathing suggests possible pulmonary involvement with a fungal or neoplastic condition. An ocular discharge may indicate nasolacrimal duct erosion. General debility suggests systemic disease.

A complete blood count, serum chemistry panel, and urinalysis should be obtained to assess overall patient status. A coagulation profile is indicated if exploratory rhinotomy is planned or if epistaxis is a major clinical sign. In addition, serologic evaluation for Ehrlichia canis may be beneficial when epistaxis is the predominant clinical sign. Serologic evaluation for Aspergillus and Penicillium species can be beneficial when fungal disease is suspected. Serologic tests for Crytptococcus, FeLV, FIV and heartworms may also be indicated. Nasal swabs for culture or cytologic evaluation are of limited value but may be helpful in identifying parasites, cryptococcoses organisms and single bacterial infections. Positive fungal cultures can be obtained in 40% of normal dogs.

Radiographs of the thorax and skull are taken to demonstrate the extent of disease involvement. Radiographs of the thorax are taken in the awake patient to evaluate for evidence of cardiac or pulmonary disease (metastasis or infection). Skull radiographs require general anesthesia to allow accurate evaluation of the nasal cavity and paranasal sinuses. Skull images are performed prior to rhinoscopic, flush, or biopsy procedures to avoid iatrogenic fluid densities within the cavities. Skull radiographs should include lateral, ventrodorsal, rostrocaudal, and rostroventral caudodorsal open mouth or occlusal views. The two most useful radiographic views are the ventrodorsal view of the maxilla made using intraoral radiographic film and the rostrocaudal projection highlighting the frontal sinuses. Skull radiographs are examined for evidence of increased or decreased tissue densities, distortion or loss of turbinates and bone, and symmetry between right and left sides of the nasal cavity and sinuses. The same changes are evident on CT and MRI images but they localize lesions better than radiographs. CT images provide good anatomic detail of bony tissues while MRI images are superior for evaluating soft-tissue structures.[3]

Rhinoscopy is useful because it allows visual assesment of lesions and acquisition of specimens for further evaluation.[4-6] The diagnostic success of rhinoscopy-assisted biopsy is 83% (78 of 94 dogs) when performed by an experienced clinician.[6] Rhinoscopy is performed on an anesthetized patient in sternal or lateral recumbency following skull imaging and sample collection for cultures. Violent sneezing with possible damage to instruments and mucosa resulting in hemorrhage may occur if anesthetic depth is inadequate. The nasal mucosa is sensitive to manipulation; it bleeds easily, and this may obscure visualization. Therefore, patience, gentleness, suction, and lavage are advantageous during this procedure. The least affected side of the nasal cavity is examined first. The rostral aspect of the nasal cavity may be visualized with an otoscope and appropriate speculum. The caudal choanae and nasopharynx can be viewed with a dental mirror or rigid scope with a 120° lens when the soft palate is retractated rostrally. Visualization of the entire cavity is achieved with a flexible pediatric bronchoscope (< 1 cm diameter) or a rigid scope (bronchoscope or arthroscope, 2 to 5 mm diameter) with a working piece (outer sheath) to allow suction, lavage, and biopsy. Both normograde and retrograde rhinoscopy is performed to completely visualize the nasal cavity and nasopharynx. After complete rhinoscopic examination, suitable biopsy forceps are used to collect tissue for culture and histologic evaluation.

Lesions that are not accessible to biopsy during rhinoscopy may be sampled by nasal flushing or coring procedures. These procedures are performed in the anesthetized patient. Gentle flushing of the nasal cavity with saline does not usually dislodge tissue for evaluation. Nasal coring, pinch, punch, or needle biopsy are more effective biopsy techniques.[6] To prevent aspiration, the endotracheal tube cuff is inflated, gauze sponges are placed in the nasopharynx and the nose is tilted ventrally during sampling. To prevent penetration of the cribriform plate, biopsy instruments should be marked and not advanced further than the distance from the external nares to the medial canthus of the eyes. One technique for nasal coring uses a stiff plastic tube inserted through the nares and vigorously moved in and out of the nasal passages while flushing saline and aspirating tissue. The collected lavage fluid, debris and tubing are examined for tissue fragments. Repeating biopsies when samples are nondiagnostic is preferred to rhinotomy in most cases.

Patients whose disease has not been diagnosed by the foregoing procedures are candidates for exploratory surgery. Rhinotomy may also be included in treatment protocols for fungal diseases, tumors, and foreign bodies. Rhinotomy can be performed using dorsal, ventral, or lateral approaches. The approach chosen depends on the location and extent of the lesion. The objectives of rhinotomy include the following: 1) To obtain sufficient samples from the nasal cavity or sinuses to achieve a definitive diagnosis. 2) To completely remove or debulk a lesion. 3) To facilitate administration or effectiveness of adjuvant therapy. 4) To minimize patient morbidity. 5) To maintain a cosmetically acceptable appearance.

In addition to a standard surgical pack, equipment which may be needed for rhinotomy includes a periosteal elevator, Gelpi retractor, oscillating saw, air drill, pins and pin chuck, osteotome and mallet, bone curette, rasp, bur, rongeur, trephine, fenestrated tubes, and synthetic mesh. If temporary carotid artery occlusion is performed in conjunction with rhinotomy, vascular occlusion

is accomplished with umbilical tape, vascular tape (Vas-Tie@, Sil-Med Corp., Taunton, MA) or bulldog vascular clamps.

Surgical Anatomy

The nasal cavity is bound by the nasal bones dorsally, the maxilla laterally, and the hard palate ventrally. The orbit contributes to the lateral boundary of the nasal cavity and frontal sinuses. The nasal cavity is separated into two fossae by the nasal septum. The maxilloturbinates fill the rostral portion of each fossa and the ethmoturbinates extend caudally to the cribriform plate and frontal sinus (Figure 24-7). When dividing the dorsoventral nasal height at the medial canthi of the eyes, the nasofrontal opening occupies the dorsal third, the cribriform plate the middle third and the sphenoidal sinus recess and caudal nasal meatus (internal nares or choanae) the ventral third. The paranasal sinuses are hollow, membrane lined, air-filled diverticuli from the nasal cavity that invaginate into adjacent bones. They are not fully developed at birth and continue to grow as the animal matures. The limits of the frontal sinus vary with the age, breed and head shape of the patient. Dogs have a frontal sinus divided into three compartments and a maxillary sinus (recess). Cats

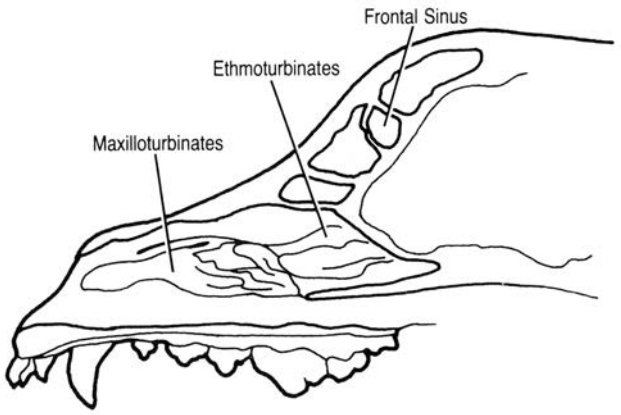

Figure 24-7. The nasal fossae are filled with maxilloturbinates in the rostral portion and ethmoturbinates in the caudal portion. The ethmoturbinates extend caudally to the cribriform plate and frontal sinus.

have an undivided frontal sinus, and in addition to the maxillary sinus, they have a sphenoid sinus.

Communication between the frontal sinus and the nasal cavity occurs through small ostia in the ethmoid region. Mucous membrane swelling reduces the size of these openings and can obstruct drainage, leading to sinus mucocele formation. The blood supply to the nasal cavity is extensive and originates from the branches of the maxillary artery, a terminal vessel of the external carotid artery.

Preoperative Preparation

Analgesics are administered in the preoperative period. After the anesthetized animal is intubated, the endotracheal tube cuff is inflated, and the pharynx is packed with gauze sponges to prevent drainage of fluids into the distal trachea. Hair is clipped and the surgical site is aseptically prepared for the selected approach.

Surgical Techniques

Temporary Carotid Artery Occlusion for Rhinotomy[7-8]

Occluding the common carotid arteries reduces blood loss during exploration of the nasal cavity, improves visualization during surgery, facilitates exploration and obviates blood transfusions in most patients. Although hemorrhage (50 to 100 ml/25 kg body weight) still occurs during removal of the turbinates and nasal mucosa, it usually diminishes within a few minutes. Suction is advantageous but not necessary for visualization. Release of the carotid arteries at the conclusion of surgery does not result in clinically significant hemorrhage and nasal packing is not necessary. The common carotid arteries can be occluded for two to three hours with no evidence of neurologic or ischemic damage in dogs. Carotid artery occlusion in cats is not recommended because collateral blood supply is inadequate to maintain cerebral perfusion.[9]

Temporary carotid artery ligation is performed after positioning the patient in dorsal recumbency with the front legs secured caudally along the chest and the neck dorsiflexed by positioning it over a pad. Incise skin along the ventral cervical midline from the larynx to midtrachea. The paired sternohyoideus muscles are separated and retracted to expose the trachea. To locate the carotid sheath, the surgeon palpates the carotid pulse dorsolateral to the trachea, then bluntly dissects the adjacent loose connective tissue and exteriorizes the carotid sheath. The surgeon carefully incises the carotid sheath and separates the external carotid artery from the vagosympathetic trunk and internal jugular vein. The carotid artety is occluded with a vascular tie (Vascular Ties®, Sil-Med Corporation, 700 Warner Blvd., Taunton, MA 02780), umbilical tape or a vascular clamp (Figure 24-8). The procedure is repeated on the opposite carotid artery and the skin incision is closed with a continuous suture pattern or staples. The surgical site is covered with an adherent, sterile dressing. Immediately after rhinotomy, the surgeon exchanges contaminated instruments and gloves and positions the patient to allow reexposure of the carotid arteries. The ventral midline incision, is opened, the carotid arteries are exposed, and the vascular clamps or ties removed. The surgeon

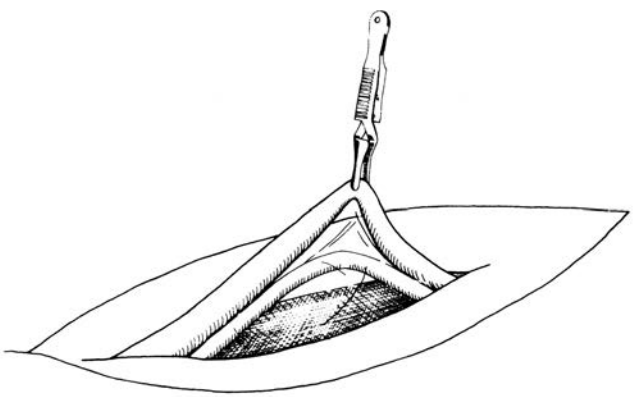

Figure 24-8. The common carotid artery is occluded with a bulldog clamp after being separated from the vagosympathetic trunk and internal jugular vein.

lavages the area thoroughly and apposes sternohyoid muscles, subcutaneous tissue and skin in separate layers.

Dorsal Rhinotomy

Dorsal rhinotomy allows access to the entire nasal cavity and the frontal sinuses.[8] After the anesthetized animal is intubated, the endotracheal tube cuff is inflated, and the pharynx is packed with gauze sponges to prevent drainage of fluids into the trachea. The patient is positioned in ventral recumbency, then the dorsum of the head is clipped and prepared for surgery. The surgeon begins the rhinotomy by making a midline skin incision over the nasal cavity and frontal sinus which extends caudal to the orbits (Figure 24-9). The dense fascia and periosteum overlying the bone are incised, elevated and retracted laterally. The bone is scored with a scalpel blade to outline a unilateral or bilateral bone flap depending on the extent of the disease and the exposure necessary (Figure 24-10). The flap is made using an oscillating saw, drill, osteotome and mallet, or trephine and rongeurs. The margins of the bone are beveled inward if bone flap replacement is anticipated. In addition, pre-drilling holes in the flap and adjacent bone margin for suture placement aids in easier bone flap reattachment. The bone flap is elevated from the underlying turbinates with an osteotome or periosteal elevator. The bone flap is reflected rostrally leaving it attached to the dorsal parietal cartilage of the rhinarium by the nasal ligaments if flap replacement is planned (Figure 24-11). After exposing the nasal cavity and frontal sinus, the surgeon suctions secretions or exudate and explores the area. The lesion and involved turbinates are removed or sampled for biopsy with forceps, a bone curette and Metzenbaum scissors. (Figure 24-12). Total turbinectomy is often necessary to eliminate extensive areas of nasal mucosa with chronic irreversible hyperplasia. One should avoid traumatizing or perforating the cribriform plate during turbinectomy. Identifiable bleeding vessels are ligated. When external carotids are not occluded it may be necessary to control hemorrhage with cautery, iced saline, or pressure. Tissues are submitted for histologic and culture evaluation . During a unilateral rhinotomy,

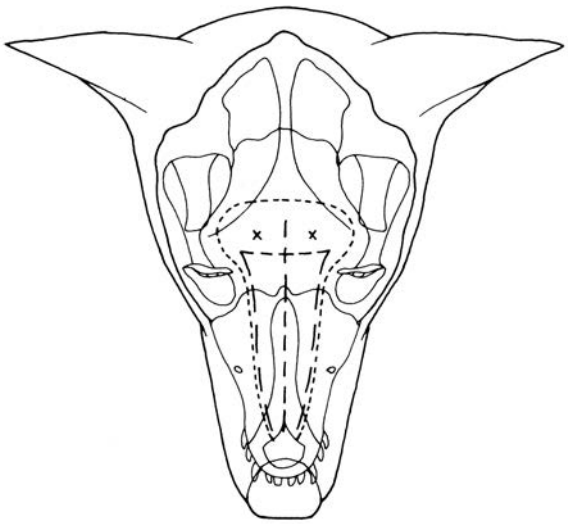

Figure 24-9. The outer dotted line outlines the approximate extent of the nasal cavity and frontal sinus. The inner dashed lines outline the bone flap for a unilateral or bilateral rhinotomy. The X's over the frontal sinuses indicate the site for insertion of a drain(s).

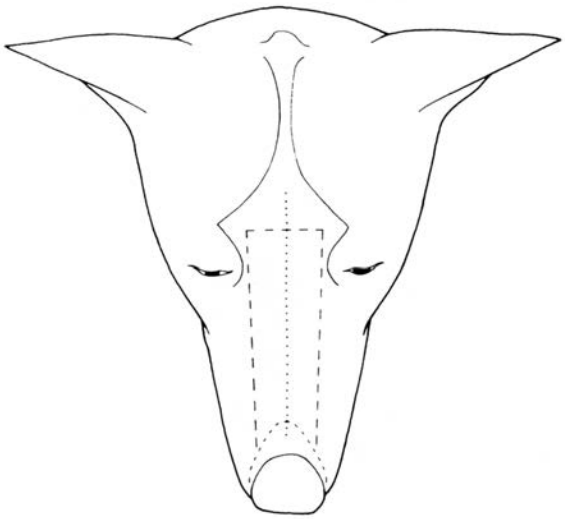

Figure 24-10. The dashed line represents bone scoring for a bilateral bone flap. The dotted line represents the location of the nasal septum, which divides the nasal cavity into two fossae.

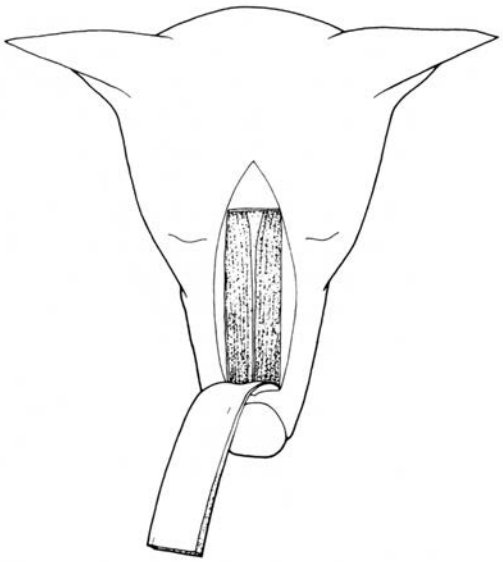

Figure 24-11. The bone flap is reflected rostrally and remains attached to the dorsal parietal cartilages.

if the nasal septum has been perforated or eroded by the disease process, the other fossa is explored and curetted through the septal defect or by creating a second bone flap. When mucoid secretions fill the frontal sinuses, the surgeon enlarges the ostia and breaks down the septae to facilitate drainage. The caudal nasal meatus (internal nares/choanae) should be probed with a hemostat to verify patency. The nasal cavity and sinuses are lavaged with saline or lactated Ringer's solution before closure to remove debris and blood clots. Fenestrated indwelling tubes are placed if necessary for adjuvant therapy. These drains are placed through a trephine hole into the frontal sinus and extend into the nasal fossa.

The bone flap is replaced or discarded depending on the extent of disease and the surgeon's preference. The flap is discarded if it is involved in the disease process or if fragmentation occurs during removal. If the flap is being replaced, drill three or

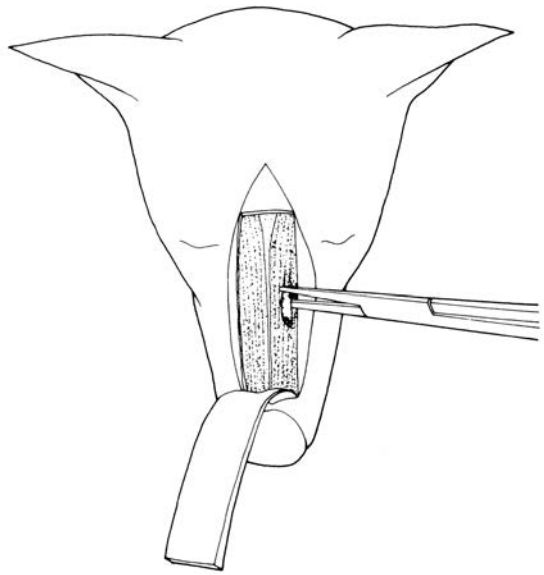

Figure 24-12. Turbinectomy begins by removal of the diseased turbinates with forceps.

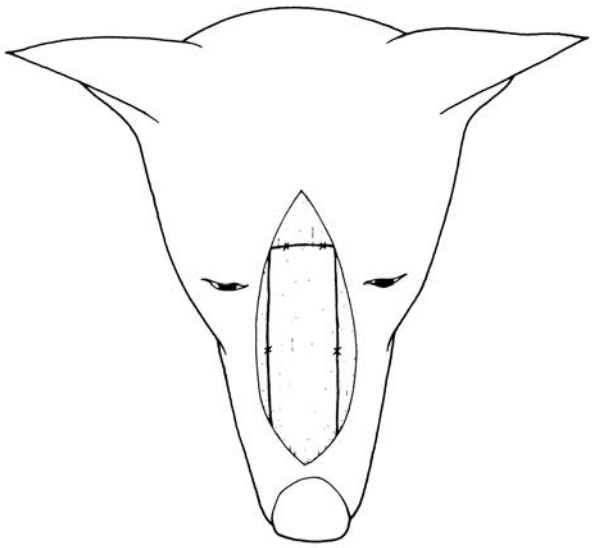

Figure 24-13. The bone flap is replaced by placing sutures through holes drilled in the flap and margins of the defect.

four holes in the flap and the adjacent margins of the defect. The surgeon then preplaces nonabsorbable sutures (nylon, polypropylene) through the holes, positions the flap, and ties the sutures to secure the flap. (Figure 24-13). One should not use wire to secure the bone flap if radiation therapy is being planned. Occasionally, when the defect is large, if the flap is discarded and cosmetics are critical, a bone graft or synthetic mesh is stretched across the bony defect and secured. Potential risks with the use of such implants include sequestration and infection. Soft tissues are apposed in three layers (fascial/periosteal layer, subcutaneous tissues, and the skin) using continuous suture patterns. Air leakage from the rhinotomy site and subcutaneous emphysema may be controlled by suturing a stent over the surgical site, placing a drain in the frontal sinus and nasal cavity or leaving a small gap between tissue edges during closure.

Technique variations may be necessary depending on the disease type and extent. Postoperative nasal flushing, prevention of emphysema, and brachytherapy for tumors is facilitated by placing a drain in the frontal sinus and nasal cavity through a trephine hole (Figure 24-14). An incision is made through the soft tissues and a hole in the bone is drilled or trephined just lateral to the midline on a line connecting the rostral margins of the supraorbital processes. Biopsy and culture specimens may be collected through this hole if not previously obtained. A fenestrated tube is inserted into the sinus, advanced into the nasal cavity and secured to the skin. The hole is allowed to heal by second intention after tube removal. Protocols for treatment of nasal fungal diseases may include packing the nasal cavity with medicated gauze or creating a stoma. Stomas are created by securing the skin edges directly to the margins of the bony defect.[10-11] Creation of a stoma facilitates topical therapy postoperatively. If the stoma is small it may heal by second intention, otherwise following conclusion of medical therapy the skin edges are debrided, undermined, and apposed. Removal of lesions in the rostral nasal cavity may be facilitated by extending the incision through the rhinarium lateral to the nasal septum.

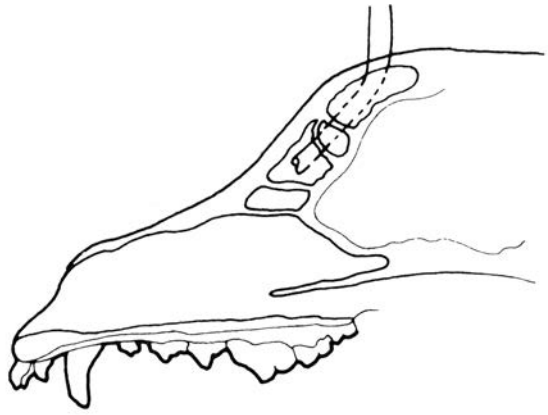

Figure 24-14. A drain can be positioned in the frontal sinus for adjuvant therapy or to reduce subcutaneous emphysema.

Ventral Rhinotomy

Ventral rhinotomy allows exploration of the nasal cavity and nasopharynx.[8] Evaluation and evacuation of the frontal sinuses is limited to the rostral half with ventral rhinotomy. Concurrent mandibulotomy may be performed to improve access to the caudal nasal cavity and nasopharynx. Although most surgeons prefer dorsal rhinotomy, advantages of ventral rhinotomy include improved cosmesis and less risk of subcutaneous emphysema. Disadvantages include incomplete access to the frontal sinuses and the potential for oronasal fistula formation.[9]

The patient is positioned in dorsal recumbency with the oral cavity maximally exposed by hanging and securing the mandible in a wide, open-mouth position. One should use mild antiseptic solutions (0.05% chlorhexidine or 0.1% or 1% povidone-iodine) to cleanse the oral cavity prior to incising tissue.

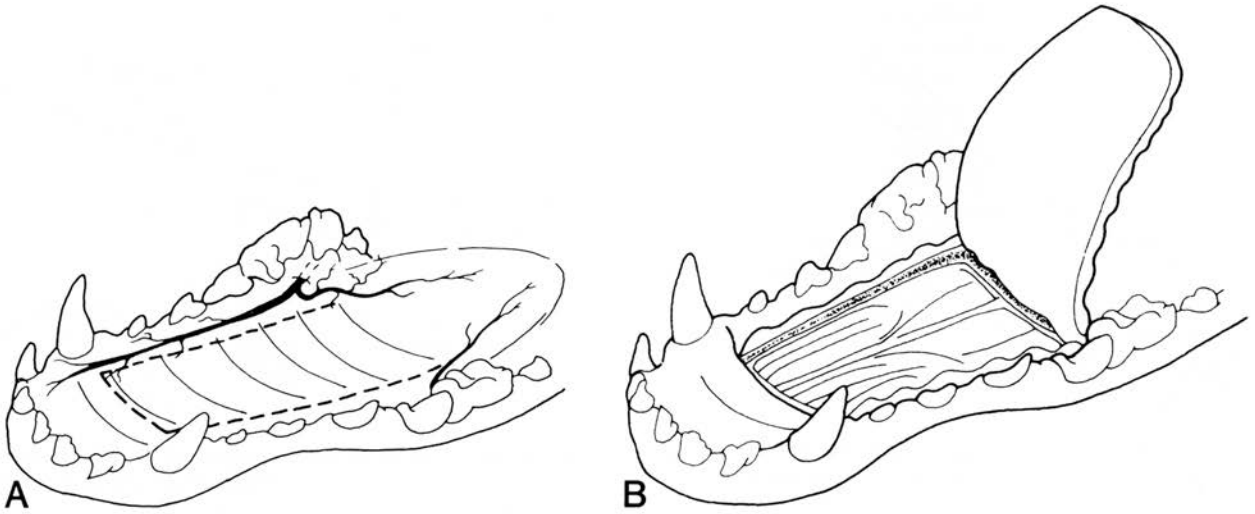

Figure 24-15. Ventral Rhinotomy: **A.** The dashed line represents a U-shaped mucoperiosteal incision made just medial to the major palatine artery when performing a ventral approach to the rostral aspect of the nasal cavity. **B.** A rectangular palatine bone flap of similar size is created and removed to expose the nasal turbinates.

Cranial Ventral Rhinotomy

The mucoperiosteum of the hard palate is incised on the midline from the level of the canine teeth to the fourth premolar to expose lesions restricted to the rostral nasal cavity. Alternatively, the nasal cavity may also be exposed using a "U" shaped mucoperiosteal incision parallel to the dental arcade (Figure 24-15A). After incision, the surgeon elevates and retracts the mucoperiosteum to expose the hard palate while preserving the major palatine arteries during incision and dissection. The major palatine arteries emerge from the major palatine foramen at the caudal edge of the fourth upper premolar and course rostrally, midway between the midline and dental arcade. Remove a rectangular palatine bone flap with an oscillating saw, air drill or osteotome (Figure 24-15B). Alternatively, rongeurs are used to create an access window in the hard palate. The lesion and involved turbinates are removed with forceps and curettage. The surgeon lavages and suctions the area prior to replacing or discarding the bone flap as with dorsal rhinotomy (Figure 24-16). The mucoperiosteum is apposed using a one or two layer closure with simple interrupted sutures (3-0 or 4-0 polydioxanone, polypropylene).

Caudal Ventral Rhinotomy

Caudal ventral rhinotomy is selected for exposure of lesions in the caudal nasal passages and nasopharynx. A midline cranial ventral rhinotomy incision can be extended to expose the nasopharynx when necessary. A midline soft palate incision is made beginning 5 to 10 mm rostral to the tip of the soft palate and extending through the mucoperiosteum of the hard palate as far as necessary to expose the lesion adequately (Figure 24-17) Stay sutures are placed in the incised edges of the soft palate to facilitate retraction and to minimize trauma. The mucoperiosteum is elevated and the hard palate is rongeured as far rostrally as necessary for exposure. The surgeon explores, removes the lesion, and lavages the area. The soft palate is apposed in two (nasal and pharyngeal mucosa) or three layers (nasal mucosa, muscle and connective tissue, and pharyngeal mucosa) with simple interrupted or continuous monofilament sutures (4-0 polydioxanone, polypropylene) (Figure 24-18) The mucoperiosteum is apposed with one or two layers of simple interrupted sutures.

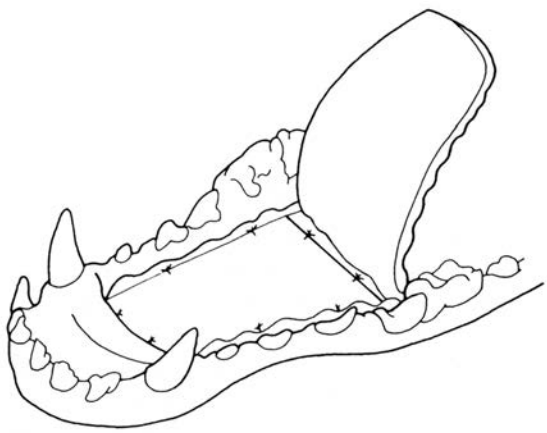

Figure 24-16. The palatine bone flap is replaced by sutures secured through holes drilled in the flap and bone margins.

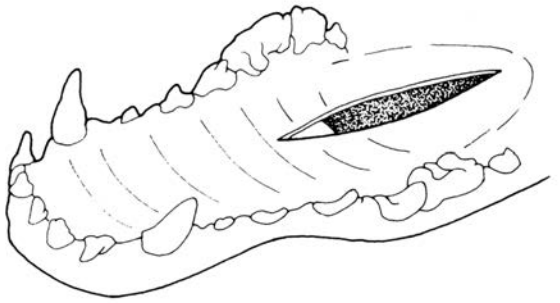

Figure 24-17. The caudal aspect of the nasal cavity and nasopharynx is approached ventrally by incising the soft and hard palates for varying distances.

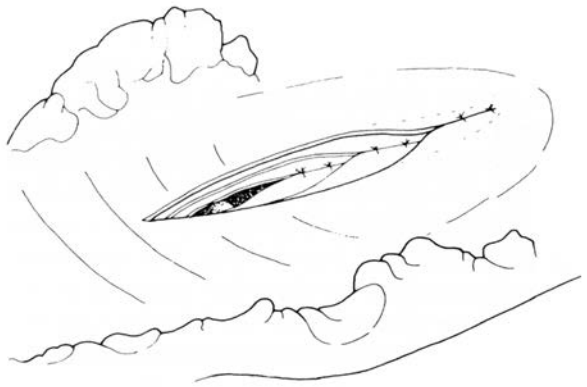

Figure 24-18. The soft palate incision is closed with two or three layers of sutures to allow good apposition of the nasal and oral mucosae.

Lateral Rhinotomy

Lateral rhinotomy is occasionally used to approach lesions in the rostral one fourth to one third of the nasal passages. Approaches using incisions through either the skin or the alveolar mucosa have been described. These approaches are performed with the animal in lateral or sternal recumbency. The surgeon directs the incision dorsocaudally from the angle of the rhinarium toward the nasomaxillary notch between the dorsal and ventral parietal cartilage. (Figures 24-19 and 24-20) The accessory cartilage is invariably transected. The edges of the incision are retracted with stay sutures to expose the rostral nasal passages. The incision is closed in three layers (nasal mucosa, cartilage or subcutaneous tissue and skin).

Alternatively, the alveolar mucosal technique provides acceptable exposure to the rostral nasal cavity and avoids transection of nasal cartilage or bone.[12] The surgeon retracts the lip dorsally and palpates the rostrolateral aspects of the right nasal and incisive bones. An incision is made through the alveolar mucosa along this ridge from the nasal bone to the rostral end of the interincisive suture. Using a periosteal elevator, the mucosa is reflected in a dorsal and medial direction along with the dorsal lateral nasal cartilage. After exploring and collecting tissue samples the alveolar mucosa is apposed with simple interrupted sutures.

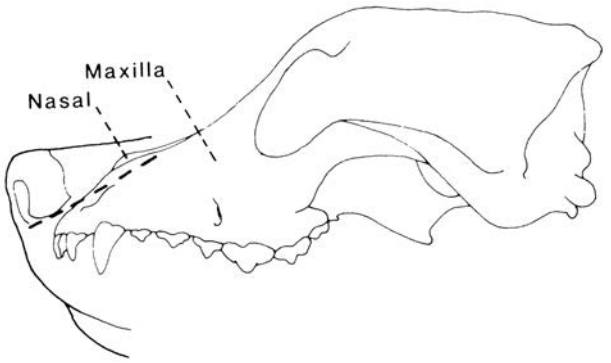

Figure 24-19. The incision for a lateral rhinotomy is directed dorsocaudally from the angle of the rhinarium toward the nasomaxillary notch.

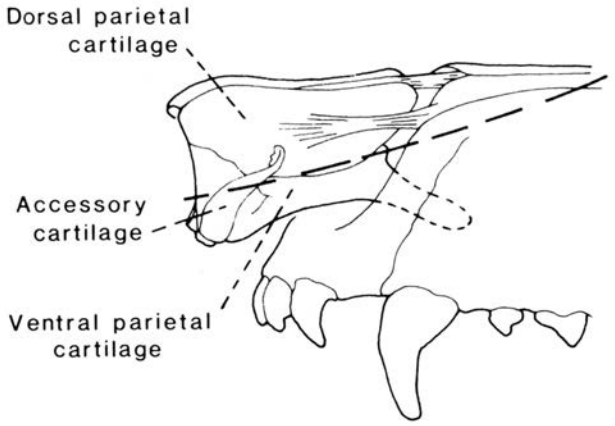

Figure 24-20. The lateral rhinotomy incision is directed between the dorsal and ventral parietal cartilages but transects the accessory cartilage.

Postoperative Management

After surgical procedures involving the nasal cavity and sinuses, pharyngeal sponges (if placed) are removed, and the animal is recovered in a slightly head down position. The endotracheal tube is removed with the cuff slightly inflated to prevent tracheal aspiration of fluid and other debris. Analgesics are given for three to five days as needed. Good analgesia is obtained with parenteral hydromorphone (or a constant rate infusion of morphine/lidocaine (See Chapter 9). The patient's vital signs are monitored carefully and supportive care is administered as needed.

Blood transfusions are sometimes (16% of cases) necessary even following carotid occlusion.[9] Sneezing and mild epistaxis are expected for several days. A serous to serosanguineous discharge occurs for several days to weeks depending on the primary disease condition and the effectiveness of adjuvant therapy. Breathing sounds are harsh and resonant. Inward and outward movement of the skin flap is expected if the bone flap is discarded. Appetite may be depressed for several days. Cats tolerate rhinotomy poorly and may not readily resume eating. Diazepam or oxazepam may be given to stimulate their appetite. Chewing on hard objects is forbidden if the hard palate bone flap is discarded. Patients are discharged from the hospital within 2 to 3 days following surgery unless complications or adjuvant therapy dictates longer hospitalization.

Complications

Complications of rhinotomy include hemorrhage, entrance into the cranium, pain, subcutaneous emphysema, airway obstruction, nasal discharge, fistula and disease recurrence. Intraoperative hemorrhage is minimized by temporary occlusion of the external carotid arteries and good hemostasis during surgery. Packing the nasal cavity is discouraged as it may lead to hyperventilation and subcutaneous emphysema; in addition removal of the packing material 2 to 3 days after surgery is painful. Postoperative hemorrhage is rare however blood transfusions are sometimes necessary to replace lost volume.

Disease erosion of the cribriform plate or curettage may result in exposure of the brain and subsequent cerebral edema. Tumor extension into the cranium should be suspected when

the animal exhibits neurologic signs or when defects in the cribriform plate are identified with computed tomography. Animals with brain edema should be treated with rapid-acting water soluble intravenous corticosteroids, osmotic agents (mannitol), hyperventilation, hyperbaric oxygen, calcium channel blockers and antioxidants.

Subcutaneous emphysema occurs when air leaks from the nasal cavity into the subcutaneous tissues at the surgical site and is usually associated with violent sneezing or obstruction to nasal airflow. Airflow may be obstructed by nasal packing, occlusion of the nares with crusted blood and secretions, or severe mucosal edema. Subcutaneous emphysema is usually self-limiting and resolves within one to two weeks. It may be prevented by suturing a stent over the surgical site, inserting a drain, or creating a stoma and avoiding obstruction of the nasal passages. Subcutaneous emphysema is primarily a cosmetic concern although it could facilitate spread of infection. The animal's comfort may improve if the subcutaneous air is aspirated and a drain is placed into the nasal cavity to reduce recurrence.

Rhinotomy is a painful procedure. Analgesics should be given at the conclusion of surgery and as needed for 3 to 5 days. Anorexia is expected following surgery and may be due to pain or a diminished sense of smell. Anorexia is more severe in cats than dogs because they depend on their ethmoturbinates for olfaction and appetite stimulation. Cats are given diazepam or oxazepam to stimulate their appetite if necessary. Dogs usually require no treatment and have a normal appetite within a few days. After ventral rhinotomy, animals should not be allowed to chew on hard objects. Oronasal fistulas develop if dehiscence occurs or when soft tissues are perforated by hard, sharp objects.

Although airway obstruction is uncommon it may occur following rhinotomy. Animals should be monitored closely during recovery. Obstruction may be due to failure to mouth breath, mucosal edema and anxiety. These animals should be sedated and provided with supplemental oxygen in a quiet, cool environment. Corticosteroids should be given to reduce mucosal edema. An endotracheal or tracheostomy tube is indicated if dyspnea is severe.

A serosanguineous nasal discharge is expected following rhinotomy. The discharge diminishes and becomes more serous as denuded bone is covered with epithelium. If the primary disease has been eliminated the discharge remains minimal and serous. If the disease progresses or the area becomes infected, the nasal discharge increases and becomes mucopurulent or hemorrhagic. Chronic infections are treated with antibiotics selected on the basis of culture and sensitivity tests.

Recurrence of most diseases is expected after rhinotomy unless appropriate adjuvant therapy is instituted. Rhinotomy for foreign body removal might be an exception if irreversible chronic rhinitis and osteomyelitis have been avoided. Rhinotomy for fungal disease should be followed with administration of topical antifungal agents, and rhinotomy for neoplasia should be followed by radiation therapy, to extend the animal's disease free period.

Chapter 25

Larynx

Brachycephalic Syndrome

Cheryl S. Hedlund

Introduction

Brachycephalic animals (especially English bulldogs, Boston terriers, Chinese Pugs, Pekinese, Shar Pei dogs, and Himalayan and Persian cats) often exhibit signs of upper airway obstruction due to anatomic and functional abnormalities. Brachycephalia is a local chondrodysplasia that occurs as a result of domestication. Brachycephalic animals are characterized by having a compressed face with poorly developed nares and a distorted nasopharynx. Their head shape is the result of an inherited developmental defect in the bones of the base of the skull. These bones grow to a normal width but reduced length. The soft tissues of the head are not proportionally reduced and often appear redundant. These anatomic exaggerations result in increased airflow resistance and increased inspiratory effort which lead to functional airway abnormalities. Brachycephalic animals with these anatomic exaggerations and clinical signs are diagnosed as having the "Brachycephalic Syndrome".

The major components of the "Brachycephalic Syndrome" include 1) stenotic nares, 2) elongated soft palate, and 3) eversion of the laryngeal saccules. Most dyspneic brachycephalics have more than one and often all components of the syndrome. Some animals, especially English bulldogs, also have tracheal hypoplasia. These abnormalities may restrict airflow so severely that the condition progresses to include laryngeal and pharyngeal inflammation and edema, tonsil eversion from their crypts, and epiglottic, laryngeal and/or tracheal collapse.

Presentation and Diagnosis

Affected brachycephalics exhibit mild to severe signs of respiratory distress depending on the degree and location(s) of the obstruction. Signs of upper airway obstruction include exercise intolerance, stertorous breathing, mouth breathing, gagging, restless sleep ("sleep-disordered breathing"), cyanosis and collapse. Other signs may include restlessness, tachypnea, dysphagia, fever and an abnormal posture. Excitement, stress, and increased heat and humidity frequently make clinical signs worse. Dogs present for stridorous breathing and exercise intolerance, gagging or episodes of cyanosis and collapse.

Clinical evaluation of patients with severe respiratory distress should be conducted in a manner that does not upset the animal to avoid exacerbating its condition. The animal should be allowed to maintain a position of comfort and be minimally restrained during initial evaluation. Prior to a more thorough evaluation and work-up, patients with severe respiratory distress are provided emergency therapy. Emergency treatment includes controlling the environment to keep the animal cool and minimize stress, providing supplemental oxygen and a patent airway, and administering corticosteroids, sedatives and other drugs as needed to stabilize the patient. Sedatives given to relieve anxiety or facilitate examination sometimes exacerbate signs by relaxing upper airway dilating muscles. Further diagnostics and treatment follow stabilization of the patient.

A tentative diagnosis of the patient's upper respiratory tract obstruction is usually achieved by obtaining a complete history, thorough physical examination, and clinical pathology results. Clinical pathology results are usually normal but may reveal polycythemia in animals with chronic hypoxia.[1] These diagnostic measures are followed by lateral neck and routine thoracic radiographs or other imaging modalities, endoscopic respiratory tract examination, and sample collection for bacterial culture and biopsy as needed. Additional diagnostic measures might include blood gas analysis and respiratory function testing.

Components of the Syndrome

Stenotic Nares

Stenotic nares are congenital malformations of the nasal cartilages which are commonly seen in brachycephalic breeds. The nasal cartilages of animals with stenotic nares lack normal rigidity and collapse medially causing occlusion of the external nares. Normally during inspiration the levator nasolabialis muscle contracts dilating the nares to facilitate air intake. In animals with stenotic nares there is little or no dilation during inspiration, and in severe cases, collapse of the opening. Airflow into the nares is restricted and greater inspiratory effort is necessary, causing mild to severe dyspnea. Severe inspiratory dyspnea results if airflow obstruction is marked. Marked occlusion of the nares results in open-mouthed breathing and can interfere with olfaction, and air warming, moisturizing, and filtering. Stenotic nares are diagnosed on physical exam by recognizing that the external nares opening in the nasal planum is narrowed, restricted or compressed by this collapsed tissue.

Elongated Soft Palate

Congenital soft palate elongation is the most commonly recognized component of the Brachycephalic syndrome. The normal soft palate just touches or slightly overlies (1 to 3 mm) the tip of the epiglottis. The elongated soft palate extends more than 1 to 3 mm caudal to the tip of the epiglottis, is often thickened and obstructs the dorsal aspect of the glottis (Figure 25-1). The elongated palate is pulled caudally during inspiration and is sometimes pulled between the corniculate processes of the arytenoids. Consequently, increased inspiratory effort is required and airflow is more turbulent. The arytenoids and palate become inflamed and irritated due to the movement of the palate against the arytenoids and airflow turbulence. At times the soft palate may obscure the epiglottis by displacing it dorsally. Diagnosis of soft palate elongation is made during laryngoscopic or endoscopic examination of the nasopharynx and larynx.

Laryngeal Saccule Eversion

Laryngeal saccule eversion,or prolapse of the mucosa lining the laryngeal crypts, is the first stage of laryngeal collapse.

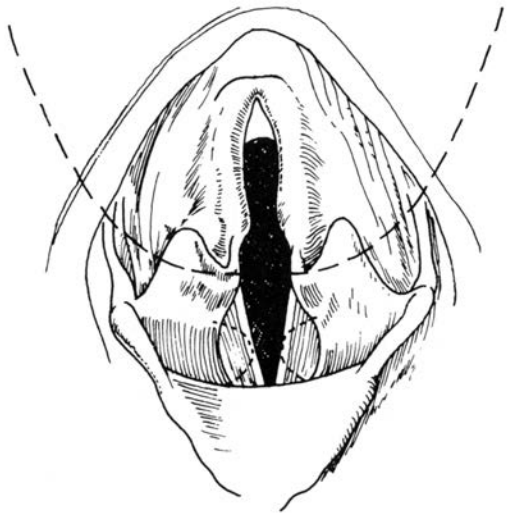

Figure 25-1. The dorsal dashed line represents the position of an elongated soft palate obstructing the dorsal aspect of the larynx. Everted laryngeal saccules (ventral dashed line) protrude from their crypts cranial to and partially obscure the vocal folds.

In their normal position between the vocal cords and the ventricular bands (false vocal cords), the laryngeal saccules are not visualized. Increased airflow resistance and increased negative pressure generated to move air past obstructed areas due to stenotic nares and soft palate elongation pulls the saccules from their crypts and causes them to swell. Everted and edematous saccules obstruct the ventral aspect of the glottis further restricting airflow (See Figure 25-1). Diagnosis of laryngeal saccule eversion is made during laryngoscopic or endoscopic examination. The everted saccules are recognized as edematous or fleshy soft tissue masses immediately rostral to and often obscuring the vocal folds. Acutely everted saccules are whitish and glistening in appearance. Chronically everted saccules are pink and fleshy. It is difficult to visualize and thoroughly evaluate the laryngeal saccules and larynx prior to soft palate resection as the soft palate obscures the other structures, and the severely affected patient may become cyanotic. For these reasons, laryngeal saccule eversion is diagnosed less often than elongated soft palate or stenotic nares. Saccule eversion may also be suspected during ultrasonographic examination of the larynx when there is a narrowed air shadow within the rima glottis.[2]

Advanced Laryngeal Collapse

Advanced laryngeal collapse is caused by chronic upper airway obstruction which results in increased inspiratory efforts and causes the cartilages to fatigue and lose their rigidity. Stage two and three laryngeal collapse may be recognized during laryngoscopic or endoscopic evaluation of animals with the brachycephalic syndrome. In stage two collapse or collapse of the aryepiglottic fold, the cuneiform process of the arytenoid cartilage and the fold of tissue connecting it to the epiglottis weaken and deviate medially (Figure 25-2). Medial deviation of this aryepiglottic fold causes further obstruction of the ventral aspect of the glottis. In stage three collapse or collapse of the corniculate processes of the arytenoid cartilages, the corniculate processes loose their rigidity and deviate medially

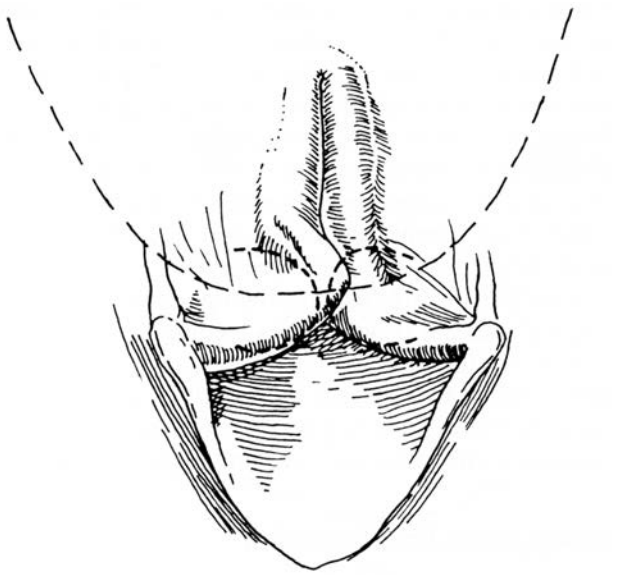

Figure 25-2. Severe collapse of the arytenoid cartilages in conjunction with an elongated soft palate (dorsal dashed line) and eversion of the laryngeal saccules (ventral dashed lines). The aryepiglottic folds and cuneiform cartilage collapse medially obstructing the ventral aspect of the glottis in stage two laryngeal collapse. The corniculate processes of the arytenoid cartilages collapse medially narrowing the dorsal glottis with stage three laryngeal collapse.

obstructing the dorsal aspect of the glottis (See Figure 25-2). The normal glottic diameter at rest is narrowed and widening of the glottis during inspiratory abduction of the corniculate processes is reduced.

Associated Abnormalities

During laryngoscopic and endoscopic examination of the airway the pharynx should be assessed for degree of inflammation and edema, evidence of redundant dorsal pharyngeal mucosa, and tonsil eversion. Tonsil eversion, inflammation and edema are secondary to air turbulence and increased breathing effort. Aberrant nasal turbinates and gastrointestinal lesions have also been described. Tracheoscopy is performed to assess the tracheal conformation and degree of inflammation. Many brachycephalics have concurrent tracheal hypoplasia and a few have tracheal collapse. Hypoplasia results in a narrow lumen due to the cartilages meeting or overlapping. These cartilages are often abnormally rigid and the trachealis muscle is often obscured or rolled into the lumen. Tracheal collapse is usually a dorsoventral narrowing of the trachea with cartilages being more flaccid than normal and the trachealis muscle is stretched and droops into the lumen. These abnormalities further restrict airflow.

Treatment

After definitive diagnosis, the syndrome is treated with the goal of achieving long-term relief from respiratory distress and preventing progression of the disease. Partial resection of the nares, soft palate and laryngeal saccules is recommended for all patients with these brachycephalic abnormalities. Patients with advanced laryngeal collapse who do not improve adequately following palate and saccule resection or those who improve and then later relapse with severe signs of respiratory distress

often benefit from a permanent tracheostomy which allows airflow to by-pass the upper airway. In addition to surgery, medical management may be beneficial. A weight reduction program is instituted for obese animals. Exercise restriction and elimination of precipitating causes may be beneficial. Provision of a cool environment and exclusion of respiratory irritants from the animal's environment (smoke, fragrances, sprays, etc) are beneficial. Perioperative administration of metaclopramide and gastroprotectants may decrease signs associated with gastrointestinal lesions.

Before surgical evaluation and treatment, special precautions must be taken because brachycephalic animals with respiratory distress are at extreme risk for hypoxia, especially during anesthetic induction and recovery. Sedatives and anesthetic agents relax the upper airway by dilating muscles and relaxing accessory muscles employed by brachycephalics to facilitate breathing. This allows the upper airway to collapse and reduces respiratory drive. Risk of complete airway obstruction at induction can be minimized by pre-oxygenating the patient, rapid induction of anesthesia with an injectable agent, and then quickly intubating the patient. Risk of complete airway obstruction during recovery are minimized by intensive monitoring and prevention of nasopharyngeal and laryngeal edema. I recommend administering an anti-inflammatory dose of corticosteroids (dexamethasone 0.5 to 2 mg/kg SQ, IM) immediately prior to or after induction of anesthesia. This reduces swelling and edema of pharyngeal and laryngeal tissues during and after surgery. Corticosteroid administration may be repeated as needed after surgery to reduce airway obstruction caused by swollen pharyngeal and laryngeal tissues. Nasopharyngeal and laryngeal inflammation and edema are also minimized by using atraumatic examination and surgical techniques. Sedation of the patient as anesthetic recovery begins will allow a slow, smooth recovery with the endotracheal tube in place for as long as possible. Administration of oxygen through a nasal catheter facilitates a slow smooth recovery and minimizes anxiety due to hypoxia. Alternatively, a tracheostomy tube is placed at the beginning of surgery and removed when the animal is fully recovered from anesthesia and shows minimal signs of respiratory distress.

Surgical Techniques

Various surgical techniques have been described to resect portions of the nares, soft palate and laryngeal saccules. Resections should be performed early in the animal's life (often before 1 year of age) to prevent progressive deterioration of airway function. I prefer resection using sharp incisions with a scalpel or scissors rather than using electrosurgical, heat sealing or laser instruments. Prior to surgery, the patient is positioned to allow for optimal visualization and lighting of the oral and pharyngeal cavities (Figure 25-3). The patient is positioned in sternal recumbency with the neck extended and the maxilla suspended from an overhead rod. The mandible is pulled ventrally with tape to maximally open the mouth and the tongue is retracted rostrally. The cheeks may also be retracted laterally to further improve visualization.

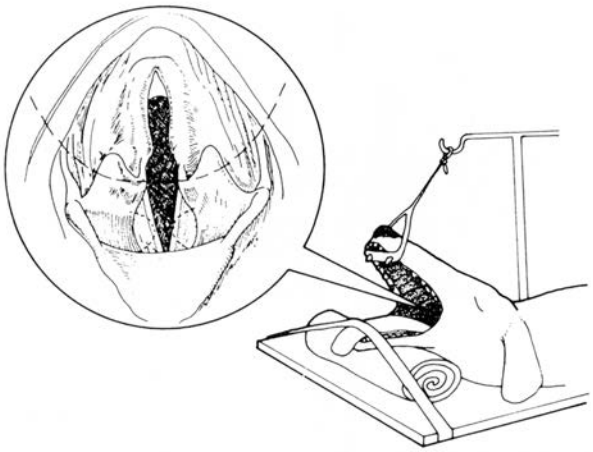

Figure 25-3. The dog is positioned in ventral recumbency with its maxilla suspended to allow and oral approach to the soft palate and laryngeal ventricles.

Soft Palate Excision

Surgery is begun by resecting the elongated soft palate. This will allow subsequent resection of the laryngeal saccules if necessary with a less obstructed view. An Allis tissue forceps is used to grasp the tip of the soft palate and retract it cranially (Figure 25-4A). The line of excision is along an imaginary line at the level of the caudal pole of the tonsil. The epiglottis may also be used for anatomic reference and the finsished resected palate should just touch the tip of the epiglottis. Once the length of palate to be resected is determined, stay sutures using 3-0 or 4-0 poliglicaprone 25 (monocryl, Ethicon, Inc., Somerville, NJ) are placed and tied in the lateral margins of the palate adjacent to the line of incision. Cranial retraction using the tissue forceps and stay sutures provides good visualization.

A scalpel blade or a sharp pair of Metzenbaum scissors is used to incise half the width of the soft palate (Figure 25-4B). The incised edges of the nasal and oral palatal mucosa are apposed using a simple continuous pattern of 3-0 or 4-0 poliglicaprone 25. Care is taken to include the nasal mucosa which tends to retract from the incision line. The remaining palate is incised, and suturing continued to the opposite margin (Figure 25-4C). The stay sutures can be used as part of the suture placed in the palate or remain separate from the incision line. Blood clots or mucus should be aspirated from the pharynx prior to recovery and extubation of the patient.

Laryngeal Saccule Resection

Stay sutures previously placed on the edges of the soft palate are maintained to facilitate retraction of the palate and improve visualization of the everted laryngeal saccules. Blood and mucus are aspirated from the glottis as necessary. The endotracheal tube is elevated dorsally and deviated to one side to allow access to the laryngeal saccule on the opposite side. Alternatively, the endotracheal tube may be temporarily removed to allow less restricted access to the laryngeal saccules, this however increases the intraoperative risks of aspiration and hypoxia. An Allis tissue forceps is used to grasp and gently retract the everted saccule rostrally and medially to allow positioning of a

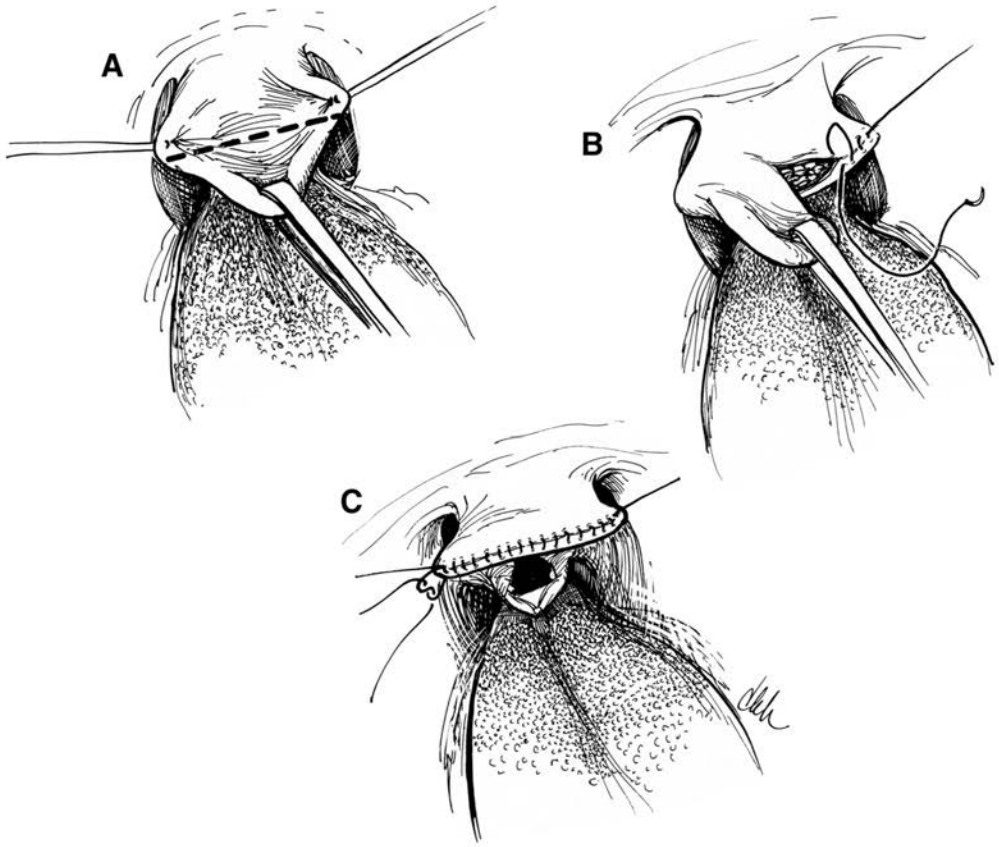

Figure 25-4. A. The tip of the soft palate is grasped with Allis tissue forceps. After noting the length of soft palate to be amputated, stay sutures are placed just cranial to the proposed line of resection. **B.** The full thickness of the soft palate is incised with a surgical blade approximately half the width of the soft palate. A length of the "stay" suture with the needle attached is used to appose the edges of the cut surface while one takes care to incorporate both the pharyngeal and nasal mucosa. **C.** After completing mucosal apposition, the suture is tied to a length of suture being used as a "stay" suture on the opposite side.

long-handled, curved Metzenbaum scissors across the base of the saccule. (Figure 25-5). The everted tissue is excised using the scissors. Amputation may also be accomplished using laryngeal cup forceps or similar biopsy instruments, laser or electrosurgery. Hemorrhage is usually mild but some surgeons twist the saccule after it is grasped to reduce hemorrhage post-excision. More severe hemorrhage is rare and is controlled with direct pressure. Care is used during excision to not inadvertently resect the vocal fold which lies immediately caudal to the everted saccule. The procedure is repeated to remove the opposite laryngeal saccule and the resection sites are allowed to heal by second intention.

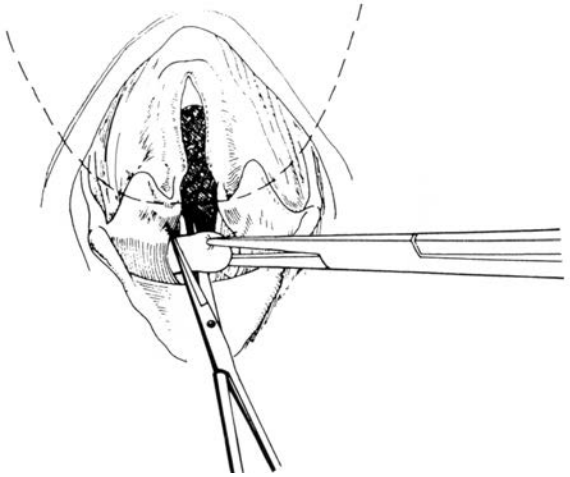

Figure 25-5. The laryngeal saccule is grasped with tissue forceps and amputated at its base.

Stenotic Nares Wedge Resection (Alaplasty)

The patient is positioned in sternal recumbency and the head taped to the table to avoid rotation. The obstructing portion of the lateral nasal planum is grasped with Brown-Adson thumb forceps to delineate and stabilize the segment of nares to be resected. Maintaining this grip, make a "V" shaped incision around the forceps with a #11 scalpel blade. First make a medial incision angled in a caudolateral direction. Then make a second incision from the lateral aspect of the nares in a caudomedial direction to meet the first incision at the vortex of the wedge (Figure 25-6) Remove the wedge of nasal planum and cartilage. Hemorrhage is controlled by applying pressure and apposing the cut edges. Occasionally, vessels are identified which may be occluded with hemostats or electrocoagulation. Align the ventral margin of the nares and mucocutaneous junction and appose the incised edges with three or four simple interrupted sutures using a monofilament absorbable suture (4-0 polydioxanone). Repeat the procedure by removing a similar wedge of tissue from the opposite naris and apposing the edges. Alternative techniques include removal of wedges of various shapes and orientations from the lateral aspect of the nasal planum or alapexy.

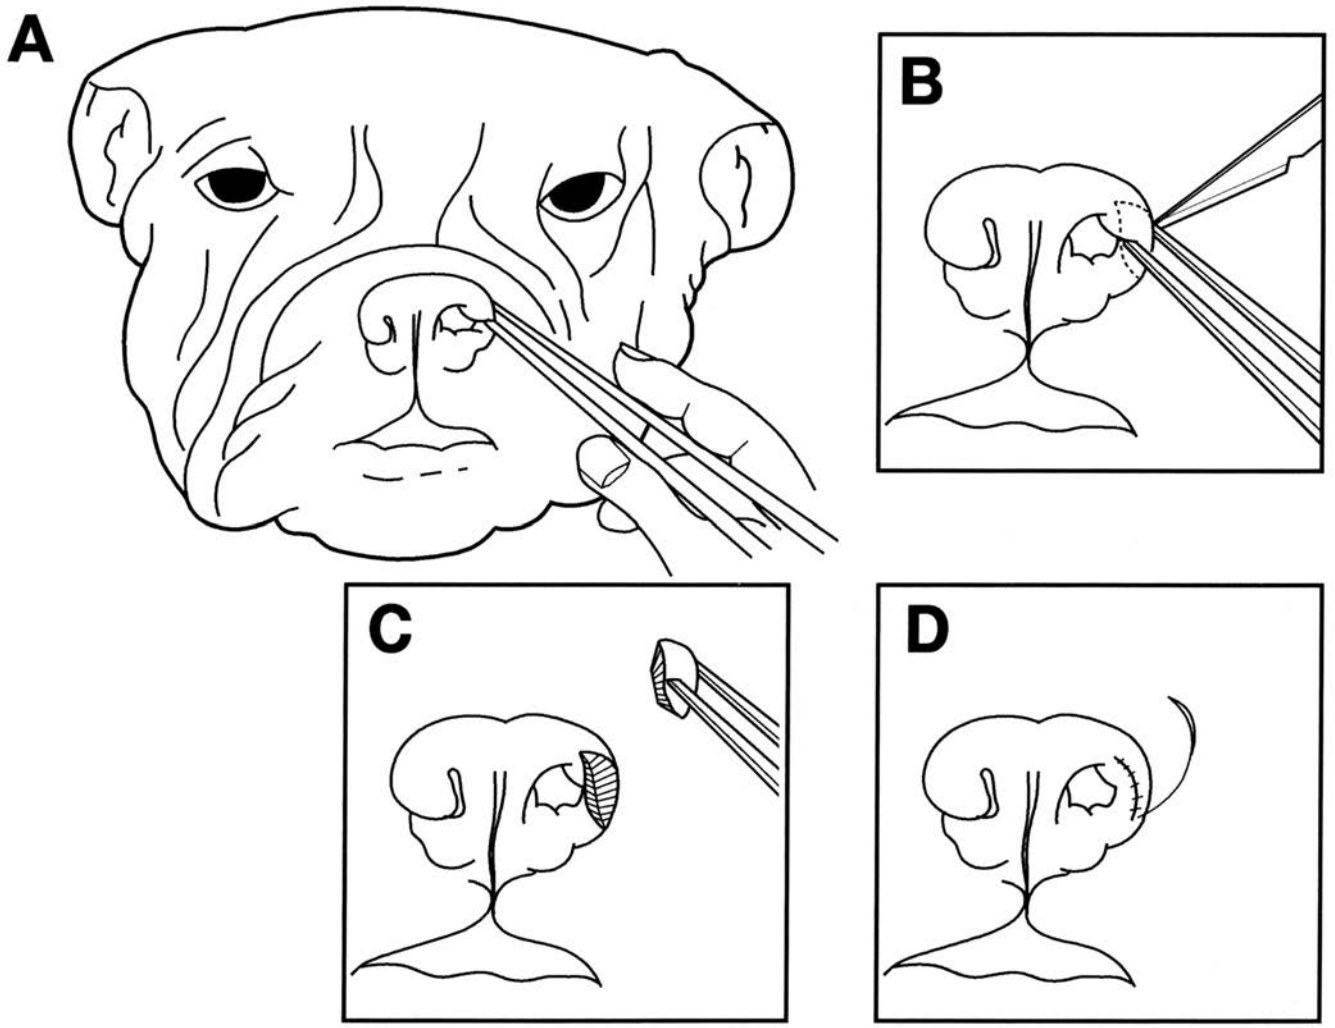

Figure 25-6. Stenotic nares resection. **A.** Resection of the nares begins by grasping the moveable margin of the nares to outline the wedge to be removed and to stabilize the tissue. **B.** Using a #11 scalpel blade a medial and the lateral incision are made adjacent to the tips of the forceps. **C.** The wedge is removed and discarded. **D.** The external nares are then widened by placing appositional sutures to appose the incised edges.

Aryepiglottic fold resection is occasionally performed in patients with aryepiglottic fold collapse. It is performed when other resection techniques have not adequately alleviated the patient's respiratory distress or concurrently with resection of palate, nares and saccules if respiratory distress is extreme and permanent tracheostomy is not acceptable to the client. Aryepiglottic fold resection is performed unilaterally through an oral approach. The fold is grasped and stabilized with thumb forceps and the fold and cuneiform process excised with Mayo scissors or uterine biopsy forceps. The tissue defect is allowed to heal by second intention.

Postoperative Management

The nasopharynx and larynx are aspirated and a nasal catheter placed for oxygen administration during recovery. Advance the catheter to the end of the soft palate if possible. Suture or glue the catheter to the skin and fit the animal with an appropriately sized Elizabethan collar to prevent the patient from removing the catheter. Keep the animal quiet and sedated to allow a slow quiet recovery with the endotracheal tube in place for as long as possible. Remove the tube with the cuff slightly inflated to withdraw any blood clots that may have entered the trachea. Begin supplemental oxygen through the nasal catheter (50 ml/kg/min) just before or after the endotracheal tube is removed. Continue nasal oxygen administration until the patient is fully recovered from anesthesia and breathing with minimal or no distress, usually 2 to 3 hours. Provide continuous monitoring during recovery and postoperatively for 24 to 72 hours as inflammation and edema may result in airway obstruction. The clinician should be prepared to reanesthetize and re-intubate or perform a tube tracheostomy in patients which experience severe dyspnea. Additional doses of corticosteroids may also be necessary and gastroprotectants are continued. Analgesics are continued for 48 to 72 hours. A weight reduction program should be instituted for obese animals.

Serious surgical complications include death due to glottic obstruction from inflammation and edema, and nasal regurgitation and rhinitis/sinusitis due to excessive soft palate resection. Inadequate resection of tissue results in persistent signs of upper airway obstruction. Excessive glottic manipulation may cause vagal induced bradycardia. Hemorrhage, gagging and coughing and aspiration may also occur in the early postoperative period.

Dehiscence of the nares may occur if the patient frequently licks or rubs its nose. Healing then occurs by second intention and may cause a pink scar. Scarring or stenosis following laryngeal saccule or aryepiglottic resection cause voice change, loss of bark, respiratory noise or progressive signs of upper airway obstruction.

Prognosis depends on the severity of the condition at the time of surgery. Partial resection of the soft palate, laryngeal saccules and nares is expected to relieve moderate to severe signs of respiratory distress in patients who do not have laryngeal collapse. Patients breathe with less effort and noise and are more tolerant of exercise and excitement. Some patients who have initially responded well to resection sometimes deteriorate and again show signs of severe respiratory distress months to years later. Laryngeal collapse has often become severe in these patients. Patients with advanced laryngeal collapse at the time of diagnosis and resection may respond unsatisfactorily to resection and require permanent tracheostomy to relieve their respiratory distress.

Treatment of Laryngeal Paralysis with Unilateral Cricoarytenoid Laryngoplasty (A form of Arytenoid Lateralization)

Thomas R. LaHue

Introduction

Bilateral laryngeal paralysis is a common cause of upper airway obstruction in older dogs. Although the disease has been reported in many breeds of dogs and in cats the large sporting breeds (Labrador and Golden Retrievers) are most commonly affected. The disease is characterized by clinical signs of inspiratory stridor, exercise intolerance, and respiratory distress, which gradually worsen over a period of months. Severely affected dogs will often progress to cyanosis and collapse. Other signs include voice change and coughing or gagging. Clinical signs are usually not evident in dogs unless the disease is bilateral. The long-term prognosis for patients with laryngeal paralysis is usually poor unless the disease is managed surgically.[1]

The surgical technique described here is a form of arytenoid lateralization called unilateral cricoarytenoid laryngoplasty. This procedure or other forms of unilateral arytenoid lateralization have been successfully used by many surgeons to obtain consistently good results in the surgical treatment of laryngeal paralysis. Partial laryngectomy has been used successfully in the past but is not recommended for the treatment of laryngeal paralysis because of the high incidence of postoperative complications. Modified castellated laryngofissure has shown acceptable clinical results in dogs with laryngeal paralysis however the procedure is relatively complex, requires tracheostomy and is not widely used.

If proper surgical treatment is performed, the prognosis for affected dogs is good, however aspiration pneumonia remains a potential life-long risk.

Etiology

The most common form of laryngeal paralysis is the acquired, idiopathic form, which occurs primarily in older, large breed, male dogs. Congenital laryngeal paralysis is uncommon. A hereditary form has been reported in Bouviers des Flandres, with clinical signs observed at four to six months of age.[2] An association between laryngeal paralysis and generalized polyneuropathy has been reported in young Dalmatians.[3] A hereditary form of the disease has also been reported in Siberian huskies and husky cross breeds.[2] Direct injury to the recurrent laryngeal nerves due to trauma or surgery is an uncommon cause of laryngeal paralysis.

The primary cause of laryngeal paralysis is dysfunction of the recurrent laryngeal nerves. The specific etiology of this dysfunction in acquired laryngeal paralysis is unknown, although a demyelinating disease has been suggested.[4] This would preferentially affect longer nerve fibers such as the recurrent laryngeal nerve.[4] A possible association with hypothyroidism

has been reported.[1] The possibility of laryngeal paralysis being an early or initial clinical sign of a generalized polyneuropathy has been suggested.[5]

Neurogenic atrophy of intrinsic laryngeal muscles, particularly the cricoarytenoideus dorsalis muscle, causes failure of arytenoid cartilages and vocal folds to abduct, resulting in upper airway obstruction. The obstruction can worsen with exercise, excitement, or hot weather as increased oxygen demand causes greater inspiratory effort (greater negative pressure), which draws the arytenoid cartilages and vocal folds medially. This can become a vicious cycle, leading to cyanosis and collapse.

Diagnosis

The importance of an accurate diagnosis cannot be overemphasized. Laryngeal paralysis occurs primarily in older, larger breed dogs. It is rare in toy and small breed dogs. Other causes of respiratory distress such as upper airway obstruction caused by intraluminal or extraluminal (thyroid) neoplasia should be considered and ruled out before laryngeal paralysis is considered the primary cause. The most common clinical signs are respiratory distress, stridor, and exercise intolerance, often with a slow, insidious onset over a period of months to years. Other clinical signs observed less commonly include voice change and coughing or gagging. Although the onset of signs is gradual, it is not uncommon for patients to have acute, severe, life threatening episodes of upper airway obstruction, particularly during hot weather and when the dog is excited or exercising.

Physical examination of patients with suspected laryngeal paralysis should include auscultation of the laryngeal region with and without mild laryngeal compression both before and after exercise.[6] In dogs with laryngeal paralysis, auscultation usually reveals increased respiratory noise (stridor) over the laryngeal region, especially during inspiration. Dogs with normal laryngeal function should not have an appreciable change in upper airway noise with mild laryngeal compression. Dogs with laryngeal paralysis will exhibit a distinct worsening of the stridor as laryngeal compression is applied because they already have a fairly narrow, relatively fixed laryngeal glottis. This may be noted while listening as the dog is panting or upon auscultation of the laryngeal region. Thoracic auscultation will often only demonstrate referred upper airway sounds, but it is extremely important in order to evaluate the patient for possible concurrent disease. Aspiration pneumonia and/or bronchial disease can occur in patients with laryngeal paralysis because these patients are unable to fully close the glottis during swallowing.

Thoracic and cervical radiographs should be obtained to rule out other causes of respiratory compromise and to document concurrent disease. In addition to a CBC and chemistry profile, thyroid status is evaluated (T4 or TSH stimulation). There is an increased incidence of hypothyroidism in dogs with laryngeal paralysis, although there is not a proven cause and effect relationship. Hypothyroidism, like acquired laryngeal paralysis, tends to be a disease of older dogs. Hypothyroidism has been reported as a cause of generalized polyneuropathies.[7] Supplementation with thyroxine will not reverse the laryngeal paralysis, but it could help prevent or slow the progression of possible hypothyroid-induced generalized neuromuscular disease that may cause peripheral weakness.

Definitive diagnosis of laryngeal paralysis is made with laryngoscopy under very light anesthesia. In lightly anesthetized dogs with laryngeal paralysis, there is a failure of the arytenoid cartilages to abduct during inspiration. *The arytenoid cartilages can also fail to abduct if the level of anesthesia is too deep.* In order to make an accurate diagnosis, the patient must be under as light a plane of anesthesia as possible and the evaluation must be of adequate duration to be sure there is no effective arytenoid abduction during inspiration (at least 5 to 10 minutes). In some cases, paradoxical movement of the arytenoid cartilages may occur where the arytenoids are drawn medially due to the negative pressure created at inspiration.[8] Similarly, the arytenoids may appear to abduct weakly on expiration; this is caused by the arytenoids being moved from their paramedian position by passive expiratory efforts. *It is extremely important to correlate any laryngeal movement with the phase of respiration.* Various anesthetic protocols have been used effectively to assess arytenoids function. I currently use propofol (2 to 6 mg/kg, IV). After initial induction and arytenoid evaluation, I administer doxapram (1.0 to 2.2 mg/kg) and continue laryngoscopy. Use of doxapram is very useful in more clearly differentiating normal dogs from those with laryngeal paralysis. It increases respiratory effort and increases any intrinsic laryngeal motion (if present).[21] In dogs with bilateral laryngeal paralysis, use of doxapram may increase paradoxical arytenoid motion. Close monitoring of the patient's ventilatory status during laryngeal examination is important and the examiner should be prepared for patient intubation with the appropriate sized endotracheal tube. Laryngoscopy often reveals laryngeal (arytenoid) edema and inflammation, which may worsen the signs of laryngeal paralysis, and may change the character of dyspnea from primarily inspiratory to both inspiratory and expiratory.[8] If laryngeal paralysis is strongly suspected in patients with moderate to severe clinical signs, based upon history and physical examination, it is advantageous to schedule laryngoscopy so that surgery can be performed immediately following laryngoscopy if the diagnosis is confirmed.

Treatment

The recommended emergency medical treatment for an acute respiratory crisis due to laryngeal paralysis is sedation and endotracheal intubation, followed by gradual wakening of the animal.[6] These severely affected patients should be observed continuously and may need emergency surgery to relieve the upper airway obstruction. It is best to perform a definitive corrective procedure if possible rather than a temporary tracheostomy.

Alleviation of upper airway obstruction caused by laryngeal paralysis can be best achieved with surgery.[2] Medical therapy, including the use of tranquilizers, oxygen, and corticosteroids may be helpful in management of severely affected patients prior to surgery. Patients with preexisting aspiration pneumonia should be treated prior to surgery and may be more likely to develop

postoperative aspiration pneumonia. Patients with laryngeal paralysis and megaesophagus (or any cause of regurgitation) have a poor prognosis due to the extremely high likelihood of developing severe aspiration pneumonia after surgery.

The goal of surgery is to provide complete relief of upper airway obstruction while minimizing discomfort and postoperative complications. After surgery, patients should be able to breathe comfortably and have a normal activity level for their age.

Unilateral arytenoid lateralization in some form (cricoarytenoid laryngoplasty is described here) has been used successfully to achieve these goals in treating laryngeal paralysis and is the procedure of choice of many surgeons.[1,2,6,8-16] Other reported surgical techniques for treatment of laryngeal paralysis include partial laryngectomy (partial arytenoidectomy with vocal fold resection) using either an oral or ventral laryngotomy approach[17,18] and modified castellated laryngofissure with vocal fold resection.[19,20]

Surgical Technique

There are several variations of unilateral arytenoid lateralization. The procedure described here has been called cricoarytenoid laryngoplasty.[6,8] The procedure involves the placement of two sutures in the same location as the cricoarytenoideus dorsalis muscle, from the caudal dorsolateral aspect of the cricoid cartilage to the muscular process of the arytenoid cartilage (through the articular surface). Arytenoid lateralization has been used as a general term or to describe the procedure where sutures are placed from the caudal border of the thyroid cartilage to the muscular process of the arytenoid cartilage.[2,9,10,15,16] Regardless of the technique used, it is advisable to become familiar with the anatomy of the cervical and laryngeal region and the specific surgical procedure. The surgical technique should be observed prior to performing it and practiced on cadavers, or performed with an experienced surgeon present if possible.

Routine endotracheal intubation is performed following laryngoscopy. The unilateral cricoarytenoid laryngoplasty can be performed on either side. I perform the procedure on the left side for consistency only. Right handed surgeons usually prefer to perform left side lateralization because needle advancement through the cricoid is easier and less awkward. The patient is placed in right lateral recumbency with a slight rotation towards dorsal recumbency. It is helpful to place a small rolled towel under the neck at the level of the larynx. A ventrolateral approach to the larynx is made, beginning with a 5 to 8 cm long skin incision over the larynx, just ventral to the external jugular vein (Figure 25-7). It is helpful to palpate the caudal border of the cricoid cartilage and the wing of the thyroid cartilage as anatomic landmarks during the approach. Dissection is continued to the lateral and dorsal aspects of the larynx through the subcutaneous tissue and the superficial muscles of the neck, being careful to avoid the external jugular, linguofacial and maxillary veins.

The dorsal margin of the wing of the thyroid cartilage is palpated and retracted laterally by use of a "stay" suture or a hand-held retractor. The thyropharyngeus muscle is incised along the dorsal rim of the thyroid cartilage (Figure 25-8). Lateral retraction of the thyroid cartilage is important in order to avoid the esophagus. A layer of connective tissue is incised just medial and parallel to the rim of the thyroid cartilage and separated bluntly. The cricothyroid articulation at the caudal edge of the thyroid cartilage is separated with scissors and/or a Freer septum elevator (Figure 25-9A). This

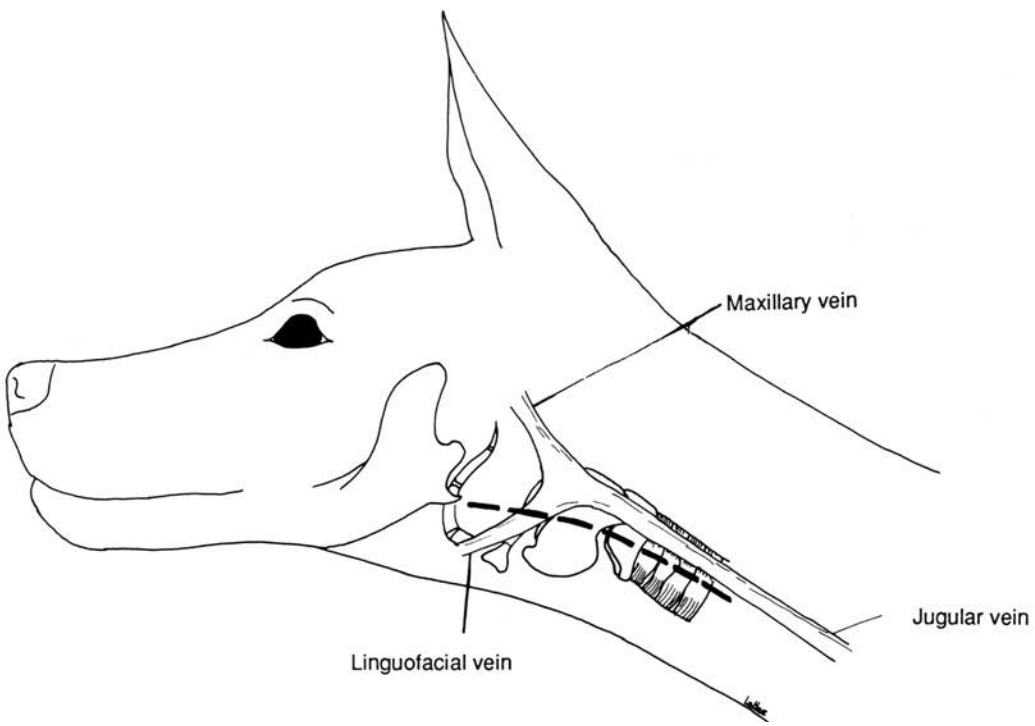

Figure 25-7. The site of the skin incision is shown by the dotted line. A ventrolateral approach to the larynx is made, beginning with an 8 to 10 cm long skin incision starting near the angle of the mandible and extending caudally just ventral to the external jugular vein. It is helpful to palpate the caudal border of the cricoid cartilage as a landmark during the approach.

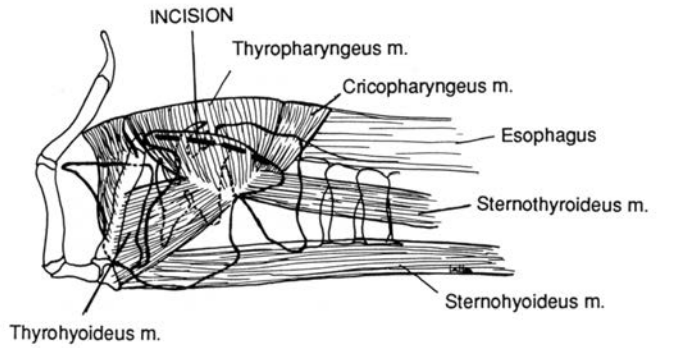

Figure 25-8. The dorsal margin of the wing of the thyroid cartilage is palpated and retracted laterally. The thyropharyngeus muscle is incised along that margin (dotted line).

disarticulation is necessary to provide adequate exposure. The cricoarytenoideus dorsalis muscle and muscular process of the arytenoid cartilage are identified. The cricoarytenoideus dorsalis muscle is undermined and incised close to the muscular process, leaving enough muscle on the muscular process to attach mosquito forceps to facilitate gentle manipulation (Figure 25-9B). The cricoarytenoid articulation is separated using blunt dissection with a Freer elevator, being careful not to damage the muscular process or penetrate the laryngeal mucosa (Figure 25-9C). The rostral aspect of the cricoarytenoid joint capsule is left intact, as this almost always allows adequate mobility of the arytenoid cartilage. The purpose of cricoarytenoid joint disarticulation is to gain mobility of the arytenoid cartilage in relation to the cricoid cartilage so the arytenoid cartilage can be adequately abducted. Laryngoplasty procedures have been described where cricoarytenoid disarticulation is not done.[13] However, some dogs have fibrosis and ankylosis of this joint. If disarticulation is not performed in these patients, adequate abduction of the arytenoid cartilage will not be achieved.

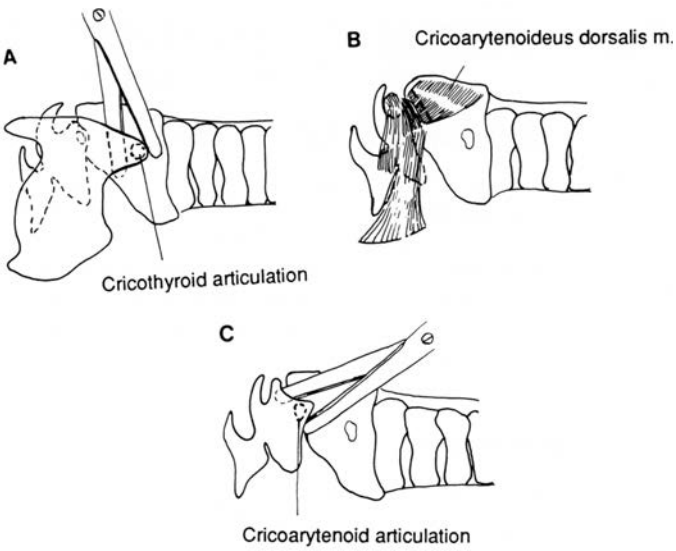

Figure 25-9. A. The cricothryroid articulation at the caudal edge of the thyroid cartilage is separated with scissors and/or a Freer septum elevator. **B.** The cricoarytenoideus muscle and muscular process of the arytenoid cartilage are identified. The muscle is undermined and incised close to the muscular process, leaving enough muscle on the muscular process to attach mosquito forceps for use in gentle manipulation. **C.** The cricoarytenoid articulation is separated using blunt dissection with fine scissors or a Freer elevator (preferred), being careful not to damage the muscular process or penetrate the laryngeal mucosa. The rostral aspect of the cricoarytenoid joint capsule is left intact as long as this allows mobility of the arytenoid cartilage to be attained. Thyroid cartilage is not pictured in **B** and **C**. It would be retracted laterally during these stages of the procedure.

When performing this procedure, I no longer incise and separate the sesamoid band that connects the two arytenoid cartilages because mobilization of the arytenoid cartilage and optimal abduction can be achieved without dissection of the described band.

The left arytenoid cartilage is now movable in relation to the cricoid cartilage. Two sutures of monofilament nylon or polypropylene (0 in large dogs, 2-0 in medium dogs) are passed closely under the caudal edge of the cricoid cartilage and directed cranially to penetrate through the cartilage on the dorsolateral aspect (approximately 5 to 8 mm from the caudal edge), being careful not to penetrate laryngeal mucosa (Figure 25-10A). These sutures are then passed from medial to lateral through the central portion of the articular surface of the muscular processs of the arytenoid cartilage at least 2 to 3 mm from the cartilage edge (Figures 25-10B and 25-10C). The sutures are tied separately (Figure 25-10D). The intact rostral portion of the cricoarytenoid joint capsule helps to prevent over-abduction of the arytenoid cartilage. Either at this point or following closure, the dog is extubated briefly while laryngoscopy is performed to confirm adequate abduction of the left arytenoid cartilage, followed by replacement of the endotracheal tube. Closure of the thyropharyngeus muscle is completed using fine (3-0 or 4-0) monofilament absorbable suture material in a simple continuous pattern. Subcutaneous tissues and skin are closed routinely.

Postoperative Management

Postoperative care includes continuous (24 hour) monitoring for dyspnea, intravenous fluid therapy, and withholding of food and water for 12 to 24 hours. Cefazolin (20 mg/kg, IV) is given at the time of anesthetic induction and repeated two hours later. Antibiotic therapy (ampicillin 20 mg/kg, PO, TID) is only continued if the laryngeal mucosa is penetrated. Patients most often do well postoperatively and are discharged from the hospital within 1 to 2 days of surgery. The most common serious complication that can occur postoperatively is aspiration and development of aspiration pneumonia. Depression, fever or coughing postoperatively should prompt the surgeon to take thoracic radiographs to rule out aspiration pneumonia. A soft, canned food consistency diet with no excess gravy or crumbs is recommended to minimize the risk of aspiration pneumonia. I also counsel owners to avoid any food that might result in vomiting, as that increases the risk of aspiration pneumonia. A voice change (similar to a debarked dog) is expected after cricoarytenoid laryngoplasty and other laryngoplasty techniques. Occasional coughing after drinking water occurs commonly in the postoperative period, but usually decreases after a short period of adaptation.[9]

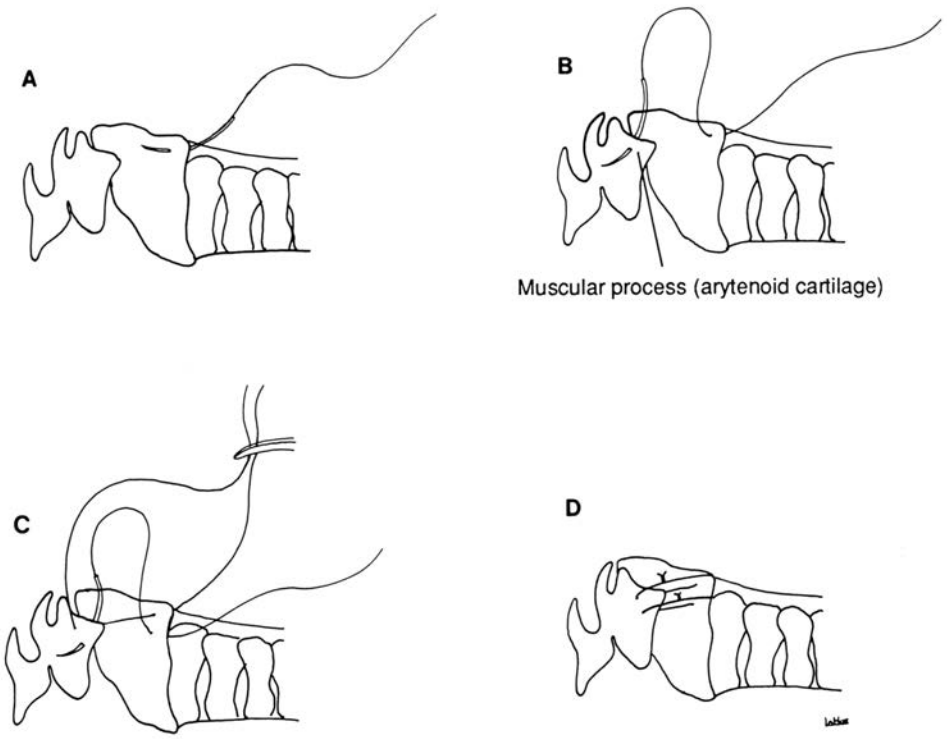

Figure 25-10. A. The first of two sutures is passed over the caudal edge of the cricoid cartilage and directed cranially to penetrate through the cartilage on the dorsolateral aspect (approximately 5 to 8 mm from the caudal edge), being careful not to penetrate laryngeal mucosa. **B.** Suture is then passed from medial to lateral through the articular surface and/or muscular process of the arytenoid cartilage at least 2 to 3 mm from the cartilage edge. **C.** The second suture is passed in a similar manner. **D.** Each suture is tied separately. The intact rostral portion of the cricoarytenoid joint capsule helps to prevent over-abduction of the arytenoid cartilage. Thyroid cartilage is not pictured. It would be retracted laterally during these stages of the procedure.

Surgical Results

Surgical techniques other than arytenoid cartilage lateralization techniques utilized in the treatment of laryngeal paralysis include partial laryngectomy and castellated laryngofissure. Partial laryngectomy usually involves partial arytenoidectomy with vocal fold resection using either an oral or ventral laryngotomy approach.

Arytenoid Lateralization/Cricoarytenoid Laryngoplasty

Unilateral cricoarytenoid laryngoplasty or some form of unilateral arytenoid lateralization has been shown to relieve signs of upper airway obstruction such as stridor, dyspnea and exercise intolerance in 82% to 100% of patients.[1,8,10-12,15,16,23] Lane reported a 97% overall success rate in surgical treatment of 167 cases of laryngeal paralysis using several modifications of arytenoid cartilage lateralization.[10] My success rate with unilateral cricoarytenoid laryngoplasty in over 500 dogs has been consistent with these results. White reported alleviation of exercise intolerance or stridor after arytenoid lateralization (with attachment of arytenoid cartilage to cricoid and/or thyroid cartilage) in 82% of dogs with laryngeal paralysis.[15] Greenfield and Venker-van Haagen reported alleviation of clinical signs of upper airway obstruction in 89% and 95% respectively with unilateral arytenoid lateralization.[2,11] Payne, et al reported results of abductor muscle prosthesis in 11 dogs, where placement of the sutures from cricoid cartilage to muscular process of the arytenoid cartilage is done without cricoarytenoid disarticulation.[13] Three of seven dogs where the procedure was done bilaterally died of aspiration pneumonia. There were no cases of aspiration pneumonia with unilateral procedures. In another study by Hammel, et al, the incidence of aspiration was reported in 7 dogs (18%).[22] Six of those dogs recovered with treatment. Snelling, et al reported 87.7% improvement in quality of life, with a 10.7% overall complication rate in 100 patients.[23]

Modified Castellated Laryngofissure

Modified castellated laryngofissure widens the glottic lumen by performing a stepped incision in the thyroid cartilage. The procedure also includes vocal fold resection and placement of mattress sutures through the arytenoid and thyroid cartilages to stabilize the arytenoid cartilages. In a report of four dogs treated with castellated laryngofissure,[19] two (50%) had no clinical signs of upper airway obstruction at 7 and 12 months postoperatively, and two (50%) had no clinical signs of upper airway obstruction at 10 and 12 months postoperatively. Another study evaluated a modified castellated laryngofissure in 12 dogs with laryngeal paralysis.[20] Signs of upper airway obstruction had either decreased in severity or disappeared in 11 of these dogs 15 to 452 days after surgery. One dog died immediately after surgery from hyperthermia, and three dogs died 1, 9, and 11 months postoperatively from non-related or unknown causes. Tracheotomy tubes were used during the operation and were maintained for a minimum of three days postoperatively in both

studies. Duration of postoperative hospitalization noted in only one case was eight days.

Modified castellated laryngofissure and arytenoid abduction techniques were evaluated using 30 canine postmortem specimens.[14] There was a greater change in cross-sectional area of the rima glottidis with modified castellated laryngofissure than with unilateral arytenoid lateralization techniques. The authors of this study suggested using modified castellated laryngofissure when subglottic luminal compromise, such as traumatic fibrosis, is present. They felt the procedure was technically more demanding, more time consuming, and more traumatic than arytenoid abduction (lateralization) techniques.

Partial Laryngectomy/Bilateral Ventriculocordectomy

Several studies have shown a high incidence of postoperative complications associated with partial laryngectomy for the treatment of laryngeal paralysis. Long term results of partial laryngectomy (oral approach) in 25 dogs with idiopathic laryngeal paralysis were as follows:[13] (52%) could breathe, eat and drink normally; four (16%) were considerably improved but still were noisy or had a cough, gag, or retch; six (24%) died of airway disease postoperatively; and two (8%) had initial improvement but were lost to follow-up.[17] Aspiration was the cause of death in three dogs. Tracheotomy tubes were placed prior to performing surgery in all cases. Duration of maintenance of the tracheotomy tube and length of postoperative hospitalization were not described. Granulation tissue or web formation across the glottic region causing airway obstruction has been reported after partial laryngectomy, particularly when a ventral laryngotomy approach was used.

Complications and long term results after partial laryngectomy for the treatment of idiopathic laryngeal paralysis were reported in 45 dogs.[18] Good or excellent results were obtained in 29 dogs (65%). Six dogs (13%) had some improvement, but residual respiratory compromise, exercise intolerance and consistent coughing. Ten dogs (22%) either showed no improvement over preoperative condition or developed fatal postoperative complications related to the partial laryngectomy. Death occurred in the immediate postoperative period (3 to 11 days) either because of pneumonia (8 dogs) or complete upper airway obstruction (1 dog). Nine dogs died of respiratory disease. Three dogs developed web stenosis across the glottis. The authors of this study did not recommend partial laryngectomy for the treatment of laryngeal paralysis because of the high incidence of postoperative complications. They felt that unilateral arytenoid lateralization may be a superior technique because unilateral lateralization provides relief from respiratory distress with a low complication rate.

Twenty four dogs with laryngeal paralysis treated with bilateral ventriculocordectomy through an oral approach at the University of Wisconsin-Madison were evaluated.[12] There was an unacceptably high incidence of postoperative complications after the bilateral ventriculocordectomy procedure. Complications occurred in 58% (14 of 24) of the dogs. The reported complications included increased respiratory stridor, exercise intolerance, and difficulty cooling off after exercise. Transverse laryngeal webbing occurred in nine of the 24 dogs (37.5%), requiring further surgery. The authors of this report recommended unilateral cricoarytenoid laryngoplasty for treatment of laryngeal paralysis in dogs.

Summary / Prognosis

It is important to recognize that while bilateral laryngeal paralysis is a significant cause of upper airway obstruction in older dogs, it is surgically treatable, with a good prognosis. Consistently good results have been obtained by many different surgeons with unilateral cricoarytenoid laryngoplasty or other forms of unilateral arytenoid lateralization. Familiarity with the laryngeal anatomy and the procedure is essential to a successful surgery. I recommend the unilateral cricoarytenoid laryngoplasty or other form of arytenoid lateralization because it achieves the goals of surgery in treating laryngeal paralysis, by relieving the respiratory distress, stridor, and exercise intolerance with a minimum of complications.

Editor's Note: Recent studies seem to confirm that dogs with laryngeal paralysis likely have a polyneuropathy. See references 24 and 25.

Chapter 26

Trachea

Treatment of Tracheal Collapse: Ring Prosthesis Technique

H. Phil Hobson

Introduction

The normal trachea is a dynamic organ composed of multiple hyaline cartilaginous rings, joined together laterally by fibroelastic annular ligaments, and across the tips of the cartilaginous rings dorsally by the tracheal membrane consisting of the trachealis muscle covered medially by ciliated epithelial mucosa. The fibroelastic annular ligaments allow for tracheal movement in any direction, whereas the trachealis muscle allows for expansion and contraction of the circumference and thus the diameter of the trachea and the volume of air that can move along the airway. Classic tracheal collapse occurs in a dorsoventral direction and results in patient symptoms varying in degree of severity from mild cough to total respiratory collapse. The canine patient is usually a middle-aged toy breed, but the age may vary, in my experience, from less than 1 year to 16 years of age.

Pathophysiology

The cause of tracheal collapse is unknown, but it is generally thought to be a congenitally predisposed, probably inherited, condition. Respiratory allergies and irritants (particularly tobacco smoke), obesity, chronic infections, trauma from collars, and endotracheal tube placement from general anesthesia have been reported to exacerbate the clinical signs. Lack of adequate innervation to the trachealis muscle is considered to be a possible cause. In a few cases, Dallman demonstrated an irregular hypocellular condition of the cartilage rings with less calcium and chondroitin sulfate present than normal. In some cases, the tracheal cartilage is softer than normal, with considerable loss of rigidity. However, occasionally the cartilage is more rigid than normal, resulting in difficulty in recontouring the cartilage during prosthetic ring placement. The cartilage rings may also be shorter than normal, especially at the thoracic inlet.

With disease chronicity, the ends of the tracheal rings become progressively further apart (Figure 26-1), allowing the tracheal membrane to sag into the tracheal lumen. Resonant vibration of the redundant tracheal membrane results in the classic honking cough. Increased negative pressure within the tracheal lumen during inspiration collapses the cervical trachea further and may balloon the thoracic trachea. Expiration results in collapse of the thoracic trachea and ballooning of the cervical trachea. Narrowing of the entire airway results in either event, especially on inhalation.

Tracheal collapse may extend into the mainstem bronchi, especially the left bronchus. Bronchial collapse may be accentuated because of compression by an enlarged left atrium. Heart

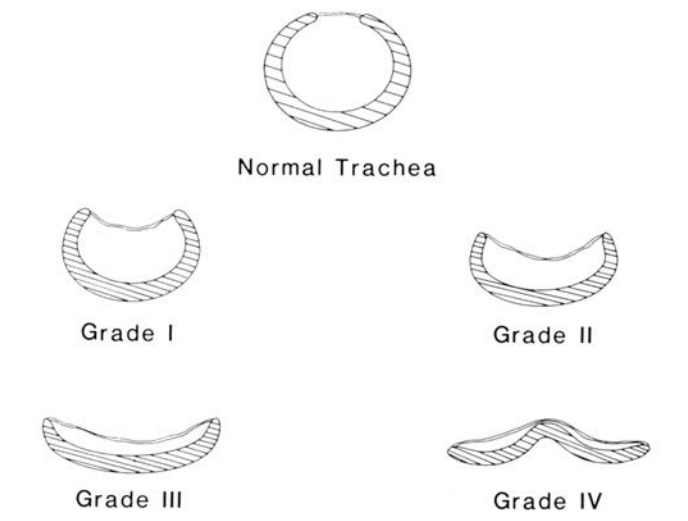

Figure 26-1. Classification of collapsed trachea. Grade I: The trachea is nearly normal. The trachealis muscle is slightly pendulous, and the tracheal cartilages maintain a circular shape. The tracheal lumen is reduced by approximately 25%. Grade II: The trachealis muscle is widened and pendulous. The tracheal cartilages are partially flattened, and the tracheal lumen is reduced by approximately 50%. Grade III: The trachealis muscle is almost in contact with the dorsal surface of the tracheal cartilages. The tracheal cartilages are nearly flat, and the ends may be palpated on physical examination. The tracheal lumen is reduced by approximately 75%. Grade IV: The trachealis muscle is lying on the dorsal surface of the tracheal cartilages. The tracheal cartilages are flattened and may invert dorsally. The tracheal lumen is essentially obliterated. (From Tangner CH, Hobson HP. A retrospective study of 20 surgically managed cases of collapsed trachea. Vet Surg 1982; 11:146.)

enlargement, especially right ventricular hypertrophy, secondary to chronic airway disease is common. Tracheal mucosal erosion or metaplasia may be seen as a result of chronic inflammation as well as from alveolar emphysema and mineralization.

Lateral collapse of the trachea or ventral collapse with minimal widening of the dorsal membrane associated with loss of cartilage rigidity is seen infrequently. Collapse caused by pressure from external masses is rare. Laryngeal function may be less than optimal.

Recently, the not infrequent occurrence of collapsed tracheas in miniature horses suggests to the author that there may be an association with the gene/s responsible for "dwarfism"/miniaturization, and bears further study.

Diagnosis

A presumptive diagnosis is often made on the presentation of a toy breed dog exhibiting a honking cough, with a history of chronic respiratory infections. Yorkshire Terriers, toy poodles, Pomeranians, Chihuahuas, and Maltese are most commonly affected. The condition has been seen rarely in mixed or larger breeds of dogs, cats, and miniature horses. The disorder has no sex predilection.

Most patients, probably those with a grade I collapse, respond to medical therapy consisting of antibiotics, cough suppressants, and corticosteroids, perhaps including bronchodilators and atropine, and these animals are not considered surgical candidates. Patients that fail to respond to conservative therapy should be evaluated thoroughly.

Collapsed tracheas can often be palpated readily in the dog with a long, thin neck, but palpation is difficult in the obese dog with a short, stocky neck. Lateral radiographs, although helpful, may yield false-negative results from ballooning of the trachea or false-positive results because of the esophagus and other tissues overlying the trachea. In the awake patient, fluoroscopic examination of the trachea provides the best evaluation of the airway, including the mainstem bronchi. However, I have seen a false-negative result. Patients in respiratory distress must be handled with care, with oxygen administered as needed. Diagnostic procedures can be life-threatening to the respiratory compromised patient.

Undoubtedly, the best evaluation of the trachea is accomplished by direct visualization, tracheoscopically. This evaluation requires general anesthesia and should be performed on those patients whose owners have agreed to allow surgical treatment if recommended or whose owners are available for consultation while the patients are still under anesthesia. Recovery of patients with severe collapse from anesthesia may be difficult, if surgical treatment is not performed.

Preoperative Considerations

The client should be well informed of the prognosis and possible complications at the outset. Dogs with less than a 50% collapse of the trachea are not considered surgical candidates. The clinical signs are not usually a result of inadequate airway diameter and are better managed medically. Early surgical intervention undoubtedly has advantages, but the degree of collapse may remain static in many patients over a prolonged period.

Periodic reevaluation is considered the best approach for these patients. Patients with a 50% or greater collapse of the trachea are likely to experience respiratory distress, especially during times of excitement, when oxygen demands are high or when respiratory infections are present. These patients are considered far less likely to respond to, or already have not responded to, conservative therapy, and thus surgery should be considered.

Postoperative infection with swelling of the mucosal lining, dorsal membrane, and surrounding tissue is always of concern, because the sutures used in prosthetic implant placement are likely to penetrate the unsterile lumen of the trachea. If infections are to occur, they are most likely during the first 2 weeks after the operation. Abscessation around a prosthetic ring when antibiotics are administered is rare. The mortality rate associated with surgery is in the range of 3% to 5% and is likely to be associated with impairment of air movement during the postsurgical recovery period.

The greatest concern during the surgery is injury to the recurrent laryngeal nerves with resulting laryngeal paralysis. The nerves lie in close approximation to the dorsal lateral aspect of the trachea just caudal to the larynx, to a more ventral medial position at the

thoracic inlet. The nerves are 1 mm or less in diameter in the toy breeds of dogs and are subject to injury during dissection of the trachea, tissue handling, prosthetic ring placement, or possibly even from the prosthetic ring itself if not placed properly.

Owners should be alerted to the potential need to perform a tracheostomy or laryngoplasty should laryngeal paralysis result. The patient's laryngeal function should be checked before leaving the operating room, and a tracheostomy should be performed if needed. A permanent tracheostomy is considered preferable by the author to laryngeal tie-backs or arytenoid cartilage resection in toy breeds of dogs with laryngeal paralysis.

Laryngeal function should be evaluated while the patient is under a light plane of anesthesia as part of the preoperative examination. Drugs with analgesic properties administered as preanesthetic agents make evaluation of laryngeal function on stimulation of the larynx more difficult and should be avoided when possible. Respiratory stimulants such as doxapram (0.5 to 1.0 mg/kg IV) may be of value in assessing the larynx for normal function. Aerobic cultures should be taken directly from the trachea, avoiding the pharyngeal area. Tracheoscopy should follow, with the patient under a surgical plane of anesthesia. Oxygen can be administered directly through the bronchoscope. Brush biopsies for cytologic evaluation should be taken of the caudal trachea at the completion of the visual examination. With proper preparation, the examination, culture, and biopsy can be completed expeditiously, thus keeping the use of intravenous anesthetic induction agents to a minimum.

Radiographs of the lungs should follow, with the intubated patient under general gaseous anesthesia. Compression of the rebreathing bag provides for deep inspiratory radiographs to be made and thus for optimal evaluation of the lungs by the radiologist. Most concurrent lung disease can be ruled in or out by these techniques. The final decision whether or not to proceed with surgery is made at this time.

When surgical treatment is to follow, antibiotics should be administered parenterally A broad-spectrum bactericidal antibiotic such as enrofloxacin that is effective against gram-negative organisms, should be used until the results of tracheal culture and sensitivity testing are available. The appropriate antibiotic should be continued for 2 weeks postoperatively.

Surgical Management

Various, surgical techniques have been proposed to treat tracheal collapse. Everting plication of the dorsal tracheal membrane has been effective in moderately affected animals with rigid cartilage rings. Chondrotomy of the ventral aspect of every other tracheal ring has also been effective in some moderately affected patients with rigid cartilage rings. Resection and anastomosis are effective when few rings are collapsed, usually by trauma. Intraluminal prosthetic dilators have been useful for the short term, but they can erode the tracheal wall, stimulate granuloma formation, or interfere with mucus clearance over the longer term. Intraluminal stents have been used and may prove very effective in the future, especially when tracheal collapse is primarily within the thorax and for collapsing principal bronchi. Problems experienced with intraluminal stents include collapse when subjected to too much flexion, failure to anchor well resulting in expulsion when coughing occurs, pulmonary edema, availability of inappropriate sizes, and uneven contact between the stent and the airway wall. Granulation tissue proliferation caused by stents may result in intraluminal obstruction.

Currently, the surgical techniques most universally accepted are those that support the trachea, including the dorsal tracheal membrane, with extraluminal prosthetic devices to which the trachea is sutured. Earlier use of long sections of extraluminal prosthetic devices restricted needed flexion of the trachea, and shorter sections applied only to the ventral aspect of the trachea failed to support the sagging dorsal membrane. Current prosthetic devices provide that support. Support is reinforced by connective tissue proliferation around the prosthesis and through the holes in the prosthesis when individual ring prostheses are used. The individual ring technique consists of the placement of four to seven individual prosthetic rings around the trachea with spacing between the rings, whereas the spiral technique is essentially a continuous spiral prosthesis.

Total Ring Prosthesis

Prosthetic rings are made from 3-mL polypropylene syringe cases by cutting the syringe case into 7-to 10-mm sections with a pipe cutter over a wood dowel rod or by sawing the syringe case into sections and drilling approximately 3-mm diameter holes with either a hand drill or with a No. 11 Bard-Parker scalpel blade, or a leather punch can be used. Five holes are usually drilled, with the syringe case ring cut at the location of the sixth equally spaced hole. Angled serrated wire-cutting scissors work well for cutting the ring to decrease its size if necessary and facilitate placement of the ring around the trachea. The ends of the ring are rounded and smoothed, as are the edges of the ring and the edges of the holes, to minimize irritation after placement. The polypropylene rings can be autoclaved or sterilized by other methods. The rings can be made larger if necessary by simply spreading the ends of the rings before suturing them to the trachea. Conversely, they can be made smaller by trimming the ends of the rings, squeezing the rings, and placing a figure-of-eight suture across the cut ends of the rings through the adjacent holes after placement, but before suturing to the trachea. Polypropylene rings may break if too much pressure is applied in either expansion or compression during alteration for size and contour at the time of surgery.

The patient is positioned in dorsal recumbency with the forelegs secured caudally. A towel roll is positioned under the neck near the shoulders. A ventral midline incision is made from the larynx to just caudal to the manubrium (Figure 26-2). The sternohyoideus and sternocephalicus muscles are separated to expose the trachea; the surgeon should avoid the thyroid vein as much as possible. The thyroid vein lies between the sternocephalicus muscles in fascia on the ventral surface of the trachea. The trachea is surrounded by loose areolar tissue and receives its primary blood supply segmentally from the thyroid arteries and its nerve supply segmentally from the recurrent laryngeal nerves. Preservation of as much of the blood supply and innervation to the trachea as possible is desirable. The recurrent laryngeal

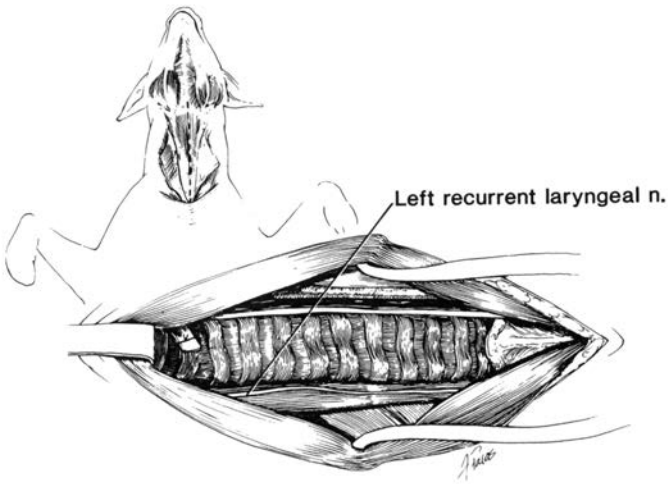

Figure 26-2. Ventral cervical midline approach to the cervical trachea. The skin incision extends from the larynx to the manubrium.

nerves lie in close approximation to the dorsal lateral aspect of the trachea near the larynx coursing more ventral medially as the thoracic inlet is approached. These nerves must be handled carefully during dissection and ring placement. No tissue should be cut without knowing that the nerves are protected. The nerves should be retracted gently by grasping adjacent tissue, not the nerve itself, during dissection.

Curved hemostats are used to bluntly dissect a tunnel dorsally around the trachea (Figure 26-3). Care is taken to dissect between the recurrent laryngeal nerves and the trachea and to gently support the nerves as one end of the ring is grasped with the tip of the curved hemostat and gently delivered through the tunnel around the trachea. The cut end of the ring is positioned ventrally. The prosthetic ring is sutured in place with 3-0 or 4-0 polydioxanone sutures passed around a tracheal ring, up through a hole in the prosthesis, and tied. The prosthesis is grasped with forceps, and the trachea is rotated in either direction to facilitate placement of the more dorsal sutures, including at least one in the dorsal tracheal membrane.

In the occasional severe case, multiple small chondrotomies must be made through the rigid cartilage to facilitate recontouring the tracheal rings to the prostheses. These tracheal cartilages may be in the shape of an opened W. Care should be exercised to cut only the cartilage and not the tracheal mucosa.

Placement of the rings is begun just caudal to the larynx and is continued caudally with approximately the width of the prosthetic ring left between each ring placed. The neurovascular supply to the trachea is carefully left intact between the rings. Movement of the endotracheal tube during surgery is essential to prevent suture from passing through the cuff of the endotracheal tube. In addition, movement of the endotracheal tube is performed after each prosthetic ring is sutured into place to prevent inadvertent suturing of the endotracheal tube to the trachea.

Rings can be placed around the trachea deep within the thoracic inlet by gentle but strong rostral traction on the trachea. This is facilitated by grasping a distal prosthetic ring that has been

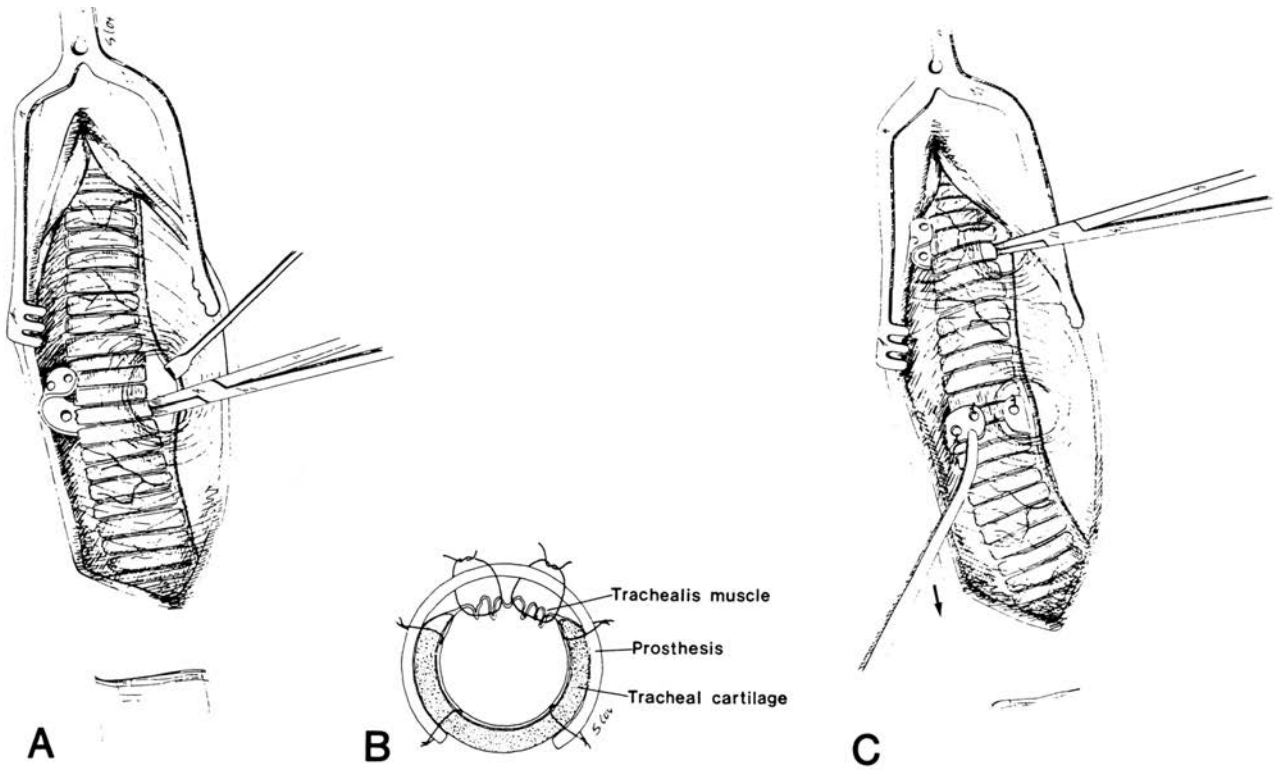

Figure 26-3. Implantation of total ring prosthesis. **A**. A small section of trachea is isolated by blunt dissection with a curved hemostat. The hemostat is then used to direct the prosthesis around the trachea. The recurrent laryngeal nerves are carefully retracted. **B.** Suture placement. **C.** Cranial retraction on the cervical trachea facilitates placement of total ring prostheses to the thoracic inlet portion of the trachea. (From Walker TL, Hobson HP. Tracheal collapse. In: Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

sutured to the trachea (See Figure 26-3). Lateral ventra retraction of the tissue from the trachea at the thoracic inlet, including the recurrent laryngeal nerves, vagosympathetic trunk, and carotid arteries, aids in placement of these rings. With some effort, these rings can be placed far enough into the thoracic inlet that, when the patient is standing in a normal upright position after surgery, the caudal prosthetic ring will be located at the second intercostal space.

Severe tracheal collapse within the thoracic cavity can be approached, preferably through a right third intercostal space, for further ring placement. This is rarely done, however, because only about one additional ring can be applied rostral to the carina. No external support can be applied to a collapsed principal bronchus. When the rings can be placed as far caudally as the second intercostal space, even in patients with severe intrathoracic tracheal collapse, inspiratory efforts should result in adequate air movement to maintain normal oxygenation as the thoracic airways balloon on inspiration. The patient, however, may still cough, even to the point of exhibiting the honking cough, and is predisposed to infections and secondary changes because of the narrow airway.

Postoperative Considerations

Laryngeal function is of prime concern. It is usually evaluated before removal of the patient from the operating room. A tracheostomy is performed if deemed necessary.

Most patients do not require further surgery, nor do they require postoperative oxygen. Most are recovered in the postoperative recovery room. Analgesics are administered as indicated. Prednisolone is often given at the end of the operation to minimize effects of irritation to the airway and the recurrent laryngeal nerves. Appropriate antibiotics are continued for 2 weeks postoperatively. Antitussives and bronchial dilators are given rarely, but they are administered if deemed necessary. Any concurrent medical problems are treated as indicated because many of these patients are older dogs with other maladies.

Editor's Note: Dr. Hobson has likely performed more tracheal ring prosthetic placements than any surgeon in the world. The surgery described here continues to be regarded as extremely valuable in the management of tracheal collapse. Some surgeons elect to place extraluminal prosthetic rings on the cervical trachea and place intraluminal stents within the thoracic trachea when indicated.

When laryngeal paralysis occurs following surgery, arytenoid tie-backs are preferred by most surgeons as the treatment of choice for the condition.

Prosthetic rings manufactured by New Generation Devices, Glen Rock, NJ, www.newgenerationdevices.com are thinner and more easily placed around the trachea than those made from syringe cases however they are more costly. The rings are currently available in 4 different diameters.

Intra-Luminal Tracheal Stenting

Chick Weisse

Introduction

Tracheal collapse is a progressive, degenerative disease of the cartilage rings of predominantly older small and toy-breed dogs in which hypocellularity and decreased glycosaminoglycan and calcium contents lead to dynamic airway collapse during respiration. Affected animals present with signs ranging from a mild, intermittent "honking" cough to severe respiratory distress from dynamic upper-airway obstruction. Various combinations of anti-inflammatories, anti-tussives, sedatives/tranquilizers, and/or bronchodilators are typically effective in alleviating the initial respiratory problems associated with tracheal collapse. In addition, weight loss, restricted exercise, and removal of

second-hand smoke or inhaled allergens can further palliate clinical signs. Careful, regular monitoring of co-morbidities such as cardiac disease or pulmonary disease may help reduce the incidence of respiratory crisis episodes. Those patients that have failed aggressive medical and environmental management, and have had other potential causes of respiratory disease either treated or ruled out, become candidates for surgical or interventional treatment.

The most commonly performed surgery for animals with extra-thoracic tracheal collapse is the placement of extra-luminal ring prostheses. Using a ventral midline cervical approach, extra-luminal support rings are carefully placed around the trachea. This technique has a reported 75% to 85% overall success rate in one report of 90 dogs for reducing clinical signs, however there is significant associated morbidity.[1] In the same study, 5% of animals died peri-operatively, 11% developed laryngeal paralysis from the surgery, 19% required permanent tracheostomies (half within 24 hours), and ~23% died of respiratory problems with a median survival of 25 months. In addition, only 11% of the dogs in this study had intra-thoracic tracheal collapse (all dogs had extra-thoracic tracheal collapse) and the authors advised against this technique in patients with intra-thoracic tracheal collapse as the resulting morbidity was unacceptably high.

The combination of surgical risk and the inability to adequately treat intra-thoracic tracheal collapse led to the evaluation of minimally-invasive surgical techniques used in humans for potential treatment options. Interventional radiology involves the use of contemporary imaging modalities such as fluoroscopy to gain access to different structures in order to deliver materials for therapeutic purposes. Specially designed intra-luminal metallic stents have been placed within the human tracheobronchial system using these techniques to treat chondromalacia, malignant obstruction, or strictures and stenoses. A number of stents have been previously evaluated in the canine trachea, including both balloon-expandable stents (Palmaz) and self-expanding (Stainless steel, Laser-cut nitinol, Knitted nitinol) stents.[2-4] The vastly superior flexibility makes the use of self-expanding metallic stents (SEMS) particularly appealing for tracheal use. Clinical improvement rates in 75% to 90% of animals treated with intra-luminal SEMS have been reported.[3,4] Immediate complications were typically minor although there was a reported peri-operative mortality rate of approximately 10%, a rather high figure compared to the author's experience. Late complications included stent shortening, excessive granulation tissue forming within the trachea, progressive tracheal collapse, and stent fracture.

Neither surgery nor stenting are cures for tracheal collapse, and to the author's knowledge, neither has been shown to slow the progression of the disease. When used appropriately in the proper patients, both can significantly improve the patients' quality of life when medications alone are no longer adequate. Below are this author's criteria for patient selection, method of stent selection, and technique for placing intra-luminal tracheal stents. It should be noted that the majority of the following information is based solely on experience as veterinary research on this subject is currently in its infancy.

Patient Selection

The diagnosis of tracheal collapse and other forms of respiratory dysfunction have been described elsewhere. The readers are referred to other materials for a complete discussion of respiratory system evaluation and related diagnostic procedures. Due to the relatively high morbidity and mortality rates associated with surgery or stenting of the trachea, these procedures are avoided when possible. Other primary or secondary respiratory disorders must be evaluated concurrently or addressed prior to more invasive therapies for tracheal collapse. Animals with concurrent cardiac and/or pulmonary disease can often benefit substantially from medical treatment such that more invasive tracheal collapse treatments can be avoided or postponed.

Whether considering surgical rings or intra-luminal stenting it is imperative that aggressive medical management has been attempted and has failed to provide a "reasonable quality of life" for the patient. In the author's opinion, this includes anti-inflammatory doses of corticosteroids, anti-tussives, and the general management considerations described above. An exception to this rule is the emergent, intubated patient which has failed attempts at extubation. An owner's inability to administer medication is not a valid reason to perform one of these invasive procedures as the majority of patients will still require medication following treatment. In addition, while the "grade" of tracheal collapse (Grades I, II, III, or IV) has been described in the literature, the author will not treat based upon the grade of collapse alone. The success of either of these procedures must be evaluated in light of the owners' expectations. It is the veterinarian's responsibility to properly inform the owner that these are largely palliative procedures and the disease is likely to progress.

Rings or Stent?

Whether to perform surgery versus stenting is a complex, controversial and unresolved question. Decisions must be made on an individual case basis, however some basic guidelines can be used. In my opinion, if significant intra-thoracic tracheal collapse is present then surgery is either unlikely to resolve the problem or be associated with excessive morbidity and therefore an intra-luminal stent should be considered. If only cervical tracheal collapse is present, then extra-luminal surgical rings may be considered. An exception may be in a geriatric patient or one with excessive co-morbidities (extensive cardiac or pulmonary disease, endocrinopathies, etc.) in which prolonged anesthesia or healing associated with surgery may present more of a concern. In addition, the author would prefer to avoid intra-luminal stent placement in younger animals as long-term follow-up (> 5 years) in tracheal stented animals has not yet been performed.

The patient with diffuse cervical and intra-thoracic tracheal collapse is an even greater dilemma. One can argue that an intra-luminal stent for the intra-thoracic collapse and surgical rings for cervical collapse might avoid some of the potential complications associated with very long tracheal stents spanning the thoracic inlet, however the alternative view would be that this approach would combine the potential complications associated

with both procedures. In these cases, the author is currently placing a single, long stent to span both the intra- and extra-thoracic trachea. Others are placing stents intra-thoracically and surgical rings on the cervical trachea.[5]

Bronchial Collapse

There remains much debate concerning the use of intra-luminal stents in patients with mainstem bronchial collapse. Unfortunately, there is currently no data available to recommend or oppose the routine use of intra-luminal stents in these patients, and therefore, regrettably, the author can only offer an opinion. The questions raised are two-fold:

(1) *Should stents be placed within collapsing mainstem bronchi?* I do not recommend stenting of collapsing mainstem bronchi. Not only will bronchial stents "cage-off" other bronchi and consequently prevent drainage from affected lung lobes, but secondary and tertiary bronchi will continue to collapse and therefore the benefit achieved will likely be minimal, and temporary, when compared to the risks. Theoretically, there may be animals in which focal mainstem bronchial collapse has been diagnosed in which placement of short bronchial stents could provide some benefit.

(2) *Should tracheal stents be placed in patients with concurrent tracheal and mainstem bronchial collapse?* Certain patients will benefit from tracheal stenting, even when concurrent mainstem bronchial collapse is present. The patient should be carefully evaluated to determine the animal's primary clinical signs. Tracheal collapse can lead to dyspnea, coughing/honking, or both. Bronchial collapse will usually manifest as a cough, expiratory dyspnea, or both. When both tracheal and bronchial collapse are present, the results following tracheal stent placement become less predictable. If dyspnea is the major clinical sign and intra-thoracic tracheal collapse is present, a tracheal stent can help relieve the dynamic obstruction. If the patient's primary problem is coughing, then it becomes difficult to determine if the coughing is secondary to the tracheal collapse or bronchial collapse. In these patients, the author always warns the owner that continued coughing will likely be present as the bronchial collapse will continue. In addition, in the author's experience, it appears that continued, intractable coughing will cause repeated cycling of the stent and may increase the risk of subsequent fracture, or predispose to the formation of excessive granulation tissue. Persistent coughing must be treated aggressively to minimize the risk of these complications.

Expectations/Risks/Discussion with the Owner

An in-depth discussion with the owner concerning the risks and expectations should take place once the decision has been made to consider tracheal stenting. Neither surgery nor stenting has been demonstrated to slow the progression of tracheal collapse and both techniques are considered palliative. Clinical improvement rates in 75% to 90% of animals treated with intra-luminal SEMS have been reported, and immediate complications were mostly minor although there was a peri-operative mortality rate of approximately 10% in one report.[3,4] Late complications can include stent shortening, excessive granulation tissue, progressive tracheal collapse, and stent fracture. Continued coughing should be anticipated in patients with concurrent bronchial collapse and these patients may have a worse prognosis. In addition, the vast majority of patients will require continued medical therapy.

Stent Selection

A general review of stents is beyond the scope of this chapter, but a brief discussion of certain stent characteristics is necessary to understand how one selects an appropriate stent type and size. This discussion will not include balloon-expandable metallic stents (BEMS) as SEMS are exclusively being used to treat tracheal collapse in animals. In their resting state (deployed, or outside of the delivery system), SEMS are expanded to their stated, pre-determined dimensions. For example, a 10 mm diameter x 70 mm long SEMS will be 10 mm wide and 70 mm long if deployed from the delivery system. Following manufacturing, an SEMS is compressed and mounted onto a delivery system using a number of different techniques. The relatively small delivery system (compared to the expanded stent diameter) allows introduction through very small holes (vascular sheath or endotracheal tubes, for instance). During placement, as the delivery system sheath is retracted, the stent expands back to its original dimensions.

Stent Material

The majority of stents being manufactured today are made of nitinol, a nickel ("Ni")-titanium ("Ti") alloy developed by the Naval Ordinance Laboratory ("NOL") which is classified as a shape-memory metal. This characteristic means that nitinol assumes a weakened, deformable state (Martensite phase) at low temperatures but it will return to, and maintain, its original shape at body temperature (Austenite phase). Laser-cut nitinol stents are cut from hollow tubes of nitinol and at cooled temperatures, the metal's properties change allowing compression of the stent onto a delivery system. Upon returning to ambient temperature, the stent favors its original design which is achieved upon deployment from the delivery system. Laser-cut nitinol SEMS are currently not recommended by the author for the treatment of diffuse cervical and intra-thoracic tracheal collapse in veterinary patients due to an unacceptably high occurrence of stent fracture (personal experience). However, others have had success placing shorter laser-cut nitinol stents in the intra-thoracic trachea only.[5] Woven, knitted, or mesh stents are designed to be compressed onto a delivery system at normal temperatures through specific design modifications. While the design of these stents facilitates placement onto a delivery system, there is a wide range of foreshortening that occurs from the design changes as well. Examples of more commonly used nitinol stents in veterinary patients currently include mesh stents (Vet Stent-Trachea, Infiniti Medical) or knitted stents (Ultraflex, Boston Scientific). Other commercially available stents used for tracheal collapse are made of stainless steel or similar alloys (Wallstent, Boston Scientific) (Figure 26-4).

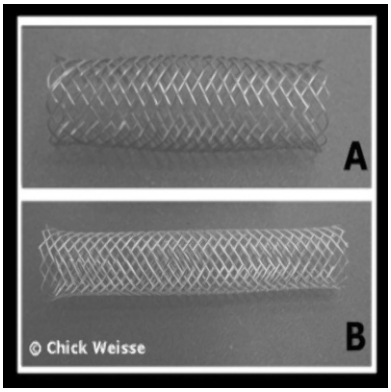

Figure 26-4. A. Mesh nitinol stent; Vet Stent – Trachea™ (Infiniti Medical). Note the rounded edges of this stent chosen to reduce potential granulation tissue development. **B.** Mesh stainless steel stent; Wallstent™ (Boston Scientific).

Foreshortening

The vast majority of tracheal stents currently placed in veterinary patients are mesh or knitted SEMS. One important characteristic of these stents which must be anticipated is the subsequent "foreshortening" that will occur during deployment. "Foreshortening" refers to the shortening of the stent that is encountered as it is released from the delivery system. The stent size, as indicated on the packaging, refers to the diameter and length at complete expansion. If the stent does not achieve complete expansion (i.e. the lumen in which it is placed prevents complete radial expansion to its original diameter), the stent will be longer than expected. In other words, the stents are significantly longer when viewed in the compressed state on the delivery system. As the stent expands radially it shortens, and as such, the ultimate length of the stent is inversely proportional to the degree of expansion (The less the stent expands, the longer it will be). This is an extremely important property of knitted and mesh stents which must be recognized and accounted for during the stent selection process. For example, the more oversized the stent chosen (diameters over 10% to 15% greater than the diameter of the trachea), the longer the stent will be when initially deployed, and the greater the tendency for the stent to shorten over time as it gradually expands to its original, predetermined diameter. This gradual shortening must be accounted for when choosing the appropriate stent length; Over-sized stents should span additional length of normal trachea beyond the area of collapse as future shortening is anticipated. In the author's experience, stent shortening typically occurs at the cranial end of the stent in a caudal direction over time, most likely due to the fact that the cervical trachea is usually larger in diameter than the intra-thoracic trachea. This difference in diameter seems to facilitate greater radial expansion of the stent in the cervical trachea. As a result, the cranial aspect of the stent slowly migrates in a caudal direction. When collapse extends to the larynx, the stent is placed to extend as far cranially as possible without contacting the cricoid cartilage. If the over-sized stent gradually shortens over time, a single extraluminal ring can be placed surgically if tracheal collapse rostral to the stent recurs and clinical signs redevelop.

Reconstrainability

While foreshortening can complicate the process of choosing the appropriate SEMS for tracheal collapse, another characteristic of some of these stents is "reconstrainability". This feature allows the operator to re-sheath a partially deployed stent in order to reposition the stent and deploy it elsewhere or remove it completely if necessary. Generally, the mesh stents (Vet Stents-Trachea™ [nitinol], Wallstents™ [Stainless steel]) are reconstrainable to varying degrees, while the knitted stents (Ultraflex™ [nitinol]) are not reconstrainable. Obviously, it is important to know beforehand whether the stent is reconstrainable. In addition, although a stent may be considered "reconstrainable", that does not mean that the stent can be removed once fully deployed. While some stents can be removed following placement, most stents currently used for tracheal collapse in veterinary patients are designed to remain in place, and as such removal would be very difficult.

Stent Sizing

In order to choose an appropriately sized stent, it is important to determine (1) the length of the collapse, and (2) the diameter of the trachea. The single most effective way to minimize peri-operative stent placement complications when learning this procedure is to appropriately determine these tracheal dimensions.

Stent Length: Simple radiography is not adequate in identifying the length of collapse as different areas of collapse will be apparent during different phases of respiration (Figure 26-5). While tracheoscopy has been historically regarded as the "gold standard" for identifying tracheal collapse, this procedure requires general anesthesia which can add significant risk in these often debilitated patients. The author prefers to identify the length of collapse in a fully awake animal using real-time fluoroscopy. In addition, it is important to induce coughing when possible as the extreme airway pressures subsequently generated will often reveal more extensive collapse than identified during more relaxed breathing (Figure 26-6). Anatomical landmarks are then identified to record the cranial-most and caudal-most extent of the collapse. In addition, mainstem bronchial collapse can often be identified during fluoroscopy and should be noted when present.

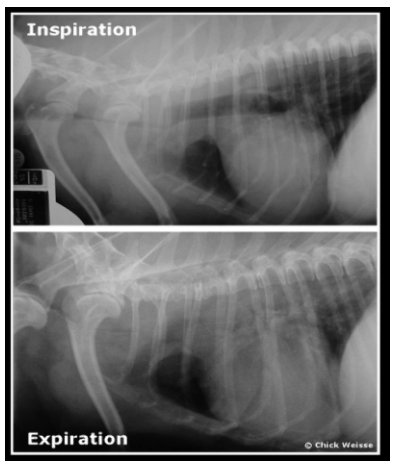

Figure 26-5. Inspiratory and expiratory lateral thoracic radiographs of a dog demonstrating cervical tracheal collapse most apparent during inspiration (top image) and intra-thoracic tracheal collapse most apparent during expiration (bottom image).

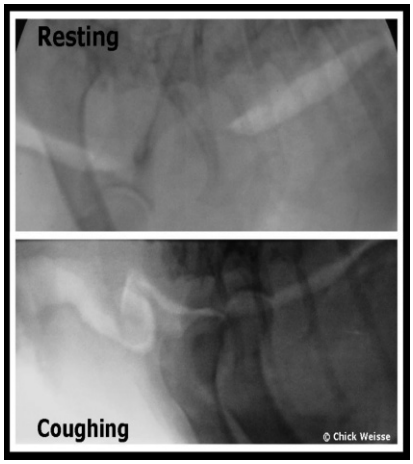

Figure 26-6. Fluoroscopic images demonstrating dramatic differences in determination of the location of tracheal collapse present during passive respiration (top image with thoracic inlet tracheal collapse) and a coughing episode (bottom image). Note the extensive collapse, and apparent folding of the caudal cervical trachea, that occurs during coughing.

On occasion, a previously well-managed patient will present that is unable to be extubated following general anesthesia for an unrelated procedure. Under these circumstances, the awake fluoroscopy technique described above will not be possible. For these rare cases, the author uses a home-made "negative-pressure ventilation device" (Figure 26-7). Following adequate pre-oxygenation with manual positive pressure ventilations, this apparatus is connected to the endotracheal tube and the dosing syringe plunger is withdrawn to 10 to 15 cm H_2O on the sphygmomanometer as a radiograph is taken to document the location of collapse (Figure 26-8).

Once the length of the collapse has been determined, the stent length is chosen to extend approximately 1 cm beyond the cranial and caudal extents of collapse. If the entire length of the trachea is affected, the stent length is usually chosen to extend from approximately 1 cm cranial to the carina to 1 cm caudal to the cricoid cartilage of the larynx. Alternatively, one could choose to place an intra-thoracic tracheal stent alone and place surgical rings on the cervical trachea.

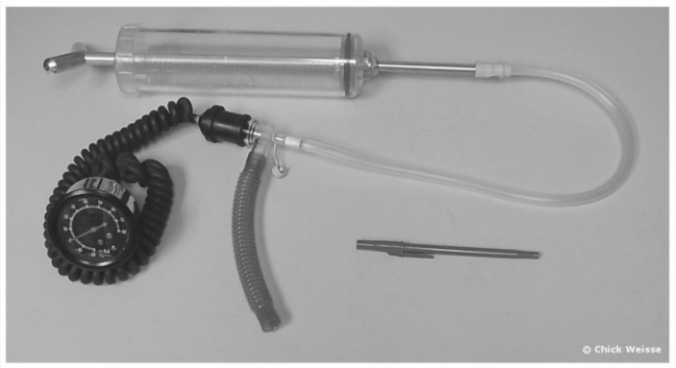

Figure 26-7. Negative pressure ventilation device that can be attached to an endotracheal tube and subsequently used to identify the location of tracheal collapse in an anesthetized animal in which awake fluoroscopy is not possible.

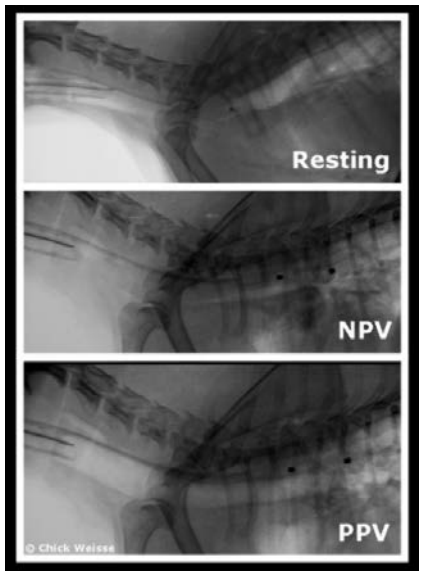

Figure 26-8. Serial fluoroscopic images of an individual dog under normal resting ventilation, negative pressure ventilation (NPV) and positive pressure ventilation (PPV). Note the extensive tracheal collapse apparent under NPV but less clear under resting respiration. Under PPV, maximal dilation of the entire trachea is apparent.

For shorter lengths of collapse, one must decide whether the animal will benefit from complete tracheal stenting versus covering just the shorter affected segment. One study identified a potential increased risk of complications in animals receiving longer Wallstents, however this finding was not corroborated in another study.[3,4] A correlation between stent length and complication rate has not yet been apparent in this author's experience and, as such, if progression of the disease is expected, the patient will generally receive stenting of the majority of the trachea. In general, the author avoids complete tracheal stenting in younger patients when possible. In older patients, or those cases in which the client can only afford a single procedure, a discussion concerning the risks and benefits of complete tracheal stenting is necessary. In general, the price of a stent is not determined by its dimensions (a 40 mm long stent is usually the same price as a 90 mm stent). Therefore, there is no financial benefit to placing a shorter stent.

Stent Diameter: The maximal tracheal diameter is typically determined at the time of stent placement to avoid having to repeat general anesthesia. It is therefore necessary to have a number of different stent sizes available. Alternatively, the stent sizing process can take place during a separate general anesthetic episode and the appropriate stent size subsequently ordered. It is the veterinarian's judgment as to whether an additional anesthetic episode places the patient at significant risk. **It is imperative that the stent diameter is not chosen based upon resting survey radiographs.** Otherwise, the stent diameter will typically be under-sized, resulting in subsequent stent migration. In addition, the author avoids using standard "magnification" values assigned to different radiographic units. These values tend to be "estimations" and are not sufficiently accurate for the fine measurements necessary in these cases.

The author places a measuring catheter within the esophagus

in order to account for radiographic magnification. Alternatively, some other measuring device can be placed externally and included in the radiograph, although placement within the esophagus is ideally located directly beside the trachea. With the esophageal marker catheter technique, the patient is placed in lateral recumbency following intubation. A wet hydrophilic guidewire[a] and flushed marker catheter[b] combination are advanced into the mouth. Using fluoroscopic guidance, the guidewire is gently advanced down the esophagus and the marker catheter is advanced over-the-wire. The soft guidewire is always advanced first to avoid damage to the esophagus by the relatively stiffer marker catheter. The marker catheter is placed within the esophagus such that the radio-opaque marks extend along the location of the tracheal collapse. The guidewire can then be withdrawn. Under fluoroscopic guidance, the endotracheal (ET) tube is withdrawn until the distal-most aspect is just beyond the larynx and the cuff is gently re-inflated. Positive pressure ventilation of 20 cm H_2O is temporarily performed to achieve maximal tracheal expansion as a radiograph is taken. The radio-opaque marks on the marker catheter are 10 mm apart; this distance is measured on the radiograph and used to determine the radiographic magnification that is then used to extrapolate the actual maximal diameters of both the intra-thoracic and cervical trachea (Figure 26-9A). It is important to take maximal measurements of BOTH the cervical and intra-thoracic trachea as these measurements can vary dramatically.

The stent diameter is usually chosen to be 10% to 20% greater than the maximal tracheal diameter to minimize chances of subsequent stent migration. The author generally inventories stents in 2 mm diameter increments (i.e., 8 mm, 10 mm, 12 mm, and 14 mm diameter) and in the most commonly used lengths. The cervical trachea is routinely larger in diameter than the intra-thoracic trachea. Stent sizing can be complicated when the difference in these two measurements varies dramatically. When the two diameters are similar (within 2 mm), the stent diameter chosen is at a minimum equal to the maximal tracheal diameter and typically no more than 10% to 20% larger than the maximal diameter.

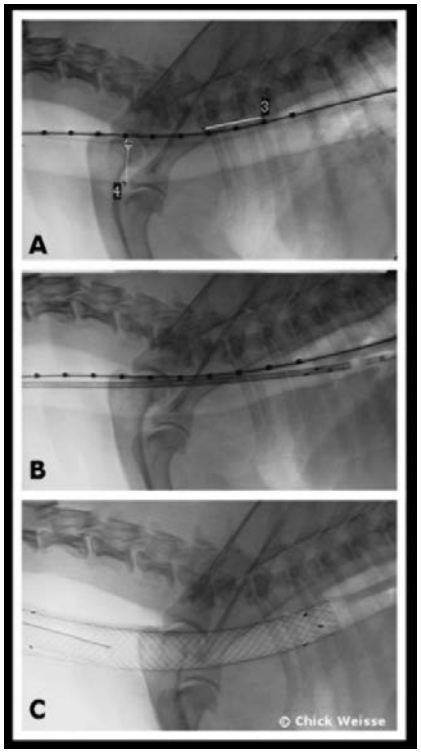

Figure 26-9. Serial fluoroscopic images during tracheal sizing and stent placement. **A.** Using PPV and an esophageal marker catheter, measurements are taken to establish the maximal tracheal diameter. **B.** The stent delivery system is advanced into the trachea. Note that the cervical and intra-thoracic trachea and in-line to facilitate atraumatic passage of the stent. **C.** Restoration of a patent trachea immediately following stent deployment.

Example 1: A dog with maximal intra-thoracic tracheal diameter of 8mm and maximal cervical tracheal diameter of 10mm would likely receive a 12 mm diameter stent. When the discrepancy between the cervical and intra-thoracic trachea is 3 mm or greater, a stent diameter that is at least 10% to 20% larger than the intra-thoracic tracheal diameter or the average of the two measurements is chosen as long as the stent will be well seated within the intra-thoracic trachea to prevent cranial migration.

Example 2: A dog with a maximal intra-thoracic tracheal diameter of 8 mm and maximal cervical tracheal diameter of 12 mm would likely receive a 12 mm (or 10 mm) diameter stent. However, one must also consider the relative length of the stent that will be located in the smaller diameter trachea. If only about 20% of the stent will be located in the 8 mm diameter portion of the trachea, adequate tracheal wall contact may not be achieved with the 10 mm stent. Alternatively, if 80% of the stent will be within the 8 mm diameter portion of the trachea, a 10 mm diameter stent may be sufficiently seated within this location to prevent migration. The advantage of the 10 mm diameter stent is that the length will be easier to determine as it will more closely achieve full expansion and therefore the length will be closer to its predetermined length.

In both examples above, if a 12 mm diameter stent was chosen, a shorter length stent would be required as the stent would not reach its full diameter and therefore the stent length would be longer than anticipated had full expansion been achieved. **These calculations are intended as guidelines and cannot be used for every case.**

Stent Placement Technique

The following description applies to placement of mesh SEMS (Vet Stents-Trachea™, Wallstents™). For information regarding placement of knitted SEMS, the readers are referred to alternate resources.

General Anesthesia and Preparation

Anesthesia protocols differ among institutions, however the author prefers a rapid induction and recovery. An anti-tussive/tranquilization combination such as butorphanol (0.2 to 0.3 mg/kg) and acepromazine (0.01 mg/kg) can be an effective premedication when necessary, however premedications are routinely avoided unless intravenous catheterization creates excessive anxiety and respiratory distress. Pre-oxygenation of the patient before handling is routinely performed. Unless contraindicated,

[a]Weasel Wire, Infiniti Medical, Haverford, PA. [b]Marker Catheter, Infiniti Medical, Haverford, PA.

a combination of intravenous propofol and diazepam are used with minimal inhalant anesthesia concentrations. Propofol CRIs are occasionally used. The use of peri-operative antibiotics is debatable and chosen on an individual case basis. Unless contraindicated, these patients typically receive one perioperative dose of dexamethasone SP (0.1 to 0.25 mg/kg IV).

The largest diameter ET tube possible should be selected (at least 4 mm inner diameter) to facilitate unrestricted passage of the stent delivery system through the tube while permitting simultaneous oxygen delivery and ventilation during the procedure. An ET tube with a radio-opaque line or markers should always be used when possible to help avoid inadvertent deployment of the stent within the tube. The use of sterile ET tubes is debatable and not routinely required by the author. Following intubation, the patient is placed in lateral recumbency. Subsequent measurements are used to determine the tracheal stent diameter as described above. The radiographic landmarks previously obtained during awake fluoroscopy identifying the length of the collapse are compared with those of the esophageal marker catheter to determine the length of stent necessary.

Stent Placement

Once the appropriately sized stent is chosen, it is removed from its packaging using sterile technique. The stent is prepared and saline flushed according to manufacturer recommendations. The operator is encouraged to practice these techniques outside of the patient before introducing the delivery system into the ET tube. **ALL MANIPULATIONS SHOULD BE PERFORMED UNDER DIRECT FLUORSCOPIC GUIDANCE.** A right-angle bronchoscope adapter (Figure 26-10) is attached to the ET tube to facilitate passage of the stent delivery system through the tube while maintaining the anesthesia circuit system. The delivery system must pass easily and without friction. Occasionally it is necessary to remove the diaphragm on the bronchoscope adapter to permit unrestricted passage of the delivery system. Before passing the stent, the patient should be positioned such that the cervical and intrathoracic trachea lie in a straight line to facilitate unrestricted passage of the relatively inflexible delivery system (Figure 26-9B). This position will minimize trauma to the tracheal wall during advancement of the delivery system. The author always places tracheal stents under fluoroscopic guidance although some have performed these techniques using endoscopic assistance alone. In addition, passage of the delivery system and stent placement can induce a coughing reflex. The animal should be sufficiently anesthetized to avoid a coughing episode during stent deployment.

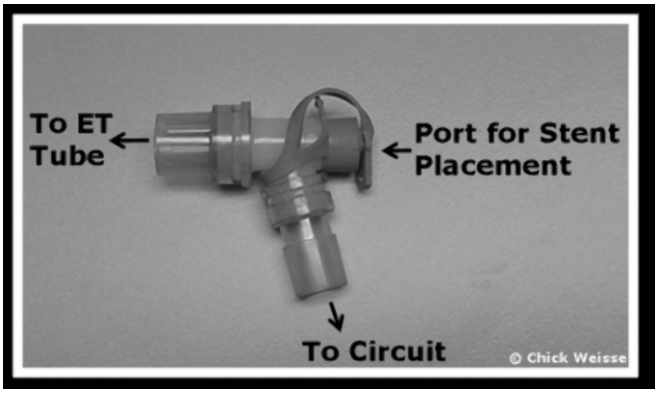

Figure 26-10. Bronchoscope adapter used to maintain a complete anesthesia circuit while passing the stent delivery system through the bronchoscope opening and down the endotracheal tube.

The radio-opaque stent is easily visualized under fluoroscopy, even when constrained within the delivery system. Once the distal end of the stent has been positioned appropriately, stent deployment can proceed. During deployment, the entire stent and delivery system combination can be gently pulled craniad if the stent is initially placed too caudally, however the entire system cannot be advanced caudally if placement is inappropriately cranial. For this reason, some prefer initially to place the distal aspect of the stent slightly (~0.5 to 1cm) caudal to the desired final location. To initiate stent deployment, with one hand on the hub (or the cannula), and the other hand on the Y-piece (sheath), gently withdraw the Y-piece (sheath) while simultaneously advancing the hub (cannula) in equal proportions (Figure 26-11). If done appropriately, as stent deployment proceeds, the distal end of the stent will remain in the same location throughout deployment. Under no circumstances should the cannula (hub) be advanced while the sheath remains stationary. This will force the stent caudally and traumatize the tracheal mucosa. These same circumstances apply to the process of stent reconstrainment. If the operator is unhappy with the location of the partially deployed stent, reconstrainment should be performed via simultaneous withdrawal of the cannula and advancement of the sheath in order to avoid dragging the stent across the tracheal mucosa. The operator should read the manufacturer's instructions to determine the degree to which stent deployment can occur before stent reconstrainment is no longer possible.

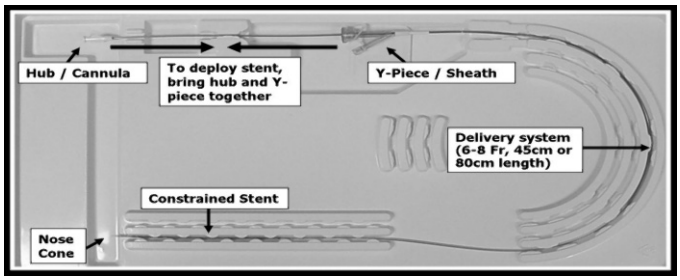

Figure 26-11. Tracheal stent mounted on delivery system within packaging.

Following complete stent deployment, carefully remove the delivery system. This should be performed under fluoroscopic guidance to ensure the delivery system nose-cone does not engage the distal end of the stent upon removal. Radiographs are taken to document the final position of the stent within the trachea (Figure 26-9C). The patient is recovered immediately, typically in an intensive care unit setting, and often within an oxygen cage. The use of butorphanol (0.1 to 0.2 mg/kg IV) and/or acepromazine (0.005 to 0.01 mg/kg IV) can be useful to facilitate smooth recovery from general anesthesia.

Post-Operative Care and Follow-Up

Patients are routinely discharged one or two days post-stenting with a 3 to 6 week tapering dose of prednisone (initial dose of 1 to 2 mg/kg/day PO), continued anti-tussive therapy (Hydrocodone 0.25 mg/kg PO q6 to 12 hours or higher doses if tolerated), and 10 to 14 days of broad-spectrum oral antibiotics. Patients with bronchial collapse and/or an observed "expiratory push" during exhalation may benefit from bronchodilator therapy as well.

Owners should be warned to anticipate an initial dry cough that should improve over the following 3 to 4 weeks. If the patient has documented bronchial collapse, the owners should expect continued coughing in the future. Aggressive medical management of coughing is imperative for a good long-term outcome. It is the author's anecdotal experience that continued coughing increases the risk of both granulation tissue formation and stent fatigue/fracture. High doses of anti-tussive medications and inhalation steroids have been useful when routine therapy is inadequate. The majority of patients will require life-long medication following tracheal stenting. The initial recheck examination is approximately two weeks post-stenting or sooner if problems arise. Repeat examinations are performed regularly (every 3 to 6 months if possible) or sooner if the patient's clinical signs worsen.

Disclosure: The author is a consultant for Infiniti Medical, LLC and has been involved in the specifications chosen for the Vet Stent-TracheaTM and Delivery System.

Tracheal Resection and Anastomosis

Roger B. Fingland

Tracheal anastomosis is indicated for management of benign and malignant tracheal stenoses, traumatic tracheal disruption, and segmental tracheomalacia. Important preoperative considerations include localization of the lesion, determination of the proximal and distal margins of the lesion, and, in the case of malignant lesions, evaluation of the animal for distant metastases. Plain film radiography, tracheoscopy, and computed tomography are helpful in localization of tracheal lesions.

Tracheal anastomosis in veterinary patients typically is accomplished by apposition of circumferentially divided tracheal cartilages with sutures placed in simple interrupted fashion (split-ring technique).[1] Alternative techniques such as overriding segments, creation of mucosal flaps, and apposition of annular ligaments are less desirable because these techniques are technically more difficult or result in critical anastomotic stenosis.[1,2] In one study, simple continuous and simple interrupted suture techniques for tracheal anastomosis after large-segment tracheal resection were compared in dogs. Differences in surgical time and anastomotic stenosis were not clinically significant.[3]

Tension has a profound effect on anastomotic healing and is the major factor limiting the extent of tracheal resection. Tracheal anastomoses consistently are successful in mature dogs when tension on the anastomosis is less than 1750 g.[4] Unfortunately, attempts to correlate grams of tension with number of tracheal cartilages have produced widely disparate results.[5] In general, 25% of the trachea (8 to 10 tracheal cartilages) can be resected in a mature dog with consistently satisfactory results. In young animals and in animals with primary tracheal disease, this number may be significantly lower.[6]

Surgical Techniques

Cervical Trachea

Preoperative planning is imperative. An endotracheal tube with a high-volume, low-pressure cuff should be used. Ideally, the endotracheal tube should be positioned proximal to the affected tracheal segment, and the entire procedure should be performed "over" the endotracheal tube. In patients with significant luminal compromise, the endotracheal tube should be positioned distal (orad) to the lesion for the surgical approach and the initial tracheal dissection. Tracheal anastomosis necessitates intraoperative manipulation of the endotracheal tube and, on occasion, direct intubation of the distal segment of the trachea. A sterile endotracheal tube should be available for intraoperative intubation of the distal segment of the trachea. The endotracheal tube cuff must be deflated when the tube is repositioned within the trachea and then reinflated before the procedure continues. Prophylactic administration of a broad-spectrum antibiotic is recommended.

The patient is positioned in dorsal recumbency, and the ventral cervical region is prepared for aseptic surgery. The skin and subcutaneous tissues are incised from the larynx to the manubrium. The trachea is exposed by midline separation of the paired sternocephalicus and sternohyoideus muscles. The segment of trachea to be resected is determined based on preoperative evaluation and intraoperative inspection and palpation. The lateral pedicles are dissected from the trachea along a segment that includes two cartilage rings proximal and two cartilage rings distal to the proposed margins of the excision. Carrying the lateral pedicle dissection beyond the proposed margins of excision facilitates manipulation of the proximal and distal tracheal segments and placement of primary anastomotic

and tension sutures. Traction sutures (3-0 polydioxanone, SH-1 taper needle, 70 cm) are placed around the right and left lateral aspects of the second tracheal cartilage proximal to the cartilage to be incised. The swaged-on needle is left in place, and the suture is looped but not tied. These traction sutures facilitate manipulation of the proximal tracheal segment and are used as tension sutures after the primary anastomosis is completed.

The segment of trachea is excised by circumferentially incising one tracheal cartilage at each end of the segment (Figure 26-12). Care is taken to incise the tracheal cartilages circumferentially in two equal halves. If the endotracheal tube was initially positioned distal to the lesion, the cuff is deflated, the endotracheal tube is directed into the proximal tracheal segment, and the endotracheal tube cuff is reinflated. On both sides of the trachea, the swaged-on arm of the lateral traction suture is passed around the second complete tracheal cartilage distal to the incised tracheal cartilage. These sutures are used to approximate and maintain apposition of tracheal segments and to facilitate rotation of the trachea for placement of primary anastomotic sutures (Figure 26-13).

The proximal and distal circumferentially incised tracheal cartilages are approximated using the pre-placed lateral tension sutures (Figure 26-14). Accurate alignment of the two split cartilages is important. The primary anastomosis is created using 4-0 polydioxa-none suture placed in a simple interrupted pattern approximately 3 mm apart (Figure 26-15). Each suture incorporates the split proximal and distal tracheal cartilages. All sutures enter the lumen of the trachea.

The dorsal tracheal membrane is exposed by rotating the trachea with the preplaced lateral tension sutures (Figure 26-16). Anastomotic sutures are placed in the dorsal tracheal membrane in a manner that ensures accurate apposition and an airtight seal.

The lateral tension sutures are tied after the primary anastomosis is complete (Figure 26-17). A third tension suture is placed on the ventral aspect of the trachea. The tension sutures should be tight enough to relieve tension from the primary anastomotic sutures, but they should not cause deviation or overlapping of the apposed ends of the proximal and distal segments of the trachea.

Thoracic Trachea

The thoracic segment of the trachea is approached through a right third intercostal thoracotomy. The technique for resection and anastomosis of the thoracic segment is similar to the technique described for the cervical segment of the trachea. Direct intubation of the proximal segment of the trachea intraoperatively usually is necessary. Direct intubation of an isolated primary bronchus may be necessary to maintain ventilation. Preoperative planning and technical expertise are necessary to ensure success.

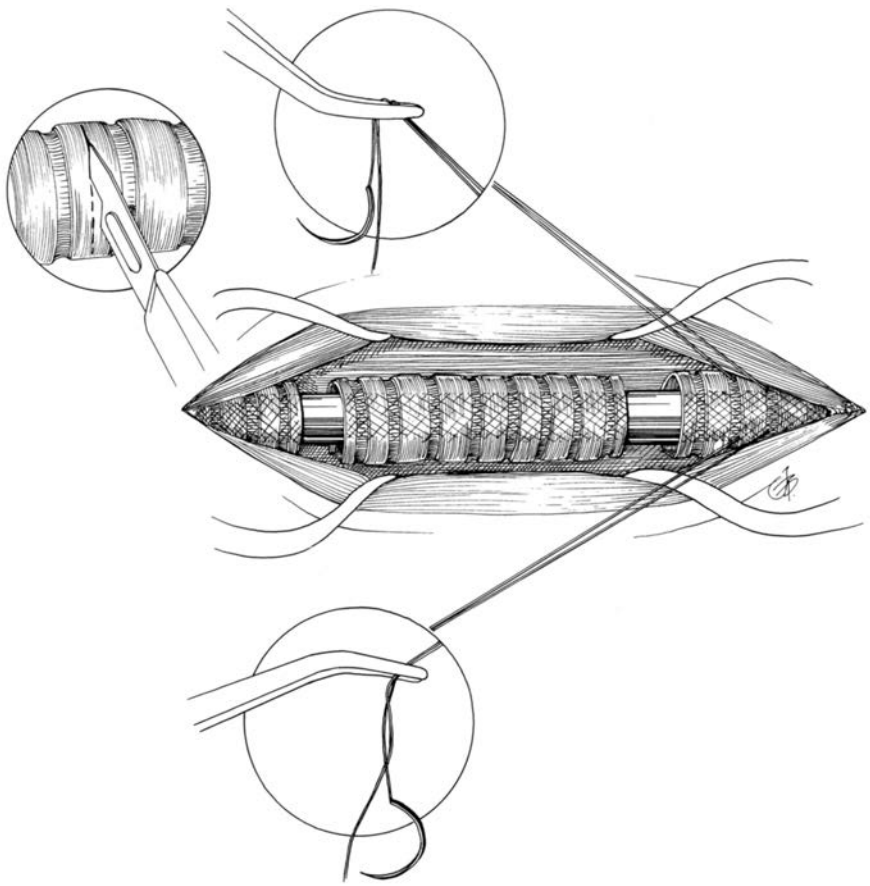

Figure 26-12. Ventral view of the exposed cervical trachea showing placement of traction sutures. The segment to be removed has been excised by circumferentially incising (*inset*) the proximal and distal tracheal cartilages.

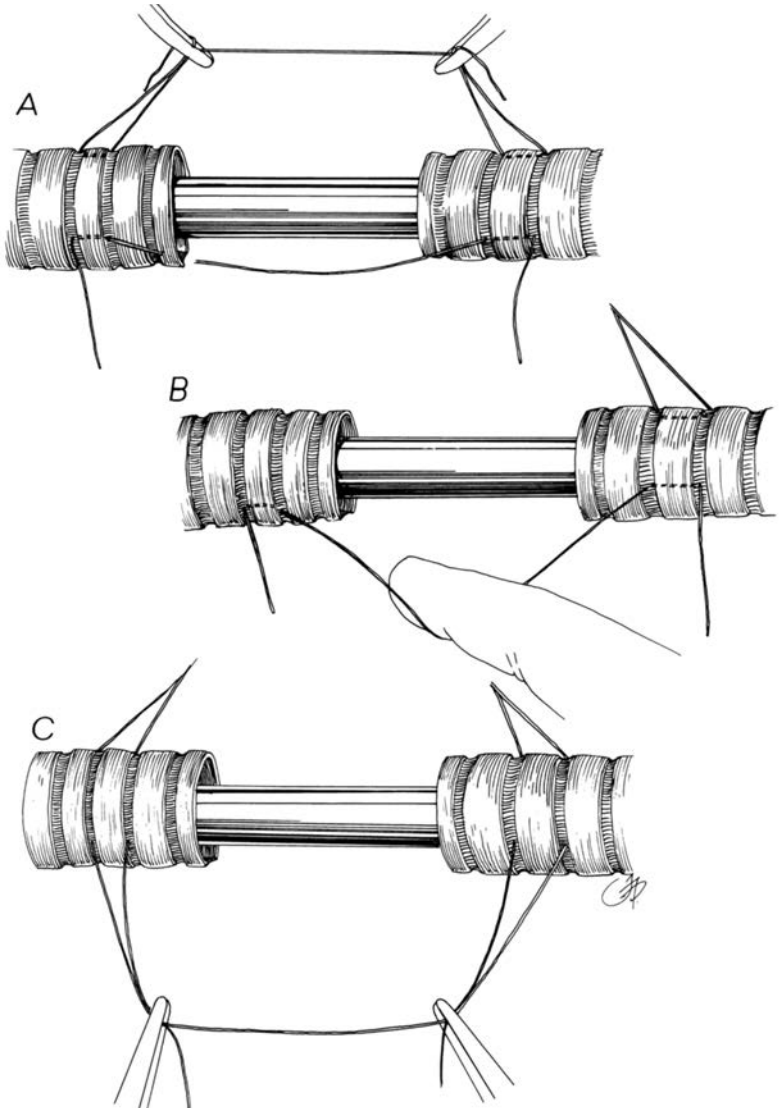

Figure 26-13. The tracheal segment has been excised. **A.** The proximal and distal segments of the trachea are joined by tension sutures. The tension sutures are drawn through the tracheal wall **B.** and are tagged to facilitate manipulation of the trachea for primary anastomosis.

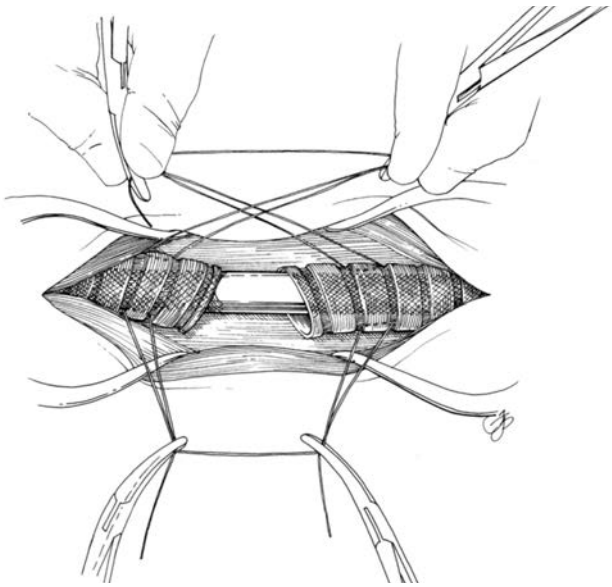

Figure 26-14. The tagged tension sutures are used to approximate the proximal and distal segments of the trachea for primary anastomosis.

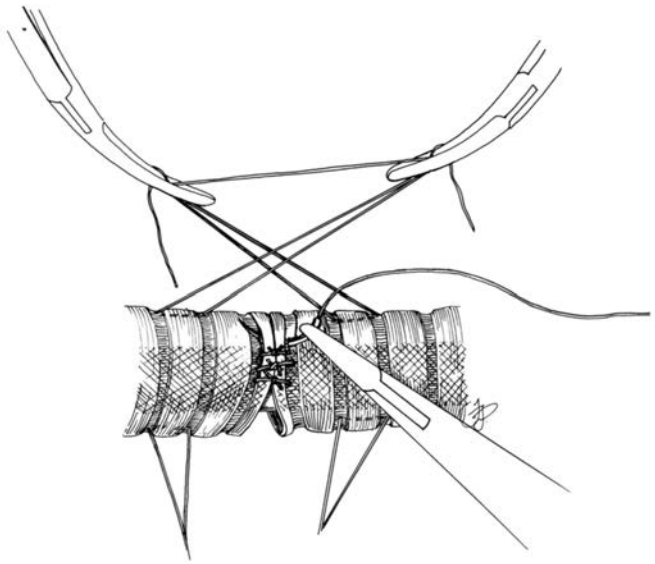

Figure 26-15. The primary anastomosis begins on the ventral aspect of the trachea by placing simple interrupted sutures around the split proximal and distal tracheal cartilages.

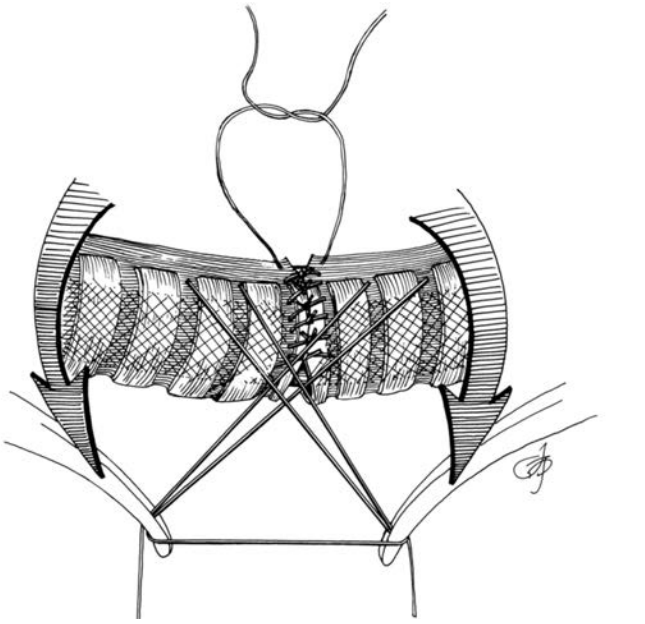

Figure 26-16. A tagged tension suture is used to rotate the trachea for exposure of the left lateral and dorsal aspects. Simple interrupted anastomotic sutures are placed approximately 3 mm apart.

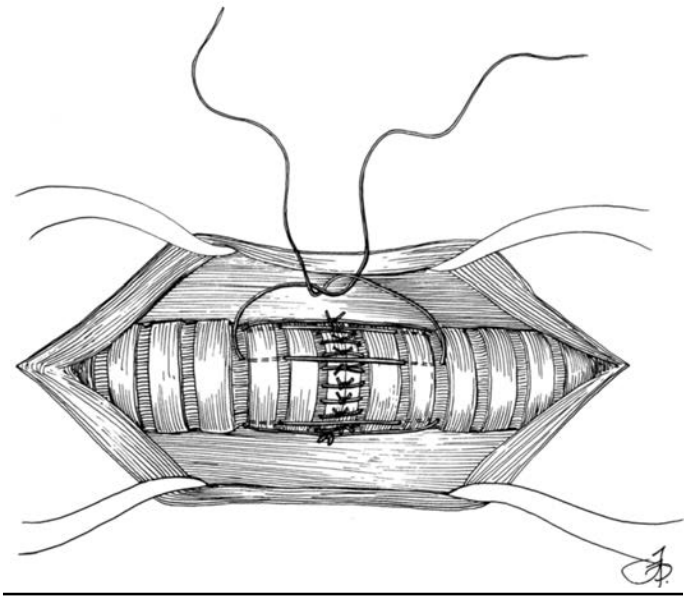

Figure 26-17. The primary anastomosis is completed, and the tension sutures are knotted. A third tension suture is placed on the ventral aspect of the trachea. The tension sutures should relieve tension from the primary anastomosis, but they should not result in deviation or overlapping of the tracheal segments.

Postoperative Considerations

Brief, atraumatic tracheal suctioning after extubation is helpful to remove clotted blood from the lumen of the trachea. The patient should be observed closely for respiratory distress for 12 to 24 hours after surgery. Postoperative respiratory distress can result from laryngeal or pharyngeal edema, occlusion of the tracheal lumen at the anastomotic site, or iatrogenic laryngeal paralysis from intraoperative recurrent laryngeal nerve injury. Antitussives and glucocorticoids are administered as needed to reduce inflammation and to suppress coughing.

The nature of tracheal wound healing ensures some degree of anastomotic stenosis. Periodic endoscopic examination of the trachea after anastomosis is helpful to evaluate wound healing and anastomotic stenosis. Anastomotic stenosis usually is not clinically significant in sedentary patients until the tracheal lumen is compromised by 50 to 75%.[7] Meticulous, atraumatic surgical technique and elimination of tension on the anastomosis usually result in a successful outcome.

Permanent Tracheostomy

Cheryl S. Hedlund

Introduction

A permanent tracheostomy is a stoma in the ventral tracheal wall created by suturing tracheal mucosa to skin. Tracheostomy tubes are not needed to maintain lumen patency following this procedure. Tracheostomas are maintained for life or until the stoma is surgically closed. Permanent tracheostomies are recommended for animals with upper respiratory obstructions causing moderate to severe respiratory distress that cannot be successfully managed by other methods. Dogs and cats with cyanosis or severe dyspnea at rest or with minimal exertion are candidates. Respiratory distress is commonly associated with laryngeal dysfunction secondary to laryngeal collapse or neoplasia, and sometimes nasopharyngeal or proximal tracheal obstruction. Before creating a tracheostoma, it is important to establish the clients willingness and ability to provide postoperative care. Although most patients requiring a permanent tracheostomy function much better after surgery, some clients will refuse the procedure and elect less beneficial surgical procedures or euthanasia.

Surgical Technique

A permanent tracheostomy is performed with the anesthetized patient in dorsal recumbency.[1-3] The skin of the ventral and lateral neck is clipped and aseptically prepared for surgery. On the operating table, the patient's forelegs are positioned caudally along the chest, and then the animal's neck is elevated and extended with a dorsal cervical pad. The proximal cervical trachea is exposed with a ventral cervical midline incision beginning at the distal larynx and extending caudally 8 to 10 cm. The paired sternohyoid muscles are separated and are retracted laterally to visualize the trachea. The endotracheal tube cuff is advanced distal to the proposed tracheostomy site. The surgeon creates a tunnel dorsal to the trachea from the third to sixth tracheal cartilages and, using this tunnel, apposes the sternohyoid muscles dorsal to the trachea with horizontal mattress sutures to create a muscle sling (Figure 26-18). The muscle sling serves to deviate the trachea ventrally reducing tension on the mucosa-to-skin sutures. Beginning with the second or third tracheal cartilages, a rectangular segment of tracheal wall three to four cartilage widths long and one-third the circumference of the trachea in width is outlined. (See Figure 26-18) Using a #11 scalpel blade, the cartilage and annular ligaments are incised to the depth of the tracheal mucosa. The surgeon elevates a cartilage edge with thumb forceps and dissects the cartilage segment from the mucosa using the blunt edge of the scalpel blade. If tracheal cartilages show any weakness or tendency to collapse, place one or two prosthetic tracheal rings cranial and caudal to the stoma. A similar segment of skin is excised adjacent to the stoma. If the patient has loose skin folds or abundant subcutaneous fat, larger segments of skin are excised to help prevent skin fold occlusion of the stoma. Excess fat is excised in obese patients to allow direct contact of the skin and peritracheal fascia. The surgeon sutures the skin directly to the peritracheal fascia laterally and the annular ligaments proximal and distal to the stoma with a series of interrupted intradermal sutures (3-0 or 4-0 polydioxanone or poliglicaprone 25) without entering the tracheal lumen. These skin-peritracheal sutures promote adhesion of the skin to the trachea and are important in reducing postoperative skin fold problems, seroma formation, and tension on the stomal sutures. An "I" or "H" shaped incision is made through through the mucosa. The mucosa is folded over the cartilage edges and sutured to the edges of the skin with approximating sutures (4-0 monofilament absorbable) (Figure 26-19). Simple interrupted sutures are placed at the corners and a simple continuous pattern is used along the sides of the stoma. Sutures are spaced approximately 2 mm apart. Precise apposition is important to minimize tracheostomal stenosis but is not always possible. Precise apposition is not possible if the tracheal mucosa is disrupted during dissection or previous tube tracheostomy, or of poor quality due to disease. If the patient does not have enough mucosa to cover the incised cartilage edges and annular ligaments, the surgeon should appose as much mucosa to the skin as possible and allow the exposed areas to heal by second intention. If necessary, sutures are passed around or through adjacent cartilages or annular ligaments. Skin edges are apposed proximal and distal to the stoma with simple interrupted or cruciate sutures. Blood and mucus are suctioned from the stoma before the animal recovers from anesthesia.

Permanent tracheostomy following total laryngectomy requires the creation of a tracheostoma after the transected end of the trachea is closed or deviated to the skin.[3,5] Closure of the transected trachea is accomplished by preserving a flap of dorsal tracheal membrane from the more proximal trachea that can be folded over the exposed lumen of the distal trachea and then sutured. Alternatively, the transected distal trachea is closed by placing a series of interrupted horizontal mattress sutures to appose the dorsal tracheal membrane to the cartilage. After using either of these closure techniques a permanent tracheostomy is performed as described previously.

Another option after total laryngectomy is to incorporate the distal tracheal end into the tracheostoma. This is accomplished by apposing the sternohyoid muscles dorsal to the distal tracheal end. Then, beginning at the distal tracheal transection site, the surgeon removes segments of four to six tracheal cartilages from the ventral aspect of the tracheal wall, while preserving as much mucosa as possible (Figure 26-20). At the most proximal aspect of the proposed stoma, the dorsal tracheal membrane is apposed directly to the skin with simple interrupted sutures. Excess skin is excised as necessary to prevent skinfolds at the site, and then the skin is sutured directly to the peritracheal fascia and annular ligaments with intradermal sutures. The tracheostoma is completed by apposing the tracheal mucosa at the lateral and distal cartilage margins to the skin with simple continuous sutures (Figure 26-21).

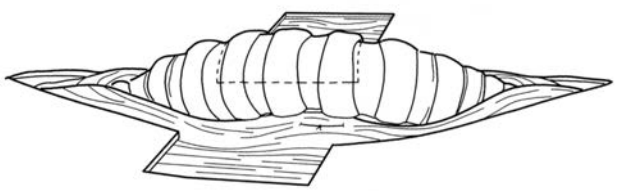

Figure 26-18. The trachea is deviated ventrally by apposing the sternohyoid muscles dorsal to the trachea creating a muscle sling. A rectangular segment of ventral tracheal wall, approximately one third the tracheal circumference and three to four cartilages long, is excised without penetrating the mucosa. Loose skin adjacent to the tracheal incisions is excised. (Reprinted with permission from: Hedlund CS: Tracheostomies in the management of canine and feline upper respiratory disease. Postoperative Care

Patients that have undergone permanent tracheostomy are monitored in the intensive care unit for 24 to 48 hours after surgery to observe for dyspnea and to care for the tracheostoma. Obstruction of the tracheostoma can result in death by asphyxiation. The stoma is inspected every 1 to 3 hours. The stoma is cleaned aseptically when mucus begins to occlude the tracheostoma or when respiratory effort increases. Mucus accumulating around the tracheostoma is carefully removed with moistened gauze sponges or cotton tipped applicators. Mucus accumulating in the tracheal lumen is removed with a moistened sterile cotton swab or suction tip. Cleaning must be performed carefully to avoid disrupting the suture line or irritating the tracheal mucosa. A water-impermeable ointment (petrolatum or boric acid ointment) or cyanoacrylate skin protectant is applied around the tracheostoma to discourage tracheal secretions from adhering and crusting. Low humidity during the first four to six days seems to reduce the amount of exudation and also promotes healing.

Initially, most animals secrete a moderate amount of mucus, with cleaning needed every 1 to 3 hours, but the interval gradually increases to every 4 to 6 hours by 7 days and twice daily by 30 days after surgery.[3,4] Patients are usually ready for discharge within 7 days of surgery; at this time, the stomas should be inspected every 4 to 6 hours and mucus removed as needed. Animals with severe tracheal irritation, secretory diseases, or those exposed to mucosal irritants (smoke, fragrances, dust, pollens, etc) may require more frequent cleaning. Most animals learn to expel mucus forcefully from their stoma in a self-cleaning manner. Hair is clipped from around the tracheostoma once or twice a month to prevent matting with mucus. Exercise and housing should be limited to clean areas free of smoke and unnecessary fragrances. Swimming is prohibited, and the stoma should be protected when sprays are used near the pet.

Owners are usually satisfied with their pet's response after permanent tracheostomy.[3,4] Most pets have improved breathing, less noisy breathing, and increased activity. Approximately 60% of dogs and cats with permanent tracheostomy (without laryngectomy) lose their ability to vocalize normally.

Complications of permanent tracheostomy include stomal occlusion by skinfolds or mucus, dehiscence, and stenosis.[3,4,6-7] Skinfold occlusion is the most common long-term complication. It may be intermittent, related to the animal's posture or continuous. Skinfold problems can be minimized by carefully assessing and excising larger amounts of skin from animals with loose skin folds during initial permanent tracheostomy surgery. Adhesions created by skin-peritracheal sutures are important in preventing skin fold problems. When skinfolds do interfere with tracheostomal airflow, skin lateral and dorsal to the stoma is excised without disturbing the mucosa-to-skin junction. Obstruction of the stoma by mucus is prevented by diligent patient observation and management. Dehiscence occurs if there is tension or irritation at the mucosa-to-skin junction.[4,6] It is prevented by using good surgical and management techniques. Dehiscence leads to a greater degree of stomal stenosis. Some stenosis occurs at all tracheostomal sites but it may progress to nearly complete stomal obstruction with dehiscence or trauma. If dyspnea recurs secondary to stenosis, it may be necessary to revise the tracheostoma surgically. Revision is best accomplished by making a skin incision from each corner of the stoma, removing an appropriate segment of skin and advancing the skin flap laterally.to evert the mucocuteanous junction thus widening the stoma (Figure 26-22).

Mortality associated with kinking of the trachea is likely (57%) to occur if the tracheostoma is created below the twelfth cartilage.[6] Defense mechanisms in the bronchi, bronchioles, and lungs are adequate in most cases to prevent pulmonary infections in animals with permanent tracheostomies. Permanent tracheostomy does not affect breathing pattern or reflexes.[7]

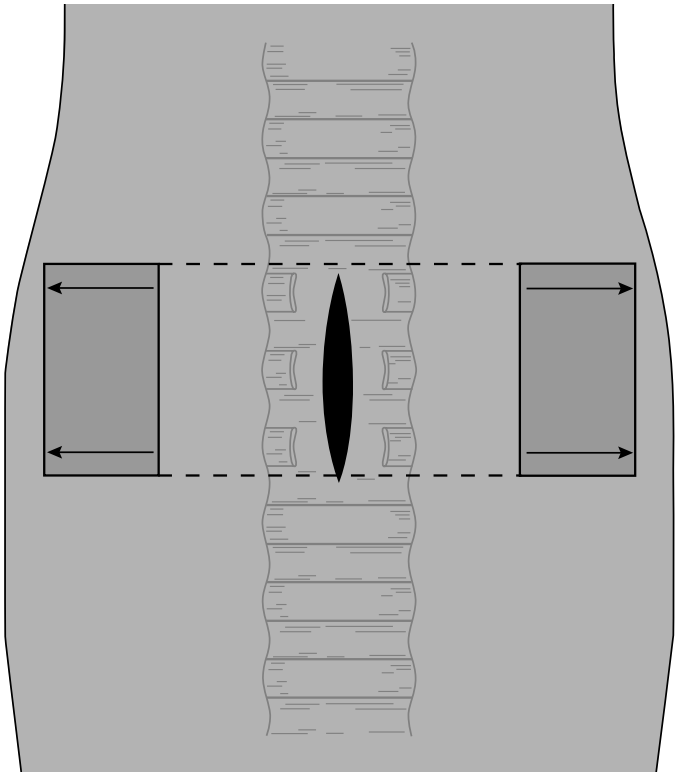

Figure 26-22. Revision of a stenosed stoma is accomplished by minimally interrupting the mucocutaneous junction. First make a skin incision extending laterally from each corner of the stoma. Then resect an appropriate segment of skin connecting the incisions on each side. Finally, apply traction to the skin flaps to evert the mucocutaneous junction and appose the incised skin edges.

Chapter 27

Lung and Thoracic Cavity

Thoracic Approaches

Dianne Dunning

Introduction

Intercostal thoracotomy and median sternotomy are the most commonly used thoracic approaches in small animals. The choice of a thoracic approach depends upon the type of access to the thoracic cavity that is needed. Intercostal thoracotomy is easy to perform and does not require special surgical instrumentation, but it permits only limited access within the thoracic cavity. Median sternotomy allows wide access to the thoracic cavity, except for the structures in the dorsal mediastinum such as the esophagus and bronchial hilus. However, median sternotomy requires access to an oscillating saw or sternal splitter. Nevertheless, median sternotomy is the thoracic approach that allows the most complete exploration of the thoracic cavity.

Surgical Technique

Intercostal Thoracotomy

Intercostal thoracotomy is chosen to provide access to a defined area of interest within one hemisphere of the thoracic cavity. Approximately one-third of one hemisphere of the thoracic cavity and its associated mediastinal structures are visible with this approach. The intercostal space chosen depends on the thoracic structures of interest (Table 27-1). In general, the cardiac structures are approached best through the fourth or fifth intercostal space. The cranial lung lobes are accessed through the fourth or fifth intercostal space, whereas the caudal lung lobes are best accessed through the fifth or sixth intercostal space. The right middle lung lobe is accessed through the right fifth intercostal space. The cranial esophagus can be accessed from either the third or the fourth intercostal space on the right or left side. The caudal esophagus is accessed on either the right or left side between the seventh and eighth intercostal space. The thoracic duct in the dog is best accessed between the eighth and tenth spaces. These are general guidelines only, as thoracic radiographs or CT should be reviewed prior to any surgical procedure to identify the most appropriate intercostal space for entry to the thoracic cavity. In addition, up to three ribs may be partially excised to improve access to the thoracic hemisphere without destabilizing the thoracic wall and compromising chest wall excursion.

To perform an intercostal thoracotomy, the patient is placed in lateral recumbency with a rolled pad placed under the thorax. An incision is made with a scalpel through the skin, subcutaneous tissues, and cutaneous trunci muscle. The latissimus dorsi and pectoralis muscles are incised parallel to the skin incision. The fifth rib is easily identified as the caudal insertion of the scalenus muscle and the cranial origin of the external abdominal oblique muscle (Figure 27-1). Depending on the intercostal space entered, either the scalenus or the external abdominal oblique muscle is incised. The serratus ventralis muscle is separated to expose the

desired intercostal space (Figure 27-2). The intercostal muscles are incised midway between the ribs to avoid lacerating the intercostal vessels, coursing on the caudal aspect of each rib (Figure 27-3). The pleura is punctured, and the incision is extended with scissors dorsally to the tubercle of the rib and ventrally past the costochondral arch to the internal thoracic vessels. A Finochietto retractor is used to expose the thoracic structures and a thoracic exploratory is performed prior to any surgical intervention.

Prior to closure of the thoracotomy, a thoracostomy tube is placed through the caudodorsal thoracic wall (Figure 27-4). The thoracostomy tube should remain open to the atmosphere during closure of the thoracotomy site to prevent inadvertent tension pneumothorax. Once the soft tissues are apposed and the closure is airtight, the pleural space is evacuated, and the thoracostomy tube is closed. Before thoracotomy closure, a local selective intercostal nerve block of the adjacent intercostal spaces is performed with 0.75% bupivacaine to decrease postoperative pain and to improve ventilation.

The thoracotomy is closed by preplacing five to eight heavy-gauge sutures around the adjacent ribs. The preplaced circumcostal sutures are used by an assistant to approximate the ribs while the surgeon ties each suture (Figure 27-5A,B). Transcostal sutures that are placed through holes drilled in adjacent ribs has

been suggested as a less painful method of closure. The serratus ventralis or external abdominal oblique and scalenus muscles are closed in a single layer with a simple continuous suture pattern. The latissimus dorsi muscle, cutaneus trunci muscle, subcutaneous tissues, and skin are closed in separate layers with a simple continuous suture pattern (Figure 27-6).

Median Sternotomy

Median sternotomy is indicated when exploratory surgery of the thoracic cavity is necessary. Median sternotomy should not be avoided because of a belief that it is associated with higher postoperative pain and complication rates than intercostal thoracotomy. Complication rates associated with median sternotomy are no higher than those associated with thoracotomy.

Median sternotomy is performed with the animal in dorsal recumbency. The skin and subcutaneous tissues are incised with a scalpel over the midline on the sternum (Figure 27-7). The pectoral musculature is incised and is elevated from the sternebrae with electrocautery. The sternum is then cut on its midline with an oscillating saw or sternal splitter (Figure 27-8). Care is taken to limit the penetration of the saw or osteotome to avoid injury to internal thoracic structures. Either the manubrium or the xiphoid is left intact to achieve a stable closure of the sternum. Finochietto retractors are used to expose thoracic structures. A caudal median sternotomy can be combined with a ventral midline celiotomy to gain further exposure of caudal thoracic and cranial abdominal structures (Figure 27-9). A partial incision of the diaphragm can be made to facilitate wider retraction. A midline cervical incision can be combined with a sternotomy through the manubrium to expose the structures of the thoracic inlet.

Before closure, a thoracostomy tube is placed subcostally and lateral to the midline (Figure 27-10). The sternotomy is closed with alternating figure-of-eight 20 to 22gauge orthopedic wires (Figure 27-11). The pectoralis muscles, subcutaneous tissues, and skin are closed in separate layers with a simple continuous suture pattern.

Postoperative Care

Hypoventilation, hypoxemia, hypothermia, acid-base imbalance, hypotension, pain and hemorrhage are among the problems that may arise in the first 12 to 24 hours after thoracotomy. Median sternotomy and intercostal thoracotomy are both associated with alterations in normal pulmonary function that may be attributed to several factors including pain. These changes may inhibit deep inspiration and may promote small airway collapse, resulting in ventilation-perfusion mismatch. Measurement of arterial blood gases after surgery provides information about ventilation and pulmonary gas exchange. Additional postoperative monitoring should include frequent assessment of drainage from the thoracic cavity, temperature, pulse rate, respiratory rate, and mucous membrane color.

Analgesia is indicated in all animals after thoracotomy. Parenteral opioids, epidural morphine, intrapleural anesthetics, and selective intercostal nerve blocks using 0.75% bupivacaine may be used alone or in combination to provide postoperative analgesia (Table 27-2).

Pulmonary Surgical Techniques

Dianne Dunning

Partial and complete lung lobectomies are occasionally indicated in small animal practice. Although the surgical techniques are not difficult, they require a familiarity with thoracic anatomy and pulmonary physiology, as well as a support staff to monitor the animal both during and after surgery to ensure a successful outcome.

Surgical Anatomy

The trachea of dogs and cats divides into two principal bronchi, which in turn subdivide into lobar bronchi that supply each lung lobe (Figure 27-12). The left and right lungs are separated by a thin but complete mediastinum. The left lung is divided into cranial and caudal lobes by a deep fissure. The left cranial lung lobe is further divided by an incomplete fissure into cranial and caudal parts, but they share a common lobar bronchus. The right lung is divided into cranial, middle, caudal, and accessory lobes. The accessory lobe passes dorsal to the caudal vena cava and lies medial to the plica vena cava, a fold of pleura that extends around the caudal vena cava. These structures should be identified during manipulation of the right caudal and accessory lung lobes. The pulmonary vessels closely follow the lobar distribution of the bronchi. Pulmonary arteries are located on the craniodorsal aspect of each bronchi, whereas pulmonary veins are located on the caudoventral aspect. Partial or complete lung lobectomy may be performed through a standard intercostal thoracotomy in the fourth through sixth intercostal space or through a median sternotomy.

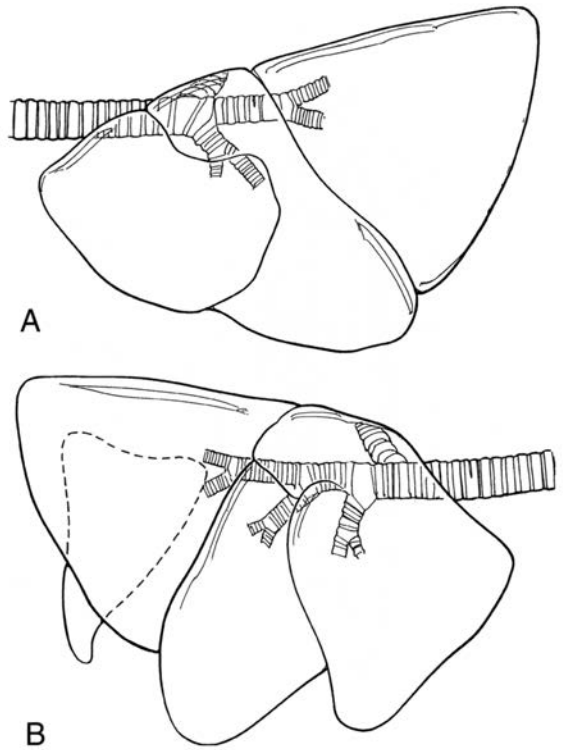

Figure 27-12. Lung lobe anatomy. **A.** Left. **B.** Right. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:162.)

Surgical Techniques

Partial Lung Lobectomy

Partial lung lobectomy is used to obtain a biopsy or excise localized marginal lesions of the distal two thirds of the lung. Partial lung lobectomy may be performed by freehand suturing or with a stapling device. To perform a partial lobectomy by hand, the lung is clamped with noncrushing vascular or intestinal clamps proximal to the isolated lesion (Figure 27-13). The lung is excised distal to the clamps. A continuous horizontal mattress pattern of 4-0 monofilament suture is placed proximal to the clamps (Figure 27-14). Delicate swaged-on taper-point needles should be used. Smooth fluid movements that follow the curvature of the needle should be used when driving the needle through the tissue to minimize air leaks at the suture line. The ends of the suture are tied and "tagged" with hemostatic forceps to facilitate manipulation of the lung. The clamps are removed, and the lung incision is oversewn in a simple continuous pattern (Figure 27-15). The incision is then checked for air leaks by submerging the lung in saline during positive-pressure ventilation of 20 to 30 cm of H_2O. Additional sutures may be placed as necessary. Some leakage of air after this technique may be expected, but this usually resolves within a few hours after surgery.

Stapling devices are now commonly available to veterinary surgeons. The advantages of stapling equipment for partial lobectomy are shortened surgical and anesthetic time, decreased blood loss, and reduction of the incidence of bronchopleural fistulas after lung lobe resection. The most useful device for pulmonary procedures is the thoracoabdominal (TA) stapler. This instrument places two staggered rows of stainless steel staples that form a B shape when compressed. The 3.5 mm (blue)

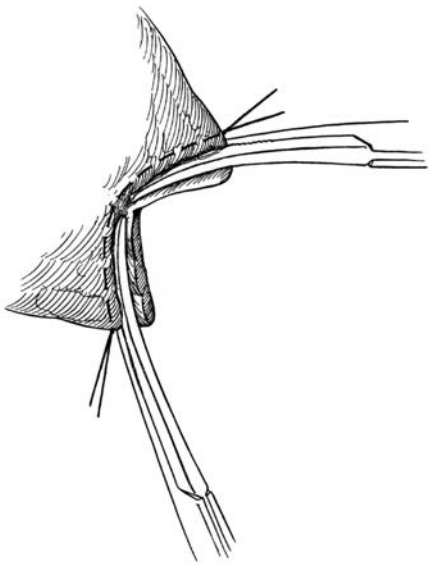

Figure 27-14. Partial lung lobectomy. A continuous horizontal mattress pattern is placed proximal to the clamps. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:165.)

Figure 27-15. Partial lung lobectomy. The clamps are removed, and the incision is oversewn with a simple continuous pattern. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:165.)

or the 2.5 mm (white, V or V3) staple cartridges may be used for pulmonary procedures. A gastrointestinal anastomosis stapler also may be used for longer staple lines. The stapler is placed across the lung and is clamped proximal to the lesion (Figure 27-16). The staple device is fired and the lung is transected utilizing the edge of the TA stapling device as a cutting edge. After the removal of the stapling device, the lung is checked for air leaks in the manner described previously.

Complete Lung Lobectomy

Excision of an entire lung lobe is indicated for severe trauma, neoplasia, lobe torsion, abscesses, or refractory infections. The affected lung lobes should be manipulated gently to minimize

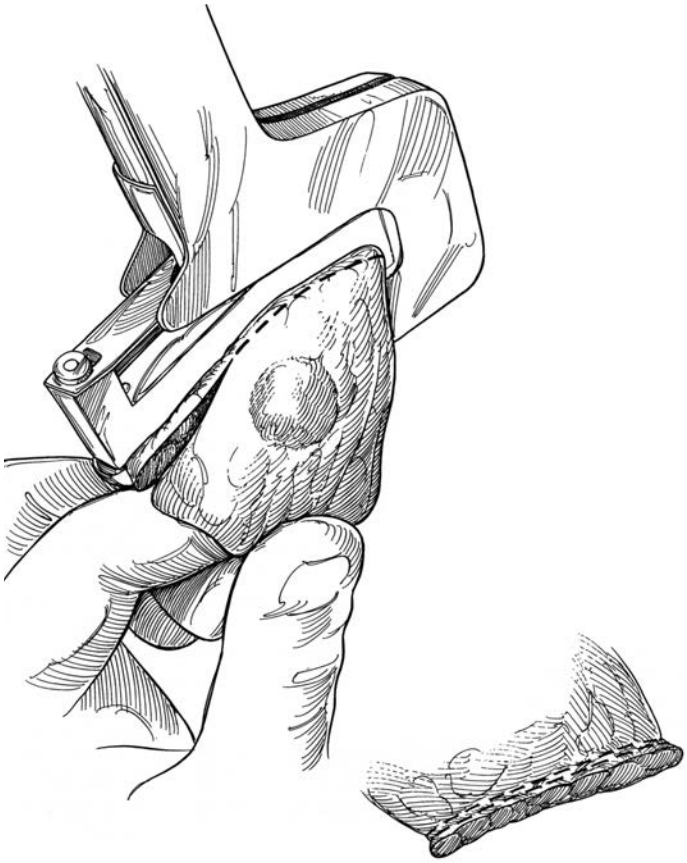

Figure 27-16. Partial lung lobectomy with staples. The stapler is placed across the lung and is clamped proximal to the lesion. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:166.)

embolization of neoplastic cells or extrusion of purulent material into adjacent airways. Dogs and cats can survive removal of up to 50% of lung lobe mass. Removal of more than 75% of the lung is invariably fatal. Because the right lung constitutes more than 50% of the lung capacity, removal of the entire right lung is contraindicated. Excision of the entire left lung is tolerated in the dog, assuming the right lung is normal.

Lung lobectomy should follow the anatomic distribution of the bronchi. The left cranial and caudal lung lobes may be removed individually. The cranial, middle, and caudal right lobes may be removed individually because they each have separate bronchi. The accessory lung lobe usually is removed with the left caudal lung lobe. Before removal of the caudal and accessory lobes, the pulmonary ligaments must be divided from the mediastinum with Metzenbaum scissors.

The pulmonary artery is accessed first by ventral and caudal retraction of the lung lobe. The lobe may be grasped gently with a dry gauze sponge. The artery is isolated by blunt dissection with right-angle forceps parallel to the long axis of the vessel (Figure 27-17). The artery is triple ligated and is divided between the middle and distal ligature. The pulmonary vein is accessed by dorsal and cranial retraction of the lung lobe. The vein is isolated, ligated, and divided in a similar manner to the artery. The lobar bronchus is then clamped with a noncrushing tangential clamp and is divided 3 mm distal to the clamp. The bronchial stump is

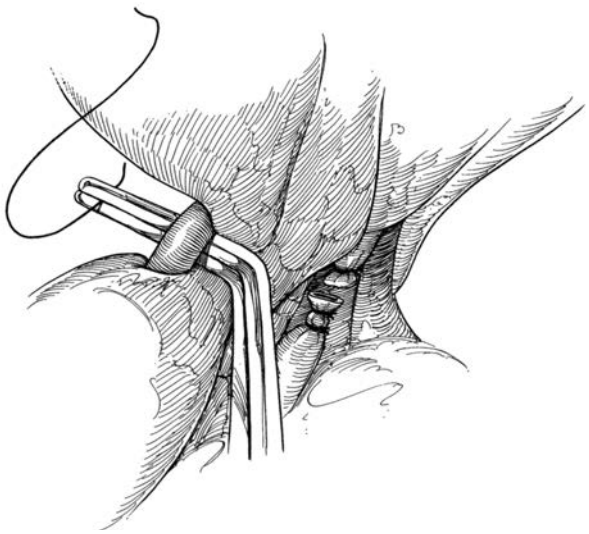

Figure 27-17. Complete lung lobectomy. Dissection of the ligatures around the pulmonary vessels is accomplished with right-angle forceps parallel to the long axis of the vessel. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:164.)

closed with 4-0 suture in a continuous mattress pattern (Figure 27-18). The tangential clamp is removed, and the bronchial stump is oversewn with a continuous pattern (Figure 27-19). The bronchus is then checked for air leaks by saline immersion.

En bloc stapling of the hilus may be used to remove large lung lobe abscesses or tumors when minimal handling of the affected lung is desired. When using 2.5-mm staples (TA 30 V or V3, white), it is rarely necessary to separately ligate and divide the pulmonary vessels. Dissection of the lung lobe from the mediastinum is performed if needed to exteriorize the lobe. The stapler is placed across the hilus of the lobe and is clamped. A clamp is placed distal to the TA stapler across the lobe to prevent spillage of material from the lobe. The staple device is fired, and the lobe is transected, using the edge of the TA stapling device as a cutting edge. After the removal of the stapling device, the hilus is inspected for leaks in the same manner as described previously.

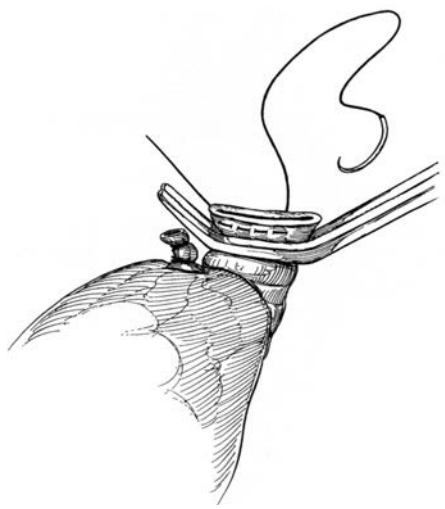

Figure 27-18. Complete lung lobectomy. The lobar bronchus is clamped and divided, and the bronchial stump is closed in a continuous mattress pattern. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:164.)

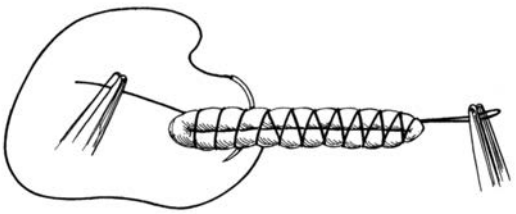

Figure 27-19. Complete lung lobectomy. The bronchial stump is oversewn with a continuous pattern. (From Orton EC. Small animal thoracic surgery. Baltimore: Williams & Wilkins, 1995:164.)

Postoperative Care

Placement of a thoracostomy tube is always recommended before closure of the thoracotomy. If the thoracostomy tube is nonproductive, it may be removed soon after the surgical procedure (see the earlier section of this chapter on thoracic approaches). Animals should be monitored frequently for pneumothorax or hemorrhage after pulmonary surgery. Pneumothorax usually resolves spontaneously after pulmonary surgery. High-volume air leaks can be managed by continuous suction until they resolve.

Thoracic Drainage

Dennis T. Crowe and Jennifer J. Devey

The ability to recognize and manage the dog or cat with various types of fluid (blood, chylous effusion, suppurative effusion, transudate) or air accumulation in the pleural cavity is vital. Although small accumulations of fluid or air in the pleural space may be easily tolerated and hence go undetected, larger amounts prevent normal lung expansion during the inspiratory phase of the ventilatory cycle and can cause a significant increase in ventilatory effort. If significant air or fluid accumulations are present, the animal may display signs of respiratory distress, orthopnea, polypnea, and poor tolerance for exercise or stress. Immediate thoracentesis of fluid or air can be accomplished with a minimal stress to the patient and may provide enough drainage to be lifesaving. Although mild conditions may

require treatment only by thoracentesis, more severe conditions require the placement of a chest tube (tube thoracostomy) and either intermittent or continuous pleural evacuation. If suppurative or infected fluids are retained in the pleural space, the patient is at an increased risk of systemic infection or sepsis. Retention of chylous effusions can lead to fibrosing pleuritis and atelectasis. This discussion reviews the common methods of pleural drainage used in small animal practice.

Needle Thoracentesis

Procedure

If the patient has any evidence of respiratory distress, oxygen should be provided immediately. This can be administered by flow-by oxygen at high flow rates (10 to 15 L/minute), oxygen mask, human nasal cannulas, nasal oxygen tubes, or oxygen hoods. Oxygen cages are not recommended because of the inability to monitor and treat the patient (See Chapter 6).

Before performing needle thoracentesis in the conscious and aware patient, a local anesthetic block is recommended. Using a 22- to 25-gauge needle 1% lidocaine is infiltrated into all layers from the skin down to and including the pleura, with a small amount of anesthetic deposited into the pleural space. The lidocaine should be buffered with sodium bicarbonate. A suggested ratio is two-thirds 1% lidocaine to one-third sodium bicarbonate. Systemic analgesia is not generally required for needle thoracentesis; however, when the patient is in pain, parenteral analgesics may also be used.

Emergency and diagnostic needle thoracentesis can be performed with various needles and catheters, including an 18- to 20-gauge hypodermic needle, a short plastic intravenous catheter, or a bovine teat cannula (Figure 27-20). In extremely small patients, an 18- to 20-gauge butterfly catheter can also be used. A three-way stopcock and a 35- or 60-mL syringe are attached to the needle either directly or by a 20-inch section of intravenous extension tubing. The intravenous tubing, three-way stopcock, syringe should be assembled and capped to maintain sterility and stored in a crash cart for emergencies. A second section of tubing, attached to the sidearm of the stopcock, is useful in directing aspirated fluids into a collection jar. This assembled apparatus can be operated by one person.

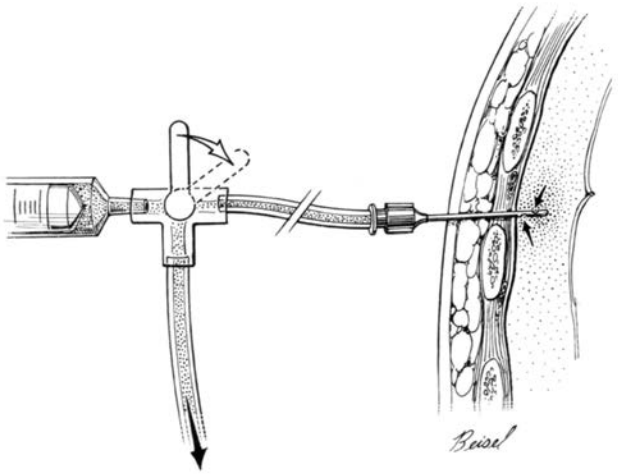

Figure 27-20. Apparatus for thoracentesis: an indwelling intravenous catheter or a bovine teat cannula, a three-way stopcock, a large syringe, and tubing from an intravenous administration set. Plastic catheters and blunt teat cannulas can remain perpendicular to the chest wall because of the low likelihood of causing lung injury. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

Thoracentesis is usually performed at the seventh or eighth intercostal space (Figure 27-21). The animal should be allowed to rest in the position providing the least stress. Usually, this is standing, sitting, or in sternal recumbency. The lateral recumbent position is only acceptable if the patient is unconscious, intubated, and being ventilated. The dorsoventral location of the puncture site within the intercostal space is influenced by whether air or fluid is to be aspirated. If air is to be aspirated, the midthoracic region is preferred, with the animal in lateral recumbency. If the animal is standing or is in sternal recumbency, air is aspirated at the junction of the dorsal and middle thirds. Fluid is best removed from the middle third of the seventh intercostal space, when the animal is standing or is in sternal recumbency. More caudal placement of a needle may lead to penetration of the dome of the diaphragm and or liver injury.

Inadvertent injury to the lung parenchyma with the tip of the needle may lead to pneumothorax, particularly if the lung is lacerated in the process. This complication can be avoided by the use of the following technique: An 18- or 20-gauge needle is placed through the skin with the bevel facing caudally. A drop of saline is placed on the needle hub, and the needle is then slowly advanced into the pleural space (Figure 27-22A). Once the pleural space is entered, the negative pressure within the thorax causes the fluid in the hub to be pulled into the chest. In cases of tension pneumothorax, the pressure causes the fluid to be pushed out of the needle hub (Figure 27-22B). The surgeon must stop advancing the needle at this point, to avoid lung injury. The needle is then tilted in a caudal direction. At this time, the bevel of the needle should be directed parallel to the chest wall, with the opening directed away from the chest wall (Figure 27-22C).

Indications

Thoracentesis used as a diagnostic procedure can provide a fluid sample for laboratory evaluation. Thoracentesis is ideal for the initial treatment of acute pneumothorax and pleural effusions and as a method of intermittent drainage of the pleural cavity for treatment of slow accumulations of fluid or air. The surgical placement of a chest drainage tube (tube thoracostomy), however, is preferred for the removal of large volumes of fluid or continuing accumulation of air in the pleural space. Clinical experience has also suggested that it is impossible to drain the pleural space adequately with simple thoracenteses when accumulations of blood, chylous effusion, or pus are present.

Complications

Inadvertent trauma to the lung from overpenetration and movement of the needle leading to lung laceration is the most common complication. This is best prevented using the foregoing technique. The intercostal vessels can be lacerated during the

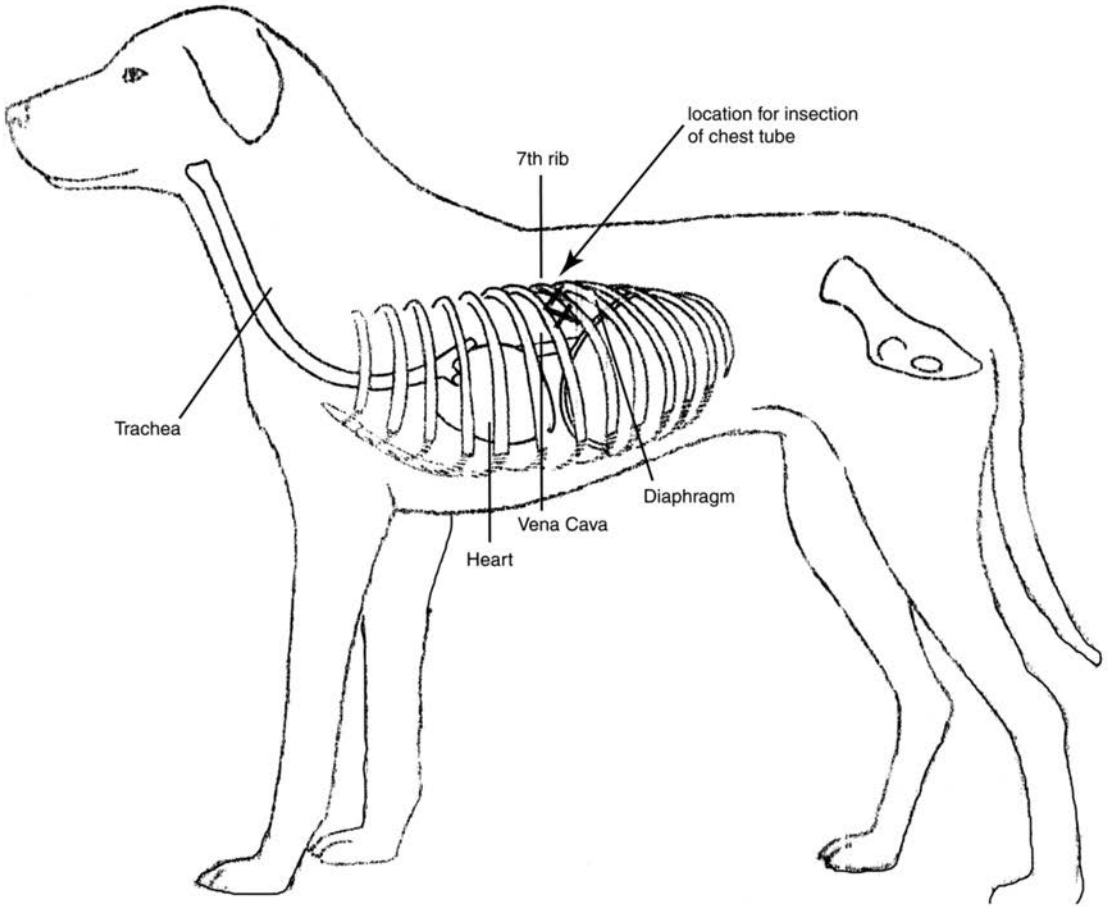

Figure 27-21. The seventh intercostal space is the ideal location for thoracentesis and chest tube insertion in most patients because of safety. Here at the junction of the dorsal third and ventral third of the space is the least danger of causing injury to vascular structures, the large airway, and the diaphragm.

procedure if the needle is introduced immediately adjacent to the ribs. A minor laceration is likely to be self-limiting; however, if an expanding hematoma is noted over the thoracentesis site, this area should be surgically explored and the vessel ligated or cauterized. Rarely, tangential laceration of an intercostal artery can cause serious hemothorax.

Minithoracostomy

Indications and Tube Selection

Various commercial thoracentesis and minithoracostomy tube kits are available (Argyle Turkel Safety Thoracentesis System, Sherwood Medical Products, St. Louis, MO; Pneumothorax Sets, Cook Critical Care, Bloomington, IN). These kits contain a medium-bore multiholed catheter (8 to 10 French) for pleural drainage. These catheters can be used for temporary drainage and may be valuable for short-term indwelling chest tubes for cats and small dogs.

Procedure

If a minithoracostomy tube is selected for insertion, the lateral chest wall at the level of the seventh to ninth intercostal spaces is aseptically prepared. A local anesthetic block using 1 to 2% lidocaine is placed. On rare occasions, the animal may require minor sedation or short-acting neuroleptanalgesia. If sedation or neuroleptanalgesia is required, it should be provided intravenously to effect, and ventilation should be monitored. A small skin incision (large enough to allow passage of the thoracostomy tube) is made. The needle and catheter system are slowly introduced into the pleural space, and suction is applied. If an indwelling system is required, the catheter assembly is advanced, the needle assembly is removed, and the tube is secured. Some systems (Argyle Turkel Safety Thoracentesis System, Sherwood Medical Products) have color indicators to detect when the pleural space has been entered. After placement, the catheter is fixed in place by suturing the tube to the fascia, and a bandage is applied. A radiograph is taken to assess tube location.

Complications

The short length of these minithoracostomy catheters may lead to dislodgment, particularly in larger dogs (A Mann, unpublished data). The catheter may also be too small to achieve adequate pleural drainage in big dogs or in those animals with rapid reaccumulations of fluid or air. Kinking can also be a problem with these catheters.

Tube Thoracostomy

Tube Selection

Tube thoracostomy involves the surgical placement of flexible sterile red rubber (Sovereign, Sherwood Medical Products), polyvinyl chloride (Argyle Straight Thoracic Catheter, Sherwood

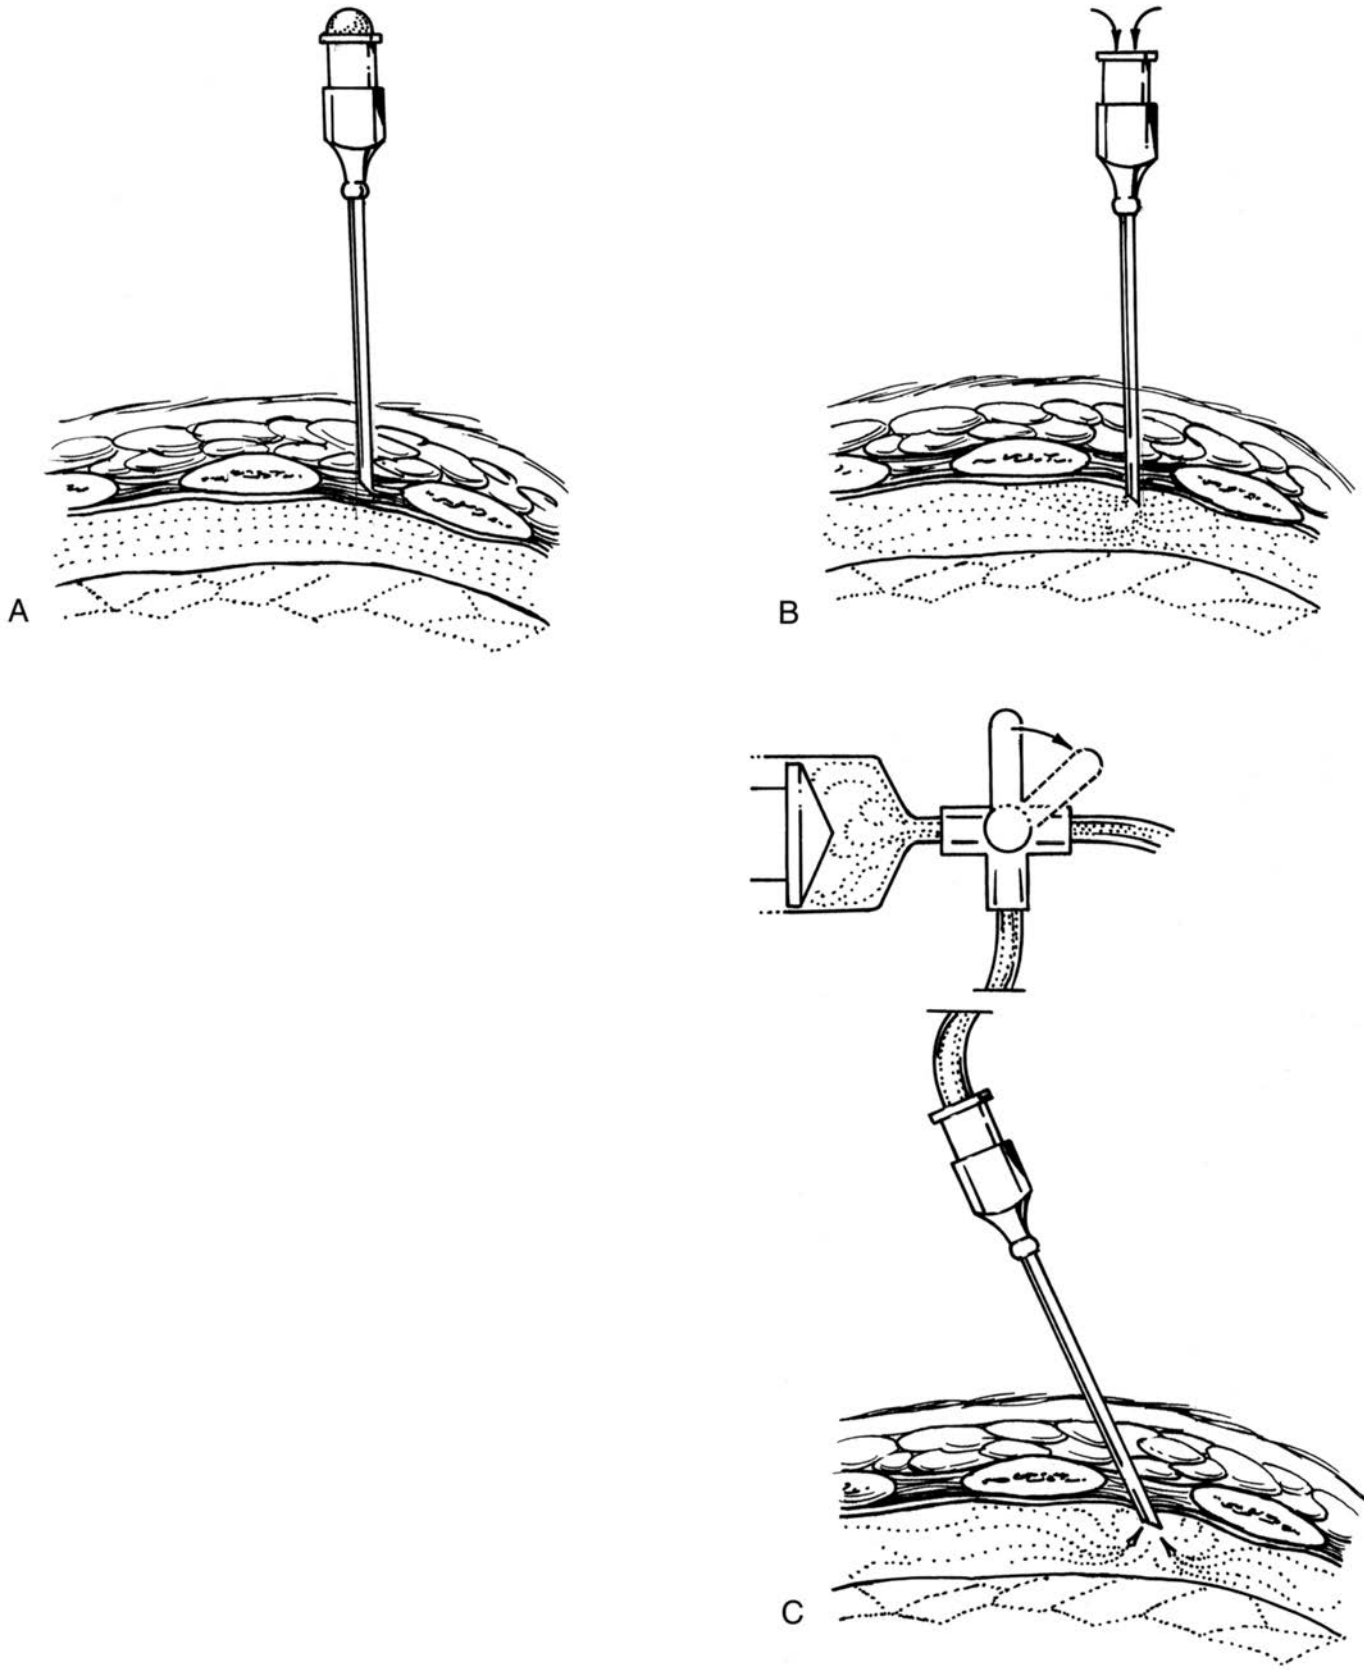

Figure 27-22. A-C. A hypodermic needle is used to evacuate air or fluid from the pleural space. A drop of saline added to the hub of the needle is used to indicate when the tip of the needle is in the pleural space. The drop of fluid is aspirated into the pleural space if the fluid is still under negative pressure. If it is under positive pressure, the fluid moves outward; if it moves outward under force, a tension pneumothorax is present. The needle is then angled to allow the bevel of the needle to face the open pleural space and is held there while aspiration is performed. (The syringe depicted in the drawing is too small for the job.)

Medical Products; Cook Critical Care), or silicone (Cook Critical Care) tube into the pleural space. Sterile endotracheal tubes can also be used if they are modified by knotting the cuff inflation mechanism, cutting the valve off, and removing the cuff. The tubing should be flexible, but not collapsible. The internal diameter of the tube should be at least one-half to two-thirds the width of one of the larger intercostal spaces (approximate diameter of a mainstem bronchus). This is important if tension pneumothorax is being treated and to help prevent occlusion by clots or viscous fluids.

The number and size of the holes placed in the catheter also influence the flow rate and effectiveness of the tube. Experimental flow studies on catheters indicate that, when three side holes are present, each additional hole increases the flow rate by only 6%. Most commercially available chest tubes contain an end hole and five or six side holes. If a noncommercial tube is used, side holes can be created using a pair of scissors or a No. 15 scalpel blade. The recommended size of the hole is approximately one-fourth the circumference of the tube. Diameters exceeding one-third the circumference of the tube cause considerable weakness and predispose the tube to kinking.

Commercially available chest tubes contain a marker strip throughout their length to allow radiographic confirmation of placement. The end of a chest tube should be placed on the ventral floor of the patient's thorax and cranial to or adjacent to the heart. In this location, both air and fluid can be drained efficiently from the pleural cavity where the tube is located. All holes must be located within the chest cavity. This placement can be verified radiographically with tubes that have a "sentinel eye," that is, an interruption in the radiopaque marker where the last hole is located. For best function, the tube should be placed no farther cranially than the level of the second rib; more cranial placement may obstruct the flow of air or fluid and may cause phrenic nerve irritation and dysfunction (Figure 27-23). In tubes where holes have been created, the last hole should be placed through the radiopaque marker for identification purposes. In some cases, because the mediastinum is intact, two chest tubes are required, one for each side of the pleural space.

Chest Tube Placement During Thoracotomy

To place a chest tube at the time of a thoracotomy, the tip of a curved hemostat is bluntly forced through intercostal muscle and parietal pleura at the seventh or eighth intercostal space or two spaces caudal to the thoracotomy incision. A subcutaneous tunnel is made in a caudal direction from the inside of the thorax to the outside for a distance of two to three intercostal spaces. A small skin incision is made at the ninth or tenth intercostal space over the tips of the hemostats. The proximal part of the chest tube is grasped, and the tube is pulled into the thoracic cavity and positioned. The tube can also be placed by advancing a curved hemostat through the incision into the pleural cavity, by grasping the distal part of the tube and pulling the tube out of the chest cavity in a reverse fashion (Figure 27-24). Cutting the distal part of the tube on an oblique angle creates a pointed end that facilitates its movement through the thoracic wall if it is placed in a reverse fashion. The tip of the tube is positioned cranial and ventral. In all cases, radiographs should be taken after the tube is placed to ensure that the tube is in a proper location and is not kinked or twisted (Figure 27-25).

Anchoring the Chest Tube

The tube is secured by passing a heavy suture on a taper needle through the skin next to the tube and into the periosteum of the rib adjacent to the tube. A hinge is created by tying 6 to 10 knots and then the suture is passed around the tube in a simple criss-cross fashion and tied with 2 knots. This criss-cross "friction knot" is repeated 2 to 3 times, and then 3 to 5 more knots are tied (Figure 27-26). The use of this friction knot avoids the need for tape, which is not sterile and can slip. A second hinge is created on the other side of the tube with the same suture, and the suture is anchored again through the skin and into the periosteum. In small patients, the suture can be passed around the rib. If this is done, care is taken to ensure that the needle does not lacerate the lung. If the suture is not anchored to the periosteum, the tube may migrate as the patient breathes and moves, and the tip may exit the pleural space. The thoracotomy is then closed.

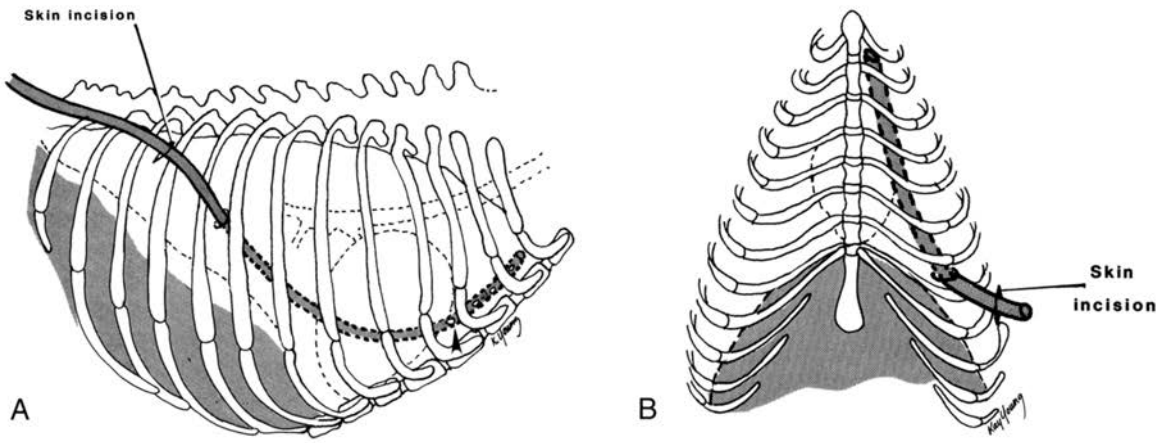

Figure 27-23. Drawings from lateral **A.** and ventrodorsal **B.** radiographs demonstrate proper intrathoracic location of the chest drain. The *arrowhead* in A indicates the location of the last side hole in the catheter as seen on the radiograph (where the radiopaque line is interrupted). (For best function, the tube should be placed no farther cranially than the level of the second rib; more cranial placement may obstruct the flow of air or fluid.) (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

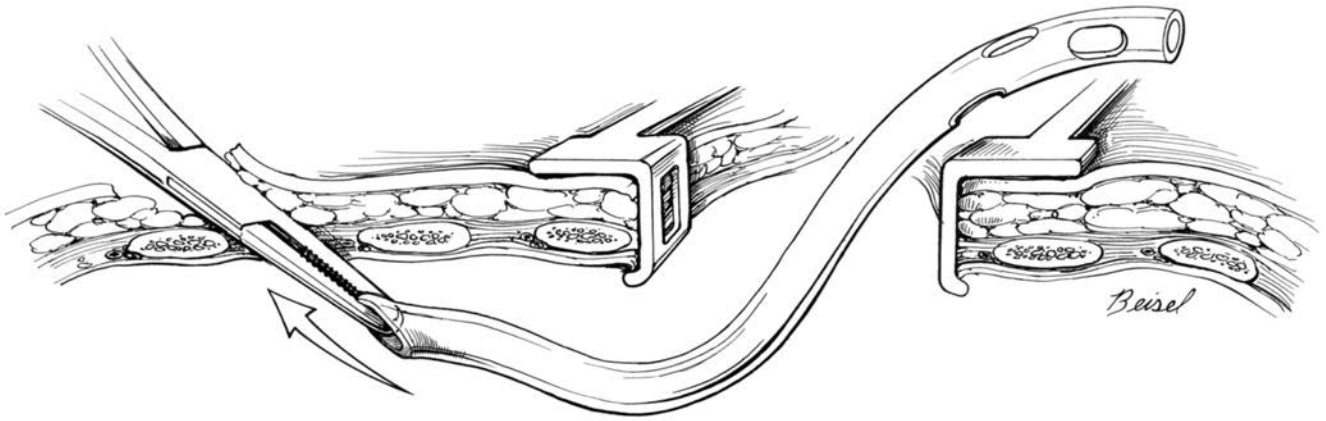

Figure 27-24. In pulling the chest drain out through the seventh or eighth intercostal space, cutting the end of the tube on an oblique angle facilitates its movement through the thoracic wall. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

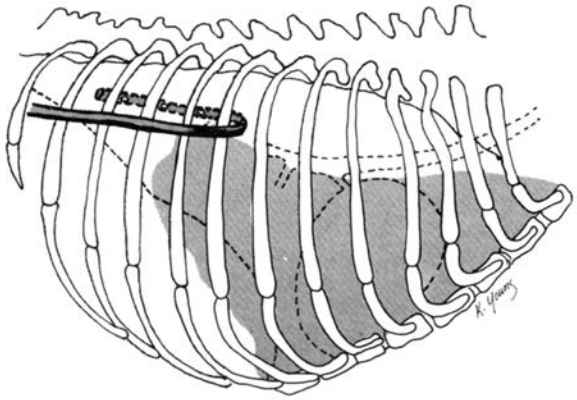

Figure 27-25. Line drawing of a lateral radiograph demonstrates improper placement and kinking of the chest drain. (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

Chest Tube Placement with the Chest Closed

A "closed" tube thoracostomy is performed outside the operating room with the patient in a sitting or standing position or whichever position causes the least distress to the animal. This factor is particularly important in patients showing any signs of respiratory distress. Anxiety and struggling may be dangerous to the animal with compromised ventilation, and restraint should be kept to a minimum, especially in cats. A small amount of a sedation can be given intravenously to effect (e.g., butorphanol [Torbugesic], 0.1 to 0.4 mg/kg, and diazepam [Valium], 0.05 to 0.2 mg/kg or acepromazine, .02 to .05 mg/kg). If the patient continues to struggle despite the sedation, the chest tube should be placed while the patient is under general anesthesia. Rapid induction is essential to gain rapid control of the airway. A cuffed endotracheal tube is placed, and positive-pressure ventilation is instituted. Ventilation is closely monitored because peak airway pressures greater than 30 cm H_2O can cause significant decreases in cardiac output. Because of the underlying disorder, delivery of normal tidal volumes may not be possible. In these patients, smaller tidal volumes with a more rapid ventilatory rate should be used.

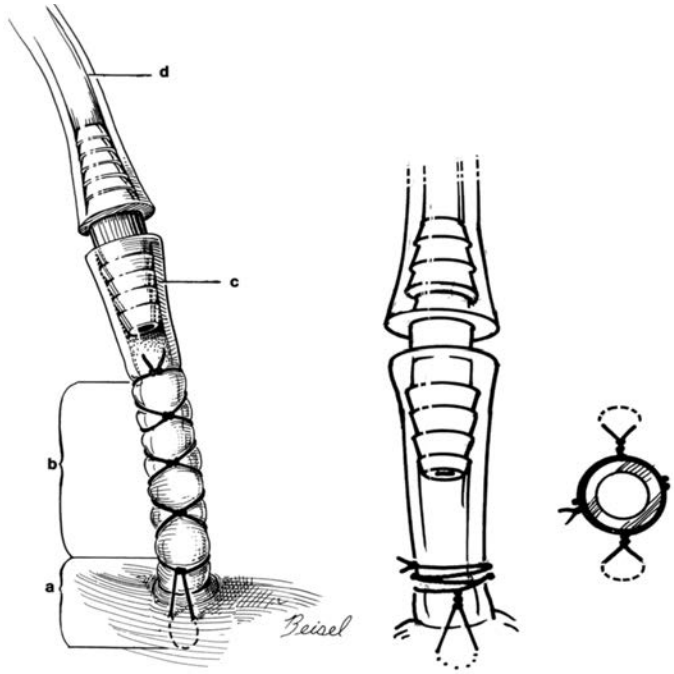

Figure 27-26. Securing the drain tube using a Chinese finger trap friction suture. First, the suture is tied without tension to prevent irritation of the skin *(a);* then, in a criss-cross fashion, multiple surgeon's knots are tied around the tube *(b),* chest catheter *(c),* and gum-rubber tubing *(d).* Although the drawing depicts a finger trap, all that is really required are several "friction knots" tied in criss-cross fashion and wrapped around the tube *(inset).* (From Bojrab MJ, ed. Current techniques in small animal surgery. 2nd ed. Philadelphia: Lea & Febiger, 1983.)

The skin is clipped over the entire lateral chest wall and cranial flank region and is aseptically prepared for surgery. Local anesthetic is infiltrated into the proposed site of tube insertion at the seventh intercostal space as previously described. This should include the nearby pleura and intercostal nerve. The skin over the lateral chest wall is pulled cranially by an assistant such that the skin over the ninth or tenth intercostal space overlies the seventh or eighth intercostal space. The skin should be pulled at least the same distance as two rib spaces (Figure 27-27A).

Using aseptic technique, a small skin incision is made in the middle of the seventh intercostal space (Figure 27-27B). Curved

Kelly forceps are then used to separate the intercostal muscles in a controlled fashion (Figure 27-27C). The tips of the forceps are inserted into the incision, and mild pressure is exerted in a medial direction; the tips are then opened to spread the tissues, and then the forceps are removed (Figure 27-27D). This dissecting action is used to create a small defect in the pleural space (Figure 27-27E). A small amount of air is intentionally allowed to move into the pleural space, to cause the lung to retract away from the parietal pleura as the tips of the forceps penetrate the pleural space. This maneuver permits the chest tube to be inserted without injuring the lung. The hemostat is left in place to allow continued identification of the thoracotomy site. A stylet is used in the tube to help guide it into the appropriate position. The tip of the stylet should not protrude beyond the end of the tube. The tube tip is then passed into the chest cavity through intercostal musculature previously separated by the tip of the hemostat and is gently guided (without undue force) into the cranioventral thorax (Figure 27-27F). The stylet is removed, and the tube is rotated to ensure that it is not kinked. The assistant releases the skin so the skin returns to its original position, thus creating a subcutaneous tunnel for the tube (Figure 27-28). The tube is then anchored as described previously. If an assistant is not available, the skin incision should be made over the tenth or eleventh intercostal space, and a curved hemostat should be used bluntly to create a tunnel cranial to the seventh or eighth intercostal space. The catheter tip is then grasped in the jaws of stout hemostatic clamps, is passed down the subcutaneous tunnel, and is forced into the chest cavity through intercostal musculature previously separated by the tip of the hemostat. This maneuver is difficult and must be closely controlled to prevent overpenetration. Practice with a cadaver is recommended. Placing a tube using local anesthetic alone can be more easily accomplished using the former technique.

Placement of a thoracostomy tube can also be accomplished using a commercially available tube and trocar stylet unit, which is pushed through the chest wall. This procedure is strongly discouraged because of the high likelihood of iatrogenic injury to intrathoracic structures and the high degree of tolerance of the first procedure described earlier. The skin over the tenth to eleventh intercostal space is pulled cranially by an assistant to overlie the eighth to ninth intercostal space. The trocar-pointed stylet is then forced through the intercostal space with a controlled thrust. As soon as the tip of the tube enters the chest, the metal stylet is retracted to just inside the cannula. The rigidity of the stylet aids in manipulating the tube into the correct cranioventral position. The assistant then allows the patient's skin to retract caudally to its normal position. Once released, the skin and subcutaneous tissue form a seal over the hole.

Bandaging the Chest Tube
